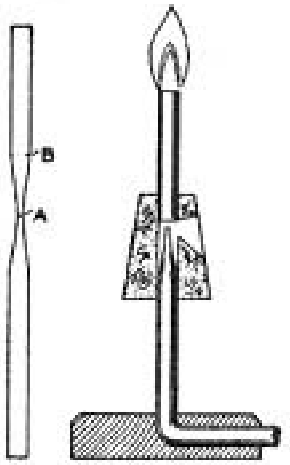
A Small Bunsen Burner

From Popular Mechanix 1915

An excellent bunsen burner for small work can be made as follows: Draw a glass tube to the shape shown, to produce a fine hollow point. Mark carefully with a file and break at A and then at B. Bore or burn a hole in a cork to fit the tube. Cut a V-shaped notch in the side of the cork extending to the hole. Bend the lower tube at right angles and insert it in a wood block, previously slotted with a saw to make a snug fit. A little glue will hold the glass tubes, cork and base together. The air mixture can be adjusted by sliding the upper tube before the glue sets.



Making Bubbles Carry Paper Figures

Popular Mechanics 1925

To make soap bubbles that will carry small paper figures is an interesting pastime. A solution made of soap shavings and water, with glycerin in the proportion of one-third, is used. The solution is placed in a bottle and shaken up until the soap has dissolved, and is allowed to stand until it settles, the clear liquid at the top being used for blowing the bubbles.

The figures are cut from tissue paper and a short piece of thread is attached through the top. The other end of the thread is knotted through a disk of very thin paper. It is best to blow the bubble through a glass tube, and when a bubble of the desired size has been formed, place the paper disk on one side; this will at once slip to the bottom. Shake the bubble off and it starts on its aerial journey carrying the paper figure.—S. Leonard Bastin, Bournemouth, Eng.

THE MEANING OF ATLAN

By KURT SAXON

Legend has it that there was once a great civilization called Atlantis. It is said that Atlantis had a highly developed technology with everything we have and more. Aside from airships, some even have said that they had links with civilizations in outer space.

The story goes on that some great cataclysm destroyed Atlantis. Some say it was from great upheavals in the earth's surface. Others say it was wiped out by atomic war. The great majority of the people died of starvation, riots and wars fought over what was left of civilization.

The survivors, most of whom were highly trained technologists, lost their great cities, industries and technology. This left them helpless and most of them reverted to savagery. From greatness they were reduced to small bands of hunters and gatherers of roots and berries.

Although Atlantis may have been a myth, the further back archaeologists go, the higher the skills acquired by the ancients have been discovered. The cave men, chipping crude flint axes and arrowheads may have been the degenerate descendants of men with knowledge and powers we can only dream of. A good example of this is the degenerate descendants of the Mayas, living like jungle animals in parts of South America today, their ancestors a once proud race, higher in science and mathematics than that of Europe of the same period.

One might wonder how such giants of science and technology as the Atlans could degenerate into the savages archeologists call the "first men".

Ur of the Chaldees, Sumer, Babylon, Egypt, Rome, etc., also rose and then fell with a crash that left their survivors in various states of savagery. They were not as primitive as the cave men since their technologies were more simple and easier understood by the survivors. Even so, the fall of Rome produced a thousand years of what we know as the Dark Ages. Tenth century farmers plowed and planted in the great Roman Coliseum, wondering at the lush harvests. They didn't even remember that that plot of land had been fertilized by the blood of thousands of gladiators and animals slain in the great arena.

Years ago, I was fascinated by how civilizations rose, provided comforts for the populace, erected great monuments to skill and industry and then fell. If they had a system which worked for them, why didn't they go on to ever higher levels of refinement? Why did such powerful nation states as Babylon, Greece and Rome fall to such illiterate savages as the Scythians, early Romans and Huns? Imagine New York City of 1880 being taken over by the Sioux. (I think they could do it today).

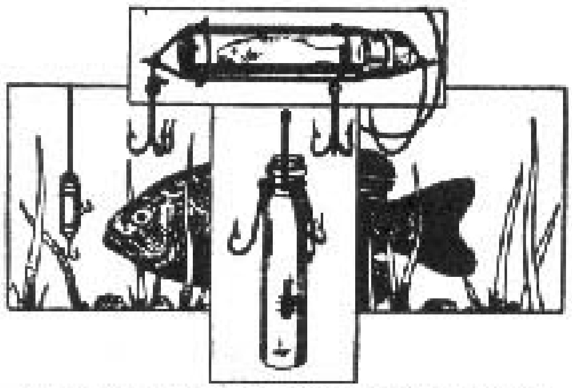
That these once great civilizations did degenerate to the point where they could be overrun by primitive barbarians is a fact. Then, after each fall, the survivors reverted to the most basic of the remaining wisdom, requiring the minimum of knowledge and skill.

The survivors were usually of the peasant class who held on to their poor plots of ground and scratched out a bare living from the soil. Warlike barbarians would descend on such peasant groups and enslave them. Requiring more food for their soldiers, for further conquests, they actually contributed to the growth of agriculture.

Live Bait Used in Fishing

From Popular Mechanics 1915

With the simple device illustrated, no fisherman need worry over running short of bait or even regarding the usual repeated baiting of the hook. A small clear-glass bottle should be procured, and several hooks wired to it about the neck, or at each end, as desired or found best after several trials. After filling the bottle with water a live minnow is placed in it, and the bottle is sealed with a cork, which is notched around the edge to permit water to enter or leave the bottle without losing the bait. If live grasshoppers, or similar bait, is desired the cork can be used unnotched to form a watertight stopper. As illuminated bait for night fishing, several fireflies can be put in the bottle.



The Bait is Kept Alive and Unharmed in a Bottle Surrounded with Hooks

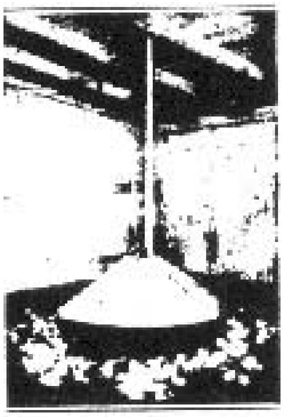
Shield for Heater in Chick Brooding House

From Popular Mechanix 1919

A shield of sheet metal, having a small heater in the center of it, provides a good means of warming a brooding house for small chicks. The heat is radiated from the shield and the chicks remain at a distance, seeking a comfortable temperature. The device may be made easily by cutting a sheet of metal to form a cone-shaped hood and fitting it with a vent passing out through the roof of the house.



Gradually, warrior dominated peasants rebuilt civilizations, often far inferior to the previous civilization. Of course, in the beginning of such civilizations, only the strongest and hardiest survived.

But as agricultural methods improved, more people were fed who would have otherwise starved and taken their weaker characteristics out of the gene pool. So unfortunately, this surplus was also the means of preserving weaklings and defectives who should not have survived. Further, such weaklings were enslaved by the ruling classes, and when not being needed for agriculture, drifted to the cities and worked at unskilled jobs or lived on the dole or by begging.

Of course, there were intelligent and skilled artisans and tradesmen in the cities. But the bulk of the population gradually was made up of rejects from agriculture.

The average Roman was jobless, a Proletarian, living on government handouts supplied largely by the Legionaires bringing back grain and other booty from foreign colonies and conquests.

Today, the Proletariat are known as unskilled workers or welfare recipients.

Every culture, as it developed and assumed greatness, nurtured a breed of politicians catering to the useless. Roman politicians financed, through exhorbitant taxes, and even their own wealth, the building of great coliseums, where were held chariot races, gladiatorial combats and various forms of entertainments such as feeding social dissidents, such as Christians to lions. They also had millions of animals collected from all over the then known world. These animals were slaughtered for the enjoyment of the simple-minded Proletarians in the stands. The Romans made extinct literally dozens of animal species.

The greater the show and the more degenerate the acts, the more votes went to the sponsoring Roman politician. Thus, the most degenerate and wasteful politicians gained the most power over the state and its people. "Bread and Circuses" was the method of not only placating an idle and riotous population, but in perpetuating a Senate nearly as corrupt as our own.

The lack of useful work, coupled with the low standards of social acceptability turned a once great nation into a herd of irresponsible, weak-willed, feeble-minded degenerates which were the greatest contributors to the nation's births. In fact, the term "Proletariat" also meant "child bearers".

When the Roman legions reached the furthest areas from which they could loot food from their subject colonies, starvation and social collapse set in.

Thus, Rome fell. Its artisans and intellectuals died out along with its degenerate Proletariat. Then came the Dark Ages ruled by illiterate princes and a corrupt priesthood, both groups of which destroyed as many of the men of reason as they could find, mainly though Inquisitions.

The illiterate princes raped the people through ruinous taxation to fight useless wars with each other and in their stupid Crusades. The Church not only sanctioned these practices, but kept hidden all the knowledge they had collected in the monasteries, which, had they released it, would have done immeasurable good. But their aim was religious domination, not social advancement. Further, the Church chose for its celibate priesthood, the most intelligent youth, whose genes might otherwise have gone to improve the race.

Today, the Church has lost most of its power, although it does its best to encourage the breeding of the poorest and most useless and degenerate of its followers. Happily, though, its loss of influence spares more intelligent men who would otherwise rob our gene pool by celibacy.

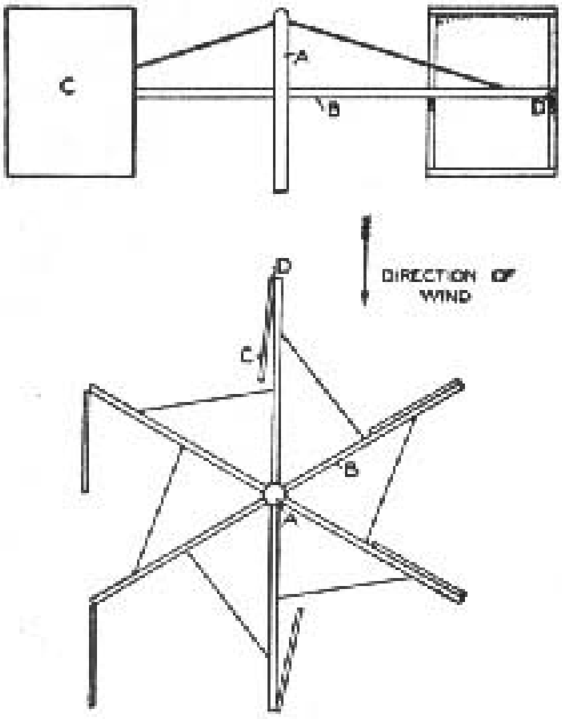
In its place, homosexuality is taking over in the free world, initiating into a life of virtual celibacy many of the best specimens of our youth. Its spread insures the robbing of our national gene pool by limiting future generations to those less attractive, intelligent, and consequently less able to contribute to society.

In its turn, our civilization rose from virtual barbarism and has achieved the highest technology in known history. Our previously vast surpluses of food and fuel have led to a surplus population made up largely of the useless and degenerate.

Windmill for Light Power

From Popular Mechanics 1915

The windmill shown in the sketch is one that will always face the wind, and it never requires adjustment. It consists of a vertical shaft, A, provided with a number of arms, B, on which are hinged square sails, C. These sails are preferably made of wood frames covered with canvas. They are provided with hinges, D, attached to the ends of the arms in such a way that they offer resistance to the wind on one side of the wheel, while they move edgewise against the wind on the other side, as shown. The shaft of the mill can either be run in bearings set on an upright post, the lower end of the shaft turning on a conical bearing, or collars may be used on the bearings to keep it in position. The power can be transmitted with gears or by a flat belt over a pulley.



Frames Hinged to the Arms

A wheel of this kind is not adapted for high speed, but direct-connected to a pump or other slow-working machinery will prove very efficient

SCIENTIFIC AMERICAN CYCLOPEDIA 1891

Candles.—*Adamantine Candles.*—100 lb. of mutton tallow; 2¼ lb. of camphor; beeswax, 4 lb.; alum, 2 lb.

Aromatic Candles.—For perfuming apartments.—Melt balsam of Peru and camphor with the material of which the candles are to be made; or the wicks may be steeped in some aromatic tincture and dried.

Cable, Twisted or Spiral Candles.—These are moulded in the ordinary way, and then turned by means of a special lathe; or they may be cast in rifled moulds, from which, on cooling,

Instead of the paradise a controlled population could enjoy indefinitely, our technology is only contributing to the breeding of half-wits, murderous psychotics, Liberals and other perverts who are bringing down our civilization by the year. Adding to this are the changing weather patterns, which will only worsen in our time, plus a growing lack of resources, causing the mass starvation of literally billions of people.

Worldwide collapse of civilization is imminent. It won't happen overnight, but in country by country and area by area, industry by industry, and so on. It could hit you tomorrow. So whether you are an auto mechanic, steelworker or nuclear physicist, you have only a relatively short time in your present occupation. Your survival is up to you.

Years ago I saw the same factors appearing in our society which had led to the collapse of past civilizations. I particularly noted the specialization of the educated, on the one hand, and the frivolous interests and idleness of the less able on the other hand.

I recalled the tales of the fall of Atlantis and its resultant barbarism. Knowing that the ignorant masses were doomed and the more able were locked into an interdependent technology, I searched for answers, as did many of my generation. I became a joiner of cults and causes, giving them all my all. But almost without exception, every faction proved to be a dead end and led by self-serving phonies or psychotic fanatics.

Again recalling the fall of Atlantis, I began preparing a method by which I could provide knowledge to intelligent survivors of the future collapse. My main idea was that the biggest problem facing the survivors would be the lack of knowledge which they could apply to their own circumstances.

As it was, the intelligent survivor could only hope to scrounge sustenance from the ruins. Such scrounging would prove futile in only a short time after the fall.

I hit on the idea of collecting all the practical knowledge of the 19th Century, as it was relatively simple and easy to apply. Also, it would insure a standard of living far from primitive and a springboard to the technology we have today. Further, it is far easier for the layman to understand than modern texts on science and crafts.

Back then, creative and knowledgeable people wrote their instructions for use by anyone interested, whether he had any background in the field or not. Today, books on science and technology are written mainly to those who are expected to be already pretty well grounded on a particular subject.

Also, they wrote in plain language, not showing off their expertise in terms only their fellow experts could understand, as is often done today. Nineteenth Century terms unfamiliar to us were not used to show off, or to conceal knowledge from the uninitiated. They were just the terms people used in those days. Most such old-fashioned terms have been updated in GRANDDAD'S WONDERFUL BOOK OF CHEMISTRY.

For years I've been collecting such knowledge and am now, and in the near future, hoping to assemble all the practical knowledge applicable to the needs of future Survivalists.

So Atlan Formularies is simply a figurative reference to the real or mythological Atlantis and a remedy for people in their comparative situation.

After the crash of world civilization there will be chaos and universal suffering and death. Yet, unlike the original Atlans we can revert to a level of technology the intelligent layman can implement.

The only savages will be those who ought not to have been born in the first place. THE POOR MAN'S JAMES BOND will help Survivalists deal with such doomed predators.

GRANDDAD'S WONDERFUL BOOK OF CHEMISTRY will enable you to make the chemical compounds you will need in your daily struggles.

MEDICINES LIKE GRANDDAD USED TO MAKE will help keep you well when your modern doctor loses his contact with the pharmaceutical companies, which will soon be out of existance. (Now part of Chemistry)

SURVIVAL FOODS, PLUS will help you to prepare and preserve the food you will need. (Now part of Survivor Vol. 1) they are wound out.

Cerophane Candles.—Melt over a water bath 50 parts of stearic acid and 5 to 6½ parts of bleached beeswax. Let it remain over the water bath for one-half hour, but do not stir or agitate. Then allow the fluid to cool, until there is a slight film on the surface. Pour the mass into moulds, which have been heated to the same temperature, but avoid stirring.

To Coat Tallow Candles with a Hard Substance which will not Crack.—Dip the candles successively into the following three mixtures: 1. 4 parts white resin; 68 parts good tallow; 6 parts camphor; 20 parts stearic acid; 2 parts dammar resin. Melt.

2. 48 parts tallow; 6 parts camphor; 30 parts stearic acid; 4 parts white pitch; 10 parts dammar resin. Melt together.

3. 20 parts stearic acid; 4 parts white wax; 30 parts tallow; 6 parts camphor. Melt.

Colored Candles.—Among the coloring matters used for candles are the following:

Blue: Prussian blue, indigo, ultramarine, copper sulphate, aniline blue. Red: Carmine, Brazil wood, alkanet root, minium, vermilion aniline reds. Yellow: Gamboge, chrome yellow, naphthaline yellow. Green: Mixture of blue and yellow colors. Purple or violet: Mixture of blue and red colors. Neutral Tints: Oxides of iron, yellow ocher, Frankfort black. Black: Fruit of *Anacardium occidentale*, aniline blacks. In order to dye paraffin candles with an aniline base, such as magenta, the dye is first dissolved in stearin, and a little of the resulting stearate is added to the paraffin.

There are two ways in which candles may be colored black: 1. Anacardium Method.—Paraffin, or whatever material is desired for the candles, is heated from 200° to 210° C. with 25% of its weight of the chopped fruit of *Anacardium occidentale*. Candles prepared in this way are equally black throughout, and yield no irritating vapors when burnt.

2. Aniline Method.—The material to be dyed is heated a few degrees above its melting point with 1 to 2% of nigrosine fat color (prepared by Destree, Wiescher & Co., of Brussels). Paraffin and spermaceti require 1%; stearin and wax require from 1½ to 2%. The candles thus prepared are said to be of a somber hue throughout, and of a jet black appearance.

Diaphane Candles.—Melt together in a steam jacket 5 lb. vegetable wax, 3 lb. pressed mutton tallow and 11 lb. stearic acid. The stearic acid and the vegetable wax are the hardening ingredients.

Home Made Candles.—Many of our readers in the rural districts will find that candles can be made economically by mixing a little melted beeswax with the tallow to give durability to the candle, and to prevent its running. The light from a tallow candle can be improved in clearness and brilliancy by using small wicks which have been dipped in spirit of turpentine and thoroughly dried.

Hygienic Candles.—Watson and Fulton prepare these by incorporating iodine and a small quantity of sulphur with the candle material, and they consider that during the combustion the iodine and sulphur are both eliminated in the free state, according to the equation:

$$4\,HI \times SO_2 = I_4 + S + 2H_2O$$

Lard Candles.—1. Dissolve 1 lb. alum and 1 lb. saltpeter in 2 qt. water over a slow fire; 12 lb. lard are added. The stirring must be kept up continually until all the lard is dissolved. Do not leave on the fire too long, as the lard is liable to be discolored. It is said that these candles are superior to tallow.

2. Solid Candles from Lard.—Cut 16 lb. lard in small pieces, put in a pot with ½ lb. alum and ½ lb. saltpeter (previously dissolved in 1 pt. water, over a slow fire). Stir constantly over a slow fire until all the lard is dissolved. Allow to simmer until the steam ceases to rise, then remove from the fire. These candles are harder than those made from tallow.

Mutton Suet Candles in Imitation of Wax.—Throw quicklime in melted mutton suet; the lime will fall to the bottom, and carry along with it all the dirt of the suet, so as to leave it as pure and as fine as the wax itself. Now, if to 1 part of the suet you mix 3 parts of real wax, you will have a very fine, and, to appearance, a real wax candle; at least the mixture could never be discovered, nor even in the moulding of wax ornaments.

Mercurial Candles.—Red sulphide or gray oxide of mercury mixed with wax, and a wick of cotton inserted therein. Recommended by Mr. Collis for partial mercurial fumigation. They are burnt under a glass funnel with a curved neck, the upper orifice of which is directed to the diseased part.

THE SURVIVOR volumes will take care of the daily problems 19th Century people handled with such ingenuity.

In short, my books will give you a level of technology both interesting and practical, useful even today. You need not fear death from want, ignorance or from human predators.

I have been told, and agree, that had I omitted the grimmer aspects of the coming chaos I could reach more people. Selling only nostalgia and 19th Century handicrafts I could appeal to far more buyers and make more money.

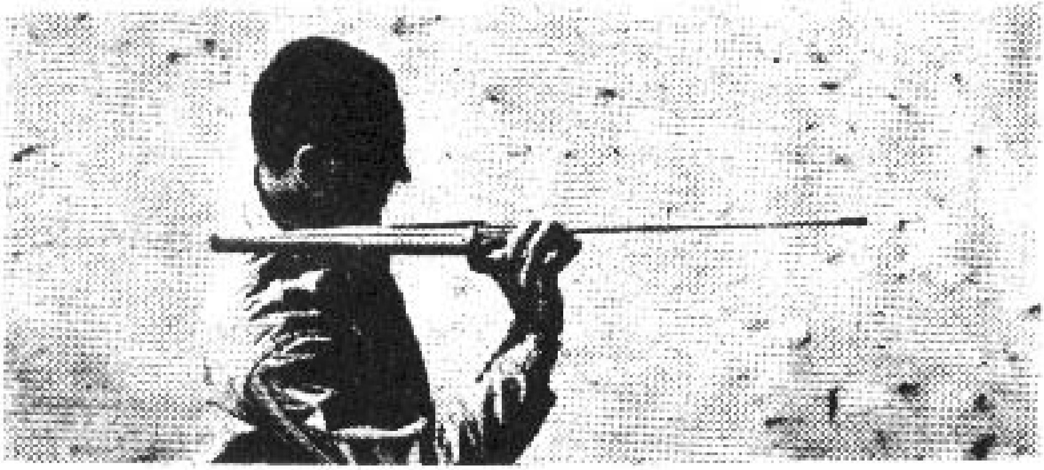
But that approach would have had me catering to hobbiests or nostalgia buffs. I'm telling it like it is. I'm not interested in hobbiests or nostalgia buffs. I'm aiming my material at the strong-minded individualist, the only type who can, and should, survive.

I have no political solutions or aspirations. My only admonition to my readers insofar as a future system is to not let another Atlantis happen again. My paramount advice to future generations would be to limit their offspring to only that amount they can provide for and manage with the love and individual care which develops strong citizens.

No social dependent should be allowed to enlarge his dependency. That is, the individual who cannot provide for himself should not be allowed to reproduce.

If this simple rule had been followed there would never have been a surplus population. Hoards of fertile idiots and genetic defectives procreating like unmanaged livestock would not have toppled nearly every civilization I've mentioned.

It is too late for today's majority to escape the fate of Atlantis. But with individual effort and stern measures of population control, Paradise on Earth could be a reality. The next generation, descended from the surviving remnants of this one, could inaugurate the next step in the evolution of human civilization. Then our surpluses could go, not to the upkeep of human vermin, but to the provision of land and well-equipped homes for all, and then even Starships.



Good Sport with a Throwing Stick

By

CHARLES and BERTRAM BROWNOLD

AMONG the weapons of primitive man, the throwing stick is one of the simplest to make and use, and it therefore has all the elements of an entertaining outdoor target game, provided space is available and sufficient precautions can be taken against accidental injury to onlookers.

Prehistoric man is believed to have used the throwing stick, and it has been found among the natives of the upper Amazon regions of South America, in Australia, in Mexico, and among our own Southwestern Indians. The model illustrated here, however, is based upon an Eskimo design, still popular in the Arctic. The throwing stick has remained in use among the Eskimos for centuries because much of their hunting is done in frail kayaks. Aided by the stick, an Eskimo can hurl a spear with great force from a sitting position without endangering his equilibrium even when handicapped by rough water, floating ice, high winds, and extreme cold. A float, usually an inflated bladder, is attached to the spear by a light line. The float guides the hunter to the impaled game and also hinders its escape.

As modified for use in a target game, the throwing stick is simply a ¾" thick piece of wood about 19" long and 3" in width at

Stearine Candles.—These are made of the stearine of stearic acid obtained from tallow, in the same way as other mould candles. They furnish a superior light and burn a long time; three or four years ago it was a general practice for the manufacturer, to add a little arsenious acid (white arsenic) to the stearine, to prevent it crystallizing, and thus spoiling the appearance of the candle; but owing to the spirited way in which this rascality was exposed by the press, it has been discontinued by all the respectable houses.

Tallow Candles.—To make hard tallow candles, use a mixture of mutton tallow, 10 oz.; camphor, ½ oz.; beeswax, 4 oz.; and alum, 2 oz.

Tallow Candles, to Harden.—Dip first in the following: Stearic acid, 50 parts; tallow, 44 parts; camphor, 8 parts; white resin, 2 parts; gum dammar, 1 part. When hard dip in other solution, which consists of 70 parts stearic acid; tallow, 24 parts; camphor, 3 parts; white wax, 2 parts; gum dammar, 1 part. For a final coating dip in 90 parts stearic acid; 5 parts of tallow; camphor, 3 parts; white wax, 2 parts.

Tallow Candles, to Make.—The ingredients are about ⅓ beef and ⅔ mutton suet. The use of 1 lb. of alum with each 5 lb. of tallow is recommended. Dissolve the alum in water, then put in the tallow, and stir until both are melted together, then run in moulds. This part of the operation is conducted as follows: The wicks are secured in the center of each mould by passing over the sticks, one of which is laid over the top of the mould (corresponding to the bottom of the candle) and the other against the bottom points of the moulds. The end of the twisted wick is fastened to the stick on the top of the mould, and is drawn by a piece of hooked wire through each mould in succession, leaving a loop outside the bottom points of the mould; the loops are secured there by the bottom stick passing through them; the wicks are to be drawn tight, and the last end tied to the upper stick. The melted tallow is then poured into the moulds and allowed to stand about six hours in a cool place, after which the bottom stick must be taken out of the loops and the candles withdrawn from the moulds. The tallow should not be heated much more than is necessary to melt it.

Wax Candles.—These are made either by pouring melted wax over the wick or by applying the wax in a soft state with the hands, and afterward rolling it smooth with a roller of polished boxwood, upon a table formed of polished walnut wood. They are then cut and trimmed. The first part of this process is usually conducted over cisterns of melted wax, and the wicks are strung upon an iron hoop suspended from the ceiling.

Imitation Wax Candles.—To tallow, purified by throwing powdered quicklime in it when melted, add 1 part of wax to ½ part tallow. This makes a beautiful candle resembling wax. Put 1 oz. saltpeter and ½ lb. of lime in 2 qt. of water. Dip the wicks in this. This prevents the tallow from running, and also improves the light.

Candle Wicks, Preparing.—To improve the light, and prevent the tallow from running, use the following preparation: 1. Steep the wicks in a solution of lime water to which saltpeter has been added in the proportion of 1½ gal. water, 8 oz. saltpeter, ¾ lb. lime. Dry the wicks before using.

2. Borax 3 oz., calcium chloride, saltpeter and chloride ammonium, each 1½ oz.; dissolve in 4½ qt. water, and filter. Soak the wicks in this solution, then dry.

Candles, Scented or Aromatic.—These are prepared by introducing a very small quantity of any appropriate aromatic into the material (fat, wax or wick) of which they are made, while it is in the liquid state. Camphor, gum benzoin, balsam of Peru, cascarilla, essential oils, etc., are generally the substances selected. Care must be taken not to overdo it, as then the candles will burn smoky and give little light.

Candles with Snuffless Wicks.—The great objection to tallow candles is the frequent necessity for removing the snuff, or charred wick, which rises into the body of the flame and obscures the light. If the wick can be exposed to the air, it will be entirely consumed. 1. This is done in composite candles by plaiting the cotton into a flat wick, which as it burns curves over. Sometimes a very fine wire is included in the wick, which is usually dipped in a solution of borax. 2. Twist the wick with one strand shorter than the others, which will bend

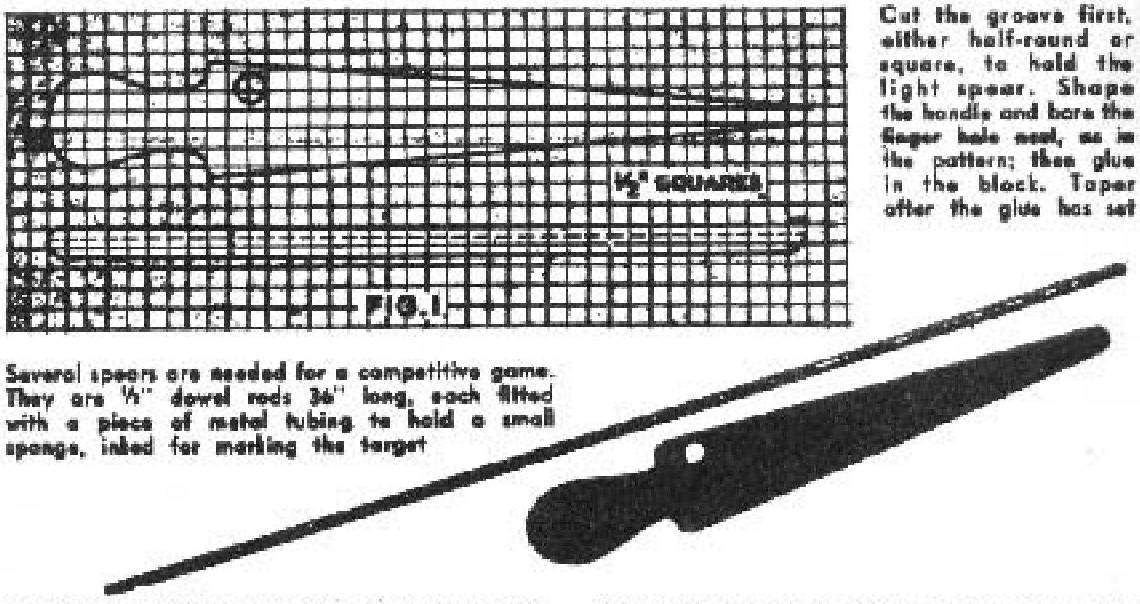


FIG. 1

Cut the groove first, either half-round or square, to hold the light spear. Shape the handle and bore the finger hole neat, as in the pattern; then glue in the block. Taper after the glue has set

Several spears are needed for a competitive game. They are ½'' dowel rods 36'' long, each fitted with a piece of metal tubing to hold a small sponge, inked for marking the target

its widest point, just beyond the handle. Down its center is a groove for a light spear. The throw, starting with the stick in a horizontal position, is overhand and with a wrist snap. Force is applied to the butt end of the spear, which rests against a stop at the end of the groove—enough force to carry the spear smartly to a target 30 yards away. The stick acts as an extension, or third section, of the arm, making it in a sense half again as long as the natural arm. This permits exertion of a forward thrust on the spear for a longer period, and at the same time the tip of the stick moves through its arc more rapidly than does the hand.

To make a stick, cut a half-round or square groove ½" wide and ¼" deep down the center of the wood stock, using a bench saw if one is available. Then shape the handle, bore a hole for the forefinger as shown in the drawing, and glue a small hardwood block tightly into the far end of the groove. After the glue has set, taper the stick to shape.

Spears are ½" dowel rods 36" long. On one end of each is fitted a piece of metal tubing into which is thrust a small inked sponge for marking the target. These targets can be made 24" in diameter from any cheap paper, or else can be purchased.

A few simple rules will help make competition exciting. Draw lines or peg down tape at 20 and 30 yards from the target, and have each player throw three spears from each of these lines for a single round. Stepping over the line is a foul or foot fault, no score being allowed for a foul throw. Score the better mark for a spear that strikes the dividing line between two rings on the target. After six rounds, total the scores to determine the winner. A different colored ink for each player will help in this by automatically identifying all hits.

Be sure that all players and spectators stand behind the throwing line and that no throws are made while spears are being retrieved. The spears are thrown with considerable force, and the metal tips could cause severe injury.

THE BICYCLE: Viable Survival Alternative

by Dr. Spoke

Ever since the "Energy Crisis" began bicycles have gained in popularity, but few people have yet looked into two-wheeled motorless transport as a viable survival alternative for the bigger crisis to come.

Even after the Fall there are likely to be stretches of unbroken pavement, sidewalks, hardpacked woods trails, abandoned railroad rights of way, bridges, tunnels, and whatnot open to bicycle travel. With an easily portable lightweight or folding bike that can be "broken down", the hardy traveler can even pack one on horseback, muleback, ox- or peopleback, on a wagon or in a boat, over wilderness trails to rideable territory beyond, along with necessary weapons and household goods. And any bicycle—even a heavy balloon-tire job—can serve as a welcome adjunct to available motor transport by lessening use of scarce parts and fuel reserves on short and long trips alike.

Lest anybody think bicycles are just glorified kiddie toys, be aware that the Viet Minh and Viet Cong won their wars by manhandling their Peugeots over the Ho Chi Minh trail with up to 500 pounds of freight apiece. The U.S. Army once supported a bicycle battalion, British paratroop commandos executed a successful raid on a Nazi heavy-water installation in Norway using foldup bikes, many big-city police departments sponsor special bicycle patrols in parks and other areas where prowl cars are ineffective, and the "humble" bicycle still outnumbers the automobile in most of the world's countries for transportation, freight hauling and other uses. Bicycles are even used on the largest supertankers for quick hassle-free trips down those huge the wick slightly when the fat melts.

Spermaceti Candles.—Spermaceti, either alone or combined with hard white tallow, forms very good candles, but they will not bear carrying about in the hand without spilling the melted portion.

ACTION OF KREOSOTE ON WOOD.

It is well known that kreosote has been applied to great advantage in the preservation of wood for engineering purposes; and a recent writer attempts to show that this is due, first, to its coagulating albuminous substances, and fixing the constituents of the cambium and cellulose of young wood; second, to its abstracting and appropriating the oxygen in the pores of the wood, and preventing its action upon the woody tissue; third, to its resinifying within the pores of the wood, and thus excluding both air and moisture; fourth, to its acting as a positive poison to the lower forms of animal and vegetable life, and protecting the wood against the attacks of all parasitic objects. It is stated that the formidable ravages of the white ant are prevented by the use of this substance, and that it may be considered as solving all the problems presented in regard to the preservation of wood, under all circumstances.

INFLUENCE OF TREES ON RAIN-FALL.

The marked influence of forests upon the amount of rain-fall of a country has recently received a striking illustration in the experience of the Australians. The result of destroying the timber in the Ballarat district has been to cause a reduction of the rainfall from thirty-seven and a half inches, in 1863, to fourteen and one-quarter inches in 1868. To remedy the difficulty, and to take proper action for restoring the forests, an inspector of state forests has been appointed by the government, for the purpose of preventing any further waste of timber, and of replanting forest trees in different parts of the country.

ABSTINENCE.—Disease may oft be cured by abstinence from all food, especially if the disorders have been procured by luxurious living and repletion. The latter overtaxes nature, and it rebels against such treatment. Indigestion, giddiness, headache, mental depression, &c., are often the effects of greediness in meat and drink. Omitting one, two, or three meals, allows the system to rest, to regain strength, and allows the clogged organs to dispose of their burdens. The practice of drug taking *to cleanse the stomach*, though it may give the needed relief, always weakens the system, while *abstinence* secures the good result, and yet does no injury.

Said a young gentleman to a distinguished physician of Philadelphia,—'Doctor, what do you do for yourself when you have headache, or other slight attack?' 'Go without my dinner,' was the reply. 'Well, if that will not do, how do you proceed then?' 'Go without my supper,' was the answer. 'But if that does not cure you, what then?' 'Go without my breakfast. We physicians seldom take medicines ourselves, or use them in our families, for *we* know that *starving* is better, but we cannot

(Continued on Page

quarter-mile decks!

But even the least migratory survivalist will find a bicycle indispensable in his homestead or business. Knife sharpeners in England utilize a small grindstone attached to a chaingear run off the rear wheel of their machine to ply their trade, and an enterprising survivalist could do this with very little effort. He could take additional advantage of fuelless pollution-free "pedal power" by using a stationary bike to turn a generator for electricity, or even gearing one to a circular saw for woodcutting. With the appropriate gears on a multi-speed bike, the operator of such equipment needn't even raise a heavy sweat! But if it's exercise you want, a bicycle on a stand is an ideal way to pass long winter months or states of siege without the inconvenience of going outdoors; you can pedal hundreds of miles right in your own living room.

Parts for bicycles are very likely to be available from junkyards, old or abandoned machines, and other sources, even when car and motorcycle parts are not; but it's still a good idea to prepare in advance by gathering up frames, wheels, tires, cables, etc. NOW. After the Fall they will be invaluable for barter and a good bicycle mechanic will be as necessary to his home and community as the farmer, blacksmith, and weapons expert. But even the rankest novice will find bicycle maintenance and repair are a snap compared to looking after any motorcycle or car. For starters I'd recommend the simple little paperback "How to Fix Your Bicycle" by Helen Garvey and Ted White, available for only $1.00 at most bike shops. This little gem gives easy-to-follow pictures and text to help the beginner solve almost any common bike repair problem—even to spoking your own wheels.

For do-it-yourself repair and maintenance of a two-wheeler only a few special tools are needed. Some old English and American (Schwinn) bikes use standard-measure tools, but most all of the newer and imported machines are metric. If you already have a car then you hopefully have a tool kit for it and most of these (sockets and wrenches) are perfectly adaptable for bicycle work. Get a metric set if your car is American. The only really special bike tools you need buy, unless you intend to set up a shop, are a chain remover tool, a freewheel extractor and a "cotterless crank tool" (all of these are specifically for 5 and 10 speeds), and a tire repair kit, cone wrenches, spoke wrench and punch for most all bikes. A more complete description of these and other tools can be found in the Garvey and White book I mentioned above.

With just a little work and ingenuity, every member of a household old enough to ride can have his or her own bike or share the use of one or more "common" bikes. I would even recommend that various types of bikes be used for different tasks depending on availability and rider preference: adult three-wheelers with carrying baskets for transporting farm products, tools, weapons, and other bulky stuff; 5 and 10 speeds for faster travel and longer trips, especially in hilly country; one or three speeds for flatter terrain and shorter trips; tandems for groups; and even Motocross bikes and mopeds. "Motocrosses" are bicycles with reinforced, heavy frames built like dirt motorcycles but without the motor, and while heavy and cumbersome will last practically forever; "mopeds" are powered by tiny engines of one hp or so and are just the ticket for frail riders who find regular bicycles too slow or tiring. They get over 160 mpg when motoring or can be propelled by auxiliary pedals with the engine off. There are several types (European and Japanese) available in the U.S. and all are fairly expensive ($400+) compared to most regular bikes, but their potential usefulness and simple upkeep (compared to cars and motorcycles) might justify the initial cost, especially when gas is scarce.

Even a lightweight 10-speed can carry a lot of stuff in frame-mounted baskets or attached bicycle trailers (manufactured or improvised). Light-weight front and back carriers are also available, the Jim Blackburn tubular aluminum model being the best, lightest, and costliest. I sincerely recommend puncture-proof tubes with sturdy tires and steel rims to stand up to rough usage and minimize flats on long trips, because a flat tire is no fun even with a patch kit handy. Good lights and reflectors are also essential, even if you don't plan to travel at night. No bicycle light is perfect and most are shabby and not worth a damn, but long years of experimenting have seen me improvise a few good ones using six-volt waterproof hunting lanterns. I recently rigged up a dandy unit able to run on either straight batteries or off a lightweight generator, thus overcoming the drawbacks of either system alone (batteries lose juice when cold and generators conk out when wet). I use a rather expensive sealed-beam diver's lamp, but an inexpensive six-volt flashlight will suffice quite nicely.

Following is a short bibliography for those who want to look further into bicycles and bicycle history. The publications marked * are especially good for beginners and should be available at most bike shops. Prices listed are as of

December, 1976. All other books should be readily available at any good library.

Alderson, Frederick. **Bicycling: A History**; Praeger Publications, NY, 1972 "BMX" Soldado Publications, City of Industry, CA. 1974 Book on Motocross Caidin, Martin and Jay Barbree. **Bicycles in War**; NY Hawthorne Books 1974 Cuthbertson, Tom. **Bicycle Tripping**; Ten Speed Press 1972 $3.95. "Bicycling"* Western Publishing Co. NY 1974 $2.95. "The Bicycle Book"* Price/Stern/Sloane Pub. Los Angeles 1972 $1.50. **Coaster and 3 speed Bicycle Repair**; Xyxyx Pub. Canoga Park CA. 1972 $3.95. "How to Fix Your Bicycle"* (Helen Garvey & T. White) Shire Press (SF) 1971 $1.00. Humphrey, Clifford C. **Back to the Bike**; 101 Publications (SF) 1972. Sloane, Eugene A. **The Complete Book of Bicycling**; Trident Press NY 1970. Smith, Robt. A. **A Social History of the Bicycle**; American Heritage Press. Woodforde, John. **The Story of the Bicycle**; Universe Books, NY 1970.

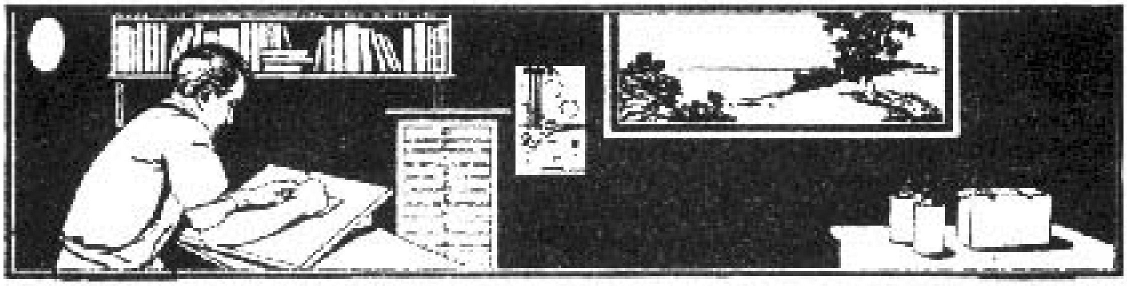
make our patients believe it.'

Hippocrates (the father of medicine) said wisely, that if a man eats sparingly and drinks little, he is nearly certain of bringing no disease upon himself, and that a *moderate* supply of food nourishes the body best. The quantity of food which nature really requires for her support is small, and he that eats and drinks moderately at each meal, stands fair to enjoy sprightliness, vivacity, and freedom of spirits. Bodies governed by temperance and regularity are rarely hurt by melancholy, or any other affection of the mind. To have a clear head we must have a clean stomach; for this is the grand reservoir in which the food is first deposited, and thence its nutritive power is distributed throughout all parts of the body.

ACETOUS CATAPLASM, or **POULTICE.**—This is made with vinegar and bran only, or with the addition of oatmeal, or bread crumbs. It is a simple poultice, but very useful for sprains and bruises. As it becomes dry, it should be moistened with vinegar.

ÆOLIAN HARP, To Manufacture an.—Let a box be made of thin deal, the length to correspond exactly to the breadth of the window in which it is to be placed, five inches in depth, and six in width. Glue on it at the extremities of the top two pieces of oak about half an inch high and a quarter of an inch thick, to serve as bridges for the strings, and within-side of each end glue two pieces of beech, about an inch square, and of length equal to the width of the box, which is to hold the pegs. Into one of these bridges fix as many pegs (like those of a violin) as there are to be strings, and into the other fasten as many small brass pins, to which attach one end of the strings. Then string the instrument with first-fiddle strings, fixing one end of them and twisting the other round the opposite peg. These strings, which should not be drawn tight, must be tuned in unison.

To procure a proper passage for the wind, a thin board, supported by four pegs, is placed over the strings at about three inches distant from the sounding board. Place the instrument in the window partly open; and, to increase the force of the current of air, open the



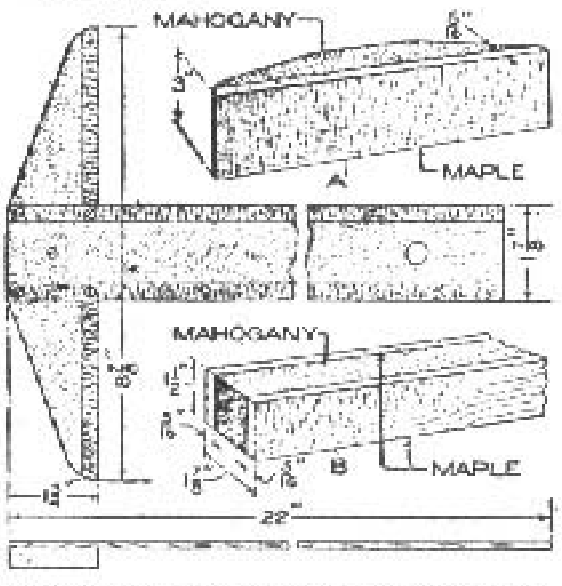
Making T-Squares

From Popular Mechanix 1919

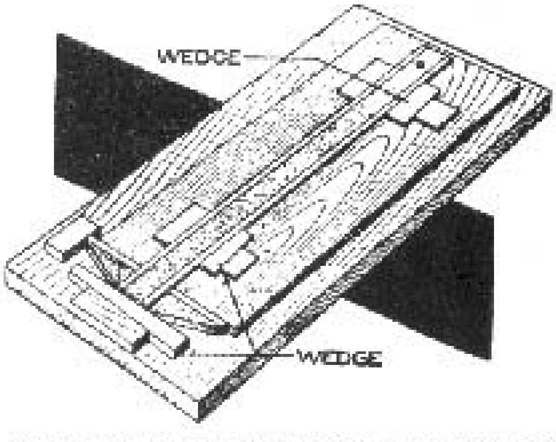
By J. B. MURPHY

THE making of a single article of any kind presents a distinct problem in itself, but the production of a large number of the same article must be done in a different way, if efficiency and uniformity in the product are desirable qualities. Taking, for instance, the making of a large number of T-squares, the material is not made up in the same manner as for one. Where a number of these instruments was required, they were made as follows, with no other equipment than bench tools and a band saw. The squares were made of mahogany having both stock and blade edged with maple. The blades were fastened to the stock with five ⅜-in. button-head screws.

The material for the heads and the blades was glued up and finished to the sizes given at A and B. The material was cut to gauge lines on the band saw, the blades being a scant ⅛ in. in thickness, and the stocks, ⅜ in. Two of each were cut from each prepared piece, first from one side and then from the other. They were then faced off on both sides, and two more pieces cut. With careful cutting, six blades and six stocks were made from each piece. This left one side of each piece to be planed after sawing. The holes for the screws were drilled with a small hand drill.



Dimensions for a T-Square of Which a Number were to be Made in Duplicate



Stock and Blade Material for Making the Parts, and the Jig for Assembling

For assembling, a jig was made by nailing a piece of stock, ⅜ in. thick, to a straight drawing board. One end of the piece was planed straight and true before it was fastened in place. Stops were provided to locate the stock and hold the blade square with it. Wedges were used to keep both stock and blade against the stops while the screws were inserted. The wedges were not driven with a hammer, but pushed in firmly with the fingers.

door of the room or an opposite window. When the wind blows, the strings produce a pleasing admixture of all the notes of the diatonic scale, in the most delightful harmonic combinations.

ALE, FINE WELSH, to brew. —Pour forty-two gallons of water, hot, but not quite boiling on eight bushels of malt, cover and let it stand three hours. In the mean time infuse four pounds of hops in a little hot water, and put the water and hops into the tub, and run the wort upon them, and boil them together three hours. Strain off the hops, and keep for the small beer. Let the wort stand in a high tub till cool enough to receive the yeast, of which put two quarts of ale, or if you cannot get it, of small-beer yeast. Mix it thoroughly and often. When the wort has done working the second or third day, the yeast will sink rather than rise in the middle, remove it then, and tun the ale as it works out; pour a quart in at a time, and gently to prevent the fermentation from continuing too long, which weakens the liquor. Put a bit of paper over the bung-hole two or three days before stopping up.

Ale, or Strong Beer, to brew.—Twelve bushels of malt to the hogshead for beer, (or fourteen if you want it of a very good body), eight for ale; for either pour the whole quantity of water, hot, but not boiling, on at once, and let it infuse three hours close covered; mash it in the first half-hour, and let it stand the remainder of the time. Run it on the hops previously infused in water, for strong beer three quarters of a pound to a bushel; if for ale, half a pound. Boil it from the wort two hours from the time it begins to boil. Cool a pailful to add three quarts of yeast to, which will prepare it for putting to the rest when ready next day; but if possible put together the same night. Tun as usual. Cover the bung-hole with paper when the beer has done working; and when it is to be stopped, have ready a pound and a half of hops dried before the fire, put them into the bung-hole, and fasten it up. Let it stand twelve months in casks, and twelve months in bottles before it be drank. It will keep fine eight or ten years. It should be brewed the beginning of March.

Great care must be taken that the bottles are perfectly prepared, and that the corks are of the best sort.

The ale will be ready in three or four months; and if the vent-peg never be removed, it will have spirit and strength to the very last. Allow two gallons of water at first for waste.

After the beer or ale has run from the grains, pour a hogshead and a half for the twelve bushels, and a hogshead of water if eight were brewed; mash, and

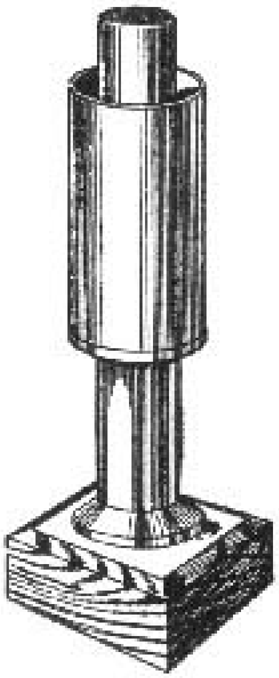
A Simple Self-Contained Motor

From Popular Mechanix 1919

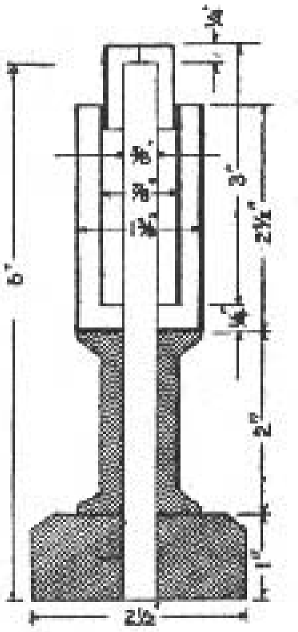


To say that the subject of this article is the simplest motor in the world is not to overestimate it, for the apparatus is not only a motor reduced to its essential elements, but combines within itself its own source of electric power, all without the use of a single piece of wire. The experiment is very interesting and instructive and will well repay a careful construction along the lines indicated, even though not in strict accordance with the dimensions given.

The first step is to procure a permanent magnet, about ⅝ in. in diameter and 6 in. long. If such a magnet cannot be conveniently secured, a piece of tool steel with flat ends should be hardened by heating it to a dull red and plunging it in water, and then strongly magnetized. This may be readily accomplished by slipping a coil of insulated wire over it through which the current from a storage battery or set of primary cells is passed. If these are not at hand, almost any electrical supply store will magnetize the steel.

A square base block with neatly beveled corners is now in order, which is trimmed up squarely and a hole bored centrally through it to receive the lower end of the magnet. Procure a neat spool and make a hole in it large enough to pass over the magnet. Glue the spool to the base after locating it in the exact center.

The outer and larger cylinder is of copper, or of brass, copperplated on the inside. It is cup-shaped, with a hole in the bottom just large enough to permit the magnet to be pushed through with a close fit, to make a good electrical contact. The magnet may be held in place by having it closely fit the spool and the copper cylinder, and by soldering the heads of a couple of small tacks, or nails, to its under side and driving them into the spool. Coat the magnet with pitch, or paraffin, from the top down, and around its connection with the bottom of the cylinder. The small thimble shown at the top should be of brass or copper, and while one can be easily formed of sheet metal and soldered, it is not improbable that one could be made in seamless form from some small article of commerce. In the exact center of the under side of the top of this thimble, make a good mark with a prickpunch, after which a small steel thumb tack should be filed to a fine needle point and placed, point up, exactly central on the upper end of the magnet, to which it is held with a little wax. The smaller cylinder is simply a piece of sheet zinc bent into a true cylinder of such a size that it may be sprung over the lower end of the thimble. This done, it is only necessary to slip the zinc over the end of the magnet until the thimble rests on the thumb tack, and then pour some dilute muriatic or sulphuric acid into the outer cylinder, after which the thimble and attached zinc will begin to rotate. The required strength of the acid and the resulting speed will depend upon the nicety of suspension and the trueness of the rotating zinc cylinder. The zinc will have to be changed, but the copper undergoes no deterioration.



PRESERVATION OF GRAIN AND SEED IN VACUO.

Some time since Dr. Louvel, of France, proposed the use of vacuum reservoirs for the permanent and definite preservation of seeds and grain of all kinds. Further experiments have been made in this direction, and it seems to be pretty well ascertained that the process has an economical value; and that while the necessary vessels can be made of large size at a moderate cost, the process of exhaustion of the air also costs but little; and once treated in this way the seeds can remain an indefinite number of years without further attention, with a certainty that all the elements, chemical or vital, of the grain will be properly preserved.

APPLYING PAINT TO PLASTER CASTS.

Porous plaster or stone may be rendered compact, and fitted to receive paint by applying a coating of a solution of one part albumen in five of acetic acid. The result is a fine, firm, adherent skin, upon which the paint may then be laid.

Preview of life in coming dark age

Western civilization doesn't have to blow itself up to tear itself down, according to Roberto Vacca. In his book "The Coming Dark Age," the University of Rome electronics and computer expert predicts a massive breakdown of our enormously complex technological systems between 1985 and 1995—a "knockout" resulting in a return to a primitive way of life- The quality that sets Vacca's book apart from many Prophet-of-Doom manifestos is the logic with which he describes not only the coming technological collapse but also its aftermath. In the following excerpt, "Preview of Life in the Coming Dark Age," he speculates on the problems facing the survivors of a catastrophe we may not be able to avoid.

* *

By ROBERTO VACCA

It is not necessary for a few kilomegatons of hydrogen bombs to explode for hundreds of millions of people to be killed.

The same result may occur by less violent and more intricate means: that is, by virtue of the fact that vast concentrations of human beings are involved in systems that are now so complicated that they are becoming uncontrollable. This hypothesis —of an apocalypse that is impersonal, casual, and unpremeditated—is more tragic than the other.

My thesis is that our great technological systems of human organization and association are continuously outgrowing ordered control: they are now reaching critical dimensions of instability. As yet, a crisis in a single system would not be enough to bring a great metropolitan concentration to a halt.

But a chance concomitance of stoppages in the same area could start a catastrophic process that would paralyze the most developed societies and lead to the deaths of millions of people.

One cannot demonstrate a priori, of course, that a chance coincidence of events—decline, congestion, and slowdown—must lead inevitably to disaster: not, at least, in a developing situation such as I describe. It seems very likely, however, that the most developed nations are on the way toward breakdown on a large scale.

Countries that are less advanced than others (either on the way to modernity, or still underdeveloped, or just backward) will only be involved in the crisis to a marginal extent. Seventy per cent of the population of the world will not be much injured by the first wave of destruction.

On the other hand, the more advanced nations will be more vulverable to the harm that will accompany the breakdown of the great systems: in the dark age that would follow, their total population might be halved.

Since these nations would include Europe and the Soviet Union, North America and Japan, some 900 million people would be involved, or about 30 per cent of the present population of the world

The death of 450 million people in the world's most developed countries would mean that scientific development, technological research, large undertakings in civil engineering, industrial mass production at low cost, the whole organizing and directive structures that function in modern society, would come to a complete stop.

Along with a certain setback that the countries of the Third World would suffer, there would be grave secondary consequences: manufactured goods, finished and durable products, medicines, production facilities and managerial know-how previously supplied by the more advanced nations—all would be missing

There is one fact that will bring notable relief to many survivors: the grim problems facing them will at least be completely different from those that have been tormenting them in past years.

The problems of an advanced civilization will be repalced by those proper to a primitive civilization, and it is probable that the majority of survivors may be made up of people particularly adapted to passing quickly from a sophisticated to a primitive type of existence.

The first benefit to be enjoyed by the surivvors will be the end of congestion: there will be too few people left in circulation to cause any congestion at all.

One must point out, however, that many who now deplore the oppression, injustice, and intrinsic ugliness of life in a technically advanced and congested society will decide that things were better when they were worse; and they will discover that to do without the functions proper to the great systems—without telephone, electric light, car, letters, telegrams—is all very well for a week or so, but that it is not amusing as a way of life.

To some of the survivors it will be an obvious advantage that so many durable goods will be available in excess of demand. The death of the greater part of a city's population will make houses and dwellings of all types available far in excess of need.

If, before the knockout (KO), there had been on an average one car to every two inhabitants of a city, after the KO there will be some two or three cars per head, and for a time the survivors will be able to satisfy their transportation needs simply by using one of the many abandoned vehicles. The car industry will disappear.

Later, when old cars have been used up and there are no new ones, abandoned cars will be the obvious source of spare parts, until new needs begin to renew industrial production. Then, production will be on a small artisan scale, fulfilling small commissions or making single parts.

Buildings will show a similar gradual breakdown — an initial superabundance resulting in the disappearance of building as a great industry. A small number of people, forced to rely on themselves, will be unequal to the adequate maintenance of the buildings they are using; and they will give no attention at all to those they are not using.

Empty buildings will be raided for fixtures or odd pieces having some structural value; and this, along with damage due to weather, will cause collapses. These will bring down other, inhabited buildings.

In the long run, therefore, houses will be much scarcer than they were before the KO, and new ruins will become a typical feature of the urban landscape. Ancient and noble ruins will be covered and obliterated by new ones in accordance with a process that was familiar in the former Dark Ages.

Vandalism will add to collapse and destruction in cities; and inasmuch as it will not cause direct harm it will not be punished, but will be one of the few entertainments still available to the young.

After the KO, as during the original Dark Ages, the distinction between new and secondhand objects will lose the great importance that it has at present. The only distinction will be between things that are effectively usable and those that are broken and beyond repair.

Again, this will happen at first because of the availability of many secondhand things in good condition. Then new objects will become extremely rare, so that there will no longer be anything derogatory about the term "used."

Further, new products will often be of much poorer quality than used products made of better material and in accordance with finer methods of production.

Before the KO the standard of living reached by a large number of people in the advanced nations made it respectable for them to buy books and antiques secondhand, but certainly not clothes: to acquire a used garment was almost unthinkable. After the KO used clothes would not only be bought or bartered; they would be heirlooms.

One hopes that at least this new state of things will gratify today's detractors of consumerism and all who are annoyed (perhaps not unreasonably) that fashion should be so powerful in the field of consumer goods.

A very severe restriction of the movement and use of cars will follow from the scarce and irregular availability of oil products and gasoline.

As a consequence, journeys for pleasure will become very rare and will be reserved for the powerful or for tramps who will have to go long distances on foot. There will be a large increase in the percentage of people who have never moved from the place where they were born, neither for work, nor for sightseeing, nor for any other reason.

The scarcity of travelers will provide opportunity for the revival of brigandage. Pilgrimage will be the motive for undertaking fairly long journeys.

Indeed, we may expect that the new dark age will favor the revival of a religiosity as simple as it will be widespread, and expressed in forms that today are unforeseeable.

In the field of economic relationships an important element in the modern consumer structure that will be missing at once is credit. In conditions of extreme instability, no one could possibly give a creditor meaningful guarantees of future payment with interest.

It is very likely that at first all forms of money will lose whatever value they have and that exchanges will be solely by barter. There intrinsic rarity will suffice to keep gold and silver coins in use, and the old convention would be reestablished whereby the weight of coins and ingots would be the sole determinant of their value: every merchant would include in his office equipment a small balance for weighing gold and silver.

Short-term advantages can accrue to the so-called developing countries inasmuch as they are actually subject to colonized by, or oppressed by more advanced countries on their way to regression. When the regression of the advanced nations becomes effectively obvious, their oppression of others will cease and the less developed nations will experience relief.

But it will probably be brief, because in the long run much graver problems will emerge, not only because finished products from the regressing countries will then be lacking, but also because generalized armed conflict is likely to be the pattern, either between nations in retrogression, or between those that have not yet advanced, or — at a more microscopic level between cities, villages, or families, and between individuals.

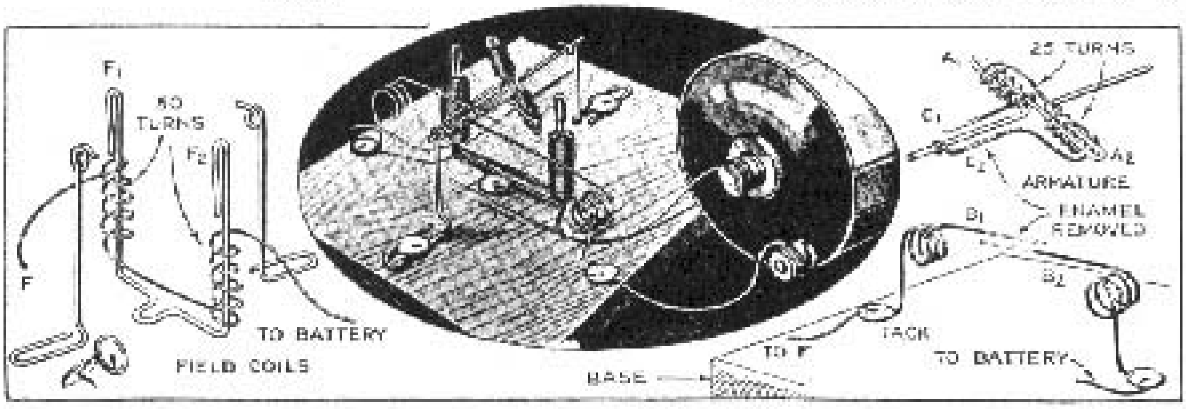
A Real Electric Motor for a Cent

From Popular Mechanics 1937



The Framework of This Small Motor Is Made from Paper Clips, While Enameled Copper Wire, Wound on the Poles of the Field Coils and Armature, Is Also Used for the Brushes and Commutator

MADE from ordinary wire paper clips and No. 26 enameled wire, this small electric motor takes only a few minutes to construct. It is a series motor and will run either on a. c. or d. c. at a low potential, such as that provided by a single dry cell.

The framework for the field coils and the armature are first made from paper clips bent to the shape indicated, and the armature supports are then made in a similar way. Wind 50 turns of enameled wire on F_1 and F_2, the direction of winding on these poles being opposite and both coils being connected together. The free end of one coil is connected to the battery while the end of the other coil, marked F, connects to one of the armature brushes B_1, shown in the lower right detail. The armature is wound next, 25 turns of wire being wrapped on poles A_1 and A_2, both coils being wound in the same direction and terminating at C_1 and C_2, where the enamel is removed from the wire, leaving the bright copper surface which forms the commutator. The brushes B_1 and B_2 are simply lengths of enameled wire with the ends brightened to form good electrical contact and wound in a spiral form, as indicated, to produce a spring effect which causes the ends to make good contact with the commutator. The field-coil frame, the armature supports and the brushes are then fastened to a wooden base with thumbtacks, and the armature is slipped in position. Carefully adjust the brushes so that they will touch the commutator lightly, the proper tension at this point being highly important. Now hook up B_2 to the other terminal of the battery and the motor will run if it has been correctly wired and properly adjusted.

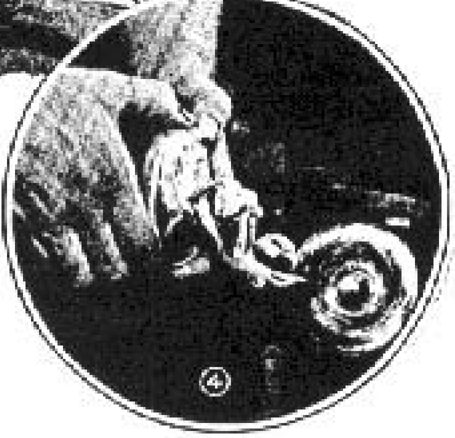
The operation of the motor can be greatly improved by having the coils on the armature balanced as closely as possible and spaced exactly the same distance from the center. This point should also be taken into consideration when forming the armature frame. The small eyes at the end of the armature supports, which serve as bearings, should make a loose fit on the armature shaft, and light machine oil may be used here to reduce friction. Drops of solder at the ends prevent the shaft from slipping out.

Electroplating

Non-Metallic Objects

THERE are innumerable non-metallic objects, such as flowers and fruit, wooden novelties, glass and plaster knickknacks, leather articles, etc., that can be given a beautiful and lasting finish by electroplating, if they are properly prepared before suspension in the bath.

The most important part of the process consists in giving the object a coating that will conduct electricity. The coating may be either sprayed on or applied with a camel's-hair brush. To 1 pt. of thin, clear cellulose lacquer add 1 oz. of copper powder. Commercial cellulose lacquer is often too thick and should be diluted by adding lacquer thinner until the right consistency for spraying is obtained. The mixture may be slightly thicker if it is to be applied with a brush. Some bronze powders, sold as copper powder, have an aluminum base and are not satisfactory for this purpose. The pure copper powder can be bought at a chemical house. The mixture should be thoroughly stirred before it is applied so that all the powder is held in suspension. This mixture is a conductor of electricity and does not offer much resistance. When the coating has dried, the object may be plated with a heavy deposit of copper, after which a surface coat of gold or silver can be added, if desired. Before the cellulose-and-copper coating is applied, the object should be thoroughly dried. Wooden objects should be boiled in linseed oil, which prevents the base coat from soaking in and cracking



the wood. Plaster-of-paris objects, which might be affected by the electroplating solution, should be slightly warmed in an oven to remove all moisture and are then dipped in hot wax or paraffin after which the copper lacquer is applied. This waxing treatment should not be given to fruits or flowers, as much of the surface detail would be destroyed.

One electroplater has produced some gleaming chromium drumsticks that are very popular. The sticks are turned out of light basswood, boiled in linseed oil, and painted with the copper-lacquer mixture. They are then given a 1/16-in. layer of copper, a thin coat of nickel, and a final plating of chromium. The sticks are plated slowly to obtain a smooth surface and are buffed between each plating operation. A weight is hung on each stick so that it will sink when placed in the plating bath. When the sticks are finished, they have about the same weight as hickory, and are practically unbreakable.

If the object to be plated has no base to which the electrical connection can be made, the conducting wire should be wrapped around it loosely and the position of the wire should be changed after each plating process, so that any unevenness on the surface, made by contact with the wire, can be buffed off, as in Fig. 4.

If the object has a base, a more satisfactory connection for the first heavy coat can be made by attaching the conducting wire to the base with a small amount of heated dental wax. The wax hardens and holds the wire in place firmly so that it can be suspended in the bath as in Figs. 2 and 3. The copper-lacquer mixture should also be painted over the wax and around the wire. This connection can be broken out after the first plating process and the wire wrapped around the article, as already mentioned, for applying the succeeding coats.

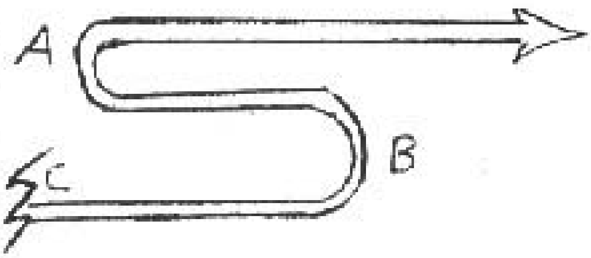
An interesting table ornament is made by gluing a few pebbles in the bottom of a small saucer and inserting a branch among them to represent a tree. Small pieces of rubber sponge glued to the branch make realistic clusters of leaves. By dipping the articles in wax and then painting them with the electrically conducting coat, the piece may be finished by plating it with silver.

MAKE A HANGMAN'S NOOSE AND ROPE HANDCUFFS

By A.D. Robinson

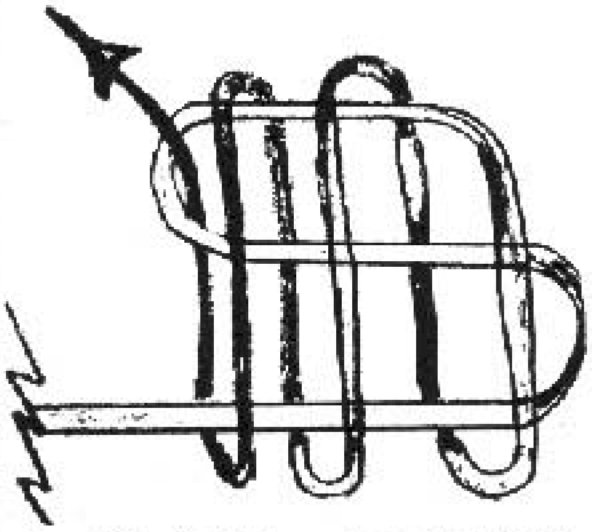
One knot that seems to hold a perverse fascination to some is the hangman's noose. It works by the slamming action of the coils striking the victim's neck, and in so doing, breaking it. An interesting sidenote is that many states have laws that attempt to regulate the number of coils a hangman's noose may have, the idea being to prevent unauthorized lynchings.

Since I've been going on about the hangman's noose, you are doubtless itching to make one of your own. To start, take some string, rope or what have you and lay it out on a flat surface as shown below:



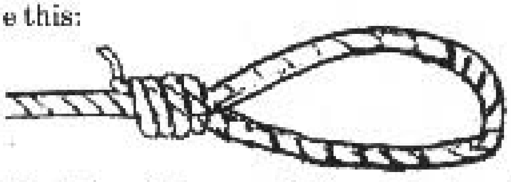
The drawing is sideways in the interest of saving space. During your first few attempts, points A, B, and C should be held stationary to prevent frustration from too many fouled knots. You can tape the points to a table or desk if you are using string, and tent pegs or similar, work well for rope. There should be a goodly amount of slack on the end that is pointed on the drawing; enough to make as many turns as desired. Don't worry about having too much excess; it is easily taken up when the knot is finished.

For your next step, make the following bends:



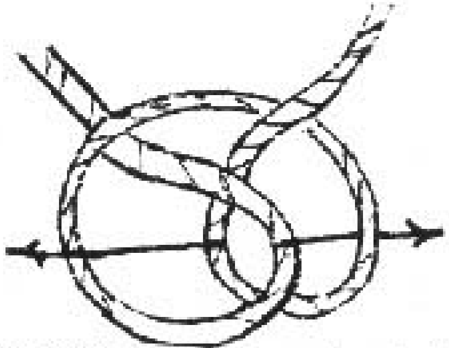
The number of turns are variable, but you get the idea. It seems awkward winding the coils around the thrice bent rope, but this feature is helpful to prevent breakage during use. You can see how embarrassing that would be, can't you?

Once you have completed your rope manipulations, the coils are pulled tight, most of the slack is cut off and the thing is done. The finished product should look like this:

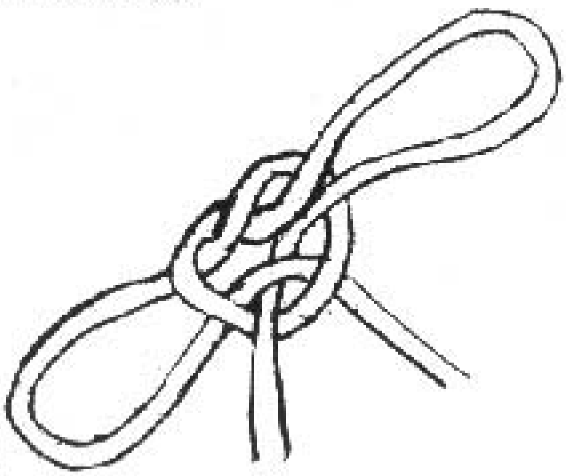


Don't be discouraged if yours doesn't look fit to appear on "Bonanza". As you practice, your skill will improve and you will be making perfect specimens with ease.

Another fun project in knot tying, and equally amusing, are the rope handcuffs. They are amazingly simple and might even come in handy someday. They are made by laying down two loops, the second on top of the first, like so:



They are then pulled through each other as shown. Illustrated below are the finished cuffs:



The victim's wrists are put inside the two nooses. The ends are pulled tight and knotted.

I trust you, the reader, to find many clever uses for both knots.

let it stand, and then boil, &c. Use add one teaspoonful of the powder to every pound of flour, and knead it well. By this powder hot rolls may be had to breakfast every morning, as its action is so rapid. Keep the powder in a well corked-bottle.

BEER, Excellent Table.—On three bushels of malt pour of hot water the third of the quantity you are to use, which is to be thirty-nine gallons. Cover it warm half an hour, then mash, and let it stand two hours and a half more, then set it to drain. When dry add half the remaining water, mash and let it stand half an hour, run that into another tub, and pour the rest of the water on the malt, stir it well, and cover it, letting it infuse a full hour. Run that off, and mix all together. A pound and a half of hops should be infused in water, and be put into the tub for the first running.

Boil the hops with the wort an hour from the time it first boils. Strain off and cool. If the whole be not cool enough that day to add the yeast, a pail or two of wort may be prepared, and a quart of yeast put to it over night. Before tunning, all the wort should be added together, and thoroughly mixed with the lade-pail. When the wort ceases to work, put a bit of paper on the bung-hole for three days, when it may be safely fastened close. In four weeks the beer will be fit for drinking.

Note. Servants should be directed to put a cork into every barrel as soon as the tap is taken out, and to fasten in the vent-peg, the air causing casks to become musty.

BILIOUSNESS. — The first thing is to allay the irritability of stomach; second, to evacuate the bowels of their acrid matter; third, to remove spasms, irritation, or urgent symptoms; fourth, to excite a healthy secretion of the liver. For these the *Neutralising Mixture* (see page 275,) will be found applicable for the purpose; give a small tablespoonful every half hour, or as often as the vomiting occurs, and when allayed take a good purgative; such as 1 oz. of castor oil, or a strong dose of Rhubarb; or a purging mixture: Glaubers salts, ½ oz.; Epsom salts, ½ oz.; spearmint water 5½ ozs.; antimonial wine, 2 drachms; tincture of senna, ½ oz.; mix, and take 2, 3, or 4 tablespoonfuls for a dose, every 3 hours until it operates. If these do not act recourse must be had to injections composed of:—Sweet milk, 1 pint; mucilage of slippery elm, 1 pint; olive oil, 1 gill; molasses, ½ pint; common salt, 1 oz.; mix. Use a large size syringe. Should there be great pain in the lower intestines add a drachm of laudanum to each injection, it will relieve the griping pain. Introduce as much of the injection as the patient can bear, to be repeated every hour or two until the

---

SURVIVAL ELECTRONICS

The following is presented to the person concerned with defending an area such as his home or farm. It is not aimed at the person who, in a disaster, heads for the hills with a knife in his teeth.

During any period of distress, it is important to know what is happening around you. Since almost all communications today are electronic, I will try to present some ideas about the simpler things that can be done.

Remember that there will always be some kind of broadcast radio service on the air. Radio stations that have had their towers and buildings knocked down by tornadoes have been back on the air in a matter of hours. That is what is expected of them, and their engineers know how to do it.

They will be sending important information about relief efforts, weather conditions, food, water and medical services that you may need very badly.

I am going to start with the first requirement -- a good AM radio. At the first thought, it seems like a good idea to buy a simple $9.98 transistor pocket radio and leave it at that, but there are some interesting problems to consider.

First, your ability to hear up-to-date information during a national emergency just may save your life. Are you going to depend on a radio that barely worked in the store it was sold in? Simply put, you need an extremely dependable radio.

Second, your little cheap radio always sounds great listening to that strong local station when you buy it, but the station you need to hear may be distant and weak or covered by static.

Third, during the disaster, are you going to run down to the local store and buy a fresh battery? Hell no. You need a long-life renewable power source.

There are several solutions to the problem. Let's call them the simplest, the cheapest, and the best.

THE SIMPLEST SOLUTION

The simplest solution is a quality portable radio. Buy only one kind -- Panasonic. Any model in the $50 to $100 price range will do which used "D" batteries, the common large flashlight battery.

Why Panasonic? I am in no way connected with Panasonic, but I have had considerable experience with the various brands of portable radios, and many thousands of dollars worth of laboratory electronic equipment to test them on. Other brands may be as good, but why take a chance?

When you buy your radio, ask for one that does not have a tape player or recorder in it. See that it has a button to turn on the dial lamp, and make DAMN SURE the store can get you the 12-V DC battery adapter so you can operate your radio from a car battery.

I am not giving model numbers, since models are changing constantly. Most changes are only external for sales appeal.

THE CHEAPEST SOLUTION

Surprisingly, you can often get a better radio for much less money, if you can use tools and do a little thinking.

The modern automobile radio is almost perfect. It is extremely rugged, uses 12-V DC, very sensitive, and uses an omnidirectional antenna.

Portable radios, including Panasonic, use a loop-type antenna for AM reception. The pull-up whip is only for FM. The reception of this type of radio is often very directional. Thus, the station that you need to hear just may be in the radio's null spot! You can waste a lot of time turning your radio trying to pull a signal in.

The whip or mast type of antenna used on the car radio works much better. It picks up stations from every direction, plus the whip is much more sensitive to weak signals than the loop. Your car radio also has special noise eliminating circuits in it to remove some of the static.

Picking your car radio takes some judgment. Follow these guidelines:

1. Pick an AM/FM from a late model, if you can.
2. DO NOT get one with an eight-track player in it.
3. DO NOT get one with tubes in it. Some special tubes made for car radios are not available ANYWHERE!
4. Use the original speaker if the radio is AM only. Many transistor radios use oddball impedance speaker.
5. Take the original electrical plugs; it will make your wiring neater and easier.
6. Simply use a piece of wire for an antenna or buy a new one. DO NOT try to salvage the original one. That heavy-looking cable to the antenna is actually very delicate.
7. Make the seller test the radio before you buy it.

Additional Note: If you own one of those God-awful mistakes from Detroit that has the "antenna" in the wind shield, put a standard car radio antenna on your fender and connect it to your radio. You will be absolutely amazed at how much better your radio will work.

Now let's get that prize of yours working.

First, you need power. Buy a good 12-volt auto battery and small charger. DO NOT get some junker from the trash pile of a gas station. A good dependable bowels are moved or the pain abated.

Apply *Rheumatic Linament* warmed, with a flannel dipped in it, to subdue pain in the abdomen.

BLISTERED FEET.—Before and after walking, wash the feet well in a solution of Sal Ammoniac—half an ounce in two quarts of water. Let not the stocking be wrinkled, or much mended, when you walk. Easy boots and shoes should be worn, and very smooth next to the sole of the foot. ——Or, the best remedy for this is to rub the feet, when going to bed, with spirits mixed with tallow, dropped from a lighted candle into the palms of the hand.

BUG POISON.—The spirit of tar is a powerful remedy, applied by means of a brush; chloride of lime is a very good wash.—Bugs have become so general a nuisance, much care is necessary to get rid of them. Bedsteads should be taken to pieces at the beginning of the year, and each part washed with a strong solution of corrosive sublimate. The crevices or cracks should be stopped up with putty, then the joints and crevices painted with white lead, to be well dried before the bed is put together. Bugs do not like paint, it is too cold for them. If the walls are infested, the paper should be removed, and the walls washed with the corrosive sublimate, (stopping all cracks in the walls with plaster of Paris.) The floor in inveterate cases, may be painted all round the skirting-board to the extent of four inches. As the corrosive sublimate is a strong poison, the bottle containing it should be marked, and a caution given to those who apply it.

Coal oil, or naptha, is said to be a sure destroyer of bed-bugs. Apply plentifully, with a small brush or feather, to all places where they congregate. The cure is effectual and permanent. Gilt frames, chandeliers, &c., rubbed slightly over with coal oil, will not be disturbed by flies.

CANCER.—A cancer is a hard indolent tumour, usually seated in some of the glands, as the arm-pits, eye, nose, lips, tongue, womb, and the female breast; the two last are most subject to it. It affects the aged more than the young, and may exist for years. It commences with a small hard tumour, increasing slowly, and attended with

battery can be used for much more than this radio, IF IT WORKS!

Build for your battery a nice wooden box with a cover and few vent holes. Place it in a cool, NOT COLD, well-ventilated place and run some heavy wires (No. 12 to 14) back to your radio. Always connect the charger directly to the battery. Use a hydrometer to check the condition of the cells and charge according to its readings. Use only distilled water to top off the cells and do not over-fill. Keep the terminals greased on the outside to prevent corrosion.

If your house has metal siding, mount the antenna outside of a window. If you're in a standard frame building, mount the antenna on the box that holds the radio.

Your radio will have two power leads. One operates the radio; the other the dial light. Put a little switch in the light lead so it will only draw power when you need the light. Make sure that the lamp and the radio power leads have fuses in them (two amps is normal). This could save you a lot of burned up wiring or a fire.

If your radio has only one speaker wire, the other terminal of the speaker connects to the case of the radio, as does the negative wire from the battery.

If you want your radio to be really HI-FI, mount your speaker(s) in a baffle.

Build a wooden box of about three cubic feet volume. Any firm wood, plywod, or particle board will do. IMPORTANT: Line the inside of the box (baffle is the proper term) with fiberglass insulation -- glass side out. Just glue the paper backing to the wood. This won't sound as good as $200 stereo system speaker, but it will sound one hell of a lot better than a bare speaker lying on a shelf.

Do the above with a good quality AM/FM stereo car radio, and you will be amazed at the job it will do. It will work better than any of the cheap three-piece stereo radios that you would normally buy. Plus, it will operate for many, many days off its auto battery during a power failure.

THE BEST SOLUTION

The auto radio is a hard one to beat. The only thing that would really be better is a professional communications receiver.

This is what used to be called a short-wave radio. There is much more to radio than just broadcast and CB. If you really want to know what is going on in the world and listen in on amateur (ham) emergency messages, this is the way to do it.

IMPORTANT NOTE: Almost all amateur, military, marine and government communications are by two modes -- teletype and voice by single side band (SSB). NO ONE uses AM except international broadcast stations. (And their broadcasts are, with few exceptions, mostly propaganda.) The value of your receiver depends on how well it will receive SSB voice transmissions.

The old short-wave sets were built before SSB became common, and the cheap, so-called multi-band portable radios, do not have the circuits called BFO's or product detectors to receive SSB. Nor are the dials designed for the delicate tuning often required.

Because of these problems, the design of the modern radio is quite different than those of years gone by.

Whatever you do, do not try to use or convert any old surplus military radio equipment. It is simply not worth the time unless you are a well-trained electronic technician with a good shop. Military equipment often uses tubes or other parts that look like they were made on Mars. Spares are difficult to find. The radios usually require 24 volts DC for power or worse, 400-cycle, three-phase AC.

The design of most surplus is obsolete—that's why it is surplus! Yes, I know it's waterproof and its paint job matches your tank; but do you really want a 30-year-old weirdo radio?

If you have the money, buy a DRAKE Model SSR-1 receiver at $350. It covers from the bottom of the broadcast band, ½ MHZ, to-way past the CB band, 30 MHZ and all the short-wave bands and ham bands in between. An excellent receiver for AM, SSB and code, it will operate from 12 volts and is made in the U.S.A.

There are several other excellent imported communications receivers available. Seek out the opinion of a couple of local amateurs to help you pick it out. I DO NOT recommend the Radio Shack equipment.

Short wave listening is a very complex subject that I can not cover here. This is where world radio communications is carried out, and whenever there is any kind of disaster or emergency, the amateurs will be on the air handling messages to and from the area.

In one serious flood in my area, teen-age hams using their own equipment provided the U.S. Army with most of its communications for two weeks!

In the meantime, you CB people will be amazed to hear the job a professional receiver will do on the CB band; far better than any CB set you have ever heard.

Remember, if the world turns into a total mess, you can always cobble up some kind of transmitter for communications, BUT ONLY IF YOU HAVE A PROFESSIONAL RECEIVER TO START WITH!

acute shooting pains; sooner or later ulceration sets in. The discharge is so acrid as to inflame the part with which it comes in contact. The place where cancer occurs assumes a purplish appearance previous to its ulceration. Ulceration gives ease for a time, but the cancer penetrates deeper, and spreads wider, corrupting the stream of life, and reducing to the greatest debility, and often terminating in death.

To Cure, remove debility, and improve the general health. Regulate the bowels, and give an emetic. Give a vapour bath made of bitter herbs, as camomile, hops, catnep, tansy, &c. and boiling water and vinegar. Occasionally rub the whole surface of the body with the following liniment;—cayenne, a tea-spoonful; salt, two table-spoonfuls; pour upon them half a pint of boiling water; infuse three hours, and then add half a pint of boiling water; infuse an hour longer, stirring occasionally. Steaming with the bitter herbs, combined as above, allays the pain, swelling and inflammation. The following pills will be of much use; blood-root, one and a half drachms: extract of dandelion, three drachms; lobelia seed, one drachm; cayenne, one drachm; senna, in powder, one drachm; add three drops of oil of mint, and form into pills. These pills will be found very efficacious in the cure of jaundice, and liver complaints.

Citric Acid will relieve the pain of cancers. Dr. Brandini, of Florence, had a patient, aged 71, affected with cancer on the tongue. An operation could not be made, for the affection was too extensive, investing the base, the sub-lingual, and the sub-maxillary glands. In the midst of his pain, the poor man asked for a lemon. It abated the pain; and the next day it gave him still greater relief. This led the doctor to try *Citric Acid;* four grains of the acid, in one ounce of water; and this, as a gargle, entirely carried off the pain, and reduced the swelling of the tongue very much. The doctor tried the same remedy on a female with an ulcerous cancer on the breast, deemed incurable. Her torments were so great, that neither she, nor the other patients could get any rest. He applied a pledget of lint soaked in the above solution, and the relief was instantaneous. It was repeated with the same success. Thus Citric Acid promises to be a great boon to mankind.—Citric Acid is prepared from lemons.

Externally apply the following;—Simmer cicuta leaves till they are soft, then mix them with slippery elm bark, to form a poultice; apply morn and night. It is valuable.—Or apply the *Irritating Plaster*, for a continual

Survive Through a Home Business

By Kurt Saxon

As our system slows down, unemployment will soar. Revenue for welfare will dwindle due to the scarcity of taxpayers and the recipients will starve. Less taxes will bankrupt the Social Security system and the elderly will starve. Industries will shut down and labor unions will go broke for lack of dues paying members. Cities will become shooting galleries and small towns will become garrisoned city-states.

As bad as this might seem, now, it has to be so you might as well prepare to ride it out.

Your only real hope in the near future is a home business. This will not only give you independence, but it will give you the confidence that destroys fear.

A home business has many advantages over being employed by others. First, you don't have to commute to work. Also, being around the home all day provides the best security as you are usually on hand to defend your home and loved ones.

Another big advantage is that a home business is almost tax-free. Everything connected with your business is deductible. Rent, utilities, your car or truck, gas and just about anything you buy and can claim as a business necessity. You can also deduct any business losses.

The factory or office worker can't deduct his rent, car, gas or any transportation expenses unless he's a traveling salesman or something similar. He must pay more for clothing so as to be presentable to the public and his fellow workers. Working for others is very expensive. Even union dues aren't deductible.

So if you work for others, you are a virtual slave. A big slice of your earnings is taken from your paycheck each payday. You never see it. You can't use it, invest it or even put it in the bank to draw interest until April 15.

Many Americans take in millions each year and pay no taxes at all. They know all the loopholes and declare only what they please. The working stiff, however, has no loopholes to speak of and he can't even cheat on his taxes. At least not where his main earned income is concerned.

Another good reason to start a home business is that you can't be fired or laid off. In that sense, it's depression-proof. Of course, if you fail in your business, you've created your own depression.

For this reason, you must practice a lot of caution and foresight. Don't quit your job until you are making as much or more from your home business as from your job.

Part of the beauty of starting a home business is that you can build it up while you are holding a regular job. There is a lot less risk in starting a home business than if you started a contracting or service business where you had to work full-time.

At this point I want to advise you against the home business come-ons in such magazines as POPULAR MECHANICS. Everyone has seen their ads for home business or to be worked out of the home, such as upholstering, locksmithing, carpet cleaning, TV repair, electrical appliance repair, etc.

These ads are all sucker bait.

First, they are written by expert ad copywriters to appeal to the ignorant and unskilled. They have their testimonials, usually from the one-out-of-a-thousand who did succeed with their business.

They know very well that most of their customers will not get a return on their investment. A person with the skill and discipline to really apply himself to such a business, would be a success at most anything and would have no need for their course.

And in most cases, it is simply a correspondence course. Such courses are so expensive, from $200 to $800, the ad writers leave out the price of the course. You have to send away for even more of their advertising.

In most cases, if your community can support the business they advertise, discharge must be kept up, as the patient is able to bear it. The douch bath has been recommended, and doubtless it has had a good effect in many cases. The following applications are useful ;—

Cayenne and lobelia seed, equal quantities powdered ; meadow-fern and balm of Gilead buds, of each 3 ozs. (these two steeped in spirits for five or six days, and made into ointment, with lard sufficient.) Unite the whole as a paste, and apply to the cancer, covering with a cloth. When the plaster is taken off wash with soap-suds.—Or burn a quantity of red oak bark to ashes, and make into lye. Boil the lye till it becomes as thick as honey. Then apply constantly. Such preparations, by their stimulating and relaxing properties, excite a preternatural discharge, or cause a sloughing of the ulcer, and thus remove or lessen it. Use one of these ointments principally, the *Black Salve* occasionally, and after much discharge, dress with an emollient ointment. This treatment has effected numerous cures. (See Black Salve.)

A decoction of narrow-leaved dock-root has been found to produce rare effects. Saturated cloths with the same may also be applied. Or the root may be powdered, and made into an ointment with lobelia seeds powdered.

CANCER.—Use the cold bath.—This has cured many.—A bleeding cancer was cured by drinking twice a day a quarter of a pint of the juice of clivers, or goose grass, and covering the wound with the bruised leaves. Another by the following receipt :—

Take half a pint of small beer. When it boils, dissolve in it an ounce and a half of bees' wax : then put in an ounce of hog's lard and boil them together. When it is cold pour the beer from it, and apply it spread on white leather. Renew it every other day. It brings out great blotches, which are to be washed with sal prunello dissolved in warm water.

If it be not broken, apply a piece of sheet lead beat very thin, and pricked full of pin holes, for days or weeks to the breast. Purges should be added every third or fourth day.—Or, rub the whole breast morning and evening with spirits of hartshorn mixed with oil. Or, keep it continually moist with honey.

CANCER PLASTER.—White oak-bark, 4 oz. ; bruise it well, and add urine sufficient to cover it. Infuse four days, boil it till it becomes as thick as treacle. Add 2 ozs. of honey, and 2 ozs. of strained turpentine gum. To make this plaster caustic, add 2 drachms of white vitriol. Spread on soft leather, or linen.—It may be applied to all kinds of ulcers, white swellings. For cancers it is invaluable.

there is already an established business in that line. But they avoid such considerations. Their aim is to make you believe that an amateur such as yourself can successfully compete with established professionals. This is unrealistic at best.

But you might ask, if their deals are really rip-offs, how do they stay in business? Well, you take any ad, full page, costing several thousand dollars for each insertion, run month after month, year after year. They couldn't afford these ads if they weren't selling a lot of those courses.

But where are their graduates? There should be a locksmith on every corner and a TV repairman in every second house on the block.

The truth is that most correspondence schoolers drop the courses after a couple of lessons. And the schools couldn't pay for those ads if they didn't threaten to prosecute the student for payment for part or all of the failed course.

Another thing wrong with the majority of such courses is their specialization. The course and the equipment you get is worthless for any other application.

Also, for a small tuition fee, you can take night high-school or college shop courses on many of the skills these correspondence schools offer.

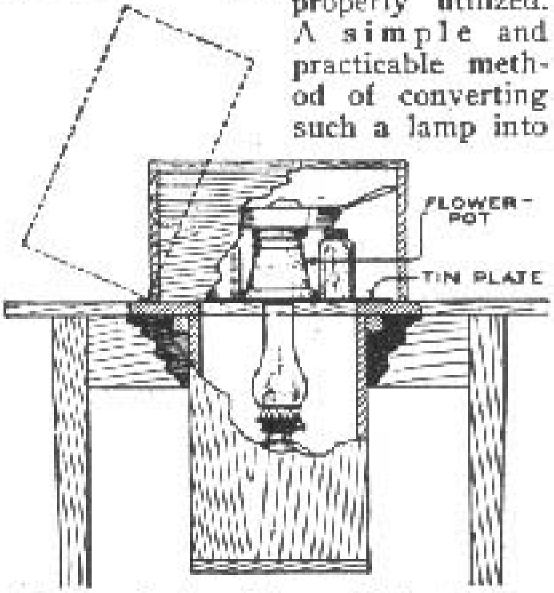
When considering a home business, instead of some exotic line, you should choose a line you are familiar with. Even if you are not so familiar with a certain line, there are so many how-to books on the market that you should be able to find just the material you need.

You should reject all lines which would not be essential after the collapse.

A Lamp Cooker

From Popular Mechanix 1919

An ordinary circular-wick kerosene lamp produces enough heat to do considerable cooking, provided the heat is properly utilized. A simple and practicable method of converting such a lamp into a cooker is as follows: Saw a hole, 12 in. square, in the top of a small table, or packing box of about the same height as a table. Cover this with a piece of sheet metal, having a 4-in. hole in the center. Place a 5-in. flowerpot over the hole in the metal, and plug up the hole in the bottom of the pot with fire clay or plaster of Paris. Vegetables in jars may be set around the flowerpot to cook slowly and a roast in a pan on top of it. A wooden box, or metal pail, large enough to cover the arrangement, should be placed over it. Air holes should be provided in the lower box and in the cover.



This Lamp Cooker will Prepare Meats and Vegetables Satisfactorily, and Is Useful for the Camper and in Emergencies

To operate the device light the lamp and when it is burning brightly, place it under the table, elevating it so that the top of the chimney is in the center and barely within the rim of the flowerpot. Use little water in the vegetables and keep the caps loosely on the jars. The roast, if well buttered, will brown nicely, and while the cooking will require considerably more time than it would in a range, the results will be as good, if not superior. The natural juices are preserved by the slow cooking at comparatively low temperature. The cover may be lifted to turn the meat occasionally. This device will appeal to campers, summer cottagers, and others.

Homemade Electric Plant from Old Auto-Truck Chassis

From Popular Mechanics 1933

Owners of a filling station and general repair shop, where electricity was used extensively, found that the cost of the current was too high and installed their own generating plant, the main part of which was an old auto truck. They set the truck chassis on blocks and fastened a multiple V-pulley on the driveshaft. Just above this, a 20-amp. generator was mounted on the frame and was belted to the driveshaft pulley by means of five V-belts, which decreased belt slippage to a minimum. The motor was altered to run on natural gas by enlarging the air vent in the carburetor. With this plant, electricity was produced at a cost of about one cent per kilowatt hour.

CARMINATIVES.—Rind of Seville oranges, 3 drachms; fresh lemon peel, 2 drachms; ginger, in powder, ½ drachm; boiling water, 8 ozs. Infuse 2 hours, and strain. Then take of the above, ½ oz.; spirit of peppermint, ½ drachm; spirit of lavender, ½ drachm.

Antiflatulant Mixture.—Oil of aniseeds, 10 drops; refined sugar, 1 drachm. Beat up together, and add, tincture of ginger, 2 drachms; peppermint water, 6 ozs. Mix; three tablespoonfuls when needful.

Another.—Assafœtida, 6 grains; rhubarb, 4 grains; oil of aniseeds, 5 drops. Make two pills, and take every five or six hours.

CARMINATIVE DROPS; for Expelling Wind.—Angelica, 2 ounces; lady's slipper, 1 ounce; sweet flag, ½ ounce; anise, 1 ounce; fennel seed, ½ ounce; catnep flowers, 1 ounce; motherwort, 1 ounce; pleurisy root, 2 ounces. Infuse in a pint of spirits of wine for three or four days, oft shaking, keeping it in a warm place; then add a pint of water, and a tablespoonful of tincture of cayenne. Excellent in flatulency, colic, nervous affections, promoting perspiration, and refreshing sleep.

Another Receipt.—Anise, dill, fennel seed, of each ½ ounce; catnep flowers, and motherwort, of each, 1 ounce; pleurisy root, 4 ounces. Infuse in brandy for 22 hours, and then strain; to children, give from five to fifty drops; and to adults, from one to four teaspoonfuls, every three or four hours.—It eases pain, produces perspiration and sleep, removes flatulency, colic, and is an excellent nervine.

CARMINATIVE PURGATIVE.—Tincture of senna, 1 oz.; powder of aloes, 10 grains; peppermint water, 3 ozs.; syrup of ginger, 1 oz. Two table-spoonfuls for a dose, repeated in three hours if necessary.

CHARCOAL, useful properties of.—All sorts of glass vessels and other utensils may be purified from bad smells by rincing them out with charcoal powder, after the grossest impurities have been scoured off with sand and potash. Rubbing the teeth, and washing out the mouth with charcoal powder will render the teeth beautifully white, and the breath perfectly sweet.

CHARCOAL MEDICINE.—It is much used in Mexico, and in South America, where few drugs are procurable, save those "simples" which the ingenuity and experience of the *Indian Herbalists* have devised. Freshly-burnt Charcoal, reduced to powder and given in water, is in great repute. It immedi-

Build a Pit Cabin

by Ron Lank

The nuclear war which the Pentagon expects to devastate North America before the end of this century will make a lot of changes in our lifestyles. One which you may wish to make and live in is a pit cabin.

Instead of building your log cabin to the usual height, build the walls on easily dug, well drained soil to a height of only three or four feet. This will save you the labor and back breaking risk of lifting logs over your head. Also, when you put the roof on you can stand on the floor and work at an easily accessible height, so you can do a good job. Install the door with the idea that you will later want to extend it downward. If the ground has a slope, put the door on the downhill side.

After the original low wall cabin has been completed you can then lower the floor by digging.

In selecting your logs, cedar should be selected as the bottom layer, in contact with the ground. Poplar or whatever else is available may be used for the other layers and for the roof. The reason I'm suggesting the use of poplar is the fact that there is so much of it around. Spruce is also excellent.

Poplar, when fresh cut, is fairly soft and easy to work. After it has dried it becomes very hard and serviceable.

In using poplar, leave most of the bark on to discourage rot. Peel off about a twenty degree strip of bark off each log from the side toward the inside of your cabin. This will control the shrinkage of the bark.

After you have the basement dug out to the size you want you can line it with cedar logs to keep the dampness from the soil out. Cedar should be used because it will be the most rot resistant wood available.

Besides the ease and safety in building, a pit cabin has other advantages. When the winter blizzards slam against the sides, you're going to be hard to get at even if one should find any openings where you didn't jam enough moss, clay and stuff between the logs. It will take less firewood and other stuff piled against those low walls to double the insulation than on a conventional structure.

With the cold wind finding it so difficult to get in, and the heat from your fireplace finding it so difficult to get out, your new home will be just plain cozy.

If somebody doesn't like you, attacking you in your roofed over foxhole can be ridiculously hazardous to his health. You may wish to camouflage your pit cabin by adding rocks to the outside insulation, leaving only a few gun slits here and there to help air the place.

Just how difficult and hazardous a pit cabin can be to attack was proven to the Mounties when they attacked Albert Johnson, The Mad Trapper, in his pit cabin in the Yukon. They nearly got him when they threw that bundle of dynamite onto the roof. There's nothing like a roof built of a row or two of good stout logs to complicate that sort of thing.

From Popular Mechanics 1932

Sheet Metal Clamped in Vise Is Bent by Means of Wooden Block and Mallet

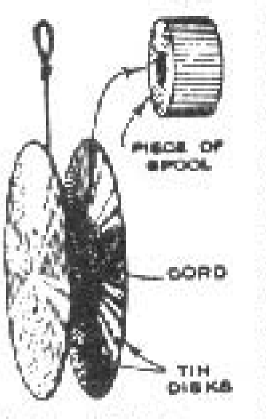
Shaping Sheet Metal without the Use of a Bending Machine

To shape sheet metal without the use of a bending machine, place a suitable length of angle iron on each side of the metal and clamp the assembly in a vise. The sheet metal can then be bent by holding a block of wood against it and striking the latter with a mallet.

Making and Using the "Bandilore"

An East Indian toy, known as a "bandilore," is made from a piece of spool, about ½ or ¾ in. thick, and two tin disks, about 4 in. in diameter.

The section of spool is tacked between the two disks, exactly in the center. Tie one end of a 3 or 4-ft. length of stout cord to the spool. The bandilore is operated by winding the cord around the spool, and holding the free end of the string in the hand. The toy is dropped and descends with great speed; just before the end of the cord is reached, the whole thing is given a quick upward jerk. This increases the speed and momentum of the disks so that the cord is wound in the opposite direction, and the bandilore climbs upward, the process being repeated as often as desired.



ately removes offensive odours from intestinal and renal discharges, and purifies the breath, it removes offensive exhalations from any part of the body, either given in water, or in the form of pills, made up in wheat flour, or gum mucilage. It removes pains about the right shoulder caused by obstructions of the liver. As an antiacid, either or combined with rhubarb, and carbonate of soda, it speedily and permanently removes heartburn. Charcoal is a powerful antiseptic, removing, or checking decay, and must be very valuable in the incipient stages of consumption.

CHLORIDE OF LIME.—Scatter chloride of lime on a board in a stable to remove all kinds of flies, but more especially biting flies. Sprinkling beds of vegetables with even a weak solution, effectually preserves them from caterpillars, slugs, &c. A paste of one part powdered chloride of lime and one half-part of some fatty matter placed in a narrow band round the trunk of a tree, prevent insects from creeping up it. Even rats, mice, cockroaches, and crickets flee from it.

CHLORIDE OF LIME.—*It is* a great purifier. One pound requires three gallons of water; use the clear solution. To purify rooms, sprinkle on the floor; and if needful, on the bed-linen. Infected clothes should be dipped in it and wrung out, just before they are washed. It purifies night commodes, and water closets, &c.

COCKROACHES, to Destroy.—Mix bread crumbs, sugar, and corrosive sublimate, and place it near their haunts.—Or mix sugar, laudanum, and water together.—They are very fond of beer, which might be substituted for water.—Some persons have found a mixture of plaster of Paris, sugar, and oatmeal, effectual.——Powdered phosphorous, oatmeal, and sugar, form a sure remedy.

CREAM CHEESE.—Put five quarts of the last milking of a cow, called "*strippings*," into a pan with 2 spoonfuls of rennet. When the curd is come, strike it down with the skimmer to break it. Let it stand 2 hours, spread a cheese cloth on a sieve and drain upon it; break the curd a little with your hand; put it into a vat with a 2 lb. weight upon it. After standing 12 hours bind a fillet round. Turn every day till dry; cover with green leaves, and let them gradually ripen on a pewter plate.

EGG PICKLE.—Boil from two to three dozen fresh eggs quite hard; then set a sufficient quantity of good vinegar over the fire, ginger, white pepper, mustard seed, and a clove or two of garlic. Having placed the eggs

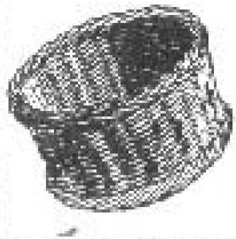
Reed Furniture

By Chas. M. Miller

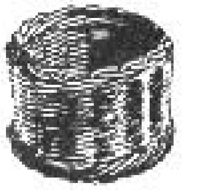
From Popular Mechanics 1915

A Reed Basket

INASMUCH as there is a great demand for reed furniture and since good weavers are comparatively few in number, it would be well to learn the process of reed weaving. The weaving operations can be learned much better through the construction of some small article, such as a basket or jardinère cover. The center is the most difficult part of the basket making, and it is best to begin with wood bottoms, as the whole basket can be kept in a much better form due to the stiffness furnished by such a bottom. It is also an approach to the reed furniture which is woven on framework. The objectionable feature of the wood bottoms is the unfinished appearance of the wood edge showing through, but this can be overcome by the use of the roll shown in the illustration.



While the wood bottoms have been used for this class of work for a number of years, the roll is new and is very popular with those who have seen and used it. The roll can be placed in many ways on different-shaped baskets, and other reed pieces, so that it is best to master this piece of work thoroughly before attempting the other, or larger, pieces that will be described later, in other articles.



The description is for a basket 5 in. in diameter and 3 in. high, as shown in the illustration. A disk of wood, ¼ in. thick and 5 in. in diameter, is required. Basswood makes the best bottom, but pine, or cedar, will do. Cut a board about 6 in. square, and draw diagonal lines on it intersecting at the center, then draw a circle, 5 in. in diameter, as shown in Fig. 1; also another circle, using the same center, 4¾ in. in diameter. Set compass points about ⅝ in. apart, and step off spaces on the inner circle to make 24 points. This will have to be tried out more than once, to get the spaces to come out evenly and just have the right number of points. Holes are bored with a ⅛-in. bit, just inside of the inner circle, back of the places marked by the compass points, as shown in Fig. 2. Cut the board on the outside circle with a coping, or turn, saw, to make the circle, as in Fig. 3. Do not saw out the circle before boring the holes, as otherwise the disk might split out in places.

The reeds placed vertically are called spokes, and the horizontal ones are the weavers. For the spokes, what is called a No. 4 reed is used. Do not wet the spokes before putting them through the wood. Allow the ends to project about 5½ in. below the bottom, as shown in Fig. 4. Place the bottom, with the spokes, in water, and soak them thoroughly, especially the part below the bottom. About 15 minutes of soaking will be sufficient to make them pliable enough to bend over at right angles. It will not injure the wood bottom to soak it with the reeds. As shown at A, Figs. 4 and 5, each spoke below the wood bottom is bent down and back of the two nearest spokes, B and C, then out between the third and fourth spokes, C and D, and so on. The last two spokes, Y and Z, Fig. 6, are forced under the spokes A and B, respectively. In this illustration the spoke Y is shown as it is being inserted under the spoke A. When this operation is completed, the bottom will have the appearance of a fireworks pinwheel.

Continue the bending of the spokes, in the same direction, up and across the thickness of the wood in front of three other spokes and behind the fourth, as shown in Fig. 7. This would not cover the edge of the wood entirely, and, for this reason, other short spokes must be inserted in front of each of the first ones before it is brought up without shells into broad mouthed jars, pour the vinegar, &c., over them. When cold tie them down. The pickle will be ready in a month. It forms a pretty garnish when cut in slices, and constitutes a piquant relish with cold meat.

EXTRACTS, to Make.—Take of the plant, root, or leaves you wish to make the extracts from, any quantity, add sufficient water, and boil them gradually, then pour off the water and add a second quantity; repeat the process until all the virtue is extracted, then mix the several decoctions, and evaporate at as low a temperature as possible, to the consistence of an extract. Extracts are better made in a water-bath, and in close vessels, and for some very delicate articles, the evaporation may be carried on at a very low temperature, in a vacuum, by surrounding the vessel with another containing sulphuric acid. Manufacturing druggists usually add to every seven pounds of extract, gum arabic, 4 ounces; alcohol, 1 ounce; olive oil, 1 ounce. This mixture gives the extract a gloss, and keeps it soft.

FEATHERS, to Clean.—Feathers may be cleansed from their animal oil by steeping them in lime water—1 lb. of lime to a gallon of water, stir well, and then pour the water from the lime.

To Cleanse Feathers from Dirt, make a strong lather of white soap and hot water. Put in the feathers and rub them for 5 minutes. Rinse in clean hot water.

FEATHERS TO CURL.—Heat them slightly before the fire, then stroke them with the back of a knife, and they will curl.

FEATHERS TO DYE.-Steep them a few hours in warm water.—*Blue* may be dyed by extract of indigo and boiling water. Simmer over the fire a few minutes.—*Green*; Verdigris and Verditer, 1 oz. each; and gum water; dip the feathers. Or mix the indigo liquor with Persian berry liquor. —*Lilac.* Use cudbear and hot water.—*Red.* Brazil wood, a little vermilion and alum, and vinegar; boil 30 minutes; and then dip the feathers.—*Yellow* by turmeric.—*Scarlet*, by cochineal, cream of tartar, and muriate of tin.—Ready prepared dyes can be purchased at the druggist's shops.

FRECKLES.—Take 1 oz. of lemon-juice, a quarter of a drachm of powdered borax, and half a drachm of sugar; mix, let them stand a few days in a glass bottle, then rub it on the hands and face occasionally.——Or, mix two-teaspoonfuls of muriatic acid with 2 ozs. of spirits of wine; and 1¼ pint of distilled water.——Or, 2 drs. of muriatic acid in 1 pint of water, and a

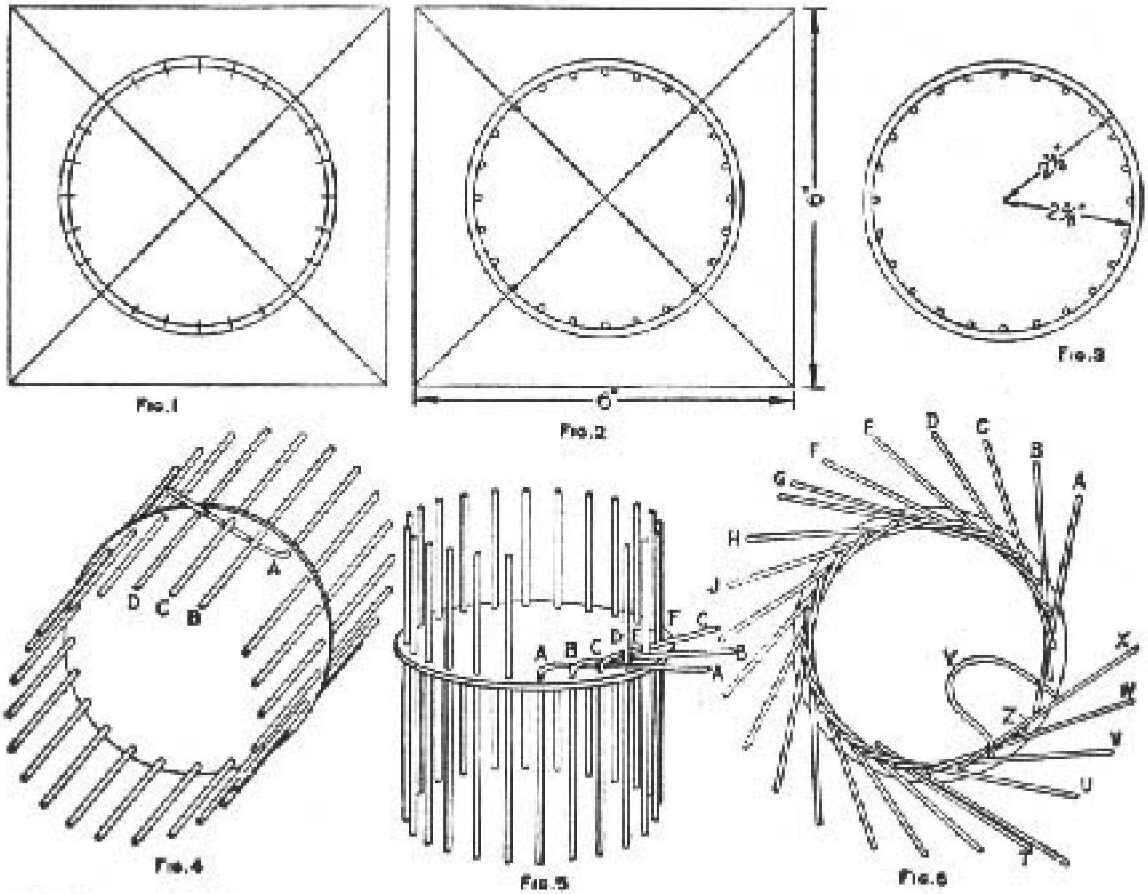


Fig. 1 Fig. 2 Fig. 3 Fig. 4 Fig. 5 Fig. 6

The Bottom is Cut from a Piece of Wood to Give Strength and to Avoid the Most Difficult Part of the Weaving; the Reeds are Attached to the Bottom and Their Lower Ends Bent as Shown

across the edge of the wood. These supplementary spokes should be about 4 in. long. The manner of inserting these spokes before making the bend is shown at G and T, Fig. 6. The double spokes must be pressed down flat, when brought up in place, without riding one on the other. If the ends are too long and interfere with the next pair, they can be cut off a little with a flat chisel, or knife, being careful not to make them too short, or the pieces will not stay in place. If there is still an open space, an extra, short spoke can be inserted to crowd the pieces together and fill up the space.

When the roll is completed, insert three weavers, of No. 3 reed that has been soaked about 15 minutes, placing them between the spokes A and B, B and C, and C and D, as shown in Fig. 8. Pass weaver L in front of the spokes B and C, then back of D and out between D and E. Weaver M is passed in front of C and D, back of E and out in front of E and F. These operations are clearly shown in Fig. 9. The weaver N is placed in front of D and E, back of F and then in front of G and H. At this point the weaver L is used again. The weaver farthest behind each time is brought in front of the two spokes nearest to it, then behind the third and out in front of the next two spokes. Do not try to use weavers longer than 8 ft., which is about half the length of a reed. When a weaver is used up, press it back to the side a little, push in a new reed about 1½ in., and continue the weaving. This is clearly shown in Fig. 10. This weaving is known as the triple weave, which cinches down well and holds tightly. The first round should be carefully worked, so as to get the ends of the roll properly pressed down flat in place. Each throw of the weaver should be well pressed down.

The break-down-tight border is used for the finish at the top. The first operation in making this border is shown in Fig. 11. The spoke A is bent over back of spoke B and out between spokes B and C. The spoke B is bent over back of the spoke C and out between C and D, and so on, until the spoke E is turned down. Then take the end of the spoke A, Fig. 12, and lay it over B, C, D, and E, in front of F, back of G, and out between G and H. The end of spoke F is then brought down, also between G and H, but back of the end of A. The end of B takes a similar leap, passes behind H and out between H and J; then G is brought down behind the end of B, in the same manner as F was brought down back of A. The last four or five spokes are the most difficult to handle, as they must be forced through the first ones to correspond with those already in place. It is best not to pull the ends of A, B, C, and D down too tightly at first, keeping in mind that the last ones must be inserted under the first ones. The last standing spokes are represented by the full and shaded lines.

teaspoonful of spirits of lavender. Apply with a camel hair pencil, or linen.—— Or, horse-radish steeped in sour milk for 12 hours, and a drop or two of tincture of myrrh. Wash two or three times per day.

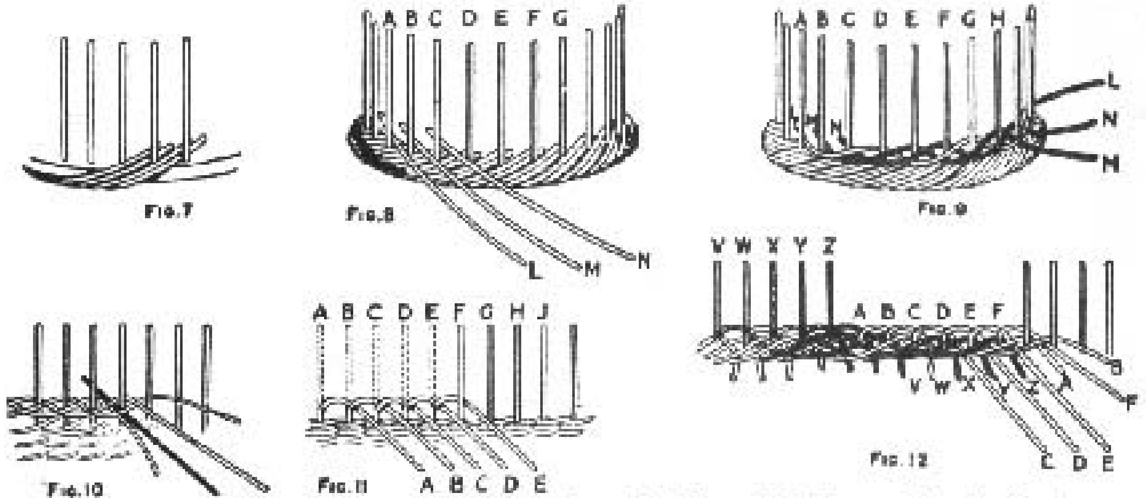
FREEZING MIXTURES.—If ice cannot be obtained, water may be cooled to the freezing point by the following mixtures:—sal ammoniac, 5 parts; nitre, 5 parts; glauber salts, 8 parts; water, 16 parts.——Or, nitrate of ammonia, 1 part; carbonate of soda, 1 part; water, 1 part.——Or mix 1 part of muriate of ammonia, or sal-ammoniac powder, with 2 parts of nitrate of potash, or saltpetre:—this forms *one powder*. The powder to be mixed with it is formed of barilla, or the best Scotch soda, powdered. This must be kept in a cool place, well corked, as must the first powder. For use put an equal quantity of these two powders into the ice-pail, and pour on them as much cold spring water as will dissolve them.

FRUIT SALT.—This excellent article is composed of 2 ozs. of Epsom Salts, 2 ozs. of Cream of Tartar, 2¾ ozs. of Carbonate of Soda, 2½ ozs. of Tartaric Acid, 4 ozs. of finely powdered sugar. Mix rapidly altogether adding a small quantity of Bromide of Potass. Put into a dry bottle, *well corked*. Take a good tea-spoonful in a tumbler glass of water occasionally. It is excellent for quickly moving the bowels, pain in the stomach, &c.

FUEL, Cheap.—One bushel of small coal or saw-dust, or both mixed together, 2 bushels of sand, 1½ bushels of clay, made into balls, or bricks, and allowed to set firmly, will supply an excellent fuel, and effect a great saving in coals.

FUEL, to Save.—Take 4 lbs. of chalk in lumps, not above ½ lb. each. Make a clear fire of coal, and place the lumps of chalk in the grate, as coal is laid. The chalk becomes red hot, so as to be scarcely distinguishable from burning cinders. A few ashes or small coal thrown lightly on from time to time, will keep up a clear bright fire all day. The same chalk may be used 3 or 4 days, when it becomes lime, and manure for gardens or allotments, or for whitewashing. Half-a-peck of coal used thus with chalk, will give a capital fire for 14 hours. The saving in coal is 1½. In grates the chalk should be kept behind, and coals in front; because chalk will not burn unless in has coal or heat on all sides of it.

FULMINATING SILVER.—Put into a small-necked bottle, resting on a little sand, one part of fine silver filings and 3 parts of nitro-muriatic-acid. When the silver is dissolved, pour the solution into a glass, add 5



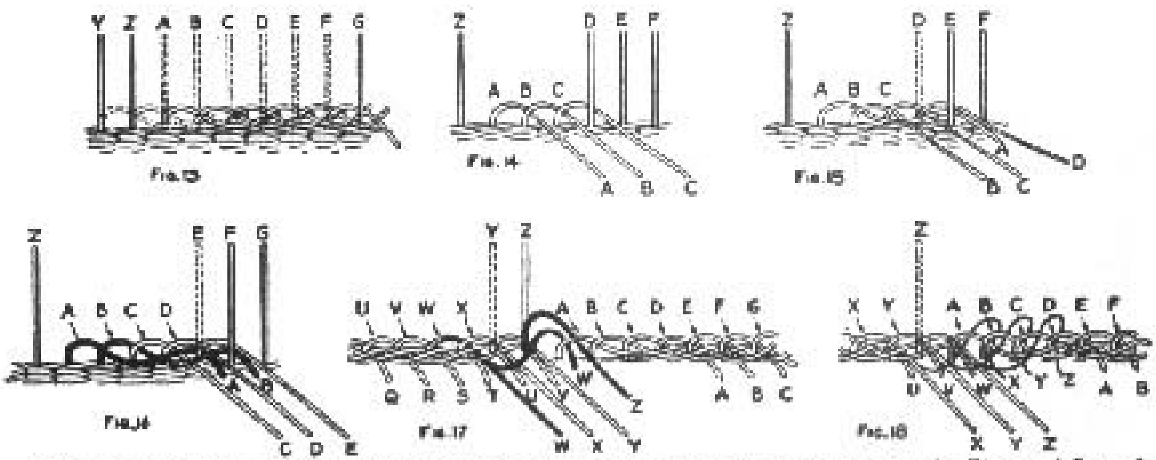
The Lower Ends of the Spokes are Turned to Cover the Edge of the Bottom, Then the Reeds are Woven into the Upright Spokes to the Right Height, Where They are Broken Down and Woven into a Top Border

If the roll illustrated in Figs. 11 and 12 is too difficult, a simple break-down can be used, such as shown in Fig. 13. To make this finish, spoke A is turned back of spoke B, in front of spoke C and back of spoke D, but not out again. Spoke B is bent back of C, in front of D, and back of E. The others are turned down the same way. The manner in which the two last spokes are turned down and inserted is shown by the double dotted lines.

The remainder of the illustrations show the method of forming a roll between the first and second spokes, where only three spokes are turned down before the throwing-across process begins. The first three spokes turned down are shown in Fig. 14, and the throwing over, in Fig. 15. The second beginning is shown in Fig. 16. The finishing of this top is shown in Figs. 17 and 18. The full, heavy lines represent the final insertions, and the reed must be in quite a sharp loop to make the end enter the right place. It is then drawn down and forced in front of the other reed that passes out between the same spokes.

When the basket is dry, the long ends can be cut off close up with a knife, being careful not to cut a weaver. If there are hairy fibers sticking out they can be singed off over a gas, or other, flame that will not smut. If it requires bleaching, brush some chloride of lime, mixed in a little water, over the reeds and set in the sunlight for a short time. It is better to leave the finish a little dark rather than use too much bleaching, as the latter will give an objectionable whitish appearance that looks like a poor job of painting.

In working the reeds, do not leave them in the water longer than necessary, as this will turn them dark. A bleached reed will stand the water much longer than in the natural state. Dampen the reed frequently while weaving it, as the weavers pack down much closer when wet. The dampening process is also required to remedy the drying out caused by whisking the reeds through the air in weaving operations. A great variety of baskets can be made from this form, viz., low, tall, tapering vase forms, bowl shapes, etc., in plain or dark weaves.



A Simple Break-Down Roll for the Top. Also a Method of Forming a Roll between the First and Second Spokes Where Only Three Spokes are Turned Down Before the Throwing-Across Process Begins times the quantity of water, then take spirit of sal-ammoniac, and pour it into the solution drop by drop, until the silver is precipitated to the bottom; decant the clear liquor, and wash it several times in warm waters, dry and place it on paper, to absorb the moisture. If a grain of this powder is put into an iron spoon, and exposed to the flame of a candle, it will explode with a loud report. The crackers are made with this powder, a small quantity being placed in a bit of paper with a pea and a bit of sand twisted up.

FURNITURE CREAM.—Linseed oil, 1 pint; spirits of wine, 2 ozs.; vinegar, 1 oz.; butter of antimony ½ oz.

FURNITURE POLISH.—The cheapest is a mixture of linseed oil and turpentine, laid on in a thin coat, rubbed off with a soft cloth and polished.

Furniture in constant use is greatly improved by washing with vinegar and water, and afterwards applying cold drawn linseed oil, rubbing it very much. It should be rubbed again in a day or two afterwards.

Or, linseed oil, 1 pint; spirits of wine, ½ gill. Mix well. Apply with a linen rag. Rub dry with a soft cotton cloth. Rub last and hard with a piece of old silk. In time it will have a most beautiful gloss. Or,

Linseed oil, bees wax scraped into, and gradually dissolved in turpentine, to the thickness of cream. Apply as above and rub well.

Or, 1 pint of linseed oil, 1 oz. of finely powdered rose pink, 1 oz. of shellac; beat well 1 oz. of alkanet root, and add it to the other. Keep the vessel in a warm place for a week, stirring now and then. This is excellent for darkening new wood, and removing marks, &c. Apply, and rub as before. Chamois leather is the best to rub with.

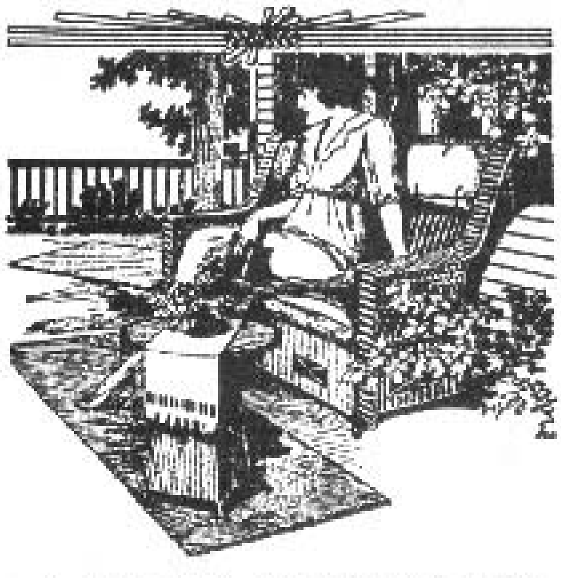
FURNITURE POLISH.—Spirits of wine, 1 pint; gum shellac, and gum lac, of each ½ an oz.; gum sandarac, ¼ oz. Melt with very gentle heat, frequently shaking the bottle. Double or treble a piece of cloth; put a little polish upon it; cover that with a piece of soft linen rag lightly touched with cold-drawn linseed oil. Rub the furniture or wood in a circular direction. Afterwards, rub in the same way spirits of wine, with a little of the polish added to it; and a very brilliant polish will be produced. Some furniture requires previous scraping with fine glass paper, on account of having been polished with wax.

Or, linseed oil, 1 pint; treacle, 8 ozs.; add a glass of gin; stir well; apply with a rag; rub till dry, and it will produce a splendid gloss.

Woven Reed Furniture

By CHARLES M. MILLER

A Variety of Small Stools and Foot Rests



FOOTSTOOLS of reed are preferable, in the home, to those made of other materials, because of their light weight, rounded edges, and comfortable, yielding tops. Reed, rattan, and similar material, used in their construction, withstand hard wear, and will not easily mar floors or furniture, a feature not to be overlooked, especially since the footstool is a favorite seat or play table of children. Several types of stools and foot rests are shown in the illustration. A stool having a framework of dowels, covered with reed, and utilizing the frame to produce a paneled effect, is shown in Fig. 3. The upper dowel of the framework is covered and woven over with the top, in the somewhat lighter stool shown in Fig. 8; the legs are braced at the ends with reed, arched and covered with winding reed. The stool shown in Fig. 11 is designed with rounded lines, the bracing dowels being set low, and a panel of openwork woven into the sides. Figure 15 shows a foot rest, the framework of which is steamed and bent, and the top slanted to provide a more comfortable rest for the feet. It is strongly braced, paneled on the sides with winding reed, and ornamented with openwork scrolls. The details of the construction of the frames and the method of weaving the reed are shown in the other sketches.

Dowels, ¾ in. in diameter, are used for the main framework of all of the stools shown. The dimensions of the various stools may be made to suit individual taste, those suggested in each instance having been found satisfactory. A good size for the stool shown in Fig. 3 is: height, 9 in.; width, 11 in.; length, 15 in. The lower of the horizontal dowels should be set at least one-third the height of the leg from the top. The braces are notched at their ends to fit the curve of the legs, and finishing nails are driven into them through the legs. The corner joints are further reinforced by a binding of reed, placed over them. The holes for the spokes are bored through the braces before the construction is nailed together. They should be bored about 1¼ in. apart, spaced uniformly, according to the length and width of the stool. The tops of the legs should project about 1/16 in. above the upper braces, so as to produce a level surface when the winding reed is applied.

The upper end of the legs must first be covered with winding reed, as shown in Fig. 2. Tack a strip of the reed on; then add successive pieces, as shown, until the end is covered. The joint of the leg and the lower brace must be reinforced, as shown in Fig. 2, by tacking winding reed over it horizontally. The braces must then be wound with winding reed, the spokes being inserted later. In winding the reed on the braces, tack one end of it to the brace at the left of a leg; then begin the winding on the brace to the right of the leg, and as each hole is encountered mark with pencil on the reed, so that if any of the holes are covered they may be found easily, when inserting the spokes. The marks should be made on the lower side.

The spokes extend from the lower edge of the bottom rail on one side to the lower edge of the corresponding rail or brace on the opposite side. Short spokes are fitted between the upper and lower rails at the ends of the stool. The top is woven complete before the sides are woven, the pairing weave being used. In this method two strands of reed are handled together, the first passing behind one spoke, and being below the second strand, and then passing in front of the next spoke, and being above the second strand, etc. This weave is shown in detail in Fig. 9, illustrating an article on "Taborets and Small Tables for the Summer Veranda," page 155, July, 1916. The weaving of the top includes the covering of the upper rails at the ends of the stool, which are wound in as spokes, the reed

FURS, to Keep Moths from.—Sprinkle them with spirits of turpentine. Or wash them with corrosive sublimate, 10 or 12 grains in a pint of warm water. Or use borax dissolved.

FURS, to Improve.—Warm bran in an oven. Rub it well into the fur several times. Shake and brush till free from dust. Rub light furs with magnesia.

HARNESS POLISH.—Take 2 ozs. of mutton suet, 6 ozs. of bees' wax, 6 ozs. of powdered sugar-candy, 2 ozs. of soft soap, and 1 oz. of indigo or lamp black. Dissolve the soap in a quarter of a pint of water; then add the other ingredients; melt and mix together; add a gill of turpentine. Lay it on the harness with a sponge, and polish off with a brush.

HORSES, to Water.—Water is as necessary to a horse as food, and horses are found to thrive better by having water *ad libitum* than by being stinted. The best way is to have the manger divided, so that corn may be in one half and the water in the other; by this plan the horse takes the water as he wants it, and not when it is offered to him. The plan of having clean water in the manger has been tried by a great number of the London merchants, and found to answer admirably.

USEFUL HORSE RECIPES.

Horse Ointment.—Resin 4 ozs.; bees' wax, 3 ozs.; hog's lard ½ lb.; turpentine, 6 ozs.; dissolve in a pipkin with a gentle heat; then add 2 ozs. of fine verdigris, stir well together, and strain the whole through a coarse cloth: cool for use. This is a good ointment for a wound, or bruise in flesh or hoof, broken knees, galled backs, bites, cracked heels, mallenders, or, when a horse is gelded to heal and keep off the flies.

Purge for a Horse.—Aloes 1 oz.; rhubarb, 2 drs.; oil of mint, 4 drops, made into a ball with honey.

Cordial for a Horse.—If the horse is weak through travel, give him a pint of warm ale, with 1 oz. of diapente in it. Diapente will comfort his bowels, drive out cold and wind, and may cause him to carry his food the longer.—Diapente is composed of gentian root, bay berries, bay leaves, birthwort, mint, and myrrh.

Sore Back.—If the saddle bruises his back and makes it swell, a greasy dishcloth laid on hot, and a cloth over it, bound on fifteen minutes, (with a surcingle), and repeated once or twice, will sink it flat. If it is slight, wash it with a little salt and water only. Alter the saddle, that it may not press upon the tender part, for a second bruise will

passing around them and being directed back in the opposite direction.

The weaving for the sides is carried around the stool continuously, passing around the legs. One of the strands in the pairing weave passes behind the leg, and the other must be wound around it an extra turn, to cover up the space otherwise exposed. The reed is wound around the legs to the lower end, the strand being tacked at the inner side of the leg.

The framework for the second type of stool is shown in Fig. 6. The two side rails are fixed into place by the same method used in making the first stool, and the frame is braced on the ends by sections of No. 12 or No. 14 reed. These are fitted into place and covered in the winding. The braces should be fitted to the curve of the leg, and nailed into place with small finishing nails. The ends where the braces join the legs and rails should be whittled down to a long, thin wedge, so that they may be bound in securely by the reed that is wound around the legs, as shown in Fig. 4.

The spokes in this model, as shown in Fig. 6, do not pass through the upper rails, but extend from one lower rail over the upper rails and to the lower rail on the opposite side. This makes it necessary that the upper rails be set slightly below and in from the top and outer edges of the legs. The lower rails should then be set in so as to be uniform with the upper ones.

The lower rails and the end braces are wound by the method used for the rails in the first stool. The tops of the legs are finished differently, however, as shown in Figs. 4 and 5. The weaving is begun at the lower rail, and proceeds until the side panel is filled to the under edge of the upper rail.

be worse than the first.

Splint.—The splint is a fixed, callous, bony excrescence, growing upon the flat of the inside or outside, of the shark bone; a little under, and not far from the knee, and may be seen and felt.—*Cure.* To take it off, first cut the hair close, then gently beat it with a round rule until it appears hot to the touch, then rub hard soap all around the edge of the splint, to prevent the blister affecting any other part, and apply on the splint the following blister ointment: mercurial ointment, 1 oz.; Spanish flies, 2 drs.; mixed well together; a little of this may be applied once a week until the splint is removed.

Spavin.—The spavin is of the same nature, and appears in like manner, on the instep bone behind, not far below the hough.—*Cure.* The same blister as recommended for splints; if it fails, firing and turning the horse to grass for 3 months, is the best method.

ICE CREAM.—Put into a bucket 1 lb. of ice broken very small; throw two handfuls of salt, among it, and have it in the coolest place you can find. Put the cream into an ice-pot, and cover it; immerse it in the ice, and draw the ice round the pot, so as to touch every part. In a few minutes put a spatula or spoon in, and stir the parts that ice round the edges to the centre. Stirring quickly increases the cold. There should be holes in the bucket to let out the ice as it thaws.

The cream for icing is thus made:—New milk, 1 quart; yolks of 6 eggs; fine sugar, 4 ozs. Mix. Strain. Heat gently, and then cool.

INDELIBLE INK.—*German Receipt*—Dissolve 20 grains of sugar in 30 grains of water, and the addition to the solution of a few drops of concentrated sulphuric acid; the mixture is then heated, when the sugar is carbonized by the action of the acid. It is said that the writing is not only of a solid black colour, but that the acid resists the action of chemical agents.

INK, Invisible or Sympathetic.—Dissolve bismuth in nitrous acid. When the writing is exposed to the vapour of sulphur, it will become quite black.—Make a weak solution of galls; write with it. To make it visible, moisten with a weak solution of copperas; moisten the paper with a solution of prussiate of potass, and it will appear blue.——Sulphate of copper (blue vitriol) and sal ammoniac, equal parts, dissolved in water, write colourless, turn yellow when heated.——Onion juice, like the last.——Solution of salt or saltpetre, shows when heated.——Write with starch water—a weak solution of iodine will make it visible.

The weavers cannot then be returned at the corner, and are cut off to extend 2 in. beyond the leg. Their ends are thinned out, and then brought around the corner against the upper rail on the end, as shown in Fig. 5. Alternately they are turned down on the leg and against the end rail, producing a covering for the corner. The strands of the top are woven over the thinned-out ends, and bound over the joint of the braces with the upper rail. The corners may be beaten gently with a block of wood to smooth them, and to bring the weavers firmly together. The weavers pass twice around the legs, as each strand is brought to the leg, as shown in Figs. 5 and 7. It will be found convenient to place the spokes in only one lower rail, as in Fig. 6, while weaving the first side panel, and the top. As the work proceeds the spokes are bound down to the upper end rails, and when the middle of the second side panel is reached, they are trimmed off and fitted into their holes, on that side.

The third stool differs fundamentally from the preceding ones in that the framework is curved at the upper ends, and the weaving of the top is carried down over the ends. The framework is shown in detail, in Fig. 9. Ash dowels, ¾ in. in diameter, are used for the framework, and the rails are notched into the main sections, and nailed, as were those in the preceding stools. The length of the curved dowels must be determined carefully, and it is desirable to have the stock longer than is necessary for the finished pieces, so that inaccuracies in bending may be allowed for properly. The distance between the legs should be such that a space of ½ in. is provided between the legs and the first hole for the side spokes, and the intervening spokes should be placed 1 in. apart. A satisfactory size is to make the stool 6 in. high, the end rails 8 in., and the side rails 13 inches.

The method of bending the dowels is shown in Figs. 12 and 13. They must be soaked in hot water or steamed, and clamped around the form as indicated, being left to dry. A pipe fitted over the ends of the dowels, to give leverage, will aid in bending them. The form is made by fitting pegs, suitably spaced, into a board, ⅞ in. or more in thickness. The curved pieces may be braced temporarily, as shown, and removed from the form when partly dried, so that it can be used quickly for the second piece. The pegs must be set close enough together so that the curve at the upper ends of the legs will not be too large, making the legs appear short. Care must be taken in bending this short curve, as the dowels are likely to break if the curve is quite abrupt. By setting the pegs solidly and making them long enough, two pieces of dowel rod may be curved in the form at the same time, and permitted to dry. A convenient tray of galvanized iron, for use in heating water for the moistening of the dowels, is shown in Fig. 10. It is 28 in. long, but may be made shorter if the points at which curves are to be made are moistened separately. A wash boiler, or any other suitable vessel, may be used for heating the water and dipping the dowels into it. After being shaped, the pieces are trimmed off to the proper height on the leg portions. Holes for the spokes are then bored through the lower and side rails, and they are notched and nailed to the legs.

The cross rails of the framework, shown in Fig. 9, are fixed into place by the method used in the previous models. The lower rails should be set about 2 in. from the floor, and are bored for double spokes. The rails are set with their outer edges ⅛ in. in from the edges of the legs, so that the weaving will be flush with the surface of the legs, rather than project slightly beyond it. The spokes for the ends and seat, or top, pass from one lower rail on one end to the corresponding rail on the other end, and are supported on the upper end rails. There are no corners to be fitted with the winding reed in this model, as the windings continue over the curves at the ends and down over the latter, by the same method of weaving as used in the top. The weaving is begun at the lower rails, and passes completely around the sides and ends of the stool, until about 1½ in. has been covered, up from the lower rails. The ends only are then covered, the strands of reed passing around the curved portion of the upper rails, and around the dowels forming the support for the top, in weaving back and forth.

The ornamental weaving at the sides of the stool is produced by spreading out the double spokes and conducting them to the proper holes in the upper rails. Several types of design may be made by crossing the spokes in various ways before setting them into the holes in the rails. The short spokes in the sides are permitted to remain with their upper ends free and longer than necessary while the 1½-in. lower section is woven. They must be cut carefully to the size necessary to form the desired design, and the ends glued into the holes.

The stool shown in Fig. 15 is designed as a foot rest, with a slanting top. It is similar in general construc-

INSECTS on Plants to Destroy.—Tie up sulphur in a muslin bag, and dust the leaves of young shoots and plants. A dredging box may be used. Sulphur increases verdure. A weak solution of alum sprinkled upon plants is not relished by insects.—Or, a thin mixture of soap and oil of turpentine painted on the stems of trees.—Or, use a solution of borax.

Painting the walls behind rose trees, fruit trees, &c., prevents the visits of spiders, earwigs, caterpillars, &c. The best paint for this purpose is gas tar.

ITCH.—It is a skin desease, infectious. Sometimes it is caused by poor living, unwholesome food, bad air, unventilated and dirty houses, dirty beds and clothes. The itch begins with small eruptions, on the joints of the fingers, on the wrists, thighs, &c. They cause a most intolerable itching, the scratching of which only spreads the disease.

Remedies:—Sweet oil, 1 pound; suet, 1 lb. Melt and macerate; then add powdered nitre, 3 ozs.; powdered alum, 3 ozs.; powdered sulphate of zinc, 3 ozs.; oil of aniseed, oil of spike, and oil of origanum, to perfume.——Or, mix 2 ozs. of lard with 1 oz. of sulphur-vivum, and a few drops of essence of lemons. Before going to bed rub this well into the affected parts. In the morning wash with soap and warm water; change the linen and clothes. Repeat the application, if necessary. Take at the same time flour of sulphur and cream of tartar, in milk, beer, or treacle.

Frequently take a Warm Bath. The greatest cures have been effected by it.

Wash the parts affected with strong rum.—Tried.—Or, anoint them with black soap, but wash it off soon.—Or, steep a shirt half an hour in a quart of water mixed with half an ounce of powdered brimstone. Dry it slowly, and wear it five or six days. Sometimes it needs repeating.—Tried.—Or, mix powder of white hellebore with cream for three days. Anoint the joints for three mornings and evenings. It seldom fails.—Or, beat together the juice of two or three lemons, with the same quantity of oil of roses.—Anoint the parts affected. It cures in two or three times using.

The following is said soon to effect a cure:—Sulphur-vivum, Venice turpentine, 1 oz. each; lard, ½ oz. Melt the lard and turpentine; add the sulphur. Apply several times a day.

Or, wash the body well in warm water, and rub it with the following preparation:—Lime, 2 ozs.; sulphur-vivum, 2 ozs. Mix in 1 quart of water. Pour off, and use it when clear.

A decoction of white hellebore, with a little lavender water, has been recommended.

IVORY and BONE, to Stain.

tion to that shown in Figs. 9 and 11, the framework being made of dowels, bent to the shape indicated by means of a form. The top and ends are woven in the manner described for the previous model. A point of difference to be noted is the bracing by means of a woven panel below the side rails, as shown in Fig. 15. This feature may be carried around the ends also, or the ends may be braced to the lower side panel by the method of bracing shown in Fig. 4. The rails around the stool are all on the same level. The double spokes for the top are fixed into the end rails, the spokes for the side panels into the side rails, and the smaller dowel placed at the lower edge of the side panels, as a support for the twisted weaving shown. The weaving of the top and the panels is by the method used in the previous model. The scrolls fitted into the open portions of the sides are tacked into place, and the strands of weaving reed carried over them, where the curves touch the upper and lower rails. A variety of designs may be worked out for the openwork. The scrolls are made of No. 6 or No. 8 reed, and should be formed on a base, as in Fig. 12, brads being used to hold them in shape until dry.

Another type of foot rest with a slanting top is shown in Fig. 14. The framework is built up of dowels, straight sections only being used. The joints are fastened by the method used in the first and second models described. The method of covering the frame is essentially the same as for the stool shown in Fig. 15, or an adaptation of that used in Fig. 11 may also be applied. Where facilities for steaming or moistening the dowels are not to be had conveniently, this type of construction will be found satisfactory, the designs being limited to straight lines, however. The method of covering the framework used in Fig. 3 is also available for the framework shown in Fig. 14, and the corners may be finished as shown in Fig. 2. Numerous variations and combinations of the types shown may be worked out readily after one has become reasonably familiar with the possibilities of woven-reed construction.

A Woven-Reed Footstool

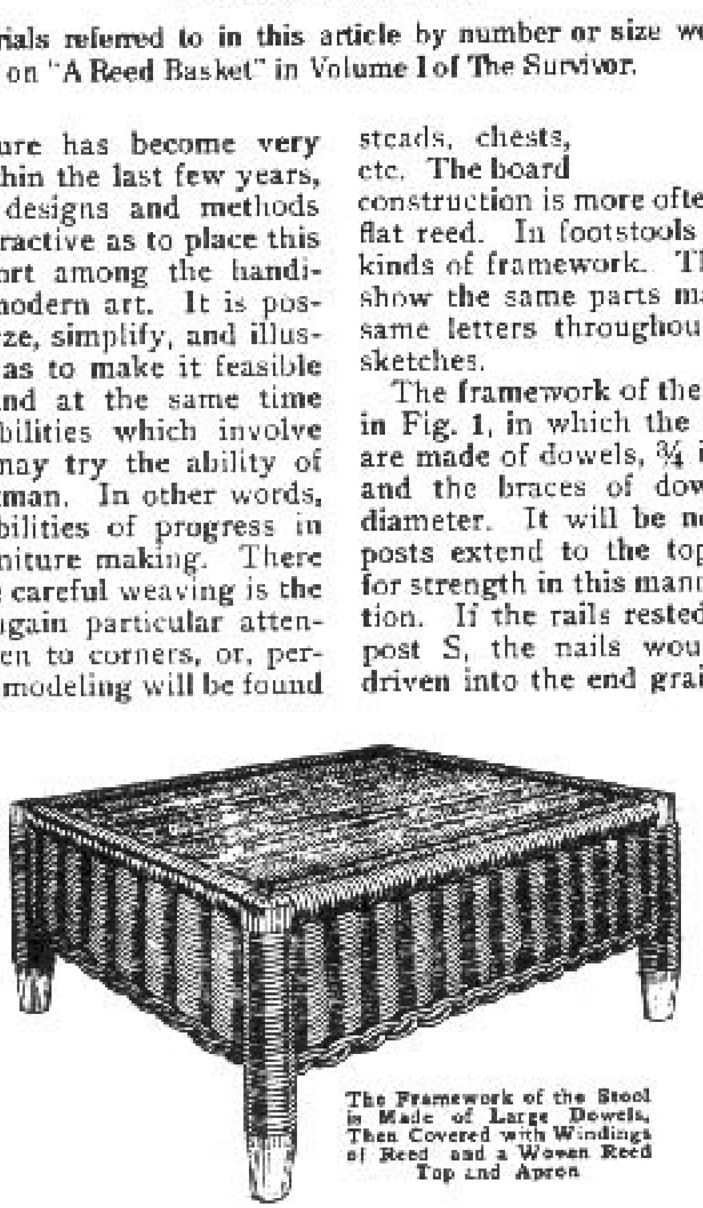
By CHARLES M. MILLER

The various materials referred to in this article by number or size were described in detail in an article on "A Reed Basket" in Volume I of The Survivor.

REED furniture has become very popular within the last few years, and the newer designs and methods have been so attractive as to place this constructive effort among the handicraft series of modern art. It is possible so to analyze, simplify, and illustrate this work as to make it feasible for amateurs, and at the same time there are possibilities which involve problems that may try the ability of the skilled workman. In other words, there are possibilities of progress in this kind of furniture making. There are places where careful weaving is the principal aim; again particular attention will be given to corners, or, perhaps, a nicety of modeling will be found necessary to bring out the proper curves involved.

Each piece of reed furniture has a framework, usually of dowels, but it may also be made of boards in such models as small tables, dressers, bedsteads, chests, etc. The board construction is more often covered with flat reed. In footstools there are both kinds of framework. The illustrations show the same parts marked with the same letters throughout the series of sketches.

The framework of the stool is shown in Fig. 1, in which the rails and posts are made of dowels, ¾ in. in diameter, and the braces of dowels, ⅝ in. in diameter. It will be noticed that the posts extend to the top of the frame for strength in this manner of construction. If the rails rested on top of the post S, the nails would have to be driven into the end grain of the wood,



The Framework of the Stool is Made of Large Dowels, Then Covered with Windings of Reed and a Woven Reed Top and Apron

—*Black*;—Rub over with diluted oil of vitriol; wash, and then steep in nitrate of silver and good ink.—*Blue*; steep in a strong solution of extract of indigo and a little potash.—*Green*; dissolve copper in nitric acid, and steep the ivory in it.—Steep in oxalic tin, and then in a strong decoction of Brazil wood, or lac dye, and alum.—*Purple*; nitric acid, 2 parts; sal ammoniac, 1 part; mix, and steep the ivory in it.

KERNELS, to Blanch.—Simply put them into boiling water a minute or two; rub them between a clean cloth, and the brown skins will soon peel off. *Almonds* and other kernels may be blanched.

KETTLES, Incrustation, or Furring, to Prevent.—Keep in the vessel a clean marble, a cockle, or oyster shell; these will attract the particles of sand.

LAXATIVE POWDER for Horses.—Crocus of antimony, finely levigated, nitre, cream of tartar, and flour of sulphur of each 4 ozs. Powder and mix well together. A table-spoonful of this mixture may be given every night and morning a few times, in a mash of scalded bran, or a feed of corn moistened with water. This powder is good for horses kept on dry meat; and for stallions in the spring, as they keep the body cool and open, and cause them to cast their coat, and make their skin as bright as silk.

LOBELIA.—An American plant, containing most valuable medical properties. It was first used with great advantage, as an emetic, by the American Indians, and was brought into notoriety by Dr. Samuel Thompson. It is emetic and stimulating, and Dr. Beech says, "from its action on the great sympathetic nerve, its effect is felt throughout the whole system. It exerts a peculiar action upon the trachea and bronchial vessels, expelling all collected mucus." It must therefore be very valuable in asthma, croup, hooping cough, and consumption. The greatest benefit from it has been found in dyspepsia, coughs, asthma, liver complaints, &c. It has relieved asthmatic subjects when on the point of suffocation by accumulated phlegm, cough, &c. Also in pneumonia of infants.

It is also a valuable sudorific; it relaxes the constricted pores of the skin, and promotes free perspiration. The leaves, seeds, and seed-vessels may be given in powder, and tincture. Dose of the powder, from a drachm, or a small teaspoonful; of the tincture, a teaspoonful.

LOBELIA, Acid Tincture of.—Lobelia herb, 1 oz.; cayenne, 2 drs.; vinegar, half a pint. Boil the vinegar, and put all into a bottle, cork well for 7

which makes the strength depend entirely on the holding power of the nail in this position, as there is no binding of the upper part to the posts in the weaving. With the post extending to the top, the nail passes through the upper part of the post and into the end grain of the rails, and the rails are bound together horizontally by the weaving.

The material for the frame consists of the following dowel stock: two pieces for rails, ¾ in. by 14 in. long; two pieces for rails, ¾ in. by 9 in. long; four posts, ¾ in. by 7 in. long, and two braces, ⅝ in. by 17 in. long. These pieces are shown in Fig. 2. If notches are cut with a small saw, a coping saw preferred, in the ends of each rail and in the braces, as shown in Fig. 3, they will fit to the posts better and make a stronger joint. While different makers use a finishing nail; a barbed or corrugated, nail; or a cemented, or glue-coated, nail, I find the best to be an ordinary 4-penny nail, which answers the purpose well. Do not drive the nail through the posts without first drilling a hole with a 1/16-in. drill. A small hand or breast drill will be needed for this work.

Before nailing the frame together, the holes for the spokes in weaving should be drilled in the rails. The spokes may be No. 4 and the weavers No. 3 reed. The No. 4 reed requires a ⅛-in. hole. The hole for the top and end side spokes may be combined, as shown in Fig. 4. The dotted lines show the vertical and horizontal diameters, and E the outside and F the inside of the rail, one hole being represented as sawed in two. The spokes for the top extend down and out at the ends, and each may be of one piece, 32 in. long. As there are no spokes at the top extending to the side pieces, short spokes must be inserted at the right time for the side weaving. The location of the holes in the side rails is shown in Fig. 2. The holes in the side rails may be drilled straight in the wood.

The pieces may now be nailed together to form the frame, as shown in Fig. 1. If the top of the side rails A are set about 1/16 in. below the tops of the posts, the weaving will be almost level, as the winding reed is thinner than the round reed. The braces D are halved at the center, on a slant, to bring their upper surfaces on a level when they are in place. The length of 17 in., as given in the material list, is not accurate, as sufficient length is given to allow the ends to be cut, in fitting them in place after the frame is assembled. The posts should stand vertical and square. Try the braces before nailing them in place, to see that they do not draw the frame out of shape.

The first operation in weaving is to cover the tops of the four posts, which is started as shown in Fig. 5. A short piece of winding reed, G, is first tacked in place. A round reed can be split if one is careful, in case winding reed cannot be obtained. Tacks used by shoemakers are just the thing for fastening these weavings in place. After fastening the weaving G in place, another, H, is put on in an opposite direction, whereupon J is fastened on the same as G, and so on, until the post is covered, as shown in Fig. 6. Perhaps a better way to cover the posts would be to tack all eight pieces on the post part C, and then weave them down together. It may not be necessary to tack them all on the rails.

After the corners are all covered, the end rails B are wound with the winding reed, the start being shown in Fig. 7, where the frame is shown in an inverted position. The reed is tacked, at

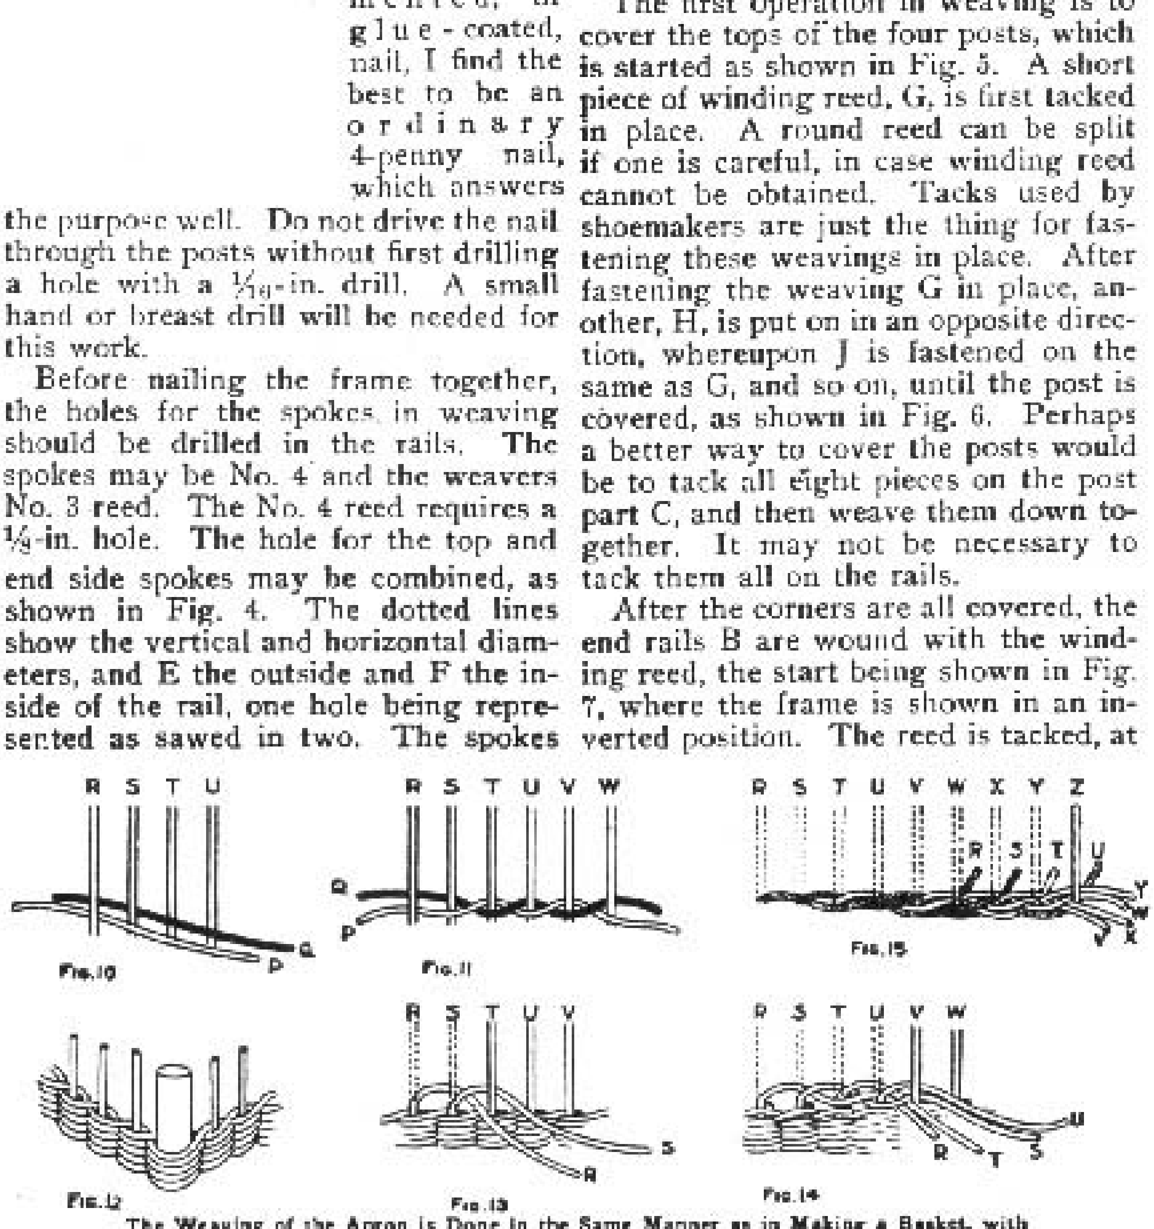


Fig.10 Fig.11 Fig.15 Fig.12 Fig.13 Fig.14

The Weaving of the Apron is Done in the Same Manner as in Making a Basket, with the Break Down to Form the Edge or 8 days. Dose for a cough, half a teaspoonful in any pleasant vehicle. Repeat when the cough is troublesome. It will require a larger dose for asthma or croup.

LOBELIA, Emetic.—Take lobelia powder, 1 ounce; boiling water, 1 pint; mix, and make an infusion. Dose: A fluid ounce to be taken every half hour, until vomiting ensues.

LOBELIA POULTICE.—— Linseed meal, ¼ oz.; slippery elm, 1 oz.; powdered lobelia, 1½ oz.; ginger, 1 oz.; whiskey sufficient to make it. Good for all inflamed parts, as the side in pleurisy, liver complaint, rheumatism, lumbago.

LOBELIA TINCTURE.—— Put 1 oz. of the powdered plant to 1 quart of whiskey. Infuse 7 days. Dose, a teaspoonful when the cough is troublesome. The tincture can now be bought at most Herbal Stores.

LOOKING-GLASSES, to Silver.—Take a sheet of tinfoil, and spread it upon a table, then rub mercury upon it with a hare's foot till the 2 metals incorporate. Lay the plate of glass upon it, and load it with weights, which will have the effect of pressing out the excess of mercury that was applied to the tin-foil. In a few hours the tin-foil will adhere to the glass and convert it into a mirror. About 2 ozs. of mercury are sufficient for covering 3 square feet of glass.

MAGGOTS IN SHEEP, to Destroy.—Water, 1 quart; spirit of turpentine, a table-spoonful; sublimate of mercury, as much as will lie upon a shilling; cork in a bottle, with a quill through the cork, so that the mixture may come a little at a time. Shake before using. Pour a little of the mixture upon the spot where the maggots are, and they will creep upon the top of the wool, and fall off dead. Apply afterwards a little train oil to the place.

MARIGOLDS, to Cultivate.—Pull up all those plants, whose flowers are less double, as soon as they appear, that they may not impregnate the others with their farina. Save the seeds from the largest and most double flowers. Sow the seeds in April in places where the plants are to remain.

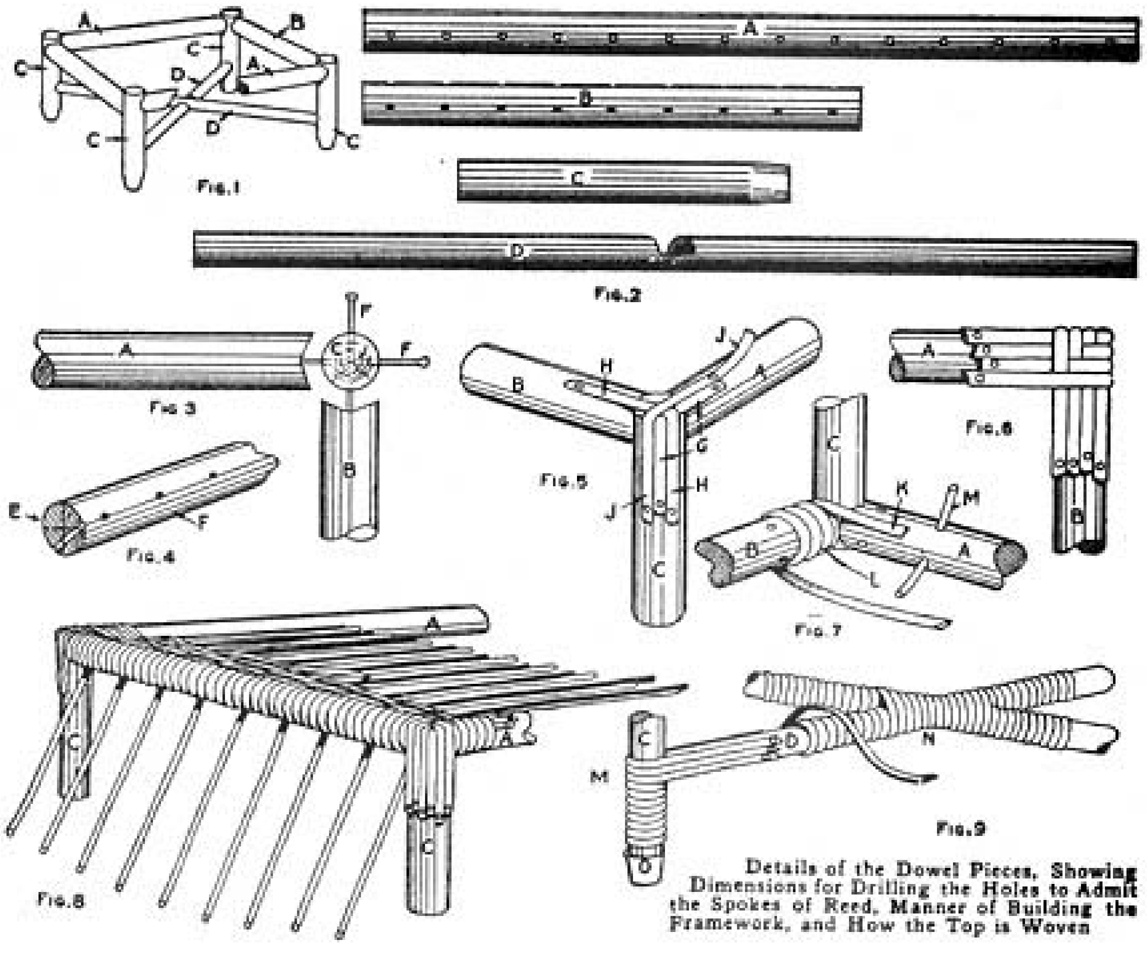
MARIGOLD CHEESE.—— Pound marigold petals in a mortar, and strain out the juice; put it into the milk when you put in the rennet, and stir them together; the milk being set, and the curd come, break it as gently and as equally as possible; put it into the cheese vat, and press it with a gentle weight. Manage the same as other cheeses.

MILDEW, to Remove.—Mix

K, to the side rail, and whenever the winding comes to a hole, a pencil mark is made to locate the hole later. This mark is shown at L. When the two end rails are wound, push a bodkin, or other steel point, in between the windings where the marks are located, to make way for the insertion of the spokes. It may appear to an observer that the spokes could be put in before the winding, but the winding cannot be properly done after the spokes have been inserted, as the windings would separate too much around them. The hole must be opened up through to the opposite side of the rail. Single spokes go through the rail, and they are only put through one end rail at first, as the weaving is much easier with one end of the spokes free, but, of course, they must be inserted in the other end before the weaving gets within 2 or 3 in. of that end. An extra spoke is inserted beside each spoke, as the weaving proceeds and after a strip has been woven ¾ in. wide. These short spokes are cut just long enough to fit in between the end rails. The weaving is done with a single weaver, and it is passed over and under double spokes as if they were one. When the weaver comes to the side rail, it is wound twice around the rail, to take up the space for the two strands across. If the weaver does not go twice around the side rails each time, either the weaving will take a curve or the side winding will be loose. The starting of the weaving is shown in Fig. 8, where the extra spokes are inserted along the side of each spoke that runs through the end rails.

After the spokes have been inserted in the opposite end rail and the weaving in the top completed, the braces and posts should be wound. Where the braces D connect to the posts C, three strips of the winding reed are passed around the post and tacked on both sides of the braces, as shown at M, Fig. 9. Where the braces cross, the winding passes around both pieces for a short distance, as shown at N. It is quite appropriate to use the brass caps O on this model, but on many stools their use has been discontinued and the winding continues down to within ⅛ in. of the bottom of the post. In case the brass cap cannot be obtained, the winding may be used also on this model.

The side weaving is called the apron, and in this case the pairing weave is used. The short spokes will have to be inserted in the under side of the side rails, and the extra spokes are added after the weaving is started and a small strip woven. The pairing weave is shown in Figs. 10, 11, and 12. The two weavers are represented by the letters P and Q. The weaver P passes back of spoke T and out between T and U. The weaver Q is then used in the same manner, and so on, around the stool. When the post is approached the weaver that comes out between the last spoke and the post is passed around the post and in behind the next spoke on the other side. It will be seen in



Details of the Dowel Pieces, Showing Dimensions for Drilling the Holes to Admit the Spokes of Reed, Manner of Building the Framework, and How the Top is Woven soft soap with powdered starch, half as much salt, and the juice of a lemon, and lay on with a brush. Let it lay on the grass day and night till the stain is gone. Or, take 2 ozs. of chloride of lime, pour on it a quart of boiling water, then add 3 quarts of cold water; steep the linen 10 or 12 hours, when every spot will be extracted.

Mix oxalic acid, citric acid, and milk together; rub into the linen; repeat as it dries; wash, and bleach on the grass.

MUSTARD.—This plant is both culinary and medicinal. As a condiment it is generally used and esteemed. As a cataplasm or poultice, it is made thus;—powdered mustard seed, 4 ozs.; vinegar, as much as is sufficient to mix it for a plaster; it is stronger by adding horse radish, scraped, 2 ozs. It is employed as a stimulant; it often inflames the part, and raises blisters, but not so perfectly as cantharides. Sometimes they are applied to the soles of the feet, in the low state of acute diseases, for raising the pulse, and relieving the head.

The white mustard acts not only on the bowels, but also on the skin. It wonderfully strengthens the whole line of the alimentary canal, improves the appetite, the digestion, and promotes sleep, and the health generally.

When the seed is used to remove constipation, take it an hour before breakfast fasting. A small table-spoonful is sufficient.

MUSTARD, to Make.—Mix the best Durham flour of mustard by degrees with boiling water to a proper thickness, rubbing it perfectly smooth; add a little salt, and a little tincture of cayenne, and keep it in a small jar close covered, and put only as much into the glass as will be used soon, which should be wiped daily round the edges.

OPODELDOC.—Dissolve 1 oz. of camphor in a pint of spirit of wine; then dissolve 4 ozs. of hard white Spanish soap, scraped thin in 4 ozs. of oil of rosemary. It may be improved by adding 2 ozs. of ammonia, tincture of aconite, or opium 1 oz., and a little oil. It is a good application for sprains, lumbago, pained limbs, weakness of joints, &c. Mixed with tincture of cantharides, or tincture of cayenne, it becomes more effectively stimulant.

PARSLEY, and other Herbs to Dry—Pick them clean from all decayed leaves. Put in a sieve; cover with blotting paper, and expose to the sun; or in a very slow oven, and turn them often; the quicker they are dried the better. Aromatic herbs, if not dried quickly, will lose much of their flavour. They may be dried also in a Dutch oven. Rub them, and pass through a

the pairing weave that the weaver behind is always thrown over the other weaver. This gives the appearance of a rope twist to the weaving, and also cinches it to the spokes and prevents slipping. Always pass the one weaver around the post twice to take up the space for the one that cuts across the corner. The weaving of the sides or apron is done with the object turned upside down, where it is in a good position for finishing off, which is sometimes called breaking down.

If the weaving has been carried far enough, the extra spokes are cut off even with the weaving, and the breaking down may be done as follows: The spoke R, Fig. 13, is shown turned down back of the spoke S, and S back of T and out. The spoke R, as shown in Fig. 14, is back of S, in front of T, back of U, and out between U and V, but as R is brought out, the spoke T is brought down back and parallel with R. Likewise the spoke S passes back of V, and U is brought down with it. The spoke T is brought back of W and V is brought down back of it. The short end of R is inserted under the roll, between the roll and the weaving, and is left extending on the inside. If it is too long, it can be cut off close to the inside of the weaving. In Fig. 15, all the short ends are shown brought through to the back as far as the weaving is illustrated. At the corners, the posts are used as spokes. To finish the roll, the spokes will have to be inserted through the roll, to correspond with the rest of it; hence, the beginning of the roll should be left loose, as in Fig. 13.

In weaving, the weavers should be kept wet, but not the spokes. Do not put the reed in water and leave it for any length of time, as it will become discolored. About 15 minutes will be sufficient to make the reed pliable, then it is best to have a sponge and bucket of water at hand, to dampen long weavers frequently by drawing the reed across the wet sponge. Besides being more workable, the wet reed, held in place until dry, stays curved in the form woven much better. Some workmen leave the reed in water for a long time and depend on bleaching to whiten it, but so much of the bleached work looks like a poor job of painting that it is much better to keep it white from the start. In case bleaching is found necessary, a little chloride of lime in water makes a good bleacher. Avoid making the solution too strong. It should be put on with a brush, so as to get it into the interstices of the weaving, whereupon the work is placed in the sunshine to dry.

Any kind of reed used will have some of the small hairlike fibers sticking out after the weaving is complete, and this should be singed off with a gas flame. A blowtorch is good for this purpose. Be careful not to scorch the weaving.

Woven Reed Furniture

Taborets and Small Tables for the Summer Veranda

By CHARLES M. MILLER

UTILITY and ready portability are well recognized features of woven-reed furniture, but the qualities which make it especially attractive for summer use in the open air, or on the veranda, are its inviting comfort and graceful lines. While furniture of this type arranged in suites makes a particularly harmonious showing, individual pieces may be used in combination with other furniture, lending a touch of variety. Small tables or taborets, of light weight and simple design, may be made by the novice, and may be adapted to a variety of uses. Footstools, jardinière stands, sewing tables, card tables, and smoking stands are some of the possibilities. Three representative types are shown in Figs. 1 to 3, and the general method of construction as well as the details of the weaving are also illustrated.

A serviceable taboret or stand is illustrated in Fig. 1. It is 18 in. high, and 17 in. in diameter on the top. The sides are 9 in. wide at the top and 14 in. at the bottom.

The framework for the top of the stand consists of a disk of wood, 16 in. in diameter, with a similar one, 14 in. in diameter, directly underneath, the edge being set under 1 in. all around. Four legs of 1-in. doweling support it, and two cross braces of doweling are placed between diagonally opposite corner posts, behind the woven portions of the side. The grain of the wood in the upper disk should run at right angles to that of the lower, to prevent warping, and the disks should be fastened together with nails or screws. Avoid putting them into the lower disk, where the legs are to be fixed.

sieve. Parsley thus prepared is very pleasant and useful; it breaks into parts as small as are obtained by chopping. When parsley and butter are wanted, it is only required to put a small quantity into the saucepan with the butter.

All dried herbs should be kept from the air in paper bags.

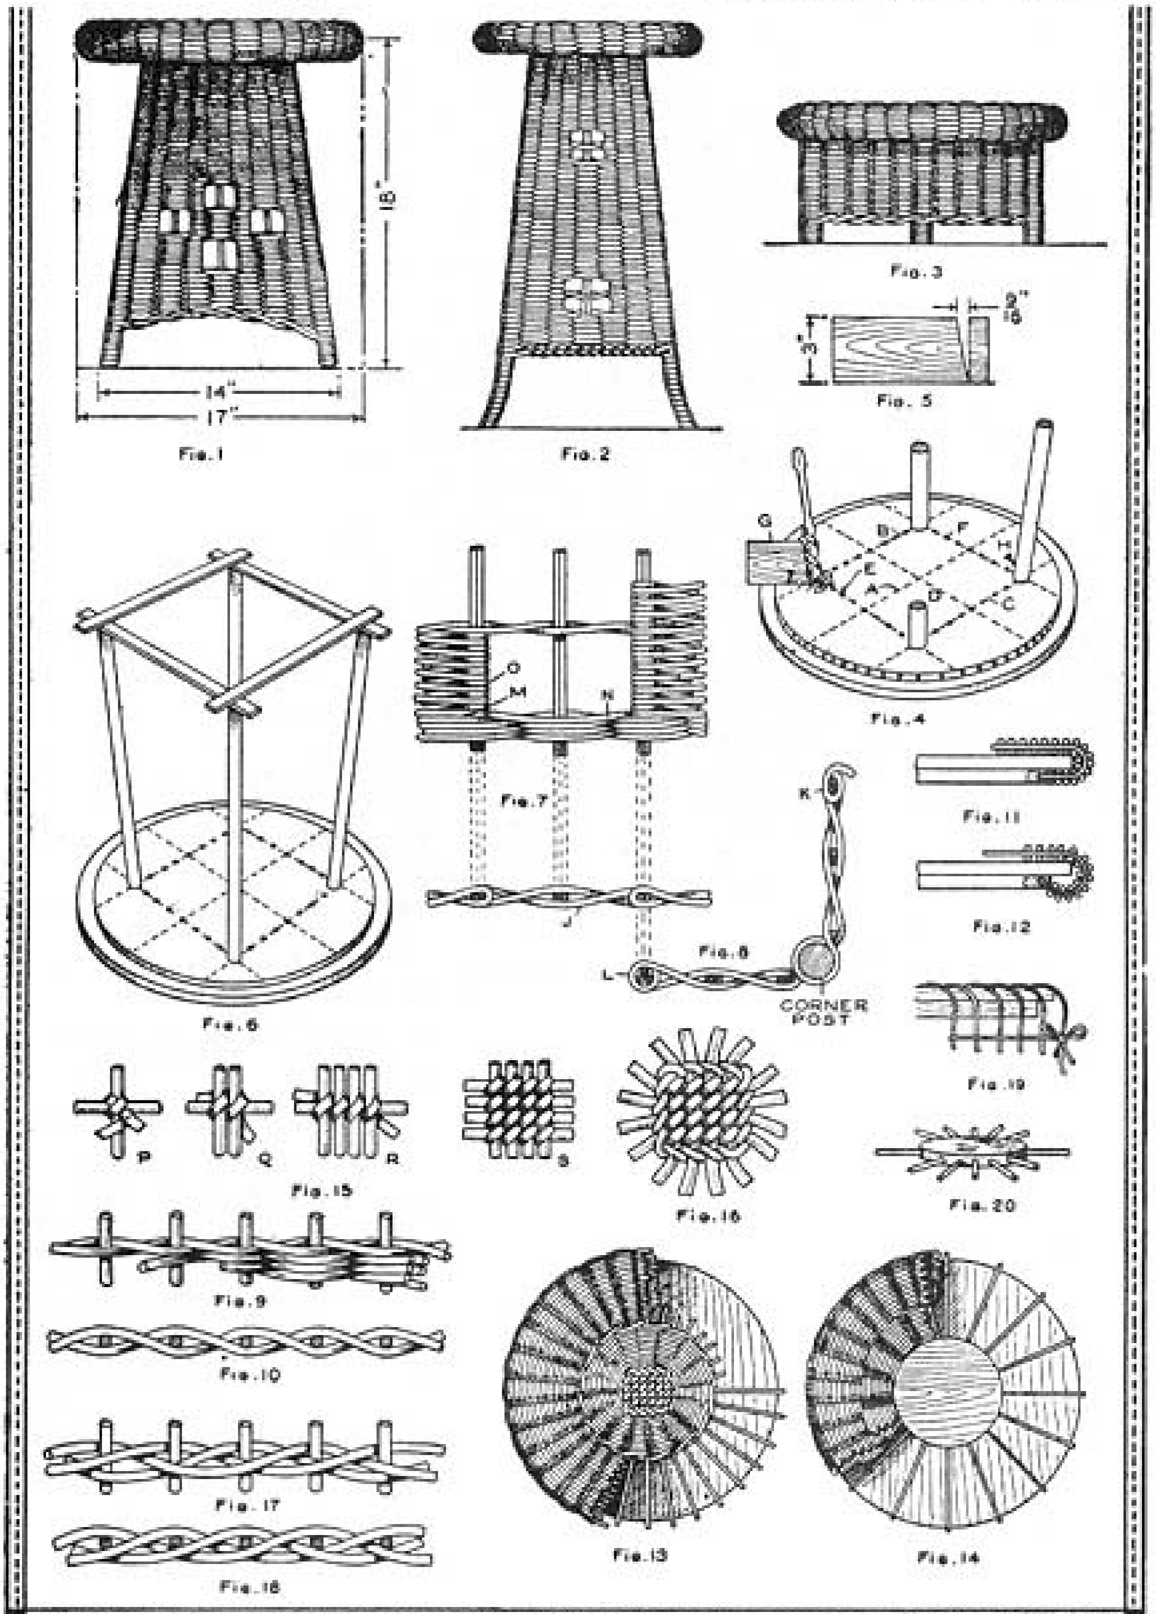
PENNYROYAL.—This plant is perennial. It flowers in August and September. It is warm, pungent, aromatic, stimulating, and diaphoretic; like spearmint, but not so agreeable. It contains a volatile oil which is obtained by distillation. The infusion is warming to the stomach, and allays sickness. It relieves spasms, hysterics, flatulency, and colic, and promotes expectoration in dry consumptive coughs. It promotes perspiration, and is most valuable in obstruction of the menses.

PENNYROYAL WATER.—Pennyroyal leaves, dry, 1½ lb.; water, from 1½ to 2 gallons. Draw off by distillation, one gallon. It is a specific remedy for female obstructions. It is good for gout, rubbing the parts with it till they are red; and if salt be added, it is good for the side in liver complaints, It is very warming to the stomach, produces perspiration, and therefore is good for coughs, asthma, &c. An infusion of the herb in hot water is nearly as good.

PENCIL DRAWINGS, to Fix.—Dissolve white resin in spirits of wine; lay the pencil drawing on its face upon a sheet of clean paper, and brush the back of the drawing with the solution. This penetrates through the paper, and as the spirit evaporates, the resin is deposited as a varnish on the drawing. It does not cockle the paper, which watery solutions will do; and as the brush only passes over the back of the drawing, none of the pencil marks are in any degree removed.

Pencil, or Chalk Drawings, to Fix.—Immerse the drawing in a weak solution of isinglass; allowing no part of the drawing to remain without the isinglass passing over it, or it will look spotty. Drain it, by holding the drawing up by one end over a plate.

PLASTIC MATERIAL for forming various objects new.—By Professor Purkins. Five parts of whiting are mixed with a solution of one part of glue. When the whiting is well worked up into a paste with the glue, a proportionate quantity of Venetian turpentine is added to it, by which the brittleness of the paste is destroyed. In order to prevent its clinging to the hands whilst the Venetian turpentine is being worked into the paste, a small quantity of linseed oil is added from time to time. The mass may also be coloured



Taborets, of Light Weight and Simple Design, may be Made by the Novice and Adapted to a Variety of Uses in the Home. They Are Particularly Attractive for the Summer Veranda. Sewing Tables, Jardiniere Stands, Taborets, Footstools, Card Tables, and Smoking Stands Are Some of the Possibilities. A Taboret, or Small Stand, is Illustrated in Fig. 1, and the Details of Its Construction are Also Shown. The Tall Stand Illustrated in Fig. 2 Involves the Same General Principles of Construction, Modified to Suit the Framework. The Footstool Shown in Fig. 3 Is Typical of Stands Having Vertical Sides

To locate the position for the legs, draw a diameter on the under side of the top, as at A, Fig. 4, and 4 in. on either side of it draw parallel lines B and C. Draw another diameter, D, at right angles to A, and draw the parallel lines E and F 4 in. from the diameter D. Where the four outside lines intersect will be the centers of the holes for the legs. These holes are not bored perpendicularly, but are slanted to conform to the slant of the leg. A template should be used in guiding the bit, as shown at G, Fig. 4. It may be constructed of wood, 3 in. wide and 5 in. long, Fig. 5. Place the gauge just outside the edge of the hole to be bored. Nail it to the board lightly on the diagonal, as shown, and guide the bit against it.

Before the legs are fixed into place finally, the holes for the spokes of the side should be bored. The parallel lines of Fig. 4 now serve another purpose, that of giving the location of the spokes. Place one spoke ½ in. from each leg, and the others 1 in. apart. The legs are utilized as spokes in the by kneading in any colour that may be desired. It may be pressed into shapes, and used for the production of *bas reliefs* and other figures, such as animals &c. It may also be worked by hand into models, during which operation the hands must be rubbed with linseed oil; the mass must also be kept warm during the process. When it cools and dries, which takes place in a few hours, it becomes as hard as stone, and may then be employed for the multiplication of these forms.

SMOKY CHIMNEYS.—Certain chimneys draw well ordinarly, but are subject to violent fits of smoking in certain winds, and generally in boisterous weather, blowing both flame and smoke into the room to an intolerable extent. For this particular class of nuisance I have for many years past adopted a very cheap and permanent remedy, which has never failed. Instead of a common chimney-pot, I fix, in the like manner, a 9-inch drain-pipe, 2 feet long, socket downwards, which gives it a firm seat; and on this I fix another like drain-pipe, having 2 4-inch double junctions, inserted obliquely into the 9-inch pipe. When the wind blows, it rushes into these lateral openings, which, having a turn upwards, direct its blast against the downward current from the top of the pot. The fixing should be in cement, and you have a cheap chimney-top, which will neither perish nor blow off. I use nothing but drain-pipes for chimney-pots, which, as well as being cheaper and stronger than any thing else, admit of a second and third story being added to them if the draught be dull, or the branch pipe top as I have described, if subject to downward gusts. For kitchen flues, 12-inch pipes are safer.—T. E. in the *Builder*.

To increase the draught in the chimney, some persons make a hole in the hearthstone, providing there is a room below, and cover it with a ventilator to protect it from cinders and ashes.

Or, inflate a large ox's bladder, and tie it by the neck to the middle of a stick, and place it across a chimney, 2 feet from the top, or at the foot of the chimney-pot. The buoyancy of the air keeps the bladder continually in a circular motion, and thereby prevents the rush of air into the funnel from descending so low as the fire-place.

SOLDERS, to MAKE:—

Solder for Lead.—Tin, 1 part; lead, 2 parts. Its goodness is tried by melting it, and pouring the size of a crown piece upon the table, and, if it be good, there will arise little bright stars in it. Apply resin when this solder is used.

Solder for Tin.—Lead, 10 parts; tin, 7 parts.

Solder for Pewter.—Tin, 1 part;

weaving. The spokes should be double, and the extra spokes may be inserted beside the original ones, after the weaving has progressed a few rounds. Number 5 reed should be used for the spokes and No. 4 reed for the weavers, which are woven back and forth around the spokes.

Drive the legs into their sockets, applying glue, and pin them with nails, as at H, Fig. 4. Tack strips on the bottoms of two pairs of legs and then fasten two strips to brace them, as shown in Fig. 6. The strips should be put on and the distance between the legs spaced before the glue sets.

It is best to weave the sides before beginning the top, so as to prevent rubbing the woven top while weaving the sides, with the stand inverted. The side spokes should be 2 ft. long and should be set into the top 1 in., with glue. Turn the top of the stand down on a table, and begin the weaving at the under side of the top. Single weaving is used for the sides, every other round passing twice around the legs.

There being four sides in the construction, there will be an even number of spokes, even though there should be an odd number to each side. The weaving would thus repeat itself, in going behind and before the same spoke each time. This is not desirable in this construction, and a change should be made each round. To do this, go over two spokes, instead of one, at the finish of a round. Such a "skip" is an Indian method, and forms a design that may be carried in slanting lines back and forth down the side of the stand. It is best to confine these "skips" to one side. Another way to overcome the repeat, as the weaving in and out around the same spokes in two successive layers is called, is to insert an extra spoke on one side, thus making an odd number of spokes around the stand. It is necessary then to conform the design of the open work for this side to the number of spokes. The design for the open work shown in Fig. 2 will be used for the stand illustrated in Fig. 1, and to be described in detail. The first of the two methods of overcoming the "repeat" will be used.

Insert the extra reed for doubling the spokes, after a few rounds have been woven adjoining the top. The method of weaving from the corner post and the making of the open design are shown in Figs. 7 and 8. The method of "pairing" for winding the reed in and out of the spokes, is shown in Figs. 9 and 10. The rear weaver of the pair of strands is thrown over the forward weaver, back of the next spoke and out. The fore weaver then becomes the rear one, and is thrown in like manner. This process is repeated in order to make the complete rounds. Figure 9 shows the weaving from the side, and Fig. 10 is a view looking down on top of the spokes and the edge of the weaving, shown in section. Pairing gives a continuous rope twist to the two weavers, and an even or odd number of spokes is equally suitable.

For the open designs of Fig. 2, one or more of which may be placed in the side of the stand, the center spokes are left free, as shown in Fig. 7. Before turning the first weaver back for the open work, as at M, start a short weaver N about two spokes back from the opening, and pair it with the regular weaver across the opening, and two spokes beyond. In turning back on the spokes, the single weaver goes twice around the spokes, as shown by the intermediate layers O. This is a short bend and the weavers must be very soft. Use short ones and wet them frequently with a sponge. A sectional view of the weaving at the opening is shown in Fig. 8, as it joins with the weaving around the corner posts. At K, the weaver turns back on a double thickness of reed, and at L, a short spoke is set back of the other two, and the weaver is wound around the three, thus lessening the abruptness of the winding. The latter method is the better. At the horizontal center of the opening, two rounds continue across the opening and around the stand. Pair a short piece of reed across at the finish of the openings, as was done at the lower end at N, Fig. 7.

After weaving to within 5 in. of the bottom of the legs, cut off the extra member of the double spokes, and soak the ends of the remaining spokes in water. Braid them into the border finish, as shown in Fig. 1. The corner posts serve as spoke spaces, and the spokes nearest them are wound around the bottom ends of the legs. Short spokes may be inserted beside the posts and wound around them if the ends of the spokes are not long enough for this purpose.

The top may be made next. Holes are bored horizontally into the edge of the under disk, as shown in Figs. 4 and 11. In Fig. 12 the holes are shown bored into the edge on an angle. This method gives a thicker rolled edge to the top, although both methods are satisfactory. These holes must be bored before the work on the top is begun. There are two ways of beginning the weaving for the top. The radial spokes may cross each other in groups of four, the upper and lower courses being bound together with winding reed, as shown in Fig. 13, or a small maple disk may be used as a lead, 2 parts; bismuth, 3 parts.

Solder for Brazing.—Copper, 3 parts; zinc, 2 parts; or sheet brass, 3 parts; zinc, 1 part. This is called Spelter, and is used for brass, iron and copper.

Solder for Britannia Metal.—Bismuth, ¼ of 1 part; tin, 1 part; lead, 1 part.

Solder, Soft.—Tin, 2 parts; lead, 1 part.

Solder, Hard.—Copper, 2 parts; tin, 1 part.

Zinc and lead are soldered with lead and tin, not quite equal parts, lead preponderating.

To use Old Britannia Metal instead of Block Tin in Solder. Take old britannia metal and melt it; and while hot sprinkle sulphur over it and stir a short time.

SOLDERING, Hard.—To braise 2 pieces of iron together, file one side of each piece bright, put on the clean face a paste made of borax and water, tie the two pieces together with several separate coils of brass wire, smearing more borax on these. Hold it over a bright coke fire, and the brass will melt and run into the joint. File off the superfluous metal. When the brass melts a blue flame will be seen to arise.

SOLDERING MIXTURE, for Iron, Steel, Copper, &c.—Take any quantity of muriatic acid, and dissolve as much zinc in it as it will take; then dilute it with ¼ as much soft water as of acid, and it will be ready for use.

This applied to iron, &c., cleanses it, and leaving zinc upon the surface, causes solder readily to adhere to it.

SPRAIN.—Hold the part in very cold water for two hours.——Or, apply cloths dipt therein, four times doubled, for two hours, changing them as they grow warm.——Or, bathe in good crab verjuice ——Or, boil bran in wine vinegar to a poultice. Apply this warm, and renew it once in twelve hours.——Or, mix a little turpentine with flour and the yolk of an egg, and apply it as a plaster. This cures in a desperate case.

Weakness remaining after a sprain is cured by fomenting the part daily with beef brine. Suppose the ancle sprained: —1st. Foment it with warm vinegar four or five times every four hours. 2nd. Stand, if you can, three or four minutes at a time on both your feet, and frequently move the sprained foot. Sometimes also while sitting with your foot on a low stool, move it to and fro. 3rd. Let it be gently rubbed with a warm hand at least thrice a-day. 4th. Two hours after every application of the vinegar, let it be just wetted with spirits of wine, and then gently rubbed.

center from which the spokes radiate, as shown in Figs. 14 and 20. The center-disk method is not difficult, and is used extensively. The other type is novel, and also quite feasible.

The spokes for the method shown in Fig. 13 are bound together in the following manner: Place two spokes at right angles to each other and wind them with winding reed, the end of the latter beginning between the two spokes, as shown at P, Fig. 15. The perpendicular spoke is uppermost. Add a second perpendicular spoke and bind it into place, as at Q. Continue this process until four perpendicular spokes have been bound in as at R. Place a second horizontal reed into position and go over each vertical spoke with a separate winding, as in the first course. Continue until four horizontal spokes are bound in, and the end of the winding reed is looped around the last, as shown at S. The spokes should be of No. 5 reed, and 24 in. long.

Four groups of four spokes each will result by following out the process described. Separate the spokes by drawing the outer ones into the corner spaces. They should have the appearance of spokes in a wheel, as in Fig. 16. Use two weavers of No. 4 reed, in the pairing weave, as shown in Fig. 16, and in detail in Figs. 9 and 10. Continue the pairing weave until a center, 8 in. in diameter, is woven. Crowd up the weaving closely, for the appearance of the top will depend much on the first few rounds. Hold the center with the left hand, and manipulate the weavers until they are well seated in their proper places.

When a few rounds have been woven, nail the center securely to its place on the middle of the top. This will leave both hands free for the weaving. After a disk, 8 in. in diameter, has been woven, begin the triple weave illustrated in Figs. 17 and 18. As the triple weave is begun, add another spoke, 8 in. long, between each pair, all around the top, making 16 new and 16 original spokes. When two or three rounds are woven, the new spokes will become secure. Continue the triple weave to the edge of the top. Measure and cut the end of the spokes to uniform length. Curve the ends over the edge to see how much will be needed before cutting, allowing about ½ in. for insertion into the holes in the edge.

Wet the ends of the spokes with water until they are pliable enough for the curve. Bending and tying them down while wet and permitting them to dry in this position, as shown in Fig. 19, is desirable also. Weave down the curve of the roll and insert the ends of the spokes in their respective holes with glue. Then with the single, plain weave on the under side of the roll, weave well up to the ends of the spokes.

For the disk-center method of construction, as shown in Figs. 14 and 20, use ½-in. maple, and cut it 5 in. in diameter for the centerpiece. To locate holes on the edge of the disk draw a line 3/16 in. from the upper edge and mark off spaces 1 in. apart, except four, which are made 15/16 in. apart, to make a convenient division, practically uniform. Bore the holes ¾ in. deep. Number 5 reed is used for the spokes and No. 4 reed for the weavers. The disk should be toenailed around its edge with brads, fixing it firmly to the top before the spokes are inserted.

Proceed with the pairing weave, as in the other method described, until 2 in. of the spokes is covered; then change to the triple weave and add additional spokes. Proceed as with the other type from this point on.

The taboret is braced by two 1-in. dowel rods, placed 2 in. above the bottom roll of the sides and extending from one corner to the other, diagonally. Their crossing at the center may be made into a halved joint, by cutting away one-half of each rod on the adjacent edges. The ends are fitted closely into the corners, and are nailed to the legs.

A taller stand or small table, the side weaving of which has been described as applied to the taboret shown in Fig. 1, is illustrated in Fig. 2. The construction in general is similar. A lighter roll is used for the top, and the bottom ends of the legs are curved outward slightly. The legs are curved by steaming the ends of the corner posts, clamping them into position, and permitting them to dry.

The footstool, shown in Fig. 3, may be made as a miniature stand, with vertical legs, and the spokes set in a circle under the top board. The spokes and weavers will carry the form, if well woven. The stool may also be braced, to withstand hard usage. It should be about 12 in. in diameter at the top, 10 in. in diameter for the body, and 6 in. in height.

The method of forming the opening shown in the side of the taboret in Fig. 1, and the weaving of the construction, will be readily understood from the method described. The principles and methods presented may be applied readily to other construction of the same general type.

* * *

TUMOURS, Cure of.—To remove tumours, Dr. Simpson, of Edinburgh, introduces a hollow acupuncture kneedle, or very fine trocar, into their tissue, and injects in a few drops of some irritant liquid, such as a solution of chloride of zinc, perchloride of iron, or creosote. The effect has been to destroy the vitality of the tumours so treated, and they have been separated. We have seen a similar plan adopted in Paris by M. Maisonneuve. He had slender stylets, made of a paste composed of flour, water, and chloride of zinc. These are baked. A puncture is made in the tumour, the caustic stylet is inserted, broken off, and left. We saw several malignant tumours treated in this manner, and some cases in which a healthy granulating surface was left, after the separation of tumours which had been destroyed in this manner.

WASHING, made Easy.—One of the best bleaching and emolient agents in washing either the person or clothing, is common refined borax. Dissolve in hot water, ½ a lb. to 10 gallons; a great saving in soap is effected by its use. The borax should be pulverized first. It may be procured in the form of crystals at any druggist's; it will not injure the most delicate fabric; and laces or other fine tissues may be washed in a solution of borax with advantage to colour, &c.

WASHING, Ready and Effectual Mode of.—Dissolve 1 lb. of soap in 3 quarts of boiling water, the night before washing. Beginning to wash, put the soap into the dolly tub, add 8 table-spoonfuls of spirits of turpentine, and 6 ditto of hartshorn. Pour upon the above 8 gallons of boiling water. Have the clothes ready assorted; begin with the fine ones. Dolly each lot about 5 minutes, wash them in hot water in another dolly-tub, if you have it, next in blue water.—When the water is getting cool, put it into the boiler to boil kitchen towels, or any greasy things.

N.B.—The quicker the washing is done the better. As soon as one lot is taken out of the dolly tub, put another in whilst the others are being rinsed.

WATERPROOFING Shoes.—Melt bees' wax and mutton suet, and when you take from the fire, add a teaspoonful of turpentine.——Or, India rubber and gutta percha, dissolved in good naphtha.——Or, yellow wax, 4 ozs.; rosin, 4 ozs.; linseed oil, 1 pint; oil of turpentine, ¼ of a pint. Melt over a *slow fire*, and when melted, take from the fire, and add the turpentine, and stir well. Remember that it is very inflammable. When required for use, melt and apply.

WATERPROOF CLOTH.—

From Popular Mechanics 1933

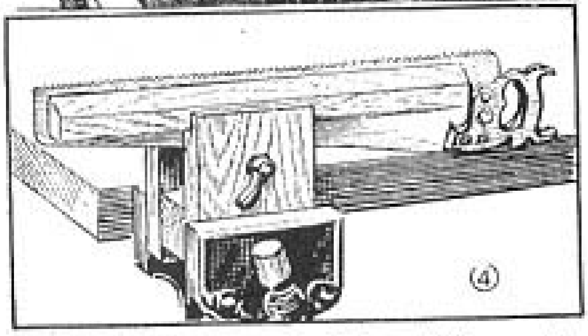
SAW-FILING

A workshop requisite

SHARP saws, kept in good shape, are as necessary to the workshop owner as a sharp knife is in the kitchen. The work is not difficult and nearly every small shop has the facilities needed for doing it. Handsaws, small circular blades, dado heads, back and dovetail saws are easily jointed, set and filed by hand.

In filing various types of blades the procedure must be governed to a certain extent by the condition of the tool. If the saw is being filed for the first time, and has not been damaged in any way, it is likely that a mere touching up of the points is sufficient. Setting the teeth should be done only when necessary. In filing a new saw the first time, every effort should be made to preserve the original shape of the tooth as this is the best guide in filing. The size of the file must suit the teeth, particularly on the crosscut saw, as the number of points to the inch varies with the size of the teeth. A single-cut three-cornered file is most commonly used in filing handsaws and the smaller-diameter circular blades. The points per inch are equal to one more than the number of teeth per inch, as will be seen from Fig. 1. This designation is used only on straight blades.

If the teeth of a handsaw have been damaged by running accidentally onto a nail or other metal object, most particularly if the teeth have been damaged only on one side of the blade, as frequently happens, it is best to joint the blade lightly before setting. This is done by making a simple holder from part of an old file as in Fig. 8, although a small jointer, as shown in Fig. 5, can be obtained at almost any hardware store. The object in jointing is to bring all the teeth to the same length before filing. Damaged teeth should be given only a light jointing; then they should be set and afterward finished to length by a second jointing. This avoids taking off too much at first which would necessitate undue filing to shape the teeth properly. As a rule, a saw in good condition should be only lightly jointed, then set and filed, but if the set is nearly out of the teeth it is better to set the teeth first, then lightly joint and file them. In every case the procedure must be determined by the condition of the blade. The degree of the set depends largely on the work to be done. If the saw is to be used exclusively on soft wood the set should be sufficient to form a slight space or valley between the alternate teeth. In hardwood, and for average use, the set should be medium. If the saw is to be used exclusively in hardwood, the set should be very light. Fig. 1 shows the approximate degrees of set to meet various conditions. The same is true of both crosscut and ripping blades.



Handsaw blades may be set by using a pin punch, as in Fig. 7, but a saw-setting tool, as shown in Fig. 9, is better as it is possible to adjust the tool so that only about one-third the length of the tooth is bent. In setting with a punch, care must be

Apply to the calico or linen 2 coats of boiled oil, a little rosin or burgundy pitch, and a small quantity of turpentine. Hang up to dry.

WATERPROOF CLOTH.—To 1 oz. of melted white wax add 1 quart of spirits of turpentine; when thoroughly mixed and cold, dip the cloth in it and hang it up to dry.

WOOD, to Resemble Mahogany.—Take two ounces of dragon's blood, (gum tragacanth) break it into pieces, and dissolve in a quart of spirits of wine, to which add a little soda; let it stand in a warm place and shake it frequently; fit for use when dissolved.

Or take four ounces of logwood, and half a pound of madder; boil in a gallon of water, adding a little pearl-ash, and 1 oz. of walnut peeling. Apply hot.

WORMS.—The worms found in the human body are mostly the *ascarides*, the thread worm, infesting the lower intestine, causing much itching and irritation about the anus. The *teres*, or long round worm, generally seated in the small intestines, and stomach.

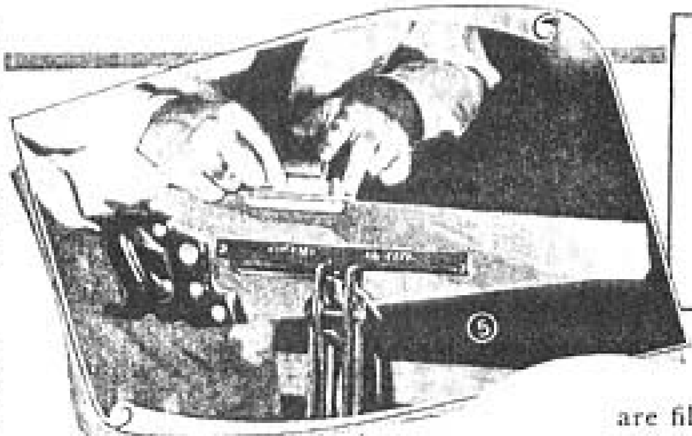
The symptoms denoting the existence of worms are common to the different species, viz. indigestion, with a variable appetite: foul tongue; offensive breath; hard, full, and tense belly, with occasional gripings and pains about the navel; heat and itching sensation in the rectum and about the anus; the eyes heavy and dull; itching of the nose; short dry cough; grinding of the teeth; and starting during sleep, attended often with a slow fever.

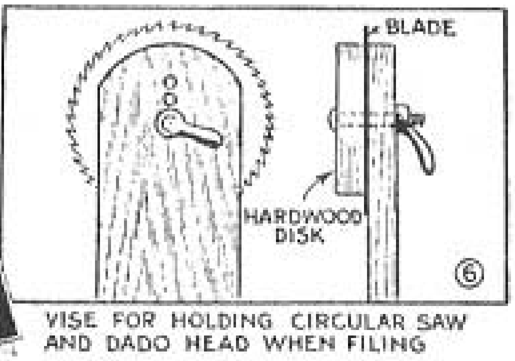
The indications of cure are, first, to clear the stomach and intestines of redundant slime, and afterwards to strengthen the stomach and bowels, so as to destroy the disposition to their generation.

Give an emetic once or twice a week, in order to rid the stomach of impurities, slime and morbific matter, the cause of worms. Attend to the state of the bowels, for they are often irregular through worms. A dose of the Composition Powder given night and morning, and bitter tonics during the day will be of essential service. This should be continued a week or two.

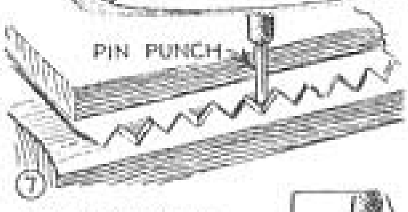
Lime-water being capable of dissolving the mucus in which the worms breed, may be taken; a teacupful two or three times a day—less for a child. Take with it the Tonic Mixture, or bitters. It is very effectual in relieving children.

The following infusion is valuable:—Best senna, Carolina pink-root, manna, worm-seed, rhubarb; of each ½ oz. Bruise them, and infuse for two or three hours in boiling water. Sweeten with treacle. Give to a child six years old from three tablespoonfuls a day.

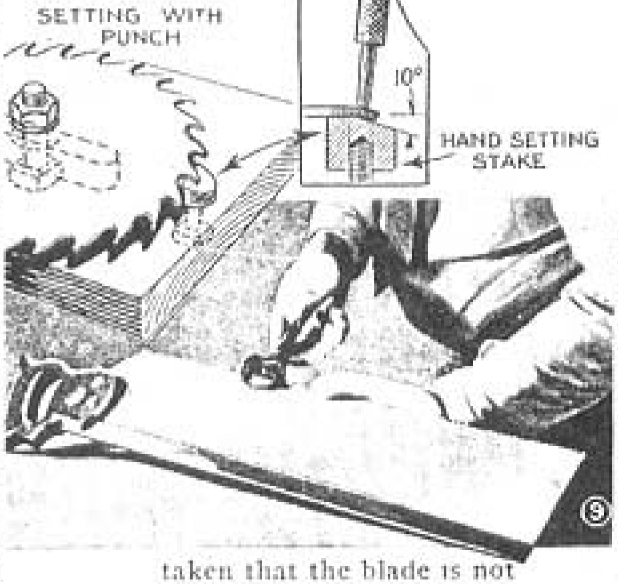




VISE FOR HOLDING CIRCULAR SAW AND DADO HEAD WHEN FILING

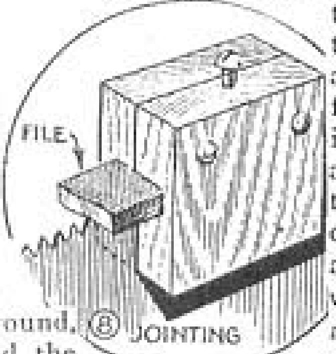


SETTING WITH PUNCH



taken that the blade is not cracked at the gullets. The hammer blow must be uniform and it is better to go over each set of teeth twice with the saw clamped between two hardwood strips. Circular saw blades, 10 in. or more in diameter, are generally set on a stake made as shown in Fig. 7. Teeth of blades under this size can be set more accurately with the ordinary handsaw set. When starting, see that the tool is properly adjusted by making a trial setting on two or three teeth, then set each alternate tooth, after which the blade is reversed and the rest of the teeth finished. Fig. 11 shows a hollow-ground, smooth-cutting or planer blade and the outside cutter of a dado head. Both blades are hollow ground and the teeth should never be set. It will be noticed that the teeth on the dado cutter are in sections consisting of four or more cutting teeth with a cleaner or raker tooth between and separated by deep gullets. On the planer blade the raker tooth precedes the four cutting teeth in the same section. On both types of blades the cleaner tooth is filed straight across and the best practice requires that its edge be very slightly below the cutting circle of the four crosscut teeth. The inside cutters of the dado head are filed the same as the cleaner tooth on the outside cutters. The cutting teeth on the outside cutter of the dado head are generally in sections of four teeth each. These must be filed the same way, that is, alternate sections of four teeth are filed from opposite sides of the blade, as the teeth of any one section are beveled the same and from only one side.

The circular-saw blade is best jointed on the arbor as in Fig. 10. The blade is reversed so that it runs backward, the table is raised so that its surface is above the cutting circle, and in this position an oilstone is laid lengthwise on the slot directly over the blade. The machine is started in the regular way and the table is lowered very slowly until the teeth of the saw strike the stone. Care must be taken not to take off more than is necessary. Stop frequently and examine the blade. When every tooth has been touched by the stone the jointing is complete. If desired, a frame to hold the stone can be made as in Fig. 15.



In filing a handsaw it is usually best practice to disregard each individual tooth and adopt a uniform stroke of the file. Though this means that we shall find it necessary to go from one end of the blade to the other several times, the method will produce a job that is nearly perfect, provided, of course, it is done with care and attention to uniformity in the length and number of strokes on each tooth and the angle of the file with the blade. By this method the filing must be continued until the teeth have been brought to a sharp point, removing all traces of the flattened point caused by jointing. If care is used in keeping the file strokes equal, the alternate teeth are reasonably sure to be of the same length. Fig. 12 shows the common angles of the file when sharpening both ripping and crosscut saws. The angle of the bevel on each tooth is determined by the position of the file with relation to the blade, both vertically and horizontally. In this, one should be guided by the original bevel on the tooth, if filing a new saw. The same is true of the

Sweets should be avoided. Salt and water taken in the morning will expel worms, especially the seat worms. It may be made by dissolving a tablespoonful of salt in half a pint of water. It may also form an injection to bring away the ascarides. — Camphor is another remedy. Dissolve 10 grains in a little spirit of wine, and add it now and then to the tonic bitters.

Various Remedies for the Cure of Worms:—

Take an ounce of tin, finely powdered, and two drachms of Ethiop's mineral, mixed together; divide it into six powders, and take one of them, in a little syrup, twice a day: when they are used work them off with a little rhubarb. Or,

Spirits of turpentine, in doses of from 8 drops to a teaspoonful, in gruel sweetened.——Or,

Jalap, ¼ of an oz.; powdered rhubarb, ¼ of an oz.; gamboge, 2 drs.; syrup of bears-foot, sufficient to make it into a paste; then make it into ordinary sized lozenges. Dose:—For a child 3 years old, ½ a lozenge; 6 years, 1 lozenge; and so on, according to years. Or,

Cowhage mixed with treacle. Give a child a teaspoonful fasting for 3 or 4 mornings successively—an adult a tablespoonful. Then give a purge.

Powdered rust of iron is a good vermifuge. It expels the worms and strengthens the constitution. To a child 6 years old from 10 to 40 grains may be given. An adult may take from a ¼ oz. It may be given in treacle or in beer. Dr. Rush says, "Of all the worm medicines that I have given I know none more safe and certain than this simple preparation of iron." It should always be followed by an aperient.

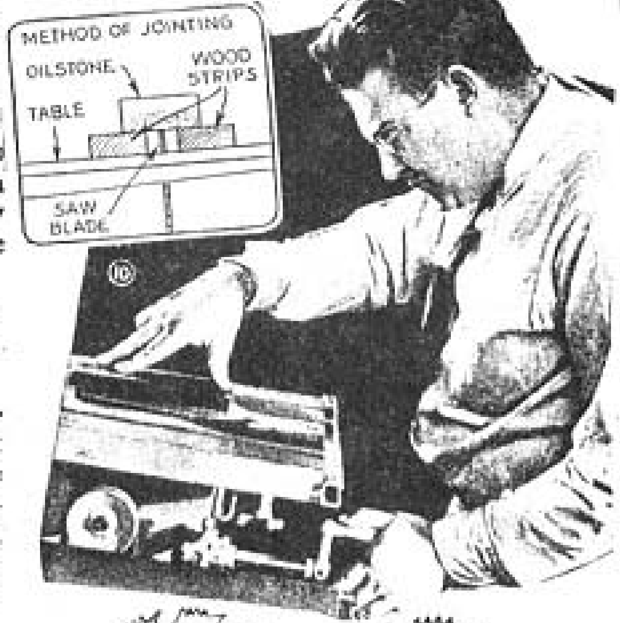
The common male fern-root is a certain remedy for the *tape*-worm. Two or 3 drs. of the powdered root to be taken in the morning, no supper having been taken the night before. It generally sickens a little. A brisk purgative is to be given a few hours after, which sometimes brings off the worm entire; if not, the same course must be followed at due intervals. For the success of this remedy, the root should be *recently* gathered; as after being kept long in the shops, its activity is diminished or destroyed.

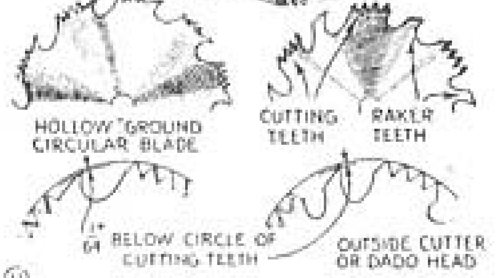
WORMS.—Take 2 tea-spoonfuls of brandy, sweetened with loaf sugar, every morning.——Or, a spoonful of the juice of lemons.

Or, take 2 tea-spoonfuls of worm-seed mixed with treacle, for 6 mornings. Or, 1, 2, or 3 drs. of powdered fern-root boiled in mead. This kills both the flat and round worms. Repeat the medicine from time to time.— *Wesley.*

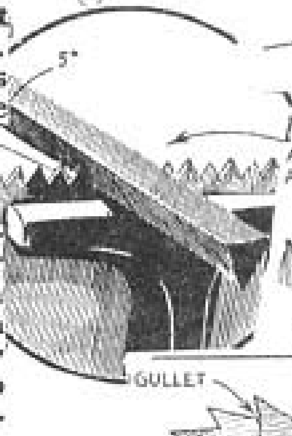
circular blade. After filing, the teeth of both hand and circular saws should be lightly dressed with an oilstone as in Fig. 14, to true up any chance inequality in the set, and to make the blade cut more smoothly. The gullets of large diameter ripping blades should be rounded occasionally with a small round file. See Fig. 13. This is known as "gumming" and is not of any particular importance on blades smaller than 10 in. in diameter. In filing, care should be taken not to run the three-cornered file deeply into the gullet.

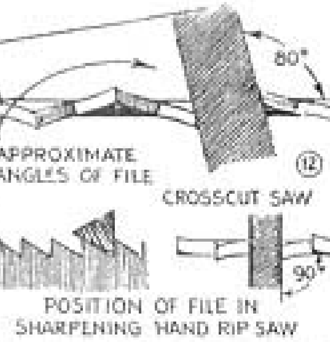
Figs. 4 and 6 show vises that may be made from pieces of hardwood to hold both the circular and straight blades for filing. In the case of both handsaw and circular blade vises, the edge of the vise should contact against the entire surface of the saw blade, just below the teeth. In the absence of suitable ready-made vises, as shown in Fig. 3, these homemade ones will serve very well.

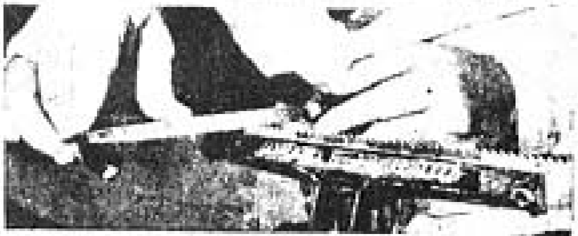




⑪







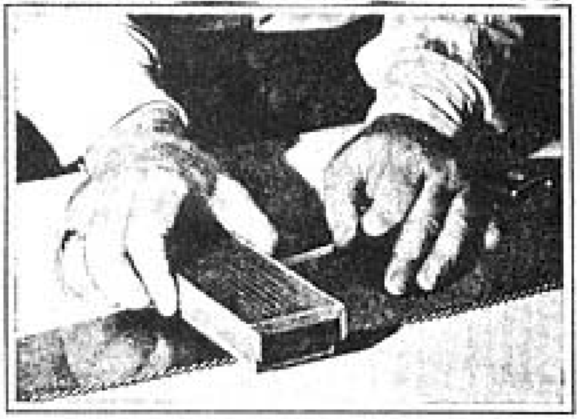


Fig. 14. Teeth of Both Hand and Circular Saws Should Be Lightly Dressed Down on the Sides

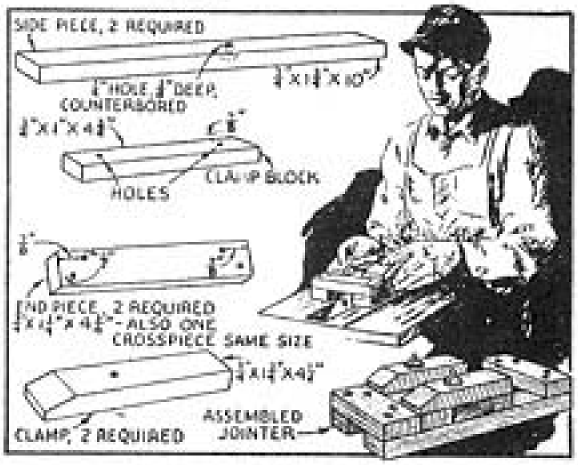

Fig. 15. A Frame for Holding the Abrasive Stone When Jointing the Teeth of a Circular Saw

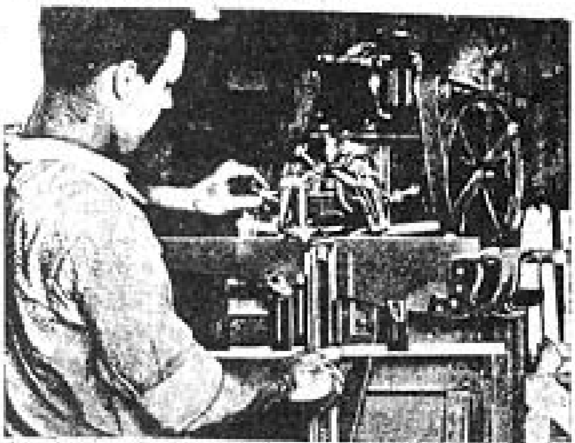
For those who would like to start a small community repair shop and thus go into the matter of saw filing on a commercial basis, investment in a saw-filing machine will soon repay one for its cost by the saving in time. Such a machine, driven by a 110-volt motor, automatically files and joints rip, crosscut, back, miter, meat and all other types of handsaws, besides circular saws from 3 to 24 in. in diameter, with 3 to 16 points per inch. It is also provided with an attachment for filing band saws from ⅛ to 4½ in. wide. Either a bench or pedestal-type machine can be obtained to best suit the space requirements of your workshop.



An Automatic Motor-Driven Saw Filer for Circular, Band and All Handsaws

YEAST, Dry.—Boil a large handful of loose hops, or a heaped tablespoonful of pressed hops, tied in a muslin bag, twenty minutes, in three pints of water; then take out the bag, and stir into the hop-water a pint of raw potatoes (grated.) Add one tablespoonful of salt, one of ginger, half a cupful of sugar, and one pint of flour; stir the flour in slowly, and pour as much boiling water as is needed to make it a smooth batter, stirring briskly while pouring it on, till all is smoothly combined. Then remove from the fire. When lukewarm add a cupful of good yeast, or one good yeast-cake dissolved. Let it stand one day in warm weather, or two in cold, stirring it down as often as it rises and foams. Then stir in good white corn meal to make it thick enough to make into thin cakes. Dry these cakes in the shade; but where the air circulates briskly, turn them over often. The quicker they can be dried, the better they will be. When dried all the way through, put them into a bag, and hang up in a dry, cool place.

Cakes should be small; not over two inches across, and half an inch thick. One of these cakes will raise four or five good-sized loaves.

YEAST, for Home-made Bread.—Boil a handful of hops ½ an hour in 3 pints of water. Pour half, *boiling*, through a sieve, upon a cup of flour, mix, and add the rest of the hop water; a spoonful of salt, half a cup of treacle, and *when warm*, a cup of yeast.

YEAST, to Make.—Thicken 2 quarts of water, with fine flour about 3 spoonfuls, boil half an hour, sweeten with near ½ lb. of brown sugar; when near cold, put into it 4 spoonfuls of fresh yeast in a jug, shake it well together, and let it stand one day to ferment near the fire, without being covered. There will be a thin liquor on the top, which must be poured off; shake the remainder and cork it up for use. Take always 4 spoonfuls of the old to ferment the next quantity, keeping it always in succession.

A half-peck loaf will require about a gill.

YEAST, to Make Another Way.—Boil 1 lb. of potatoes to a mash; when half cold, add a cupful of yeast, and mix it well. It will be ready for use in two or three hours, and keeps well.

Use double the quantity of this to what you do of beer-yeast.

To take off the bitter of yeast, put bran into a sieve, and pour it through, having first mixed a little warm water with it.

SURVIVING FATIGUE

by
Bill Abreu

An ever increasing problem among many individuals is fatigue. Fatigue has many causes, physical strain being only one of them. However, other causes include: lack of oxygen (as the case may be in higher altitudes), lack of salt, sugar, or water, and high temperatures. Fatigue can also come from a combination of these and other contributing factors.

Firstly, physical exertion does indeed cause fatigue, as anyone who has worked hard for long hours is well aware of. For a long time this was thought to be the only cause. But when studies were made it was found that sometimes people who worked extremely hard felt fine, while others who had worked the same or even less hours were totally exhausted. This at first confused physicians who soon came to realize that fatigue could be brought on by demands, other than physical, which the body makes. Thus the problem is that it is often difficult to recognize exactly what makes you feel tired.

Fatigue is also caused by jobs. Workers get home and feel like doing nothing after dinner but sitting down and watching television. Usually this worker will attribute his weariness to the job itself or the fact that he has been working so hard. Actually most human beings use about one third or less of their full capabilities.

Strange as it may seem, it has been shown that productivity drops when working hours are lengthened. But when they are reduced the rate of production increases, forcing the worker to put more labor into each hour. Interesting to note is the fact that people who work night shifts are usually prone to more errors and will produce less than they would during the normal daytime shift. This is because of a timing device in the human mind called the circadian rhythm which tunes our body functions to the rotation of the earth. It also helps to explain why some people feel more tired in the morning than they did the night before, while others are exactly the opposite. Often, fatigue results when a person exerts himself at certain hours when his body adjustments dictate that he should not. Understanding one's circadian rhythms can be a great benefit to feeling and working at your best. To do so a few simple questions should be answered.

First, take into account how you feel when you get up in the morning, when you go to bed, and at what times. Then decide if this schedule changes when you go on vacation or elsewhere. When do you eat your meals? Are they at strict patterns or at random? Most helpful is accounting the times of day when you usually are the most happy and when you are low.

Sometimes it is difficult to change your ways if there definitely is a conflict in your body clock. It is, however, fairly simple to take certain precautions. Of course, you should avoid any physical or mental exertion at times when you are least productive. If you feel tired when you awake in the morning then you might try waking up or going to sleep at different times. Obviously it is best to do the most important tasks when at your highest peak of the day. Or writing a nasty letter to someone when you feel your worst. If you eat meals at regular set times you can change your eating habit schedule and see if you notice any differences in your highs and lows.

Sleep also has a lot to do with fatigue. A person who has too much sleep may perform just as badly as one who has had too little. At wake up time some people will fall back asleep for those "just few more minutes." This usually results in fatigue and sluggishness for the day because of the fact that their whole schedule has been thrown off. Keeping a regular sleeping schedule so that your body can properly adjust to it is also important. If you decide to try changing the time that you go to sleep, then you should stay with that set time for a few weeks. And rather than hopping right out of bed in the morning at the sound of the alarm, it helps to lie awake for a few moments and stretch or sit up. This will save you from the sudden shock of transferring from a dream state to reality, and allow the blood to start flowing. Instead of coming fully awake at around noontime, you will be most alert in the morning.

Exercise, though it can be a cause of tiredness, can also help relieve fatigue. The best kind of exercise for this reason is one which is not too strenuous. Naturally, after a few sets of tennis you would be tired and worn out, however, a short walk can be especially helpful in overcoming fits of fatigue. For one think, walking gets the blood circulating, allowing more to flow to the brain where it is much needed. Another added benefit of walking is that it relieves strain on the heart. Thirty percent of the circulation of blood is done by the legs when walking. The constant motion pushes the blood upwards through the body and to the heart, reducing the chances of heart problems.

The way you eat can also have a lot to do with whether you feel fatigued or not. It should go without saying that the four basic food groups (milk, meat, vegetables, and bread) are much needed in your diet to eliminate the chances of fatigue due to poor nutrition. But often the problem lies not in the kinds of foods eaten, but when they are eaten. Many people have gotten into the habit of eating very little in the morning and afternoon, and then gorging themselves for dinner. This is not a good practice, for the blood becomes overloaded with calories in the evening, a time when the person will most likely do nothing to burn it off. It has to pump harder to absorb the food, leaving the brain with less blood. This lower amount of blood to the brain causes fatigue and leaves the individual feeling light-headed.

Breakfast greatly affects how one feels during the course of the day. However, the idea that people need to stuff themselves with food in the morning to support them through the day is a misconception. Too much food at any given time again results in the blood having to absorb it all. While it is a good idea to get the requirements in the morning meal, one does not have to eat an entire feast. Vitamin C cannot be stored in the body so a glass of orange juice or a slice of grapefruit should be consumed in the morning. Cereal is also good for people who are trying to keep their weight down, for it contains low fat. Eggs, on the other hand, contain high cholesterol and iron which can be beneficial but should not be eaten in excess.

Another important cause of fatigue is boredom. When a person is bored he may resort to eating or sleeping. There are, of course, other alternatives but these two are the most common. It is no secret that an uninteresting book can make you feel drowsy. And in most cases this drowsiness is unjustified. A person may have gotten plenty of sleep the night before and be feeling just fine in the evening when along comes his neighbor with films of his wife and brats. It is then when the normally alert person must start stifling yawns to remain courteous to his guests.

Monotonous jobs are the major causes of boredom. Even if the job appears interesting at first, it can quickly become dull after being overdone day after day. Some assembly line workers can carry out their jobs and productivity well because they think about more pleasant subjects while working. When finished with their hours it has been shown that they can scarcely remember having worked at all. Daydreaming seems like a no-no while on the job but there is absolutely nothing wrong with it as long as it does not interfere with one's working performance.

The most obvious way to escape job boredom is to get a different job; however, this can often be difficult to do. If this change of occupation is impossible then the alternative of daydreaming may provide a limited relief. During long breaks a short nap can be taken. Though it sounds like a child's pastime, short sessions of sleep can be excellent for recharging one's vitality. When off the job and boredom still occurs exercise has been found to be a good cure. Exercise results in mental alertness and provides the bored person with something to do in his idle time. Again, a brisk walk is the perfect kind of exercise for relieving this boredom.

There are a few simple practices which can be done for fits of fatigue when quick revitalization is needed, such as an upcoming important meeting or party. Lying down with one's feet elevated for a few minutes can sometimes increase consciousness by providing less blood for the legs and more for the brain (though the temptation is great, it is wise to avoid closing your eyes when doing this). Boredom often comes from those who use their minds for countless simple and menial tasks. Enrolling in certain community groups or school classes will relieve the effects of boredom and supply the individual with something more important to do other than deciding what to watch on television. Niacin (as mentioned in issue 6, volume 2 of The Survivor) can be helpful against fatigue, in that it opens wide the vessels and capillaries and allows blood to flow (which, incidentally, explains the flushing sensation).

When times get worse and you must adjust to a different kind of living, fatigue may be a major problem. But, as of now, it is simply one which must be overcome like the many others that exist in these troubled times.

DOUBLE ROOFS PROVIDE IDEAL SHADE FOR POULTRY COOPS

From Popular Mech. 1919

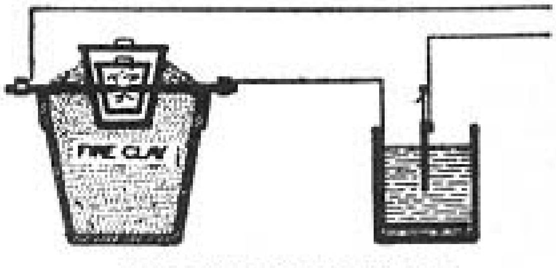
Having no native shade in our city chicken yard, we noticed one summer that the hens, especially those in the low brooder coops, became droopy and exhausted from the excessive heat. We studied the construction of the U. S. Weather Bureau thermometer shelter, which usually stands out in the sun, and is no larger than our brooder coops. It has a double roof with free air-circulation space between the roofs, hence the inclosed thermometers are exposed to a true-shade temperature. We then placed an extra roof on each of the brooder coops, leaving a 6-in. open air space between, the top roof being supported at the corners only. The arrangement proved so effective that the hens sought the coops, against the heat of unventilated inclosures on quiet, hot days.

How to Make a Small Electric Furnace

From Popular Mechanics 1915

The furnace consists of a large flower pot containing an ordinary clay crucible about 6 in. in height, the space between the two being packed with fireclay. Two ¾-in. holes are bored through the sides of the crucible about half way between the top and the bottom. Holes corresponding to these holes are molded in the fireclay, which should extend several inches above the top of the flower pot. A smaller crucible is placed inside of the large one for use in melting such metals as copper, brass and aluminum. With metals that will melt at a low degree of heat, such as tin, lead or zinc, the large crucible can be used alone. Each crucible should be provided with a cover to confine the heat and keep out the air. The electrodes are ordinary arc-light carbons.

The furnace is run on an ordinary 110-volt lighting circuit and it is necessary to have a rheostat connected in series with it. A water rheostat as shown in the sketch will serve to regulate the current for this furnace. Small quantities of brass or aluminum can be melted in about 10 minutes in the furnace.—



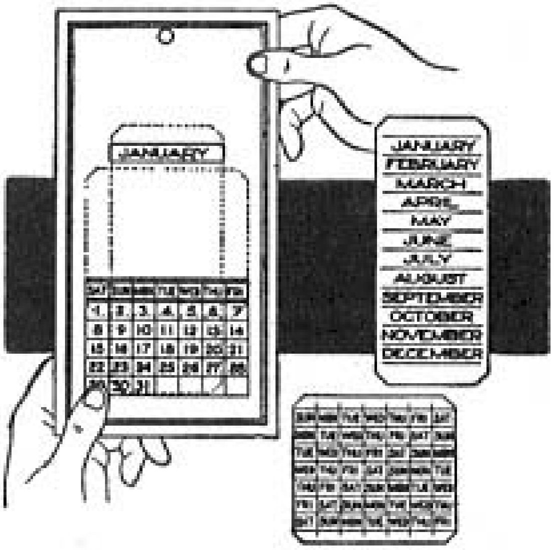
Electric Connections to Furnace

◆

A Perpetual Calendar

From Popular Mechanix 1919

It is only necessary to set this calendar the first of each month, by sliding the insertions up or down, to get the proper month or week. The calendar, as it is shown, is set for January, 1916. Saturday is the first day and Friday the seventh, and so on. It is not confusing and can be read either by the day or date. If the day is known it will show the date, and if the date is known it will show the day. The illustration clearly shows the parts, which can be cut from heavy paper or cardboard.

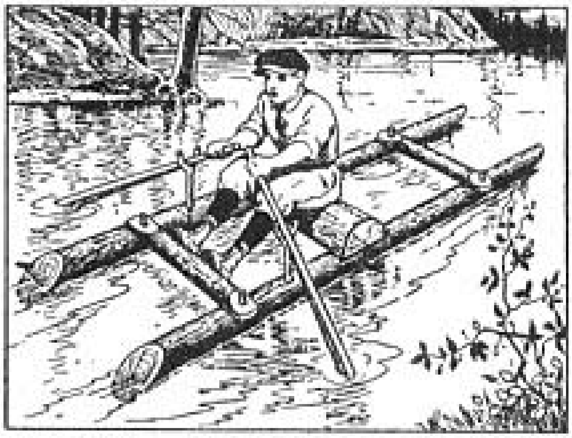


It Is Only Necessary to Change the Sliding Pieces to Set the Calendar for Each Month

Making a Catamaran Raft

From Popular Mechanics 1925

A simple raft, that will meet the requirements for an inexpensive and simple boat, can be made from two or three logs in the manner indicated in the drawing.



A Useful Boat, Built of Logs as a Catamaran Raft, Takes the Place of a Regulation Rowboat When the Latter is Not Easily Obtained

Two logs, about 12 ft. long, are used for the sides, and connected with crosspieces, spikes or wooden pegs being used to secure the parts together. A piece of split log answers for a seat, and two forked branches, inserted into the sidepieces, make satisfactory oarlocks. In the absence of regulation oars, pieces of board can be cut to approximately the proper shape.

SELF EMPLOYMENT FOR ANYONE

By Kurt Saxon

There is something about working steadily for someone else that dulls the human mind. Security is the main reason people give for fixed employment but the unrealized drawback is dependence.

With fixed employment you have a measure of security only if the business is growing. You may even advance, getting higher wages. But when the business levels off, so does your pay. And as the pay scale becomes fixed, so does the routine. So you are at a dead end and become just a part of the machinery.

A worker can go for years doing the same thing and getting the same pay. Except for cost-of-living raises, which seldom make up for inflation's gain in the same period, spendable income remains about the same.

When a business hits its peak and is serving as big a part of its market as it can reach, it usually starts going downhill. This is because the market has been saturated. There is no more room for development, no new money coming in.

Then, even cost-of-living raises are hard to come by. Then come the strikes. Raises are given, prices of the products are raised, fewer people can buy and less money comes in. As inflation eats into your strike-won raise, you must strike again, get the prices raised, lose even more customers and on and on.

That's the way it's getting to be all over the country. So if you work for others and think you have security, you may be insane. You'd better check that out.

The main drawback of a fixed income is your dependence on things staying as they are. Rising inflation and increasing bankruptcies are threats to just about every wage-earner's livelihood.

My early career was wasted in wage-slaving. I was uneducated, unskilled, unbalanced and a drifter from job to job. I could never keep a job long but the worst times were when I had a job I could do and stuck at it for up to a year. This was a waste of time as my savings never equalled the price of anything worthwhile.

When I was going to college I worked part time at a hospital doing kitchen duties for $27.00 per week take-home. This was in 1960 and my rent was only $6.00 per week for a room with sink and a hotplate. I spent maybe $3.00 per week for food so I didn't need much.

Just the same, the hours were from four to eight p.m. and I didn't like the work or the money. But a full-time job would have kept me out of college.

I was bitching to a wino name of Charles who lived in the same rooming house. He was a house painter and suggested I get in the trade. I'd never painted but had seen him at it and figured if he could do it, anyone could. I had watched him on a ladder once, hanging on with an elbow, with a fifth of Thunderbird in one hand and a brush in the other. He fell often but worked when he wanted to.

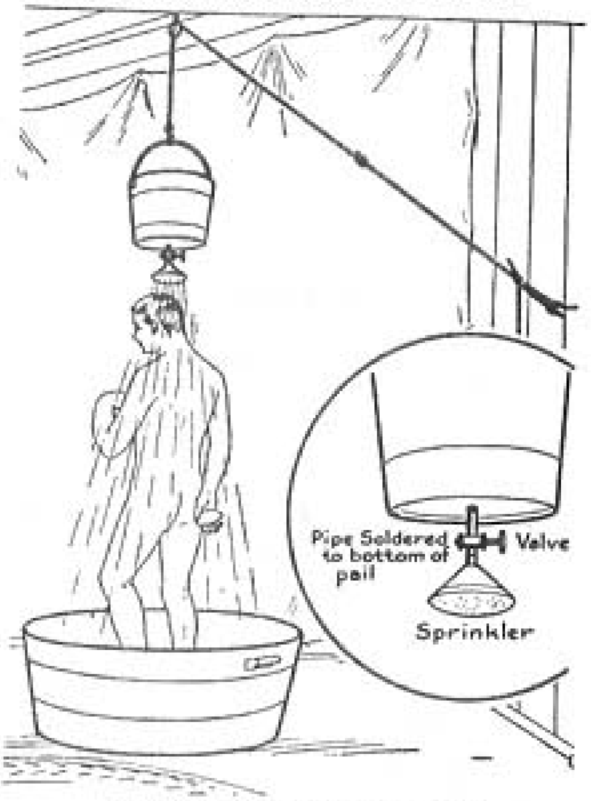
He wrote an ad for me: Painter; Fast, Reliable, Good References. $2.00 per hour and the rooming house phone number and who to ask for. It cost me about $3.00 to run it a week in the Work Wanted section of the local paper under PAINTING. Then I quit my job and sat back. I had to because I'd have been at work when anybody called. It's dumb to quit one job before getting another. So if you work, put in the ad the time you will be home to accept calls.

That lying ad took effect the first afternoon it ran. I got a call from an old lady with a tiny kitchen. I told her over the phone that for $2.00 per hour I'd supply the labor and the tools but she'd have to buy the paint. She had the paint ready and I stopped by the Dime Store and bought a paint roller, pan, three different sized hand brushes and a plastic drop-cloth.

I took this on the local bus and started my first paint job. The old lady showed me into her dark red kitchen and pointed to the bright yellow paint and went into her front room to watch TV.

I poured too much paint in the pan and just dipped in the roller, as the pan

Homemade Shower Bath



A Shower Bath That Costs Less Than One Dollar to Make

While in the country during vacation time, I missed my daily bath and devised a shower bath that gave complete satisfaction. The back porch was inclosed with sheeting for the room, and the apparatus consisted of a galvanized-iron pail with a short nipple soldered in the center of the bottom and fitted with a valve and sprinkler. The whole, after filling the pail with water, was raised above one's head with a rope run over a pulley fastened to the roof of the porch, and a tub was used on the floor to catch the water. A knot should be tied in the rope at the right place, to keep it from running out of the pulley while the pail is lowered to be filled with water, and a loop made in the end, which is placed over a screwhook turned into the wall. If the loop is tied at the proper place, the pail will be raised to the right height for the person taking the shower bath.

The water will run from 10 to 15 minutes. The addition of some hot water will make a splendid shower bath.

Device Enables Crosscut Saw to be Used by One Man

From Popular Mechanics 1925

A device which enables one man to use a crosscut saw is shown in the illustration. Two posts are driven into the ground about 6 ft. apart. Near the top of each of these is fastened a pulley, and midway between the posts is fastened another pulley, as shown. A sawhorse is placed beside one of the posts, the handle

was too full to allow rolling the roller on the pan's ramp. This doesn't work and it was several tries before I got the idea of pouring some paint back into the can and rolling off the excess paint on the pan's ramp before rolling it on the ceiling.

You can't imagine the mess at the beginning. I had paint on me and had a totally yellow arm and a soaked torso through my shirt. If that sweet old soul hadn't been in the front room watching TV, she'd have fired me in the first five minutes.

I'm pretty smart so I got the hang of it in the first half hour. I did that little kitchen in four and half hours and got $9.00 and even compliments.

A few days later this pervert called me and asked if I'd paint bare-chested. I was pretty naive and didn't understand and told him that I wouldn't consider painting bare chested as I got enough paint on my chest as it was without painting shirtless.

That first week I painted two kitchens, a garage and a bedroom. After awhile I seldom had to put in an ad. I got a lot of repeat business and, working only when I wanted to, averaged $34.00 per week. That wasn't much, even in those days. But it was more than I had gotten at the hospital and in fewer hours and was sufficient for my needs. If I wanted something more, I'd just work another day or two. So even in this poor trade my income wasn't fixed and I could choose my hours. I could have worked all the time if I'd wanted to.

Just in case you might want to try this, here are a few tips. Get a book on decorating and study the painting section. Then go to a paint store and have a clerk tell you what you'll need. Your ideal start would be to paint as much of your own home as you can for practice. A couple of days painting your own quarters would get most of the bugs out of your technique.

Charge about a third of what a Union painter gets. Don't worry about Union interference. People who hire bargain painters want bargains. They won't pay Union rates and so don't really expect Union skill. Union painters wouldn't be interested in such jobs, anyway.

Three dollars an hour for non-professional work is fine, especially since you don't have to declare it for taxes. It's all yours unless you want to pay taxes on it. Most of the guys I knew in the trade never declared their income because there was no way the Feds could check.

No matter what, do as good a job as you can and be extremely honest. I was never asked for a reference but those who I would have used as references hired me for one job after another. These were mainly landlords who hired me to redo vacant apartments.

After a time I charged $2.50 per hour and could have gotten more had I become a contractor.

Never work for a non-union contractor. You won't be fast enough to make a profit for him and he'll fire you. If you are fast enough you might as well be a contractor yourself.

Contracting is where you give an estimate and accept a set fee for the job. When people asked for an estimate I would say I needed a license to be a contractor so I just charged by the hour with no estimates. I didn't have the kind of mind where I could examine a job and tell how long it would take.

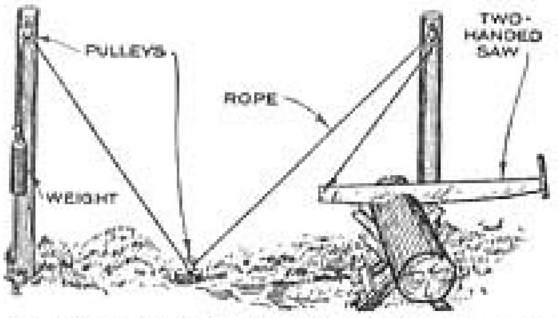
Contracting is more profitable, and I'm not sure about the license, but when you make an estimate, you're stuck with it. If you estimate a job will take eight hours and it drags out to sixteen, you'd be better off working by the hour.

I worked this way, off and on, for years. I was temperamentally unsuited for steady work. But I could be charming and polite to anybody for a few days, which kept me a fine fellow through most of my bigger jobs. Most of my customers were very nice and liked my work, although I was never really fast.

If I could do it, you can, too. You'd be surprised how much work goes begging because unskilled people don't know they could do it and skilled workers price themselves beyond the property owner's means.

Work in painting, home repairs, etc. is all over the place and you'll learn this if you'll only put in an ad. One place I was painting at, there was this young removed from one end of the saw, and the end of a rope passed through one of the bolt holes and tied.

The other end is passed over the pulley on the first post, under the center pulley,



A Two-Handed Crosscut Saw Is Easily Handled by One Man If This Rigging is Used

over the pulley on the other post, and a heavy counterweight is then fastened to it. With this arrangement, the saw may be easily handled by one man.

PAINT MADE FROM POTATOES

From Popular Mechanics 1931

Potatoes provide the base for a cheap and durable form of paint suitable for use particularly on farms for gates, fences or machinery exposed to the weather. One pound of potatoes are peeled and well baked. They are then mashed in three or four pounds of boiling water and passed through a sieve. To the mixture is added two pounds of powdered chalk mixed with four pounds of water. This forms a sort of glue capable of receiving any kind of color, even powdered charcoal or soot for a fine black.

PLANTS GROWN IN AIR-TIGHT BOTTLES

Popular Science 1936

RAISING plants on synthetic soil in bottles sealed against outside air, moisture, insects, and plant parasites, is the remarkable accomplishment of a Millburn, N. J., woman botanist. The artificial soil, which provides a scientifically balanced food for plants, consists of agar-agar, a seaweed derivative, combined with various chemicals. Poured into bottles, it congeals into a translucent, gelatinous mass. Seeds and spores are planted with a platinum needle and the glass containers are sealed with cotton wadding. In their individual, sterile "greenhouses," the seeds rapidly develop into healthy, thriving plants. A moist atmosphere containing the essentials for plant life is maintained through the agency of the chemicals and the plants themselves; with each change of temperature, mist forms inside the glass and "rains" back on the plants. Given sufficient light, the plants will grow for years, or until they are too big for their containers, when they can be transplanted to larger bottles or to an outdoor garden. Delicate

moron also doing painting on a picket fence. He didn't even scrape off the old, loose paint.

I noticed he had wet his pants and asked the lady how such a nebbish could get work from anybody. She said he only charged $1.50 an hour and did all sorts of little odd jobs. This was mainly for old people who simply couldn't handle any sort of labor and preferred a mental defective to no one at all.

I met many other odd-jobsmen. They started out just as people who could do something, or were willing to try. They simply advertised that they could do a certain job and they had been busy ever since.

It doesn't matter what you do. Painting, hauling, odd jobs, home repair, carpentry, electrical work, typing, babysitting; a few lines in your local paper will keep you busy. An old fellow who was going with my mom had been a painter. He told me he had worked my system all during the depression and had always lived well.

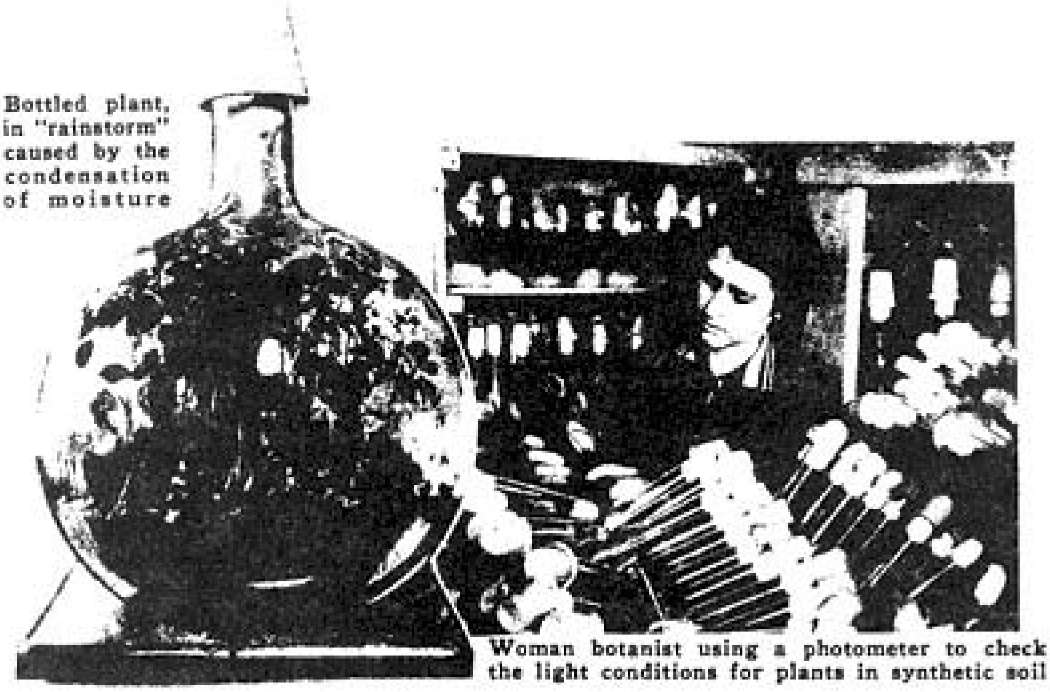
It isn't all roses. You'll get an occasional griping, abusive customer you can't please. Then there are those who'll want you to be licensed, bonded, insured and all that. If you do your best at say, $3.00 an hour, they're getting a good deal. If they don't appreciate that and give you a hard time, to hell with them. They're stupid. But this type is rare. Most of your customers will be just good, poor people who need a bargain and have sense enough not to give a bargain like you a hard time.

If you happen to be a professional and a Union tradesman, this sort of work would be moonlighting. I knew professionals who cut their pay by a third to be independent. A Union painter or electrician would contact apartment house owners and be on call all the time. No need to worry about licenses. If you're giving a landlord a bargain, he's not going to turn you in to the Union or the licensing place or the IRS or anybody.

So if you are temperamentally unsuited for steady work or have been laid off or fired, put in an ad. Even if you're in fine shape and just need some extra income, put in an ad. If employed, you can tell a caller you'll be free on the weekend or at night. They don't care when you work if it's convenient for them.

You try getting work this way, even if you have a job, and you'll be surprised how needed you really are. You'll never be worried about unemployment again and the worse the economy gets, the more secure you'll be. Places have to be kept up and if money is tight, Union workers stay home.

Another good point is that while you're working on such jobs you are still free to follow up leads on better opportunities. You can also go to school or work on some home business that you don't expect to make money on for awhile. So if you are too young for steady work, retired, slightly handicapped, a dingbat, have a rotten work record, or whatever, you are still highly employable in this field.



Bottled plant, in "rainstorm" caused by the condensation of moisture

Woman botanist using a photometer to check the light conditions for plants in synthetic soil and rare plants are said to be easy to raise by this method and when transplanted outdoors, they prove exceptionally hardy. Because the chemical soil is nearly transparent, botany students can observe and study all the stages of root development.

Moth Balls on Roosts Keep Lice Away

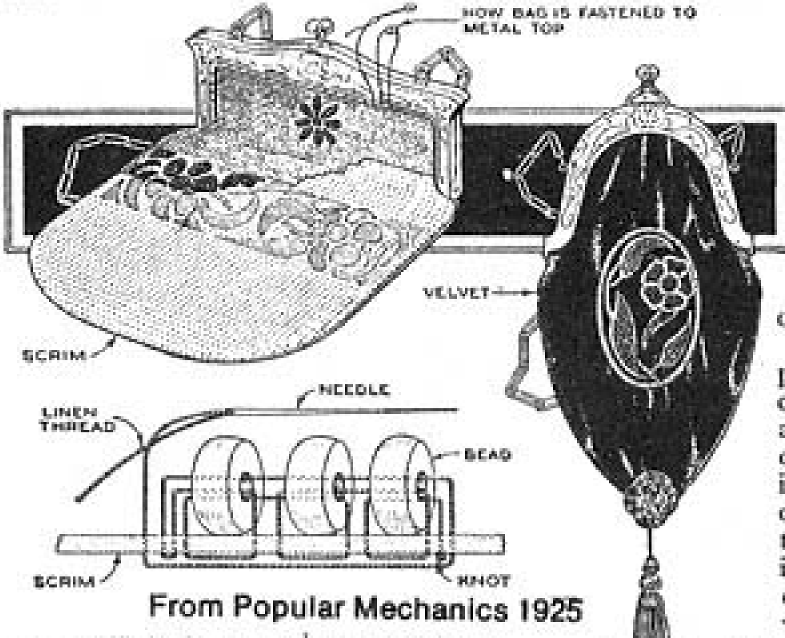
From Popular Mechanics 1931

Moth balls have been found highly effective in keeping lice out of a poultry house. The roosts were fitted with blocks, each of which accommodated just one hen and thus prevented crowding. A hole, large enough to receive one moth ball, was then drilled in each block and also in the roost between the blocks, as shown in the drawing. In attaching the blocks woodscrews were used, these being driven in from the underside of the roosts. It seems that lice cannot endure the strong odor of the moth balls.

Moth Balls Held in Holes Drilled in Roosts Keep Lice Away from Hens

Making Beaded and Velvet Handbags

Beads have been used by woman for thousands of years, and she has not yet wearied of stringing beads on threads and applying them to a background to form various articles of use and ornament, such as the attractive beaded handbags that are at present so popular and —so expensive. However, there is no obstacle to prevent anyone making her own bag at a cost of only the trifling sum required for materials and time. The materials required for the bag are, a metal top, which may be obtained from most stores, ¼ yd. of scrim, lining material, and the necessary beads. In making the bag care should be taken to have the lines of the scrim run up and down, as these lines serve as guides for sewing on the beads.



From Popular Mechanics 1925

METHOD OF FASTENING BEADS TO SCRIM

Beaded Bags are So Easily Made That No Woman need Deny Herself the Pleasure of Owning One. The Decorations may be Worked Out to Suit the Individual Taste

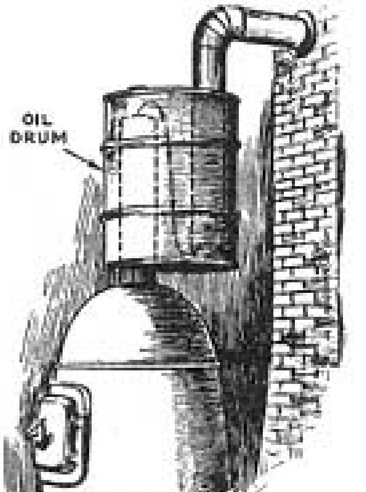
Make an accurate design of the pattern to be reproduced, on tissue paper, and trace it onto the scrim with a "4H" pencil, a hard pencil being used to prevent blurring. After the design has been traced, it is filled in with water-color paints as nearly as possible the color of the beads used.

The beads are sewed on one at a time, guided by the lines of the scrim. Linen thread should be used; this is knotted, and the needle is drawn through from underneath, taking a bead of the proper color on the needle. As shown in the drawing, each bead is securely sewed to the fabric. About every third bead the thread is taken back through them in the manner shown; this makes the bag stronger and the row straighter. It is necessary to make each row straight across, working in beads of each color as it occurs in the design traced on the fabric.

Another effective and pleasing bag consists of colored-bead designs applied against a background of dark velvet, or satin. As it is not possible to trace the design on the surface of these materials, the pattern is applied to the underside of the cloth, and is then worked out with colored threads, which gives the worker the necessary guidance, the beads being applied as described. Instead of using beads, the same idea can be pleasingly worked out in cotton yarns of different colors. The design in this case is traced on tissue paper sewed to the material at the exact location, and the yarn is applied through the paper, which is torn off when the work is finished.

Getting Extra Heat from the Stovepipe

From Popular Mechanics 1931



Usually the heat passing through the stovepipe and chimney is practically wasted, but with the arrangement shown in the drawing much of it is radiated into the room. Take an oil drum and put two lengths of stovepipe inside as shown; then mount the drum over the stove, and brace it to obtain the necessary rigidity. The path of the smoke and hot air through the drum and up the chimney is indicated by arrows.

BARKLESS DOGS BROUGHT FROM AFRICA

Popular Science 1936

These four dogs are of an African breed recently brought to England. They are never known to bark

MUTE but far from "dumb," four voiceless hunting dogs, the first of their breed ever to be seen in England, were exhibited at a recent international kennel show held in London. Short-haired and with sharply pointed ears, the curious animals have never been known to bark. The dogs are called "Basenjis," and were imported from Africa, where they are used for hunting by some of the remote tribes inhabiting the central part of the continent.

Survival Tools

By T. Fitzgerald

The most basic and deadliest weapon ever known is, of course, the human mind. It has the capacity to turn even every-day items into devices capable of maiming and killing, whether in defense or offense.

Beginning at a lower level we will consider ways of using simple and often disregarded items for food gathering and/or defense/offense in an environment of complete collapse.

Several years ago a railroad surveyor was checking a section of track in the Rocky Mountains. He was alone with no weapon. Upon rounding a curve in the track he found himself facing an angry Grizzley Bear. Faced with almost certain injury or death, this man killed the bear in two minutes without injury to himself. How? Very simple. The trackbed was of stones approximately two inches through. He blinded the bear by throwing stones, keeping out of reach meantime, and then proceeded to stone the bear to death. This man was lucky, the next man who tries this may well be killed instead. It does prove, however, that no man is ever unarmed: he only thinks he is.

The stone is probably the oldest weapon in the world. Some of its advantages are choice of size and shape, readily available, unlimited quantities. Also it comes in many styles: The brick or half-brick is probably the style most familiar to city-dwellers. The manner of use is still the same.

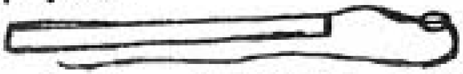
Some disadvantages of stones as weapons are they are short range weapons, they come in sizes too big to throw and sizes too small to do any good, and they can be thrown back at you, possibly by someone with better aim than you.

Large stones are good for defending heights as they can be simply dropped and stones too large to be thrown can thus be used. It is very difficult to throw a stone of any size back up at you to any advantage.

To attain any distance and real force with a stone the thrower must have assistance. The throwing weapon PAR EXCELLENCE and of undoubted age is the sling. The classic example is David and Goliath.

There are two basic types of sling. The first is two straps of flexible material (leather boot laces are excellent) joined by a pocket. The projectile is placed in the pocket, the two ends are held in the hand and the sling whirled round and round the head. At the right moment one strap is released (often there was a loop on the end of one strap to go over a finger), the pocket opens and the stone hopefully flies to the target. Actually, with practice this can be a very accurate and deadly weapon. Depending upon the length of the straps, the projectile, and the method of whirling and release, the extreme range of this type of sling can exceed 300 yards. The ancient Romans and Greeks cast lead sling balls in order to increase the range of their slings as war weapons. These balls often had such mottos as "take this" inscribed on them.

The second type of slings involve a staff or stick. There are two main types of staff slings. The first having a staff about 4 feet long. One strap of an ordinary hand sling is attached to one end of the staff, the other strap being made long enough to be held with the butt of the staff and thus give an extra length to the outside curve of the swing and so give more velocity to the projectile.



Another type of staff sling, employed mainly in military service, was a stout staff with the pouch held securely to it by one strap a few inches from one end. The other strap was fitted with a ring which slipped over the point of the staff. With a stone or ball in the pouch, the staff was held in both hands and swung from behind straight over the head just like driving a stake with a sledge hammer. At a certain point the stone shot forward forcing the ring off the end of the staff and opening the pouch.

A modern sling is of course the slingshot which propells a ball by the force of rubber bands.

Any of these slings is an excellent means of providing meat for the pot with almost no noise and NO expenditure of possible irreplaceable rifle or shotgun ammunition. With the exception of the modern slingshot they are also proven in battle.

Probably the second weapon that man discovered on his way down from the trees was the club. At first merely a broken tree limb it later evolved in many ways.

Wooden missiles have been used as serious weapons of war and effective hunting weapons since prehistoric times and, in isolated parts of the world, continue to be used still.

There are two basic kinds of wooden missiles. The first is the straight club variety, generally with a large knob at one end, which is thrown and is meant to stun or kill with a blow. Of course, these can also be held and used to strike blows in the classic manner of a club or bat if the enemy or quarry is close enough. These straight clubs ranged from 3 foot long types used by West African natives to break animal legs at a few feet distance to the clubs of Fiji, about 18 inches long with heavy knobbed ends.

The African KNOBKERRI was the most popular of the throwing clubs, being about 2 feet long, with a narrow rod-like handle. These could be thrown with great force and accuracy. These were used with great effect against Hyrax (Rock Rabbit) and PAUW (a quail-like bird). Two hunters moved about 50 yards apart. As they roused their quarry they threw their clubs so that in dodging one club the quarry almost always was hit by the other.

The native Australians practiced throwing their clubs so they struck the ground several feet in front of an enemy and bounced up, thus being harder to dodge than if thrown straight at the target.

The second club variety is the curved clubs, which if flattened and properly shaped can fly in a variety of courses and even return to the thrower. The common name of such an interesting weapon is the boomerang.

Contrary to popular belief such curved throwing sticks, even the returning type, are not strictly a product of Australia. The word boomerang, strictly speaking, applies only to the curved wooden Australian throwing sticks, but are now used to describe any flat, curved throwing weapons, for sport or war, that can or cannot return to the thrower.

The true boomerang that returns must be thrown with a great jerk to give it a spinning motion. When the forward motion dies, if the boomerang is still spinning fast enough, it will slide backwards through the air, often behind the thrower. This violent jerk when throwing causes an accuracy and velocity loss. Therefore, the returning boomerang is seldom used for anything but birds and exhibitions. The thrower also is in great danger when one returns as it is still spinning fast enough to injure or even kill if a person is hit in the head.

Actual shapes, weights, and sizes are actually just a matter of choice. The light return boomerangs have been thrown as far as 50 yards. Heavier, curved, throwing sticks, meant only for hunting or war and not to return, have been known to break bones and have a range of up to 150 yards. Each individual stick has its own characteristics when thrown and must be thrown in the same manner each time to fly the same. One stick may fly straight for 50 yards and suddenly dive down, for example. This means that there is not as much danger in an enemy throwing such a stick back and causing you injury as you may have thought, because he would not know how to properly throw your personal throwing stick.

In India both iron and wood boomerangs

were widely used.

In ancient Egypt boomerangs are known to have been used as far back as 4000 B.C., generally as sporting weapons for wild ducks, but also as a fighting weapon. A type of boomerang sharply curved on one end is still used in Abyssinia and the Upper Nile.

The Hopi Indians of the American Southwest also had their own version, known as a rabbit stick, for its principal target.

SURVIVAL TOOLS - #3

T. Fitzgerald

Next up on the list of weapons is the spear.

With the end of a stick pointed and hardened in a fire, prehistoric man was able to inflict effective wounds in a large animal, or in his fellow man. Later refinements were stone or bone tips, then metal.

One very important contribution to the development of the spear is a stop, or crossbar, behind the point. This prevented the spear from penetrating too deeply in a large animal, thus putting the spearer into range of the teeth, claws, antlers, or whatever, of the spearee. The spearmen could thus hold on to the end of the spear to fend off his opponent until it dropped from loss of blood or the hunter's companions finished it off.

Spears for hunting gradually evolved until they were perfected in the sixteenth century. Hunting spears were between 6 and 7 feet long, with a blade of 12 to 18 inches long and were used for all types of game, bear spears being larger in all proportions. Animals were either hunted down with dogs or driven into nets. Sixteenth century hunting spears were also well regarded as military weapons.

Lance and spear were originally interchangeable generally, but from the seventeenth century on, lance usually applied to a spear with a long shaft and small head. Today regarded primarily as a war weapon, from early times it was often used for the hunt. As a hunting weapon the lance had limited uses. It could be counted on for a certain kill only on small game, but it gave a horseman a better chance of reaching and slowing down the quarry so a sword or spear could be used.

Spears and lances were of various lengths, to over 20 feet long. The long spears and lances were at a decided disadvantage in bushes, trees, and high grass. Eventually a short spear, 6½ feet long, with a stout staff with a lead weight on the butt, was evolved. These were normally used on a horse and properly used could bring down a powerful animal, but brought the quarry dangerously close to both horse and rider.

Throwing spears, also called javelins and darts, were short, light spears that have always been hunting favorites. Often they had feathered tails, like an arrow, to insure additional accuracy. Top darts were also thrown from the top castles of naval ships. Throwing spears were usually from 3 to 4 feet long with a blade 4 to 7 inches long. The shafts were usually wood but all steel models were popular. The range of most throwing spears was probably 50 to 70 yards, but a French traveler in Persia in 1670 claims distances of "six or seven hundred paces."

To enable all but the heaviest of spears to achieve respectable distance an artificial aid, known as a spear thrower, is needed. The simplest is a loop attached to the shaft. The spear was rested in the hand and thrown by the first 2 fingers hooked through the loop. A similar loop was used in some areas that slipped off the spear as the spear was released. Another type was strap with a loop to fit the butt of the spear and the remainder of the strap wound around the shaft. The free end of the strap was grasped and when thrown, the spear was given a spin, supposedly contributing to accuracy as well as distance.

Light throwing "arrows" are used in England for distance contests only, and have little or no value except for amusement. To throw them a loop that slips off as the arrow is released is used. The record throw for this type of throwing spear is over 372 yards. A regular arrow can be thrown by this method 200 yards easily.

The most effective and efficient spear thrower was the throwing stick* found in Australia, Central America, and the Arctic. Almost all were of wood, between 1½ and 2½ feet long, and many were carved. The basic design is a flat board with a grip at one end and a projecting pin or tooth at the other end. The spear was placed along the stick and held by the fingers, the butt of the spear placed at the pin. With the throwing stick the force of the throw was at the butt of the spear, in many cases doubling the range of a spear. Some Australian aborigines reached distances of almost 100 yards. The Australian spear thrower was normally fashioned in a long bowl-like manner to enable it to be used as a holder for berries and other food stuffs.

Spears with multiple points were also made. The only real value of these pieces seems to have been as fishing spears and for use as frog stickers.

Harpoons are a specialized type of spear used for such activities as hunting whales, seals, walrus, polar bear, sometimes deer, driven or found in the water, and hippopotamus. I doubt there will be much call for harpoons and harpooners.

*Throwing stick called an "atalatl" (Eskimo work) B.S.

SURVIVAL TOOLS - #4

T. Fitzgerald

The rope or creeper noose has been a hunting weapon since man became man. Set up or suspended in the trails of wild animals, attached to the end of a long rod for birds, or even for fishing, it was the cheapest, the simplest of hunting tools, and often the most successful. Early American Indians were prone to capture deer by a loop in the deer trails and lighter rope or cords served both Indians and early settlers for providing the main ingredient for rabbit stew.

To be able to move and give range to the noose the lasso was devised. This is merely a rope with a loop on one end and is now normally thrown from horseback. American Indians were known to use a lasso from a canoe on deer found swimming in lakes and rivers. The Roman mosaic at Utiqa shows a hunter on horseback lassoing a stag. Pictures on Scythian amphora (jugs or jars) found at Chertomlyk show Scythians breaking-in horses using lassos.

From time to time the lasso has also been a successful war weapon. The Sagartians carried no weapons except daggers and ropes made of twisted thongs. When they engaged their enemies they threw out their ropes, with nooses in the end and whatever anyone caught was dragged toward them and, man, or horse, was put to death. One of the "five weapons of war" in the Sinhalese MAHAWANSO was a rope with a noose, running in a metal ring.

Whatever its use in war, the lasso is primarily a hunting weapon. It has been used as such in almost every country in the world. Scandinavian and Lapp hunters have relied on it for capturing reindeer and bear; American hunters have taken mountain lions with it; early Californians were known to rope bears; in Southeast Asia heavy lassos are used in capturing wild elephants; and some cowboys of the old west tried to rope anything they thought no one else ever had. It was in the American West and the Pampas of South America that the lasso actually became famous and it is still used there for controlling horses and cattle.

The American lasso is from 45 to 60 feet long, made of horse hair, leather, hemp, or other materials. One end has a ring, generally of metal, by which the loop is made. Lassoing looks easy. The hunter makes a loop of 5 to 8 feet, holds it in the throwing hand, whirls it rapidly around the head, and releases it at the animal so it will fall around the head or legs. The method of throwing can be varied and the accuracy with which it can be thrown at a full gallop is surprising. However, the skill required to throw a lasso thus is not easily acquired and the lasso has only a limited range.

Equally or more effective than the lasso is the bolas. They have longer range and the skill required is much easier to attain.

South American bolas are of three types: One ball on one thong; two balls, one on each end of a cord; and three balls attached to cords and the ends attached together. The one and two ball bolas are nowhere near as effective as the three ball bolas.

The cords, of plaited or twisted leather, are from 3 to 10 feet long; the balls, of iron, wood, or stone, and enclosed in leather weigh from 1 to 1½ pounds each.

To throw the bolas the thrower takes one of the balls in his hand and whirls the other two round and round his head; then, taking aim, he releases them. They spin through the air; and, when they strike an object, wind around it, crossing each other, and firmly bind the object. When the balls are stone they have enough force to break a horse's leg.

Balls of wood and as large as a turnip are used in bolas for capturing horses without injury. Balls of iron can be thrown to the furthest distances. The main problem in using bolas on horseback is to be able to ride well enough to whirl them so steadily round and round the head so as to take aim and release them, all the while at full speed. On foot the art of the bolas is easily learned.

Another way to throw the bolas is to grasp the cords where they join and twirl the three balls together. In any event, the effect is a pattern of shot about 8 feet across that will tangle and disable rather than kill. Each cord can be as much as 8 to 10 feet long, making a pattern about 20 feet wide. The range of the bolas is from 30 to 60 yards on foot and 80 to 100 yards on horseback.

Eskimos use a lighter bolas for catching flying birds. From 4 to 10 walrus ivory or bone weights are tied to cords of sinew or seal intestines 24 to 30 inches long with a short handle of brass or feathers where the cords join. Carried in a pouch slung from the neck from which they are quickly extracted and thrown, the bolas are said to be effective at ranges of 30 to 60 yards.

The American Indian version was used in the northern areas and was two stones joined by a single cord. One stone was held and the other was twirled round the head. Thrown with a side throw across water at swimming ducks, the stones could skip scross the water for amazing distances and were quite successful in snaring or stunning ducks before they could be alarmed and fly.

SURVIVAL TOOLS - #5

T. Fitzgerald

Often thought of only as a child's toy, a pea-shooter is in fact a miniature of a very deadly and useful instrument. Other weapons call for manual dexterity or strength. The blowpipe or blowgun calls on the power of a man's lungs; the air blown out forcefully thru the blowgun propells the projectile with great force.

Often thought to be merely an invention of primitive South American Indians, blowguns were actually much more widespread in their use. Illustrations in many European manuscripts from the Middle Ages show blowguns being used for hunting rabbits, birds, and other small game. Because of the large variety of other projectile weapons blowguns were not in great demand. Nevertheless their production and use did not die out. During the middle 1800s England had a passion for making walking canes with one or even more uses above that of a simple cane. Included in these dual-purpose canes were some hollowed out for use as blowguns. Advertisements listed tubes, darts, pellets, pellet moulds, targets; touted their use for rooks (crows), pigeons, rabbits, vermin, etc., at ranges of up to 50 yards, and acclaimed them as a pleasing source of indoor amusement. They further bade the purchaser to beware of imitations.

By use of a self-made blowgun, an American reported kills on hares as far as 60 yards during World War II.

The blowgun's use outside of Europe is mainly confined to two regions. One is in Asia from Ceylon around to Borneo and New Guinea reaching to Japan. The other is Guiana, Brazil, and Ecuador in South America, also appearing in Mexico and the south-east USA.

Native blowguns are of three types: 1) bored from one piece of wood or bamboo, 2) two long pieces of wood, each flat on one side, are grooved on the flat side and joined to form a tube, and 3) two hollow reeds or canes, one inside of the other. This last type uses very light weight reeds and two are used for sufficient strength. A wooden mouth piece is normally used on all of these. In Borneo a heavy wood blowgun is made from 6 to 8 feet long (type 1) and a blade tied to the muzzle so it can also be used as a spear.

Length of blowguns varies from about 4 to 5 feet to an extreme of over 11 feet. This longer one is used by Guiana Indians. Made from a very thin reed inserted into a length of palm, it only weighs about 1½ pounds.

Bores of blowguns seem to be fairly standard at about ½ inch.

Projectiles are either clay pellets or darts. Pellets require much effort to produce enough force to stun a bird and about 40 feet seems to be their useful range. Darts are much more useful. Borneo headhunters use darts 6 to 9 inches long and 1/16 to 1/8 inch in diameter with a pith cone fastened to the base. These are extremely light and so relatively harmless in themselves. However, they are coated with poison. Six out of ten darts can be put into a potato at 50 paces. Properly prepared and weighted, the headhunters insist they could kill a rhino.

In the Malay Peninsula a heavier dart is used, with an iron point and twisted, cone shaped piece of bark at the base, plus poison.

The Japanese used a sliver of bamboo with paper feathers, also poison.

South American Indians use leaf stems of palm about 9 inches long, with or without poison, padded with cotton at the base.

South India users shot a miniature harpoon. A barbed head fit loosely on the shaft and the two were connected by a piece of string wound around the dart.

American Indians had their version also and used milkweed fluff tied on the base of a wooden dart.

The blowgun is primarily for use within a distance of 50 to 60 yards at birds and small animals. With poison it is also capable of being used against about anything you can think of, including man. Careful preparation, and care that the flight of the dart will not be disturbed by a puff of wind or breeze, allows nearly a 150 yard range.

Modern, machine made, blowguns are available for under $10 from various firms, come complete with darts, and extra darts are available for a small cost. Or, make your own.

SURVIVAL TOOLS #6

By T. Fitzgerald

Bows

The world record distance for an arrow from a handheld bow was recently set at 1077 yards using a modern recurve bow and a special short arrow. Hunting arrow distance records are at 500 yards.

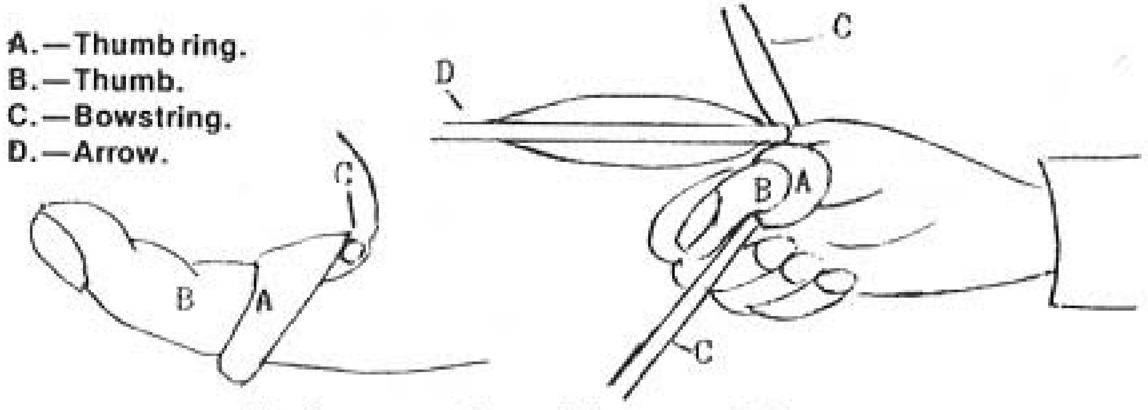
Bows have been in existance since

Paleolithic times (from 750,000 years ago). Actual bows dating from Neolithic times (from 10,000 B.C.) have been recovered in Switzerland. Made entirely of yew wood and 5 to 7 feet long, they are of the type of bow termed a self-bow.

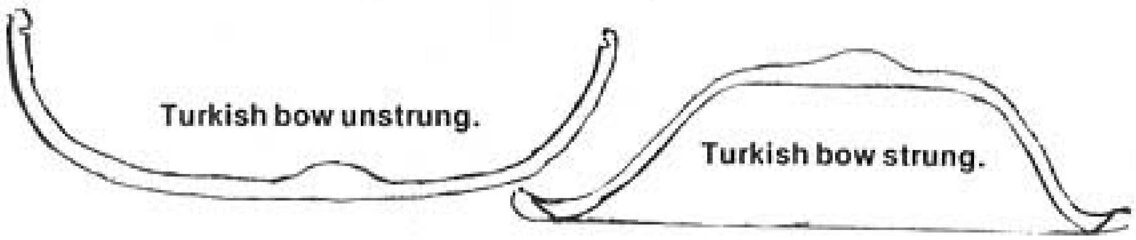
1. Shorter bows from Neolithic times averaging 40 inches long have been found in Asiatic Russia. Some were of wood reinforced on the belly with strips of antler or horn, others were apparently laced with sinew to prevent the wood breaking. These were the earliest forms of composite bows.

After a strong glue was perfected, the three materials, wood, horn and sinew, were joined into one strong piece, shaped and fitted with two notches for the bowstring. A bark or skin cover often kept it from getting damp or excessively hot.

To increase the strength, the ends of the bows were made to curve away from the holder when the string was loosened or removed.



The fingers can be curled up or straight.



Turkish bow unstrung.

Turkish bow strung.

2. In Egypt in 3500 B.C. both one-piece and composite bows were being used. Later, several Egyptian kings boasted of killing elephants, wild bulls, and lions, using bows.

Bows were made of various materials. Some woods used were yew, bamboo, mulberry, birch, beech, sumac, cherry, spindlewood, elm, and whatever was at hand. Also used in various combinations were oxhorn, sinews of various animals, various types of glues, silk, leather, various metals, ivory, birch bark, water buffalo horn, bone, etc. Almost every combination of these seems to have been tried at various times.

3. Possibly the ultimate bow was the Turkish composite bow. Short, about 3 feet 9 inches, unstrung, and three feet two inches when strung, this bow is extremely strong and elastic and requires a pull of about 118 pounds or more.

The bow is mostly flexible horn and sinew glued to a very thin piece of wood--1/8 to 1/4 inches thick except for the handle, and from 1/2 to 1 inch wide. The wood offers no strength and is only the core on which the other parts are glued. Because of its length and thinness, the wood is fashioned in three parts; the limbs and handles, which were fitted together, and glued.

4. The inside of the bow is lined with two pieces of horn about 1/4 inch thick and are butted together.

The outside or back of the bow is formed by a strip of ox or stag sinew about 1/4 inches thick.

Thin bark, leather, or skin, is then glued over the sinew to keep it from damage or damp. The horn is not covered. In the better bows the outer covering is then painted red and decorated, dated, and signed by the maker.

Bow strings were originally made of sinew, which was easily spoiled by rain or fog. Later, silk bowstrings were introduced. Sometimes wax was used on the silk bowstrings, but it was not considered absolutely necessary.

The arrow length is normally between 25 and 26 inches.

To draw such a powerful bow, one cannot use his fingers. Instead a "thumb ring" is used. This is a ring, of ivory or other hard material, fitted on the thumb, with a "lip" on the side worn inside, which is used to draw the bowstring. It would seem that drawing a bow with such a ring would hurt the thumb but it is simply not so. You can bend a strong bow further and easier with such a device and the range of the arrow is always further when using a thumb ring than with the conventional finger pull. The bowstring release with the "lip" of the ring is quick and clean.

The best distance achieved by a Turkish bow is over 800 yards, using flight arrows. The range with a war arrow is in excess of 400 yards, using a strong bow and a strong archer.

Compare this with the famous English long bow, a self bow of yew. The maximum range with a flight arrow is 340 yards, and the range with a war arrow is about 200 yards.

Bows have of course been used in virtually every area of the world, for hunting, offense, and defense, but none was so effective as the Turkish bow.

Arrowheads come in a wide variety of shapes, sizes, and materials, beginning with a sharpened stick, then fire hardening the stick, pointed antler, bone, stone, and finally metal.

Against birds and small game a large blunt head is often used. Against just birds, a double-pointed, broad headed, point is used to inflict a large wound and rapid bleeding if a killing blow is not dealt immediately. And, when the target is fellow man, an even greater variety of designs is used.

Bows have even been developed to shoot stones instead of arrows. These have only limited powers though, and are only good for small game and birds at relatively close ranges.

Bows are constructed as simply or as complicated as desired. New on the market are two completely different bows, using to entirely new principles. One has two limbs and a number of pullies. It is more powerful than a conventional bow and easier to draw. The other type has a series of pullies, ONE limb, and a large moveable arc fixed to the other end. More conventional bows are available as one piece or takedown models. Arrows are available in various woods, aluminum, and fiberglass, with an assortment of fixed or interchangeable heads.

The disadvantage of the bow is the extended time and practice needed to become truly expert with one. Advantages such as ease of manufacture of bow and the arrows to go with it, silence, and effectiveness, make it well worth the effort.

SURVIVAL TOOLS #7

By SFC Theodore Fitzgerald

Before we proceed further, it is important to recognize yet another survival tool developed by ancient man, but still used today. The "tool" was the domestication or taming of wild animals and of course the products of the original taming are still with us and used every day.

Dogs are the most important animal to be considered here. Their use in survival atmosphere will spell the difference between life and death to many, many, people.

Dogs were originally used for hunting, burglar alarms, and at times for food when times were rough. All of these applications are still current. A dog will be a most vital part of almost any survival effort, especially if things get as dangerous as is likely in a state of complete collapse. A dog will be almost worth your life as a danger alarm when strangers get near. You will need to train your dog not to bark, however, merely to give the alarm. A barking dog could bring a gang upon you. And, if you have a surplus of dogs, you may have to use them as a food source at the onset of collapse. You may be able to reach no other source of food for hours or even days. Any way you look at it a dog can save your life.

I do not believe that dogs will be of immediate value as hunters after the collapse. For a considerable length of time after the collapse you will not want to do anything to draw unwanted attention to yourself, and hunting would do just that. You would be a walking invitation for an ambush and your dog would probably be too interested in hunting to alert you.

Dogs are also useful for transportation of goods. In the winter they can pull a sled. Winter or summer they can carry a light pack. If you are moving around much this will be a great fatigue saver for you and will not hamper the dog, unless the pack is too heavy or improperly fastened. Don't pack your spare ammunition or first aid kit on the dog though, keep such valuables in your own pack.

Horses will probably gain their major importance sometime after collapse. I do not foresee an immediate demand for horses, burros, etc. Later, of course, they will be of almost priceless value as draft animals for plowing, pulling wagons, etc. Their immediate value will be as food animals. Very few people will need much transportation after the first few critical days, but they will need food. The same reasoning holds for cattle; their immediate value will be as food.

This is not to say that you should slaughter any cows and horses you see because of their food value. On the contrary, if you are not immediately in danger of starving, you should make every effort to keep any cattle or horses in good condition. They will be invaluable aids for long term survival, which is what it is all about. You should also keep any goats you can because they are too quick to go completely wild and are correspondingly almost impossible to recapture later. They are also much easier to keep than cows and give good milk too.

Cats are a bit harder to classify. In ancient Egypt they were trained and guarded the granaries, much as dogs are trained and used. An added benefit was the mice and rats they caught, thus doubly protecting the grain. I do not know how one could train a "guard cat" but they are still valuable as mice and rat catchers. Here, once again, the immediate value will probably be as food.

Guinea hens are good to eat, lay eggs, and will give a loud alarm if strangers approach. Here too, though, they may call attention to your presence that you may not welcome. For an established survival group, capable of fighting off a sizeable group of marauders, they should be of sufficient value to offset this drawback.

Specimens such as cormorants for fishing, hawks for catching birds, etc., are not considered to be of survival value. They are toys for an advanced or secure culture.

Exotic species, such as elephants, will not be considered either.

Pigs are of great value in long term survival. Besides their obvious advantage as food, they are quite intelligent and easily trained. In France they are still trained to hunt truffles, an underground fungus esteemed as a food delicacy. In the middle ages they were often trained to be as good a guard as a dog. If you are hard up for transportation, they even grow large enough to ride. Given the space and opportunity, they will use the same area each time for a toilet and given a pool of clean water to lie in they will forego mud and remain quite clean. You may even decide to trade in your dog for one after seeing all of these good points.

I have only considered those birds and animals with definite survival advantages. Chickens for example offer no survival advantage as, undoubtably, wild game birds will greatly increase and become correspondingly easier to obtain. They require much more care than guineas with none of the advantages.

METHANE GAS AS AN ALTERNATE FUEL/ENERGY SOURCE

By T. Fitzgerald

BACKGROUND:

Methane is a renewable fuel/energy source. Manufacture of it is nothing more than speeding up nature's million year manufacturing process. For uncounted eons plants absorbed the sun's energy and, through the process of photosynthesis, stored it in organic carbon-bearing compounds. When the plants died, anaerobic bacteria (those that live out of contact with free oxygen) consumed the decaying vegetable matter, and as part of their metabolic process, combined one atom of carbon with four of hydrogen. The resultant molecule (CH4) is methane.

Natural gas, as found in underground reservoirs, or as it come bubbling out of marshes in the form of swamp gas—the process is still going on today—is mainly methane, but also contains 5 to 16 percent ethane (C2H6) and sometimes as much as 8 percent hydrogen.

Natural gas is important because there is a lot of potential heat energy stored in those molecules of carbon and hydrogen. Burn a cubic foot of it and you will get somewhere between 1000 and 1100 BTUs (British Thermal Units—a means of measuring energy). Methane gas produces about 678 BTUs per cubic foot.

Methane gas can be used effectively in the place of natural gas or propane by simply drilling the orifices (gas openings) of the stove, lantern, etc., being used, slightly larger as methane is not as "hot" a fuel as natural gas or propane. Caution must be used, just as when using natural gas or propane, as methane gas is explosive when mixed with oxygen in as small a ratio as 14 to 1.

INTERNAL CHEMISTRY OF
METHANE GAS PRODUCTION:

1. Anaerobic digestion of waste material will occur at temperatures from 32 to 156 F. The action decreases below 60 and production is most rapid at 85 to 105 and 120 to 140. A temperature of 90 to 95 is the most nearly ideal for stable methane gas production.

2. The proper pH range for anaerobic fermentation is between 6.8 and 8.0. Acidity higher or lower than this will hamper fermentation. The introduction of too much raw material can cause excess acidity (a too-low pH reading) and the gas-producing bacteria will not be able to digest the acids quickly enough. The addition of a little ammonia can raise the pH value very fast. If the pH grows too high (not enough acid), fermantation will slow until the digestive process forms enough acidic carbon dioxide to restore balance.

3. Although bacteria responsible for the anaerobic process require both carbon and nitrogen in order to live, they consume carbon about 30-35 times faster than they use nitrogen. Other conditions being favorable, then, anaerobic digestion will proceed most rapidly when raw material fed into a methane digester contains a carbon-nitrogen ratio of 30:1. If the ratio is higher, the nitrogen will be exhausted while there is still a supply of carbon left. This causes some bacteria to die, releasing the nitrogen in their cells and—eventually—restoring equilibrium. Digestion proceeds slowly as this occurs. On the other hand, if there is too much nitrogen, fermentation (which will stop when the carbon is exhausted) will be incomplete and the "leftover" nitrogen will not be digested. This lowers the fertilizing value of the slurry.

4. Dry vegetable matter has a carbon content ranging from 5,000 to 8,000 BTU per pound; that of green algae, or pond scum, is as high as 11,600 BTU per pound.

5. The "solution" must be agitated to keep it in solution and to preclude the buildup of a hard crust, thus limiting the production of gas.

6. Methane gas also does not pose a half-life hazard for thousands of years as does atomic energy.

TWO SIMPLE METHANE GAS DIGESTERS:

See illustrations one and two

A THREE STAGE TANK METHANE GAS DIGESTER:

See illustration three.

TWO METHODS OF COLLECTING/STORING METHANE GAS:

See illustrations four and five.

THREE METHODS OF USING METHANE GAS TO GENERATE ELECTRICITY:

See illustrations six, seven, and eight.

"SCRUBBING" METHANE GAS TO REMOVE IMPURITIES:

1. Hydrogen sulfide ($H2S$) is present in methane gas. It supposedly will "eat" metal in digester tanks and will ruin or impair an engine if it isn't filtered out of the methane before being used as fuel This is only theory and many people with experience with methane gas doubt it is present in quantities large enough to be harmful.

2. Methane gas can be "scrubbed" or "cleaned" in various ways by filtering it through:

a. Iron filings which are supposed to absorb H2S.

b. Limewater to remove carbon dioxide.

c. Calcium chloride to extract water vapor.

d. Wood shavings to extract water vapor.

PRODUCING LIQUID FUEL FROM METHANE GAS:

Methane gas can be compressed and bottled, but it has been agreed by most people who claim knowledge in the field of methane gas production that this is not too practical in most cases.

The most economical and best storage of methane gas would probably be in collection tanks (see illustrations four and five).

Methane gas can be transferred to storage bags or gas bottles carried on a vehicle and used to propel that vehicle, as was done on a limited basis in World War II. This is normally not satisfactory and the best possible uses of methane gas are probably in generating electricity (see illustrations six, seven, and eight), and/or used as a substitute for natural gas in heating and cooking.

Methane gas can be "scrubbed" or "cleaned" to remove harmful (?) impurities.

Once produced, methane gas can be converted to liquid form in several combinations that make acceptable motor fuels, either by themselves, or mixed with gasoline. Only the carburetor must be adjusted for handling the different fuel. The formula

$$1\ O_2 + CH_4 + CO + H_2O \xrightarrow[\Delta \\ \text{PRESSURE}]{\text{CATALYST}}$$

yields anything from formic acid to benezene. The chemical proportions, catalysts, temperature, etc., must be varied to determine the best product mix.

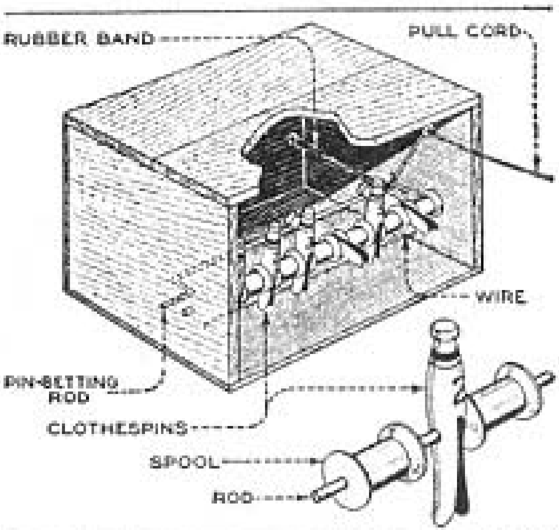
Shooting Gallery for Toy Pistols

From Popular Mechanics 1925

Skill in shooting toy pistols, blowguns, and similar harmless weapons that use peas, marbles, or wooden darts for ammunition, can be easily acquired by practicing on a target of the type shown in the drawing. Clothespins, spools, and some wire are about the only materials required. The clothespins, a spool between each pair, are placed on a stiff wire or small rod and fitted in a box, as shown. Back of the clothespins and a little above their lower ends is a second wire that holds them upright; this wire should be placed so that the pins will lean forward a little. When these targets are knocked over by an expert—or lucky—shot, they are caught by the pin-setting rod at the back; this rod is bent from a piece of stiff wire, and is held horizontally by a rubber band. When all the targets have been knocked over, or after each marksman's turn is over, the pins are reset by a pull on the cord tied to the pin-setting rod. If desired, the clothespins can be painted and designated by numbers.



A Pistol Butt for Indoor Use, by Means of Which the Young Marksman can Improve His "Shot," with Harmless Weapons Such as Marbles, Peas, and Darts

The easiest way to do this is to burn an O2 flame in an atmosphere of methane and collect what condenses. (Run a gasoline engine(perhaps to turn a generator) on a much-too-rich mixture of methane and air, channelling the exhaust into an auto radiator, which is submerged in water or otherwise adequately cooled, and collect the condensed liquid—which should be OK. By adjusting the fuel mix and the length of pipe between the engine and radiator—and, thus the time before quenching of equilibrium reactions—you can get almost any combination of products. Of course, this will involve a bit of experimentation and you will probably not get a useful mixture immediately).

TWO VALUABLE BY PRODUCTS; GARBAGE DISPOSAL AND FERTILIZER:

It is becoming more of a problem daily to dispose of garbage and waste. One mixing of my small lawn produces in excess of 40 pounds of grass clippings. A methane digester uses garbage, paper, leaves, sawdust, grass, manure, etc., as its source for the production of methane gas. When an excess of sawdust, paper, etc., is used, a balance of internal chemistry must be achieved (see INTERNAL CHEMISTRY OF METHANE GAS PRODUCTION above). The digesters shown in illustrations 1 and 2 can be filled up and when the methane cycle is complete be emptied and then refilled for another cycle. The digester shown in illustration 3 is better "fed" less quantities each day as the slurry will move through as the methane is released. Once the material fed into the digester has been processed for its methane gas it is gradually expelled/discharged from the back of the digester (the type shown in illustration 3) as new material is fed into the front. This "waste" or "slurry", both liquid and solid, makes excellent fertilizer, probably better than any commercial fertilizer available today and at no extra cost.

This will not be the answer for all, but for others this may be the answer to self-sufficiency and independence.

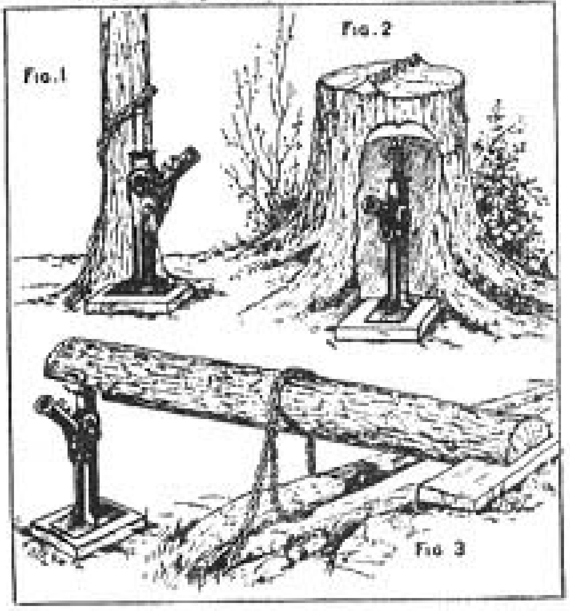
If AC power is desired a transformer is necessary, otherwise you will have to use appliances with DC motors.

Jack Aids in Clearing Land

From Popular Mechanics 1925



Pulling Up Stumps, Small Trees, and Roots with the Aid of a Track Jack Leaves the Ground Ready for Immediate Plowing

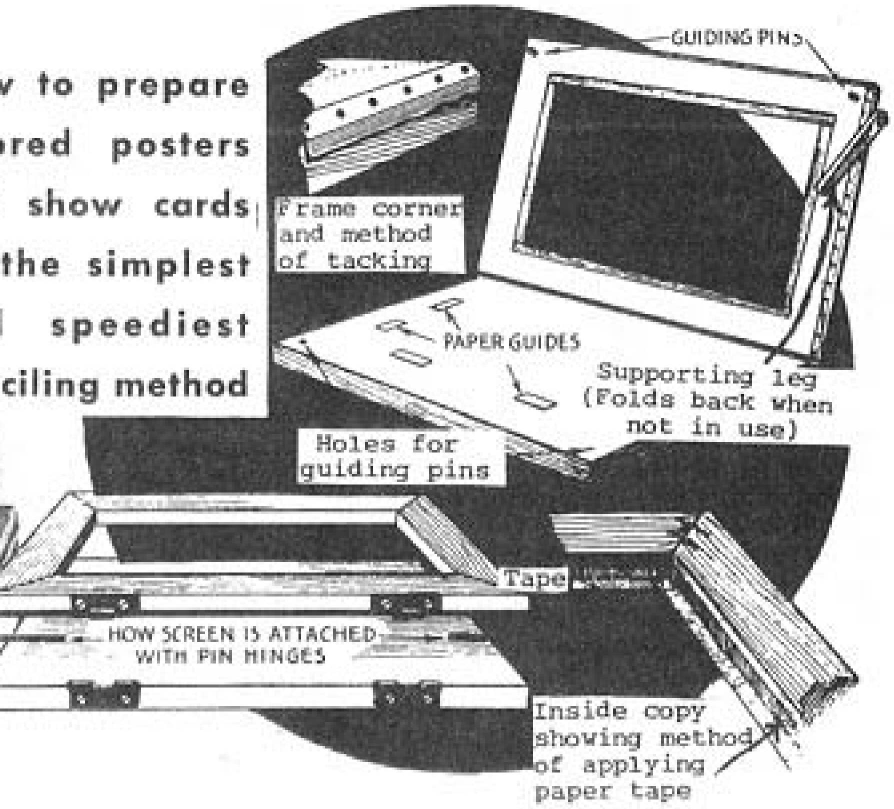
An ordinary ratchet jack makes an effective tool for pulling roots and stumps from cleared-off land, and for uprooting small trees, as shown in Fig. 1. Figure 2 shows a method of pulling stumps: a recess is cut in the stump for the jack to bear against. In the case of large stumps, it would possibly be better to crack it into several pieces with stumping powder and extract the pieces in the same manner. For removing the main roots of a tree, they are cut off as close as possible to the stump and pulled out of the ground by the method shown in Fig. 3, an excavation around the root being necessary to place the chain in position.

Pulling stumps, instead of burning them, has the decided advantage of leaving the ground in good shape for plowing, the humus is not burned out, and if the soil is clayey, it will not be burned hard as brick.

Silk-Screen Printing

How to prepare colored posters and show cards by the simplest and speediest stenciling method

The thick mass of paint is drawn across the back of the screen with a squeegee. A single well-regulated stroke is sufficient



DO YOU ever need quantities of attractive posters to advertise an amateur theatrical show, club party, or home workshop exhibition? Would you like to know a way to earn extra money printing show cards and posters? Then you should get acquainted with the silk-screen process. It is, in essence, a process in which thick paint is forced, by means of a squeegee, through a stencil attached to a tightly stretched screen of silk or other suitable material. It is simpler and more rapid than ordinary stencil printing and leaves no troublesome connecting links to be touched out.

By repeated printings, through properly cut and registered stencils, any number of colors may be applied. The method may also be extended to print on wood, metal, celluloid, fabric, glass, and other materials.

The essentials are a wooden frame, a baseboard or wooden table top, material for a screen, loose-pin hinges, tacks, gum-paper tape, artificial shellac, a squeegee, and the necessary paint and paper or poster board.

For making a small frame, 1 by 2-in. furring strip is excellent; 2 by 2's would be better for a larger frame. The inside dimensions of the frame should be large enough to allow a margin of about 4 in. at each end and 2 in. at each side beyond the largest poster you intend to print. Plane a ¼-in. bevel around the outer edge of one of its sides.

The baseboard may be made from an old drawing or bread board, or the frame may be hinged directly to a wooden table top. Loose-pin hinges are used so the frame may be detached instantly for inspection or cleaning.

For screens, professionals generally use stencil silk or silk bolting cloth. The former costs about $3 a yard, the latter from $6 to $10. Both may be bought from any large dealer in art supplies. For the limited requirements of the amateur, however, ordinary white organdie, costing only 40 or 50 cents a yard, may be used.

Whatever the material, it must be stretched as tightly as possible over the frame and tacked along the bevel. Turn the frame over and seal the inside juncture of frame and cloth with cellulose tape or adhesive paper tape. Apply a strip of tape over this, on the outside.

With the frame hinged to the baseboard and closed down, drive a nail through each of the sidepieces of the frame right into the baseboard about ¾ in. deep. Pry the frame from the base, clip off the sharp points of the nails, and enlarge the holes in the base a trifle. These nails and holes will insure accurate register.

To support the frame between printings, make a leg of wood, 6 or 8 in. long, and attach it with a single screw to the right of the frame, as shown.

The simplest way to make a stencil is to paint it directly on the screen with lacquer, shellac, or enamel. This method, however, leaves a slightly ragged edge. Other methods involve loose paper stencils, photography, and patented transfer films. The following is a proved method, easily carried out, that produces clean-cut results:

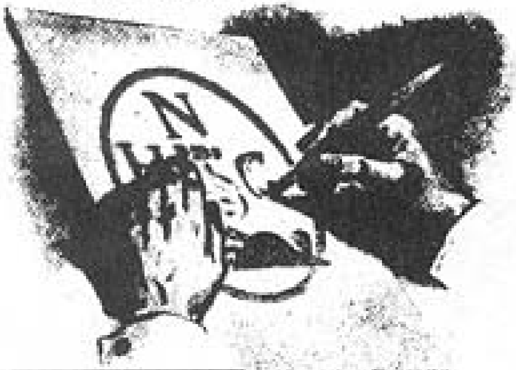
First draw your lettering and design in detail on a piece of cardboard or poster board the exact size of the poster-to-be. If it is to be of more than one color, the design may be painted in the desired colors, or colors may be merely indicated with a dash of crayon.

Fasten a sheet of tracing paper smoothly over the finished design with a thin coating of rubber cement. Allow the rubber cement to become partly dry before attaching the tracing paper. Now give the upper side of the tracing paper a coat of artificial shellac. This comes under various trade names and is recommended for screen work because it may be washed out more easily than real shellac.

Next, choose the first color you wish to print and carefully cut through the outlines of all the parts of the design of board, the same thickness as your poster, are glued to the base as shown to act as guides.

Without disturbing the original, the frame is closed upon it, several thicknesses of newspaper are laid on the inside of the screen, and the screen is pressed into contact with the stencil that color. Use a sharp knife and barely cut through the tracing paper. The

The mounted tracing paper is cut with a sharp knife



parts of the stencil that are to be open should then be peeled from the cardboard.

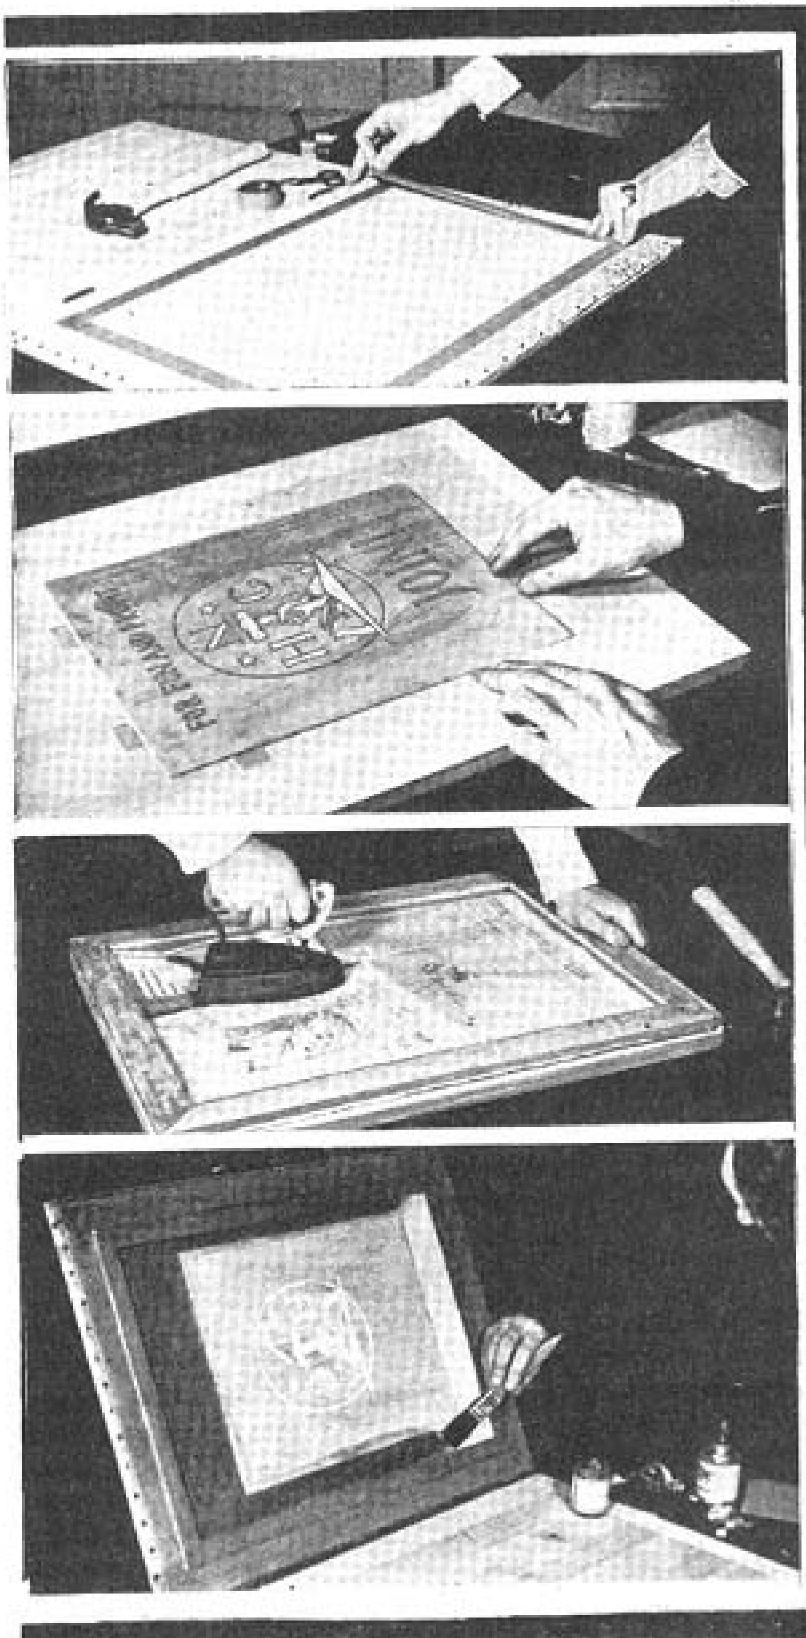
Now take your original, with the stencil on it, and center it on the baseboard. Four little rectangles of cardwith a warm flatiron. If properly done, the stencil becomes firmly attached to the underside of the screen, and the cardboard original may be peeled from it. Any mishaps to the stencil may be patched with bits of tracing paper and shellac. Fill the space between the stencil and the frame with a coat of shellac.

The essentials for a good paint are that it be thick enough not to run, yet thin enough to go through the screen without clogging; it must have body, and it must not dry too quickly. Beautiful oil colors, prepared especially for silk-screen work, may be bought in large paint stores. In a pinch, ordinary flat oil paint may be used. First allow it to stand twelve hours or more, skim off the oil that floats on top, and add a little litho varnish. For silk-screen use, paint must be as thick as apple sauce.

Good water-color paints may be made by adding dyes or show-card colors to a base of molasses or corn syrup mixed with thick starch paste, with a little glycerin added to prevent too rapid drying. Proper consistency must be determined by experiment.

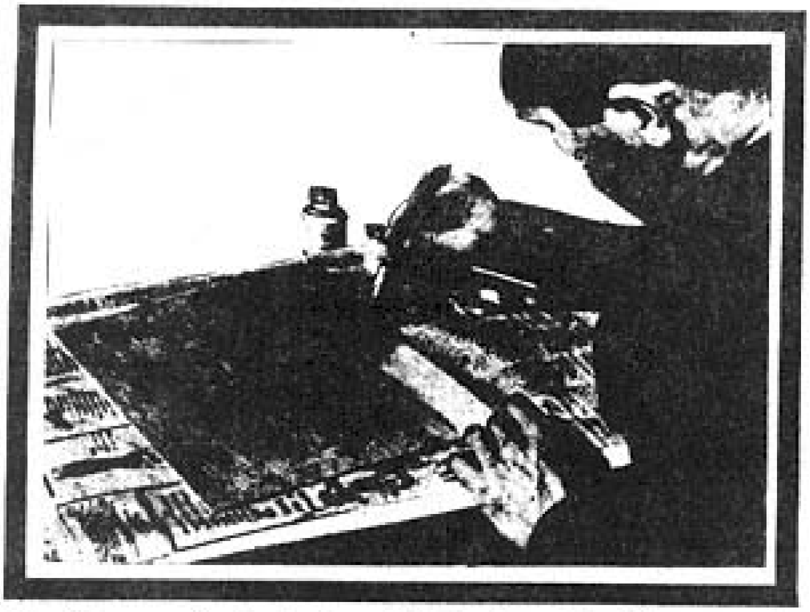
To print, dump a quantity of paint into one end of the frame, raise the frame, place a poster sheet against the guides, and lower the frame again. Then place your squeegee blade behind the mound of paint and draw it with an even stroke across the back of the screen. An ordinary window squeegee will serve the purpose, although special squeegees are made for screening. By varying the angle of the blade in relation to the screen, the amount of paint forced through may be controlled. For the next poster, the squeegee is drawn back the other way, and so on.

After the entire run is made with the first color, the remaining paint should be washed out and the stencil removed with alcohol. The stencils for the second and succeeding colors are made and mounted exactly as the first stencil.



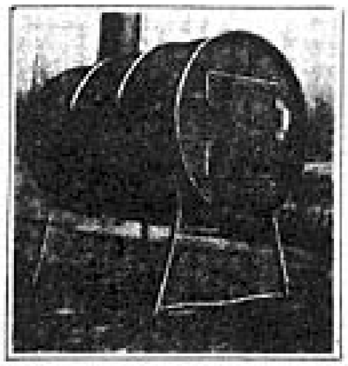
First, paper tape is applied to edges, inside and outside. Second, centering the drawing and stencil. Third, heating screen to make stencil stick. Fourth, shelacking margin.

Next page



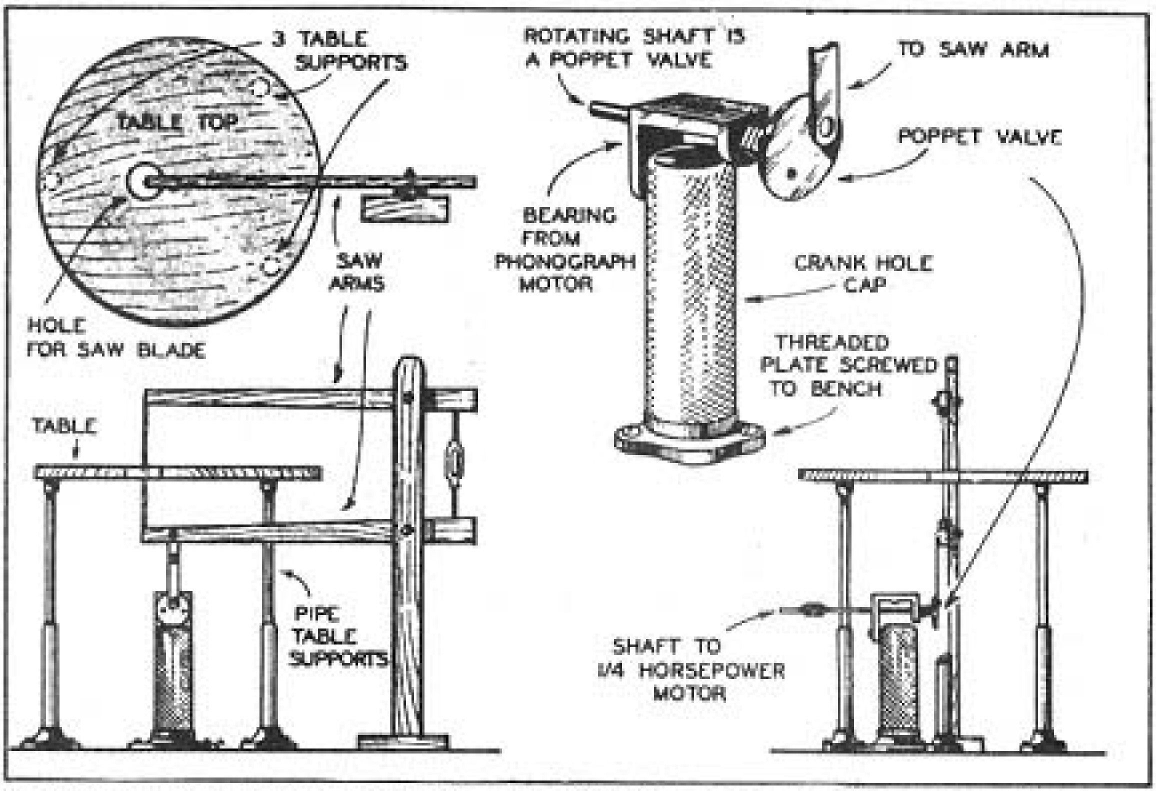
Tracing paper is attached smoothly to the original design with rubber cement; then artificial shellac is applied to the tracing paper.

Keep Warm With Stove Made From Oil Drum



A SURPRISINGLY practical and sturdy stove can be made from an ordinary oil or alcohol drum, as illustrated in the accompanying drawing. The legs may be made from heavy strap iron, which is bolted onto drum. To make the door, simply cut out a section about 14x14, attach a pair of hinges to one edge, reinforce it with tin, then bolt back in the position shown. In the top cut a 6-inch hole and solder around it a piece of tin to take the chimney pipe. An old bike bell makes the draft on the door.

Efficient Jig Saw from Scrap Parts



Jig saw is assembled as illustrated in drawings. Note ingenious arrangement of cam to operate saw arm.

From Modern Mechanics 1931

YOU can turn out some neat scroll work on this simple little jig saw, which is made from a few scrap pieces that every workbench fan usually has around. The arrangement of the saw arms is extremely simple, and are assembled as illustrated above. Mounted on the wooden upright, they should be greased at the pivot points so that they will swing easily. The saw table consists of a wood disc, which is supported by three pipes with flanges, as shown. The blade passes through a one-inch hole bored in the position shown.

The novelty of this saw lies in the device which transmits power to the saw arm. To an upright made from a crank hole cap is attached, as illustrated above, a bearing from a phonograph motor. The shaft and cam are made from an old poppet valve, the connection to the saw arm being made by a piece of strap iron. The motor for operating the jig saw may be connected to the shaft by gears, belt, or joined directly. A quarter horse motor will run the saw without a hitch, but a one-eighth horse will do in a pinch. In operation always keep all parts well oiled to insure smooth running. Attachment of the saw blade is simple; merely bore holes in the ends and bolt the blade to the ends of the saw arms, keeping the joint well greased to prevent heating. The drawings above illustrate arrangement of parts.–

How to Keep Flies Out of the House

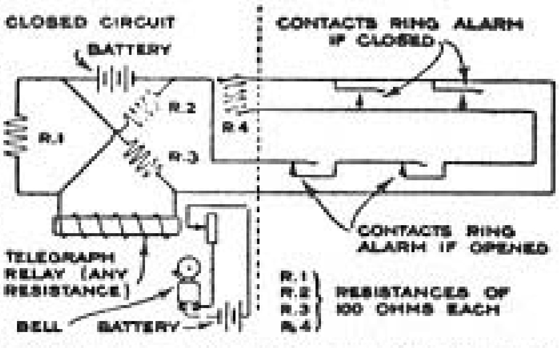
From Popular Mechanics 1928

There are fly swatters, fly papers and various kinds of poisons for getting rid of house flies, but all of these have some disadvantages. A better and more effective way is to take a small clean sponge and place it in a dish after dipping in very hot water. Immediately after dipping the sponge, apply a few drops of oil of lavender on it. Flies do not like the odor, and will leave any place where it is present. If the sponge is moistened about twice a day, flies will not come around.

Burglar-Alarm Circuit

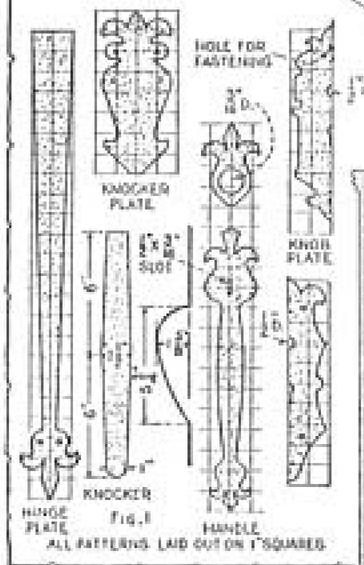
From Popular Mechanics 1925

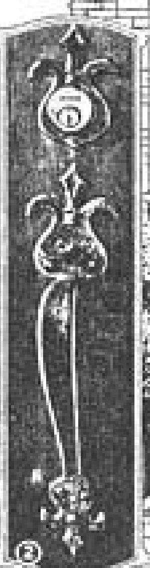
The burglar-alarm circuit shown in the drawing cannot be put out of order without giving an alarm. The only special apparatus required are a relay, which may be of most any type, four coils of equal resistance, and the closed-circuit battery. With the alarm circuit completely connected as shown, the relay will remain inoperative because both sides of the battery, positive and negative, are connected to each end of the relay winding through equal amounts of resistance. The relay is in a neutral position with respect to the battery and receives no current. Now, should the side of the bridge forming the alarm loop become unbalanced, short-circuited, or broken, the current would flow through the relay winding, causing it to operate and ring the bell, or other alarm device.—C. M. Crouch, Minneapolis, Minn.

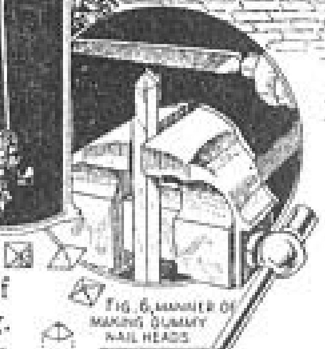


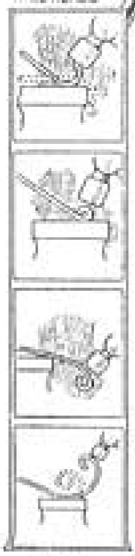
A Burglar-Alarm Circuit That cannot be Tampered With without Giving an Alarm; Short-Circuited or Broken Wires Cause the Bell to Ring

HAND-WROUGHT HARDWARE

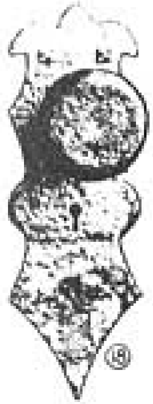








From Popular Mechanics 1931

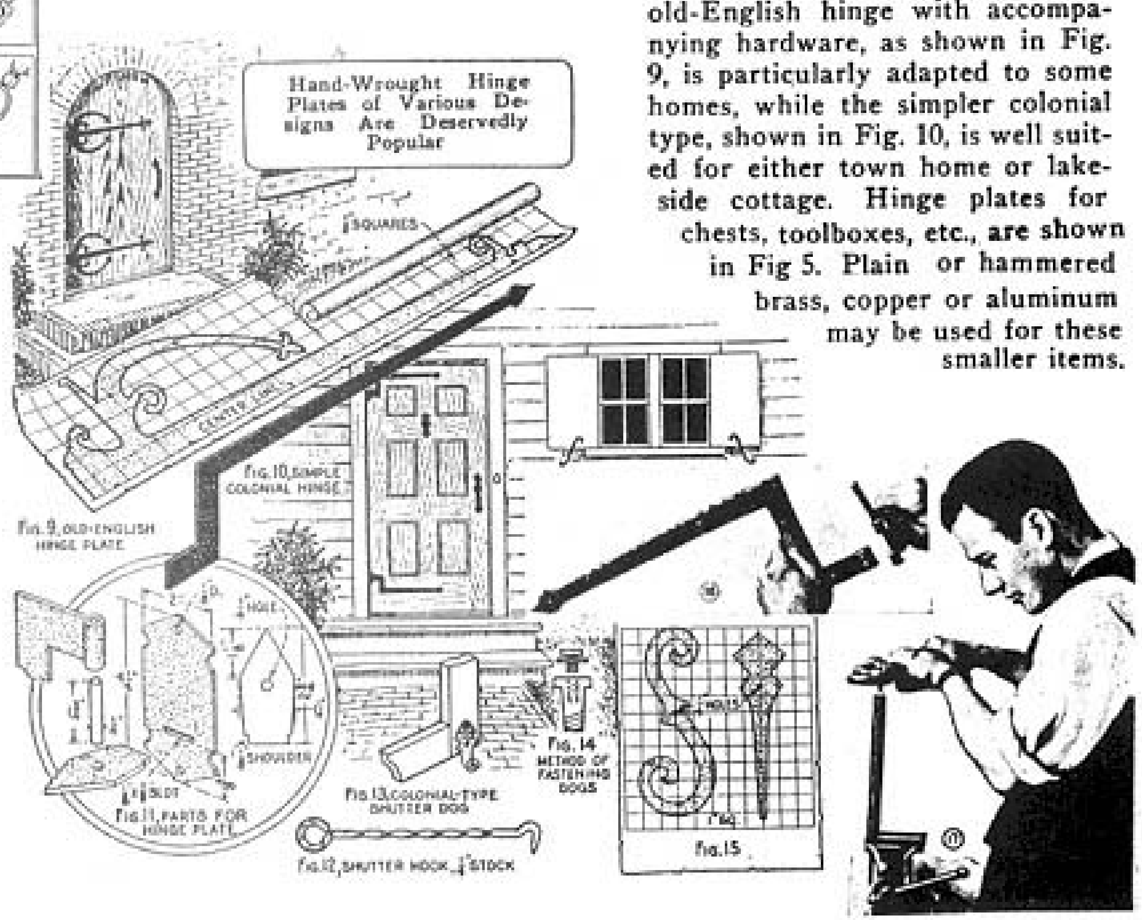


DRESSING up the oak doors with hand-wrought hardware calls for a handle, knocker and hinge plates to correspond.

One of the simplest types of hinge plates is pictured in Fig. 1, with accompanying trim to match shown in Figs. 2 and 3. The making of the hinge demands, first of all, a paper pattern ruled off in 1-in. squares on which the design is drawn. The completed pattern is transferred to the stock, which can be either ⅛-in. wrought iron, or ⅛-in. Swedish iron, which is of the same general malleability but of finer texture. Soft steel, which is considerably harder than either of the others but of fine quality and fairly practical for shaping "cold," can also be used. Brass and copper, too, produce beautiful effects. The design is first cut out with a hacksaw and cold chisel, as in Fig 4, and the edges are then smoothed with a file. Holes should be drilled through the hinge at the points indicated to take fastening nails, and as the door itself is not dependent on these fastenings, they may be held in place merely with hand-forged pyramid-headed nails. These can be made quite simply by filing the heads of round-headed galvanized nails to obtain the proper shape, or by making dummy heads from a ⅜-in. square piece of wrought iron, as shown in Fig. 6. The bar is first drilled lengthwise down the center, the end is filed to a pyramid shape and the filed portion then sawed off. The dummy head thus formed is held in place with a small finishing nail, after which the dummy head is lightly peened over the nail head to cover it.

The door knocker to match this set of hinge plates is made from two pieces of ⅛-in. stock and shown in Fig. 3, while its pattern is given in Fig. 1. The bending from eye to curl can be done by working the stock on a flat surface with a hammer, as shown in Fig 7. The eye is hammered first; then, by gradual rolling from the smaller curves into the larger ones, the complete curl of the knocker is fashioned. The piece can then be slipped over a section of pipe and lightly hammered to take out bumps and hollows. Fig. 8 shows the assembly of the two pieces, the knocker portion being held to the plate with a soft-metal rivet, fitting the turned-over portions of the plate. Like the hinge plate, the fastenings are fake nails, but these should be as long as possible in order that they may have greater holding power. Round-headed wood screws may be used throughout, if the heads are hammered down later. A door handle and plate, in a matching tulip design, to fit any standard cylinder lock are also shown. The handle portion of the lock proper is bent to shape and is rounded in the front, while the concave back can then be built up with solder hardened with antimony. If the handle is of the knob type, the knob should also be hammered, as in Fig. 18.

Other designs in door trim are equally feasible. The more ornate old-English hinge with accompanying hardware, as shown in Fig. 9, is particularly adapted to some homes, while the simpler colonial type, shown in Fig. 10, is well suited for either town home or lakeside cottage. Hinge plates for chests, toolboxes, etc., are shown in Fig 5. Plain or hammered brass, copper or aluminum may be used for these smaller items.



Hand-Wrought Hinge Plates of Various Designs Are Deservedly Popular

Finishing the hardware is often done by applying about three coats of linseed oil, burned off with each successive application, which blackens the metal. This is the best finish for exterior hardware. After the blackening process, the high spots are brightened by rubbing with emery cloth, and spar varnish is applied. Another popular finish is obtained by rubbing the material, if brass or copper, with fine powdered pumicestone, soap and water. This will leave the metal quite bright for a time, but it soon changes to a deep, rich bronze color. If desired, copper can be oxidized by dipping it into a mixture of liver of sulphur and water, brought to the boiling point. The pieces are then rinsed in clean water, after which a fine brush and pumicestone are used to slightly brighten the high spots. -

It is quite practical to go a step farther and make actual working hinges, as shown in Figs. 11 and 16, for use on shutters and light doors. Attractive shutter dogs or "hold-backs," to match almost any design, are shown in Figs. 13 and 15. Both of these are cut from flat iron to the dimensions indicated, and are held in place with a ¼-in. bolt, which is tapped into a lagscrew, as shown in Fig. 14. The shutter-dog design in Fig. 13 should be made slightly concave so that the sharper edges will not mar the shutter. Hooks are also quite necessary if a semi-adjustment of the shutters is desired. These are readily fashioned from ¼-in. square stock, as shown in Fig. 12, while the twist can be made by means of a pipe wrench, with the stock inclosed in a ⅜-in. pipe to prevent kinking, as shown in Fig. 17. The eye and hook are formed later.

The Horse as a Survival Tool

By Patrick Wastie

For many hundreds of years before the advent of "modern" (and wasteful) transportation such as automobiles, planes, etc., the horse was the major means of transportation other than foot. The Arabs were probably the first to domesticate horses. After the crash, automobiles, etc., won't be much good for awhile since the sources of hydrocarbon fuels will be shut down. That's where the horse comes into the picture. Although not economical for individuals, groups would be wise to latch onto some horses and maintain them. Care is basically simple and comes under four headings: 1). Food, this is probably going to be the single most expense of owing a horse. There is no average quantity of feed for a horse. Every horse is different and needs to be fed accordingly. Some factors influencing feeding are how much work it is doing and how old it is. Of the grains used to feed horses. Oats is the one that is used in the greatest quantities. Second is corn. Both these grains are grown without too much difficulty so your horse need never go hungry if you have a farm. Commercial feed is a mixture of oats, corn, barley, various nutrients, and molasses. This glop is called sweet feed and is pretty sticky on account of the molasses. If you live where the summers are hot, adjust your feed level as the amounts of carbohydrates in sweet feed can cause an animal to get sick in hot weather. Sweet feed is about $5.00 for 50 lbs. or 10 cents a pound.

Hay is also a consideration. Don't buy junk hay. Steer away from hay advertised as "cow hay." This doesn't mean you have to go out and buy $5.00 a bale hay. Just make sure it is not junk. During the cold part of the year feed your horse one or two "flakes" (a bale of hay is about 10 or 12 sections or flakes) twice a day to provide roughage and nutrients normally provided by grass.

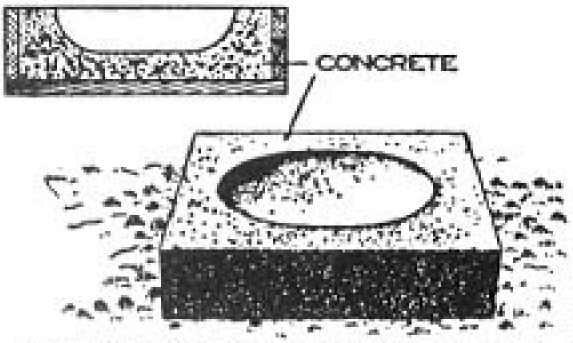
A mineral block is also necessary to provide trace minerals and salt. They weigh fifty pounds for the large size but you can get them in 5-lb. brick sizes. Put your block in a basket or some other form of holder so that it can drain properly. Pasture is usually about 1-2 acres per horse. Remember, if things get hard, horses can make people-feed, if need be. 2). Water is probably the easiest thing to come by (unless you live in California). A horse needs plenty of clean, cool water to maintain itself. A horse has been known to drink 10 gallons of water in a day's time. Keep that in mind. When choosing a watering container, try to allow 8-10 gallons for every horse using that trough. The poor man's trough is simply a used bathtub that is plugged. 3). Shelter is the least necessary item of horse care. Sure, it looks nice to have a barn to put your horses in, but is it really necessary? Most horses prefer to stay outside. In some of the most blinding storms, a horse won't go into a stall door 3 feet away. So, building a barn can be a great waste of money; but the choice is up to you. 4). Health care, is best left to a veterinarian. However, there are a few things that can be done by yourself. Examples are giving injections, taking temperatures, etc. Most health care is routine, such as having hooves trimmed. But in the event of an emergency, don't hesitate to call a veterinarian. Better safe than sorry.

The above is only meant to whet your appetite for an in depth review. Go to your public library and check in the animal care section. They should have some excellent material on horse care. If they don't then they should be able to order it. Good luck!

CONCRETE WATER BASIN FOR POULTRY

From Popular Mech. 1919

A concrete worker was asked by a farmer to build a concrete basin for watering the poultry. Having no forms at hand, the mechanic used an ordinary washbasin and a wood box as shown in the illustration. The basin was greased before it was placed in the concrete. The completed concrete basin was buried with its upper surface level with the ground.



An Ordinary Washbasin was Used to Shape the Depression in the Concrete

---

Homemade Soap Washes Clothes without Rubbing

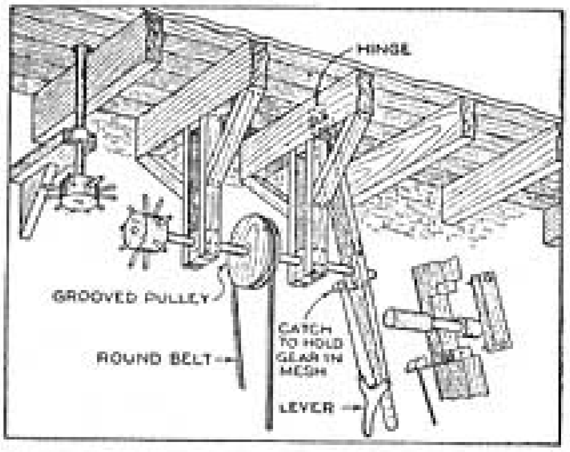
From Popular Mechanics 1931

A soap, which will wash clothes without the usual rubbing, but only rinsing, can be made of common laundry soap cut into thin slices, 2 lb., sal soda, 2 lb., water, 10 qt. Mix the above ingredients and boil for two hours, after which the solution should be strained. Put the clothes into a tub, adding 1 lb. of the soap to every bucket of water. Let the clothes soak in this solution overnight, after which they are thoroughly rinsed.

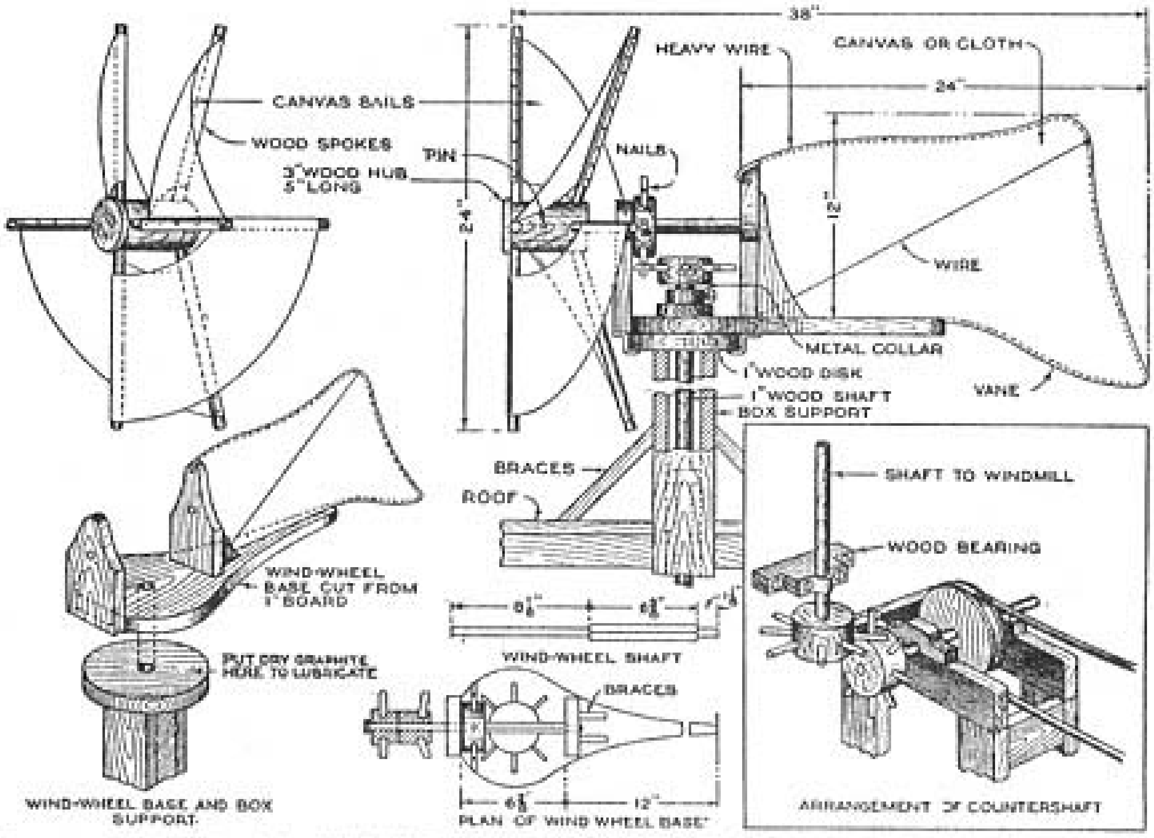
Windmill Power Plant for the Amateur's Workshop

From Popular Mechanics 1925

COMPARATIVELY few amateur mechanics have their shops equipped with any device for operating light machinery by power, and many others have forgone the pleasure of such machines and tools on account of their lack of power. This article describes and illustrates a windmill that will deliver sufficient power to drive light lathes and similar machines. All parts of the mill are of such simple construction that little or no difficulty should be encountered in its making.



A Simple Gear Shifter for Starting or Stopping the Machinery Driven by the Windmill Power Plant



Constructional Details of the Windmill Power Plant: Such a Plant Is Capable of Operating Light Lathes and Similar Machinery. Besides, It can be Used for Operating Such Things as Churns and Ice-Cream Freezers on the Farm, Where Its Assistance Is Particularly Desirable

The wind wheel proper is simplicity itself, consisting of a wooden cylinder into which eight wooden spokes are driven. The canvas sails are attached to the spokes in the manner indicated, and given a coat of varnish. A hole is bored through the wooden cylinder to take the rounded end of the shaft, a pin serving to hold the two together.

One-inch boards are used for the wind-wheel base and its box support, as indicated, the vertical pieces of the base being drilled to accommodate the wind-wheel shaft. A simple gear, having a square hole through its center, is secured to the square end of the shaft; this gear consists of a wooden disk of suitable size in the circumference of which headless nails, evenly spaced, are inserted.

The vane, which holds the wheel to the wind, is made by sewing canvas over a stiff-wire frame, and varnishing the same as the canvas sails. The wind-wheel base rests and revolves on a wooden disk nailed to the top of the box support, plenty of dry graphite being used between the two surfaces to lubricate them.

The vertical shaft has mounted at its upper end a gear similar to that on the wind-wheel shaft, with which it meshes, as indicated in the drawing. A metal collar and setscrew serve to keep the two gears in mesh. The power of the windmill is transmitted to the machinery, underneath, by another set of gears in the manner shown in the insert.

For starting and stopping the machinery, a simple gear shifter is provided, as shown in the smaller drawing. A wide groove is cut in the shaft over which the gear-shifting lever is fitted, as indicated. To hold the gears in mesh while the machinery is in operation, a catch which engages the bottom of the shaft hanger is made, simple means being provided for releasing the catch so that the gear shifter can be moved.

Of course, the operation of such a power plant is dependent entirely on the wind, but if there is any wind blowing, no matter from what direction, the windmill will operate. Such an apparatus can be arranged to drive such small machinery as churns and ice-cream freezers, and the speed can be regulated by varying the size of the driving and driven pulleys. The gears, however, for ease in construction, should all be of the same size.

IS YOUR DOG FIT TO JOIN YOUR SURVIVAL GROUP

by Ron Lank

I would like to emphasize that the lifestyle I am writing about will be only a temporary expedient. It will exist only while those people who were unprepared are in a state of panic and dying for stupid reasons, even though potential food and other means to save themselves are at hand. Soon you will have to go ahead and begin the steps to rebuild, because only by doing so you ensure your long term survival.

It is difficult for anyone to look at his or her own dog objectively, someone else's dog perhaps, but not that one special dog. You will be in no position to own a pet. Your dog will have to be cold bloodedly considered for what value he or she may be to you as a fellow Survivalist.

The job which your dog would be given would be the one it knows instinctively, sentry duty. With Fido, the night shift sentry patrolling,it would be very difficult for anyone to murder you in your sleep.

On the other hand your dog has to eat. Also it would be impossible to stay inconspicuous as you must if some idiotic mutt keeps yapping at songbirds. When it comes time for you to go hunting, most extreme co-operation would be required from your dog for it to remain quiet while you stalk your supper.

The show dogs as a group can be by-passed for survival use. They are bred for looks, not brains.

The sporting breeds offer possibilities, provided that the dog that interests you has been bred for the field, not show. Even then it would be best to avoid the very finest of these. You want an adaptable dog, not a specialist. At least the hunting breeds have one vital ingredient, brains.

The breeds of dogs which have been deliberately bred to be house pets also offer possibilities. They are small, and usually alert and intelligent. Avoid any dog with a stiff price tag, because as the price goes up you approach the brainless show dog strains. Many of these dogs are high-strung; avoid them. Among these small pet types you will find many individuals, each with the potential to become an alert sentry that doesn't eat much and has brains enough to keep quiet.

Don't deliberately pass up any dog of any breed because of its small size. A cold wet nose in your ear followed by a whining snarl will have you instantly wide awake with your fists clenched around your rifle, should the need ever arise.

For general defense size would mean nothing. Even a well trained team of killer dogs is apt to see their expensive training wasted by a carefully placed fusilade of your bullets cracking over their heads and thudding into their targets.

The German Shepherd has some excellent strains, but like any of the larger breeds, it eats. The lower priced strains tend to be vicious and stupid. If you can stash away a considerable quantity of dog food, get one from a reputable breeder. Tell him you want the dog as a house pet that could provide home protection. That way you'll get a sentry with the two vital ingredients that a survival dog must have, brains and common sense.

I don't blame you if instead of visiting a kennel to pick up that perfect Survivalist, you try to make do with your present dog. Your dog may be just a spoiled mutt at the present time, but when your behavior reveals the extreme gravity of the situation, your dog will either watch you very closely for leadership, or die of heartbreak because his good old days are over.

Your dog will have to learn to respond to hand signals. The two most important of these are the finger over your mouth meaning "quiet," with the other hand clamped around the dog's muzzle at first for emphasis. The other is the finger speared straight down at the ground, meaning "sit."

A disobedient dog could end things for all of you with one blunder at the wrong time. It is only natural for any dog to test you occasionally, just to see what it can get away with. Such behavior must be countered by the most extreme reprisal at the earliest possible moment, preferably from the heavy belt around your waist. I realize that delivering such a beating would sicken you with its brutality. But I hardly think that death coming to you and your group in the form of starvation or a gang of looters would be any less brutal! A bit of leniency is not really leniency if it results in a few dead Survivalists.

Such strong-armed leadership will help your dog to understand the seriousness of the situation. It will show your dog that you are sincere when you give him an order and will show that you are a powerful leader, well worth following, because you are capable of overcoming the problems that lie ahead. Such leadership will give your dog a feeling of security. Your dog will very quickly smarten up and make sure that you don't exercise such strong armed leadership too often, at least not on his backside.

There is a chance that your friends are apt to mutiny against your strong-armed treatment of your dog. There is another way to teach discipline to your dog. However, it would be best to have your dog already familiar with it when the time comes. It is known as parade squaring the dog.

After your dog's next act of disobedience tie a fifty foot or longer rope to your dog's collar, at one end of the discipline area. Order the dog to "sit." If your dog refuses, give your dog a swat with an empty glove, not hard enough to get people hysterical, just hard enough to impress your dog.

March the full length of the rope, uncoiling it as you go. If your dog starts to follow you, give the dog a swat, return the dog to position and repeat the "sit" order.

March the full length of the rope, without your dog. Turn around and call the dog. If your dog refuses or doesn't come fast enough, help the dog by reeling him in hand over hand. Tell your dog to "sit." March to the far end of the discipline area with your end of the rope in your hand. Call the dog. Reel the dog in if you have to. Tell the dog to "sit." Start marching another lap, and repeat and repeat and repeat.

After the last time you have to swat your dog, do fifty more laps of the discipline area. Untie the rope from your dog and try one last lap without it. If your dog obeys, you are done. Pat your dog and go do something else.

If your dog refuses, brace yourself. Next time you get your hands on that dog the two of you have, hopefully, only fifty one more laps to go.

No one will seriously object to you disciplining your dog this way, because of the small amount of brutality. Your dog will find this method of discipline at least as severe as the strong armed method because of that horribly prolonged monotony. Either way, your dog will get the idea. You order. He obeys!

When the time comes, your dog will have to adapt to some grim new foods when our conventional dog food runs out. He will see that you to have had to adapt to new foods. Switching over to a diet consisting of rabbit guts, and such slop, will be made a lot easier by watching you and your gang share the rest of the rabbit.

Some dogs will stubbornly refuse to accept such traditional dog food. There is no point in throwing the guts away and offering your dog something better, something that a human being could eat. Any dog thrives on such treatment, and yours would be a fool not to take advantage if you can be suckered in. Not all dogs are fit to be Survivalists. Leave the guts alone. Let them wait for your dog. Offer no alternative food. Turn your back on your dog and the guts, and tell the others to do the same. Let your dog decide. To your dog it will be a matter of life or death. Your dog has more right than you to make the final decision.

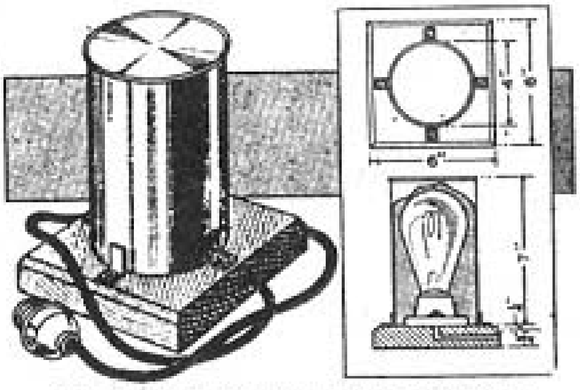
Unless your dog has been hopelessly spoiled, he or she will make the transition more easily than anyone else. The dog that barks at the postman, and later wags his tail and prances around to greet you at the door is already half way there.

A FIFTY CENT ELECTRIC STOVE

From Popular Mech. 1919

Few persons realize what an intense heat may be developed when the globe of an ordinary incandescent lamp is tightly inclosed, largely eliminating the loss of heat. When the lamp is inclosed, the temperature will increase until the rate of radiation is equal to that at which the heat is generated. A good reflector is a poor radiator, hence, when the metal wall surrounding the lamp is bright and shiny, both inside and out, the heat is reflected inward.

To make a small stove that will keep liquids warm, melt paraffin, dissolve glue, etc., procure an ordinary 16-cp. carbon lamp, a porcelain receptacle, and a bright, clean tin can, about 4 in. in diameter and 7 in. long. Thoroughly blacken the bottom on the inside, and then solder on four small brackets, cut from sheet brass or copper, so that the can may be held down firmly, when inverted on the base. The latter should preferably be made of hard wood, with the upper edges beveled, as shown. Next bore the hole for the wire or flexible cord. Fasten down the porcelain receptacle, connect the wiring, screw in the globe, and screw down the tin can; the stove is then ready for operation.



A Handy Electric Stove can be Made at an Outlay of 50 Cents

Practical Food Storage

By Tommy Murphy

Some foods store a lot better than others, and the temperature at which they are stored is an important factor. Generally, we want to have at least a one (1) year supply of food on hand. One year is adequate as it is enough to see you through the four seasons so that at some point you will be at the proper time for planting vegetables. Cost is always a factor in such planning, so it is best to use the food items that are most easily adapted to everyday use. The ordinary foods available from retail stores are not entirely satisfactory for storage. Since the storage life is not very long, these foods must be replaced on a periodic basis. They are bulky and require considerable storage space. Why consider this type of food in our plans? Well, basically because of the low cost, easy availability, most are ready for consumption with no cooking required, and for the most part, no additional water is required for preparation. These factors have to be weighed against the short term storage life.

Since we are thinking about a one year supply, at first thought, storage life might not seem to be very important. There would be no problem if we could know that the items we wish to stockpile were fresh when they came off the shelf. Since the items have probably been there a short while, and in the warehouse prior to then, it is comforting to know that most of the items that we want to store have a shelf life that is longer than might be supposed.

It is easy to build up a supply of goods that are packaged in the conventional way without a strain on the budget. It is usually quite easy for my better half, for instance, to find, say peaches, on a super special and to buy several cans extra for our stockpile. Then she puts the date of purchase on each can with an indelible marker, and as the shelf life reaches one year, she rotates the goods into the menu and replaces with fresh supplies. This method requires a little record keeping and a little work, but it sure is satisfying to look over the hoard and know that we won't be caught short; it really creates a good feeling of security.

In planning a food reserve, good nutrition is very important. It is expected that in a survival situation, individuals will be under a lot of stress so it is best not to spring any new or unusual food on them. Stick to basic family favorites. Go to the local library and check out books on family nutrition, and have the pertinent charts and tables photocopied. Survival demands a lot from a person, and failure to observe a reasonable balance between fats, proteins, and carbohydrates, in order to insure an adequate supply of vitamins and minerals, can cause health problems.

The storage life of supermarket foods varies. Generally the foods that are least refined are the most stable. Salt and sugar for instance, can be stored for a long periods without deterioration if they are kept dry. Certain dried foods such as beans, peas, and rice also have a long storage life if protected from insects and moisture. At 70 degrees F., it is possible to store unrefined foods and unprocessed cereals and seed foods for periods of time in excess of 10 years if properly packaged. Also such dehydrated items as instant coffee and tea, instant puddings and gelatin, can be stored, again if properly packaged, for 7 to 10 years.

The problem with most canned goods of high moisture content is that they spoil mainly because of corrosion and thus deterioration of the metal can. Even with this disadvantage, cannned goods can be stored at a temperature of 70 degrees F. for a 2 to 4 year period. Containers that are made of glass are better suited for long term storage, but many food items that are available in cans, are not in jars, and of course, breakage could occur.

We have found that buying food for storage is a very good hedge against inflation. Also by buying food in case lots we save even more. So, buy food and save more money in a year's time than you could earn on a savings account in a bank. Not only is it an economical matter to buy now and store but it ensures that you have a reserve for any emergency.

As a rule to follow in the shelf life of foods, remember that temperature plays an important factor. Try to keep items as cool as possible but DO NOT let canned goods freeze. The rate of food deterioration will double for every 15 degrees increase in temperature. For instance, an item stored at 55 degrees, with a 4 year shelf life, will only have a 1 year life if stored at 85 degrees.

When choosing canned goods, reject any cans that have defects, such as rust spots, or dents. You might as well start with cans that are in good condition. When opening a package or can that has been stored for some time, carefully check the contents for edibility. Look for any change in color, odor, in texture, such as caking, curdling, or jelling, mold growth, interior rust, fermentation, etc. If it is the least bit suspect, do not use it. Sometimes a container will appear rusted or whatever on the outside, but the contents will be perfectly safe.

The following list will give you an idea of typical items and shelf life to be expected at 70 degrees F.

Item:	Package type:	Storage Life at 70° F.
Applesauce	glass	2 to 5
Apricots	can	2 to 3
Beef Stew	can	2 to 4
Beans and Franks	can	1 to 4
Beef Goulosh	can	2 to 4
Beef Bouillon	glass	2 to 3
Beverage/Base	glass	2 to 3
Coffee, Instant	glass	2 to 5
Corn Beef Hash	can	2 to 4
Chicken & Dumplings	can	2 to 4
Chicken	can	2 to 8
Corn	can	2 to 3
Jam	glass	2 to 5
Luncheon Meat	can	2 to 3
Lima Beans	can	2 to 3
Milk, non-fat, inst.	can	2 to 5
Peanut Butter	glass	2 to 5
Potatoes, Instant	can	2 to 5
Peas	can	2 to 5
Peaches	can	2 to 3
Pears	can	2 to 3
Raisins	carton	2 to 3
Roast Beef	can	2 to 4
Tuna	can	4 to 8
Condensed Soups	can	1 plus
Vegetable Oils	can	2 plus

Most food storage lists such as those from the Office of Civil Defense, show shorter shelf life than this one, mainly because they consider the conditions under which most people would store canned goods, and thus are typical or average. Now the people who read THE SURVIVOR, are not typical or average. We make sure our stuff gets the very best treatment as does any "tool" of survival.

Dried foods are in the same ballgame but come under different rules. Water is needed for their preparation and cooking is needed, (except some dried fruits can be eaten as is). Dried foods are usually stored in bulk containers, rodent, insect, and rustproof galvanized cans, which can be purchased at most feed and seed stores, or co-op's, etc.

It is desirable to store grains, such as wheat, corn, rye, etc., together with a hand grinder. These items store much better in their original form than in their refined state.

Certainly there is a limit to the amount of food that you can store. The purpose of a food reserve is to get you through rough times and in good shape in order that you may have a chance to provide for your future needs. There is really no secret to being a Survivor, just a common sense awareness of how delicate and vulnerable our nationwide system of food distribution is to any upset, whether manmade or natural, and preparing accordingly. With adequate food reserves as well as associated goods, come what may, you and your family have a good hedge on Survival.

Survive Through Handwriting Analysis

By D.C. Besly

"His handwriting shows him to be treacherous!"

Nineteen hundred years ago, Emperor Nero voiced the above observations concerning a member of his court. It was the first known recorded conclusion regarding man's inner character as reflected by the mark of his hand.

The significance about Nero's statement is the paradox of the kettle calling the pot black. If history is accurate, it is doubtful if Nero's handwriting could have stood up to a searching, in-depth analysis.

Nero reputedly murdered his mother and later his wife. Rumor blamed him for the great fire in Rome, but he accused the Christians. It would be interesting to have graphic evidence of the emperor who recognized treachery in others while obviously holding a lofty opinion of himself. A universal failing that is current to many modern day politicians and others with special interest axes to grind.

The analysis of handwriting allows the analyst to see the inner being as he really is as opposed to what he pretends to be. It strips away the veneer of shame to lay bare the truth of reality. An acquaintance to whom this writer once demonstrated an exercise in analysis later commented, "Next to a twelve-gauge shotgun, that's about the best self-protective device I've seen yet! You can really tell who the phonies are !"

Subsequent articles in the months to come will fully explore violence in youth, dishonesty, integrity, leadership, mood, emotional response, vitality, cunning, hypocrisy and a diverse galaxy of useful genres and accessories too numerous to catalog here. For the moment, some uses and history will be dealt with.

The ancient Chinese recognized the psychology of handwriting. King Jo-Hua, who lived between 1060 and 1110 as a philosopher and painter of the Sung period, observed that "handwriting infallibly shows whether it comes from a vulgar or noble-minded person."

Cardinal Richelieu observed, "If you give me six lines written by the hand of the most honest of men, I will find something in which to hang him!"

In France, every educator must have a working knowledge of graphology, not only to understand themselves better, but also to determine basic conflicts in their students, the better to guide them in addition to determining and developing latent talents and abilities. Additionally, a truck driver is not employed in the same country until his handwriting is given a thorough, in-depth analysis to determine if he is a safe and careful driver, but also to determine honesty, if the job requires the handling of cash and valuable merchandise.

There are twenty-five distinct trait strokes that reveal dishonesty, but only four such strokes need to be present in a specimen of script to disqualify a prospective employee for a position of trust. The signature of a recent late long-time bureau chief of the nation's leading law enforcement agency revealed six strokes indicative of dishonesty. The moral being, one never knows when and where such unexpected evidence will present itself.

On the staff of every school in Argentina is a graphologist whose task it is to keep track of student progress, and to detect and root out negative traits before they become deeply rooted. The program is also geared toward guiding each student toward his best potential.

Lloyds of London has been using graphology in its business dealings for over sixty years, and there's no more conservative firm in the world than Lloyds.

The CIA uses graphology as does the FBI, who denies it for reasons best known to themselves. In certain clandestine cloak-and-dagger circles, the waste-basket contents of rival interests are gathered and analyzed to learn strengths and weaknesses about political rivals, particularly of an embarrassing nature. Such knowledge of another's intimate personality that reveals chinks in his armor could be an invaluable lever in future dealings as most everyone has a skeleton or two of one kind or another hopefully locked up in the closet.

It is only natural that graphology should have its disclaimers. Its poor image in America is chiefly the result of the science having fallen into disfavor through being identified with quackery, the occult, tea-leaf readers, astrologers, whose daily forecasts apply to every person in the world born under a certain sign, and pseudo-graphologists who give one-shot analysis resulting from a punch-card machine at carnivals and county fairs.

All of the above have given the science a stigma identified with turban-wearing enigmatic "sees all, knows all, tells all" oracles sitting cross-legged in front of striped tents.

Graphology does not predict leisurely moon-lit ocean excursions to tropical, flower-scented climes, culminating in some romantic episode with some vaporous dream idol with the inevitable pot of gold at the end of the rainbow. The only thing graphology can predict is how an individual may be expected to react under a given set of circumstances. The discipline reveals the best and worst facets of personality, and those seeking an ego trip would be happier consulting a fortune teller rather than a handwriting analyst.

Most academician and layman disclaimers deny the accuracy of the science chiefly because of a subconscious fear of self-revelation, if the truth but be known. In addition to being a fascinating subject, graphology is also frightening, comparable to being on a par with window-peeping. As such, it isn't any wonder that those with paranoic guilt-complexes about some personal weaknesses would hotly deny and shun something that reveals the true inner being. It might be mentioned at this point that it is generally agreed among psychologists that the degree of one's guilt may be determined by the vehemence of his denials. The Watergate Case is a good example in support of this theory in that many who stoutly denied any connection later pleaded guilty when no further avenues of escape presented themselves.

Those particularly in entrenched positions do not like to have their snug ways of life threatened, and fear of self-discovery could have an ego-shattering effect by finally revealing themselves to be quite the opposite of what they pretend to be. Many high-placed individuals who demand a graphological analysis of subordinates for a wide variety of professional and business purposes do not themselves submit to a similar analysis.

Once a student has mastered the art of conducting an analysis, no one will ever be able to deceive him again. The tragic part of becoming adept at the science is that it totally removes the aura of mystique that surrounds individuals—particularly the glamorous type—and reveals their true inner being as opposed to what they pretend to be.

In his excellent book, HANDWRITING—REVELATION OF SELF, world prominent graphologist Dr. Herry O. Teltscher states: "World events and complex political situations at home and abroad demand that our political leaders possess the necessary intelligence, fortitude and character strength, and insight to cope efficiently with the vast array of national and international problems. The analysis of the handwriting of prominent statesmen and leading executives (with periodic check-ups for health reasons) would be of invaluable assistance to the democratic process itself. It is important that candidates for the highest office of the land and other statesmen considered for sensitive key positions in government possess the mental astuteness, the balanced judgement, the emotional stability, the talent for diplomacy so essential at the conference table. Similarly, the analysis of the handwritings of foreign leaders would aid in giving us the intimate know-how in dealing with them."

In this connection, the pathology of the late President D. Roosevelt at the time of his re-election to a fourth term was a good example of how a sick man can irreparably damage a nation's future for generations to come as indicated by his decisions during the Yalta Conference. A victim of an advanced neuro-vascular disease, he should have retired from office without further delay, as much in his own interest as in that of the nation.

Graphology, which is a social science, unlike mathematics, which is an exact science with hard and fast rules. Any science that deals with personalities cannot be exact as no two of us are exactly alike.

It seems that our Creator has subtly planted certain characteristics within our physical and mental beings that not only makes us unique, but which distinguishes each of us from our fellows, and which also provides researchers with a wealth of endless material regarding the mystery of man.

In his never-ending search for knowledge, man has found that no two sets of fingerprints are exactly the same. As a trained former fingerprint technician, this analyst has fingerprinted many sets of identical twins, and for the most part their fingerprint classifications were at wide variances. Fingerprints are accepted world-wide in court as positive proof of identity. Similarly, the legal system of all five continents is based on the assumption of the identity of the signature, and modern money transactions would be impossible if the least doubt existed that signatures could be disregarded in money transactions.

In a nutshell, fingerprints tell who we are. Handwriting tells what we are!

Police can determine the identity of an originator of an anonymous phone call by simply making a recording of the call, later making recordings of voices of suspects, then comparing results to obtain matching voice patterns.

It seems only logical that our Creator also provided man with the means of obtaining an insight into his character and personality by the evidence produced by the mark of his hand. The only mystery is why a certain stroke represents a certain trait, but exhaustive studies over the past 70 years keeps lending added weight to the fact that stroke formations do indeed reveal character traits.

Actually, the term "handwriting" is a misnomer. "Brainwriting" more accurately describes the action because muscular movements of the forearm, wrist and hand extended to the writing instrument are only incidental to the strokes: the direct projection of the writer's thinking. As mind is the builder, whatever is predominent in one's thinking will also be reflected in script.

It makes no difference how the writing instrument is held, the results will always be the same be it the right or left hand, between the stubs of the arms of an amputee; the mouth or toes of one born without arms, or the mechanical steel hook substitute for a hand. Education or lack of same makes no difference, nor does legibility or illegibility. The indicators will always be present to the experienced eyes of the analyst.

The only way handwriting can change—other than through a series of exercises recommended by a graphotherapeutist to root out corrosive negative traits—is for the personality to change for either better or worse, or as new skills are acquired or latent talents developed.

The uses of graphology are as varied as human experience, and may be applied to determining character, personality and aptitudes. Loan companies and credit managers may use it in connection with determining a loan seeker's responsibility toward his debts. Personnel managers can determine if a prospective employee is the right person for a particular position, or in finding those within an organization qualified for promotion to posts requiring leadership and managership ability. Parole and probation officials can determine if attitudes have actually changed in those seeking parole, and can keep current on their progress as well as the probation officer determining basic conflicts in youths brought before the board to decide on future action.

A pre-matrimonial compatibility analysis would save much future mental, physical, emotional and financial exhaustion. Love is indeed blind, and many rush into marriage for no more reason than physical attraction during a time when the lovers are putting their best foot forward to make a favorable impression. Quite often it is her sex appeal that is most desirable while she barters that for comfort and security. It is only after the honeymoon when guards are down that each returns to his true personality and troubles begin. Some couples are mature enough to adjust to one another while many cannot, thus resulting in all the disagreeable activities resultant to severing matrimonial ties. This tragedy is compounded when children are involved.

Individuals considering going into partnerships in a business could very well submit their respective scripts to analysis to determine if they could get along. Each could determine his best potential for their mutual benefit.

Psychiatrists learned in graphology claim that they can delve deeper into a patient's psyche from the evidence of a couple of pages of script than a month on the couch will reveal.

Medical graphologists are now determining the presence of cancer through script up to three years before it is detected medically.

Dr. Robert Neglar, professor of psychology at the University of Minnesota long ago adopted graphology as one of his favorite testing devices. He states that the science has repeatedly proven to be the quickest and most accurate testing device yet known.

And last, but by no means least, graphology may also be used as corrective therapy. By changing a negative stroke that could have a corrosive, psychosomatic influence on such a writer, and replacing it with a positive stroke, the deteriorating influence will eventually be eliminated, thus enriching the life and personality of the individual.

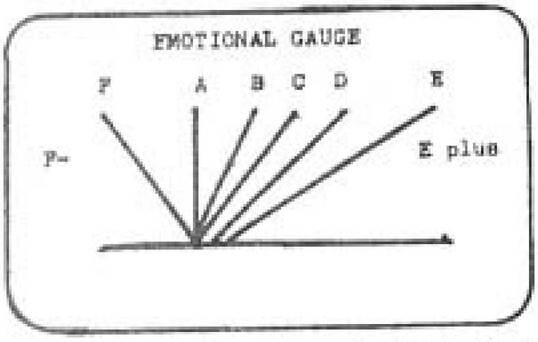
The script of public figures may be studied to determine if they are really sincere in their promises to the public, or if achievement to high office means only a lever to achieve their own personal whims. In the months to come the scripts of many past and present individuals will be closely examined among which will be the Kennedys, Nixon, Ford, J. Edgar Hoover, Carter and a host of others.

By D. C. Besly

Before getting into the many specific signs indicating traits that alert us to the deceitful, criminally inclined, the con-artist and troubled child, it is important to understand how emotions influence all traits.

It is dangerous for the amateur to try to determine character on a one - for - one basis. That is, to point to a single stroke or two indicating a certain trait on the basis that it is representative of the total personality. All influences must be taken into consideration to obtain an accurate portrait of the personality. No two of us are exactly alike despite our many similarities. Each of us is unique in our individual way. This is quite evident in medicine, where one remedy may cure while another has negative side effects. This uniqueness must be taken into account in evaluating character and personality.

The emotional nature is the foundation upon which all traits in a writer's character and personality trait is rooted in the emotions; the soil in which it developes, and which influences all other traits in the personality. The slant of handwriting reflects a writer's emotions; indicating the degree of expression and restraint.



The above is a reproduction of a transparent emotional gauge used to measure slant. One may obtain a protractor from any stationery or office supply firm. By using the above as a guide, determine the emotional response of themselves, their friends, relatives, children, business associates or whatever.

The gauge is placed upon handwriting with the horizontal line of the gauge coinciding with the baseline of the letters. Script written on unlined paper is best. Lined paper exerts an unnatural control with many writers unable to adhere to ruled paper. The analyst draws in his own baseline, then places the gauge at a point where a letter touches the baseline at its lowest point with the slant indicator emerging at the highest point of the letter, measuring only the upstrokes thus:

One hundred consecutive upstrokes are measured to obtain the predominent area of emotional response, or how the writer may be expected to respond most of the time. You may draw your own conclusions regarding the above specimen after you've read further.

For now, we will be concerned with explaining the various areas of emotional response as they influence the personality.

The F minus slant, very reclined, indicates emotional response ranging from low to complete indifference. Reactions are repressed, behavior evasive, attitude generally reluctant. Interests are chiefly egotistical. Such persons are independent, hard to get along with, difficult to fathom.

The F - A, reclined slant, indicates the introvert. A cold exterior masks inhibited feelings. Attitude will be diplomatic if script is superior, hypocritical and insincere if inferior. In general, the backhand is undesirable. Individuals who write that way are too reserved, often indecisive, not straightforward, and sometimes contentious. Self - interest is a dominating factor in this area. These persons are chiefly concerned with how they may benefit from others. Their attitude is not what is the best course, but "What's in it for me!" These individuals are often quite capable of putting on a convincing act of friendliness, gregariousness and sympathy for appearances sake, but it is chiefly a pose for effect and personal gain. It may be detected by the unnatural backhand slant, a type of script that is definitely negative while also revealing withdrawal. Backhand is not taught in any school of penmanship. Both the F minus and F - A slants are beyond poise and judgement. These persons construct a shell of isolation about themselves and withdraw from the world in general, and as in the case for women, chiefly marry for comfort and security. A test conducted several years ago by a leading international graphology society revealed that the F minus and F - A slants composed a small minority of 5.3 percent of those tested.

The A - B slant represents vertical writing. Objectiveness is indicated. Mind over matter. The head rules the emotions. The subject has complete self - control. The attitude is apt to be undemonstrative, independent, detached, even indifferent. The keynote is cautiousness. Self - interest is still the dominating factor. Such writers are more interested in the "I" than the "You!" They seek the best course to follow. This area of emotional response makes up about 13.6 percent of the study group. President Lyndon B. Johnson's script was chiefly objective. He was also an aggressive arm - twister as well.

B - C slant. Lightly inclined. Signifies a normally sensitive and healthily emotional, well - balanced person when handwriting is superior; when inferior it generally shows mediocrity and conformity. This area of emotional response has been described as the slant that reveals the best marital partners because it is half - way between the two extremes of reclined and inclined script: euphoria and hysteria. However, there are two sides to the coin regarding all character and personality traits. In one respect we have the controlled mind softened by sympathy. On the other hand the emotions are held in check by the controlled mind. In other words, we have a collision of thought and feelings, which evaluates to ambivilence. This latter can evaluate to a split personality, or schizophrenia under certain conditions. This is nothing to become particularly alarmed about as many of us have this characteristic to a greater or lesser degree from a mere trace to predominent, depending on circumstances. Research has revealed that the B - C slant has been found to be the chief writing slant of forgers and confidence artists who use their wits for deceptive purposes, and makes up about 14.0 percent of the study group slant. It is the chief slant of Senator Edward Kennedy.

C - D. Inclined. Signifies an ardent, affectionate, amiable, very sensitive and emotional nature. This slant makes up about 15.7 percent of the study group.

D - E. Very inclined. Signifies an intensively alive, ardent, passionate, responsive, susceptible individual. Often a veritable brush fire when supported by great depth of emotions. Also signifies one who frequently jumps to conclusions before having all the facts in hand, and who reacts immediately, instinctively, without thinking and upon impulse. Such a writer will often say and do things on the spur of the moment that are later regretted when ample time to cool off has passed. Such writers are inclined to over - react, and often express themselves through a variety of physical gestures. This area of response is the most predominate among individuals, and represents 33.0 percent of the study. One may witness the conduct of the impulsive at political rallies and sports events by the cheering, yelling, stomping, waving of arms, whistling, applauding, screaming, jumping, swarming onto playing fields to beat their heroes on the back or murder the opposing team. Madison Avenue advertising writers are well aware of mass childish impulsiveness, and exploit this potential customer weakness to the seller's advantage with clever slogans and attractive packaging. The familiar bosomy, bikini-clad sex goddess pictured on a wide variety of men's products as always been a successful come-on promoting sales if for no other reason than to get the picture and fantasize. One need but stroll through a super-market to observe housewives impulsively grabbing with both hands to fill shopping carts to overflowing with junk foods. The traits of gullibility and submissiveness further lend support to impulsiveness. If you are the impulsive type, learn to control it. Later articles will cover such methods of control.

E and E plus. Acutely inclined. Signifies one who is fervid, excessively romantic, passionate, jealous, easily offended, demonstrative, excessively romantic, a veritable volcano; and in certain instances, hysterical. In fact, hysteria is perpetually smouldering beneath the surface awaiting the proper set of circumstances to trigger it. The occasion, luckily, may never arise, but it is always present. It must be taken into consideration if the slant is predominate or merely occasional. One whose slant might measure fifty percent or more of the script would be more apt to lose control than one whose slant measured less than a dozen strokes. The weaker or stronger a trait, like all other traits, the more or less likely the change of expression. The hysteric exaggerates and over-dramatizes every ailment and difficulty, and is likely to lack deep ethical feelings. Former President Nixon had strong presence of hysteria in his script. Nixon's personality will be covered in a future article. Of the seven areas of emotional response found in personality, the E and E-plus is the second most predominant area of emotional response, and makes up 17.5 percent of the study.

The above indicates the masses are chiefly impulsive, jumping to conclusions without having all the facts at hand, or are hysterical, having the capacity to lose self-control under extreme emotional experiences when facing a crisis. Not exactly an encouraging picture, but something which may be hopefully corrected when educators finally realize the harm that has been done for centuries by the built-in auto-suggestion inherent in the school copy-book method of penmanship that reflects the negative qualities of those who designed the exercises. After all, penmanship teachers are not graphologists, more the pity. If we are to survive, we must learn self-control!

Constantly changing slant. Writing that reflects a variety of slants indicate the unpredictable individual. These persons are like a reed in the wind that bends every which way with each vagrant breeze. Ambivilence is present along with contradictory inclinations; to yield or to protest; remembrance of things past and hope for the future; resignation and optimism; opposition and assent; selfishness and altruism. There may be a split personality with conflicting loyalties and tendencies. Such variable slant may indicate frustration because the writer is torn between love and hate with eventual nervous fatigue. It is the sign of general inferiority, lack of discipline, laziness, erratic, capricious, agitated, nervous, excitable, fickle, indecisive, non-conforming, and lack of good judgement. Such persons will greet you warmly one day, then cooly ignore you the next. One never really knows how to take them.

SURVIVE THROUGH HANDWRITING ANALYSIS

D.C. Besly

Shortly after he left the presidency, a press release quoted former President Richard M. Nixon as stating, "We, as a country, have to provide strength and leadership."

This from a "leader", whose capacity for leadership was about as low as it is possible to get, and who is least qualified to discuss the subject.

Leadership, the ability to assume command is very often filled by those who do not possess the ability to any great degree. They have achieved their positions by having been in the right place at the right time when it was necessary to fill a managership vacancy with whatever material was at hand. For the most part, history reveals that the world is and has been run by mediocrities who have arrived on the basis of a small talent, or who were the tools of higher-ups, sworn to carry out the programs of special interest groups.

Leadership is the sum of many parts. First of all there should be education, training and experience. A leader cannot indulge in self-consciousness, self-centeredness, or be greedy. There should be no lust for power or to domineer. There should be a capacity for diplomacy free from the taint of hypocrisy; initiative, and the ability to organize. There should be a need for responsibility with the competence to handle responsibility. There should be broadmindedness—respect for the opinions of others—practicality and unselfishness.

A leader cannot be emotionally or mentally unstable, have temper, irritability, conceit, be ill-mannered, ostentatious, vain, a show-off, egotistical, or hold a grudge even when challenged. A good leader is one who himself has first learned to take and carry out orders, and should possess no defiance to higher authority or hold resentment.

Former President Nixon possessed many of the above mentioned negatives as shall be graphically indicated. As the previous article explained emotional response at considerable length, it will be seen that Nixon's script reveals emotions running wild for lack of control. The extreme E plus slant gives unimpeachable evidence of this. Here is emotional instability. As previously pointed out, the hysteric exaggerates and over-dramatizes every difficulty and ailment, and is likely to lack deep ethical feelings.

An over-inflated ego is indicated in the above by the super-elevated capital letters indicating a God-like self-image. Capitals two and one half times the height of middle zone letters denote the egotistical, conceited person. The higher the capitals the stronger the trait. Here is one loving display with a strong sense of exaggerated pride evaluating to vanity. Vanity is self-love, and as such admits to no faults or mistakes.

That Nixon loved display was evidenced by the pomp and ceremony surrounding White House activities such as the comic-opera uniforms the security forces were outfitted with in assuming a "palace guard" image following one of Nixon's visits to Europe where some remnants of decadent royalty still exists. The band always struck up "Hail To The Chief" each time he appeared in public along with trumpeters sounding "Ruffles and Flourishes". If any president was ever a bloated ham for theatrics and attention, Nixon took first prize.

Additional evidence of Nixon's lack of touch with reality is found in the super-elevated small letter "d" in the first name. Graphologically, the small "d" indicates the presence or absence of pride, depending on height. In this instance, it indicates vanity gone wild. Upper loops represent the abstract imagination: plans, ideas, theories, and spirituality if other supporting traits are present. The different height of the upper loop of the small "h" as compared with the small "d" are inconsistent, indicating theoretical instability.

The extreme height of the "d" reveals a power-drunk vanity that is reaching beyond its grasp. Vanity seals off one's guilt sense. It is pseudo self-esteem, and as such is above the law that governs ordinary folks. Such a writer's thoughts are not dominated by sober thinking, while at the same time the unusual height reflects unrealistic idealism and flights of fancy and illusions of grandeur. Here also is revealed a fantasy world into which such a writer retreats when he feels that the world of reality does not accept him.

Below is an example of Nixon's signature during his final days of office. The shocking change reveals personality deterioration, aided and abetted by an extremely emotional being who could not stand up well in the face of a crisis. Hysteria overcame the super-narcissist. Maybe someday the masses will cease to judge every aspiring politician in terms of Simon-pure morality that is even rare among the clergy.

Just a cursory examination of Jerry Ford's signature reveals unrealistic ambitions parallel with Nixon's. Here again is the God-like self-image of the over-inflated ego along with the small letter "d" reaching beyond its grasp, or "out of this world" to quote the moderns. The up and down covering stroke of the "d" without a loop formation, indicates one who is less than candid in keeping his innermost thoughts, feelings and plans secret. Inhibition and insincerity are the basic meanings of concealing strokes.

Jerry Ford

Like the formation in Nixon's first name, the exaggerated height of the "d" reflects unrealistic ambition and flights of fancy. Ford has already admitted that he "misses the White House". No doubt the absence of a cheering, handshaking public has made itself felt. Once a politician has fed at the public trough, he never seems to get over it, and often tries and tries again following a loss of office.

The jerky movement of Ford's script lacks rythm, reflecting his accident prone clumsiness in repeated falls, bumping his head and dropping things.

Nixon chose his successor well. Ford's pardon of his crony was a skin graft over a cancer. Nixon put Ford in office so one hand could wash the other. Ford was the politician closest to Nixon's policies.

The glaring similarities in both the Ford and Nixon signatures give unimpeachable evidence that these two birds of a feather were cut from the same cloth! Additionally, that weird configuration of the lower loop of the capital "J" in Jerry, along with the triangular pointed formation of the small "y", indicates the bedroom athlete. Any complex, diverse configurations in lower loops reveal erotic fantasy that takes unconventional forms.

For the moment, it should be remembered that any exaggeration in script indicates abnormality.

The diverse formations of the same capital letters: "J", "E", and "C" in the Carter signature reflects a dual, or split personality. This rule always applies when letter formations are written in diverse forms. The last name, Carter, tends to taper like a wedge from the "a" to "r". This tapering indicated presence of diplomacy.

For the most part, diplomacy has always been regarded as an admirable trait. A trait often used to gain one's points, evade an issue, or avoid a busted nose and loosened teeth. I maintain the positives will take care of themselves nicely. It's the negatives one has to be alert for in order to survive this competitive, cut-throat rat-race. When one becomes familiar with the negatives and how they influence character, then we are better prepared to deal with them in protecting ourselves. So here goes with all the stops pulled out!

A diplomat has been described as one who "remembers a lady's birthday, but forgets her age." A diplomat—whether the suave, morning-coated, striped pants type representing matters of state, or a seducer using soft soap to charm a victim—is one who is adroit in dealing with people. The diplomat is skillful in negotiations, and can maneuver successfully and without friction in difficult situations.

The true purpose of diplomacy is to prolong a crisis by pouring oil on troubled waters. Other terms for the trait are: dissimulation, cunning, pretense, feign, artful dodger, machination, double-cross, chicane, hocus-pocus, knavery; take your pick. In the presence of evasion, secrecy and downright deceit, diplomacy evaluates to hypocrisy.

Remembered statements of former Secretary of State, Henry Kissinger were masterpieces of evasion. He chiefly spoke without imparting information of any significance. Some examples were, "We have made significant progress. Our views are in complete accord!"

Most bureau chiefs along with presidental press secretaries have a well-cultured talent for speaking bureaucratese—that frustrating native Washington dialect that uses long words and complicated sentences to convey practically nothing. Regardless of any speaker's position, any listener to such verbal beating about the bush should be immediately alerted to the fact that such speakers have something to conceal.

As previously stated, diplomacy may be recognized by tapering words and letter forms, thus:

m - Woman

The Tapering of Diplomacy

Graphic indicators that lend diplomacy that taint of hypocrisy are: evasion, self-deception, secrecy, intentional deceit, lack of emotional control and fluctuating moods. Any one or all may color diplomacy's effect.

Evasion is recognized by the double hook in letters as evidenced in the first capital "C" in Carter's signature where the capital "E" and "C" are connected. Other graphic indicators of evasiveness may be found in the small "a", "c", "d" and "g," thus:

a - c - d - g

Double Hooks of Evasion

The evasive individual maneuvers to obtain desires not by expressing an untruth, but by evading the truth. Its presence indicates a deep-seated feeling of insecurity which can only be overcome by the individual's acquisition of more than he actually needs as the hook formation also has the additional value of the acquisitive, grasping individual. Such individuals have a talent for "talking around" a subject.

Here too is found the over-inflated ego represented by the over-large capital letters along with the super-elevated small "t" in Carter. Here again is the unrealistic idealism and flights of fancy reaching beyond its grasp that were so much in evidence in the Ford and Nixon signatures.

Significant is the lack of i-dots in Jimmy, revealing carelessness with details. Those who omit i-dots lack well-grounded ethical ideals. The very low placement of the t-bars reflect extremely low goals and vision so necessary toward planning long range programs so important to good leadership. Carter does not think very far into the future, a thing that seems consistent with far too many former chief executives who were more concerned with the immediate now and feathering their own nests than with the nation's general good. The t-bars are extremely weak, showing a decided lack of will-power. Carter can be easily pressured. His choice of cabinet members and aids indicates this weakness.

I know of no analysts who have mentioned the presence of shark's teeth in Carter's signature. Easily overlooked in script, shark's teeth are characteristic of those whose business it is to profit, broadly speaking, through people's credulity. Prominent analyst Billie Rosen states that the writer of a certain type of "m" is a dangerous person. It is typical of the person who wants to profit through the gullibility of others in outsmarting them. It takes naivete to fall prey to the shark's tooth writer, and whenever a naive person and a shark's tooth writer meet, the former is in for some quiet, systematic and pitiless bloodletting. Americans are the most gullible persons on earth, chiefly evaluating a person by what he seems to be as opposed to what he really is.

Shark's teeth may be seen in the final small "m's" in James and also Jimmy where the final top stroke ends then comes leftward in a curve that resembles its namesake. Checkmarks have been placed to call attention to the significant area, thus:

Shark's Tooth "m"

The spacing of disconnected letters between the "t" and "e" in Carter, and the "i" and "m" in Jimmy reveal intuitiveness: the capacity for very rapid deduction from an instantaneous observation. Carter revealed this quality during his debates with President Ford whose performance more closely resembled an akward, tongue-tied bumpkin with an accident-prone mind as well as body.

Intuitiveness infers keen and quick insight resulting from immediate perception and comprehension. (This does not mean that intuitiveness is infallible. The discoveries of intuition have always been developed further by sober reflection and logic. In ordinary life, intuition is a powerful but dangerous means of acquiring knowledge. Sometimes it can hardly be distinguished from illusion. Those who rely upon it entirely are liable to mistakes. It is far from being always trustworthy, depending upon likes and dislikes, bias and predjudice. But the great man, or simple soul whose heart is pure, can be led to the summits of mental and spiritual life by its strange quality.)

Here we evaluate intuitiveness with evasion, diplomacy and shark's teeth, and the result is instinctive cunning. It will be interesting to observe the future. Citizens should not look forward to that ever-sought eventual pie-in-the-sky paradise with great rewards for little or no physical effort. Politicians have been promising this dubious state of affairs for as far back as I can recall, but things keep deteriorating in spite of all mortal man's think tanks and brain trusts can do about it.

Leadership? What do you think!

An Effective Trap with Live Bait

I have used a number of different kinds of traps but the most successful of them is that shown in the drawing. Many small fur-bearing animals are fond of chicken meat. The fox will catch a chicken and carry it off, the mink and weasel will cut the throat and bite the head, etc., and a coon will catch one if he has a good chance. I give them a good chance, or at least they think so, by baiting my trap with a live chicken. The way I do it is to make a box about 12 in. square and 3 ft. long. This box is made of old lumber so that the animals will not be suspicious of it. Each end of the box is covered with wire mesh, the wooden ends being removed entirely. The mesh at one end is attached to a frame hinged to the box to permit putting a chicken in and taking it out. Two more boxes are made of similar size with one end screened securely, and a screen trapdoor fastened in the other end. The three boxes are then taken to the place frequented by fur bearers. The chicken is put into the center box, the hinged end is securely fastened, and the boxes are then placed in a row with the chicken box in the center as indicated. The trapdoors are set and all is ready for the catch. At night an animal will try to get the chicken by crawling into one of the end boxes. Once in the box the door closes and it is caught. The chicken box is long enough to prevent the animals from molesting the chicken in any way, except frightening it. This is the only way I ever was able to catch a live fox without hurting it. I have caught several this way and mink, weasel, coon and even an opossum will occasionally crawl in.

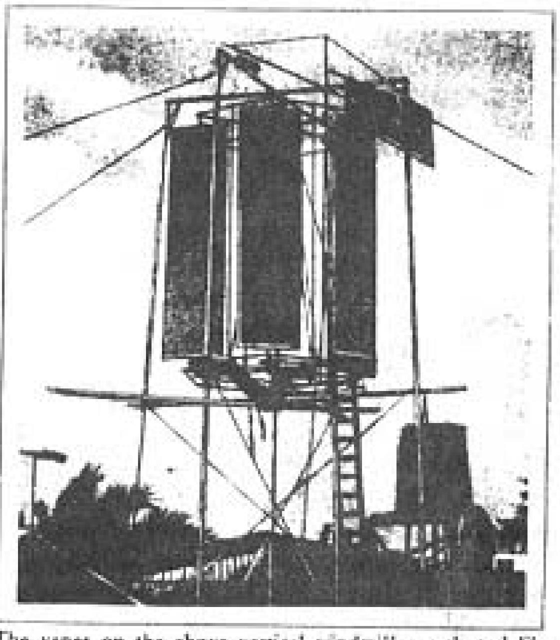
Vacuum Powers Vertical Windmill

SIXTY per cent of the power developed by a new vertical windmill is derived from the vacuum formed by the vanes.

The vanes of the power mill are shaped like airplane wings, thereby making use of vacuum as a power generator, the inventor claims. The mill will develop 20 horsepower in a 15 mile an hour wind.

The windmill was designed to generate power for pumping operations near Bellflower, Calif. Each vane is 12 feet long and three feet wide and is made of lightweight metal. Vanes are mounted on a tubular structure that rises far above surrounding roofs.



The vanes on the above vertical windmill are shaped like airplane wings to form a vacuum to generate more power.

The Survival Mentality

By Paranoid George
(Co-hero of WHEELS OF RAGE)

SAVING AND HAVING

"Either man must be content with poverty all his life or else be willing to deny himself some luxuries, and save, to make the base of independence in the future. But if a man denies the future, and spends as he earns (whether his earning be one or ten dollars a day) let him look for lean and hungry want at some future time, for it will surely come, no matter what he thinks. To save is absolutely the only way to get a solid fortune; there is no other mode. Those who shut their eyes and ears to these plain facts, will be forever poor, and for their obstinate rejection of truth mayhap may die in misery. Let them so die and hang themselves. But no. They take a sort of recompense in cursing fortune. Great waste of breath. They might as well curse the mountains and the eternal hills. For I can tell them fortune does not give away real substantial goods. She sells them to the highest bidder. Men never make so fatal a mistake as when they think themselves captives of fate—'tis the sheerest folly in the world. Every man may make or mar his life, whichever he may choose. Fortune is for those who by diligence, honesty and frugality place themselves in a position to grasp hold of fortune when it appears in view. The best evidence of frugality is the five hundred dollars or more standing in your name at the saving bank. The best evidence of honesty is both diligence and frugality."

The above words were printed one hundred years ago, on May 13, 1877 in THE HUMBOLDT TIMES. At that time Humboldt County was a vital and developing sector of Northern California. In those days, especially in the western states, America was still a young and vigorous nation, peopled by energetic, practical men and women. They lived by the tenet, "If you need a helping hand, you'll find one at the end of your arm."

Neighborly sharing and cooperation were valued and necessary, but an individual's prime responsibility was to be self-reliant and productive. In that way he became an asset to the community and earned respect. People were held to be responsible for their own futures. Thus, a truly progressive society was built, morally and materially.

Today, however, Humboldt County has become modernized. The area now swarms with welfare recipients and the county is dependent on continuous Federal funding to avoid depression conditions. And so goes the rest of the nation.

Today, any local newspaper bold enough to print an editorial like "Saving and Having" would be deluged by indignant letters from Liberals and welfare recipients alike.

Our present welfare-oriented society confuses degeneration with progress. We are told that the idea that everyone should pay his own way is both archaic and heartless. That those who produce should be forced to guarantee the futures and opportunities of those who neglect to plan and provide for themselves properly, and we support the vast and ever-growing sub-culture of the parasitic Welfare Class.

Indeed, the Welfare Class has become a major power block in America and its members are self-righteous and assertive in demanding a better and more bountiful standard of living. It is provided, of course, by forcing those who do produce to support them by ever-increasing taxes.

A century ago it was no fun to be a freeloader and all but impossible to survive as one. Unheard of were the Federally funded programs to take the misery out of poverty and to support able bodied welfare leeches. Those who would not, or could not, produce, simply did not survive to demand a free ride from productive citizens. If a citizen was dissatisfied with his standard of living, there was every incentive to better himself by saving or learning a useful trade needed in the community. He knew that if he didn't care about himself, nobody else would.

In contrast are the arrogant welfare lice today, backed by the Liberal creed and a sense of deserving. It interests me sometimes to hear what some of these pathetic parasites have to say about life and the world. And so I found myself talking to a typical welfare brood sow who was "on the county" as she put it.

Well over 200 pounds of bloated pork, this able-bodied young woman was a second generation welfare case. She wore a garishly colored tent-like garment and her hair was frizzed out, looking like a used Brillo pad. Between sentences she stuffed her mouth with potato chips from a large box at her side. In one hand was a king-sized beer. From the next room came the foul-mouthed cacaphony of her two whelps at play, undernourished, in contrast to their gross mother.

"It's a rotten life and a stinking society," she asserted.

"Oh," I said, "And what's stinking about it?"

Well, if you was on Welfare you'd know how it is to be poor," she accused. "On the first and fifteenth of the month I get my checks and I can have a good time and live right for a couple of days. But after the party's over and the money's spent, all's I got is my Food Stamps."

"All you can get with them is grub, and I'm on a diet. So I have to sell them so I can get cigarettes and beer to last me. But I think I'm pregnant and at least that'll mean a raise. At least Medi-Cal pays my medical bills and I live in Government housing. But Hell, you can't spend that. I want to live decent; at least they owe me that much!"

When I suggested that perhaps she could get a job and get out of the Welfare rut, and perhaps ask the father of her kids to help with their support, she exploded with indignation.

"If I got a job they'd cut back on my Welfare and I'd be no better than a nine-to-five chump and be working my tail off for $2.50 an hour. If you'd ever been on the County yourself, you'd be smart enough to know that.

"And if I had some pair of pants supporting me and my kids, they'd cut me clean off Welfare. What do you think, I'm stupid?"

I asked her if she didn't feel ashamed that a lot of people do work at low income jobs and get no Food Stamps or Medi-Cal, who have to pay taxes so that she could get Welfare while refusing to work.

"That's their problem," she snorted. "I have my own life to live. And don't give me any of that work ethic jive. That went out with high button shoes."

Indeed it did. And that is why today's society is saddled with a vast herd of worthless human baggage who would never have survived a century ago, amid the vigorous, survival-oriented communities of our grandfathers. People who looked to their own ingenuity to cope with disaster, not dependent on giveaway programs to survive.

Yet, Nature has a way of cleansing itself. And when our highly technological society collapses due to its incompatibility with the laws of Nature, the gravy train will grind to a halt. Then the Welfare masses will simply starve. Also decimated will be the ranks of the unprepared, geared only for survival in the present artificial environment of our cities. Technology will then revert to that of the 19th Century. Morality must likewise follow.

Survival will be the province of those who, like the clear-thinking and productive men and women, once built functioning, bountiful communities many years ago. They had the wisdom to realize that there can be no permanent place for parasites.

The Ticket to Mental Health for Survival

By Paranoid George

(Beginning with a short excerpt
from WHEELS OF RAGE)

"When they got back to the mausoleum the other two ghouls had left. In his drawer, Paranoid George was kicking and screaming and trying to get out. If they hadn't gone back for him he could never have gotten out.

"When they opened the drawer he sat up with his empty gallon wine bottle. He was slobbering and was out of his mind. He was so drunk that when he woke up in the darkness and couldn't get out he actually believed he had been interred. He clambered out of the drawer yelling, 'Buried alive! Buried alive!'

"Then he ran out to his bike and roared off into the night screeching over and over, "Buried alive!"

"Big Mike and Pinochio left Gargantua with his bent up machine and went to get the camper. They came back soon and loaded up Gargantua's scooter. Then they all went home to Big Mike's and partied the rest of the night waiting for Paranoid George.

"When Paranoid George made his way out of the cemetery he wandered around for quite awhile before finding his way back to Glendale. He was cold and drunk. Feeling a maudlin need for some warmth and spiritual comfort he stopped by a Catholic church and parked his bike.

"He went up the broad steps and opened the door and looked inside. There was no one around so he went into the lobby and peered around the corner at the altar down in front of the church. There was a priest busy arranging some candles and a couple of worshippers kneeling in prayer.

"Stumbling around sadly like the beaten sinner he was, he found an open confessional and went in and sat down. To his credit, he didn't know where he was. When he closed the confessional door its darkness might have reminded him of the crypt but there was a grille in the side for the confessor to talk through. It let in just enough light to make the place cozy.

"Soon he slumped over and went fast asleep. Sometime very early the next morning he accidentally hit the switch turning on the lighted sign which read, 'Priest is in.' It was probably because the light was on that no real priest opened the door to the confessional.

"About seven o'clock a beautifully built girl sat down at the grille and began her confession. 'Father forgive me for I have sinned.' Paranoid George woke up to hear the girl going on to tell about what she had done with, to and for her boyfriend last night. He listened in amazement as she described positions he could only imagine in a motorcycle pileup. She painted a picture that would make the average skin flick look like an old Victorian morality play.

"Paranoid George still had no idea where he was. All he knew was that a girl he could barely make out through the grille was telling him the horniest story and had to be hot and wanting him.

"When her message was only too clear to him he said, 'Okay, baby, let's make it. My place or yours?'

"For a minute the girl couldn't believe what she heard. When it finally registered she started screaming and going into hysterics. That brought five priests and a bunch of citizens running. She pointed to the confessional and shrieked, 'That goddam priest in there propositioned me!'

"The citizens were shocked and the monsignor who was with the priests jerked open the confessional door. When the priests got over their amazement at seeing Paranoid George sitting there in his black robe and vampire makeup they dragged him out and stood him on his feet.

"When the girl got a good look at him she hollered, 'I confessed to that? Jesus, God Almighty; what is it? It looks like a Muppet!'

"The monsignor shouted, 'Young man, how dare you sit in there and take a confession. You're undoubtedly disturbed. Made up like that you must be against everything the Lord stands for. You must be some kind of devil.'

"No I ain't." Paranoid George raged. 'I'm a Christian. I was saved at a showing of Elmer Gantry.'

"Then he turned and bolted out of the

church. He hopped on his scooter and tore off down the street yelling, 'Buried alive! Buried alive!'

The foregoing is a scene from chapter seven of WHEELS OF RAGE, by Kurt Saxon. The book is about the Iron Cross Motorcycle club and our zany adventures. Those of you who have read it will remember me as an off-beat, often comical character.

But there was nothing comical about the paranoid, sometimes bizarre, thoughts and feelings which constantly tormented my fevered brain. Thus triggering most of the looney behavior which earned me the nickname of Paranoid George. Common sense will tell you that most people who have to get drunk or high before they can have a good time, and those who must indulge in hostile, anti-social behavior in order to feel fulfilled are often tormented individuals.

In my case it was the paranoid feelings of persecution that drove me to drink all the rot gut Red Mountain Burgundy I could chug down my gullet. Also to wind up doing 90 days in the pound for stomping some naughty old coot who I figured was trying to get queer with me.

If you are a troubled soul, your problem might take the form of spells of depression, unexplainable anxiety, outbursts of temper, or maybe just a growing feeling that people don't show you enough respect. In any case, you are very unhappy. Your inner feelings may tend to result in social behavior which others see as wierd. They begin to see you and react to you in a negative way. You sense this reaction and become even more frustrated and begin disliking people. This of course results in additional anti-social behavior, be it verbal or physical. Or you may just withdraw into your own little world. This syndrome is no fun, as I know, having been through it myself.

For example, up until recently I used to wear sunglasses with two-way mirrors for lenses. That's because I felt people were staring at me. In the past I'd have a compulsion to stare at a person every few seconds to make sure he wasn't staring at me. Not wishing to tip my hand by exhibiting my own odd eye action, I began wearing the glasses. In this way I could check out any suspected starer in, say a waiting room, up to 50 times without letting him know I was looking at him.

Unfortunately, I found that one of the best ways to guarantee plenty of people giving you funny looks is to go around wearing specs with two-way mirrors for lenses. As you can imagine, I began to find lots of proof that I was being stared at, especially when I'd show up wearing those sunglasses indoors or on rainy days.

As time went on, things got worse and I felt that my enemies were gaining on me. Indeed, they were my best friends. At night I developed insomnia. Sometimes I sensed a vague warning bell inside me that the chick sleeping next to me might turn into a giant spider as soon as I drifted into dreamland where nightmares were the norm.

When things began to reach their utter madness, I became afraid to be alone. But I was also afraid to be with people. I developed a terror of elevators, airplanes, mirrors, cancer, heart trouble, the dark and the supernatural.

After much introspection I came to the conclusion that all my problems were the result of a black magic curse upon me by a wizard who was masquerading as a faggot in Glendale, California. When I reached the point where I began to have hallucinations, I determined to put a stop to this persecution. After I found that stomping him did no good, my further plans of attack included contacting a sorcerer to make up a counter-spell which would save me from cutting his head off. In a word, I was nuts.

If any of this sounds like you or a friend or loved one, whether you feel you're reaching the point of no return or simply exhibiting some of the milder, though unpleasant, neurotic thought patterns, take heart. You may be merely suffering from a condition which you can correct within minutes.

The chances are great that you, like myself, can find glowing mental health and tranquility. It may come so soon and so easily that you may be amazed, as I was at my own speedy recovery. As I write these words, I sit here with a peaceful, anxiety-free feeling. I feel generally good these days. Gone is the erratic behavior, crazy thoughts, nightmares, insomnia, depression, and paranoia. I threw my reflecto specs in the garbage last week and I feel fine.

At this point you may expect me to thank Freud that I sought expert psychiatric help in the nick of time. Or that I'll endorse Trancendental Meditation or even self-control.

Not at all. In fact I took psycho-therapy for six months, as an alternative to a jail sentence. But I was so paranoid that I wound up accusing my therapist, a patient and personable young woman, of being a secret bull-dyke who was plotting to get me committed to a nuthouse on behalf of womens' lib.

What did cure me, however, was fructose and niacin. As a result of taking these I've started thinking straight. And I no longer suffer from the CHEMICAL IMBALANCE which had in fact been the real cause of my so-called mental problems. I have a niacin deficiency brought on by low blood sugar.

I make no pretense to being an expert in the field of psychology or even in nutrition. I do, however, know what has caused a miracle in me and have since observed niacin and fructose work on other secret squirrels with amazing results.

I don't blame you if at this point you are a bit skeptical. My first experience with niacin and fructose came one evening when, as usual, I was going crazy and beginning to hallucinate. If someone had told me then that after dropping 600 mg of niacin and couple of teaspoonsful of fructose I'd be perfectly normal, I wouldn't have believed it. Yet, that's exactly what happened.

I'd recently moved to Eureka to go to work for Kurt Saxon on the staff of THE SURVIVOR. One night I was at Kurt's place and we were sitting around drinking beer and enjoying light conversation. For no particular reason I suddenly got the idea that Kurt was crazy and he planned to poison me, work black magic on me and in general had ideas about doing me in. "He can't do me in, man," was my exact thought.

But the most alarming thing I noticed was that his forehead suddenly seemed to be increasing in height while his face started getting smaller. At the same time, his eye movements and gestures appeared to get quick and erratic. His whole appearance was rapidly changing into that of a super-looney psycho who resembled Emperor Ming from Flash Gordon. The guy seemed to be going bananas right before my eyes!

"Hey," I demanded, "what the hell is going on here? You can't fool me. You're planning some rotten scheme and I won't put up with it!"

Naturally the conversation deteriorated rapidly at that point and the recriminations flew thick and fast.

Somewhere along the line, Kurt started talking about niacin and fructose as a cure for depression and paranoia. He produced a small plastic bottle of what appeared to be aspirin and a jar of fruit sugar, or fructose. He then suggested that I might have a niacin deficiency. I didn't believe it.

But about then I was ready to try anything, even if it was to prove it didn't work. So I picked up the bottle and shook six of the little white tablets into my palm. Tossing them in my mouth, I downed them with a couple of gulps of Colt 45, followed by a teaspoonful of fructose.

The first thing I experienced was a burning sensation that felt like a sunburn all over my body and I thought I'd been poisoned for sure. I looked in the mirror and saw that my face had turned beet red, exactly like a sunburn. I later learned that this is a harmless reaction caused by the niacin releasing trapped histimines in the body. It's called flushing.

Along with this flushing I suddenly experienced a wave of carefree self-assurance and tranquility. My thinking became crystal clear. My paranoia and visions of plots and poisonings had vanished in seconds. In fact, I could recall my crazy mental process of a few minutes before and I felt free and confident to discuss my former wierd ideas. I laughed at them as the absurd delusions they were.

The effect of the niacin and fructose had been dramatic. And though I didn't know it at the time, the high that I experienced was merely the feeling which most people have who are not chronically depressed. In any case, I'd been cured of lifelong depression and paranoia in ten minutes.

These days, instead of taking six niacins like the first time, which was too much, I just take one and a level teaspoonful of fructose every few hours, especially if I begin to feel low.

I'm told by a nutritionally oriented psychologist that the effect of niacin on most people is not usually so sudden as it was with me, though the result is the same. Usually a reserve has to be built up over the period of two days to a week. But it works.

So if you have periods of anxiety where you feel something is wrong without really knowing what, or get depressed for no readily apparent reason, niacin and fructose may be all you need. Tranquilizers have the same effect on depression and paranoia but they just suppress the wild imaginings without healing the system, as is done through the use of niacin and fructose.

Consider the probability that you may have a niacin deficiency like I have. If you do, you're actually among the lucky. Niacin can be bought at any drug store without a prescription. It's just a vitamin and sells for a little over a penny per 100 mg tablet. Fructose is simply fruit sugar and can be bought at any health food store for about $2.00 a pound.

When you get a flushed feeling from niacin it simply means you've taken more than your system can handle at that time. try one 100 mg tablet and a level teaspoon of fructose. If you don't get flushed or feel better within 15 minutes, take another tablet and some more fructose. If even one tablet is too much, break it in half. In a short time you'll know how much to take to feel better without flushing. It won't be long before you build up a niacin reserve and then you can take one tablet and a spoon of fructose whenever you feel depressed, anxious, enraged over some small aggravation, etc.

Often when a person is depressed and anxious, his feelings signal his adrenal gland to release adrenalin for fight or flight. But since there is no actual problem worth fighting or running from, he is left with a feeling of impending doom coupled with impotent rage. Then he clobbers some dude, or beats the wife and kids, or starts shooting up the neighborhood and gets the SWAT team in. This works the same on women and is the main cause for child battering.

What fructose does, in combination with niacin, is to block off the unnatural flow of adrenalin. This simply takes away the urge for violent action against whatever petty little annoyance crops up during a period of depression. Fructose can work wonders for anyone subject to alternating fits of depression and anger.

Millions of people have chronic low blood sugar, or hypoglycemia, as part of their physical makeup. Millions more produce this condition by eating too many carbohydrates such as breads, potatoes, etc. which the body converts to sugar. Then there is candy, soft drinks, refined sugar used for sweetening, etc. Putting all this sugar into the system causes quick highs, followed by an equally quick low which lasts a lot longer than the original high. This is what people mean when they talk about low blood sugar. When your system can't handle sweets, you experience highs followed by miserable lows. This is bad enough on the mind and the emotions. But it is also a signal that you could be developing diabetes.

So knock off the excessive carbohydrates and drop refined sugars altogether.

Fructose gives you the same high without the resulting low. Adding fructose to the diet can mellow you out if you have the erratic symptoms of low blood sugar. You may find that you can deal logically and assertively without being the victim of feelings of anxiety and inner panic when confronted with a stressful situation. Nor will you be in danger of losing out to a surge of irrational fury and the desire to kick somebody's teeth in over a trivial matter or imagined threat or insult.

When I began taking fructose I followed a program. On the first two days I took two rounded teaspoonfuls of the granulated fructose dissolved in water every two hours. When I went to bed I had about five rounded teaspoonfuls dissolved in a glass of water next to me so that I could drink some when I woke up during the night.

Following this procedure saturates your system with fructose and your adrenal gland gets a total rest for two days. I found myself to be totally collected during the two days and I reacted to all situations intellectually rather than emotionally. The "flight or fight" responses were greatly dulled.

On the third day I began taking a level teaspoonful of fructose three times a day and that's what I take now, along with a greatly reduced dosage of niacin.

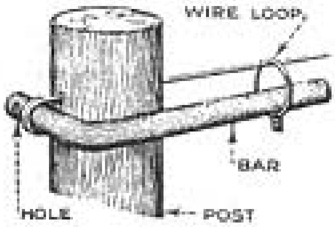
There's nothing as good as fructose for killing the urge for soft drinks or sugar. It won't make you fat. In fact, if you have a weight problem, fructose and niacin will give you a natural lift which brings with it energy you didn't know you had. You'll burn off that extra weight just in the course of your daily activities. Fructose is widely prescribed for overweight types. In some European clinics, fructose is even prescribed for diabetics.

Between niacin and fructose, I now find that I'm pretty together and I seldom have the urge for sweets, or even alcohol, by the way. Alcohol is also converted into sugar by the body. A depressed type drinks and soon his blood sugar drops and he's terribly depressed. The only way he knows to get back up again is to take another drink, and on and on. Niacin and fructose takes away the depression so he simply loses the urge to keep chugging down the booze through all his waking hours. So fructose and niacin is not only the cure for depression and overweight, but it's also the only known cure for alcoholism.

If your system is shot through years of troubles, both real and imagined, you may need fructose and niacin from now on. But both substances are relatively cheap, very easy to get and can be stored indefinitely. Considering what might lie ahead; mounting tensions, lack of medicines and general chaos, a lifetime supply of fructose and niacin could keep you reasonably collected through most of the chaos to come. These two items could be the cheapest and most important elements in your survival program.

A Simple Wire Stretcher

A novel arrangement, that is simply installed on any wire line to facilitate lowering or raising, or to maintain a uniform tension, is shown in the drawing. It is made from a bent bar of round iron. Such a device is being used, in one instance, to keep wire clotheslines taut, so that no props or other supports are necessary. The wire is led through a hole in the post and fastened through a hole drilled in the bent bar. Turning of the bar crank winds the wire around it and tightens the line. The crank is held in place and prevented from unwinding by a loose loop, or link, which is slipped over its end.



How to Deactivate a Time-Bomb of Stress, Tension and Anxiety

by Cyrus Dickenson

Do you hear a strange ticking? Not a loud ticking. Actually it might be more of a vibration, and one that is somehow connected to your body and heart. That's it, your heart pounding! Has someone somehow wired a bomb to your heart? No, of course not, but it may very well feel like it if you are tense, full of anxiety, and under the stress well known to Survivors.

Where does stress, tension, and anxiety come from? Well, they can come from practically anywhere. But that question could easily be one of the most important you ever ask yourself. Actually, tension and anxiety are the result of stress that gets out of hand. This can be the result of the stress being (1) overwhelming (ie. ten men against one), (2) too many stresses at once (ie. fired from job, bills piling up, a bad cold, wife leaves you, or she comes home, etc.), (3) not knowing what the stress or stresses are or where they are coming from, or (4) unchanging, unending stress, including boredom. Then, stress can turn to anxiety and tension because the mind and body become exhausted with no relief, no rest, relaxation, or variation.

If we are to deactivate tension and anxiety we must identify the stress or stresses and deactivate we must or fail to survive. When anxiety reaches high levels for periods lasting days, weeks, or months, our body and mind begin to fail. Ulcers, heart attacks, heart pounding, rapid breathing, ridiculous fears, poor or unpredictble mental function, as well as a host of other troubles besiege our system. In short, we become physical and mental wrecks hardly worth saving.

Why would it be hard to detect stress when it's obviously all around us? Well, for the very reason that most people are looking all around themselves and usually fail to look within. Now I don't mean within one's head, but within his body chemistry. Often others try to convince us that there is something wrong with our minds, but we are foolish if we accept this as the cause or source of stress.

People whose body systems are in good balance don't have anxiety attacks, (I repeat, do not have anxiety attacks), are rarely tense, and enjoy a stressful situation, as it becomes a challenge to deal with and overcome, or reduce the stressful situation. So, if you are having a rough time coping, don't make the mistake of blaming all your problems on other people, places or things, or your mind. They are stress contributors but do not by themselves cause anxiety attacks. Only when your body is out of balance can other people and situations contribute to your anxiety attacks and tension.

One of the best clues that the disturbing stress is coming from within the body chemistry is if the person tries to self medicate with such things as alcohol, cigarettes(chain smoking), drugs, or lots of sweet, gooey candies, pastries, pies, cakes, cokes, or huge amounts of white bread and other starchy foods. This is an attempt to reduce stress by raising the low level of sugar in the blood stream. This helps momentarily, only to make things much worse shortly thereafter.

Anxiety is our bodies' response to unyielding stress. Anxiety can be felt by a pounding heart, rapid breathing, headaches, fearfullness of people, places, or things that don't usually scare us, or just a feeling of uneasiness. Anxiety is real. We never have to guess if we are anxious or not. Stress, also, is real in every case and is the cause of anxiety. In order to get rid of anxiety we must find the true source of the stress. This is our toughest and most important task.

There are two places to look for that disturbing stress. One is "out there" stress. The other is "internal" stress. The "out there" stress I will leave to you Survivalists to deal with. I am a Survivalist also, but my specialty is with "internal stress." I am convinced that one must check out the possibilities of internal stress before exploring for "out there" stress because an out-of-whack metabolism or body chemistry can fool us into seeing other people or situations as the cause of our anxiety attacks. When this happens we waste ourselves defending against the wrong target while the actual source of our discomfort continues to tear our system down. We could bomb and terrorize all the idiot's or organizations we don't approve of from now till doomsday and would never be satisfied till we get rid of the stress that actually is causing the uneasiness.

What if we determine that an imbalance or internal stress is caused by our eating, smoking, drinking, or other habits? In other words, if we have located a possible source of stress on our body metabolism, how do we get rid of it?

Many people do not want to hear the answer to this, but it can be extremely rewarding. The answer is DIET. Diet can reduce or eliminate anxiety attacks and tension, depending on how strictly the diet is kept. Usually when people hear this they cringe. To have to give up "habits" sends one into a quiet panic. It hits right in the gut. But don't take the hard way out of this by saying "Baloney that's the stupidest thing I've ever hear of!" Believe me, the easy way is to think about this through your own common sense after you carefully listen to a plan to eliminate anxiety attacks. There is no justified reason to panic. The thing you subconsciously fear the most will not happen. That fear is that you will have to give up your habit (like sugar and coffee for example) and you will feel even worse than you already do. Right?

As you read on, a plan will be spelled out to you where you can give up your habits while replacing them with specific foods that will not only avoid serious withdrawal, but will leave your body in a state of balance and feeling better physically and mentally than you can remember or even imagine. This is no exaggeration but like anything else one must have a personal experience before fully appreciating it.

Here's how it works. All food and drug habits (or cravings) are caused by LOW BLOOD SUGAR. When our blood sugar is low our body signals us to eat. The first signal is hunger sensations. If we ignore this then our body tells us in other ways like irritability, tension, aggressiveness, fatigue, light headedness, dizziness, cold clammy and sweaty skin, nervousness, or fear, and when mixed with other stresses that we are dealing with in our life, anxiety attacks will result.

Hunger is triggered from a drop in the level of sugar in the blood stream and not by how much food is in the stomach. The proof of this is that people are fed sugar and other nutrients through a vein, sometimes for months, without ever feeling hungry. This is why many people feel hungry or want to chain smoke, or drink etc., even if they are full. Their blood sugar level is still low. What goes in their mouth only satisfies momentarily or for an hour or so and then they feel even worse than before.

What makes some people crave certain foods, drinks, or other drugs, and not other people? The answer is faulty sugar metabolism. Some people are born with, and others develop, imbalances in the body chemistry. For example, a special part of the pancreas, called the isles of Langerhans, can be too sensitive to sugar. This part of the pancreas makes insulin (which the diabetic doesn't have enough of). Insulin normally keeps levels of sugar from being too high. When too much insulin enters the blood stream the supply of sugar drops. Then we feel crummy. So we eat, drink, smoke, or take drugs which all, in one way or another, briefly raises the blood sugar and then causes an even lower level to follow for those with the imbalance. The quick rise makes us feel good, then the drop makes us feel worse.

Are you starting to see the dilemma here? The harder the guy tries to get his badly needed energy up, the worse his whole life gets. His energy is either too low or it's going up and down like a yoyo. And when the blood sugar is low the first organ to be affected is the brain, which uses a piggish 25% share of all the body's energy supply.

To make things worse, when the pancreas constantly keeps the blood sugar down, other body defenses try to help out and make things worse. The adrenal glands, which are normally used only for emergency energy, release their many hormones, which make us want to run or fight for our life. This is confusing to others as well as ourselves. Then when we find ourselves in a real need to defend or escape, our adrenal glands are too exhausted to do us any good. Did you ever rip the phone off the wall during a domestic squabble? Or, scream and rant and rave over nothing? This can happen and does when the adrenals are doing their thing at the wrong time. This kind of stress we can do without. We try to avoid low blood sugar by eating or taking things that give us a lift. This plan backfires for those whose glands overreact. The reward is more low blood sugar. This, of course, lowers our chances of survival out there in the rat race of life.

This lengthy explanation is necessary before sense can be made out of what to do about it. There are three basic foods: proteins, fats and carbohydrates. We need all of them to be healthy. To deactivate the time-bomb of anxiety we must understand carbohydrates. Simply put, they are sugars and starches and would include fruits, vegetables, grains, and especially table sugar and honey, white bread and white rice. Common sugar, white bread, white rice, and alcohol are the most deadly time-bombs because they are wired directly to a hyperactive pancreas.

In short, we must stay away from the quick energy sources we need so badly. So, we must replace these explosives with carbohydrates (sugars and starches) that work more slowly. This includes whole grain breads and pastas, brown rice, beans, lentils, seeds, nuts which also have sufficient protein components which slow the reaction in our bodies. To this we can include the high protein groups of meat, fish, fowl, and dairy products. A normal amount of fat will be obtained in these high protein foods even without eating the fatty parts of the meat.

What I have just described is commonly called a high protein, low carbohydrate diet and at the end of this article will be a book list for you to refer to as this article is limited to describing the stress factors causing tension and anxiety attacks. These inexpensive pocket books usually refer to low blood sugar as hypoglycemia. I urge anyone who suspects they have problems with low blood sugar to read these books, which can be found in health food stores as well as other book stores and libraries.

Basically, the diet stays away from rapidly absorbed or refined carbohydrates and relies on more slowly absorbed carbohydrates and especially proteins which are not normally used by the body for energy. Rather, they provide material for tissue building and repairing as well as nerve functions. This diet teaches you to think protein instead of sweets, starches, or alcohols when you need an energy lift. This is an excellent diet. But one problem is that it takes the protein awhile to break down in the body and eventually be available as sugar or an energy source. Once the energy arrives however, it lasts for several hours. So if one eats small to moderate amounts of protein several times a day he can usually avoid that yoyo existance.

Within the last few months an exciting new addition has been added to this diet which quickly curbs one's desire to take addicting foods, alcohols, and other drugs. It is FRUCTOSE, also called levulose or fruit sugar. This must never be confused with other sugars which are strictly forbidden. Fructose has been separated from other sugar in a chemical process in Europe and is now marketed in the U.S. The beauty of this sugar is that it (1) does not stimulate the isles of Langerhans to produce insulin, (2) it gives quick energy to the brain and body. It also has the same amount of calories as table sugar. Synthetic or artificial sugars only trick you into thinking energy is soon to come. It won't. Fructose will give you the energy you need without activating that time-bomb of tension and anxiety attack. Fructose will not helpif taken without the special diet because the other sugars and starches will still trigger the low blood sugar. Fructose looks and tastes about the same as table sugar and is slightly sweeter. It can be purchased in health food stores and through mail order. It is expensive but easily worth trying. Prices can range from four dollars a pound to as low as $1.30 per pound which I found in a Co-op store. Tablets are available for a ready supply away from your kitchen. Refer to the booklist to follow for more details and technical information on fructose.

Good luck on your new diet and the new life to follow.

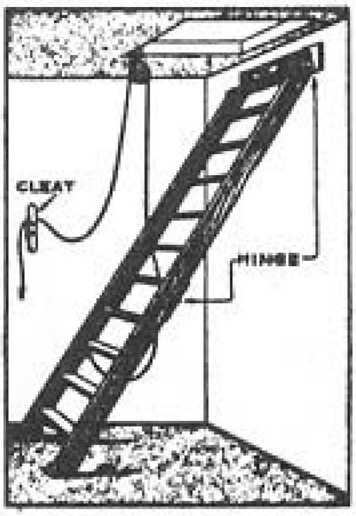
Folding Attic Steps



The steps shown in the drawing are particularly serviceable when the opening to the attic is located in a closet, or small room, where there is insufficient space for swinging a full-length ladder to the ceiling. The upper end of the steps, or ladder, is attached to the wall with hinges, as indicated. The side rails are sawed in two near the middle, the cut being made in a diagonal direction to afford a longer bearing and to bring less strain upon the strap hinges by which the sections are joined. **By means of a rope and pulley, the lower section is folded inward against the upper section when the steps are drawn up. The steps are held in the raised position by taking several turns of the rope around a cleat on the wall.**

Insects Killed with Glue

From Popular Mechanics 1931

A new method of exterminating insects on evergreen trees about your home is suggested by experiments at the State University of Ohio, where it was found that a solution of glue and water was an excellent insecticide. The solution is made by mixing glue, 1 lb., and water, 5 gal. It is sprayed on the trees and holds the insects in the same manner as flies on sticky paper, without injuring the trees. Besides killing the insects, it also prevents their eggs from hatching.

SURVIVING WITH MENTAL PROBLEMS

By Bill Abreu

Some recently proven theories held by doctors and nutritionalists may shed some truth on the old saying, "you are what you eat." In fact, from what tests and studies have shown, it is possible for certain foods (or lack of) to be the cause of an irritable or temperamental disposition (not to mention depression, fatigue, and a variety of many other mental problems).

Food allergies, though mostly well known for causing physical problems, such as cramps or hives, can frequently cause anti-social behavior in many individuals. These allergies differ from inhalation or skin allergies in that their reactions can be delayed for a period of hours or even days. When this situation occurs the food allergy can then be linked to addiction, on the basis that the only way in which the person can temporarily relieve the allergy is to eat more of the same offending food.

One large contributor to food allergens is food additives and pollutants which can be found in cured meats (i.e. hotdogs, ham, etc.) to act as a preservative. These additives, while giving the meat an attractive red color and stopping the growth of bacteria, can cause reaction such as depression, weariness, hyperactivity, or tension.

But other foods, apart from additives, can also cause reactions in certain people. To find a person's allergen a doctor has the patient fast for four to six days. At the end of that period the patient is fed the suspected food and if a change in behavior occurs (though it may be subtle or drastic) the cause can then be diagnosed.

More specifically, salicylate, a chemical found in food coloring the flavoring agents, is a known- allergen linked to hyperactivity. This chemical causes a swelling in the lining of the brain (which is then called cerebral swelling or allergies), hence the anti-social behavior. In experiments with hyperactive patients it is shown that when salicylate is eliminated from their diets, the majority of patients calm down significantly.

The list of foods containing salicylate is quite unfortunate, being that they are the foods which many people are most fond of; candy, cured meats, soda, and strangely enough even some children's chewable vitamins (it's amusing to think that Flintstone's Vitamins can turn a child into a tyrannosaurus rex—very loosely speaking of course).

Salicylic acids can be found largely in aspirin. This is very significant when one takes into account that 27 million pounds of aspirin is consumed yearly (enough to treat 17 billion headaches). Even worse is the fact that tests have proven that aspirin has no more pain-killing effect than does caffeine. Furthermore, it is believed that aspirin, among other drugs such as insulin, would now have a difficult time being passed onto the market if they had to meet the strict standards of today. Salicylic acid, aside from causing cerebral swellings, can also harm the mucosal cells which line the inside of the stomach, unless the tablets are buffered or if food has been eaten prior to the drug's consumption.

(If aspirin must be bought, it is best to purchase the least expensive brand, because all aspirin must pass the same U.S.P. requirements.)

As of now you might be looking back through your memory, trying to find an instance where you ate an aspirin or hotdog and suddenly were transformed into a raving madman. The truth is that the reactions are not that drastic nor that immediate in most people. The situation would more likely be that the person is easily offended or quick-tempered (which might be alien to his normal personality) due to certain foods he has been eating for some time. Though the change to anti-social behavior is gradual, the process to revert back to a more calm and normal disposition can sometimes be remarkably fast. There have been cases where mothers have noticed prominent changes in their child's behavior within a very short time; all for the better. (And what about Paranoid George's ten minute cure for his problems as described in Vol. 2 of THE SURVIVOR.)

To find your allergen, if you suspect that something is making you tense or irritable, can be fairly simple. First, the most likely suspected food (or perhaps a whole food family) is eliminated from your diet for three days. If no change in attitude occurs then you move on to eliminate the second suspected food. Finally when a change does occur you simply check to see what food has most recently been eliminated, and obviously drop that food from your diet completely.

To treat mental problems without using standard methods, doctors will sometimes use the orthomolecular or the megavitamin therapy. There is not too much difference between the two, except that more vitamins are consumed by the patient with the megavitamin therapy. Both of these treatments are much safer than the usual methods continuously used and in many cases they have even proved to be better. For one thing, no foreign elements, such as drugs and tranquilizers, are introduced into the system, and those excess vitamins which the body does not use are simply gotten rid of, being that they are water soluble.

However, it is not necessary to have a doctor lay out a specific diet to fit your personal needs, when it is possible for the same results to be accomplished by following a few simple and common sense methods.

The first thing to do is to have a healthy diet. This is not say that you should immediately run out to your nearest health food store and buy sea weed, bird seed, or what have you. A well rounded diet of foods containing the minimum requirement level can be found and prove helpful to one's mind as well as one's health.

It is unwise to drop sugar of all forms from your diet as some might instantly assume (this would be difficult to do anyway, since sugar can be found in so many foods). A drop in sugar content can cause depression, grouchiness, or fatigue Also, too much sugar can over-stimulate the pancreas into pumping large quantities of insulin into the bloodstream to handle all the sugar. With all this insulin in the system the sugar's original purpose is thereby defeated. As mentioned in THE SURVIVOR, fructose is an excellent substitute for over-refined sugar which is contained in many sweets.

Minerals are also an important part of every diet and can be just as beneficial to your mental health. In a well-diversified diet, a sufficient supply of minerals will be found in milk, milk products, table salt, meats. The most abundant and important of minerals is calcium which is essential to every living cell. When a calcium deficiency is present the effects are much like those of a sugar or niacin deficiency. However, it can easily be corrected by eating more calcium-filled foods such as green vegetables, lean meat, and milk, or by simply taking calcium tablets which can be bought, non-prescription, at any drugstore. Calcium tablets are good also for relieving headaches (better and safer than aspirin), alleviating pain (two or three can be taken before dentist visits), or for curing insomnia.

Vitamin C can also be important for your survival diet because it detoxifies the effects of allergens which might somehow work their way into your system, despite precautions taken to avoid them. Often, the trouble-causing allergen can be found in some foods you might be unaware of or have overlooked.

Vitamin B6 is used largely in megavitamin therapy for the treatment of allergies to food additives, wherein the patient is denied offending foods containing additives and given large doses of vitamin B6 along with minerals and other vitamins. It has been shown that hospital patients lacking vitamin B6 tend to develop depression, nausea, and vomiting. Once these patients are given dosages of vitamin B6 they quickly change back to normal with no side-effects.

Vitamin B1 (thiamine) aids in producing energy. However, this is not to say that with consumption of three or four of these vitamins you will suddenly be able to do heavy work or run miles without tiring. Vitamin B1 when taken with a well rounded diet of other vitamins and foods can be helpful. People without vitamins B1 are fatigued, and constantly exhausted.

These vitamins, if taken properly and incorporated with a survival diet, can be favorable to one's physical and mental well-being. When the situation arises where getting along with your fellow survivalists is one of the main objectives in surviving after the crash, it will be best to have a complaisant attitude to keep peace in a group. Eating healthy foods and proper vitamins can be the key to survival in such a situation.

But this situation changes dramatically when the deficiency is corrected. By way of foods, vitamin B1 is included in bread, cereals, and unrefined foods such as peanut butter.

Vitamin B3 is simply niacin, a vitamin which is sometimes referred to as the "morale vitamin," and is discussed extensively also in Volume 2, of THE SURVIVOR.

In that calcium is helpful in relieving pain and headaches, vitamin D aids in promoting the absorption of calcium. Vitamin D can be obtained from homogenized milk and when taken in capsule form, should be consumed after a meal which might contain fat. Because vitamin D is used very little, it may sometimes be sold by prescription.

PICTURE FRAME AND TRIANGLE CLAMP

From Popular Mechanics 1915

A picture frame or triangle is quite difficult to hold together when fitting the corners. It is still more difficult to hold them together while the glue dries. The clamp illustrated will be found quite satisfactory in solving this problem, and at the same time is very simple to construct and easy to manipulate. The material list for making the clamps and corner blocks is as follows:

Picture frame clamp:
  4 pieces, 1¾ by 1¾ by 15 in.
  2 pieces, 1¾ by 1¾ by 5 in.
Triangle clamp:
  3 pieces, 1¾ by 1¾ by 10 in.
  1 piece, 1¾ by 1¾ by 4 in.
Corner blocks:
  4 pieces, ⅜ by 3¼ by 3¼ in.
  8 pieces, ⅜ by 1 by 2 in.
The pieces mentioned are of oak, S-4-S.
  1 piece ⅜-in. maple for dowels
Hardware:
  10 bolts, ¼ by 2 in.
  4 bolts, ¼ by 3 in.
  2 bolts, ⅜ by 6 in.

The picture-frame clamp consists of the four arms A, B, C and D, Fig. 1. A ¼-in. hole is bored in one end of each piece, ½ in. from the end. A series of ⅜-in. holes, 1 in. apart, are bored along the center in each piece. The two short pieces, E and F, have two ¼-in. holes bored in their centers, ½ in. from each end. These pieces are bolted to the four arms with ¼-in. bolts as shown in the sketch. A ⅜-in. hole is bored in the middle of each piece E and F for one of the 6-in. bolts K.

The four corner blocks G, H, I and J, Fig. 1, have a ⅜-in. hole bored in the center of each and a dowel glued into it with the end projecting 1¼ in. on the under side and level with the surface on the upper side. Each of the corner blocks is fitted with two pieces like X, Fig. 2. Each of these pieces has one end round or a semicircle, and in its center a ¼-in. hole is bored. The other end has a ⅜-in. hole bored ½ in. from the end.

After making the small pieces, take the four corner blocks G, H, I and J and draw a line on the upper side in the center, with the grain of the wood, and mark the angles as follows, so that one-half the angle will be on each side of the centerline: On one end of the pieces G and H mark a 90-deg. angle, on the other end a 45-deg. angle, on the piece I mark a 90-deg. and 30-deg. angle and on J mark a 90-deg. and 60-deg. angle. Mark the number of degrees of each between the sides of the angle. Place two of the pieces marked X, Fig. 2, on each of the corner blocks, one piece on each side between the different angle lines, so their round ends will be toward the center and toward each other with a space of ¼ in. between them. Clamp the pieces to the corner blocks and bore the ¼-in. holes through them to secure perfect alinement. Put the bolts in and turn the pieces first to one angle and then the other, and while in the respective positions, bore the ⅜-in. holes ⅜ in. deep in the corner blocks. Glue a dowel in each ⅜-in. hole of the small pieces, allowing it to project ¼ in. on the under side so it will fit in the ⅜-in. hole in the corner block. Be sure to countersink the holes for the heads of the bolts. All bolts should be fitted with wing nuts. All that is necessary to change from one angle to another is to loosen the nuts and swing the small pieces around so the dowel pins will drop into the other holes, then tighten the nuts.

The triangle clamp is made in the same manner as the picture-frame clamp, except that the arms L and M, Figs. 2 and 3, are half-lapped into the crosspiece P. The bolt O is ⅜ in. and the head is cut off. Drill a ⅛-in. hole in the bolt, ¼ in. from the end, and bore a ⅜-in. hole in the end of the arm N. Insert the headless bolt O in this hole and drive a nail through the side of the arm N, so it will pass through the hole drilled in the bolt. This keys the bolt in the end of the arm N.

To clamp a picture frame, set the corner blocks G, H, I and J to the 90-deg. angles and adjust them on the arms A, B, C and D to accommodate the size frame to be made, as shown in Fig. 1. Tighten the thumbnut on the bolt K, and this will draw all four corners together with the same pressure. The corners can then be examined to see if they fit properly. If they do not, saw in the joints with a backsaw until they do fit.

The triangles are clamped in the same way. The corner blocks are set to take the proper angles. The ends of the bolts should be slightly burred over so that the thumbnuts cannot be turned off.—

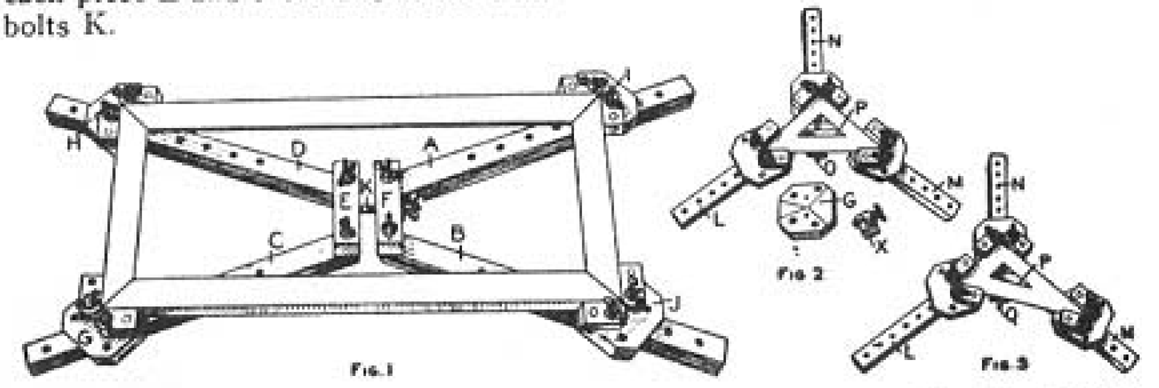


Fig. 1

Fig. 2

Fig. 3

The Corner Blocks on Both Picture Frame and Triangle Clamps are so Constructed That They Hold the Molding together While Fitting the Corners and also Hold Them Securely While the Glue is Hardening

SURVIVAL OF THE FITTEST

by Tom Murphy

It all began on a seemingly normal day. At least as normal as the days had been being, each day's news being filled with near panic events, droughts, floods, many food crop failures, a new oil boycott, sharp rise in inflation, shortage of manufactured goods, massive power failures, increased terrorist activities, crimes of violence. People were scared and rightly so. It seemed that everything was building up to a peak, you could feel the tension in the air.

I was not too worried since I had made advance preparations some time ago to ensure the security and safety of my family. We had bought a small farm well off the beaten path, 6 acres but quite remote, the closest neighbor being a half-mile away. We had been established over 3 years, building up a nice sized garden, a good well, and had lots of trees for plenty of firewood. My wife Susan is a very prudent person and she believed as I do in being prepared for any occurrance.

Since we're so far out in the country, we're more subject to power failures, so I had acquired an A.C. generator for emergency use. The deep well has an electric pump and lots of fresh water is important, not only for drinking and washing but for sanitation too. The generator is housed in a concrete building together with drums of gasoline, lubricants, tools, and other survival supplies, as well as a small chemical lab. Drums are not ideal for the storage of gasoline as they tend to rust, however they will last for many years. Gasoline will keep almost indefinitely if kept in a closed system. It's the exposure to air that causes it to deteriorate. I had on hand 8 drums for a total of 440 gallons plus 10 in the generator or 450 gallons. With careful use it would last for years or at least hopefully till things had stabilized. In that period of time, we would have had a dug well completed as well as expanded food supplies. So with power for the well, for communications equipment, deepfreeze, etc., we should be o.k. The generator has a good muffler system and is in a sound concrete shelter, it makes very little noise, which is very desireable. I didn't want to call attention to my little stronghold when the chaos occurs.

Over a period of years we had accumulated a good assortment of survival supplies—all with the idea in mind of not being able to get it if we didn't have it already. Travel would be very dangerous during the panic, so we decided to do without a lot of luxuries so we could be prepared. It sure is better to have something and not need it, than to need it and not have it. Some items are critical to life support, such as medical.

I left work early in the afternoon, listening to the truck radio—lots of bulletins coming on from the big cities, demonstrations, blackouts, some looting—the military had been placed on alert, and some National Guard units called out to help maintain law and order. I was going to stop by the grocery store, but the parking lot was jammed with cars and there was a large crowd in front of the store. Unbelievable—right here in a small southern town—people get scared and it's like a wildfire. I turned the truck around and headed for the house—looks like the time to put plan A into effect.

Susan met me at the door, with a worried look on her face—"Tom, I'm afraid it's starting to happen." I told her that I believed that also, and to start plan A—which is to notify the people that were to come to our retreat for safety and mutual defense—Susans' parents, my parents, and John and his family (Susan's brother), who lived 70 miles away. After quick phone calls to all, we began our own emergency preparations, which were not extensive as we had been on "alert" for weeks. I looked with satisfaction at the large store of foodstuffs, bedding, clothing, guns, ammo, tools, books, and agricultural supplies. Wished it could have been more but we did the best we could in the time we had since we became aware of the situation. Commercial power was still working, so we began filling the water jugs. I cut off the butane to the hot water heater to conserve, but left it on for the cookstove. I checked the gauge, about 2/3 full, 250 gallon tank. I had in storage four 50 gallon tanks, so cooking should be no problem for a good while.

Sure glad it's summertime, won't have to worry about burning wood with resultant smoke for at least four months, again so as to not call unwanted attention. With the new woodburning heater, there's not much smoke anyway compared to our old open fireplace. Checked the camping stove, two burner, 16 gallons of gas, Kerosene, 10 gallons, with two lamps, one lantern. I broke out the shovels and pickaxes; sure going to be a lot of digging when help gets here—defense positions, mantraps, punji holes, booby traps and warning devices. I had long ago made up duty rosters and plans for fortifying the homestead.

Considering the amount of work involved, I had thought about doing a lot of it as I went along. However, I didn't want to call undue attention to my future plans. All I needed was to have company drop in and see the field fortifications and thus start asking questions. This occurred once when someone dropped by my communications shack and saw a few cases of canned goods and said, "Boy, I'll know where to come to when I get hungry." There's no way to explain to this type of person—sure hope he doesn't try to show up. Hate to be hard-hearted but if we share with everyone that comes along, I would be denying my family to benefit someone else who screwed off and spent their money on color TVs and boats while we did without to preserve ourselves. Everyone had the same chance to prepare and if they didn't see the need, then maybe they were too dumb to survive on their own. Nature weeds out the inferior.

I thought about my half-brother whose idea was to head for the woods, with what he could carry on his back. I left him a standing invitation to come be with us when he got tired of tramping around. I believe that he'll make it o.k. For many months he has been backpacking into the woods on the weekend, lots of experience gained, as well as getting into shape—well equipped, compass, topographical maps, etc. He knows well enough to make his presence known before he tries to come in. The old wild west idea—shoot first and ask questions later—hard words but it's gonna be a hard life.

He had one thought that sure seems to make sense. Some talk about "Bugging" out and including books on how to survive; he feels that experience is what counts, if you have to have constant reference to a book, your chances are reduced. I have an extensive library, but I have lots of things I need to grab if we have to "bug" out. A static location is best from the standpoint of defense, with fortifications and enough people to defend it. It can be overrun, but damn hard to do, the attackers have to pay the price.

Someone's coming! It's our parents in pickup trucks with a big load on the back of each—foodstuffs, bedding, weapons, etc., welcomed manpower and goods. Sure hope John will get here before dark. News getting worse, everything coming unglued. Had a quick meeting while I outlined the course of action—sent two of my sons out on guard duty, heavily armed, with C.B. walki-talkies for communications. I had an Army surplus field telephone system which would be used on occasions when we didn't want to transmit over the air, and "they" have radios too. A couple of folks started stringing wire, one using a garden spade to make an opening in the ground while the other put the wire in the slit made by the spade. Other wires were put down and run to stakes around the perimeter of the land.

The chain of command had been discussed on previous occasions. I pointed out that this was my house and my land, and most of the supplies were mine—thus we don't vote on issues. I listen to advice and counsel, but I make the decisions—sure stops a lot of problems before they get started. It was hard for the parents to accept this, but they did. After all, they could have prepared and invited my family and me over. Then of course, I would do as I was told. They didn't, I did. So that's the way it is.

Getting darker, John still hasn't arrived from the city—the ladies are in the process of supper, early to bed for all but guards, no lights at night. Well, no lights at all at least from commercial sources, power just failed, radio on batteries, all hell has broken loose. People going nuts, the whole system has ground to a halt—Overseas looks the same. The economies of too many countries are tied up too much with that of others, one affects the other.

Everyone into bed, I cut off the radio, get my rifle, 45 automatic, and flashlight and go down to the driveway entrance. Skip is at the curve of the driveway, covering the entrance. He's seen several cars go by, but all is quiet. Gary has the dog with him, we hear a dog barking in the distance, our's has been trained to not bark, but to give indication of "something out there." Sure dark tonight, overcast. There's someone coming, gravel road, can hear a long ways. I went to the edge of the woods to take position at the side of the entrance, in a ditch. Two vehicles, a car and a truck, stop short of the entrance. "Hey Tom, it's John"—flashlight check, sure enough—mighty glad to see them.

Both the car and truck are loaded down with supplies. John said it was a good thing they lived on the edge of the city as he thought that they would not have made it if they had been further in. He said it sounded like the opening day of deer season. Lots of gunfire coming from the main section. There were a number of people out of gas on the roads leading out of the city, but just no way to help them.

Well, left Skip on guard duty and pulled the car and truck up to the house. Sure a lot of vehicles around now. Started to unload but decided to wait until morning in order to not show lights. Also decided to take gas tanks off most vehicles and close park them around the house for additional bullet proofing. Also had sandbags to be filled to put next to walls. Hard to get everyone settled down again, but soon quiet again—time goes fast—time for guard change—quick call on the C.B. to alert guards of change—(their walki-talkies have earphone jacks, which they are using, also squelched tight, with short antennas as we only need short range communications and they have some freedom of movement without being tied to telephone system. In the daytime with better visibility the telephone system will be used mainly.

I'm getting some shuteye, I go on guard duty at 3 AM. Quiet night, just the way we want it to be. Sun coming up, looks like a nice day, hot though. There sure is a lot of work to be done today. Had a quick breakfast—got enough water for several days—deep freeze should keep for 3. Listened to radio, National Emergency, President pleading for calm, law and order—gangs of looters going amuck, stealing and killing anyone in their path. Looks like we really need to be on the alert.

Went ahead and ran the A.C. generator, put freezer on lowest setting, ran well and filled and refilled all available containers. Sure glad I soundproofed the system as much as I did. Can hear it running only a short distance away. Ran it for two hours. It's a big job to get things organized, with as many people as we have (21), it takes a lot of food—the garden is in great shape, lots of stuff needs picking today. Betty (John's wife), is in charge of food, procurement and inventory. We are going to utilize the garden to the fullest extent possible and save the other food supplies for wintertime use. We have a large supply of jars and lids, so there should be lots of home canning this summer. The only workable way to get this done is to go back a long way—the women and children do their work, the men stand guard, hunt, and heavy work. This is the most workable system, no place for women's lib in a survival situation. Our forefathers survived and maybe that's why.

I've gotten the digging started, a system of defense positions first—then obstacles next to impede any assault. The only way to defend the house is to have a system of foxholes or fortified positions away from the house—if we tried to defend from the house about all it would take would be one attacker getting close enough to hurl one firebomb. By putting our main positions of defense away from the house, the women and children firing from the house gives a good second system. Also each fortified position has clear angles of fire so that if an attack came from only one direction, fire could be directed from all positions toward that direction. We have to stay on the alert and not be surprised.

I monitor the radio quite often, things are very bad indeed. The C.B. radio has occasional calls for help, no way. Things are starting to settle down into a routine, and that's not good. A routine leads to complacency which leads to carelessness. I changed the guard schedule up. Supplies are holding out real well, fuel consumption is low, mainly because the ladies prepare easy, quick to cook, stick to the rib type meals.

It's into the fifth week now, we saw some smoke east of us yesterday afternoon, and heard some faint shooting, must be three or four miles off, there's a small town in that area. Don't know, but it looks bad. Stepped up the watch, that means that everyone goes around armed—believe we are prepared. The defenses look good, but I suppose could be better, but then there are limits to what you can do. I have seen signs of activity from my neighbors—looks like they've holed up like us. Being in the country, all have a good start on survival. Lots of water, from dug wells, to creeks and ponds. Again we hear the sound of gunfire, closer this time. Plan B into action, carefully, homemade explosives are taken from cool storage underground to the stakes around the perimeter, wires attached, and the charges buried. This is extra manpower to defend against an assault force. Top alert—no outside activities, guards doubled.

I have dreaded it, and now my worst fears are realized. There are people coming down the road, armed, 16 in all. There's a sideroad or two off the road before my place, leading nowhere really, and some of the group is checking each road out. Their intentions are obvious. The word is given, War Footing, everything is ready, all positions are manned. I'm in the command fortification with the explosive control box, each charge on a separate switch, system armed. We are discovered by two, one goes back and through binoculars I see a discussion under way. The one is joined by another, they advance up the road. "That's far enough!" I shout. They stop. "What do you want?" I asked. "Oh," they said, "we are just looking for supplies. Do you have any extra?" "No, I replied, move on!" "Sure," and off they went.

More discussion, still from the road area. A couple run up behind a seemingly natural cover and open fire on the house—and from the house comes a pitiful reply of a couple of .22s from the ladies. We must deceive the attacker, so that all will commit themselves and can be destroyed. If we had committed ourselves at first, their tactics would have changed. As it was, they staged a mass assault, all at one time, which is just what we wanted. Hold your fire, hold it, let the ones in front go past the explosive charges, the ones behind are over the charges now—detonate—the explosives work very well, the ones in front are stunned, quickly fire and fire again. Nothing moves. A body count, the same as were observed coming down the road. Looks like we got them all. Guards out, still max alert. I checked the bodies, a real dirty looking bunch, one has a sack full of paper dollars. What a fool! All of their worries are over, except for one still alive, but not for long.

Things are peaceful once again, sure had a job with the burial detail. We salvaged everything before burial, including the paper money. Think I'll wallpaper my bedroom. There are very few radio stations on the air, communications have really broken down. Everything is disorganized and there's no telling when the situation will stabilize. We'll just stay on the alert and do the very best we can under the circumstances. No person could ask more.

I often think of all the misery that has occurred and will continue to occur. The old, the weak, the sick, the very young, the defenseless, all assaulted for the things they might have that would be desirable. Once the restraints of society are off, the dregs of the human race come creeping out of their holes, the worst side of man comes out. I am thankful we were prepared and I believe we will survive mainly because we became familiar with arts, crafts, survival information, first aid, chemical processes, firearms, etc., all add up to insure, as in nature, The Survival of the Fittest!

Five Shop Machines Fold into a Portable Box

By C. A. VAN DERVEER

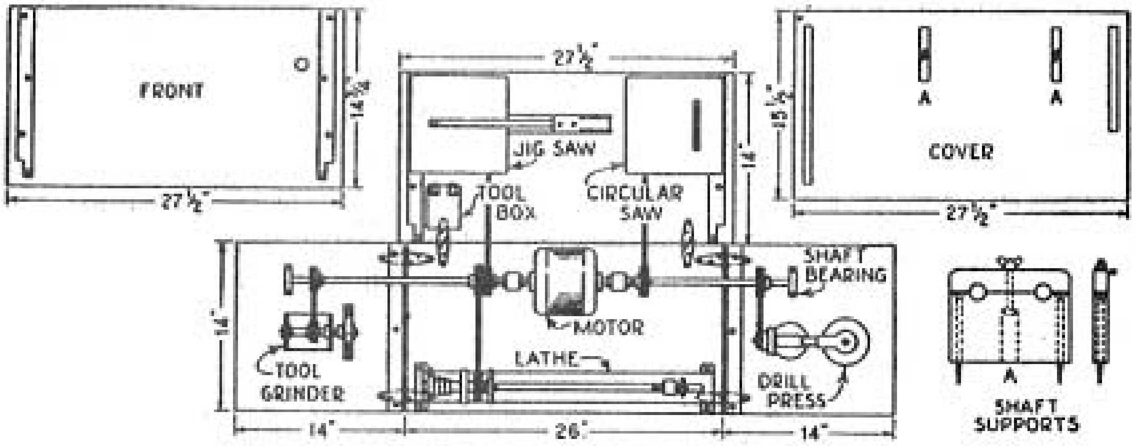
Popular Science 1936

A PORTABLE workshop containing a drill press, lathe, emery wheel, jig saw, and circular saw, which folds into a box the size of a tool chest and can be placed on the running board of an auto, may easily be devised by anyone who wishes to take his shop with him from place to place. It can be set up on a table wherever a 110-volt 60-cycle plug is available and is ready to operate within a few minutes.

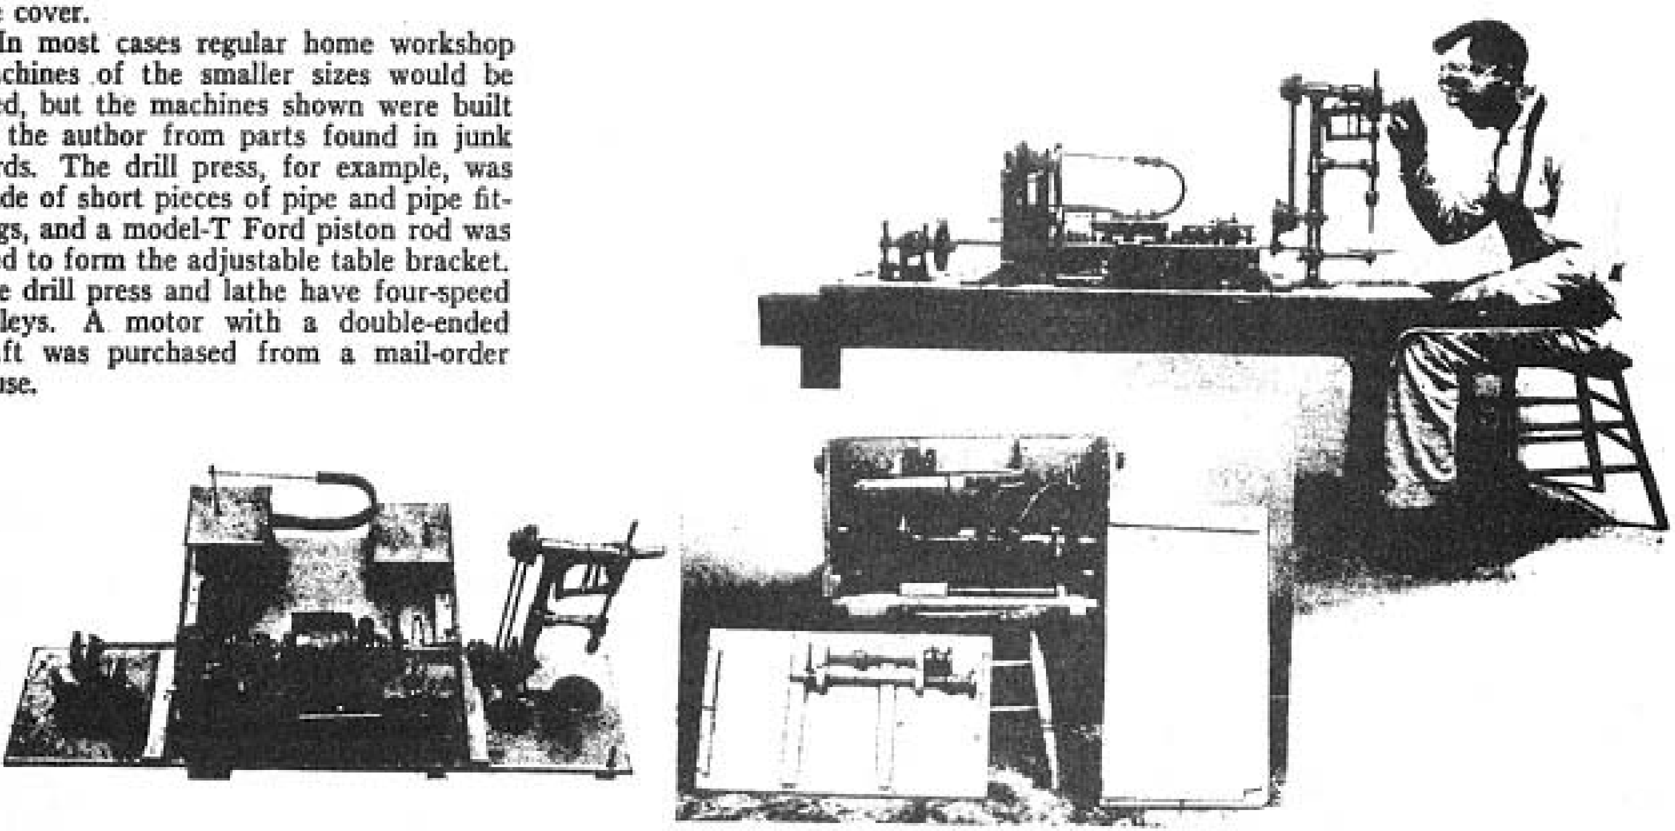
The photographs and drawing show the general layout. Ordinary ¾-in. boards are used throughout. Be careful that the various parts are perfectly square. It is necessary, of course, to put cleats on the boards to prevent splitting and warping; and these should be placed across the grain.

When the shop is to be moved, the shafts are uncoupled from the motor, removed from the bearings, and secured to the cover.

In most cases regular home workshop machines of the smaller sizes would be used, but the machines shown were built by the author from parts found in junk yards. The drill press, for example, was made of short pieces of pipe and pipe fittings, and a model-T Ford piston rod was used to form the adjustable table bracket. The drill press and lathe have four-speed pulleys. A motor with a double-ended shaft was purchased from a mail-order house.



The front and top or cover of the box are removed and the remaining parts are opened out flat by means of hinges so that the machines and motor may be set up as in the drawing above. The outfit is also shown in the photograph at the left



The machines set up for use and, left, how they are packed in the box. The shafts are uncoupled and clamped to the lid. The outfit includes a small lathe, jig saw, circular saw, grinding wheel, and drill press

CHICKEN OF THE SWAMP AND SUBSTITUTE SHRIMP

By Jim and Stephanie Watters

I've always liked frog legs, but I'd never thought much about finding them in the city until the slump. While driving home late one rainy night I kept seeing frogs of all sizes on the highway. When some nice bullfrogs started jumping in front of my van, I couldn't imagine where they had come from, but I couldn't stand to see all that good chow just hop away. I got on some streets where the traffic was slower, and just began stopping and picking them up. The big fellows would sit there starting into my headlights and I'd slip around behind them and grab them.

That really started me looking for frogs in town. I located all the ditches and ponds in the city limits. Some of them looked more like garbage cans than I would like, but when I went back late that night, I could see plenty of red eyes among the beer bottles. In one little pond behind our church parking lot, I counted over twenty pairs of eyes and took home twenty-four pairs of legs. That little depression doesn't even have water in it all the time, but it had plenty of frogs. The big ditches near the local high school and another church parking lot has kept us in frog legs for the past two summers. The boat-launching pads near the park are another good place. And the people at the restaurant within easy walking distance of our house don't know that the ditch behind their place holds better food than they sell. There are plenty of other good places, but I mentioned all these just to start you thinking of how many places you probably drive by everyday and never notice.

Let's say you've thought of a few places and you're ready to try your luck. How do you intend to catch the frogs? (And incidentally, they don't have to be real bull-frogs. Just take any frog that you think is big enough to eat. Leopard frogs and green frogs make good eating, too.) You can catch frogs with a hook and line, shoot them with pistols, rifles, shotguns, air-rifles, or bow and arrow, or net them, or club them, or spear them. I prefer spearing, or gigging, as we call it down here. Gig heads should be a part of your survival gear, anyway. Go ahead and buy a couple or be a real survivalist and make some. For a handle, I've known some folks to get by with a broom handle, but I prefer an eight to twelve-foot bamboo handle because, with it I can reach all the way across a ditch. For a light, I have done all right with just a two-cell flashlight but you'll do better with a head-lamp—it leaves both hands free—or at least a six-volt lantern. Stick your little two-cell in your hip pocket for a spare, along with some recycled plastic bread bags to put your frogs legs in. Sometimes I carry a folding wire fish net to keep them in and cut the legs off at home. But if you're by yourself I'd recommend cutting off the legs and carrying them in bags. Cut them off at the hump where the legs join the back-bone. You can eat the whole frog, as we have done, if you want to, but most of the meat in on the back legs.

Frogging is more fun and more productive with a friend. With one of you on either side of a ditch, you'll find a lot more frogs, because he can see them under the overhanging vegetation on your side and you can do the same for him. Also, a direct beam seems to hold the frogs better. Anyway, it's nice to have a buddy with you when you're scrounging around our cities at night. Frogs aren't the only things that come out at night, unfortunately.

Preparing frogs for the table is easy. Just slice the skin across the hump on their back, stick a finger under it and pull it off the legs like panty-hose. Cut through the leg bones at the hump and slit the belly back toward the legs. Cut off the feet, pull out the nerves that look like strings so he won't upset the wife by jumping around the pan, trim around the rear vent if you like, and toss him into a pot of water to soak a minute while I rest.

All right, it shouldn't take as long for you to do all that as it did for me to write it. I prefer to soak my game for a while before I cook it, and I always like to freeze my frog legs before cooking. Believe it or not, it makes them more tender. But neither the soaking nor freezing is really necessary. When you've washed off those beautiful frog legs—and even your hoity-toity mother-in-law will tell you how pretty they are—you may want to just toss them in the frying pan right away. That's easy enough. Just roll them in flour or corn-meal and fry them in deep fat, or just a little hot grease. Add a little salt and pepper and try them, and you'll see why I'm a confirmed frog-freak.

Now, about those substitute shrimp I mentioned in the title: have you ever tried crayfish? We call them crawfish down here, but whatever you call them, if you like shrimp you'll like these little critters, too. Chances are you'll find them everywhere you find bullfrogs because the bullfrogs enjoy eating crawfish, too. Crawfish are easy to catch at night by hand or with a little minnow net, or if you find the really big ones, a forked stick. There are other ways to catch them faster and in greater quantity but you ought to be able to catch enough to make crayfish cocktails while you're spearing the main course.

When you get home, drop them alive into boiling water. They're ready to eat when they have turned bright red, but cook them up to 10 minutes if you're going to use them in cocktails. Most of the meat is in the tail which will be easier to shell if you take the crawdads out of the boiling water and put them immediately into cold water.

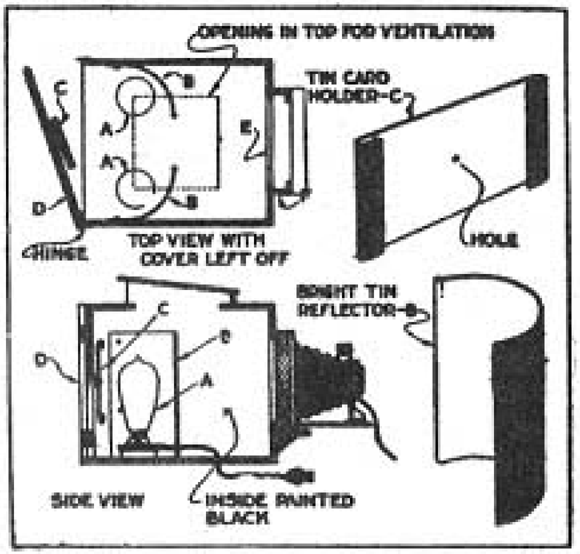
Well, there you have it—food good enough a gourmet or even your mother-in-law. You can begin now to learn important survival skills right in the city. There are many other good techniques you can learn to incorporate with these, if you'll just turn off the idiot box and get down to it. It's not enough to read how—you have to go do it yourself. Someday the simple survival skills you can learn now may help keep your family alive in hard times. But if it never comes to that, you can enjoy a sense of self-reliance while you chow down on that delicious free food.

Improvised Post-Card Projector and Enlarging Camera

From Popular Mech. 1919

AN outfit which may be used for either projecting picture post cards or enlarging photographic negatives was assembled as delineated in the illustration. An ordinary camera, which provides the lens and bellows, is required, in combination with a dark box which can be built in the home workshop. The method of construction is this:

Make a box about 8 in. square out of



An Ordinary Small Camera, Fitted with This Attachment, Becomes an Enlarging and Post-Card Projecting Camera

½-in. planed soft-wood stock. Nail the sides, but omit, for the present, the top and the bottom. The two openings thus left will be called the front and the back. Mount an 8 by 8 by ½-in. board, D, which constitutes a door, on the back with hinges and provide a hook to hold it shut. Cut a square hole, of the same size as that of the opening in the back of the camera which is to be used, in another 8 by 8-in. piece, E. This will constitute the front board. This front board is so cut that it fits in between the sides of the box instead of on the ends, as does the back. In the top, cut a square hole for ventilation. A hood is provided over this hole to prevent light being thrown forward.

When using the arrangement as a projector or magic lantern two 40-watt tungsten lamps, A, are required. Each lamp is mounted in a porcelain receptacle held on the floor with screws. A lamp cord, one end connecting the two lamps in multiple and the other fitted with an attachment plug, passes through a hole in the floor of the box. Form the two reflectors, B, of 8 by 7-in. bright tinned sheet-iron pieces, each having holes along one of its edges to admit of attachment. The reflectors are bent to a semicircular contour before mounting. The card holder is detailed at C. It is a piece of tinned sheet iron bent to the form shown so that it will hold a post card. A hole is drilled in its center for a screw pivot. It can then be fastened to the center of the back door and can be turned into position, for either horizontal or vertical pictures.

A washer is inserted on the screw between the holder and the door. The thickness of the camera body having been determined, a slide is fastened to the front board, as diagrammed, to support this body.

Before it can be used as a projector it must be adjusted to operate with the camera of the type and size available. The adjustment, which must be made in a darkened room, having on one of its walls a white screen on which the image will be projected, is effected thus: Remove the back from the camera and place the camera in the slide without extending the bellows. Open the shutter. Insert a card in the holder C. Light the tungsten lamps. Now move the front board, with the camera carried on it, back and forth within the box until the components are in focus, that is, until the most distinct image obtainable is reproduced on the screen. Then, illuminate the previously darkened room and nail the front board in

THE PROBABILITY OF NUCLEAR WAR

By Kurt Saxon Written in 1978

Although nuclear war becomes more pointless and suicidal each year, its threat looms ever larger. Logically, such a threat is remote. But since bureaucrats and politicians are seldom logical, nuclear war could occur at any time.

However, there are some misconceptions concerning nuclear war which makes its likelihood seem greater than it actually is at this time.

First, we are led to believe that Russia has a nuclear defense setup which would save up to 80% of its populace. Such estimates are absurd. Even if Russia had shelter capacity for the 200 some odd million people that figure represents, this would only make matters worse.

Surviving a major nuclear attack is only the beginning. The devastation of the cities, industries, croplands, etc., would insure the certain death of the majority of survivors.

Many seem to think they would simply load this vast horde of survivors on transports and have them invade America. But aside from highly mobile weapons systems dodging American missiles on the world's oceans, Russian shipping would be pretty well wiped out.

If the Russians got in the first punch and destroyed America's capability to fight outside our borders, so what? To destroy America as a functional system is no guarantee of any successful invasion.

The examples of past invasions of Russia and China should convince anyone that conquering continents takes more power than any nuclear survivors will have left.

America is vast, 2700 miles wide by 1600 miles thick. On the occasions I've flown from coast to coast, I've been impressed and even bored by the emptiness of our land. The logistics of subduing all that space would be beyond the capability of even present-day Russia. Nuclear survivors would not even attempt it.

Besides, the Russians remember the problems facing the German invaders and the damage done to them by guerrillas. The Russian guerrillas were amateurs, compared to Americans. And the Americans didn't have much luck subduing the Vietnamese. Modern techniques of guerrilla warfare make the armed civilian more than a match for any army of occupation.

America has more weapons in civilian hands than are owned by the rest of the world combined. Civilian disarmament is only a Liberal's fantasy. Books on improvised weaponry are so widely distributed that even total confiscation of guns, if possible, would only be wasted effort.

Total surrender to Russia by our government, before a bomb was dropped, would serve only to destroy our government and bring on nationwide anarchy. No Russian general would willingly send his men into a mess like that.

Too many people see Russia as a monolith just waiting for an excuse to attack. The reasoning is that as they get hungrier they will have less and less to lose by attacking.

This would be logical except for the Chinese. The Mongols were the most successful invaders of Russia. Their sheer numbers made them invincible. Modern Chinese see the Mongols as their ancestors, although, technically, they weren't. At any rate, the Chinese believe they have a right to Siberia and other areas controlled by Russia.

The Chinese and the Russians have hated each other for centuries and no similarity of ideology will change that. Moreover, each considers the other, not America, to be the major threat to its existence.

Russia has more men on the Sino-Soviet border than in the Warsaw Pact forces. Estimates of Chinese military personnel and civilian militia on or near the border, prepared for invasion, are as high as 100 million.

Russians are so certain of a Chinese invasion that they won't allow a Chinese restaurant in their land, lest it harbor a spy. That's just a little item the position thus determined. These adjustments having been made, paint the box, inside and out, a coat of dead black. Everything should be painted black except the reflecting surfaces of the tin reflectors and the incandescent-lamp bulbs. The front board having been fastened, subsequent focusing can be effected by shifting longitudinally the lens board of the camera. The image of any sort of a picture that will fit in the holder can be reproduced. Colored post cards will project in their natural tints.

To make enlargements with the same box, a few minor changes are necessary. When employed for enlargements the tungsten lamps, which are required for projection, are not used. They may, however, remain in the box and can be disconnected from circuit by unscrewing them a few turns. The negative, or film, which is to be enlarged, is held in the opening E. Where a film is to be reproduced, it is held between two pieces of glass which are fastened to the inside of the front board with small clips. If a glass negative is used, the two additional glass plates are unnecessary. If the negative does not fill the opening in the camera, a mask cut from heavy black paper will be required to cut off the light.

The light for the enlargement is furnished by another tungsten lamp mounted in a porcelain receptacle which is screwed to a board which constitutes a base. This light source is moved about in the house until it is directly back of the opening E in the front of the box and until the light is distributed equally over the entire negative. To focus, move the camera backward or forward. While focusing, use a yellow glass, or ray screen, to cover the lens. When focusing has been completed, the shutter is closed and the ray screen removed. Then stop down the lens to bring out detail, and expose.

Completely Homemade Ice Cream

by Susan Kramer and Mike Thompson

Commercial ice cream is one of the most adulterated foods on the market. Ethylene glycol (same chemical they use in anti-freeze), formaldehyde, and rat poison are just a few of the goodies you may be eating in your luscious looking sundae. So why not take the time to make your own ice cream?

Get yourself a nut and a bolt, a quart

which happens to be true.

The Chinese are just waiting for Russia to get into it with America. Then they will pour across the Sino-Soviet border in waves of millions and millions, through the rain of atomic missiles, over the fortifications, and then on to Moscow.

The Russians know that a war with America would mean an automatic war with China. No matter how desperate they become for food and resources, an adventure against the Americans would only set them up for slaughter by the Chinese.

So don't be bothered by Russian threats and political doubletalk over here. But don't discount nuclear war as an impossibility.

America, Russia and China are becoming desperate for resources. Russia and China have oil enough for their immediate goals, since only a small percentage of their supply is used by civilians. But their future economy and military needs demand that they latch onto the fabulous wealth of Africa.

American politicians are just as intent on grabbing Africa's resources as are the others, but they are not so obvious about it. Before he left office, Henry Kissinger was over there trying to get the Rhodesians to sell out and leave. His next move would have been a similar arrangement with South Africa. He felt confident that with the African whites out of the way, he could make solid agreements with the black nationalists. Then, in gratitude to Kissinger for removing the whites, the blacks would sell their resources to America, rather than to the Russians or the Chinese.

Of course, the Russians and Chinese are arming the blacks and promising them all the weapons, and even foreign personnel, to do the job. Whoever wins, it will be the same for the blacks as it was in the 19th century. Whether a mine is operated by the Americans, Russians, or Chinese, the foreigners will get the minerals and the Africans will get the shaft.

During the 19th century, Europeans divided Africa among themselves and there was little friction. But three major powers who need so much will not make such divisions. Each group wants it all.

I believe Africa will be where it really begins. One confrontation after another is inevitable. As the Russians commit more men and resources to Africa, the Chinese will send more men to the Sino-Soviet border.

Sooner or later, the Chinese will invade and the Russians, fearful of America, will try to knock us out so we can't invade. Then everyone with nuclear missiles will dump them on whatever foreign devil is handy.

This doesn't worry me since I've taken nuclear war into account. Survival shelters of my design will keep the inhabitants safe for months. In coming issues I'll detail such plans which any capable person can utilize.

Proposed and present Civil Defense survival shelters are mainly death traps, both the family and the group types. A two-week survival shelter is an absurdity. Your need for shelter and guaranteed sustenance will last for months, not weeks.

The idea is to have homes with as much area underground as above. A foot of concrete, steel and earth between the shelter area and the aboveground quarters would insure a family's survival from anything but a direct hit.

If you plan such a shelter, here is an instance where you should not tell your neighbors unless they too show the same interest in a permanent underground home. In the meantime, you could still urge them to make such preparations as I've outlined before. A person who prepares for one calamity is already well on the way to preparing for a worse one.

Of course, you probably couldn't keep such preparations secret from your neighbors anyway. But don't worry about that. Once you are tucked in, you can wipe out anyone upstairs at the push of a button. Holocaust, rioting, famine, plague, will not affect you. You can stick your head out often enough to see how things are going.

In future issues I will detail survival homes anyone can build themselves with little money. But unlike the publicized fallout shelters, useless now except for storage, these will be livable and an actual part of the home. In this way, you won't see such a shelter as simply an extra expense in your survival budget.

jar, and any gear driven hand-drill. If you don't have a hand-drill, you may want to read instructions for a home-made one on page 122 of the "Survivor", volume one. Punch a hole the size of the bolt you plan to use in the center of the jar lid. Starting from the bottom of the lid, push the bolt through the hole and fasten with a nut. Clamp the end of the bolt into the hand-drill. Now fill the quart jar with an ice cream mixture consisting of creamy milk, sweetening and flavoring. For flavoring you might like carob, chocolate, fruit or vanilla beans. Vanilla beans must be cut into small pieces and heated in milk to extract the flavor. Do not use any extracts containing alcohol as this will screw up the process. Next fill up a container (four quart size is ideal) with an ice and salt mixture with the ratio of about three parts ice to one part salt. Salt in the ice makes it possible to obtain a temperature of below 32 degrees. Place the jar with the ice cream mixture into the center of the salt and ice container. Attach the drill and begin turning very slowly for the first five minutes. Then a faster speed can be maintained. You should open the jar when the mixture begins to get hard, and scrape the sides of the jar so that the mixture can harden throughout. When the entire mixture looks just like ice cream, you're done!

* * *

In the meantime, price home power plants. A gasoline or methane driven generator will supply the electricity. Several 55 gallon drums filled with fuel and water will last for months if used sparingly.

Grains bought in bulk and sprouted for humans and rabbits will insure against hunger. Good books, tools and compatible shelter mates will help pass the time.

WEATHER FORECASTING

By DON CART

Interrupted communications will mean interrupted weather service. Be prepared to forecast your own weather. The U.S. Weather Bureau has prepared the following chart.

Barom'tr	Wind from	Weather Indicated
High and steady.	SW to NW	**Fair & little temper'ture change for 1 or 2 days.**
High & rising rapidly.	SW to NW	**Fair followed by rising temperature & rain w/in 2 days.**
Hi & falling slowly	SW to NW	**Rain in 24 to 36 hours.**
Very hi & falling slowly	SW to NW	**Fair and slowly rising temperature for 2 days.**
Hi & falling slowly	S to SE	**Rain within 24 hours.**
Hi & Falling rapidly.	S to SE	**Increasing wind w/rain in 12 to 24 hours.**
Hi & falling slowly	SE to NE	**Rain in 12 to 18 hours.**
Hi & falling rapidly	SE to NE	**Increasing wind w/ rain in 12 hours.**
Hi & Falling slowly.	E to NE	**Summer, light winds, fair; winter, rain in 24 hours.**

Lo & rising rapidly	Going to W	**Clearing & colder.**

A home weather station will be a definite advantage to you. First you will need an aneroid barometer. If you buy a new barometer, do not bother setting it according to the directions. All you will be using it for will be to determine whether the barometric pressure is rising or falling. You will also need a wind direction indicator. You can use a tree or a vane. You don't need to worry about wind velocity; just note whether it is light, medium, hard, or extra hard.

You will also need two thermometers. Mercury thermometers are more accurate than alcohol thermometers, but are also more expensive. The first thermometer is to record the temperature. The second is used to measure relative humidity.

To make the second thermometer serviceable to measure relative humidity, attach a cotton wick to the bulb at the bottom of the thermometer. Next bore a hole at the top of the thermometer (be careful not to break the glass tube). Attach a round handle to the thermometer in such a way as to allow the thermometer to swing freely.

To use, record the temperature on the thermometer. Wet the wick with alcohol (water will do, but is not as good) and twirl the thermometer for thirty seconds. Record the temperature which will be lower. Divide the higher temperature into the lower, subtract the result from one, and multiply by 100%. This will give you the relative humidity. For example, if the higher temperature was 65°—60+65=.12; 1-.12 =.88; .88x100%=88%.

You may wish to have a rainfall indicator. Build a wooden box so that the inside height of it is the height of the beaker you will use. Have the top slanted away from the center. Bore a hole in the center of the box, the hole being the same size as the diameter of the beaker. (Drill several small holes in the bottom of the box for drainage). Put a door in the box. Set the box with a beaker in it out in the open and you're all set.

Keep a log of your weather observations and record them every 12 hours.

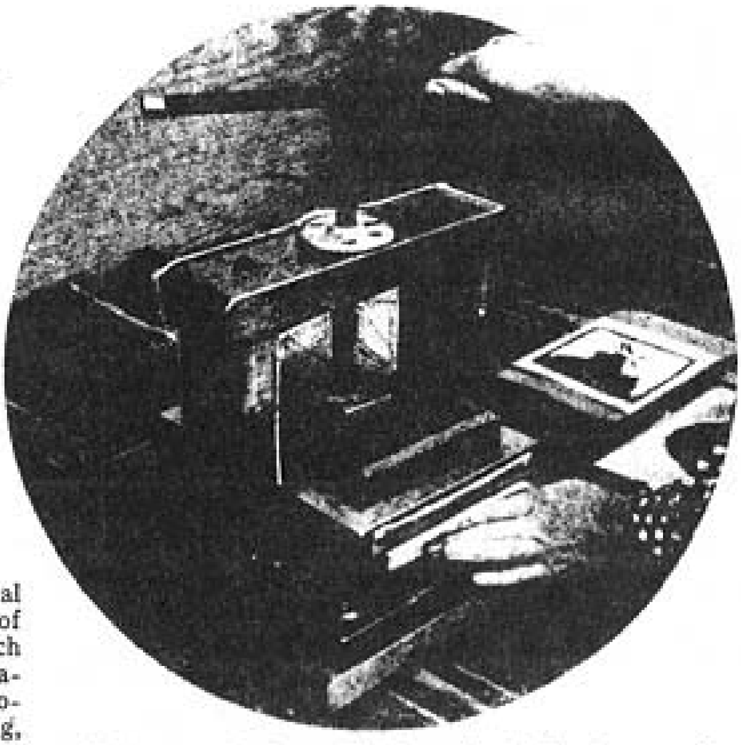
Two Helpful Hints

1. Keep your thermometer in the shade, protected from the wind for a more accurate reading.

2. Turn your television to channel 13; turn the brightness down all the way. Now turn to channel 2. When a tornado is in your area, the television screen will become very bright.

Utility Press

FOR BLOCK PRINTING



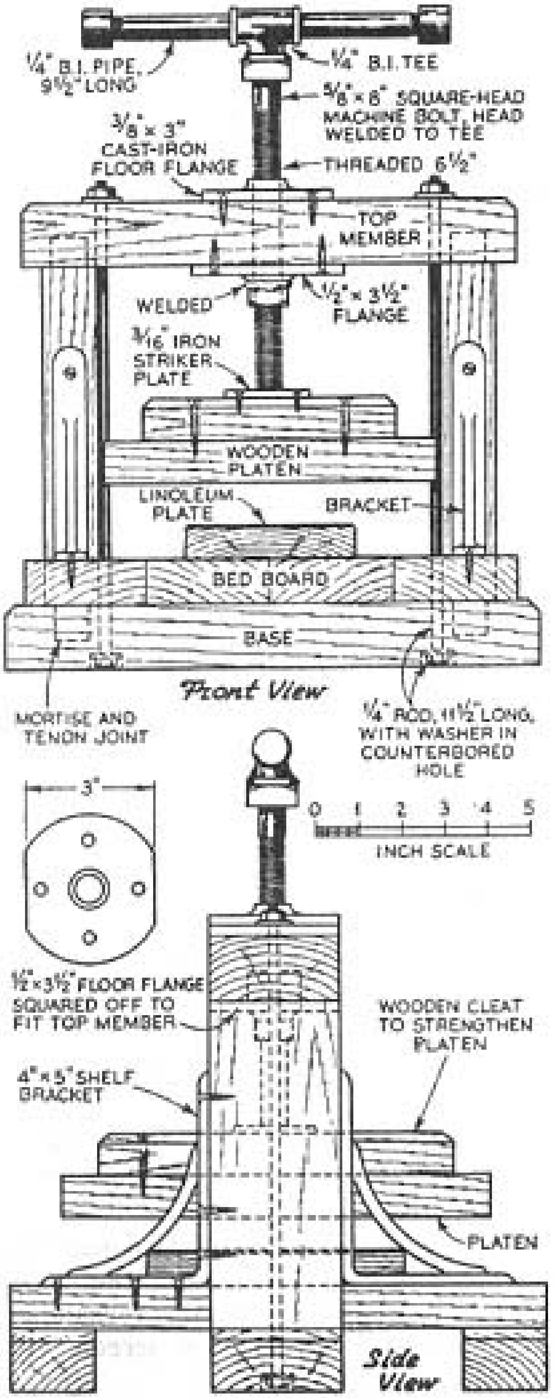
Making a print from a linoleum block. The bottom of the platen is padded with cloth thumb-tacked to the ends

THE design of this practical screw press is the result of considerable experience and much experimentation in the use of various types of presses for linoleum-block printing, bookbinding, veneering small panels, making inlaid pictures, and other gluing and pressing operations. The bed will take work measuring 7 by 10 in. or smaller.

Either oak or maple is used for the wooden parts, and the total cost should not exceed three dollars. The entire assembly is screwed and bolted together. Glue is used for the mortise and tenon joints, and four shelf brackets stabilize the side supports.

The working drawings show the size and position of all members, and the list of materials has been determined from actual working conditions. Only two suggestions are necessary to assist the novice. First, the two outside bed boards are to be scribed and cut to fit tightly around the side supports; second, the platen is to be grooved at the center of either side deep enough to form a guide working against the ¼-in. rods.

It is an excellent plan to oil, varnish, or shellac the wooden parts.—

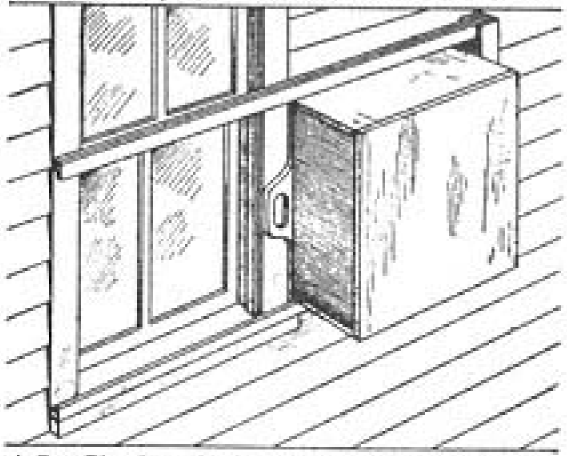


List of Materials

2 pc. 1½ by 2 by 12½ in., for outside bottom supports.
1 pc. 1½ by 3 by 12½ in., for middle bottom support.
4 pcs. 1 by 2⅜ by 12½ in., for bed.
2 pcs. 1¼ by 3 by 9½ in., for side supports.
1 pc. 1½ by 3 by 11½ in., for top member.
1 pc. 1 by 7¾ by 10 in., for platen.
1 pc. 1 by 6 by 8¾ in., for platen cleat.
NOTE: This material is either oak or maple.
2—11½ by ¼-in. hex-head rods, with washers and nuts.
4—4 by 5-in. wrought steel japanned shelf brackets with 24 flathead black wood screws, ¾-in. No. 6.
1—8 by ⅝-in. squarehead machine bolt, threaded 6½ in., with nut.
1—½ by 3½-in. cast-iron floor flange, to be welded to ⅝-in. machine-bolt nut.
1—⅜ by 3-in. cast-iron floor flange, reamed to form collar for bolt.
1—¼-in. black iron tee reamed to receive ¼-in. pipe handle and welded to head of ⅝-in. machine bolt.
1—¼ by 9½-in. black iron pipe, threaded both ends for handle.
2—¼-in. black iron pipe caps, for handle ends.
1—2 by 3/16-in. flat iron for striker plate, drilled and countersunk for four No. 6 flathead wood screws.
24—1¾-in. No. 6 flathead bright wood screws, to fasten bed to bottom support; 6—⅝-in. No. 6 screws, for striker plate and ⅜-in. floor flange; 4—¾-in. No. 6 screws, for ½-in. floor flange; and 4—1½-in. No. 6 screws, to fasten platen cleat to platen.

A Window Refrigerator

A simple method of constructing a window refrigerator that will not obstruct the light is shown in the illustration. A box was made the width of the window and was fitted to slides fastened outside the window on the side of the house. The exposed sides of the box were inclosed completely and the inner side was provided with two sliding doors. A handle was fitted to the side of the box so that, by reaching out of the window, the box could be drawn in front of the opening easily. Several shelves were fitted into it and the materials stored were not easily molested. Trunk casters attached to the bottom of the box improved the action on the lower rail.

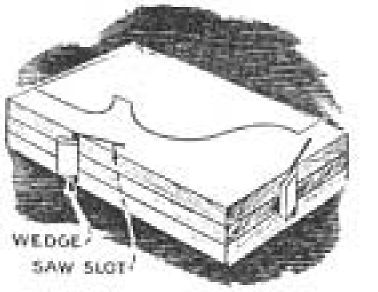


A Box Fitted on the Outside of the Window to Slide in Grooves Provides a Convenient and Inexpensive Refrigerator for Winter Use

How to Cut Duplicate Pieces on a Bandsaw

From Popular Mechanics 1928

It is often necessary to cut out a number of duplicate pieces on a bandsaw. Sawing three or four at once means, of course, quite a timesaving, but the pieces must be securely held together during the operation. An easy means to this end is to cut two or more tapered slots, about 1 in. deep, in two adjacent edges of the material as indicated and then drive a small wedge into each slot. The wedges will hold the pieces together firmly and prevent their slipping apart while the sawing is done.



SERIOUS SURVIVAL FISHING

By Jim & Stephanie Watters

Serious survival fishing is based on these assumptions: 1. You need enough fish to feed a hungry family; 2. Due to some risk factor (such as hostile survivors or unsympathetic game wardens) you don't want to spend too much time at the scene; 3. Due to those same risk factors you need methods that leave no sign of your activities in the area.

These are serious problems that rule out most conventional fishing methods. But poor folks down here in the South have been getting around them for years. Most of them use some type of trap.

One of the easiest traps to make is constructed from old automobile tires—one of America's most plentiful unnatural resources. Lace the sidewalls together with wire or heavy string. Stand the tire up and cut three or four holes into the tread about 2½ to 3 inches across. These will be for fish to swim into to hide or to eat the bait. Now, directly down from the big holes you cut, gouge several small holes into the tread, and it wouldn't hurt to gouge a few into the sidewalls if you're not very strong. These are to let out the water when you go to pull up your trap. Keep them small or you'll lose the tasty crayfish that often go into the tire along with the catfish, perch, turtles, eels, and crabs. Tie a rope or wire around the tire at the top where you cut most of your entry holes. That way when you quickly pull up your catch, they will not be able to swim out.

Tire traps sometimes work without bait because fish use them for hiding places, but they're most effective with bait. Spoiled left-over food, rabbit guts, almost anything you can think of will work. The worse it smells, the more action you'll get.

Set your tire traps in the bend of a creek where the water is deepest, and conceal the rope leading to it. Try not to leave too many tracks in the soft mud and check your traps from a different approach each day. When you clean your catch, save the guts and scraps for bait; don't leave scales on the bank.

If you can scrounge enough old wire fencing, you can make a very effective trap that I prefer to all others. Make a cylinder of the fencing about 10-20 inches in diameter and three to four feet long. (I have used bigger ones but they are hard to carry along a woods path and require much deeper water for complete concealment). Over this cylinder of heavy fencing wrap some small mesh stuff like that used for chicken coops or rabbit hutches. Close up one end of your cylinder completely.

Next, make a funnel of the small mesh wire and fasten it into the other end. Leave an opening in the end of the cone of 2½-3" diameter. Now to get your fish out more easily, cut a flap in the small mesh wire somewhere on the side of the cylinder, and cut out one mesh in the heavy form fencing beneath it. Tie it shut with three or four pieces of soft copper wire. Tie a rope or wire (which is easier to conceal) to your basket trap and head for the water with some good stinking bait tied up in an old sock or even table scraps in a paper sack (so they won't wash away too quickly). Follow same directions as with tire traps.

Basket traps are also very effective when placed in culverts or drainage pipes or any narrow place in a creek or canal. We sometimes catch muskrats in them. If you want more rats than fish, use apples and cattail roots for bait, and make your funnel opening a little larger. Or you can catch big snapping turtles by using a bigger funnel and a bloody bait.

The muskrats are very good eating if you remove the musk glands in their hind legs. Their fur is soft and very long-wearing. The snappers are good eating; all turtles are edible, but the snapper is especially good. You can expect to catch all kinds of turtles in a basket trap. I don't recommend stink turtles or horse turtles, but the others aren't bad if you stew them.

If you can't find the fencing to make the cylinder for a big basket trap, you can make a box frame trap of wood and cover it with any small mesh wire—the smaller, the better. Instead of a funnel opening, make it like an inverted pyramid. These traps work well, too, and are easier to conceal in shallow ponds.

If you're living out of your backpacks and can't scrounge any tires or fencing for traps, you can still get plenty of fish for your family. Find a black walnut tree and pick up a sackful or a shirtful of walnuts with the husk still on the nutshell. Pound them up, tie them into your shirt or bag and with the line attached, throw into a pond or slow-moving stream. In just five minutes you'll be able to pick up fish coming to the surface. You can use the mashed up berries and leaves from a chinaberry tree also. It's very common around old homesteads here in the south. I've also heard that crushed poke salad roots and berries will work but I've never tried them because I know they're poisonous to people too. Whatever you use, when you get enough fish, pull out the bag or you will destroy all the fish there, and that's stupid.

There are other methods of serious survival fishing, but these are the ones I'm best acquainted with because they are best suited for my area. In your retreat area, you should determine which type would be best for you. If you are going to be near the ocean or even a little creek, find out how the local poor people trap fish and crabs. I got a lot of good information on illegal but effective fishing methods direct from our local game warden! If you have the money, but a few commercial crab pots or fish traps and use them for a pattern to build more.

Whatever method you use, if you do it right, you'll catch more fish with less work than you will with hook and line. And most important, you can do it without as much chance of giving your location away to roving scavengers. Here on the east coast, it is definitely a better way of getting protein under survival conditions than trying to hunt small game. It's easier and safer for the beginner or the old expert. So save your ammo and try some SERIOUS SURVIVAL FISHING!

MINI AND MAXI SURVIVAL KITS

By Alfred Orel Norton

The mini and maxi survival kits were developed by Ron Hood who operates a survival school in southern California as well as teaching survival courses at the University of California at Los Angeles.

One should always carry the lightweight mini kit on one's person: either around the neck or in a pocket. The kit's contents may be placed in a 35 mm. film canister. The kit is useful for general camping as well as personal survival. The kit's contents are: 5 windproof and waterproof matches, 2 exacto razor blades, 15 feet of 8lb. test monofilament fish line, five number 14 trout hooks, five B.B. split shot, fifteen feet of number 24 brass wire, 4 small safety pins, five feet of 1" adhesive tape, one dime, one shoe lace, five aspirin, a bouillon cube, a needle, a toy balloon (long), a match striker, and a whistle.

The windproof and waterproof matches, which may be split down the middle to produce ten matches, are invaluable in starting a fire. They burn for seven seconds giving off a very intense flame. Of course, one brings the small portion of a match striker to ignite the matches. If facing extremely difficult weather conditions, such as, rain with high wind, these matches will provide the spark for a warm fire.

One can attach an exacto blade to a

thin piece of wood by using some of the adhesive tape. The knife will aid one's cleaning a fish, and will also serve as an eating utensil. One can also use the knife to make incisions if bitten by a poisonous snake.

Since fish are a good source of protein, and in case of being marooned at sea a source of fresh water, the fishing tackle in the mini kit is extremely useful. Monofilament fishing line is strong and compact. If not used for fishing, one can use it for tying, sewing, or making a snare. The B.B. shot serve as sinkers. One can also gig the fish by hooking the fish anywhere and pulling it in. After all, your life is at stake. All's fair in survival.

The brass wire can be tied in an elliptical loop to form a snare. Also it can be used for general tying or binding. This wire could be used in lashing sticks together to form a large spear.

The safety pins are invaluable in the repair of rips in clothing or equipment. Also an open safety pin can serve as a fish hook.

Adhesive tape helps in first aid. By forming butterfly clips, it can be used to close wounds. This means that one need not have a suture kit, complete with cat gut. One can also tape blisters which are easily formed on the trail. In winter, snow blindness, produced by the snow's reflections, can cause total disability for several days. The adhesive tape can be used to make snow goggles by taping over regular eye glasses leaving only a slim slit for visibility.

The dime can be used to call for help. It also makes a fishing lure, attracting fish by its reflection.

Not only can the shoe lace be used to carry the mini kit around the neck; it is also useful as a bow string for a fire-making bow. In order to use the bow, one attaches the shoe string to both ends of the branch or bow, allowing enough slack to permit it being twisted once around the drill. By turning the drill over the string the resulting heat will ignite the tinder in the fire board's notch. After the tinder's ignition, remove the board and fan the tinder until it bursts into flame.

The bouillon cube provides salt and can be used to flavor wild foods.

The needle is invaluable in removing splinters and draining blisters. By using the fish line or thread from a garment one can use the needle to sew. If magnetized the needle can serve as a compass needle.

The balloon serves as an emergency canteen It will hold up to three or four quarts of liquid. A tied-off short sleeve will make a carrying sling for the filled balloon.

help. It saves one's wind and is more effective than shouting.

The Maxi kit can be carried in a coffee can. Together the Mini and Maxi kits offer the full range of survival skills. The contents of the Maxi kit are: four feet of surgical tubing, a file (half of a 6" file), a plastic tube tent (1 man), a whistle, compass, knife, thirty feet of nylon cord, a candle, a Mallory flashlight, half a road flare, 2 or 3 zip lock bags, and a small can.

By punching two holes in the coffee can, one can insert a length of wire and carry it easily.

One can use the tube tent and surgical tubing to construct a solar still. Puncture a pin sized hole in the tent at a point which will be over a water container. After digging a 2½' wide by 2' deep hole, line the hole with vegetable matter. Place the coffee can at the center of the hole below the hole in the plastic. Support the plastic with rocks. Using a stone have the plastic about two to three inches above the can. Before using the plastic one should roughen one side using sand or a rock. When water begins to drip, be certain it's falling into the can. The surgical tubing allows drinking of the water without disrupting the distilling process. Incidentally, the solar still will produce up to three pints of water per day. Several stills can be made by cutting the tube tent, for one needs at least two quarts of water per day. The zip lock plastic bags can be used as reserve canteens in addition to the balloon.

The surgical tubing can be used for the motive force for snares or can be used to make traps or a slingshot. Also it will serve as a constriction band in first aid, such as for snake bite.

The file, preferably a bastard file, can be used for flint and steel fire making. It also can be used to sharpen knives and offers a good surface for striking matches. Finally, the file can be used for making wood or bone tools.

The tube tent (3 ml. thick), made of clear plastic, offers shelter and serves as a ground cloth or rain tarp.

When using the whistle, blow three times—the international distress signal. Whistles are useful for signalling other members of the party and scaring away animals, such as, cattle.

A Silva compass is essential for navigating. Such compasses range from the Polaris ($4.50) to the Ranger ($24.95). All Silva compasses have an adjustable bearing marker and a straight edge. This makes taking bearings, back bearings, allowing for declination from true North, and orienting a map much easier.

A knife is the most important survival tool. The knife should be of high quality, such as, a Swiss Army Style by Victorinox or Wenger. The Buck hunting knife is acceptable.

The thirty feet of nylon cord should be at least 260 pound test. One can use it to erect the tube tent by tying the cord to two trees and suspending the tent on the cord. One can hang food over a tree limb, hopefully keeping it out of reach of bears and other varmints.

The candle is useful for light. A scented candle is preferable. Be careful that the candle does not tip over. One should not have the candle in the tube tent as tents are extremely flammable. The candle Will heat a small container of food or start a fire in wet conditions.

The two cell Mallory flashlight is compact, durable, and can be held in the mouth, leaving one's hands free.

A road flare costs about 69 cents. One only needs to carry the top half end with striker. It can be used for emergency signalling or for starting a fire in very wet conditions.

Zip lock bags serve not only as emergency canteens, but also as containers for wild food stuffs or preserving freshly caught fish.

The small can serves as a container for other Maxi kit components. It also can be used as a canteen or as a cooking pot.

In order to cut costs, make four or five kits. One can include in the Maxi kit a wire saw for cutting firewood and constructing a shelter. Also one can bring some Chia seed in a small salt or pepper shaker. Chia seed is high energy concentrated Indian food.

Lois and David Bassett in front of home.

Family living in plastic house

WAHKON, Minn. (AP) — David and Lois Bassett and their three children are snug and warm, even though several layers of plastic sheeting is all that separates them from temperatures as cold as 48 below zero.

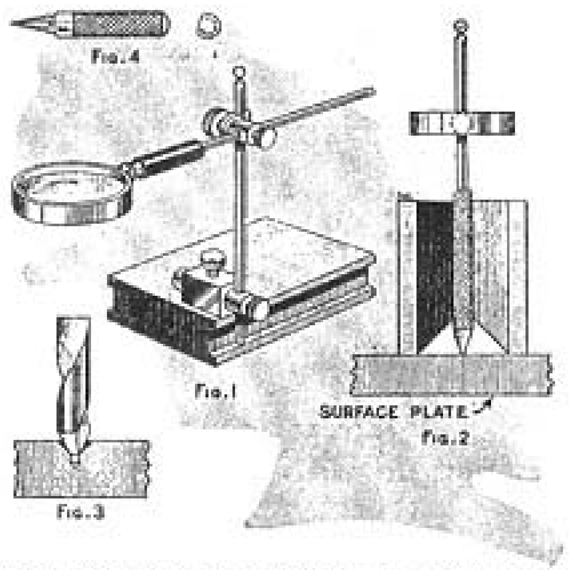
The Bassett family is spending one of the coldest Minnesota winters on record in a shelter made of tree branches covered with polyethylene sheets.

Bassett, 25, said the winter weather scared the family a little, but they wanted to get onto their own land so he built the shelter near Mille Lacs Lake in central Minnesota in November.

Kinks on Accurate Drilling

From Popular Mechanics 1928

I have been using a few kinks in laying out jig work for the drill press with great success. A large magnifying glass, held by a clamp so that the worker's hands are free, is better than a small one. One method of holding the glass is shown in Fig. 1. It can be set to any angle. If no precision center punch is available, the surface gauge or a V-block can be used as in Fig. 2. This keeps the punch at right angles to the work. A flat scriber of the kind shown in Fig. 4 should be used, as a round one sometimes causes inaccurate work. The punch should be accurately ground to a sharp point, which will facilitate marking the work at the intersection of two lines. Use a center combination drill of a diameter smaller than that of the center-punch mark, and make the angle sharper. For instance, if the center punch has an angle of 60°, that of the drill should be about 70°. Then follow this up with a drill like the one shown in Fig. 3. This has a tendency to make the drill follow the hole. If dividers are used, keep them sharp at all times. Whenever possible, use a scale graduated in fiftieths or hundredths of an inch, because the lines on these scales are finer than those on more coarsely graduated rules. Such fine graduations enable you to set your dividers more accurately. If you are not sure of the accuracy of a layout, drill small holes, that is, smaller than the finished size, insert the drill rod of the correct size and measure over all with a micrometer. If there is any error, use a round file to enlarge the holes so that the next-size drill corrects the error. I have found that it pays to blue the work, even though it costs more than rubbing bluestone on it, as this enables you to see the lines more clearly. If the above rules are strictly followed,



Sharp Tools and the Application of a Few Handy Kinks Will Help in Drilling Accurate Holes

SURVIVAL AND THE PARANOID

by Kurt Saxon

..."**One suggestion**; you should have the newsletter folded the opposite way. The large title attracts the attention of the mail people and people's family. I don't want everyone to know that I'm stocking up and thinking they can come to me for help. So please have THE SURVIVOR folded backside out"...

..."**I'm also wondering** if it is possible to have a subscription to your publication, THE SURVIVOR, and/or back issues, sent to us in plain envelopes, First Class, if necessary. Inasmuch as we live in a very conservative community, receiving your publication in a plain envelope would prevent alarming our local postmaster!"...

The above two writers may not be clinically paranoid but they demonstrate the simple inconvenience of paranoia. Both are so afraid of their own neighbors that they will miss out on THE SURVIVOR. No big thing in itself. But what else are they missing out on just because they don't dare let their neighbors in on their preparations?

The term "paranoid" is used constantly but hardly understood. The clinical definition of paranoid is one with delusions of grandeur coupled with feelings of persecution. (A lesbian is a mannish depressive with delusions of gender—pass it on). A paranoid believes he has gotten to the hidden truths of matters most important to him. He also believes that such knowledge makes him dangerous to those actually running things.

Believing there are enemies all around, fantasizing about plots and such, gives him a feeling of importance, of being in the know. But that feeling of importance is counteracted by the terror of the realization that one's enemies will step on him like a bug once he learns enough to be really dangerous to them.

Paranoids can't accept our social decline as a result of climatic change, surplus population, reduced resources, mental defectives and other natural influences which have been knocking out civilizations throughout history. No, paranoids see a plot behind the whole thing.

Some group, easily identifiable to the initiated and aware, is manipulating civilization. Our collapse is imminent. THEY are destroying everything THEY can't control when the time comes. Then, THEY will step in, run up THEIR flag and assume complete control. THEY will then destroy all those who anticipated THEIR fiendishness.

Of course, these Agents of Darkness have sympathizers in every neighborhood. THEY are also entrenched in the Justice Department with links to every local police station and dog pound in the United States.

So the idea of surviving civilization's collapse is actually incomprehensible to the paranoid. He may play at survival but THEY will win in the end. Of course, it all depends on security.

To the paranoid, his only chance lies in secrecy. If a few hundred of the right type can survive, in spite of all the traitors planted in their midst, good will eventually triumph.

The above doesn't fit every paranoid but too many hold to this general pattern.

When I began THE SURVIVOR, an old man wrote to me about his homemade security system, his advanced age and his ability to survive whatever adversity might strike. I thought he was such a fantastic old man I wanted to share him with others as an example of self-reliance in old age.

I printed his letter and address, thinking he would like to correspond with elders in like circumstances, or young folk needing a granddad figure. As soon as he got the issue with his letter in it he sent me a screaming note about how I'd exposed him to the world, lowered his property values and generally put him in jeopardy.

I answered saying that no one else within over a hundred miles of his town took THE SURVIVOR. If his homemade security system was offensive to a and the tools are kept in good condition, no trouble will be experienced in drilling holes within limits from .003 to .005-in. center-to-center distance.

Fixture for Forming Wire Links

From Popular Mechanics 1928

A Simple Jig Which Will Facilitate the Making of Links of Equal Size

An inexpensive fixture for forming eyes or loops in wire links is shown in the accompanying illustration. It is designed to be held in a bench vise and consists of a block, A, into which are fitted two pins, the distance between their centers being equal to the distance between the centers of the loops or eyes to be formed. Two smaller pins, also driven into the block, locate the preformed wire centrally with the eyes. A hole, D, equal in depth to the length of the wire forming the eye, is drilled in the end of the block, and an adjustable stop, E, is tapped into the end as shown, and locked by a nut. The lever L, which is used for forming the link eyes around the pins, has a pin, G, and it is drilled at F to fit the link-forming pins.

The process of making wire links is as follows: First cut off the wire to the developed length of the links. Next insert one end of the wire in hole D and bend it until it touches stop E. Repeat this bending operation at the opposite end of the wire, being careful to keep the bends in the same plane, so that the partly formed link will lie flat in the fixture. At this stage of the forming operation the link is shaped as shown in the detail. The lever L is placed in position on one of the pins so that pin G engages the wire and the eye is then formed by rotating the lever about the pins, after which the forming operation is repeated at the other end of the wire, producing the complete link as shown in detail S.

realtor or a potential buyer it could be taken out with no loss of property value. Nothing I said mattered. He was going to sue if I didn't take his address out of the survivor.

I told him his address would be out the next printing, he had no case and he ought to get his head read. This might have calmed him down except some reader had to go and send him a letter. This started him off again and we had another go-round.

Nowadays I'd just have thrown his letters away, cancelled his subscription and forgotten him. But then I was concerned. I felt I had caused him anguish and wanted to make amends.

However, once you've gotten on the wrong side of a paranoid, there's no making amends. I'm now a part of the plot.

Anyway, my point is that paranoia is not funny. It is also a serious drawback to anyone's attempts to survive or to better himself on any level of endeavor.

Paranoia is simply exaggerated and useless fear. Normally, everyone is afraid at times. Normal fear leads to normal caution. But when fear becomes obsessive caution, distrust and universal suspicion, it becomes paranoia.

For instance, say you decide to become a tightrope walker. If you are clumsy and awkward and hung over and strung out and normal, you will fear falling because of a lack of ability. If you really want to be a tightrope walker, you'll go over your shortcomings and eliminate them, thereby fitting yourself to become what you want to be.

But if you are paranoid, you will disregard any of your own short-comings. You will reason instead, that the Circus World is controlled by people who will feel threatened by any success you might achieve. Lest you become a star in their private world, they'll hire someone to shoot you off that highwire.

So the paranoid is actually a self-imagined winner, beaten before he starts. If he isn't actually mentally ill, he has an overactive imagination, putting non-existent obstacles in his own path. Instead of developing his abilities, taking his lumps and successes as they come, he relieves himself of the challenge by stacking the deck against himself. He's really just a cop-out artist.

Usually he has MBD (Vol.1 p 64) which keeps him in a state of arrested development. He's like a child who imagines himself the hero of his fantasies but sees his parents and elders as blocks to any successes he might achieve. An adult with this problem has lofty fantasies but replaces his elders with various authority and power figures who might feel threatened by his achievements. So he doesn't really try to improve his circumstances. In his fantasies he feels little guilt about being a loser. After all, if he weren't so magnificent and superior, would the forces of International Crud be united against him?

Every paranoid, however, has sane moments the same as I do. He realizes that whatever is really keeping him back, he's far behind and he's not very happy. Maybe something got in his way during childhood which made him stop testing the system. That's the key to it all; testing the system to see what one can get away with.

All chidren do, and if their elders understand and don't over-punish, the child will have a good idea what he can get away with and how far to go in finding his limitations. But if a child has overly strict parents, or MBD, punishment might be so severe, or seem to be, that testing the system is not worth the effort, or it may even seem downright dangerous. So the guy reaches adulthood, either not trying anything, as an individual, or becoming such a Secret Squirrel no one will ever know what he's doing.

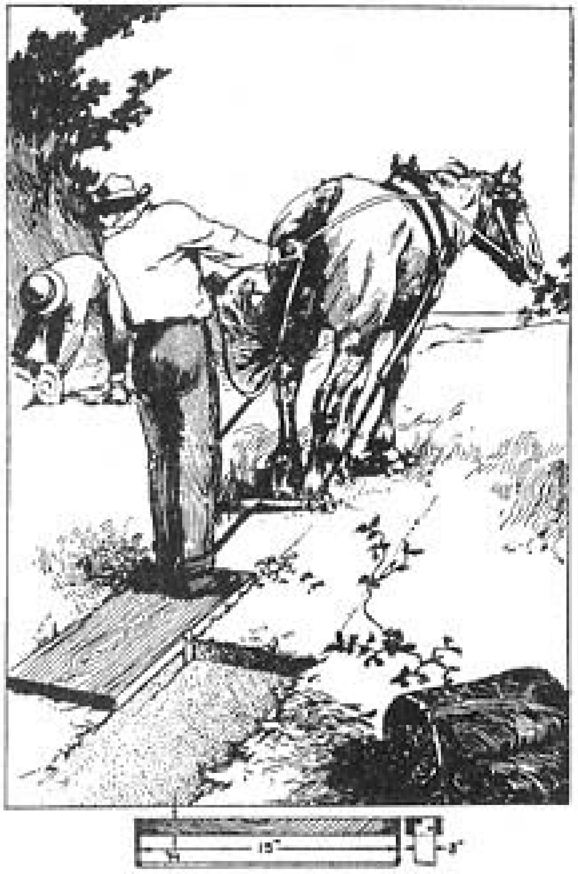
This would be all right except the paranoid often tries to impose his own fears on others who share his stated goals. This can be a drag, especially in my case.

Years ago I saw books hinting at do-it-yourself mayhem. They promised a lot more than they delivered but suggested that any stronger stuff would be suppressed. Well, I'd dabbled in paranoid gutter politics for years and didn't believe such material could be suppressed. I set out to write, publish and sell the most outrageous, potentially destructive manual ever created on this

A HORSE DRAWN SOD CUTTER

From Popular Mech. 1919

The cutting of a considerable area of sod is tedious work when done by hand, and it is difficult to make the sections of uniform thickness and size. These important features are provided for by the use of the homemade sod cutter shown in the sketch. To start a cut across a meadow or lot, a notch is cut in the turf for the blade, and the device is set into place, stamping it down to give a good start. The operator stands on the plank in front of the blade, and a little practice will soon determine the best position for ease in operation. When a cut has been completed, the cutter is dragged to a fresh starting place, the driver turning it over on the upper side. The strips are cut into suitable lengths and piled conveniently for removal with a stone boat or wagon.



With This Device Sod may be Cut Quickly and of Uniform Width and Thickness

The device may be made of any suitable width; 15 in. between the inner edges of the blade, and the latter set to cut a depth of about 2½ in., being desirable. The board is a 2-in. plank, about 4 ft. long. The blade should be set with the cutting edge slanting slightly downward so as to make the device "bite" into the ground. A smaller cutter may be made for use by boys, several of whom may draw it.

planet. If interested parties had the power to suppress knowledge, they would suppress the work you know as THE POOR MAN'S JAMES BOND.

Well, first I was talked to by the D.A.'s man and our local FBI agent. Interesting. Then I was subpoenaed to a Senate Hearing in Washington, D.C. They paid my plane fare both ways, put me up in a hotel room with TV and let me rave at a panel of bemused Senators. I had ever so much fun and got a lot of laughs.

There was not one request that I stop publishing the material; there was no threat to my person, my freedom or to my economic security.

I've sold about 40,000 copies of the work over the past five years with no interference from anyone. Yet, I still get orders for the PMJB which are wrapped in aluminum foil so Federal Agents can't read them by X-Ray. Some orders are so coded to protect the identity of the one wanting it that the book comes back marked, "Addressee Unknown". Paranoia!

Common sense might suggest that since it's legal for me to write it, publish it and sell it, a customer can legally own it. Despite the fact that, to the best of my knowledge, no one has ever been hassled for owning the PMJB, paranoids around the country consider ordering it the last thing they will be allowed to do before being led away.

No matter. What really bugs me about paranoids is their attitude toward THE SURVIVOR. THE SURVIVOR isn't an underground publication. It isn't political; it doesn't advocate any sort of criminality or extreme social activism. Nor is it pornography. THE SURVIVOR is a family publication. Plain envelope, indeed!

Anyone really interested in Survival will have to drop all his paranoid fantasies. The ones who inspired this editorial are too afraid of their neighbors to have an effective chance at surviving.

Survivalists must examine each fear and eliminate it. There are enough real things to fear without being hung up on imaginary fears.

Every fear is an unconfronted weakness. I'm no longer afraid of the calamities which face the general populace. I faced my fears and eliminated their cause.

At one time I thought my mail might be monitored. Instead of frustrating the monitors by going out of business, I called my postmaster and had a long talk about it, wherein it was explained to me how mail was monitored and why mine wasn't.

I think everyone gets flashes of paranoia where he entertains irrational fears. But rather than give in to such fears and work out elaborate habit patterns to reinforce them, one should go straight to the source and confront it.

Such an action not only eliminates a fear but makes it harder for new fears to settle in. Practice makes boldness and the Survivalist must be bold.

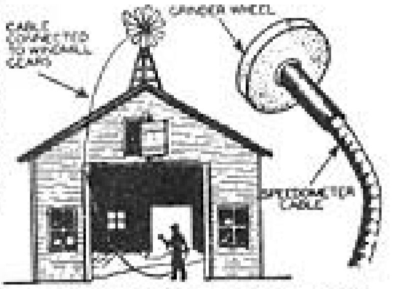
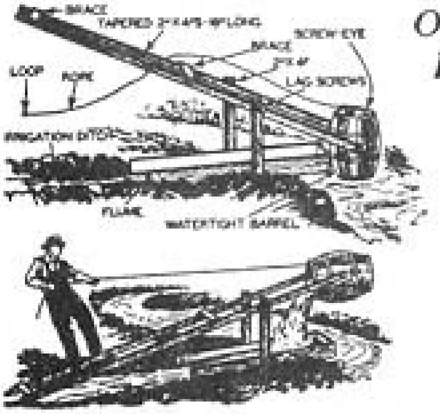
Windmill Powers Grinding Wheel Thru Cable

HERE'S a new angle on motive power for operating a small emery wheel. Lay hold of an old auto speedometer cable and hook one end of it to your wind mill (if you have one) and the other to the grinding wheel. Of course, the wheel will have to be geared up, about 2 to 1, but this will be a simple task. The wheel can be used in any position and can easily be carried about.



Modern Mechanics 1932

One Man Operates Irrigation System



A NOVEL and highly efficient one-man irrigation system is in use in many of the northwestern states. The scheme entails the use of a vinegar barrel, which is supported between the ends of two 2x4 inch pieces 16 feet long by means of lag screws. Two 2x4 inch pieces are then driven into the bank as close to the edge of the water as possible to support the arms. The ratio of the length of the arms should be approximately 1 to 4; that is, the barrel end should be 4 feet long, the operating end 12 feet long. The barrel is pivoted one inch above center so that it can be inverted easily. To operate, the arms are raised, lowering barrel into water.

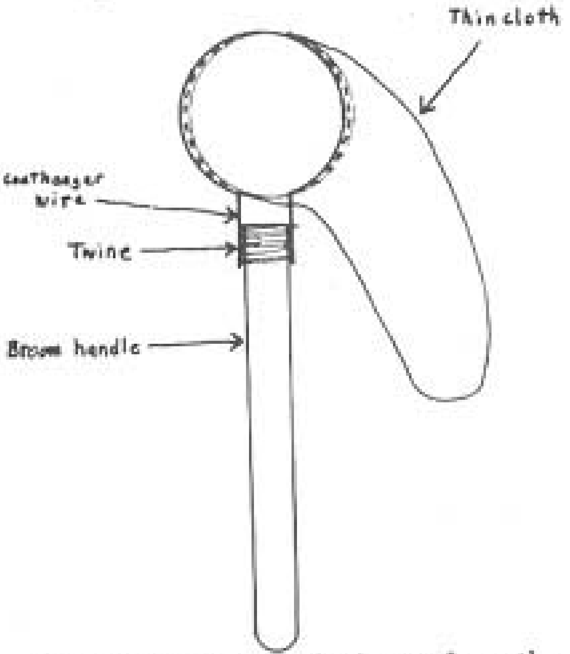
Capturing Insects for Livestock Feed

By Bill Abreu

In feeding fish, chickens, or whatever animals you might be raising, the best source of food to use is insects. Insects will provide them with ample protein, resulting in a healthy livestock. Also, insects cost nothing to capture and they need not be bought in stores, thereby leaving extra money leftover for survival needs.

Before you go ahead and start your search, however, it should be known that monarch butterflies and furry caterpillars can be toxic when eaten, so it is best to avoid these. But flies, grasshoppers, beetles, and small insects are excellent in feeding animals and the supply is always plentiful.

One way to catch insects is to go out and capture them in their own habitat using a net. The drawing helps to illustrate how a simple net can be constructed using household objects, such as a broom handle, thin cloth or panty hose, and preferably thick coathanger wire for the net's frame. For catching small insects which thrive in the grass, a sweeping motion (back and forth) just under the top of the grass blades may be employed.



When trying to get the insect from the net into the container the netting can be lifted, as most insects have a tendancy to fly upwards to escape. Once at the top of the net, the jar or container is slipped inside and placed over the insect. The lid is set over the top of the jar and the netting slid out of the way, allowing you to tighten the lid. Another way of getting the insect out of the net is to use an aspirator which will be discussed more fully in a moment.

If slightly stronger material is used in making the netting, aquatic insects can easily be captured. This method is especially simple in streams, wherein the net is placed in the water, letting the current sweep the insects into the net.

An aspirator is a device used for drawing an insect into a pill bottle container. A straw or stiff tubing is placed through one end of the bottle and a flexible tube of desired length is pushed through the other end. On the end of the rubber tubing is attached a small piece of screen to prevent the insect from escaping. The tube with the screened end is placed inside the mouth and when an insect is spotted, one strong inhalation breath is taken, sucking the insect directly into the bottle. A slightly improved aspirator can be used when close to an electrical outlet. Instead of using a flxible tube, the suction end of a vacuum cleaner is placed over the open pill bottle end. This system will allow you to pull in more insects at a much faster rate. Of course, the manual version must be used when there is no electrical supply present.

If this is too much work for you then there is an alternative. Rather than going out to catch insects, you can have them come to you. It is no secret that at nighttime insects are attracted to lights. There are different theories as to why they do this (one is that they confuse the light with the moon) but this is unimportant as long as you know how to make use of this instinct.

A white sheet is strung out against a wall and a light bulb placed in front of it. After a short while many insects (not just moths) will gather on the sheet where they can then be easily collected using an aspirator or net. A cardboard box can be used as a trap if the light is placed inside it and a small opening made at the bottom. Once the insects are inside they will remain trapped until morning when you are ready to collect them.

A trap for capturing ground insects can be constructed using a coffee can and some bait. First, a small pit is dug in the ground and the can placed inside so that the pit's depth matches the can's height. The insects are attracted by the bait's scent and they fall into the can, unable to climb back up the smooth metal walls. The best bait to use is a form of decaying vegetables or a sweet substance. A mixture of brown sugar, beer (use only a little so that you have enough for your next party), and molasses is stirred in a sauce pan with a medium flame until it forms a thick syrup. This bait can be placed in the above mentioned trap or can be applied, in patches, to walls or trees. When applied to these surfaces it should be placed where the odor will travel the best.

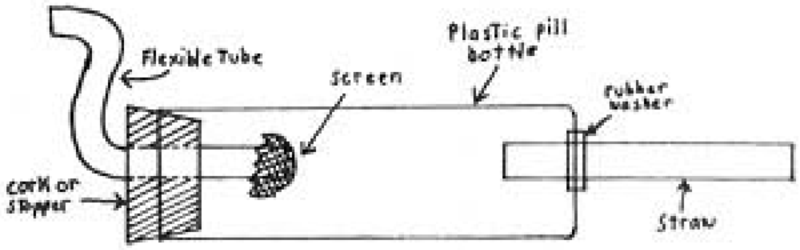
When looking for insects it should be remembered that they can be found almost anywhere: on trees, under bricks or stones, on leaves, between cracks, burrowed in the ground, amid moss, in streams, or in old houses. If you live in the city it is best to use the light and sheet method to attract them to you. Often silverfish (which are actually insects belonging to the thysanura order) can be found in bathtubs or sinks and though they can escape quickly, it is wise not to rule them out as a possible food source. If you have a garden you can find many small insects living there, in which case you can use the vacuum method (as mentioned on page four of THE SURVIVOR) as long as the vacuum bag is empty.

Another way to keep up your supply of insects is by breeding (or rearing) them at home. To raise crickets and grasshoppers a large container—like an aquarium or large can—is filled with four inches of moist sand and some pieces of shredded newspaper are scattered around. A screen is placed over the top of the container so that the insects will not jump out. About twenty to forty fully grown crickets are caught and all are placed inside the cage, half of which should be females; identified by the lance-like protrusion coming from the end of their abdomen. A water-filled pill bottle with cotton stuffed in its open end and placed on its side will provide a constant supply of drinking water for the insects. After about twenty or more days baby crickets will begin to appear and in approximately two months they will be fully mature.

When the temperature drops below seventy degrees a light bulb should be suspended inside the cage without providing too much heat. Because crickets and grasshoppers are actually clean animals, the cage should be cleaned frequently of uneaten food and fatalities. For an idea of how many insects to expect, the female cricket lays 150 to 500 eggs in one or two months. For more information on crickets look on page 197 of THE SURVIVOR in the Chamber's Encyclopedia.

Now for the last (and for some the fun) part of preparing insects as animal feed: once you have what you need the insects must then be killed without poisons or insecticides for obvious reasons. The other alternative is to drown them in hot water, though for beetles this takes some time, as this species dies hard. You can place the insects in a wire cage or a cloth bag and then submerge them in a sink or bucket of hot water. For moths, butterflies, or other large insects a pinch between the thumb and finger can be applied to the thorax (the segment behind the head). Sometimes this takes practice but its advantage is that is kills the insect instantly. Its disadvantage, however, is that it takes a brave—or foolish—person to use this method on bees or wasps. Aside from crushing the insect to a disgusting pulp, these are the only two procedures which can be applied.

Using insects to feed your livestock can be profitable and will leave you with more food for yourself, your family, or your survival group.



ASPIRATOR

Unarmed Combat [Combato]

by Bradley J. Steiner

Cont. from Vol. 1, page 131

Last lesson we discussed the basic low side kick, applicable to any sort of frontal oncoming attack, except the sort where the enemy is armed with a firearm. You also larned basic front choke-hold counters, and I touched upon some rudiments of serious personal defense.

Sparring is woefully inappropriate as preparation for actual hand-to-hand combat. There are many reasons why this is so, but I want to mention just one, for now:

The high kicks, the leaping jumps, the spinning, wheeling and acrobatic lunging techniques you see in the kung fu flicks (and at martial arts demonstrations) are strictly for "show" and for exercise—and I don't care what the black belt "experts" say. Ask some fancy high kicker what he'll do in an elevator, on a stairway, in a hallway, on an icy street or in a crowded store, etc. when trouble starts. Ask him if he'll start his showy moves when some junkie cut-throat is slashing at his neck with a razor. Or, will he simply GO IN, and rip and tear and punch and claw for the VITAL ZONES? I think we both know the answer. Anyway, for unarmed self-defense, forget the fancy stuff. Remember that a fight starts fast and close, and that if you intend to win it, you'd better get it over with before 20 or 30 seconds' time passes.

I'm going to stress three things this month—

ELBOW STRIKES
KNEE KICKS
HEAD SMASHES

—all close-in weapons, intended for use in a serious fight where you can't afford to fight fair.

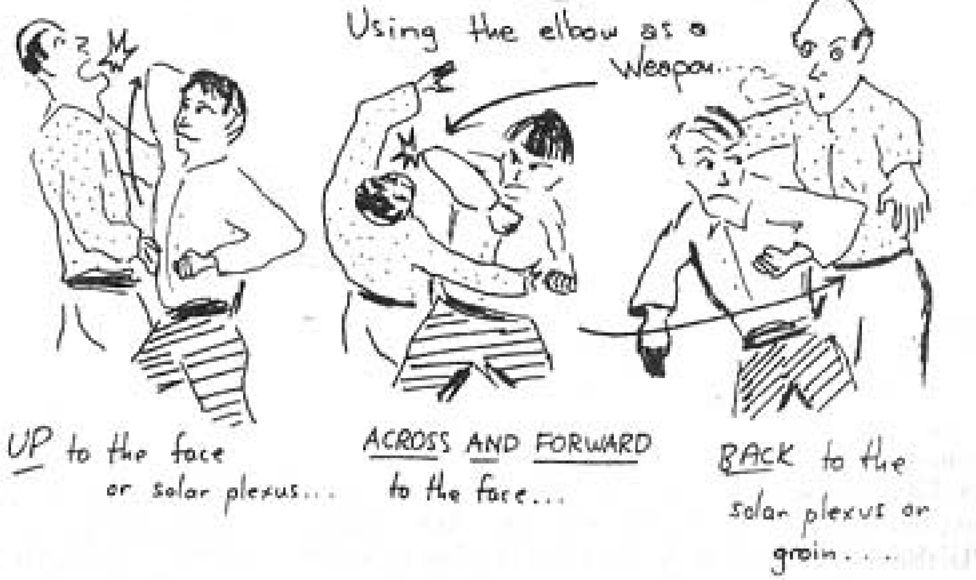
Even a small man, or woman, can deliver powerful elbow, knee and head smashes, with a little practice. Using a heavy bag for strengthening one's blows is a good idea, but it's not 100% necessary. Remember that VITAL ADRENALIN FLOW will automatically speed up when your life is threatened, and you'll be both immune to less-than-fatal injury, and quite capable of delivering sufficiently strong blows with the "natural" weapons you've got.

Don't wait until your enemy is in the process of landing his sixth blow before you go into action. People, just like animals, have a "sense" for danger. When your SENSE tells you that physical assault is immediate: HIT FAST, HIT HARD, and HIT FIRST!!! Give no man an even break in a fight! Never hold back, and GIVE NO QUARTER, once violence is upon you.

KNEE BLOWS

It helps to seize the opponent's shoulders and pull him toward you as you kick. Drive your knee up AS HARD AS POSSIBLE, AND REPEATEDLY, into his testicles. Keep kicking until he collapses. You can apply this counter when a man grabs your lapel and yanks you in towards him. If a close-in choke hold is taken about your throat, this knee blow is also appropriate. Any encumbering, under or over-arm body hold provides you (if the opponent grabs from the front) with a perfect set-up for the knee blow.

Alternative to the knee blow administered to the groin, the FACE makes a dandy spot for a nice, vigorous knee kick. This is the sweetest answer to a front dive and tackle attempt. It can be applied even when the opponent is



standing in front of you, erect. Just grab his hair or ears or head, and knee his groin. Then yank him forward and down, HARD, as you push his face down into your knee kick. Kick twice, just to be sure.

ELBOW BLOWS

Keep the fist very tight, and bend the arm fully. Swing the elbow HARD, exactly as illustrated. Whenever possible, try to execute your blows against an opponent AS HE COMES IN TOWARD YOU. This magnifies and doubles the strength of your blow. Elbows make strong, vicious surprise weapons, and can deliver blows much harder than you'd probably realize. Practice is essential, though. Get "fluid" with fast, accurate elbow smashes.

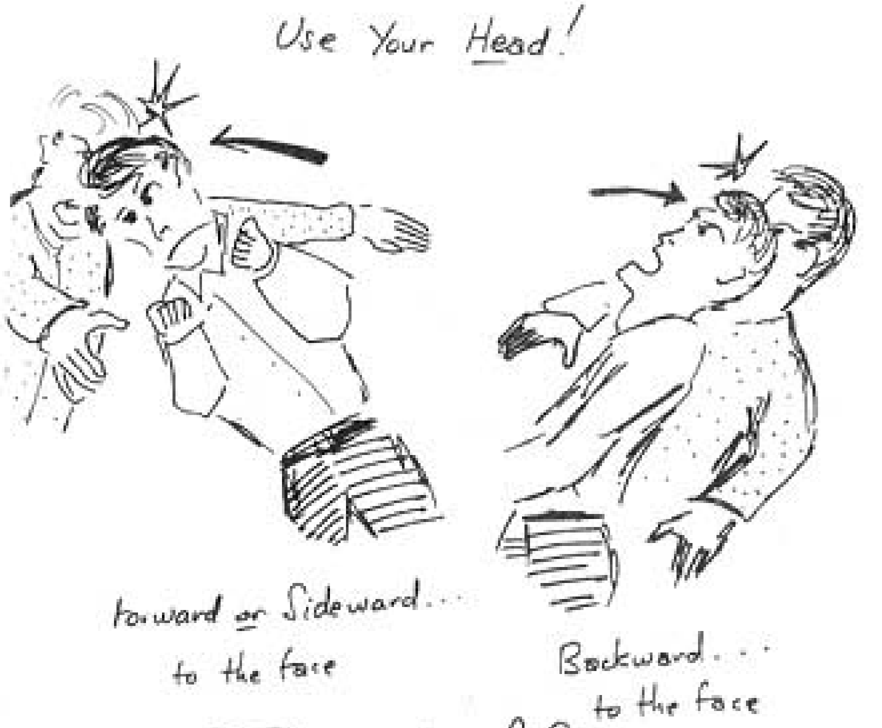
HEAD SMASHES

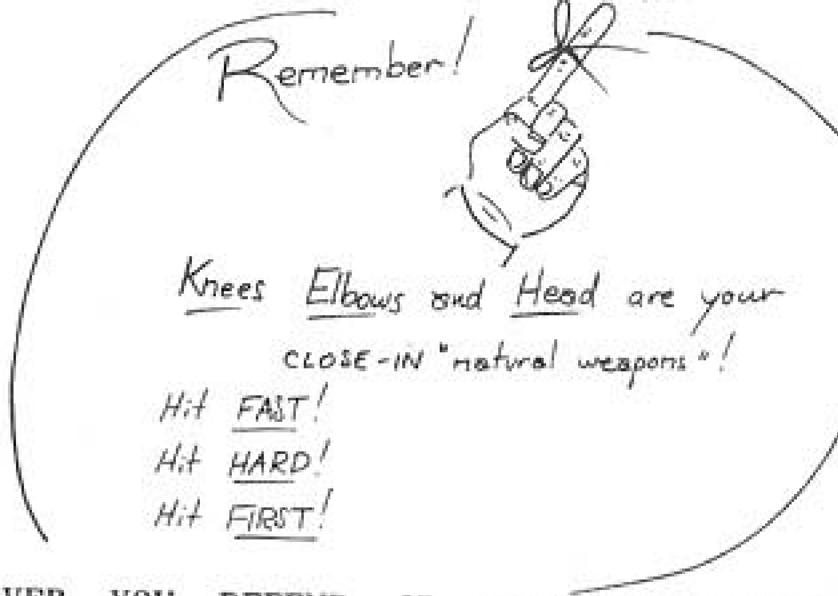
Get into the habit of butting the nose of your antagonist with your head. It won't hurt you a bit, but it will provide a super opportunity to gain "clearance" for throat attacks, kicks, etc. Use whenever the enemy grabs in close, especially when he pins your arms from behind in a bear hug. Snap the head back HARD.

Girls should greet an unwelcome "Romeo" by first PRETENDING TO WARM-UP TO HIS ADVANCES, AND SMILING AS THEY "PUCKER" FOR A KISS. Suddenly, WHAMMO! Bash the bastard's nose hard, and drive knee to groin. Most persuasive.

Well, I've left you with some nice games to play until next issue. Be careful in practice, puh-leeze. I accept no responsibility for injuries or accidents you or your partners (or your attackers) incur.

One last thought, before I sign off for this issue: YELL LIKE A MADMAN WHENEVER YOU DEFEND OR ATTACK. Grimace, shout, turn savage! That's the way to WIN. And WINNING's what unarmed combat is all about.

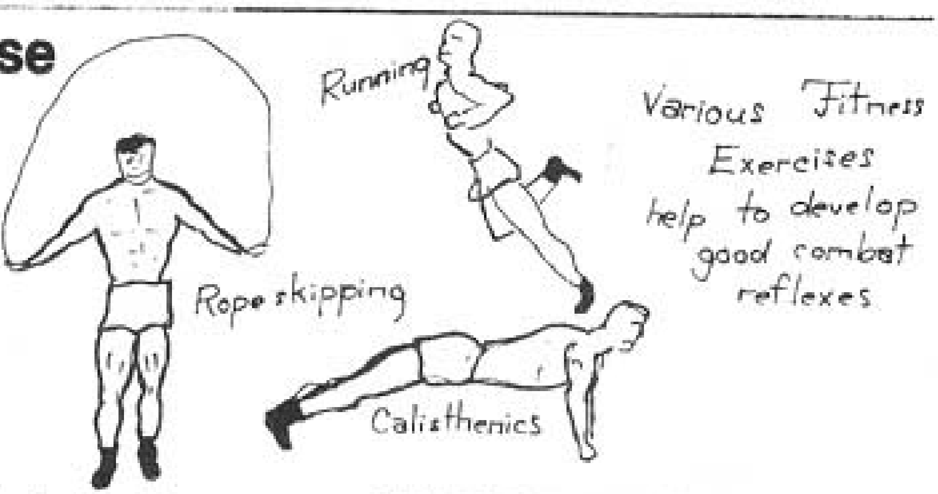




Reflex-Building for Self Defense

(How to reduce your reaction-time for personal defense situations)

By Bradley J. Steiner



Knowing what exactly must be done to meet and deal effectively with a physical assailant is one part of the answer to having an EFFICIENT response ready in your personal defense repertoire. HAVING THAT RESPONSE UNDER PERFECT CONTROL, TO THE EXTENT THAT IT CAN BE "TRIGGERED" INSTANTLY -- at your opponent's attack--is the other part of the answer. If your reflexive-response to an attack is slow, then it might just as well not be made; for it will begin long after the opposition's attack has "landed"!

One major purpose of my self-defense system, Combato, is to SIMPLIFY, to the greatest extent possible, the TYPES OF RESPONSES one trains with, so that the time required in the learning process to become proficient is reduced considerably. This is also why I am opposed to sparring and competition. These aspects of practice only increase one's GENERAL ABILITY TO TRADE BLOWS WITH ONE WHO FIGHTS IN THE SAME, PRE-DESIGNED MANNER AS ONESELF, ACCORDING TO THE "RULES" THAT HAVE BEEN DRAWN UP BEFORE THE CONTEST OR MATCH. The important thing is to DEAL WITH THE ACTUAL SITUATIONS, work out the best responses, then "internalize" those responses, so that they come into play with lightning rapidity when they are needed. This means DRILL. It means repetition of technique, until the stage is reached where an opponent's onslaught will "trigger"-- WITHOUT YOUR EVEN BEING

AWARE OF IT!-- the appropriate response.

In past articles I have dealt with certain basic personal defense ("Combato") applications. In future articles and books, I will deal with many more, in addition to training suggestions, body-development skills, etc. For now, I want to explain how you, the Survivor, can condition yourself and hone your reflexes to a razor's edge; so that whatever techniques we've so far discussed, can truly become "your own"--i.e. become "internalized" and imbedded within your subconscious mind. Once this is accomplished, you will react IMMEDIATELY and CORRECTLY to whatever sudden attack your opponent thrusts upon you.

THE GROUND-RULES OF TRAINING

The following are the general all-encompassing "basics" that apply to techniques of combat I've covered in past issues of THE SURVIVOR, and to techniques and combinations that will be covered in future issues.

1. KEEP YOUR OVERALL LEVEL OF PHYSICAL CONDITION HIGH; TAKE CARE TO GET AND STAY IN GOOD SHAPE-strong, fast and flexible.

The shape you're in enables your body to DO what your mind LEARNS. It is a glorious myth that strength and condition don't matter in the martial arts! Don't believe it, brothers! Armchair self-defense experts often end up in wheelchairs. Or worse!

I wrote a book on physical conditioning specifically for combat and survival ("FIT TO FIGHT! COMBAT CONDITIONING FOR PERSONAL DEFENSE AND SELF-SURVIVAL!") Paladin Press, P.O.Box 1307 Boulder, CO 80302 should have this manual available within a few months. Meanwhile, do everything you can to get in shape-and stay that way! No serious student of defensive skills or even survival can afford to neglect basic fitness. Mike Brown's articles on budget equipment and fundamental fitness training are great. They're as good an introduction to PRACTICAL and SIMPLIFIED physical training as you'll find. In addition to Brown's work, let me urge that you: Learn to jump rope, and then do so, for about 5 minutes every day. Do push-ups, leg-ups, sit-ups and some chinning, as well as jogging, or even running in place.

Being in good all-round shape permits personal defense skills to be learned more easily, applied more effectively and "remembered" by your nervous system more surely.

2. BE VERY CAREFUL TO SPEND YOUR TIME LEARNING ONLY SIMPLE, PRACTICAL TECHNIQUES.

This is not merely a plug for my COMBATO. It is a warning that could save your life. DON'T, if you are purely defense and survival oriented, involve yourself with complex, "showy" skills. These detract from your focus on the practical, simpler methods, and they SLOW reaction time, by giving you an ASSORTMENT of maneuvers from which your brain will be obliged to "choose" in a critical emergency. Keep things simple-simple-SIMPLE! Get those few fundamental moves that ALWAYS WORK, and drill them. Drill them until they're coming out of your ears!

In these articles in THE SURVIVOR, I will enumerate, over a period of time, a wide variety of effective, simple, proven defense skills. These moves will lack the beauty and grace of, say, classical Aikido or Karate; and they will lack the finesse, possible, of many widely-taught jiu-jitsu techniques; YET THESE ARE THE SIMPLE MOVES YOU NEED WHEN YOUR LIFE IS ON THE LINE. I urge you again: KEEP THINGS SIMPLE. Unless you are in the martial arts for sport and play, DO NOT clog up your mind and reflexes with a quantity of "pretty" but nonetheless questionable moves. By narrowing down on, say, two and only two simple choke defenses, you can DRILL these to the point where they will become SO FAST, SO STRONG, SO EFFICIENT and SO ACCURATE, that they will be virtually 100% guaranteed to work. Any opponent thus assailing you, will be triggering his own demise! His attack will serve as the ignition spark that sets into blindingly-fast action your pre-drilled defense combination. Every attack against you will become the first step of the would-be attacker's destruction!

3. PRACTICE THE ACTUAL PHYSICAL TECHNIQUES-EVEN IF YOU MUST DO SO ALONE, WITHOUT A PRACTICE PARTNER.

The art of Karate has an aspect of training that is as poorly understood today, as it is widely practiced: KATA. We hear instructors and students say that Kata is "essential because it is traditional". We hear others say that it is "unnecessary because it is senseless and primitive". And so on. The truth is that KATA, when properly studied, is the surest way to develop potent unarmed combat skills. The reflex-building and training of the mind and nervous system for combat in Kata is simply fantastic.

Kata-practiced PROPERLY-enables the Karate student to IMBED both the reflexive/mental responses and the muscular/physical responses to all possible attacks DEEPLY IN HIS "BEING". The catch of course is that traditional Kata requires many, many months or even years of study, before it produces the desired results. This is because it covers HUNDREDS, even THOUSANDS of techniques, and must be reviewed and drilled DAILY, for success in actual combat to be the result of training.

Today, in Combato, what I do is use a form of MODIFIED or SIMPLIFIED KATA that narrows down and very simply deals with select, necessary defenses. The exact same movements are either drilled with a practice partner (cautiously) or by oneself. PROVIDING YOUR MENTAL STATE IS CORRECT, you will be preparing yourself perfectly for the "real thing". What is important is to fully understand the physical techniques movements and then PUT YOUR BODY THROUGH THOSE MOVEMENTS, REGULARLY.

While going through the techniques it is necessary, especially when practicing alone, to VISUALIZE AND VIVIDLY IMAGINE THAT YOU ARE ACTUALLY UNDER ATTACK. This means that practice must be, and also must not be, mechanical repetition. It must be repetition, in the sense that practice must be DRILL; but it must not be "mechanical", in the sense that repetition of technique without "feeling" and without "emotional immersion" cannot "take". Only practice that VIVIDLY CONDITIONS YOU, AND PUTS YOU THROUGH THE EXPERIENCE, SO TO SPEAK, can prepare and train you.

4. WHEN YOU PRACTICE IMAGINE THAT IT IS "THE REAL THING", AND WHEN YOU ARE NOT PHYSICALLY PRACTICING, IMAGINE YOUR SITUATIONAL RESPONSES AND COMBAT TECHNIQUES. The human nervous system is both strange and wonderful. Believe it or not, the vivid IMAGINING of an event can produce within one the conviction (within the nervous system) that one has "experienced" that event. Thus, if you sit down quietly in a chair, every day for five minutes, and concentrate hard on imagining, say, your defense maneuver against a frontal choke hold, and ACTUALLY SEE AND FEEL your satisfactory, trained response to the attack, you will be doing something just about as effective as actually practicing the technique! I say "just about" as effective, because unless you do something other than imagining to keep your body fit and strong and flexible, you'll not possess the CAPABILITY of doing the defense maneuver under fighting conditions-even though you might well "know" it perfectly.

The more your mind's eye SEES you going through the right defensive tactic, the more that defensive tactic will imbed itself in your mind and nervous system. Keep programming yourself, regularly, patiently and, of course, WITH THE MOST EFFECTIVE TECHNIQUES, and sure enough, your reaction-time will reduce itself to a hair's breadth! You will in not too long a period discover that an aggressive approach from anyone under any circumstances AUTOMATICALLY, without your having to "think things through", brings your physical and mental powers into efficient defensive play.

In essence, what I'm speaking of here is my modernized or "updated" version of the mental state inherent in Karate KATA performance.

ANOTHER ASPECT OF THE PROBLEM

There is another aspect of the problem of building fast defensive reflexes. It is this:

Too many basically decent people have, what I call, a "stop-brake" within their minds that automatically "prevents" them from taking IMMEDIATE aggressive, violent action. This, ironically, is the penalty a decent person pays for not having the psyche of a criminal or thug!

You see, violent criminals are conditioned to act/feel or think and decent people are conditioned to think or feel/act; so there's a problem in self-taught reaction-timing. A punk or a thug looks at you, then mashes your face in. You, on the other hand, unless you've been correctly self-conditioned, look at and see the thug, then YOU REQUIRE A MOMENT OR TWO TO "REASON OUT" THAT, INDEED, THIS CREATURE "DESERVES" ROUGH TREATMENT, BEFORE YOU KICK HIS CROTCH IN. All very, very noble of you, I'm sure; but potentially a fatal policy, I'm afraid!

Reaction on your part to aggressiveness must be INSTANT VIOLENT COUNTERATTACK! Nothing less, nothing slower, nothing but IMMEDIATE, VIOLENT COUNTERATTACK.

There is no way to achieve this "change in your psyche" unless you will devote some attention to cultivating a NEW thought pattern, regarding violence and violent threats. Learn to distinguish between PEOPLE and violent CRIMINALS. People deserve, it is true, careful and thoughtful responses, based in part upon your considerations of justice, ethics and fairness. Violent aggressors DO NOT! There is a difference.

IN LEARNING TO BE COMBAT-READY, THE SURVIVOR MUST LEARN TO BYPASS THE THOUGHT-PROCESS WHEN HE DEALS WITH THOSE WHO, THEMSELVES, REFUSE TO THINK. THE SURVIVOR STUDYING SELF-DEFENSE LEARNS THAT THERE IS NO OBLIGATION WHATEVER UPON HIM TO BE "REASONABLE", "JUST", "ETHICAL" OR "FAIR", WHEN HE IS DEALING WITH THE SCUM-ELEMENT WE KNOW AS THE VIOLENT CRIMINAL.

Hesitation is a great retarder of proper reflex response. If you wish to learn effective personal defense, learn-if you are attacked-NOT to hesitate. Go right into action-at once! Immediately! No delay!

Practice, so long as you are convinced that it is incumbent upon you to be fair, will do little to decrease your reaction time. Until you have settled, once and for all time, the question of "should you or shouldn't you go all-out, and do so at once" in the face of violent attack, you are working at awfully-reduced efficiency.

Some years ago, in New York, a tournament-winning black belt karate practitioner was knifed to death while riding home from a date, on the subway. Why? Not, certainly, because he lacked the knowledge of what techniques he should have used to protect himself. He died at the hands of two scummy misfit animals BECAUSE HE GRANTED THEM THE SAME TERMS OF CONDUCT HE WOULD HAVE GRANTED A NORMAL HUMAN BEING: HE TRIED TO TALK REASONABLY TO HIS ASSAILANTS WHEN THEIR INTENTIONS WERE INEVITABLY APPARENT.

The youth, a fellow named Ramirez, tried to REASON with the two varmints who sat beside him on the train and threatened him, while they demanded money. Witnesses said that the young black belt NEVER EVEN MADE AN ATTEMPT TO FIGHT BACK-even when the chance to do so was glaringly open to him.

HESITATION. THE ERROR; thinking that what is appropriate with one's neighbors is appropriate with violent, human (or I should say, sub-human) pestilence. Had Ramirez responded to the demand for his money by rising from his seat and kicking in the face of one of his assailants, as he ripped out the eyes of the other, he would probably be alive today; and there would be two less ounces of scum-rot inhabiting New York and cluttering up her streets.

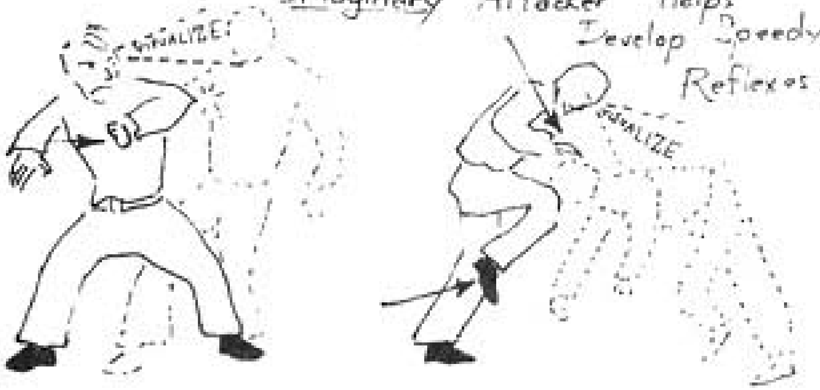
Ramirez had been trained to SPAR, to COMPETE; not to fight—not to SURVIVE!

Once, a student of mine (a young girl of about 14 or so) was walking home from school, when she was accosted by some stump of rot. He stepped in front of her and reached to take her arm. Two seconds later she was grinding her heel into the side of his face. She didn't HESITATE. She didn't STOP TO DECIDE. When the threat came, she RESPONDED-INSTANTLY!!

There is nothing spectacular about basic personal defense-COMBATO. It is simple, based upon simple techniques, applied vigorously, with not a second's delay between the materialization of the attack, and the materialization of your defense. The two are one: like, to use a classic Oriental illustration-Yin Yang. One follows inevitably into the other, even as the other comes into being. With one, there is the other. When the aggressor's attack becomes a reality, your defensive combination is there at once you cope with it.

The development of the true fighter's

Repetition of Basic Techniques Vs. Imaginary Attacker Helps Develop Speedy Reflexes!



Elbow strike counter follows break of front choke

Head of "assailant" is seized and jerked forward, and knee kick follows to "face" — ALL IN THE MIND!

reflex-reactions is NOT beyond your grasp. It is possible to you, and it will provide you with the self-confidence and security you need-IF you take the trouble to work for it. I assure you, it is worth you while.

Get and stay in good shape. Narrow down your technique-repertoire, to include only the best and simplest techniques. Practice-practice-practice those few, simple techniques. Use vivid imagination and concentration to prepare mentally and to program your nervous system and, finally, work toward the development of a rational, self-serving survival philosophy that encourages you to differentiate between humans and scum, and, most important to ACT accordingly. In the face of aggression, this means to act INSTANTLY!

Do your best to assimilate the message in this article. I would not have written it if I did not know that it was crucially important to every survival-conscious individual. In issues of THE SURVIVOR to come I will elaborate upon many, many good battle-proven techniques. If you really learn to apply what I've said here, those techniques will inevitably become an effective addition to your "survival repertoire".

INVISIBLE INK

Ammonium chloride, ''sal ammoniac'', dissolved in 15 to 20 times its weight of water makes an ink that is invisible, but becomes dark brown or black when pressed with a hot iron, or held at a distance above a small flame. This is as good a sympathetic ink as any, is easy to prepare, and is not dangerously poisonous.

The salts of several metals have long been favorite materials for sympathetic ink. These salts are not all colorless when in the solid form, or in strong solution, but invisible marks made on paper with very dilute solutions can be developed by suitable means. Among these salts are lead acetate, ferric sulphate, mercuric chloride (corrosive sublimate, dangerous to handle and very poisonous), copper sulphate, cobalt chloride, and nickel chloride. In addition to being turned brown or black by the fumes of ammonium sulphide, writing with any of the salts can be developed by heat, and still other means can be employed with some of them. For instance, if the ink is made with ferric sulphate, a solution of gallic or tannic acid will turn the writing black, and potassium ferrocyanide will form prussian blue.

Of the salts just mentioned, cobalt chloride is in some respects the most interesting. When a solution of the salt in water evaporates to dryness, the chloride appears in crystals that are red, though not intensely so. If the solution used as sympathetic ink is so dilute as to be only of a moderately deep pink, the thin layer of the salt that is left on paper when the writing dries will not be perceptible. If the writing is kept for some time in rather dry air, or is warmed slightly, the cobalt chloride loses most of its ''water of crystallization'', and is then so intensely blue that the writing is visible. Exposure to moist air, as by breathing upon it, makes the writing vanish because the blue salt regains water of crystallization and turns red. These changes back and forth can be repeated many times, but if once the secret writing should be heated too strongly when warming it, the chloride will char the paper, and the writing will then be permanently black.

As a means of developing writing done with a variety of inks, iodine is interesting. It is preferably used as the vapor given off by the solid element at ordinary temperatures, though the tincture diluted with water can be employed. If a thin solution of boiled starch is used for the writing, iodine will turn it blue. The color disappears after a time, and more quickly by gentle warming. Writing with a solution of soap becomes yellow or brown because the soap absorbs iodine vapor more easily than paper does. This color soon vanishes because the iodine is so volatile. Copper sulphate and lead acetate are colored temporarily, while marks made with mercuric chloride show as white on a background of yellow paper. If the writing is done with distilled water, iodine vapor will color the letters a little more strongly than the background. The water disturbs the sizing at the surface of the paper, and thus allows the iodine vapor to be absorbed more readily there than elsewhere.

Another type is as follows:

Water	640 cc.
Acetone	350 cc.
Phenolphthalein	4 g.
Caustic Potash	1 g.

Writing with this ink is made visible by ammonia.

How to Make Disappearing Ink

A writing fluid that will disappear and can be caused to reappear when desired can be made as follows: Mix linseed oil, 30 drops, ammonia, 1 fluid oz., and water, 5 fluid oz. To make the writing appear when this ink is used, dip the paper in water. As soon as the paper dries the ink will disappear again.

KNOW YOUR ENEMY

By Martin Donnelly

In an old war that happened once, the generals and their staff psychologists used to tell us that we needed to understand the motives of our opponent. This was just great, except that we never got to know him until the jungle growth parted and there he was with his bayonet already only inches from our chests. Many of us, on ships and in aircraft, never even so much as saw him at all.

Unhappily, something of the same sort may take place in a survival situation, if in a different way. Here the enemy may be all around us, and we won't recognize him even when face to face.

There are, however, some standards for judgment though they may be far from infallible.

One psychological characteristic of an enemy of society is an exclusive devotion to self. Call it self-centeredness. Such a man is often amoral, that is, congenitally lacking in any consciousness of moral responsibility. This type may be hard to spot. But there are symptoms. He will be reluctant to cooperate with others in a survival group, unless there is direct and immediate benefit to him. He will tend to hoard his own personal resources, not share. Perhaps only in little ways, but detectibly, he will take rather than give.

Beyond the amoral man is the true psychopath. Here is a clinically disordered personality. He literally does not know the difference between right and wrong. Such a man is extremely dangerous, for the very reason that his motivation is so simple. He goes straight toward his objective--his own self preservation--because he is incapable of thinking of anything else. And, by the way, this man may be very good at survival, again as a result of concentration upon self.

Now, it's one thing to judge a member of a group, who can be observed. But what if you meet a stranger? You do not know this man, and have no way of judging him. Here your only recourse is to be open and friendly, but guarded. Open and friendly, so as not to arouse suspicion on his part by showing suspicion on yours; remember that he will be judging you too. Guarded, so as not to leave yourself open to exploitation.

There is no easy answer to the question of the stranger. In a survival situation we need each other, we have to trust. We can only try to avoid trusting blindly.

To further complicate matters, there is yet another consideration. We have spoken here of other members of a group, and of the stranger, as possible enemies. But the true enemy may be within yourself.

Here is the most difficult problem of all. For to know one's self is very hard indeed. Self examination takes great moral courage. Yet we all of us have faults that should be taken out of the dark recesses of our minds and looked at. The ability to withstand stress varies greatly between individuals, and depends upon just what sort of stress it is.

One example occurred during a military arctic indoctrination exercise. A member of the group suffered secretly from claustrophobia, the fear of confined spaces, but thought he could handle it so told no one. He came awake from a dream at night, alone in a cramped snow shelter he had built as part of the drill, and in a sleeping bag that had a sticking zipper. The sudden feeling of intolerable confinement panicked him; he tore the zipper apart with his fingernails and ran blindly out onto the ice of the Bering Sea. His action endangered others and nearly cost him his life.

It's no disgrace to acknowledge a personal problem. Most of us are good at one thing, not so good at another. The thing is, we need to accept and to give help. And to try to anticipate, for good or bad, what we may expect from one another.

None of this is to say that you should be looking over your shoulder all the time, fearful of others. Nor need you be too introspective and fearful of yourself. True that in our civilization we have become too interdependent, and that survival requires self-reliance and an attitude of watchfulness. But it also mandates cooperation, between individuals and groups. Most people, in the final analysis, will recognize that they must help each other.

We need only to learn and understand the frailities of human nature, including our own. To know our enemy, whether without or within, so that we may all survive.

OINTMENT FORMULA

by Stan Anderson

It is well to know how to prepare a good ointment which may be used for many things from boils to burns. When one prepares such an ointment, one may be assured as to the actual contents and if it is made with various herbs there is little chance of the harmful side effects of some of the commercial preparations that are on the market today. Besides this, there is the satisfaction of gaining some worth while do-it-yourself knowledge as well as the joy of productive work.

For best results it is well to communicate with the spirit of the plant, tell it what you plan to use the ointment for and thereby gain its blessing upon the project. It has been found that more beneficial results from the ointment will be had if this procedure is followed first.

For the majority of ointments the following plan is suggested as it has produced good results for all who have tried it.

Place into a double boiler pan one and a half pounds of lard (preferably beef lard as it has good drawing properties) add two ounces of bee's wax and place the pan into the oven at between 180 and 225 degrees until the lard and bee's wax is melted. The lower the temperature used to melt the wax and lard the better. Make sure that the pan is stainless steel, earthenware, unchipped enamel or glassware as certain metals will precipitate toxic materials into the ointment.

To the melted lard and wax add a pound of fresh or one half pound of the dried herb or combination of herbs that you desire to use. You will know when you have enough herbs by pressing them down firmly so that the liquid barely covers them. Place the pan back into the oven at the same temperature for three to four hours. After the first half hour press the herbs back into the liquid so that they remain covered. After three hours lift the herbs with a fork to see if they are getting brown and brittle. When this happens the lard as a catalyst has drawn the value out of the herbs and they may be removed.

Strain off the liquid into a measuring cup and pour such liquid into small wide mouthed bottles to cool. In warm climates more bee's wax may be added so that the ointment does not re-liquify. When no more liquid can be poured from the mixture, place the herbs into a potato ricer or wrap them in a clean white sheet and squeeze them in order to extract the rest of the liquid. In the event that some of the ointment hardens on various utensils they may be placed in a pan and replaced in the oven to re-liquify so as to not have any waste.

Label the jars as to the contents and proper usage and place a couple pieces of scotch tape over the labels so that they will not come off.

Ointments are for external use, use no more than is necessary unless it is covered so that the grease does not rub off.

One combination of herbs which has proved to be quite effective in many situations is Comfrey, Plantain, Golden Seal Root powder and Myrr. Using the above method, fill the pan with half Comfrey leaves and half Plantain leaves, add two heaping tablespoons of Golden Seal root powder and two heaping tablespoons of Myrr powder.

The Plantain and lard have a drawing effect, the Comfrey sooths and heals, while the Golden Seal and Myrr also heals as well as produces an antiseptic effect. This ointment has proved to be effective in burns, cuts, boils and absesses, blood poisoning, poisonous bites and stings, itching, infected wounds, rashes and external ulcers.

Good luck on your ointment preparations and don't forget to include a jar of the above multipurpose ointment in your survival pack.

A New Survival Gun

by Martin Donnelly

Before we get into any arguments here, almost any kind of weapon can be a survival gun and we all know it. If I were pressed, the 300 year old wheelock in my collection would do. Or we can, any of us, roll our own, given a length of metal tubing and some wood and wire and a handful of matches. Also true.

But let's be reasonable. I'm not going to walk around with a thermonuclear missile slung over my sholder, and neither are you, although it would be handy if we are to survive against man. But if we're talking about survival against nature, with an emergency capability against man, then the problem gets cut down to size. We need a gun that is light in weight, easy to pack, durable, and effective. Within the limitations these criteria inexorably impose.

The true survival weapon is a product of the air age. It came into being because airmen needed a compact weapon that could be carried in emergency packs during flights over unfriendly terrain. One of the best of these is the still current "Explorer" Model AR-7, in its civilian version, made by Charter Arms. This is a magnificant survival arm. It's a semi-automatic .22 Long Rifle, weighs only two and a half pounds, takes down so that its barrel and action can be stored in its hollow stock, and it floats. With this rifle I can fire a two-inch group offhand at fifty feet, and I'm no expert shot. I can't fault this gun in any way, as a survival weapon.

However, times change. Something new has come on the scene just recently. This is the Garcia "Bronco" 22/410 over and under, distributed by FI Industries of Washington, D.C. This combination gun is all metal, with a skeltonized stock and pistol grip, and a unique rotate-open action. It isn't pretty. But it's rugged, simple, and inexpensive. And it shoots.

It'll get you a one-inch group from rest, with the rifle barrel, at twenty five yards. The shotgun barrel will pattern a good 50% at thirty yards with 7½ shot. This is shooting.

The gun takes down, almost instantly with a twist of the wrist. The package measures twenty inches. It weighs 4½ pounds. The action opens by rotating or twisting the paired barrels to the left, a method so simple that it makes nonsense of claims that an over/under action absolutely must be enormously complicated and expensive. The weapon is all steel, and has a near-rustproof black crackle finish.

It might be argued that the Bronco over/under is so much of a compromise, with its limited two-shot capability and diminutive calibers, that there's not much left to go with. I wouldn't take it out for elephants myself, nor would I feel exactly confident about its man-stopping effect against an enraged Phillipine Moro tribesman. But it'll get you a lot of small game. And there aren't that many Moro tribesmen around these days; I think that your average aggressor, if he has sense enough to be walking around by himself, will not like the thought of a .22 LR hollowpoint in his chest cavity and a .410 shotload in his belly.

SODIUM CHLORATE FROM SOLIDOX

By David Metz

With potassium chlorate both difficult and expensive to obtain, I set about looking for ways in which the survivalist could produce his own supply. So far, that line of experiments has not worked. Instead I have discovered a cheap easy source of sodium chlorate.

Sodium chlorate and the more familiar potassium chlorate are chemically almost the same. Both contain the chlorate ion, a combination of the gas chlorine with the gas oxygen. The oxygen is the important part. The difference is that the atom of potassium metal has been replaced with an atom of sodium metal. Since both metals have some similarities the two chemicals are very much the same.

There are some differences; I'll cover these later.

Our cheap source of sodium chlorate is Solidox pellets. These are sold in hardware stores for three to four dollars a two pound can. Solidox is used as a source of oxygen gas for a small portable welding set.

The Solidox pellet is about 1"x4" and is black in color. They are made in slightly different formulas to provide oxygen at different rates to suit the different setting of the welder. The oxygen gas is produced by burning the pellets in a special cannister.

The formula of the pellet appears to be 80% sodium chlorate, to provide the oxygen. The rest is glass fiber to hold the burning pellet together and black powder that appears to be a mixture of powdered charcoal and manganese dioxide. The charcoal serves as the fuel to burn the pellet and the manganese dioxide acts as a catalyst to increase the amount of oxygen released.

Our job is to extract the useful chlorate from the rest fo the mixture. Luckily for us the waste materials are all insoluble in water. The desired chlorate is very soluble in water.

The first step is to break up the pellets so they will dissolve easily. Break up the pellets inside the bag they come in. Avoid breathing the dust as sodium chlorate is toxic.

Dissolve the now powdered Solidox in hot water. Start with about two quarts. Stir the mixture well to dissolve as much of the chlorate as possible.

Next prepare the filter. I used a large funnel made of plastic. The funnel is supported with a wire hoop over a kettle. The filter material is ordinary cheap paper towelling. Pick the kind that does not have holes in it and use two layers.

While your Solidox solution has been sitting in its container, most of the waste material will have settled to the bottom. Pour the liquid through the filter funnel. The resulting liquid should be clear. If it's not, filter it again.

Dump the black glop from the filter into the container with the other undissolved waste material. As before, let it settle after you have added some hot water to it. This time just use a pint. Then filter as before. This last step insures that all of the chlorate has been dissolved.

At this point, discard all of the waste materials. If your separated chlorate solution is still cloudy, filter it again.

There are two ways to remove the water from your chlorate solution. Since moderate heat will not break down the chlorate, the fast way is to boil the solution until a thick paste is left. Then spread this paste on paper towels to dry out the last of the water.

The other way is to evaporate the water. Place the solution in a shallow pan in the sun. If the pan is dark colored it will absorb more heat and the drying process will be faster. Note that the chlorate solution is corrosive like most salts. Use plastic or other lined containers that do not rust easily.

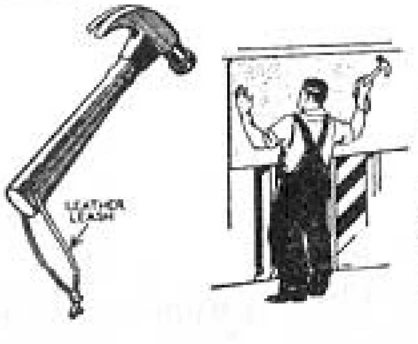
If you were careful you should now have a little over 1½ pounds of sodium chlorate for your troubles. And at a price of less than $2.00 per pound.

Here are the differences between the two chlorates. First, sodium chlorate is TOXIC. It is used for killing weeds. Be careful, do not get it on the skin or ingest it. Unlike potassium chlorate, the sodium compound will readily absorb water. Thus anything holding it must be carefully water-proofed. When sodium chlorate is used in pyrotechnics it burns with an intense yellow-orange flame.

Note that when sodium chlorate burns it releases its oxygen and becomes ordinary table salt. Expect it to be very corrosive if used in primers and propellants.

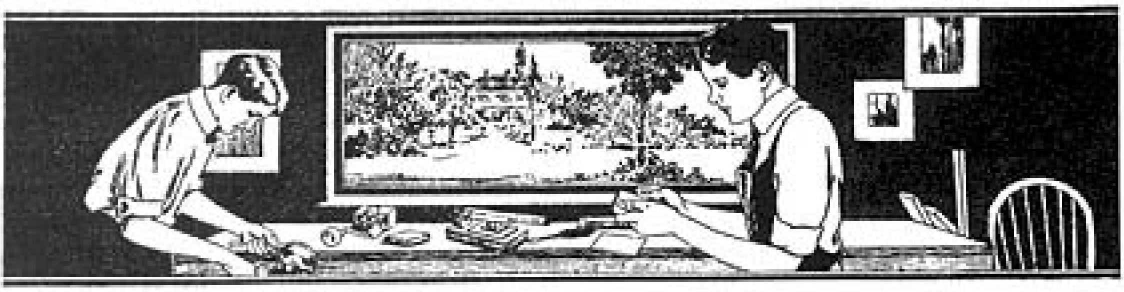
Like potassium chlorate, the sodium compound can be used in igniters. It works perfectly in sugar/sulfuric acid system igniters. It can also be used mixed with sulfer to make percussion caps. Note that not all formulas may work with the sodium chlorate substitute. Sodium is not as reactive as potassium.

The possibility exists that a simple exchange reaction will convert sodium into potassium chlorate. If I can make this work, I will report it in a later article. LAST SAFETY NOTE: When evaporating any chemical solution, do not boil it to dryness. Impurities present could cause a fire or explosion.



Leather Leash on Hammer Keeps It Always Handy

WHEN doing a carpentry job, what could be more handy than to have the hammer attached to your wrist with a leather leash, as shown in the accompanying drawing. When not in use the hammer swings from the wrist, leaving both hands free. A downward scoop of the thumb replaces it in the hand. Any piece of heavy leather or cord will do the job.—



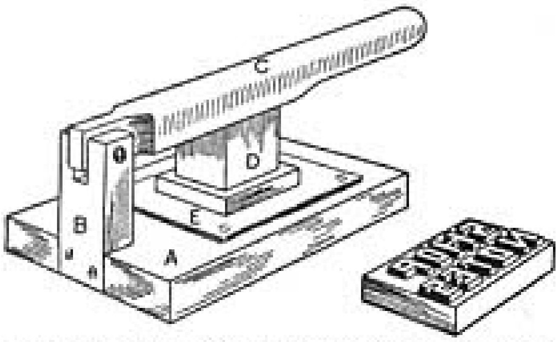
Homemade Cut Press

From Popular Mechanics 1915

The person who has a little ability in making wood cuts with a knife will find it very interesting to make the press shown in the sketch. A fair job of printing can be done with the press, using printer's ink spread on a piece of glass with a hand ink roller, such as can be purchased cheaply of any dealer in printing supplies.

The press may have a base, A, of any size to suit, but one 1½ in. thick, 6 in. wide, and 12 in. long will be found to serve best for most purposes. It must be smooth and level. Hard wood, such as maple, beech, or birch, is best for all parts. The post B is 1¼ in. thick, 2 in. wide, and 5 in. long. Before setting it, slot the upper end for the end of the lever. This is done by making a saw cut, 1¾ in. deep, ⅝ in. from either side and cutting out the core to make a slot ¾ in. wide. A ¼-in. hole is then bored through the prongs to receive a stove bolt that connects them with the lever. The post is fastened with screws and glue in a notch cut in the center of the base end.

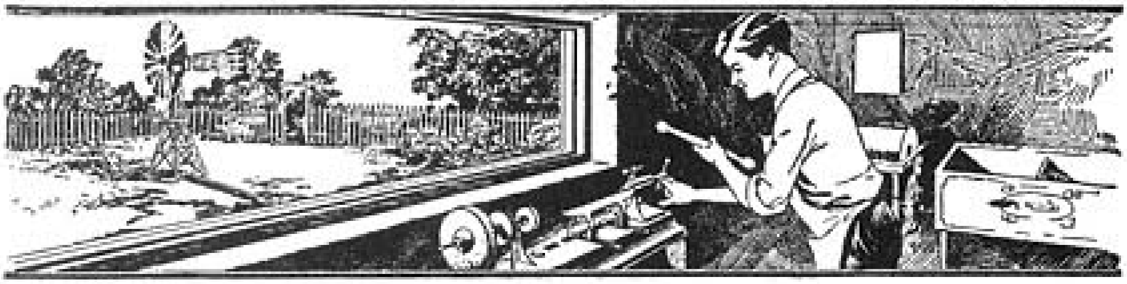
The lever C is made of a piece of wood ¼ in. square and 10 in. long. At the forward end the sides are pared away to form a tongue, or tenon, that will pass between the prongs of the upright, and a hole is bored through it to match those in the prongs. The entire upper surface of the lever is rounded and the under surface is rounded, beginning 6 in. from the tenon end. Glue to the under side of the lever a block, D, at the end of the under, flat surface. The block should be about 1¼ in. square by 1½ in. long. If the under side of the base is crowning, either level it with a plane or nail cleats across the ends for feet. A washer is used with the stove bolt in connecting the lever and post.



A Hand Press for Printing from Cuts Made of Wood, Using Ordinary Printer's Ink

The cuts are made of small blocks of wood, about ¾ in. thick and of a size to take the characters desired. These blocks must be level and the printing side made smooth with very fine sandpaper, or a scraper, before the characters are laid out. Boxwood is best for cuts, but pearwood, applewood, birch, or maple will do very well. Mark out the characters backward, using the pencil very lightly. Then, with the small blade of a knife, made as sharp as possible, cut around the outlines, holding the knife slanting, and remove the adjacent wood by cutting in at a reverse angle to meet the boundary cut. Gradually deepen the cuts around the characters until they stand in relief about ⅛ in., then score V-shaped grooves, checkerboard fashion, across the remaining high surface that is not a part of the design, and chip out the resulting small blocks to bring the entire secondary surface of the block to a uniform level with the portions adjoining the characters.

A touch of glue to the back of the cut will set it securely enough to the bottom of the block D for printing, and allow its removal without injury when desired. To get a uniform impression in printing, place paper on the base, as at E, to the thickness required. For controlling the printing position on the stock paper, pins or tacks can be stuck into the base and each sheet to be printed laid against these guides.—

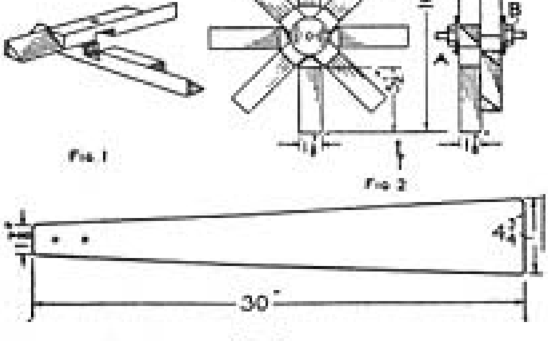


A Power Windmill

From Popular Mechanics 1915

The windmill shown is somewhat different from the ordinary kind. It is not a toy, nor does it approach in size the ordinary farm windmill, but is a compromise between the two, and in a good strong wind, will supply power enough to run a washing machine, a small dynamo, an emery wheel, or any other device used in the home workshop. The wheel is about 5 ft. in diameter, with eight blades. The over-all length is about 6 feet.

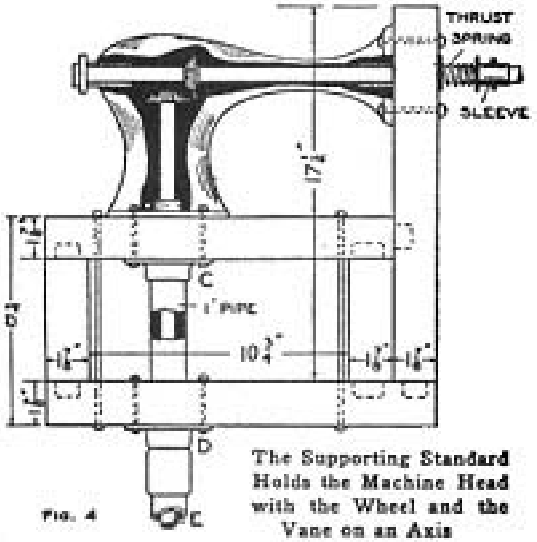
The windmill is easily made and the cost is within the means of the average boy. There is not a part used in its construction that cannot be found about an ordinary manual-training shop. The most difficult parts of the construction will be described in detail. Symmetry and smoothness of design should be preserved and the parts made as light as possible consistent with strength and durability.



The Hub Consists of Two Parts, Each Having Four Arms for Holding the Blades

The Wheel

As shown in the drawings, the wheel has eight blades. Ordinarily the use of eight blades makes it difficult to construct a hub of sufficient strength



The Supporting Standard Holds the Machine Head with the Wheel and the Vane on an Axis to carry them. Where so many blades radiate from a common center it is almost impossible to provide an anchorage for each blade. To provide a maximum of strength coupled with simplicity of design, the plan of using two hubs of four arms each was adopted in the construction of this mill. The ordinary hub of four arms is simple to make and quite strong. Four pieces of straight-grained oak, each 16 in. long and 1⅞ in. square, are used in constructing the hubs. The manner of notching each pair of pieces together is shown in Fig. 1. The slope for the blades is made to run in opposite directions on the ends of each crosspiece. The slope is formed by cutting out a triangular piece, as shown.

The two hubs, thus formed, are mounted on the shaft, one behind the other, in such positions that the arms will be evenly divided for space in the wheel circle. These details are shown in Fig. 2. The blades, Fig. 3, are made of thin basswood or hard maple, and each is fastened in its place by means of two ⅜-in. bolts, in addition to which a few brads are driven in to prevent the thin blades from warping.

The Gears

This windmill was designed to transmit power by means of shafts and gear wheels, rather than with cranks and reciprocating pump rods, such as are used on ordinary farm mills. To obtain this result, an old sewing machine head was used. Such a part can be obtained from a junk dealer or a sewing-machine agent. The head is stripped of its base plate with the shuttle gearing; likewise the needle rod, presser foot, etc., are taken from the front end of the head along with the faceplate. The horizontal shaft and gear wheel are taken out and the bearings reamed out for a ½-in. shaft, which is substituted. The shaft should be 2 ft. in length, and 8 or 10 in. of its outer end threaded for the clamping nuts which hold the two hubs in place, as shown at A and B, Fig. 2. The gear wheel is also bored out and remounted on the new shaft.

The supporting standard is constructed of oak, with mortise-and-tenon joints, as shown in Fig. 4. The width of the pieces will depend on the kind of sewing-machine head used. It may be necessary also to slightly change the dimensions. The machine head is fastened on the support with bolts. A sleeve and thrust spring are mounted on the shaft, as shown. The sleeve is made of brass tubing, of a size to fit snugly on the shaft. A cotter will keep it in place. The sleeve serves as a collar for the thrust spring, which is placed between the sleeve and the standard. This arrangement acts as a buffer to take up the end thrust on the shaft caused by the varying pressure of the wind on the wheel.

The Vane

To keep the wheel facing the wind at all times, a vane must be provided. It is made of basswood or hard maple, as shown in Fig. 5. It is not built up solid, air spaces being left between the slats to reduce the wind resistance. Unless built in this manner, the vane is liable to twist off in a gale. The horizontal slats are ¼ in. thick, and the upright and cross braces ⅜ in. thick, while the long arm connecting the vane to the supporting standard is ½ in. thick.

The supporting standard, carrying the wheel and the vane, must revolve about a vertical axis with the changes in the wind, and this vertical axis is supplied in the form of a piece of gas pipe which runs through the supporting standard at the points marked C and D, Fig. 4. Ordinary pipe fittings, called flanges, are bolted to the frame at these points. The coupling in the gas pipe beneath the supporting standard serves as a stationary collar to support the weight of the whole mill. The vane should be placed correctly to balance the weight of the wheel.

The shaft passes through the framework of the mill on the inside of the pipe, as shown at E. A ⅜-in. soft-steel or wrought-iron rod is satisfactory for the shaft, as no weight is supported by it and only a twisting force is transmitted. The use of a larger rod makes the mill cumbersome and unwieldy. The upper end of the shaft is fastened to the shaft that projects from the under side of the machine head by means of a sleeve made of a piece of ⅜-in. pipe. Two cotters hold the shafts and sleeve together.

At the lower end of the shaft, inside the workshop, the device shown in Fig. 6 is installed. The purpose of this appliance is to provide a horizontal shaft upon which pulleys or driving gears may be mounted. The device is constructed of another sewing-machine head similar to the one already described. The head is cut in two and the separate parts mounted on suitable supports. The gap between the sawed portions permits a pulley to be fastened on the shaft to serve as the main drive. The wheel propelled by the treadle of the sewing machine will make a good drive wheel. The small handwheel, originally mounted on the machine-head shaft, is left intact. This arrangement gives two sizes of drive wheels. Heavy sewing-machine belts will serve to transmit the power.

The Tower

The tower can be built up in any manner to suit the conditions. Ordinarily sticks, 2 in. square, are suitable. These are well braced with wire and fastened securely to the roof of the shop. The arrangement of the tower with the mill is shown in Fig. 7.

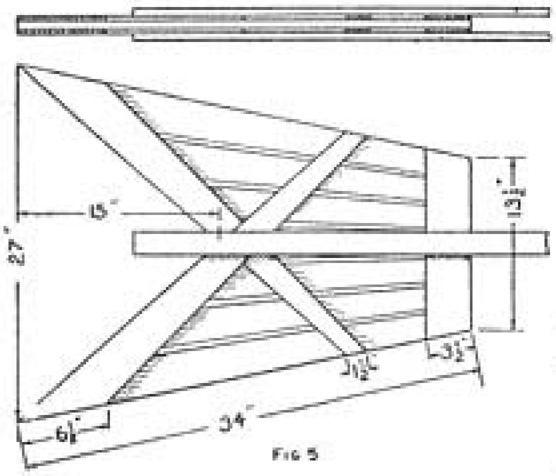


Fig 5

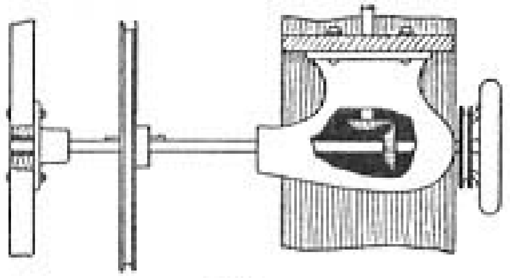

Fig 6

The Lower End of the Shaft has a Horizontal Shaft Geared to It for the Drive Pulleys. The Vane Construction and the Manner of Building the Tower on Which the Supporting Standard Revolves

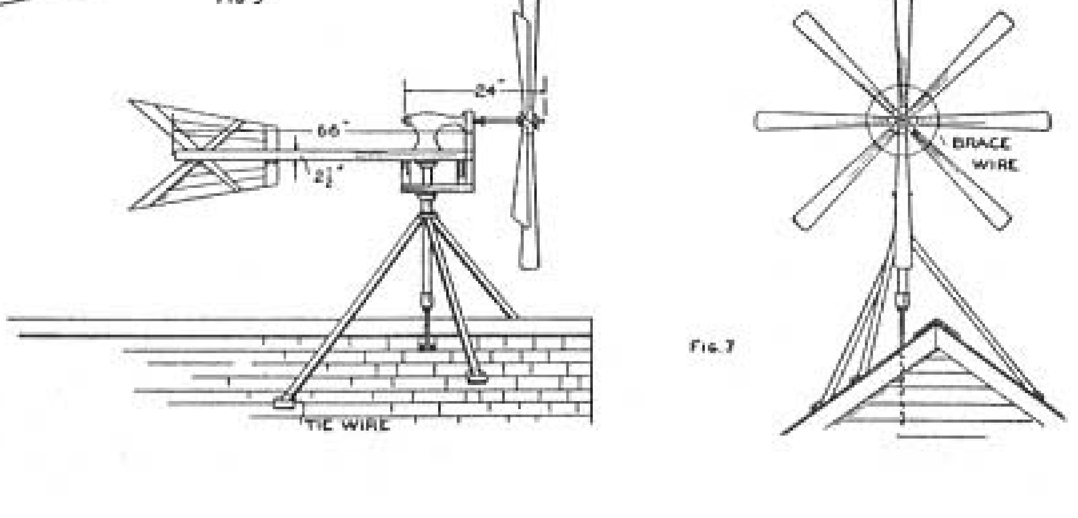

Fig. 7

waiting to bring them out at the next big political rally. At any rate, they can be made even more devastating with the addition of a few ounces of lead in the tip.

So there you have it, my friend—lathework can be an interesting and profitable hobby, or even a home business. Like anything else, you get out of it what you put into it.

Good luck on your new hobby or home business!

Put Your Garden in the Test Tube

...EASY EXPERIMENTS SHOW CHARACTER OF SOIL

From Popular Science 1937

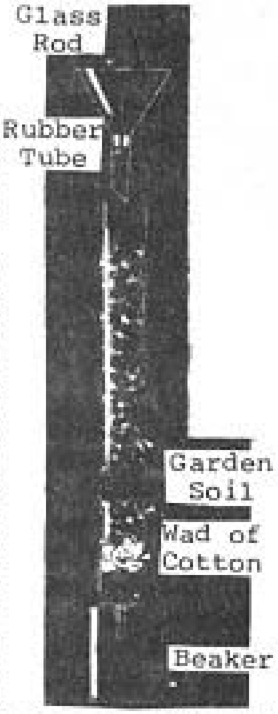
By RAYMOND B. WAILES

HOW is your garden growing? If the plants appear sickly or underdeveloped, a horticulturist would look first for injurious insects. Then he would examine the soil to see whether it is the type that the plants need.

Perhaps the earth should be a little more acid, or alkaline. Possibly it needs more of certain plant foods such as phosphorus or nitrogen—for all kinds of house and garden plants, as well as shrubs, trees, and farm crops, have their own favorite kinds of soil. Plants die and crops fail, all too often, because the grower does not know their soil needs, or because no means of testing the soil is at hand.

However, any amateur chemist can readily test the soil of his own garden. Only the simplest of chemical equipment is required. Just one special precaution need be taken. Test tubes, testing plates, measuring devices, and even the experimenter's hands must be scrupulously clean—in the chemical, as well as the ordinary, sense of the word. Every trace of scouring powder or soap used in washing up your home-laboratory ware, for example, must be carefully rinsed away; otherwise the natural alkalinity of these substances would ruin the delicate test that determines whether soil is acid or alkaline.

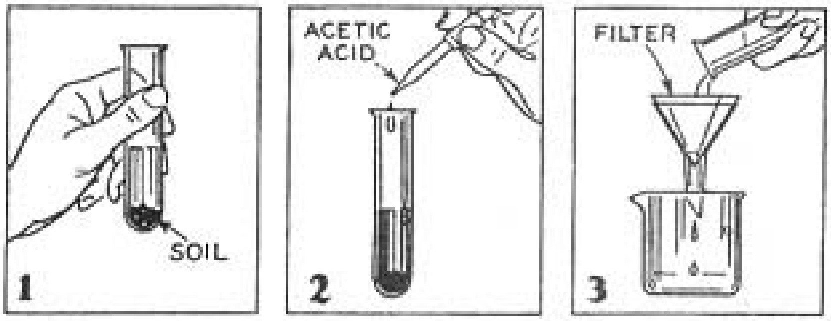
You might imagine that a simple way to test the acidity or alkalinity of the earth from your garden would be to break a moist lump of it in two, press strips of blue and red litmus paper between the halves, and observe the final color of the test strips.



This will not work, however, as litmus is not nearly sensitive enough for soil testing.

The "indicator" or testing material that will serve your purpose is a solution, in water, of a dye commonly spoken of as "brom thymol blue." If you like tongue-twisters, you can call it by its full chemical name, "dibromothymolsulphonphthalein." You can obtain the small quantity of the dye that you will need, in dry form, from any well-stocked dealer in chemicals or microscope supplies. Take a tenth of a gram of the test chemical and dissolve it in about 200 cubic centimeters (nearly a drinking glass full) of water, meanwhile heating the water gently—say, to sixty degrees centigrade (140 degrees Fahrenheit). Then dilute the solution with more water to a total volume of about 330 cubic centimeters. Tap water may

THIS SIMPLE TEST READILY REVEALS THE PRESENCE OF PHOSPHORUS



Place a half teaspoonful of the earth in a test tube and add a small amount of water

Now add one drop of "one-to-three" acetic acid (one part glacial to three parts water)

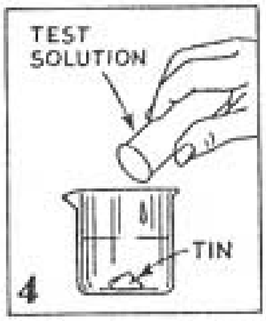
After shaking the contents of the test tube for half a minute filter into a beaker be used if necessary; to insure accuracy, however, it is always preferable to use distilled water in making up reagents, or test solutions.

Brom-thymol-blue solution responds to an alkali, even in small amounts, by turning blue. When the dye solution is made neutral—neither acid nor alkaline—it takes on a dark-green hue. In the presence of an acid, it turns yellow or orange, according to the degree of acidity.

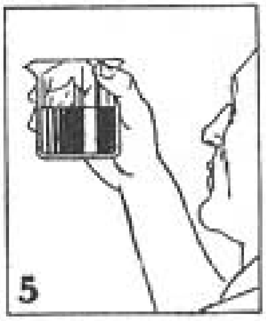
For soil testing, the solution should be neutral or dark-green. Therefore, the yellow solution you obtain from the solid dye must be neutralized with clear, filtered limewater (calcium hydroxide solution). A few drops should be sufficient. Don't attempt to judge the color of the brom-thymol-blue solution by looking at a bottleful or beakerful; pour a sample of it into a test tube, and hold the tube between your eyes and the light. If you have added too much limewater, the liquid will be blue. A drop or so of extremely dilute acid (taken from a solution, say, of one drop of strong sulphuric acid in 300 cubic centimeters of water) may then be added to the entire batch of dye solution to bring back the correct color. If you use too much acid and the solution becomes yellow, add limewater again, and so on, until you finally obtain the dark-green color that you want.

Keep the test solution, if possible, in a bottle made of the kind of glass used in transparent oven ware. Ordinary glass is slightly alkaline and may turn it blue; however, its color may always be corrected immediately before use, as just described.

To test the soil in any garden or field with your solution, collect bits of earth here and there and mix them thoroughly to obtain a representative sample. Then place a pinch of the soil upon a glazed white porcelain plate, a bathroom tile, or an artist's slab. Add enough of the neutral test solution to the soil to make it watery. Also place a few drops of the solution elsewhere on the plate, for comparison and to make sure it has the proper dark-green color. After half a minute, carefully tilt the plate, allowing the liquid to drain from the soil and flow across it. If this solution is now yellow or orange, the soil is acid. If the drained liquid is blue, the soil is alkaline.



Put a piece of sheet or lump tin in a little of the filtrate and add test solution

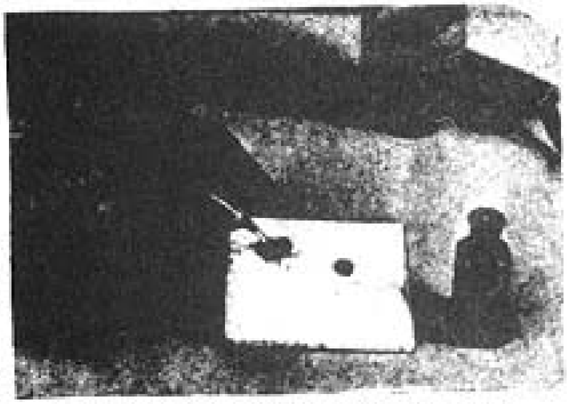


If a blue color appears in the liquid, the soil contains the desirable phosphorus

To prove that soil readily absorbs potassium, let a solution of potassium chloride or potassium carbonate seep through soil in this apparatus. The liquid that comes out contains hardly any of the potassium

Traps for insects are made by spreading a poisonous mixture in jar lids and bottle caps

The dye solution used in testing soil for acidity or alkalinity should be made neutral by adding limewater or a weak acid solution, as needed, until it takes on the characteristic dark-green hue



TESTING THE SOIL FOR ACIDITY

Place a pinch of the soil on a bathroom tile and add enough of the test solution to make it watery. After half a minute, drain off the liquid and observe the telltale color

Gardening books will supply the rest of the information you need—the soil requirements of various plants. Azaleas, rhododendrons, mountain laurel, and broadleaf evergreens, for example, prefer an acid soil. If they are planted in a soil that is alkaline—say, one containing limestone, buliding plaster, or lime—they will surely die. The soil may be replaced with earth from the woods, or may be treated with applications of ammonium sulphate, aluminum sulphate, tannic acid, or flowers of sulphur, to put the plants in their proper environment.

Your brom-thymol-blue solution will also come in handy for testing the water of your outdoor lily pool and your indoor aquarium. This water should be faintly acid, if your fish

he solution used for testing the acidity of your soil also will tell you whether water in your indoor aquarium is acid or alkaline. It should be faintly acid

are to thrive. To a ten-cubic-centimeter sample of pool or aquarium water, add half a cubic centimeter of the dark-green soil-testing solution. If the liquid turns blue, then it is alkaline, and the contents of the entire aquarium should be acidified with a drop or two of very dilute muriatic or sulphuric acid. Repeat your test after you have done this. If the sample now turns yellow or orange, it is definitely acid—in fact, too much so. Aquarium water of the correct acidity should give an in-between, greenish-yellow color with your test solution. If the dark-green color of the reagent undergoes no change whatever, the water is neutral; it will support fish life, but not as well as water that is very slightly acid.

Phosphorus contributes to the fertility of soil, in the form of phosphates of calcium, magnesium, and iron. You can test earth from your garden for the presence of phosphorus with an easily prepared reagent. Dissolve about two and a half grams of ammonium molybdate crystals in twenty-five cubic centimeters (about seven teaspoonfuls) of distilled water using heat to hasten solution. Filter the resulting liquid, if it is turbid. Then pour it into twenty-five cubic centimeters of pure, strong nitric acid. Finally add fifty cubic centimeters more of distilled water. Keep the solution in a glass-stoppered bottle.

TO TEST soil for phosphorus, place about a half teaspoonful of the earth in a test tube and add water to make a total volume of about thirteen cubic centimeters. Now add one drop of "one-to-three" acetic acid (one part of strong or "glacial" acetic acid to three parts of water). Shake the contents of the test tube for half a minute, and filter. To one cubic centimeter of the filtrate, or liquid that passes through the filter, add a piece of clean sheet or lump tin (not "tin" foil from a candy bar, which is actually aluminum) and five cubic centimeters of your ammonium molybdate test solution. If a blue color appears—a reaction requiring about half a minute—then the soil contains the needed element phosphorus. The depth of the shade of blue indicates the amount of phosphorus present.

Plants require nitrogen, too, and get it from nitrate compounds in the soil. You can make a nitrate test solution by dissolving three one-hundredths of a gram of an organic chemical known as diphenylamine in twenty-five cubic centimeters of strong, chemically pure sulphuric acid. Keep this strongly corrosive liquid in a glass-stoppered bottle. If its color changes in time to blue, brown, or pink, it is worthless for your purpose and a new batch must be made up.

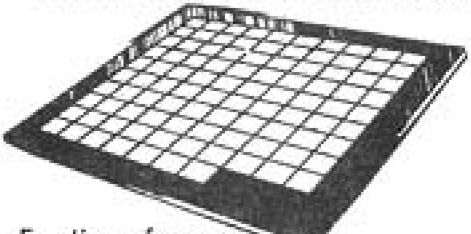
To test soil for nitrates, follow the same preliminary procedure as in testing for phosphorus. That is, place half a teaspoonful of the soil in a test tube, fill with distilled water to a volume of thirteen cubic centimeters, add a drop of one-to-three acetic acid, shake for half a minute, and filter. Now place one drop of the filtrate on a glazed white porcelain plate and add six drops of the diphenylamine test solution. A blue color develops if nitrates are present.

POTASSIUM, or "potash," in various forms of chemical combination, also serves as a valuable plant food in the soil. Solutions containing potassium give a yellow precipitate when treated with a reagent known as sodium cobaltinitrite. To prepare this, mix two cubic centimeters of a ten-percent solution of sodium nitrite (not nitrate), five or six drops of a dilute (say, ten-percent) solution of cobalt nitrate, and one cubic centimeter of strong (glacial) acetic acid.

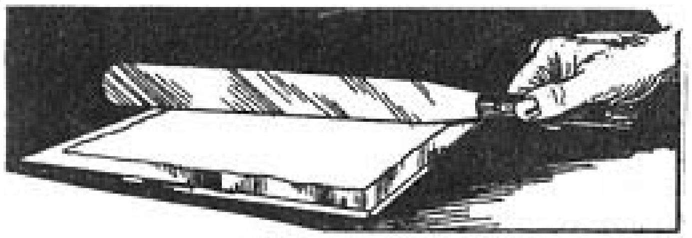
With this reagent, you can show that a fertilizer rich in potassium, such as potassium chloride or potassium carbonate, can be applied to the soil with the assurance that little of the compound will be carried away by drainage or excessive rainfall. Dissolve about a gram of either of these potassium chemicals in a liter (roughly a quart) of water, and let the solution seep through ordinary garden soil in a vertical glass tube of about one-inch diameter. The liquid may be admitted a little at a time through a "choked-stem funnel," made by plugging an ordinary glass funnel with a short strip of rubber tubing and using a pointed glass rod as a stopper. The bottom of the one-inch tube contains a wad of absorbent cotton that holds in the soil and allows the solution to filter through. Test the liquid that has passed through the soil with your sodium cobaltinitrite reagent. You will observe little or no yellow precipitate, while the original solution gives a conspicuous amount, showing that the soil effectively absorbs the potassium.

ANTS can be a nuisance both in the garden and in the home. You can make a good ant trap by first dissolving about three quarters of an ounce of ordinary washing soda, and then about an ounce of arsenious oxide (called also white arsenic), in a quart of water. This makes a solution of sodium arsenite. Since it is poisonous, do not use any household utensil in making it up, but employ a tin can that can be thrown away afterward. Mix one fluid ounce of your solution with about a pint of honey or molasses, to serve as bait for the ants. Pour the mixture over pieces of wrapping tissue, or excelsior, resting in old preserve-jar lids, and place the traps about the garden and the house.

Incidentally, you can readily destroy silverfish, the insect pests that play havoc with books by eating the pages and the binding with the same sodium arsenite solution. Instead of mixing the liquid with honey or molasses, however, combine it with starch or flour to form a paste, and smear the mixture in old bottle caps, where it will harden. Place these little poisonous disks about the house wherever the insects are found—but be sure to keep them safely out of reach of children, remembering especially that a crawling baby delights in putting every conceivable object in its mouth. The poisonous ant traps, of course, should be hidden or safeguarded.



Fractions of a gram of a chemical can be measured by dividing a larger, spread-out amount

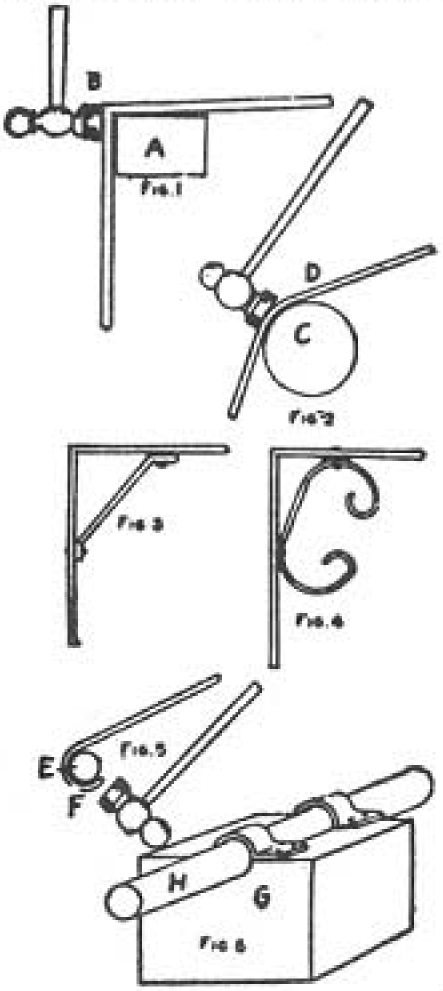


Easy Designs in Ornamental Iron Work

From Popluar Mechanix 1913

Many an industrious lad has made money manufacturing the common forms of wood brackets, shelves, boxes, stands, etc., but the day of the scroll saw and the cigar-box wood bracket and picture frame has given way to the more advanced and more profitable work of metal construction. Metal brackets, stands for lamps, gates, parts of artistic fences for gardens, supporting arms for signs, etc., are among the articles of modern times that come under the head of things possible to construct of iron in the back room or attic shop. The accompanying sketches present some of the articles possible to manufacture.

First, it is essential that a light room be available, or a portion of the cellar where there is light, or a workshop may be built in the yard. Buy a moderate sized anvil, a vise and a few other tools, including bell hammer, and this is all required for cold bending. If you go into a forge for hot bending, other devices will be needed. Figure 1 shows how to make the square bend, getting the shoulder even. The strip metal is secured at the hardware store or the iron works. Often the strips can be secured at low cost from junk dealers. Metal strips about ½ in. wide and ⅛



THE REAL ENERGY CRISIS

by Kurt Saxon

A while back, President Carter admitted to the nation that by 1985 the world will be using more fuel than it produces. This was a promise of doom for the majority of the Earth's population, but few understood it as such.

Consider: Unrenewable fuels maintain world civilization. The world's standard of living has been dropping steadily for years due to the increasing scarcity and consequent higher costs of fossil fuels. The cheap and easy to get fuel has all been gotten, except for various limited government and privately owned reserves.

Now drillers go deeper for oil. They go to undeveloped areas for it. They drill under the oceans for it.

Coal companies must dig deeper for coal. They must move more earth to get it even if it is close to the surface. Stripped land over coal beds must be replaced at high costs.

Oil and coal must be transported greater distances, adding to its cost.

All this is pricing many home owners out of the fuel market. Prices for manufactured goods go up constantly as a result of higher energy costs.

So as bad as things are, they will get worse. Carter implies that by 1985 the home owner will have gone as far as he can go. At that time he will be one of the priorities dropped in favor of industry. This also applies to gasoline for privately owned vehicles.

So in 1985, when more energy is being used than is produced, the private individual won't be able to buy petroleum products at all and the coal for homes will cost at least three times as much as it does now.

So by Carter's figures, your world ends in 1985. Of course, he's only a politician and isn't expected to know anything for sure. His understanding of the problem comes mainly from other politicians, wishful-thinking Liberal trash, for the most part, who don't dare tell it like it is.

They collect the statistics and set the deadline for real trouble always an election or two in the future. The present figure of 1985, eight years in the future, is childishly optimistic in light of the worldwide climate changes. Another super cold winter will knock off a projected year due to more emergency fuel use. Then the turning point year will be 1984. If the following winter causes still another fuel drain, the projection will then be 1983, and so on.

And don't forget the drouth. Going deeper or farther afield for water takes enormous supplies of energy.

No politician can accept the death of his constituency any more than your average flea could comprehend the death of his dog. The worse things get, the more a politician will implement purely political solutions. This involves transferring responsibility from one agency which can't handle a problem to another agency which can't handle it.

Thus, everyone looks busy and the public is pacified for a little while longer. Then the optimists start beating the tired old drum about shale oil, offshore oil, Alaskan oil, more effective use of coal, solar power, wind power, etc. By 1985, they imply, new sources of energy will replace what is running out now.

In the case of shale oil they estimate 600 billion barrels. But companies that have investigated the costs of wringing it from the rock are bailing out. A plant capable of producing 100,000 barrels of oil a day would cost $1.5 billion and could not sell the oil for less than $18 a barrel. Arab oil costs $12 a barrel. You can be sure that by the time Arab oil goes to $18 a barrel, shale oil will cost even more.

These figures don't take into account the fact that the shale oil deposits are in an arid region. It takes massive amounts of fresh water to process shale oil operations. The area has barely enough for agriculture and public use. Forget shale oil.

If you want a laugh, or a good cry, consider offshore oil. Leaks and blowouts from offshore rigs are an ecological nightmare. Blowouts have happened before and still, a professional crew can put a blowout preventer on in. thick are preferable. The letter A indicates a square section of iron, though an anvil would do, or the base of a section of railroad iron. The bend is worked on the corner as at B, cold. If a rounded bend is desired, the same process is applied on the circular piece of iron or the horn of an anvil. This is shown in Fig. 2, at C. This piece of iron can be purchased at any junk store, where various pieces are always strewn about. A piece about 20 in. long and 4 in. in diameter is about the right size. The bend in the metal begins at D and is made according to the requirements. Occasionally where sharp bends or abrupt corners are needed, the metal is heated previous to bending.

Although the worker may produce various forms of strip-metal work, the bracket is, as a rule, the most profitable to handle. The plain bracket is shown in Fig. 3, and is made by bending the strip at the proper angle on form A, after which the brace is adjusted by means of rivets. A rivet hole boring tool will be needed. A small metal turning or drilling lathe can be purchased for a few dollars and operated by hand for the boring, or a common hand drill can be used. Sometimes the bracket is improved in design by adding a few curves to the end pieces of the brace, making the effect as shown in Fig. 4. After these brackets are made they are coated with asphaltum or Japan; or the brackets may be painted or stained any desired shade.

In some of the work required, it is necessary to shape a complete loop or circle at the end of the piece. This may be wrought out as in Fig. 5. The use of a bar of iron or steel is as shown. The bar is usually about 2 in. in diameter and several feet in length, so that it will rest firmly on a base of wood or stone. Then the bending is effected as at F, about the bar E, by repeated blows with the hammer. After a little practice, it is possible to describe almost any kind of a circle with the tools. The bar can be bought at an iron dealers for about 40 cents. From the junk pile of junk shop one may get a like bar for a few cents.

A convenient form for shaping strip-metal into pieces required for brackets, fences, gates, arches, and general trimmings is illustrated at Fig. 6. First there ought to be a base block, G, of hard wood, say about 2 ft. square. With a round point or gouging chisel work out the groove to the size of the bar, forming a seat, by sinking the bar, H, one-half its depth into the wood as shown. In order to retain the bar securely in position in the groove, there should be two caps fitted over it and

upside down, as happened in the North Sea. That caused 8.23 million gallons of oil and mud to spew out in eight days, creating a 4200 square mile oil slick. First reports indicate little ecological damage. But all that oily mud settling on the spawning beds may just ruin hundreds of square miles of fishing grounds.

Phillips Petroleum lost $120 million on that blowout. That will be passed on to you.

Ecologists are against atomic energy because of the risks. The risks in offshore drilling are far greater.

Alaskan oil was touted as the big oil crisis bailout. Now it is acknowledged to be only a temporary stopgap, if that.

Greater use of coal is seen by many as a way to relieve the fuel crisis. Coal is not the answer. It is becoming harder to get all the time, which makes it increasingly more expensive. Companies using it will have to install scrubbers to remove most of the sulphur and other pollutants, adding more charges to everyone's bill.

Most average people with some foresight resign themselves to the eventual use of coal over oil. They say coal was used before oil and will take over after oil is no longer available.

This sounds fine except that coal is a major pollutant. It was replaced by petroleum largely for this reason. In 1870 the sulfuric acid given off by burning even high quality coal having the least sulphur content was eating away the buildings in New York City. (See editorial, page 46).

In 1870, New York City had a population of 942,292. Today, New York City's population is about ten times that.

Even with scrubbers, coal burned for about ten million New Yorkers would kill them all. White House Energy Advisor, James Schlesinger now says that New York City and Los Angeles won't have to burn coal. This would have to apply to just any city with smog problems.

If your city has a smog problem, you should realize that even scrubbed coal would intensify the problem to the critical level. So since city dwellers, largely unemployed, can't maintain the rising utility costs, the cities will die.

If coal were used nationwide in quantities Carter envisions, coal pollution would be catastrophic. In 1870 our population was only 38,558,371 and coal pollution was a serious problem. There are about 200 million more people in the U.S. today.

Concerning solar and wind energy, read my editorial on page 36.

Over the weekend, the TV carried a story of clam bed pollution off Long Island in New York. Health officials had extended the off-limits zone for clamming another 300 yards out.

This was due to the sewage New Yorkers allow to run off into the Atlantic. Clam pirates were violating the area and taking potentially contaminated clams to sell to their fellow New Yorkers. Aside from the pirates, most clammers were either digging clams further out or going out of business.

Logic would suggest that the sewage should be kept out of the ocean, both for the safety of swimmers and to insure the purity of the food taken from offshore waters.

New York has a smog problem and a sewage pollution problem. By diverting the sewage into methane generators, one problem would be solved and another eased. The methane from the sewage would go for cleaner power and the ocean food would be made safe.

Friends or Allies: Choice for Survival

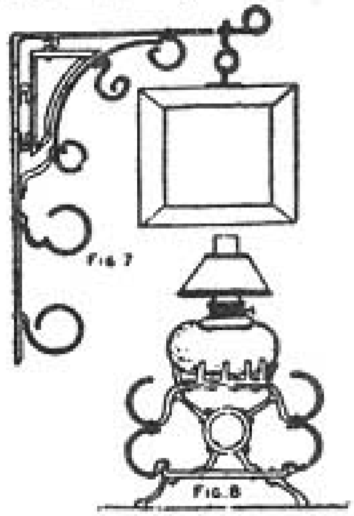
By Kurt Saxon

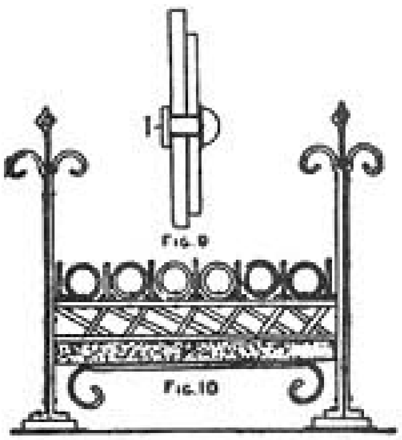
In the 1950s, several thousand people had nuclear fallout shelters built, usually in their back yards. At first they met only ridicule by those neighbors who considered themselves above such hysteria.

In time, however, it occurred to those neighbors that something had changed in their relationship with the shelter builders. Often, those who had set-screwed to the wooden base. These caps may be found in junk dealers' heaps, having been cast off from 2-in. shaft boxes. Or if caps are not available, the caps can be constructed from sheet metal by bending to the form of the bar, allowing side portions or lips for boring, so that the caps can be set-screwed to the wood. Thus we get a tool which can be used on the bench for the purpose of effecting series of bends in strips of metal.

Since the introduction of the laws requiring that signs of certain size and projection be removed from public thoroughfares in cities, there has been quite a call for short sign brackets, so termed, of the order exhibited in Fig. 7. These sign-supporting brackets do not extend more than 3 ft. out from the building. A boy can take orders for these signs in almost any city or large town with a little canvassing. The sign supporting bracket shown is merely a suggestion. Other designs may be wrought out in endless variety. A hook or eye is needed to sustain the ring in the sign.

The young man who undertakes to construct any sort of bracket, supports, frames or the like, will find that he will get many orders for lamp-supporting contrivances, such as shown at Fig. 8. It is hardly necessary to go into details for making these stands, as every part is bent as described in connection with the bending forms, and the portions are simply riveted at the different junc-





been friends for years came to despise each other.

It usually started like this: Sam would say to Paul, the shelter builder, "Paul, I don't believe there's going to be a war. But if it happens, I'll know where to come."

Paul would say, "But, Sam, it's not a matter of belief. If it happens it'll happen and if it doesn't happen, it won't. Neither of us believes our homes will burn down some night. But we both have fire insurance. So my shelter is simply my nuclear war insurance.

"What if you had fire insurance and I didn't? If my house burned down, without insurance, I could never rebuild. Would you allow me to move my family in with you on a permanent basis?"

Sam might say, "But that's a poor analogy. I'd be glad to put you up for a few weeks and even help you to rebuild."

"But," Paul would reply, "We both make about the same wages. What if I bought a boat instead of fire insurance, thinking, "What the hell, I'd rather play with a boat than sit around home worrying about an unlikely fire. Besides, good old Sam will bail us out. He's our ace in the hole.

"Would you want to be our ace in the hole if we left our welfare up to you while we ran around in a damn boat while you sat home worrying about a fire?"

"Harping on the boat again," says Sam. "I said you could use it."

"Forget the boat," says Paul. "The point is, that you considered the boat more important than nuclear war insurance. You have all kinds of insurance but you don't seem to know what insurance is. It's not negotiable. You have hospital insurance and I don't and I get sick; tough on me. You buy fire insurance and I don't and my house burns down; your insurance company wouldn't rebuild my house.

"Like your life insurance, my shelter is nuclear war insurance which covers only my family. If you want that kind of insurance, buy it. Don't expect to use mine."

By now, Sam is seeing that friendship has its limits and he resents it. "Okay," he says, "Just suppose your war should break out. So I haven't prepared. But we've been friends for years and I never put you off when you needed help. And you've always been on hand to help us. But now, when it's a matter of life and death, our friendship isn't worth a bo-diddly? Is that what you're telling me?"

"It's not a matter of friendship," says Paul. "My shelter was built for my family of five. It's for two weeks; maybe four if we absolutely had to stay longer. You crowd your family of five in there and we'd all be dead in a week."

"Maybe so," says Sam, "but the point is, you would just keep us out, knowing we would all be sprawled around the door, dead as mackerals. (He breaks into sobs.) And my littlest, Jenny, she's only five, you know. Before I'd let you close her out, I'd come with a gun."

Such arguments would go on to the point where the neighbors were no longer friends. I never heard of a case where, rather than break up as friends, the other neighbor built a shelter.

Telling the improvident their time is running out seldom motivates them to prepare. The improvident are the improvident. That's their nature. They know their basic helplessness, but will seldom admit it. They are more likely to react with hostility to survival advice than to begin their own preparations.

The difference between one who prepares and one who doesn't is more important than a difference of opinion. If you prepare to survive, you deserve to survive. Those who can, but won't prepare, don't deserve to survive and the species would be better off without them. If you have the kind of intellect that's geared to survival, it may be a matter of genetics. Your neighbor may lack these survival genes. Therefore, becoming his means of survival could not only doom both of your families to death, but if you should make it, you would have enabled a non-survival type to further pollute the gene pool. That's a no-no, although you might take in one of his brighter children if you really have enough room. If you are really in a position to save someone, you tures. Both iron and copper rivets are used as at I, in Fig. 9, a cross sectional view.

The best way is to bore straight through both pieces and insert the rivet. In some cases the rivet is headed up in the bore and again washers are used and the heading effected on the washer. Copper rivets are soft and easily handled, but are costly as compared with iron rivets.

Good prices are obtained for the guards for open fireplaces made in many varieties in these days. The return of the open fireplace in modern houses has created a demand for these guards and in Fig. 10 we show a design for one of them. The posts are made sufficiently stiff by uniting two sides with rivets. The ends at top are looped as shown, while the ends or butts at the base are opened out to make the feet. Rings are shaped on forms and are then riveted to the base cross-piece as illustrated. Crosses are made to describe to central design and the plan is worked out quite readily with the different shapes.

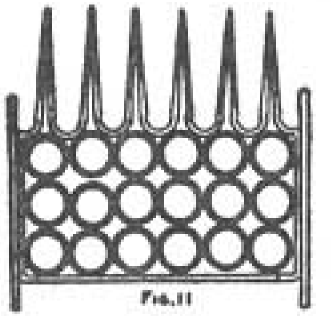


Fig. 11

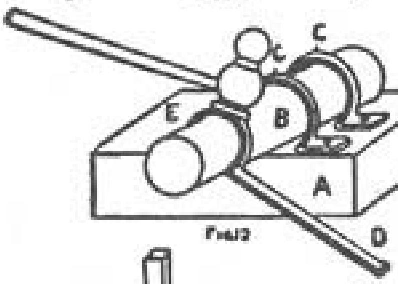

Fig. 12

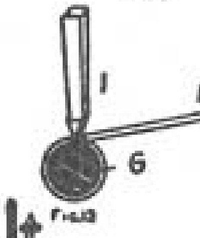

Fig. 13

Fig. 14

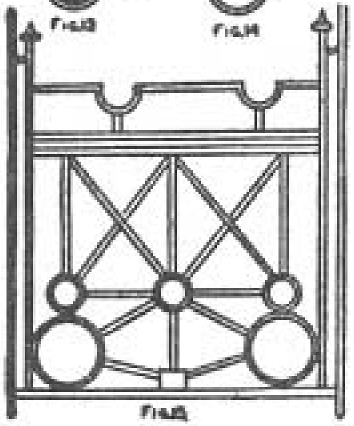

Fig. 15

The making of metal fire grate fronts has proven to be a very interesting and profitable occupation for boys in recent

ought to be selective. But don't be too callous. Without basic human compassion, you might not be worthy to survive, yourself. Aside from making you seem callous towards others, your preparations puts you out of the Good-time-Charley field and you are seen as a part of the establishment. You are then no longer a buddy, but someone to use when things get rough. It's hard to explain but it's sort of like when you go into business for yourself; your wage-earning friends tend to drop away. You have a kind of security they can't aspire to. So they either drop away as friends or become actually hostile.

So you see, friendship ends when you establish a permanancy and security your friends can't aspire to. Maybe they don't care to put out the extra effort or money. Maybe they're just lazy or stupid. It doesn't matter why they drop away. Just recognize the fact that Survivalists are likely to see their friends drift away.

So don't expect to impress a friend with your preparations. It's far better to get him sold on the idea of making his own preparations.

It's very likely you can't get your friend to exert himself to make any survival preparations. Serious preparation would upset his whole lifestyle.

Most neighbors would rather rationalize away the danger than do something about it. Say you bought a house on an earthquake fault. So a guy comes and tells you you'd better move or get shook to pieces.

So there you are, with everything you have threatened with destruction. A Survivalist would move, taking his losses in money, energy and time.

But the average person would rationalize away the danger and never bring up the subject again. If he was smarter than average he would try to unload the property on some sucker, of course, never mentioning the fault.

So if you broach the subject of survival to a friend and he gives you the horse-laugh, just think of him as one who knows his house is built on an earthquake fault. He'll give you nothing but rationalizations as to why nothing will happen. Best just to ease away from him and tell him nothing further of your plans.

Since survival is the most important subject today, and only a few recognize it, you can't waste time with friends who have little potential as allies. The time is coming closer when if a neighbor isn't an ally, he's highly likely to become an enemy.

Only those who are working on their own survival programs are fit to associate with at this point. I'm not suggesting you snub your friends or give up on non-survivors altogether. This would be rude and stupid. Besides, an intelligent friend might finally come around to your way of thinking as things get worse.

So just be businesslike when talking survival. It's very serious, so the drinking buddy would be more likely to be offended than interested.

In survival programs, an ally is worth any number of friends. In the coming months, you will learn to sort out your allies, who are aware of the coming crash, from your friends, who think you're a nut if you worry about anything but where your next baseball ticket is coming from.

As you come in contact with more Survivalists, you will be bored with your old buddies, anyway. And they will be bored with you, too. So don't feel panicky at the thought of your old cronies drinking without you.

Of course, your first choice of allies should be among your friends, especially neighbors. If you and your neighbor both had a roomy, livable shelter, you could link them up with a tunnel.

Such a setup would enable you to share the burden of buying supplies. Tools, books and the various items of hardware could be shared, rather than having to buy two complete sets for two families.

Linked shelters would also permit visiting for moral support and economy. They would also be handy to resist assault. If one's shelter were under assault by the mob, the other could go through the tunnel and help fight them off. When the mob finally gave up and went off to die of radiatior sickness, life in the shelters could become downright social.

In this way you can see how a neighbor who is an ally can be of great times. Not long ago it was sufficient for the ingenious youth to turn out juvenile windmills, toy houses and various little knickknacks for amusement. The modern lad wants more than this. He desires to turn some of his product into cash. Therefore we present some of the patterns of fire grates which boys have made and can make again from scrap iron, with few tools and devices, and find a ready market for the same as soon as they are made. Figure 11 is a sketch of a form of fire grate bar or front that is constructed with a series of circles of strip metal. The best way is to go to the hardware store or iron dealer's and buy a quantity of ¼-in., ½-in., and ¾-in. iron, about ⅛ to 3/16-in. thick. In fact 1/16-in. metal would do in many cases where the parts are worked out small in size. The ⅛-in. metal is very strong. Then after getting the supply of strip metal in stock, procure the usual type of metal worker's hammer, a cheap anvil, a 9-lb. vise, a cold chisel, a file or two, and a round piece of shaft iron, about 3 in. diameter and 2 to 3 ft. long. This piece of iron is represented at B, Fig. 12.

The iron is held in position by means of the straps of metal C, C, which are bent over the shaft tightly and grip the board base with set or lag screws as shown. The wooden base should be about 2 in. thick and large enough to make a good support for the iron shaft. The process of bending the rings in this way is as shown. The piece of strip iron is grasped at D. Then with the hammer the iron is gradually worked cold about the mandrel as at E until the perfect form is acquired. After the form is finished, the strip at the terminus of the ring is cut off. In order to get a steady base the wooden part may be bolted to a bench. In Fig. 13 is shown the method of clipping off the completed ring. The cold chisel is held upright, and by delivering several blows with the hammer upon the same, the point is caused to chip through the metal and release the ring. The shaft or mandrel is marked G. The cold chisel is indicated at I and the position where the hand grasps the strip is at H. The final operation in shaping the ring is by driving the protruding cut, lip down, to the common level of the opposite point, thus giving us the finished ring with the lips closed on the mandrel as at J, Fig. 14. These rings can be turned out in this way very speedily. The next operation involves the process of uniting the rings in the plan to shape the design. The design work is often worked out ahead and followed. Some become so proficient that they can develop a design as they proceed.

benefit. But a neighbor who depends on you to save his bacon is not only not an ally but he could become your worst enemy.

One way to help a neighbor to become an ally is to introduce him to other Survivalists. Then he will feel that you're letting him in on something. Also, if you have three or four guys in your home talking survival, your neighbor will feel he's the isolated minority in his stand that this is the best of all possible worlds.

Even if your area is an unlikely target for a nuclear bomb and underground shelters are not in your plans, the ally principle is still very important. You just can't waste time with a friend who is of no use in your survival plans.

An ally can be a person you don't even like, socially. But if your ally shares your enthusiasm for survival, he will be far more useful to you than a friend who agrees with you on everything but survival.

PARANOID, FROM PAGE 556

A guy hiding his survival preparations might as well forget it. His neighbors are more important to his chances than any survival gear. The neighbors I'm talking about are working people who are acquaintances and potential friends. I'm not suggesting one share his plans with welfare bums, winos, dopers and general trash. No. I'm talking about decent people who simply don't share our views at this time. These people will come around to our way of thinking in time.

The Survivalist's early preparations will give him status in his neighborhood as things get worse. The neighbors will listen to him in the near future if he will only give them the chance to agree with him now. But if he automatically writes them off as hostile and potential looters, that's exactly what they'll be when things get really bad.

I think some of you get survival preparations confused with having a fallout shelter. If you had a shelter and your neighbors didn't, you would be severely mobbed in the event of a nuclear war. Your neighbor's lives would depend on getting in. But an extra supply of food, weapons and trade goods in your home would not give rise to panic. There would be nothing immediate about it.

There won't be a government message saying that everyone with a stock of survival goods will live and those without will die, period. There won't be a stampede to your place. Before things get bad enough for your neighbors to loot you, they will still have time to imitate you, although not as cheaply or with your wide selection.

But let's say you're a real Secret Squirrel and have made your home a storehouse of arms, food, etc. No one knows and finally the system collapses and your neighborhood goes through the turmoil you might expect.

Now your neighbors, who you've considered enemies, have managed to fight off some bands of looters and are setting up neighborhood defense and help organizations. Instead of being among the leadership, you are simply one who shares what they have because they think you are in need.

You're in real trouble because if your neighbors find out you've been holding out and taking help from them, they'll shoot you. If you don't take their help, they'll find out why and shoot you for holding out.

Your only real chance now is to give your neighbors the benefit of the doubt or move to an isolated farm. In any event, the more allies you have, the better your chances. But if all you see now are enemies, that's all you'll see when you need friends the most.

Survival Shelters and the Dependent Aged

By Kurt Saxon

"Dear Mr. Saxon:

"I really enjoyed Vol. 2, No. 6 (Pages 235-250) of THE SURVIVOR. Especially the article "Survival of the Fittest," by Tom Murphy, and "The Survival Shelter," by yourself. However, at the end of your shelter article you wrote something that is very disturbing to me, regarding older people.

"You state, 'Steel yourself to keeping her out. Better to reject anyone whose life in nearly over.' Later you mention the elderly, unbelievably to me, along

Figure 11 is a design of grate front used for various purposes in connection with grate fires. The series of rings are united by a rivet between each at the joining point. With thin metal the holes can be punched with an iron punch and hammer on an anvil where there is a hole to receive the point of the punch after the punch penetrates the metal. For the heavier forms of metal a drill is necessary. A metal drill and brace can be purchased very cheaply for this work. After drilling the holes, the parts are erected and the rivets inserted and headed up as each addition is made. Thus the series of rings are united and then the side pieces are similarly riveted. The points at the top are then worked out and joined on. These points are filed down to the necessary taper after the union is effected. The finishing work involves smoothing rough places with a file and painting. Asphaltum makes a good black finish. Some of the best designs of grates are bronzed. Some are silvered. The different designs are finished as desired by customers.

Figure 15 is another design of grate in which the process of shaping the rings is like that in the first design. There are some half circles in this pattern and these are framed by shaping

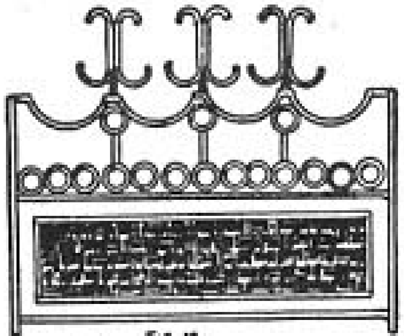

Fig. 16

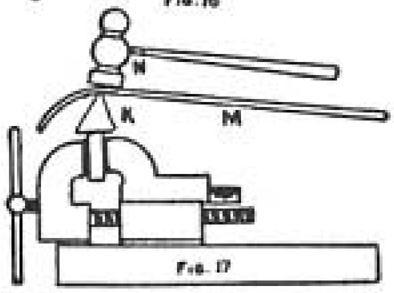

Fig. 17

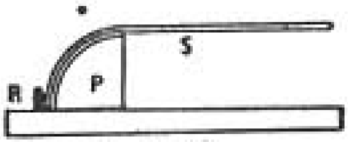

Fig. 18

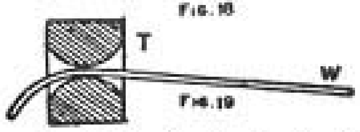

Fig. 19

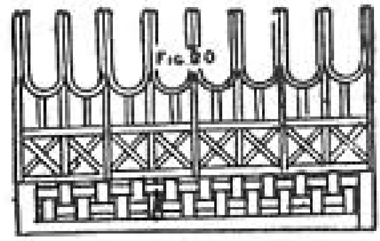

Fig. 20

with the retarded, criminals and perverts, as 'unfortunate and helpless.'

"Mr. Saxon, I could hardly believe what I was reading. I had to check again who it was that wrote the article. I was disappointed to see that you did. Is this all you think of older people? Let me speak in their defense.

"First of all, who can consider anyone over 70 years old as anything but a Survivor? What about all the priceless knowledge they have accumulated? These old folks lived the very life that we Survivors will face some day. Who better to have in a shelter with you? Did you ever meet an older person who didn't know about animals and gardening? I never have. Old folks need very little sleep and very little food. If not senile, most of them are walking encyclopedias and history books.

"In short, they have been where we are going. How can you suggest that we turn such valuable resource away from our shelters? I would sooner have an old man or woman with me than nearly any useless young punk or bitch.

"To think that you, of all people, would classify old folks as parasites really makes me think twice about where your head is at.

"Well, you've done so well otherwise that I will allow you this one mistake, drastic as it is. Please think about it, Mr. Saxon.

Sincerely,
Ron B.
Calif.

The above letter is typical of many idealistic Survivalists. Without love and compassion for others, society would be a worse jungle than it is. However, I think a lot of my readers may just doom their own hopes of survival by including in their programs those who could not survive without our modern technology, anyway.

A person of seventy who is hale and hearty, has his wits about him and is making his own survival plans, may have a better chance than most younger Survivalists. Such a one would be more likely to keep me out of his shelter than the other way around. I'm not worried about the self-reliant elders, who make up a big proportion of my readership.

The type of elders I suggest excluding are those who have given life their best shot years ago. They are retired, feeble and given to dozing when not watching soap operas.

Increasingly, we read of elders stealing food from stores. Never on a police blotter before, but now they are brought in for petty theft. Others scrounge for food in garbage cans. These are the improvident. Their whole working lives were spent earning wages from others. They were never self-reliant in the first place. They end their days in miserable little rooms, rest homes or in a corner of their often grudging children's homes. All such elders are too dependent on a given system to survive without it.

Being old is nothing to be ashamed of but the sanctity of age for its own sake is a myth.

The Granddad image I've tried to project through so much of my writing has nothing to do with old people. "Granddad" was a young person, 20-40, living in the nineteenth or early twentieth century. The most important quality he possessed was self-reliance. Self-reliance has always been the individual's best guarantee of survival.

In those days there were no supermarkets and people did have to know how to do a lot for themselves. Only the affluent paid others to do services around the home. The average person had to do for himself or do without. Today, the average person will call in a $15.00 an hour plumber to put a washer in the sink faucet.

As goods and services became more available and cheaper, more people became less self-reliant as a matter of course. This is normal. A woman who would scrub floors on her hands and knees with all the labor savers on the market would be stupid. A man who learned a dozen household skills just to save money would be just as stupid. (For other than a faucet washer, I call a plumber).

In the last century, survival skills were not simply a person's trade, but consisted of home maintenance, food processing and such. Later, a man the same about the mandrel with the hammer. In order to get the shoulders close and the circle complete it is necessary to heat the metal. A coke fire can be made in a hole in the ground. Then procure a tin blowpipe and blow the flame against the metal at the point to be bent. This metal will become red hot very soon, and can be bent readily against the anvil and the circular form. Let the metal cool off on the ground after heating. Fig. 16 is another design which can be wrought out. The middle adjustment is wire screen work which may be bought at a hardware store and set into the position shown. Fig. 17 shows a chipping off device useful in connection with this work. Metal chippers can be bought at any tool store. The chipper is placed in the jaws of the vise as at K, and secured there. The strip of metal in process of cutting is marked M. The hammer head is caused to strike the metal just over the cutting edge of the chipper. The quick, hard blow causes the cutting edge to penetrate far enough to sever the piece. Bending cold with a wooden form is done as in Fig. 18. The wooden form is marked P and is about 8 in. wide and 7 in. high, forming a one-sided oval shape. There is a pin R set into the base board of the oval form and the strip of metal for bending is grasped at S and the other end is inserted back of the pin R. By applying pressure, the strip of metal is bent to the form.

Figure 19 shows the hour-glass wood bending form, made by selecting a piece of hard wood block, about 6 in. square and boring through with an inch bit. Then the hole is shaped hour-glass like. The view is a sectional one. The block is placed in a vise and the strip for bending is inserted as at T.

The strip of metal is grasped at W and can be bent to various forms by exerting pressure. Fig. 20 is another type of fireplace front, constructed by uniting the shaped metal pieces. In fact an almost endless variety of designs can be wrought out after the start is once made. A good way to figure the price on the grate is to add up the costs of the parts and charge about 12 cents per hour for the work.

PLANING ARROW STICKS

From Popular Mech. 1919

While making some bows one day I discovered I had no suitable dowel sticks for the arrows, so I started to make them out of ¼-in. square stock. I found it rather difficult to plane these pieces until I hit upon the scheme

could be free of most of this drudgery at little cost. When people no longer needed most survival skills, later generations never learned them in the first place.

So what's all this about an older person being a goldmine of information? Take a 70 year-old person; born in 1907. By the age of 20; starting a family; well into a trade. Year, 1927.

By that time, the only survival skills the average American knew was the job that gave him his living. This was especially true in the towns and cities.

Women in the cities of 1927 were little more able to cope with gut-level survival situations than are women today. They didn't raise livestock, make butter, soap, etc., and they bought most of their clothes and just about everything they needed. Farm women bought every labor saver they could afford from their Montgomery-Wards or Sears catalogues.

So the person who is 70 years-old today is hardly likely to be an encyclopedia of 19th century crafts. There are far more young people of today learning such skills than there are elders with any useful memories of such skills.

An old person is just someone like you or me who has lived a lot of years. If you stop learning after you establish a trade, you'll be no smarter at 70 than you are now.

At 45 I know many old people. I lived with old people during my college period when I lived at the Wino Arms in Long Beach, Calif. There were a lot of retired old fellows there, just waiting to die.

One was Cap, an ex-skipper with a memory which kept me amazed. He could remember every word that passed between him and a ruined woman he took up with on the old Bowery. He could detail the complete action of a brawl that happened in a Singapore dive in ought-seven.

But when I tried to pin him down to any relevent thing about the old days, I'd draw a blank. All he and the others could recall was personal trivia, having no practical or historical value. Later, when I got into this field and quizzed many elders about common old skills I lucked out completely. They all remembered people who knew such things, and some even remembered having done such things themselves. But when it came to detailing the process or updating it for today's use; forget it. They had no need to retain such knowledge, don't you see? So over the years they forgot critical steps in the processes they had had some knowledge of, the same as you or I would.

So put the matter of the old person in the shelter in its proper perspective. If you consider saving an elder under any survival circumstances, don't do it because you will need that person. With rare exceptions, you won't. If you save an elder it will be because you love that person.

Now that we've established (as far as I'm concerned) that saving an elder is most likely an act of sheer altruism, let's see what this would involve.

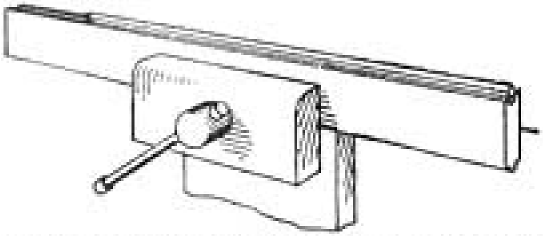
First of all, an elder is set in his ways and faced with the idea of going underground and then coming up to total chaos, he'd probably rather take all his prescription medicines at once and finish himself off.

Let's say, however, that he means to ride it out. (And when I say "he" I mean Granny, too). So the elder goes down into the shelter, finds it uncomfortable and boring and simply dies. It's as simple as that. When you are all battened down and the elder dies, as you must realize is almost a certainty, what would you do with the body?

Actually, the saving of persons whose further enjoyment of life would be cut off by such hardship would be cruel. Better to put a little something in the tea. Besides, if there is really room enough in your shelter for a person of little or no value to your survival programs, common sense dictates that that person should be a neighbor's child. At least a child has potential.

The question of whom to save in such a circumstance is largely academic. Who knows what horrible decisions an individual will have to make at the last moment?

There is a book that is out of print but which you might find in your library. It is "Flight in the Winter," by Jurgen Thorwald. This deals with Germany during the invasion by Russians at the end of WWII.



Planing the Corners from Square Stock by Placing Them in the Groove of a Flooring Board

shown in the sketch. I procured a piece of ordinary tongue-and-groove flooring and clamped it in the bench vise, then drove a nail in the groove to act as a stop, and in no time I had the sticks planed into arrows.

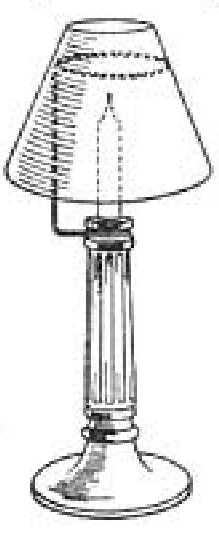
How to Bake a Fish in Clay

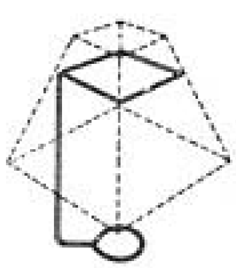
A clay-baked fish is so simply prepared, compared with cooking it in camp, that it will be hailed with delight. The best kind of clay to use for the purpose is the gray clay generally found along streams, but in the absence of this, ordinary red clay will answer. The fish is cleaned and washed, stuffed if desired, and sewed up in the ordinary way; the head of the fish may be left on. The clay is packed around the fish so that there will be a 2-in. thickness of it at all points, and it is then ready to be tucked into the fire. Previously, a hot hardwood fire has been kept going; ash is to be preferred because it produces hot coals that last a long time. It is generally a good idea to convert the evening campfire into a heap of coals for the purpose. The fish is placed at the bottom of the coals, covered, and left overnight. In the morning the coals are scraped away, and the hard-baked clay crust broken away with the camp hatchet, exposing the thoroughly cooked fish, savory and palatable to the last morsel. A 5 or 6-lb. fish makes an ideal bake.

A Candle-Shade Holder

From Popular Mechanics 1915

A holder for either round or square shades can be easily constructed from a piece of heavy copper wire to fit on a candlestick. One end of the wire is looped around the upper end of the candlestick, then bent so that the main part will be vertical. The top end is shaped into a circle 2 in. in diameter or a square having sides 2 in. long, as desired.





Two Forms of Shade Holder Made of Copper Wire for a Candlestick

Aside from Hitler's National Socialist doctrines in that period, the German people then, before and since, have been close in culture and attitudes to Americans. They were a very stable people, for the most part.

Thorwald recounted an instance of gut-level survival, to which I'm afraid most Americans would act similarly.

As the Russians moved in, looting, raping and murdering civilians, there was this last German ship leaving a certain port, headed for an area the Russians wouldn't reach. (I don't remember the ship or the port, as I haven't seen the book in years).

Germans swarmed in huge crowds trying to board that last ship. The captain announced that only people with children could get on. As the word spread, people went around the town stealing children for use as boat tickets.

Many lucky adults actually threw their own children over the side to wives or husbands waiting 40 feet below on the dock. Most children who were caught, died from the impact. The great majority fell into the water or onto the dock itself.

Just as a sidelight, that packed ship was later sunk by the Russians, making it the greatest loss of civilian life in any single ship disaster.

If the Germans, supposedly the most disciplined people in the West, could act like that, what will you do when it's every man for himself?

THE GENE POOL & SEXUAL SURVIVAL

By Kurt Saxon

A deer herd is led by the ablest buck. He takes all the does and fights any challenging bachelor. Bachelors may never breed, but they stay, giving alarms and fighting off predators while the does feed in the guarded area. They are still in the gene pool. When the leader weakens or is killed, the best bachelor takes over.

The ablest wolf in a pack is usually the only breeder. Pack bachelors hunt and guard the leader, his mate and pups. Females born to the pack leave with the strongest bachelors and begin their own packs.

Sex among wild animals is only a driving urge to survive genetically. The male is not turned on unless there is a nearby female in heat. The urge being seasonal, the animals are peaceful for long periods between mating. Humans are not regulated by seasons so they are ready just about all the time.

Primitive groups of men were regulated basically the same as the deer herd or the wolf pack. The best man had all or most of the women to himself. But since the procreative urge was fairly constant among both sexes, there had to be rules, lest constant infighting destroy the group. Humans had to ritualize, traditionalize and rationalize sex.

The Bible is the most explicit record we have of primitive peoples; nomadic herdsmen and small village groups. Here is graphic evidence that primitive peoples replaced the animals' natural sexual restraints with the taboo.

These taboos were just as strong with primitives as biological regulation was with animals. The human bachelor, too, had to wait his turn for an available female. He could only find gratification through winning a female in battle or buying her from his chief.

When Jacob considered himself worthy to reproduce, he went to his third cousin, Laban and asked for pretty Rachel. The price was seven years of servitude. Then Laban gave him his older daughter, Leah, instead of Rachel, Genesis 29:21-26, saying he wanted to get rid of his firstborn first. Laban got Jacob to work still another seven years for Rachel.

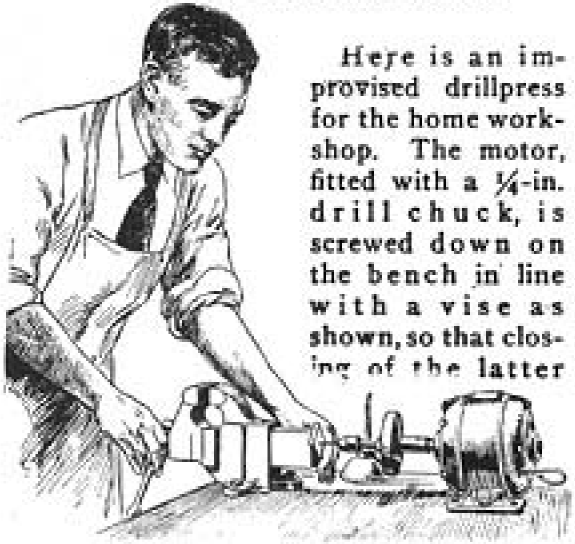
As hard on Jacob as that was, it shows that he accepted the rigid sexual taboos of his culture. Like the animal bachelor, Jacob was resigned to celibacy until his mating was approved. As most men in his culture, he had to struggle to pass on his genes.

As agriculture developed and more people could survive with less effort, cities came into being. Here, there were not the controls faced by deer, wolves, and simple herdsmen like Jacob.

The city fathers had the best and the most females. Males without property

Drillpress Improvised from a Vise and Electric Motor

From Popular Mechanics 1932



Small Chuck on Electric Motor and a Vise Form Drillpress for Odd Jobs

Here is an improvised drillpress for the home workshop. The motor, fitted with a ¼-in. drill chuck, is screwed down on the bench in line with a vise as shown, so that closing of the latter pushes the work against the drill. This arrangement is quite satisfactory for odd jobs where the work does not justify the expense of a regular press.

DETECTOR INTRUDER

By Tommy Murphy

Electronics can be put to many uses in the situations that will confront a person in a survival situation. Electronics makes it easy to have a bunch of sentries to stand guard for you. An advance warning system can consist of simple materials, some thin copper wire, a few staples, some conductor wire, a battery and alarm, either visual or aural, or both. I prefer both as I do not want to be tied up by watching light. If the perimeter is penetrated, I want to know instantly about it.

I would suggest that a number of automobile headlights be rigged up on high beam and put in locations that will give you a circle of bright light. The sudden glare will blind an aggressor and give you an edge if the intrusion occurs at nighttime. You cluster the lights as it is quite possible that an attempt would be made to shoot them out. Then of course, that would pinpoint the location. Notice that I use a 12 volt car battery, car headlights, and as many other parts from automobiles as possible. There will be lots and lots of cars and trucks laying around to salvage from. Also the electrical system can be used in a homemade wind generator to keep those batteries charged.

Now if we are going to use electronic equipment in our little stronghold, it stands to reason that we should learn as much about it as possible. You could keep

or influence took the leavings for wives or had access to prostitutes. Prostitution may have been encouraged by the leaders to keep bachelors away from their harems. Homosexuality may also have become tolerated for the same reason.

Thus, the leaders controlled the gene pool, so did not feel threatened by the vices of common folk. At any rate, with the institution of cities, sex became associated with pleasure.

Sex was not fun to Jacob; it was just a relief of his natural urge. To his wives and concubines, it was only for the conception of children, a primitive woman's only chance for fulfillment and recognition.

The fact that Jacob didn't even know he was mating with Leah instead of Rachel, Gen. 29:25, shows that the act was as simple and one-sided as the sex act can be. This is reinforced by the tale of Judah and his daughter-in-law, Tamar. (Gen. all of chapter 38). After the Lord killed two of her husbands, Tamar despaired of being got with child. She then played the prostitute and seduced Judah on his way to shear sheep.

Now, Tamar was around the house constantly, but Judah didn't recognize her when he mated with her. No kissing or foreplay. Just wham-bam-thank-you-maam. That was sex among primitives.

On the woman's part, there was no involvement. She was just a vessel; an incubator. In Deuteronomy 25:11, the law states that if a woman touches a man's "secrets", even in defense of her husband's life, her hand was to be cut off. This taboo concerning the male organs was just a reinforcement of a woman's non-involvement in the sex act.

Non-involvement for the female was essential since the husband was often away. Had she considered sex itself as pleasure, she might have been attracted to other men. So sex among primitives was only for relief and procreation. Only in the cities had sex become a way of life, rather than simply a part, and therefore a vice.

In primitive, close-knit societies, violations of sexual taboos had consequences understood by all. If a man's son took up with prostitutes or other men, his father was denied grandchildren. If a bachelor deer should choose the best young buck for a mate, when the lead buck was out who would fight for the does? A lesser qualified buck would pass on the genes while the prancing bucks fed with the girls. End of herd. If a bachelor wolf frisked with the next in line for succession as pack leader, on the death of the leader a lesser qualified bachelor would take over and the pack would die out. In Jacob's group, life was so hard and infant mortality was so high that no one could be spared from contributing to the gene pool. Had he took up with a fellow herdsman, he wouldn't have worked fourteen years to get Rachel and then the Christmas card business would never have had a chance.

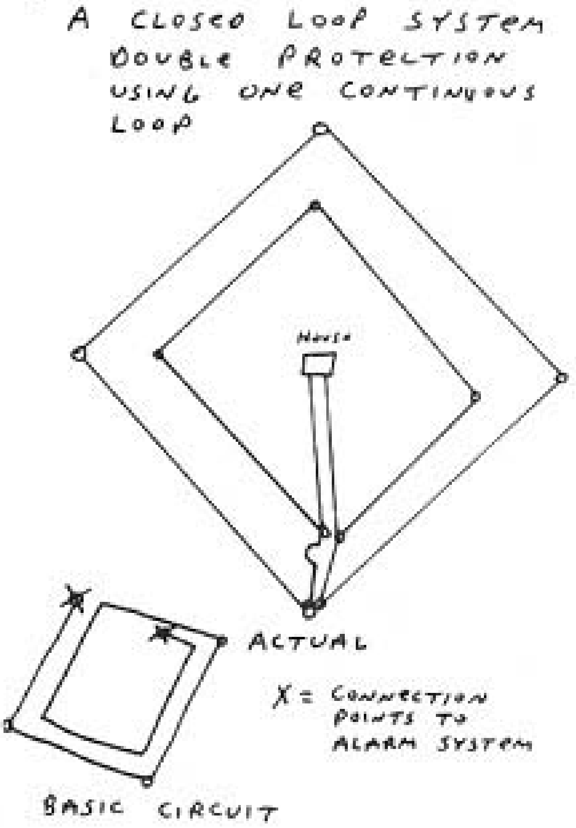
As primitives became less primitive and more children lived, it became easy for them to lose sight of the importance of the gene pool. So elders set about codifying the sexual taboos into law. But since sex is usually done in private, the laws would have been hard to enforce. The best method known to them of enforcing genetically proper sexual behavior was to say that the laws were given and enforced by the local diety. This worked, after a fashion, but as people merged and traded gods back and forth, the sex laws became adulterated and their real purpose was generally lost sight of. This was especially so in the cities.

Enforcement of the sex laws was in a large part responsible for the Israelites' antagonism to city folk, their loose ways and their many gods. They feared any influence by foreigners and their often more sexually liberal gods.

Today's people seem ignorant of the natural laws concerning their gene pool. This is especially so in this country, where homosexuality is promoted as a purely private matter and an individual right.

Opposing this growing attitude is Anita Bryant and her Save Our Children campaign. I admire her stand and that of all her supporters. But her main emphasis seems to be on religion. Primitives have almost universally been anti-homosexual, regardless of what gods they worshipped. To ascribe a lots of spares but the better way is to learn to keep what you have going. If you are going to use a survival tool, learn as much about it as you can. Electronics for our use does not have to be complex or difficult. The simpler something is, the less parts there are to go bad. With this perimeter detection device (anyone can make it) yet it works as well or maybe better than many sophisticated warning devices. The important thing to remember is secrecy in the installation. Hide the trip wires well.

The major disadvantage is that the circuit is live and uses battery power all the while it is in operation. However, the current consumption is small. The thin copperwire is strung around the area you wish to have covered in a double-loop, so that you have double protection just in case someone gets by the first section of wire. The wire can be stapled to stakes or trees throughout the perimeter area. As long as the light on the system is on, then the system is alright. When the light goes out, the buzzer will sound, and to tell if it is just a bulb failure or not, there is a built-in check for light failure. Note that six volt bulbs are used in the system, because of the voltage drop that occurs in the long run of warning wire.



The relay is of the type that uses very little current and is quite sensitive. The relay is held in a pulled-in position by the voltage through the system. If a break occurs, the relay will drop out and cause the buzzer to sound as well as the indicator light to go out.

Now you are using electronics, in a simple form but very effective. With just the use of your hands and a few bucks, you

purely genetic law to a specific god obscures the purpose of the law.

Anita says that since homosexuals can't reproduce, they must recruit. This is her most valid point and conforms to the law governing the gene pool. Since recruitment is epidemic in our time, this point should be elaborated on almost to the exclusion of other arguments. But in quoting scripture so often, she makes homosexuality a Fundamentalist Christian issue. People who aren't Fundamentalist Christians and have no concept of the gene pool, simply consider anti-homosexuality to be religious bigotry.

That this is not at all the case is proven by the attitude toward homosexuality by Russia and Red China; communists and therefore atheists. In Russia, homosexuals are sent away, seldom to be heard of again. In China, homosexual seduction is punishable by death, as it should be here.

As a Survivalist, you may consider our culture too far gone to be concerned with a bunch of perverts taking themselves out of the gene pool. You may believe they are natural defectives and so the species would be better off without their genes. Also, with so many more people than the nation can properly handle, the less children born, the better.

The truth is, however, that homosexuals are not necessarily natural defectives. And concerning the surplus population, to call robbing the gene pool "birth control" is insane.

If homosexuals preyed only on inferiors there would be some positive results. But whereas the normal male wants the prettiest, healthiest girl, the homosexual is attracted to the best looking, healthiest boys around him.

Psychologists have found no evidence that any virgin is naturally oriented toward homosexuality. There is no such thing as a born homosexual. Homosexuality is a learned preference. Also learned are the effeminate mannerisms and speech patterns.

Homosexual seduction usually occurs when a young person has passed puberty but as yet has had no real sexual experience with another. He is often lonely, confused and alienated. He is then befriended by a homosexual and seduced. Since it's his only sexual experience and part of a friendly relationship, it can become his preference, and then he's out of the gene pool.

Not all youngsters are approached. Not all attempted seductions are consummated. Often, a lad is approached by a stranger and given a particularly disgusting proposition or is offended by unwelcome physical contact. In his ignorance he believes there was something about him that told the pervert he would be receptive. Doubting himself from then on and wanting to remove any such doubts from the minds of others, he becomes a "queer baiter". The queer baiter often contributes to homosexuality. Not content to insult obvious homosexuals, he will taunt a virgin lad with "fairy", "sissy", etc., because the boy may be gentler and quieter than other boys. If the taunting gets to the boy and makes him doubt himself, he may be a pushover for the first homosexual he meets. A father who nags his son to go out for sports and be a "man", often drives the kid right into the arms of the coach.

Homosexuality is indeed epidemic in our land. Los Angeles alone is reputed to have at least 30,000 or more little boy prostitutes, some preteeners. Homosexuals say they aren't interested in little boys. They would have you believe the real culprits are child molesters—pedophiles.

These wretched pedophiles sometimes kill their victims and most often injure them physically and/or mentally. The victim of the child molester is usually traumatized and so is hardly likely to seek more of the same treatment.

No, the 30,000 little boy prostitutes in Los Angeles and elsewhere were seduced by predatory homosexuals who treated them gently and paid them. And 30,000 little boy prostitutes couldn't get by in the trade without a large clientele of active homosexuals who do indeed like little boys. There are at least 200,000 homosexuals in Los Angeles County and over 100,000 in San Francisco. Homosexuality is addictive and since it is spreading like a plague, you might even say it's contageous.

get a security system to surround your entire house. A system in your home is good of course, but that means that they are getting mightily close. This way you have a little time to give them a greeting.

PARTS LIST

I1—ALARM LIGHT—Use 6 volt bulb in system due to voltage drop through loop. Radio Shack #272-318 or 272-319 bulbs. Light—Radio Shack #272-324 or 272-325.

R1—RESISTOR—82 OHM, Radio Shack #271-008, ½ watt.

S1—PUSH BUTTON SWITCH—Radio Shack #275-1547, normally open.

RELAY—Miniature type, Radio Shack #275-230 or 275-004.

B1—BUZZER—Radio Shack #273-051.

BATTERY—Any 12 volt—prefer automobile.

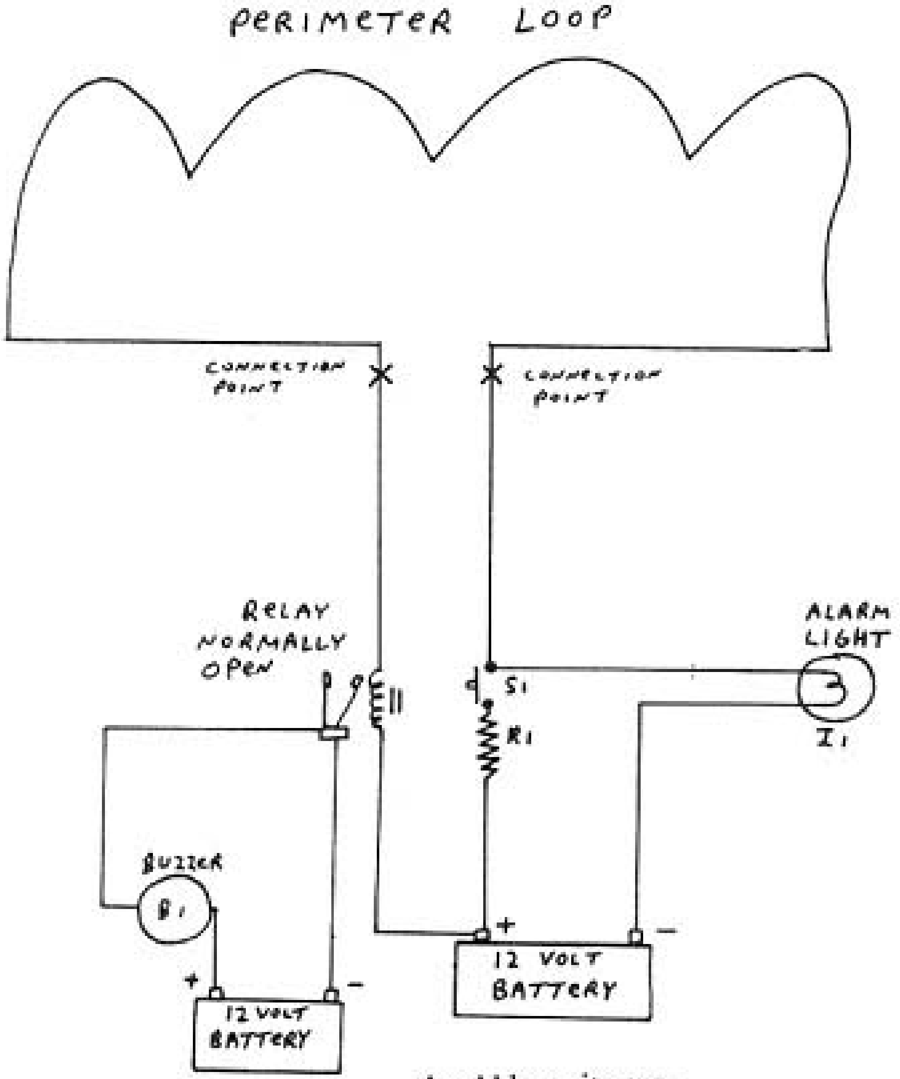
WIRE—#26, Radio Shack #278-005.

With the new tolerance toward this vice, every child is more vulnerable now. Especially when he sees perverts parading across the TV screen to the cheers of Liberal "heterosexuals".

One such Liberal is Jim Dunbar, a San Francisco talk show host. A while back, I heard him say he was encouraging his fifteen-year-old son to be tolerant of homosexuals. I was glad to hear him say that. Anyone who has done as much as Jim Dunbar to spread the acceptance of perversion deserves to have his line die out.

On the same station, I saw Chip Carter come out publicly endorsing "Gay Rights." When the son of the president of the United States openly approves faggotry, who then can say it's wrong?

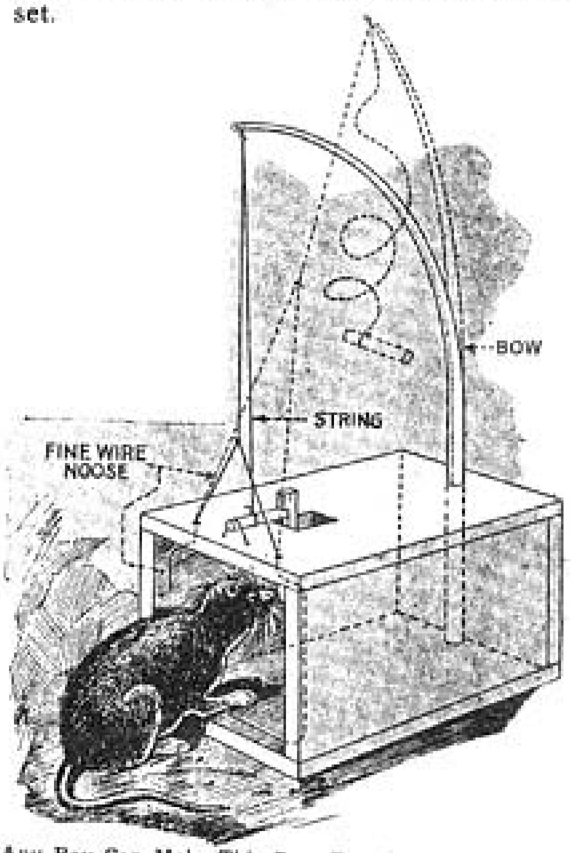
There is little you can do about the national gene pool. But you must guard your own family gene pool. You should tell your youngsters that if any adult gets overly friendly and tries to pet or fondle them, they should come home and tell you. Now with homosexuals agitating to teach as identifiable perverts, our national gene pool is in even more danger. If I had a kid whose teacher was an admitted homosexual, I'd see that teacher on the road or under the ground.



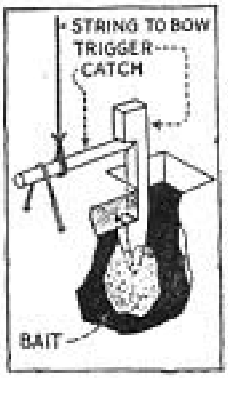
How to Make a Bow Trap

From Popular Mechanics 1928

A bow trap is easily made and is very effective for killing rats and mice. To make one suitable for rats, nail together four boards, 8 in. long and 5 in. wide. Drill two holes, 1 in. from one end, to hold the bow as shown. Also cut an opening, 2½ in. from the opposite end, for the trigger. Drill two holes, 2 in. in front of the trigger hole, for the noose, which should be made of fine wire. The bow is then attached; it should be quite supple and strong. Whittle out the trigger and catch, and nail a small loop of string to the box to hold down one end of the catch, the trigger being used to hold the other end. Tie strings from the bow to the noose catch as indicated, carefully taking up all slack from the noose. Adjust the catch string so that the noose will fill the space in the box opening when the trap is set.



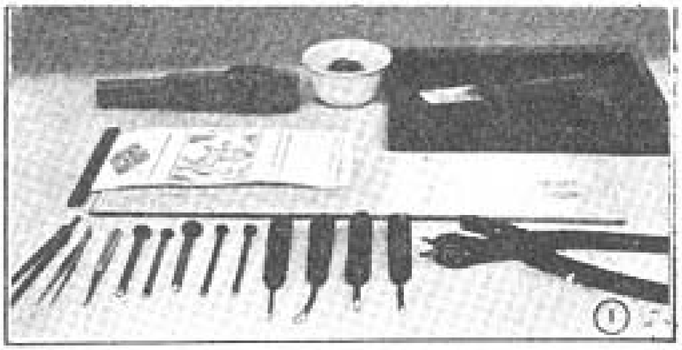
Any Boy Can Make This Bow Trap for Catching Rats and Mice



BORAX DELAYS SETTING OF PLASTER OF PARIS

Plaster of Paris may be used for patching cracked casts and similar work without undue haste if powdered borax is added in the proportions of 2 oz. to 1 lb. of plaster. Mix the powders well in their dry state and then add cold water until the resultant paste is of the consistency desired. The plaster will take almost twice as long as usual to become set and unworkable. This is a formula often used by dentists and doctors.

It's Easy to Tool LEATHER



From Popular Mechanics 1932

DECORATIVE leather tooling is so simple that the veriest amateur can do a pleasing job. Although the work can be done with only a nutpick, a small thumb-shaped modeling tool will greatly improve the original job by bringing it into sharper relief, and, as the beginner gains skill, an assortment of homemade stamping dies, punches, and other tools, as shown in Fig. 1, may be added to obtain a variety of pleasing designs.

For a billfold, only four tools are required: a nutpick, a modeler, a stamping die for the borders and a leather punch. The most satisfactory material is English tooling calf, which has a velvety surface and retains impressions readily. Ooze calfskin or split cowhide with ooze finish are also suitable. A test of proper leather is to indent it with the thumb nail. If the impression is retained, the material is suitable. After obtaining the leather, lay out the design shown, or any other of your selection, on a sheet of paper. In choosing design, pick one in which the lines are not too intricate nor too close together. It is best to cut the leather oversize and trim it down after the tooling has been done, as the beginner may pull the piece out of true shape. Besides, a little extra leather permits the use of thumbtacks or paper clips in tracing, without marring the edges. Get a piece of heavy plate glass, such as part of a windshield, or a slab of smooth slate or polished marble, upon which to lay the work. In tracing the penciled design, you can fasten the work to a smooth board with thumbtacks. Either a hard pencil or a nutpick is suitable for tracing, leaving the design plainly visible on the leather. If the point of the nutpick is sharp and has a tendency to scratch, round it off slightly with a file and smooth with fine emery paper or an oilstone. There should not be the slightest roughness on any of the tools. A modeler can be made by cutting off 2½ in. from the pointed end of a spike, as in Fig. 7, flattening and bending the end, and then grinding it round, somewhat in the shape of a tiny thumb. Set it in a hardwood handle, Fig. 8, so that the end extends about 1¼ in. While making this tool, you may as well add a pebbling die and a flower stamp, as shown in Fig. 8, as they will come in handy on subsequent work. The pebbling die is merely the end of a flattened bolt or spike, grooved with a three-cornered file. The flower design is made in a similar manner. Other dies in great variety can be added from time to time, among which a star is often useful.

With the design traced on the leather, deepen the lines with the nutpick as shown in Fig. 2, having first moistened the leather with a wet sponge, and keep it moist but not too wet as you proceed with the work. After the lines have been indented, use the modeler to press down the leather around the main outlines of the design and to work it into relief, as shown in Fig. 7. Do not attempt this, however, where lines are close together, as in the hairs of the lion's mane, in petals of flowers and leaves, etc. The background around the figure can either be pebbled with the nutpick or with the pebbling tool. For large surfaces, the latter makes for less heavy work, although the former may perhaps give a more pleasing effect. After the tooling has been completed, cut the piece to finished size, laying it flat on a board and using a sharp, thin knifeblade against a metal rule or straightedge.

For a billfold, cut a plain piece the same size as the tooled piece. Score the tooled piece lightly where it is to be folded, then fold the two pieces along this line, using the hardwood creaser shown in Fig. 10. Note that the inner piece will then extend slightly beyond the outside section; trim the former flush. When this is done, the billfold will fold naturally, without a bulge on the inside piece. With a pair of dividers, or a rule and sharp pencil, lay out centers of the holes for the lacing on the tooled piece. They should not be over ¼ in. apart on centers and ⅛ in. from the edge. Use a leather punch of about 3/32-in. diameter, and punch holes in the inner and outer pieces, as well as the card-pocket flats, at the same time so that all holes will register. If you cannot buy thongs cut to suitable size from the shoemaker or leather-supply house, lay a long strip of calfskin on a smooth board, with

Your Billfold, Purse or Belt Can Be Greatly Improved by Simple Designs Brought into Relief with a Few Homemade Tools

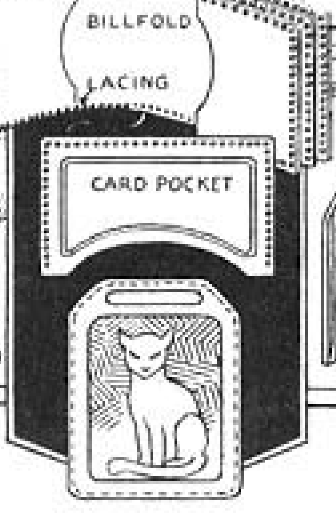

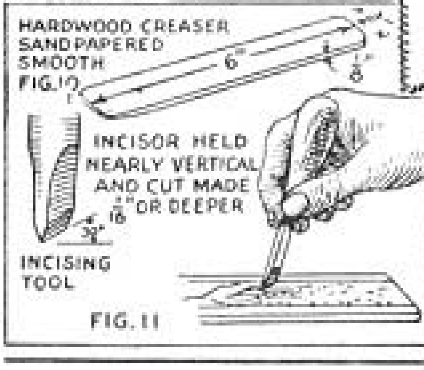

FIG. 10

FIG. 11

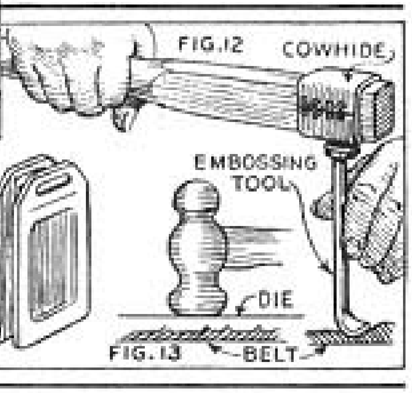

FIG. 12

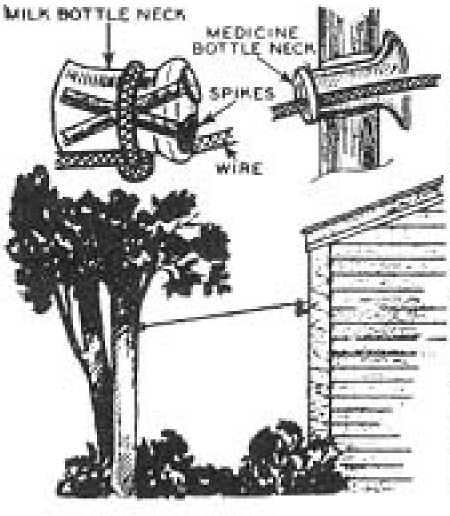
FIG. 13

the grain, and run the knife along the edge of a steel ruler, cutting off strips about 3/16 or ⅛ in. wide. Splicing can be done by tapering the ends ¼ in. and using leather cement. The lacing is shown in Fig. 9. At the corners, the thong should be passed through the hole twice.

Embossing a belt is not at all difficult, but requires time and patience. Of course, it can be tooled by the method just described, but the embossing will not be as distinct as when a die is used. Buy a strap of cowhide, ooze finish, about 1¼ in. wide and the required length, with an extra 5-in. length of heavier cowhide to serve as a die. Lay out the flower design, as shown in Fig. 4, on the latter piece and cut it in outline with an incising tool, which is ground from a round file, has a 30° V-shaped edge and leaves a very distinct incision. See Fig. 11. Hold the tool with a firm grip nearly vertical, cutting to about 1/16 in. or more in depth. Next lay the belt strap flat on the marble or glass slab, moisten it, place the die over it and pound with a hammer as in Fig. 13. This presses the belt leather down between the incisions of the die, and forces it up along the lines of the design, leaving them in sharp relief. The die pattern is used successively along the length of the belt until the entire piece is embossed as shown in Fig. 5. The petals and leaves can be brought into very prominent relief by using an embossing tool around the edges, as in Figs. 6 and 12. This tool consists of a spike with the end flattened, bent to a curve and then ground to the shape shown. It is worked around borders of the design and tapped with a cowhide-covered stick, as hammer blows would be too sharp for this work. The depressions can be made even deeper by first using the pebbling tool and then smoothing out the marks with the flat-surfaced embossing tool. After the embossing has been completed, a buckle and straps should be sewn on by a cobbler to insure a first-class job. The background of the design can then be darkened with black leather color.

An endless number of useful and attractive objects can be made by the amateur as he gains experience.



Bottlenecks Make Serviceable Insulators

BOTTLE necks, being made of glass, are ideal for insulators when secured firmly to a pole or inserted through a wall. The easiest method for separating the neck from the body of the bottle is by the use of a gas soaked twine, as described in the handikink item, "Emergency Ice Bag from Inner Tube, Mason Jar." To make an outdoor suspension insulator use a milk bottle neck, secured to the pole with two nails driven in as shown in the accompanying drawing. For a lead-in insulator, the neck of a medicine bottle serves best. It should be slanted downward as illustrated. A little putty will hold the glass firm in the wall.—

How Much Will a Mother Love Her Baby?

Cleveland *New York Times*

Most of the time at the Rainbow Babies' and Children's Hospital here, the doctors talk about children and their mothers. But sometimes, they talk about goats.

Goats provide an extreme example of how nature makes sure that offspring are protected. In the first ten minutes of her kid's life, a goat mother identifies it as her own and becomes firmly attached to it. But if the kid is removed for those early minutes, the goat mother will reject it.

Two pediatricians — Dr. Marshall Klaus and Dr. John Kennell — assert that something similar, although less extreme, happens when humans are born.

From their own research and clinical experience and from studies their work has spurred elsewhere, Klaus and Kennell have concluded that the contact of human mother and child in the first hours of a baby's life — perhaps in the first minutes — may have a long-lasting effect on how attached the mother will be to the child.

Although a mother's attachment nearly always does occur anyway, Klaus and Kennell say that in many women it may not form as easily or as obviously without extended early periods with the baby.

They say the findings are especially important for mothers who are more likely to have difficulty becoming close to their babies — because their children are malformed, premature or unwanted.

The doctors, who are both professors of pediatrics at Case Western Reserve University, which is associated with the Rainbow hospital, say that in one carefully controlled experiment they studied mothers who had had hours of early contact with their babies and compared them with others who have had only brief contact.

A month after the children are born, mothers who have had more early contact with them are demonstrably more affectionate — they fondle their children and gaze into their eyes more than do the other mothers.

At one year, when these mothers are observed at the doctor's office, the same affectionate ones hover about their children more, soothing them. They are less eager to leave their children with anyone.

At two years, they speak to the children with a greater number of words and questions and with fewer commands than do the other mothers — a finding that could have implications for intellectual development.

Kennell says the studies indicate that "the earlier you put mother and child together for extended periods, the more powerful the effects will be." Increasing contact any time in the first three days appears to be effective. But both Kennell and Klaus are convinced that there is something especially important about the time mother and child spend together in the first hour or 90 minutes after birth.

During that time, they say, the baby and mother both seem to be in an unusual state of mutual receptivity. The mother, if she has not been made drowsy by drugs, is at the peak of excitement. At the same time, the baby is more alert in the first hour than he will be later. The baby's eyes may be open for as much as 45 minutes; later they will be closed 90 per cent of the time.

The baby's wakefulness is important, Klaus says, "because the mother can't make love to a baby unless the baby makes love to her."

The lovemaking the pediatricians describe is a kind of primeval dance. The mother gazes into the infant's eyes for increasingly long periods of time, all the while talking to the child in a high-pitched voice — because the mother is somehow aware that babies are more receptive to higher pitches.

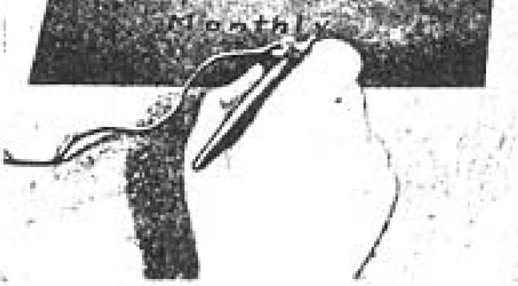
The voice is the dance music. The baby's movements often synchronize exactly with the rhythm (slow-motion pictures reveal an eerie precision in the infant's body movements as the mother talks). And the infant is following the mother's face, too.

Since early contact appears to be powerful in affecting the behavior of mothers, say Klaus and Kennel, why make the attachments more difficult to form by using procedures that keep mother and child apart?

So they support the recent trend toward "family-centered" childbirth that allows parent and child to be together immediately.

You Can Write on Metal

with this easily made vibrating electric pencil



A battery or a small transformer supplies the current required to operate the pencil

By KENDALL FORD

TOOLS and other metal objects may be permanently marked for identification with a homemade vibrating electric pencil of the type illustrated. It may be easily made from odds and ends.

The handle is shaped as in Fig. 1 from a piece of close-grained, round wood, ¾ in. in diameter and 6 in. long. A piece of maple dowel forms an excellent handle, but if it is not available, a satisfactory substitute may be made from an old broom handle. Drill a ⅜-in. hole in the large end of the handle to a depth of 1⅛ in., and a 5/32-in. hole to a further depth of ⅛ in., as shown. Then cut a recess in one side of the handle for the armature spring.

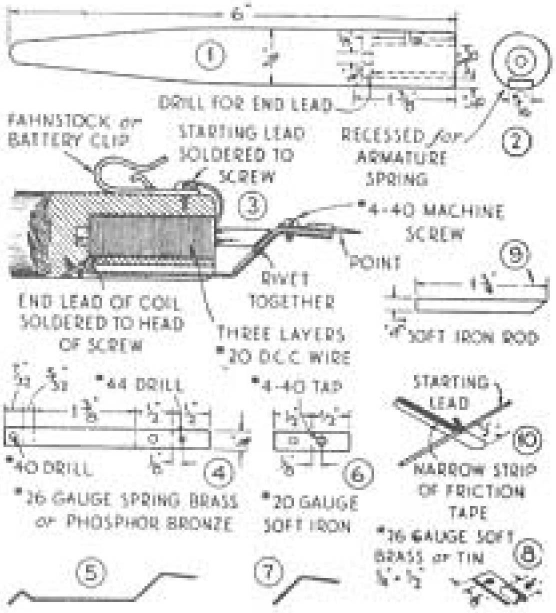
Obtain a piece of soft iron rod, 5/32 in. in diameter, and cut to the size and shape indicated in Fig. 9. A 12-penny nail has an approximate diameter of 5/32 in. and will serve satisfactorily for this piece.

Approximately 6 ft. of No. 20 double cotton-covered wire will be required for the coil. Place a narrow strip of friction tape along the iron rod, or core, and start the winding ½ in. from the pointed end. The end of the wire is placed over the tape (Fig. 10), after which the end of the tape is folded back over the wire. When the first turn of the coil is completed, it will pass over the folded end of the tape and secure the starting lead firmly in place.

Continue winding until within ⅛ in. of the opposite end of the core. Then fold over the tape and begin the second layer of the coil. As the second layer is started, place a narrow strip of friction tape on the opposite side of the core and proceed as in winding the first layer. Three layers of wire should be wound on the core, with the ends brought out as shown in Fig. 3. Shellac or paint the coil to serve as a binder.

Obtain a piece of No. 26 gauge spring brass or phosphor bronze, ¼ in. wide and 2¼ in. long. Mark off sections and drill as shown in Fig. 4. This piece, together with those shown in Figs. 6 and 8, serves as the armature and point holder. Drill all the holes with a No. 40 drill, except where a No. 44 drill is indicated. Shape the spring as shown in Fig. 5. Cut a piece of No. 20 gauge soft iron to the size shown in Fig. 6, drill and thread as indicated, and bend to the shape shown in Fig. 7. Rivet pieces 5 and 7 together with a piece of soft iron wire, as shown in Fig. 3.

A piece of No. 26 gauge soft brass or tin should now be cut to the size shown in Fig. 8. Drill as indicated and bend so as to form a groove for holding the needle or copper point securely to the armature. Secure the needle holder to the end of the armature with a No. 4-40 machine screw.



The handle, the assembled working point, and details of armature, spring, and other parts

Insert the coil in the handle and bring the starting lead to a small Fahnstock or battery clip, as shown in Fig. 3. A clip taken from an old radio "B" battery will serve. When securing the clip to the wooden handle, take care that the wood screw does not extend into the coil. The end lead of the coil should be brought out through a small hole previously drilled from the spring recess to the end of the large hole in the handle.

Fasten the armature to the handle with a small wood screw, and solder the end lead of the coil to the screw, as shown in Fig. 3. Glue a piece of tape or thin cardboard over the spring recess, and paint the handle a suitable color.

The point may be an old phonograph needle or a pointed piece of copper wire, but since the effect of each varies on different metals, it is advisable to experiment with both. In using the pencil, one wire from the source of supply is connected to the article to be marked, and the other wire is connected to the clip on the pencil. From four to six volts will be required to operate the pencil, and this voltage may be obtained from either a battery or a small transformer. The pressure applied to the pencil should not be so heavy that it will not allow a free movement of the vibrator.

SURVIVE IN THE CITY

By Boyd Hill

There are a great number of people who, when the balloon goes up, can not or will not get out of the bigger cities. Take me, for instance; I'm old enough to be your grandfather, severely damaged physically, totally dependent on special medicines, and unable to get out or stay out in the boondocks to survive.

Yet I intend to survive. Here's how......

Not everybody can bug out when the time comes for rioting and looting in the cities. The elderly and the ill are chained to urban existance. Yet even under the worst conditions they can give themselves a better than 50 % chance of coming through alive and well.

But first of all dismiss any thoughts of nuclear problems. Chances are a thousand to one that nukes will be like gas--much feared, much talked about, but never used--in major conflicts, that is--because, like biological warfare, it can rebound too terribly on the first user. For that matter, if it ever comes to such bombings just forget survival planning. Living through it will be a matter of luck, and nothing else.

Civil disturbances are a different matter. They have happened already, and will do so, more and worse, in the future. They also will spread out into the countryside, particularly so long as gasoline is available.

But remember this: No matter how terrible the conditions may be, they cannot last forever. If the government is strong enough, it will put down all the trouble inside of ten days. If the governmental force is absent, the disturbances will burn themselves out inside of three weeks. So if you are prepared to live isolated and protected for only 20 days, you will almost certainly survive the violence.

Also remember that civil disturbances almost always give plenty of warning. Tension builds up, and there are many small riots before the big one. Even so violent a time as Watts lasted much less than a week. Anybody can survive a full week without any preparation, so long as he has a home that cannot be burned out through misadventure. Just stay inside with the door locked and barricaded, and all lights out all the time, and wait until your radio tells you the All Clear is in effect.

A toilet tank and bowl holds enough clean, sterilized water (it's the same that comes out of your kitchen tap) to last two people comfortably for a week, for drinking, cooking and scanty washing purposes. In the hot South Pacific in War Two the GI's managed perfectly well on two canteensfull--two quarts-- each day. Anybody who is worried about a little contamination in a toilet bowl and tank can put a teaspoon of Chlorox or Purex in each, and be thereby easy in the mind.

Food really is no short-term problem. Practically everybody above the total poverty level has far more edibles stowed on their shelves than they realize. And besides, face up to it; a person can go for 30 days without--even sometimes to their physical improvement. Just five days of canned edibles on the shelves can be stretched, by quarter-rations, into 20 man-days of food.

Sanitation will be most important when one is cut off from the world and running water. But the solution is cheap and simple. Get an inexpensive plastic bucket with a tight-sealing lid, a dozen or so strong plastic bags larger than the bucket, a bottle of deodorant-disinfectant such as Pine-Sol, and a few of the wire "twisters" used to close breadbags or other plastic containers. Put a bag in the bucket, lapping the bag's edges over the rim of the bucket. After using, put in a squirt of the disinfectant, twist the bag closed and seal with the twister wire, and put the top on the bucket. Each new use, untwist the bag top, then re-seal. A dozen bags will last two people more than a month. So it may smell a little? That's better than being dead. Dead people smell a lot--and a lot worse, for that matter.

Riots are not continuous, nor do they stay in one location. They flare up and down, and move from place to place. When the trouble dies down around your place, join the looters or the lawful, to augment your necessary supplies of water, food, disinfectant, ammunition, medicine, or whatever.

And if the edibles have been swept clean from your market, look in the pet food section. Canned or dry cat or dog food--along with dog biscuits-- are nutritiious provender and some of them (so I'm told) are reasonable tasty.

Being ready takes little time or money. Have, or be able to get, containers for 10 gallons of water per person; have your sanitary bucket, bags and disinfectant stowed under the sink; keep a week's supply of canned goods on hand, and a bag or two of dry dog food.

Be able to close your door securely. Get a doxen lag screws and, when the time comes, drill the door so it can be screwed shut all the way around from the inside.

Make up a sign on yellow paper or cardboard; if you have access to an IBM Selectric typewriter you can prepare a very official document reading:

STAY OUT! DANGER!
QUARANTINE
This dwelling has been exposed to BUBONIC PLAGUE death. Do not open until fumigated.
/S/ Joseph Blow, MD
JOSEPH BLOW, MD
CITY HEALTH OFFICER

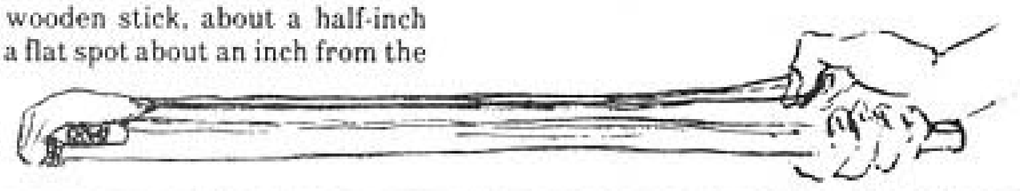
Put this on the outside of your door with thumbtacks or tape, and it will probably be better than a barricade against prowlers.

So lock yourself in, keep your lights off, don't try to cook, don't go near the windows unless they are shaded, and just settle down to sweat it out. Chances are excellent that the disturbances will expire before you do.

SCOTTISH SLING STICK

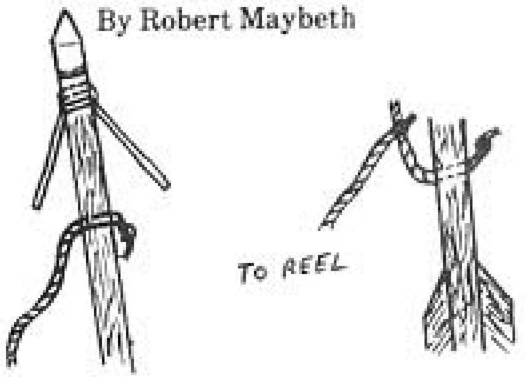
Take a wooden stick, about a half-inch thick. Cut a flat spot about an inch from the top. Tie a soft leather pouch to the flattened tip, and run a looped thong from the pouch to about six inches from the other end. Hold a small rock or such in the pouch, against the flat spot of the wood, holding the rock in place by tension in the thumb holding the other end of the stick.

Swing the thing as pleases you best, and release by slacking your thumb. These sticks can be made as long as one likes, with an increasing power and range. However, if they are much longer than about 14 inches, after a few dozen casts you'll develop a sore arm and shoulder you'll regret for a long time.



HUNTING FISH WITH A BOW

By Robert Maybeth



HOME-MADE FISHING ARROW

For thousands of years, men have been fishing with bows. In some countries, bowfishing predated the rod and reel. Even today, bowfishing still has a place in these days of graphite rods and computer designed lures. Whereas rod and reel fishing is a largely passive sport, bowfishing allows you to actually hunt your fish, rather than waiting for it to come to you.

All that a bowfishing rig consists of is a reel or other device attached to the bow to hold the line, and a barbed arrow attached to the line.

Some states permit archers to take the so-called "rough" fish, while other states forbid bowfishing entirely. It's always best to check your local laws, lest you find your gear confiscated by an uncooperative game warden.

If you don't already have a bow, get a good target or hunting model with at least a 30 pound draw weight. You won't need a powerful hunting model as the shooting range is nearly always under ten yards.

In the equipment category, the next thing to get is a reel and line. Sporting goods stores and mail order houses sell reels for as little as three dollars, including line and the wire frame you tape to your bow below the handgrip. It's easy to make your own, though. You don't even have to use a reel; coiling your line in a plastic drinking cup works fine. A paper clip holds the line (usually about 75 yards worth) in the cup until the arrow is shot. The line should be at least 60 pound test, as the arrow always comes to the end of the line with a great yank that will snap weaker line. Be sure to tie the end of the line to the bow.

The best (and most expensive) fishing arrows are made with shafts of solid aluminum or glass. They are best because of their lack of bouyancy, which gives them more hitting power than wood or hollow aluminum. If you're hard up for cash, it's okay to use wood arrows. But they will deflect more and hit with less force.

You can buy barbed arrows at the sporting goods store, but it's much cheaper to make them. Just sharpen the head of a regular field point, then drill a hole through the shaft an inch below the tip. Insert some stiff wire and bend it a single turn around the shaft. Lastly, bend the protruding ends upwards and snip the excess wire to complete the barb.

It is open to debate whether fishing arrows need fletching or not. The short range involved usually negates any stabilizing effect feathers might have; nevertheless, some bowfishermen swear by them anyway. It's your choice. If you opt for fletching, there are sprays available to waterproof the arrow's feathers.

About the best way to attach the line to the arrow is to drill a couple holes through the arrow's shaft—one a little behind the tip, another near the arrow's end, below the fletching. The line goes through both holes, resulting in a more stable flight than if you had just used a single hole.

Most states that don't entirely prohibit bowfishing allow archers to take "rough" fish—gar, eel, suckers, mudfish and carp. Carp is the bowfisherman's favorite prey and is found in waters all over the U.S. They can be stalked, like deer, or shot from a pier or boat. Whichever method you use, get as close as you can before the shot.

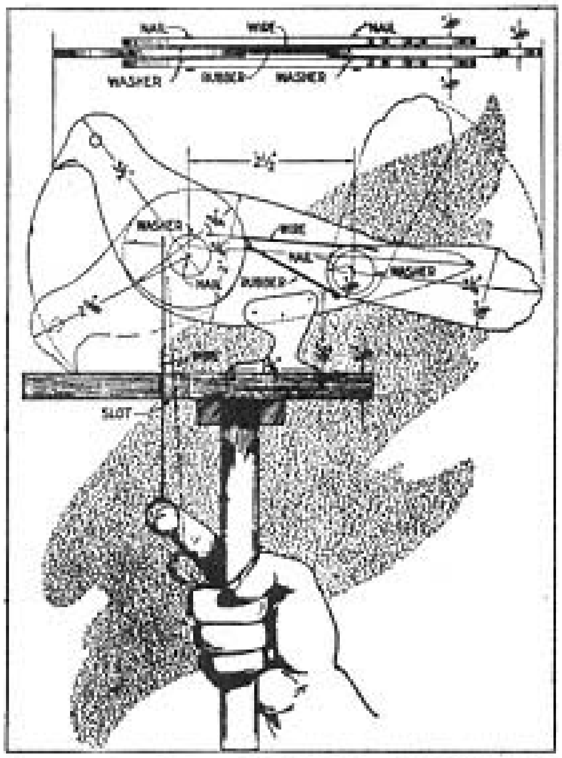
Another favorite prey are frogs. More common than carp, they are small and elusive targets but stay on the surface for minutes at a time. For instructions on preparing them for eating, see Jim and Stephanie Watters' article on page 190, #4. I doubt if you will run into any problems with your local Fish and Game man while hunting frogs. It beats shooting them with a shotgun, anyway.

The most pressing problem in bowfishing is light refraction. Because of it, fish look closer to the surface than they actually are. Also, an arrow starts deflecting upwards the moment it hits the water. Therefore, you'll have to aim below your target in order to hit it. Practice with weighted balloons in shallow water before you go fishing—it'll pay off at dinner time.

Mechanical Toy Pigeon Made of Wood

Popular Mechanics 1919

When the head of the mechanical pigeon is lowered the tail rises, and the reverse. It is constructed as follows: Make paper patterns for the parts, which consist of two body pieces, a head, a tail, and the foot piece. The shape of the parts is shown in the sketch, the front body piece being removed to show the connections of the rubber and wire controlling the movements. The view above shows the fastening of the parts with nails. The main sizes of the parts, which are made of 1/8 to 1/4-in. soft wood, are: head, 1 3/4 by 3 1/2 in.; body, 2 by 5 1/4 in.; tail, 1 1/4 by 3 1/4 in.; foot piece, 1 3/8 by 1 1/2 in. Mark the shapes on the wood, cut them out, and mount them, with a rubber band connecting the head and tail, as shown. Nail the foot piece between the body pieces, and pivot the head and tail on nails. Connect the head with a wire, having a loop on one end. Make the holder, and cut a slot into it for the draw wire, operated with the finger.



Draw on the Wire and the Head and Tail Bob Up and Down

A TOY HORSE THAT WALKS

Popular Mechanics, 1919

This toy, amusing for the youngsters, and their elders as well, will repay one for the making of it. Use a cigar box for the carriage, making it about 10 in. high, and shape it in the design shown. Nail a piece of wood, 1/8 by 2 by 4 in. wide, on each side of the carriage, and drill 1/8-in. holes in them for the axle. For the horse, take a piece of wood, 1/2 by 4 by 6 in. long, and draw an outline of the head, neck, and body. Cut this out and drill 1/8-in. holes where the legs are at-

FIRST PRINTING OF "THE NIGHT BEFORE CHRISTMAS" IN A PERIODICAL

HARPER'S
NEW MONTHLY MAGAZINE

No. XCI.—DECEMBER, 1857.—Vol. XVI.

A Christmas Garland of American Poems.

From "The Poets of the Nineteenth Century."
8vo. Superbly Illustrated. Harper & Brothers.

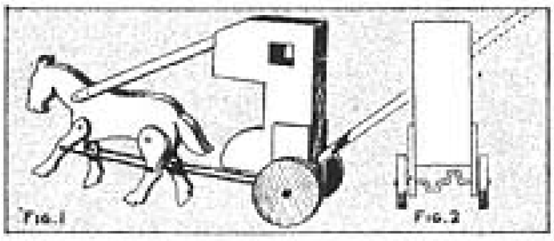
A VISIT FROM SAINT NICHOLAS.

CLEMENT C. MOORE.

'TWAS the night before Christmas, when all through the house
Not a creature was stirring, not even a mouse;
The stockings were hung by the chimney with care,
In hopes that St. Nicholas soon would be there;
The children were nestled all snug in their beds,
While visions of sugar-plums danced in their heads;
And Mamma in her 'kerchief, and I in my cap,

tached.

Cut the legs as shown, about 3½ in. long. Attach them with small bolts, or rivets, allowing space to move freely. The wheels are made of pine, ½ in. thick and 3 in. in diameter. The axle is made of 3/16-in. wire bent to the shape indicated, ½ in. at each offset. Fit the wheels on the axle tightly, so as not to turn on it, the axle turning in the pieces nailed to the sides of the carriage. The horse is attached to the top of the carriage by a strip of wood. A 3-ft. wooden handle is attached to the back of carriage to guide it. Wires are attached to the legs, connecting with the offsets in the axle. ☐

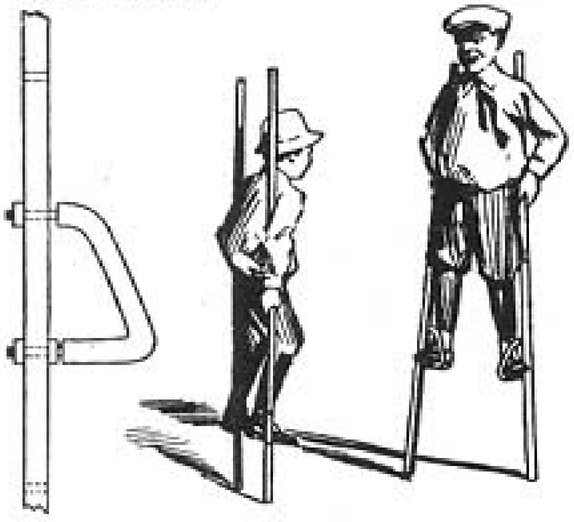


The Toy is Pushed by Means of the Handle, Causing the Horse to Walk

Adjustable Stilts

Popular Mechanics — 1915

The beginner with stilts always selects short sticks so that he will not be very far from the ground, but as he becomes more experienced, the longer the sticks the better. Then, too, the small boy and the large boy require different lengths of sticks. The device shown makes a pair of sticks universal for use of beginners or a boy of any age or height.



Stilts Having Stirrups That can be Set at Any Desired Height

To make the stilts, procure two long hardwood sticks of even length, and smooth up the edges; then begin at a point 1 ft. from one end and bore 12 holes, 3/8 in. in diameter and 2 in. apart from center to center. If there is no diestock at hand, have a blacksmith, or mechanic, make a thread on both ends of a 3/8-in. rod, 12 in. long. Bend the rod in the shape shown, so that the two threaded ends will be just 2

Had just settled our brains for a long winter's nap;
When out on the lawn there arose such a clatter,
I sprang from the bed to see what was the matter.
Away to the window I flew like a flash,
Tore open the shutters and threw up the sash.
The moon on the breast of the new-fallen snow,
Gave the lustre of mid-day to objects below,
When, what to my wondering eyes should appear,
But a miniature sleigh, and eight tiny rein-deer,
With a little old driver, so lively and quick,
I knew in a moment it must be St. Nick.
More rapid than eagles his coursers they came,
And he whistled, and shouted, and called them by name;
"Now, *Dasher!* now, *Dancer!* now, *Prancer!* and *Vixen!*
On, *Comet!* on, *Cupid!* on, *Donder* and *Blitzen!*
To the top of the porch! to the top of the wall!
Now dash away! dash away! dash away all!"
As dry leaves that before the wild hurricane fly,
When they meet with an obstacle, mount to the sky;
So up to the house-top the coursers they flew,
With the sleigh full of toys, and St. Nicholas too.
And then, in a twinkling, I heard on the roof,
The prancing and pawing of each little hoof—

As I drew in my head, and was turning around,
Down the chimney St. Nicholas came with a bound.
He was dressed all in fur from his head to his foot,
And his clothes were all tarnished with ashes and soot;
A bundle of toys he had flung on his back,
And he looked like a peddler just opening his pack.
His eyes—how they twinkled! his dimples how merry!
His cheeks were like roses, his nose like a cherry!
His droll little mouth was drawn up like a bow,
And the beard of his chin was as white as the snow;
The stump of a pipe he held tight in his teeth,
And the smoke it encircled his head like a wreath;
He had a broad face and a little round belly,
That shook, when he laughed, like a bowlful of jelly.
He was chubby and plump, a right jolly old elf,
And I laughed when I saw him, in spite of myself;
A wink of his eye and a twist of his head,
Soon gave me to know I had nothing to dread;
He spoke not a word, but went straight to his work,
And filled all the stockings; then turned with a jerk,
And laying his finger aside of his nose,
And giving a nod, up the chimney he rose;
He sprang to his sleigh, to his team gave a whistle,
And away they all flew like the down of a thistle.
But I heard him exclaim, ere he drove out of sight,
"*Happy Christmas to all, and to all a good-night!*"

in. apart from center to center. The thread on the straight horizontal end should be so long that a nut can be placed on both sides of the stick. A piece of a garden hose or small rubber hose, slipped on the rod, will keep the shoe sole from slipping. The steps can be set in any two adjacent holes to give the desired height.

A Porch Swing

[FROM POPULAR MECHANICS 1919]

The seat of the swing consists of a board, 30 in. long, 14 in. wide, and 1 in. thick, with holes bored in each corner for the ropes. The rail at the top is made of four oak pieces, two of them 30 in. long, for the sides, and the other two 18 in. long, for the ends; all 3 in. wide and ⅞ in. thick. The ends of these pieces are finished rounding, and holes are bored in them for the supporting ropes. The supports for the rails consist of four pieces of ¾-in. pipe, 15 in. long. The ropes are run through the holes in the ends of the rails, down through the pipes and through the holes in the seat board, where they are knotted.

A Porch Swing Having a Rail That Incloses the Person Sitting in It

A rope tied to a convenient post or screw hook makes a handy way to give motion by pulling. To get into the swing, raise one of the side rails on the rope.

A Wire-Walking Toy

Popular Mechanics 1919

A daring wire-walking performer who, unmindful of the fact that a misstep may mean destruction, keeps on

A Christmas Story

I was in Australia a few years ago and found that Christmas came in summer. It was still December 25th but Australia is on the bottom side of the Earth and seasons are just opposite to what they are in America. When it's winter here, it's summer down there. They celebrate Christmas there, too, but since it comes in summer there is no snow so they don't have the same kind of Christmas stories we have. In fact, it didn't seem to me to be like Christmas at all but Australians are pretty good at pretending and besides, Australian kids weren't going to be left out of the gift-getting business, snow or not.

I decided to write a Christmas story which would fit them and thought you might like to read it.

Australians speak English, but not like Americans, at least with a lot of words Americans haven't thought up. Also, a lot of them don't pronounce their H's. A long time ago many Australians were miners always digging for gold and opals and such and were called "diggers". The angels in the story are called diggers because of that.

SANTA'S KANGAROOS

by KURT SAXON

It was Christmas Eve in Australia and all the kiddies were waiting for Santa Clause.

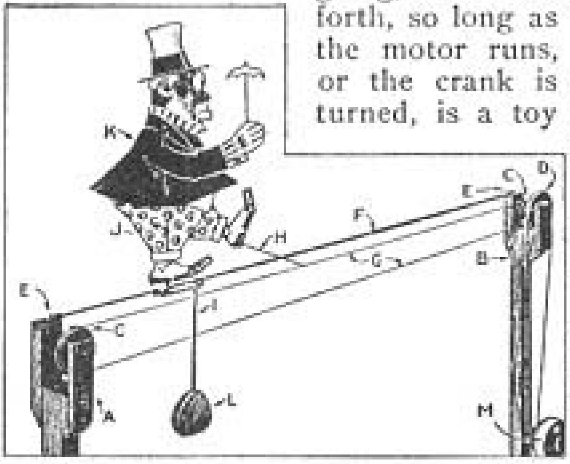
Some of them had been very good for a little while during the past year. They were looking over lists they had made with just about every toy you can imagine written down.

Those who had been naughty nearly all last year were waiting just as eagerly. They figured Santa was an old softy (and he usually is) and would only remember when they had been helpful. Like keeping out of Mum's way when she was picking up their toys or telling Daddy when they threw the kitty down the well so that he could rescue her before she drowned.

Yes, they were all waiting. And, to be sure, Santa *was* coming.

His sleigh was piled high with koala bears and boomerangs and cricket bats and prams with dollies in them and ever so many other things.

It was very dark that night so Santa had his red nosed reindeer to guide him. This deer was very good at this sort of thing and had brought him through the worst weather for years. But there was something up ahead



going, back and forth, so long as the motor runs, or the crank is turned, is a toy that boys can make easily. The wire is stretched, not across Broadway, but between two 1 by 1-in. standards, held upright by guy cords, or fixed to a baseboard. They are fitted with forked tops, at A and B, and pulley wheels, C and D. A wire, F, is fastened to two of the prongs, at E, and a black thread, G, runs over the pulley wheels. A carriage, I, is formed from a 12-in. length of stiff wire, and weighted, at L, to balance upon the tight wire. The figure K is cut from stiff paper, and made to turn upon the carriage upright J, and braced with thread, at H. Thus the figure is always drawn forward, revolving on the support J at the end of each trip. Power to turn the thread is transmitted from a hand crank or motor, M, by means of the double pulley wheel at

Mechanical Toy Alligator of Wood

Popular Mechanics 1919

A toy alligator that opens its mouth and wags its tail as it is pulled along can be made of wood by a boy, with a jackknife. The various parts, as shown, are cut from soft wood, ½ in. thick. The method of fastening the parts is shown in the side sectional view. When the wheels turn, the cams A, set on the crank portions of the wheel axles, raise and lower the jaw and tail. The upper jaw is 1 in. wide at the widest part, and 3 in. long. The lower jaw is smaller, and the same length. The body is 6 in. long, and tapering in width from 1½ to ¾ in. The tail is 4¾ in. long, and ¾ in. wide. Holes are drilled in each piece near the edge, at joining points, through which wires are drawn, and clamped, as at B. The legs are shown in detail. They are attached to the body by drilling a 1/16-in. hole in each, and a hole through the body, through which the fastenings are passed. The lower end of the legs are fastened to the base,

that the guide deer didn't know about and so wasn't looking for.

It was an artificial satellite. That's one of those things the Americans and the Russians have been shooting up into the sky so they can hear it say "Beep, Beep, Beep." I'm not saying whose it was but they should have taken the nasty thing back down. At least, on Christmas Eve!

Well, you guessed it. The guide deer didn't see it and the sleigh ran right smack into it. Santa was knocked out of the sleigh and the toys were scattered all over the clouds and the sleigh's runners were all bent out of shape.

As if this weren't enough, the reindeer were frightened out of their wits. Now, as you know, reindeer are very nervous animals and get upset over the littlest things. Anyway, they all jumped out of their traces and went as fast as they could toward the North Pole.

Well, there was Santa, just sitting on a cloud wringing his hands. He was wondering what all the Australian kiddies would think when they didn't find any toys that morning.

And the satellite was hovering around his head and going "Beep, Beep, Beep?" Beep, Beep, Beep?" Santa grabbed it and sent it spinning in the opposite direction to what it had been going. "That should make whoever put it up there ask some pretty funny questions," he thought.

But there he still was. With the toys all out of their sacks and his sleigh runners all bent. Now, it's a scientific fact that a sleigh won't fly through the sky with its runners all bent. Anybody knows that.

While he was sitting there, a Digger angel named Frank appeared and sat down beside him on the cloud.

"You got troubles, Mate?" asked Frank.

"I sure do," said Santa. "Look at this mess. How'll I get them all together again? How'll I fix my sleigh? I think I'm going to be sick."

"Don't worry, Mate," said Frank. "I'll get 'elp and we'll fix you up straight-away."

Then Frank gave a whistle and three more Digger angels appeared on the cloud. They were all got up just like Frank with floppy hats with big, broad brims. But so you could tell they were angels they had on white gowns and big wings. Two of them had bushy red beards and the other one had great moustaches which hung down on both sides.

"Mates, this'ere's Santa Clause," said Frank. And to Santa he said "And these 'ere are the 'Arrigan brothers: 'Arry, 'Erbert and 'Umphry."

"Pleased, I'm sure," said Santa.

'Arry, 'Erbert and 'Umphry grabbed their hats by the tops, raised them a foot off their heads and let them drop back down.

"Now, Mates," said Frank, "we got to get the toys back into the sacks and straighten the sleigh runners. 'Arry and 'Erbert, you round up all the toys whilst I and 'Umphry works on the sleigh."

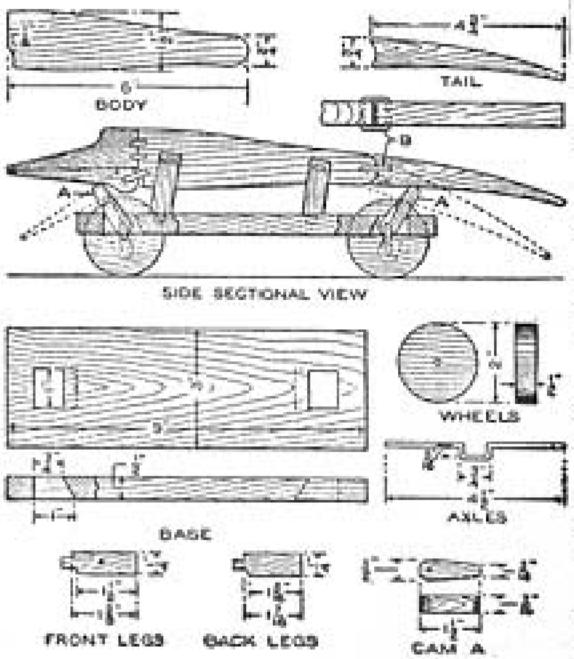
'Arry and 'Erbert straight-away bounded off and began picking up toys and cramming them into the toy sacks. While they were doing this, a Quantas jet liner came into view just below them. 'Arry immediately threw a boomerang at it. The boomerang looped down in front of the plane and barely missed cracking the pilot's windscreen. The jet liner seemed to go out of control, then, bucking up and down and swerving from side to side.

As soon as it got back on course 'Erbert appeared in its path pushing a pram with a dolly in it, like a woman crossing a street in traffic. Again the plane bucked up and down and swerved from side to side. Then it turned around and flew back to the Sydney Airport.

As soon as the plane landed the pilot was called to the office to explain his return. "Well, Sir," he said, "here I was, sixteen thousand feet up, mind you, and a boomerang whizzes past my windscreen. *Of course* it upset me. I lost control of the plane for a minute then straightened her out again.

"Then, just up ahead, I sees this bloke in a floppy hat and with wings on and he's pushin' a pram with a dolly in it. Sixteen thousand feet up in the air and nothing under him. And pushing a pram with a dolly in it. Of course I turned around and came back."

which is 3 by 9 in. long. Square holes, 1 in. wide, near each end, are provided for the cams A. The axles and wheels are made as shown. The axles fit



The Alligator is Drawn Along with a String, and the Jaws and Tail Flip Up and Down

tightly in the wheels, so that the latter can move the axles around with each turn. The axles are made from ⅛-in. wire, bent as shown, and should be long enough, after passing through the bottom, to extend through the wheels on each side.

He was going to tell the story all over again but some nice men took him to a place where he could rest.

In the meantime, 'Arry and 'Erbert had got the toys all back in their sacks. Frank and 'Umphry had straightened the sleigh runners and everybody was happy but Santa.

"Now you're all right, Mate," said Frank. "She's just as good as new and not a toy was lost."

"That's fine," said Santa, "but how can I go without a team? My reindeer are probably half way home by now."

Frank thought a moment and said, "Well, Mate, we'll just have to outfit you with kangaroos."

The 'Arrigan brothers seemed delighted with the idea and immediately disappeared. Santa didn't much think it would work but since Frank disappeared just a moment later he couldn't ask for explanations.

The four Digger angels scrounged the outback around Alice Springs and soon caught eight bouncing roos. They had to drag them back by force because the kangaroos didn't have any Christmas spirit at all.

But finally they got them to the sleigh and all hitched up. They even gave them names: Bunyip, Geelong, Pimba, Gympie, Roto, Quilpie, Joe and Sam.

As soon as they were ready Santa shouted, "Giddyap," and off they went, hopping through the sky as nice as you please. But it was a dark and stormy night and Santa sorely missed his red-nosed guide deer.

He had hardly gone any distance at all when 'Arry and 'Erbert appeared with another kangaroo. They called him Fair Dinkum and his nose was even redder than that of Santa's guide deer. They had got his nose like that by filling him up with good Aussie beer.

Then Santa started off again led by Fair Dinkum the red-nosed kangaroo. And soon the job was done and every city, town, village and bush camp in Australia had been visited.

When Santa got to Darwin and left the last of the toys he found his reindeer waiting for him. They had gotten over their fright and had gone back to look for him. But when they saw the sleigh pulled by those jolly kangaroos they figured they could take a rest during his Australian run.

When Santa got to them they welcomed him heartily and frisked about his sleigh. Soon the kangaroos were unhitched and replaced by the reindeer.

Then Frank, 'Arry, 'Erbert and 'Umphry waved goodby to Santa and disappeared with all the kangaroos. Santa yelled "Thank you and Merry Christmas" toward the spot where they had been standing.

Then he turned his reindeer north and headed home.

The End

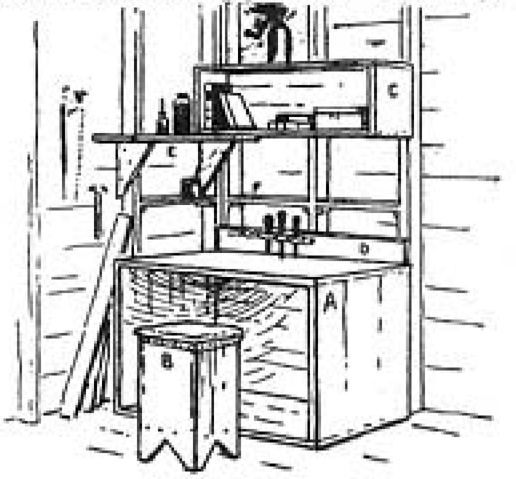
CHEAPLY AND EASILY MADE TOYS

Here is another selection of toys any parent can whip up for the little ones which will give them lots of playing time with less breakage and at practically no expense.

There are more such homemade toys in Volume one of THE SURVIVOR.

TOY-MAKING

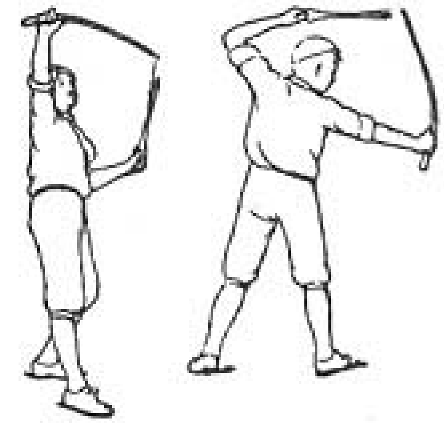
SOMEWHERE in your house there must be a corner where you may have a little workshop of your own. With some packing boxes of different sizes, such as you can buy at a grocery or dry-goods store, you can make a bench, a stool, and a shelf or two, like those shown in this sketch, and so make a beginning. For tools you will need a saw, a hammer, a try-square, a good jackknife, a plane, a ruler, and compasses. A pair of stout scissors will do for cutting paper, cardboard, leather, tin, and so on; and a pair of cutting pliers will be useful for cutting wire. Perhaps you cannot get all these tools at once. Never mind; begin with a jackknife, a saw, and a hammer, and add other tools as fast as you can pick them up. As soon as your family know of your enterprise, they will be likely to remember it in making Christmas and birthday presents. Begin, anyhow. Your shop will grow, and your love of it will grow. There is no satisfaction quite

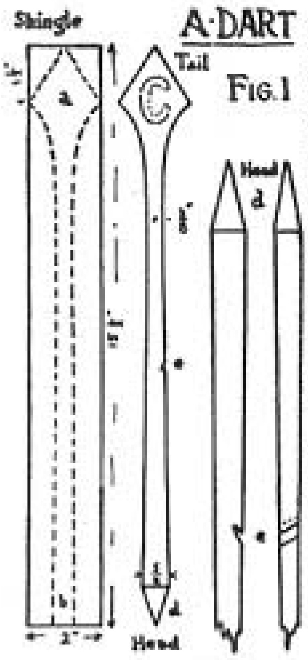


like that which comes from making things with your own hands.

A DART is a good thing to begin with. Find a piece of straight-grained shingle two inches wide, and cut it as shown in Fig. 1. After you have sharpened the head end, balance the dart on the edge of your knife-blade and at the balancing point cut the notch. For a whip handle you will need a springy stick such as you can easily cut from a roadside thicket. Cut it two and a half feet long, and a little less than an inch through at the butt end. A stout string or thong a foot long knotted at one end and tied to the stick at the other will complete the whip-bow. Holding bow and dart as in the picture, sling the dart with a motion such as you would make if you were to whip a fiend and had but one chance.

In the making of even this simple dart you will have learned two things at least. One is that it pays to save and store away in your workshop odd pieces of wood, string, rawhide, shoe-leather and such like. Part of the fun of a workshop is the chance it gives you to gather materials that will come in handy at one time or another. The other — a very different sort of thing — is that wood splits along the grain. Of course you knew that to start with; but no matter how skillful and experienced a woodworker you may become, you will always have to take account of the grain of your wood, whether whittling, or planing, or carving, or sandpapering. Working with the grain is like smoothing a cat's fur the right way, — all is serene and as it should be; working against the grain, — well, you know how the cat likes it!





A·DART

FIG. 1

The plan given on this page is for a PADDLE-WHEELER of the stern-wheel type. You know that on shallow rivers and on rivers in which there are sand bars to go over, like the Mississippi and the Ohio, stern-wheelers are much in use. They go pretty well in bath-tubs, too. By consulting the plan you will see that the hull should be fashioned from a ¼ inch slab of soft wood, the outline being patterned on a piece of 3 by 8 inch paper folded lengthwise to make both bow curves just alike, marked on the wood and cut out with the scroll saw.

Remember in cutting out the square inside corners of the paddle opening not to force the saw but to keep it working up and down while you turn the wood slowly. And then when you come to the second inside corner you will have to back out and make the last cut from the outside, unless you have a scroll saw large enough to allow the length of the boat to pass between its shanks.

The construction of the rest of the boat is made clear in the diagram. A tack-hammer will be found useful in nailing the parts of the paddle-wheel together. If one of these parts splits, keep patient and try another.

FIG 4 SHOWS PADDLE IN PLACE AND TWISTED

SLIP THE BAND OVER WHEEL AND NOTCHES TWIST UP TIGHT, SET IN WATER AND LET GO

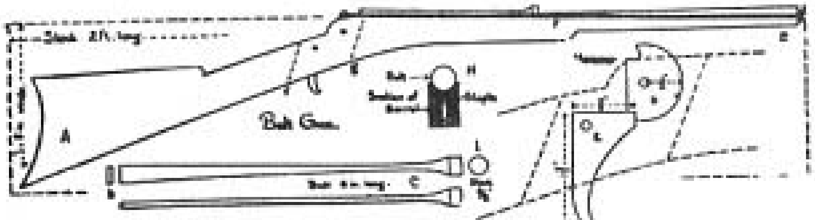
F. G. SANFORD '09

You can add realism to the short voyage by sticking a small Christmas candle into the hole of the spool and lighting it.

Here are drawings that show you how to make a BOLT GUN, with which much fun may be had during long indoor winter evenings. A description of the making is on the next page.

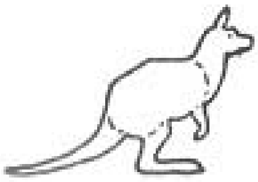
To make the gun, get two pieces of very thin pine or whitewood board, ⅛ inch thick, 2 feet long and 5 inches wide, and another board of the same length and width, but ¼ inch thick. On one of the thin boards draw the outline of the gun. When this has been whittled or scroll-sawed out, use it as a pattern and cut the other boards accordingly. Tack the three together, the thinnest one in the middle, with three small brads; and smooth the three parts into one gun-stock.

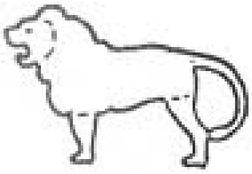
Whittle or saw out D and E, the trigger pieces. Then pry off one side of the gun; and, laying the trigger in position, mark lines *f* and *g*, and cut out of the middle piece a piece along these lines. Then pry off part F of the middle piece, and remove ⅛ inch from its upper edge. Bevel the edges of the thin pieces

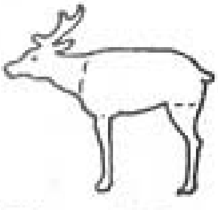


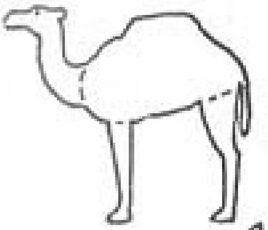
so that when the parts are brought together again, the barrel will look like the section drawn at H, end view. Then put all the parts together, running brads through the two trigger parts in such a way as to pivot them properly. You will see the wisdom of marking the points at which these pivot brads are to enter, before you finally fasten the stock parts together.

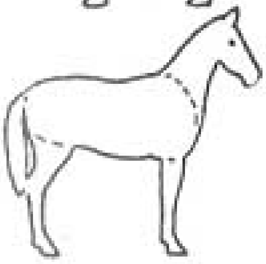
By means of a staple, fasten to the end of the barrel a good spunky rubber band, 3 inches long and ¼ inch wide. With this you can throw bolts of wood as straight as a rifle-ball across the room at a target of paper pinned upon a rug thrown over a chair; and moderate care in the aiming will do away with any risk of damage to the vases on the mantel.





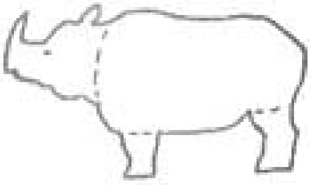


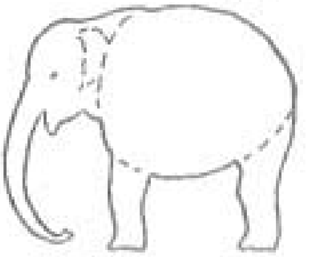


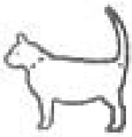


There is a wide field to range when it comes to selecting and making the animals that are to be the inhabitants of our ark. Here on this page are given designs for what will be surely a sufficient number to start with. The outlines are extremely lifelike, and the effect is especially real when the figures are made up of three thicknesses so that they will stand.

First of all make your patterns. If you decide to make the animals of just the size shown on this page, trace off the outlines on very thin paper, and transfer them to the wood by using carbon paper. Get some pieces of very thin wood, and select three pieces that will match up pretty well in size for one of the figures. You may have to saw them a little. Wood such as the school chalk boxes offer, is a handy gauge for this work. Nail these pieces lightly together with small brads, and lay off the pattern on the top piece. Then cut out all three together. The pieces are then to be taken apart, and certain of them changed. In the case of the elephant, for example, the two outer thicknesses of the head part should be cut away, along the line indicated in the diagram; while the middle piece should have the head left on, but the legs cut off. In each case, you see, the center-piece is to bear the head, and the outside pieces are to bear the legs. Where there is a tail, that also is to be on the center-piece. When the parts are cut out according to this scheme, they should be glued together; and when they are set, the sharp edges may be rounded off and as much carving done as you care to try. Finally comes the coloring. This should be done with oil colors, preferably, as these colors have a rich appearance. It is better not to try to make many gradations in the color of any one animal, simplicity being safer and more attractive.







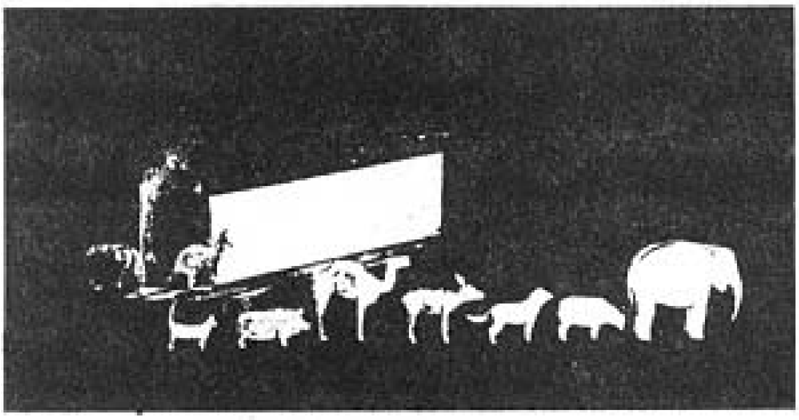


Fig. 9. Noah's Ark.

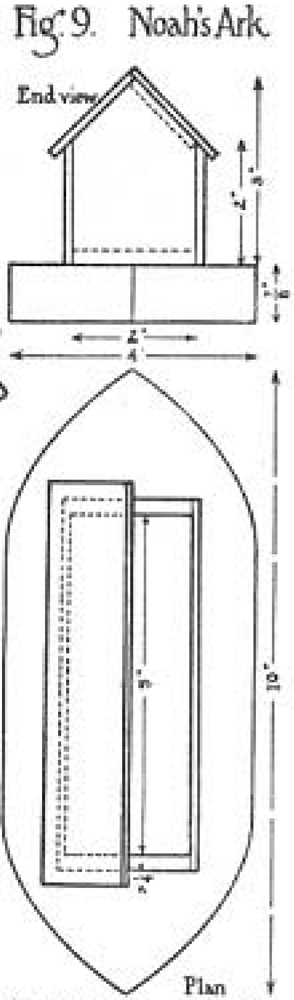
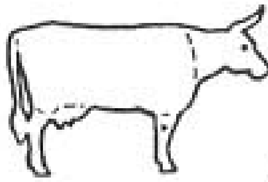
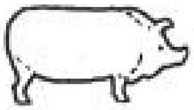
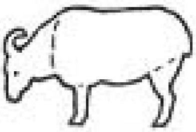


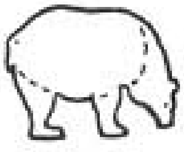
One-half of roof removed to show the interior.

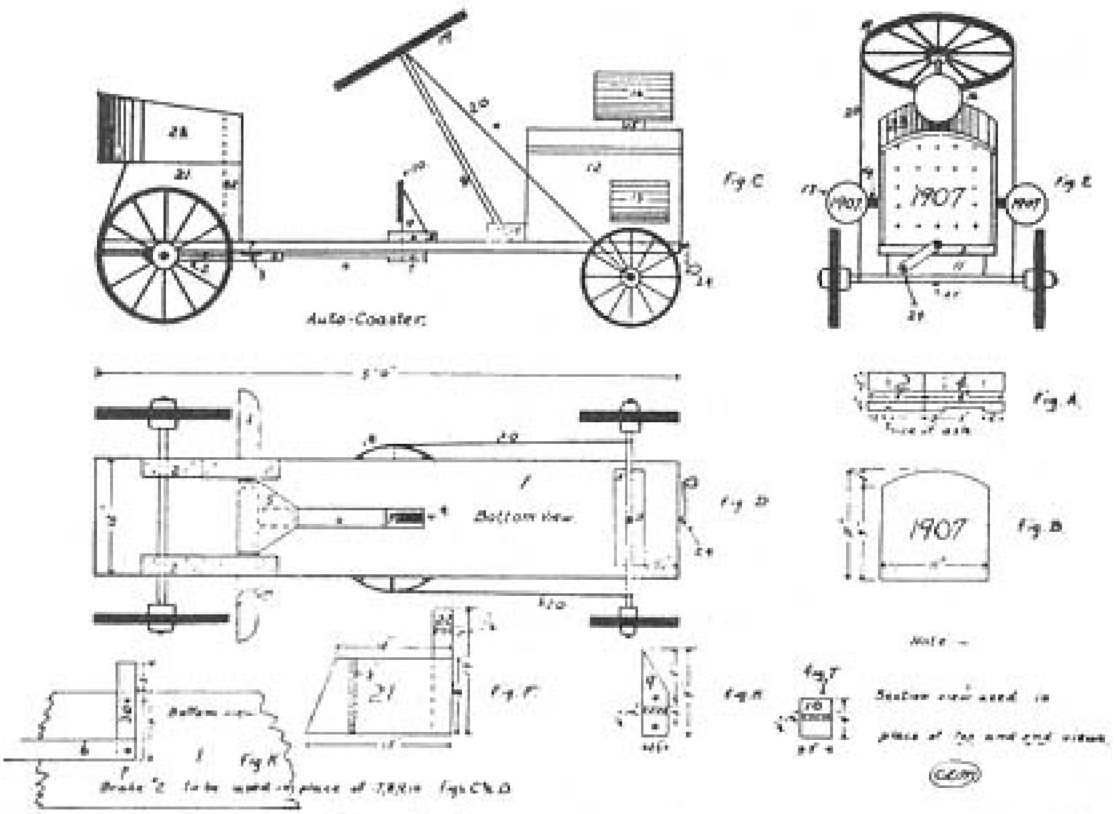
The NOAH'S ARK is not so hard to make as might be imagined, and it is a most delightful toy. Begin with the bottom of the house, two by five inches, and build around that. You will need two duplicate gable ends and two sides and two roof pieces, almost everything being two by two in this ark as should be the case in every well-regulated ark. You will notice that one roof piece is nailed in place, while the other is left removable, and is caused to stay in place by means of an extra piece glued to its under side (see dotted lines in end view). The boat is sawed and shaped from a 7/8" board. The parts should all be put together with brads. Once together, the ark should be painted in bright colors. The deck, as you will see in the illustration, may be lined out with different colors; and there should be a painted window at each end, or how could the dove get out? It would be a pity not to have Noah and his family, as well as the animals which are to be explained on the next page, and do you think you could whittle them out? It is not difficult. Short pine sticks are easily carved.











Here is an AUTO-COASTER that will give you almost as much fun in summer as a bob-sled or double-runner will in winter.

The first thing to do is to find a pair of stout wheels. These are to be fitted to the 12" × 5' bottom board of one-inch planking. The board must be raised sufficiently from the front axle, by means of a "riser" block, to be level, the front axle being lower than the rear. This "riser" carries the king-bolt or pivot of the front pair. To the under side of the bottom board and four inches from the end screw two strips 1″ × 2″ × 6″, with a groove cut to receive the axle. Extending beyond these strips fasten two brake-straps, 1″ × 2″ × 8″, each provided with a groove ½″ by 2″ by 4″ to admit the brakes (see 4 in Figs. A and D). Two and 4 in the Figs. A and D may be made in one piece; but remember that the measurements here given are for 14″ wheels, so that a change in the length of the strap and the location of the 'groove would have to be made if your wheels were of a different size. lamps are to be bolted in place in a similar way. Use cans with slip tops that may be replaced after the bolting has been done. Measurements for the seat can be taken from the diagram. The rounding top is made of a cheese box with the front cut and straightened out, and the sides tapered. Two sorts of brakes are possible, but the foot-brake is to be preferred. Paint the car red, and don't forget the tail-number. If you wish, you can fix your dark-lantern within the search-light can. When "off," the brake should rest one inch from the wheels.

The hood is made of a box 12″ × 12″ × 16″. The boards are to be removed carefully and replaced when the box-ends have been shaped as seen in Fig. B. Before putting the last board on again reach in and bolt the search-light on. The search-light is a 2 qt. can. Through it and through the pivot-block (1″ × 2″ × 2″) and the top board of the hood bore a hole for the bolt, which should be set just tight enough to allow the light to turn. The side

No-soil garden

Chicago Tribune, Sunday, July 3, 1977

By Joseph Egelhof

SYRACUSE, N. Y.—The navy cooks at Argentia, Nfld., are getting a year-round salad garden.

It will be in three trailers, each 12 by 42 feet. One will grow tomatoes, one lettuce, and one cucumbers.

From that growing area the cooks will pick enough vegetables to make 400 high-quality salads every day, forever.

All that from 36 by 42 feet of garden? How?

It will be a "total control" growing system, developed here by General Electric Co.

Destined for use one day in space habitats, GE's new concentrated gardening may revolutionize vegetable production.

The Pentagon has just signed a contract for a movable system for the U. S. communications base at Argentia. It could be parked anywhere, from the Arctic to the deserts, and still function.

THE GE ENGINEERS and horticulturalists here say they have seen amazing improvements in the production of vegetables.

Compared with greenhouse crops, they are getting 20 times as much lettuce, nine times as much tomatoes, and six times as much cucumbers, measured in pounds per square foot of growing area.

The comparison with field-grown crops is even more spectacular. Forty times greater for lettuce, 30 times greater for tomatoes, 50 times greater for cucumbers.

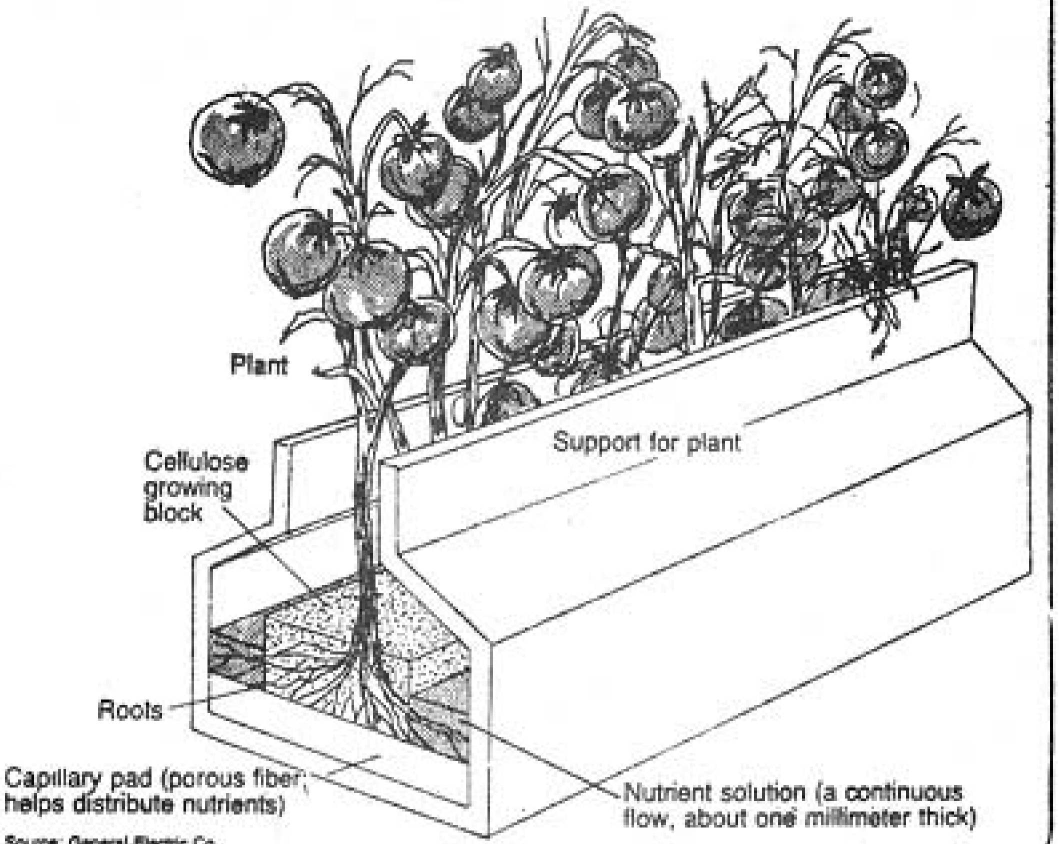
The plants are grown in open-topped troughs without soil. A thin film of recirculated nutrient fluid trickles through their roots from one end of the trough to another. The troughs are mounted on Christmas-tree type racks so the vertical as well as the horizontal dimension is filled, to take advantage of all of the carbon - dioxide enriched atmosphere. The racks are movable, so space for only one aisle is needed. The "sun" is a combination of high-intensity electric lamps. The temperature and humidity are controlled. You enter through airlocks.

THF ARGENTIA system will have a fourth trailer to house the nutrient tanks and pumps and other machinery.

Happy with their success, the GE engineers envision modules in other sizes. A refrigerator size, to hold ornamental plants for offices or possibly a year-round small garden for homes.

Commercial systems might be in the five-acre size, said Engineer Lewis W. Fogg. He is manager of the controlled-environment agriculture task force set up four years ago by Thomas I. Paganelli, vice president who heads GE's electronic systems.

Hydroponic growing technique



Source: General Electric Co.

A five-acre tomato system would produce 8 million pounds of tomatoes the first year. Output would rise gradually to 11 million pounds a year.

Fogg envisions three such five-acre plants spotted around Chicago to take care of the metropolitan area's entire need for "premium-grade" tomatoes.

THE GE CROPS are of uniform high quality and the system can be adjusted to produce varying tastes.

GE grows lettuce to standard sized heads of three-quarter pounds in 21 days from the time the seedling is transplanted. But it added another six days and produced a head weighing 2.2 pounds and 20 inches in diameter. Too big for the home refrigerator but ideal for the restaurant market, Fogg thinks.

The engineers keep the quality high when growing giant lettuce and cucumbers. They think four-pound cucumbers that don't have to be peeled could be marketed wrapped in pieces.

Fogg said his group is using "physiological manipulation" on the plants.

"WE EXPOSE the tomato plants when they are seedlings to cold shock, 10 days in a much lower temperature than normal," he explained. "The plant 'thinks' it is going to die, so its life processes speed up. When we put it in the warm module, it is well ahead of normal. It throws its first cluster about six inches from the root and becomes a very short, thick-stemmed plant with three clusters at six-inch intervals."

The short plant is suitable for the rack-type growing structure.

GE is going into ornamental plants to supply a company in the "plant party" business.

"That's a geranium we grew from seed in 6 weeks," Fogg said. "The greenhouse operator normally takes six months."

Pharmaceutical companies have asked GE to grow the digitalis plant to eliminate silica impurities and get a uniform, hopefully higher percentage of the vital alkaloid.

"WE HAVE GREAT confidence we can increase the alkaloid by use of nutrient factors and growth regulating," Fogg said.

Although economical on water, the process is electricity-intensive, with 30 per cent of the cost going for power. But Fogg said in total energy of all kinds consumed per pound of product, "We are very competitive with the California farmer."

Some people can't believe GE is producing live tomatoes.

When a Syracuse supermarket operator offered some to market-test the quality, saying GE had produced them in its plant, one customer reported back that they were "better than real tomatoes."

The TANKS ARE COMING

(Practical Hydroponics)

COPYRIGHT 1948
by
EARLE AUGUSTUS SPESSARD

An interesting, if illegal, example of indoor growing is the detailed article on page 23 of THE NEW IMPROVED POOR MAN'S JAMES BOND, "Marijuana Grower Shakes DEA". The grower spent about $75.00 per unit on two 4 1/2 x 2 1/2 foot units he built largely from easily available scrap. His plants matched a normal six month's growth in only nine weeks from seed. His lighting was by regular fluorescent shop lights and used only about $5.00 per month in electricity.

This same method can be used to grow tomatoes or other plants.

PREFACE

The present world-wide interest in hydroponics, judging from the many letters which have come to the writer's desk, stems from the age-old desire to have at hand an abundant supply of fresh, tasty food. The world is still hungry. And in those places where it is either dangerous or impossible to grow vegetables, many have come to look to hydroponics as a possible relief from the difficulties.

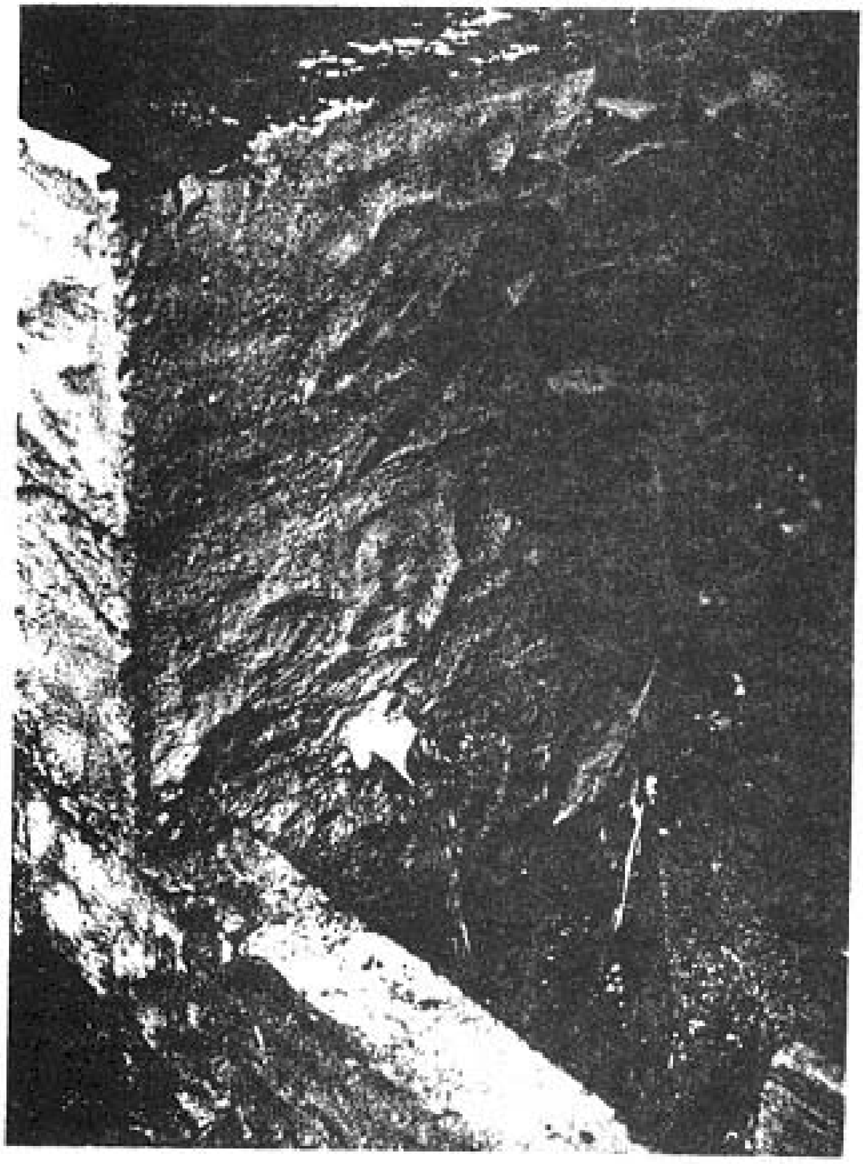


ILLUSTRATION 1. Corner of the feeding-tank, showing the nutrient-solution flowing into the feeding-channel by way of the faucet. A branch of one tomato plant showing a half-mature tomato can be seen growing next to the wall of the feeding-tank. Photograph by Mr. Ray Bruce.

But, in spite of this interest, there is little of practical value in the excellent bulletins and books on the subject which the average individual can use to advantage. The first objective of this volume is therefore to translate some of this valuable information into a language understandable to anyone with intelligence enough to raise a good garden.

The present systems of hydroponics were designed and developed in the interests of fundamental research. It was never expected that they could be used by people in general. A recent visit with most of the important investigators confirms this opinion. These systems are about as perfect in performance as could be reasonably desired, and are to be highly recommended for use in greenhouse establishments, and by anyone having the scientific and technical skill required to operate them. But for the man with limited time, training and money, it is generally agreed that they cannot be made practical.

Considering the above named conditions, the writer began, several years ago, the development of a hydroponic system which would do away with most of the mechanical and technical features, yet allow the evident advantages of the other systems. The second objective is, therefore, to explain in detail how to construct and operate this simplified form of hydroponicum.

I have not attempted to make things easy, or to oversimplify. I have deliberately tried to make certain sections interesting reading. The book can have little interest for those who wish to make a plaything of hydroponics, or to grow plants for amusement. It is intended for those who wish to eat better through their own efforts. The language is not for the plant-physiologist, or the technically trained.

It is for the gardener, whether he be a professional or one who enjoys his little back yard.

There is another group for whom the book is written, namely, those individuals who wish to make a living growing vegetables and flowers for the home market. This group consists of people who intend to do their own work and market their own product through local dealers. In fact, the system to be described was developed in precisely this way. It is expected that in a generation or so, through this system, every village, town and city will be supplied with the major portion of its perishable food supply.

The third objective of this book is, therefore, to lay out the general pattern for future hydroponic development in the world, and to induce serious-minded people, everywhere, to begin laying, in this generation, the foundations for this development.

This book is an enlargement of a mimeographed edition published and distributed by request in 1947, under the title *How to Construct and Operate a Spessard-Hydroponicum*, in the form of five "Lessons." Through these lessons, this simplified form of hydroponics is now in operation in every major country of the world, by one or more individuals. Some of these have consented to make reports on their success or failure, and to give weather conditions. Photographs on pages 49, 135, 143, 155, indicate the success of "students" with the use of the type of hydroponicum to be described. It is hoped that through this means, among those of us interested in having hydroponics become generally useful throughout the world, an interchange of valuable information will be possible. Indeed this is necessary, since up to the moment no Departments or Ministries of Agriculture have taken practical steps to satisfy the present desire for information.

ILLUSTRATION 2. A crop of pole Lima beans growing in a unit from which a crop of tomatoes was harvested earlier in the season. The figure in the background indicates the height of the vines. Photograph by Dr. Charles Deevers.

An explanation might be given here for not emphasizing what is commonly known as "deficiency" troubles. The obvious answer is that if we propose to give a plant what it needs, there won't be any deficiencies. Thus, why worry the beginner with such matters? But there is another reason. The information published is often contradictory, and thus confusing; or, it was derived from observations made on greenhouse material. These conditions do not necessarily hold in outdoor growing, in regions where weather changes are often violent.

CHAPTER 1

Hydroponic Systems Now in Use

I. THE BACKGROUND

A. PUBLIC REACTIONS TO NEW IDEAS. When the public first learns that a new and practical device has appeared ready for use, it receives the news with eager excitement, and waits to see who will first be fool enough to try it out. During this initial period the "sucker-baiters" have their little day, and the stupid victims come, in time, to wonder once more why they were so easily "taken in." But a few will work quietly at testing the new device, with the idea of bringing it into general use; perhaps, of improving it. So has it been with hydroponics since its introduction to the public by Ellis and Swaney, 1938; Turner and Henry, 1939; Gericke, 1940, and Laurie, 1940, through their separate books on the subject. In those references the reader will find the names of some of the many people who have, in one way or another, contributed to the development of hydroponics, as well as the principal universities and experiment stations in the United States and Canada, where the significant work in hydroponics was initiated and carried to completion.

What the public does not know is that for at least a decade before any of these books were published, growing plants hydroponically for commercial use had been going on in a few places. Also, it rarely learns that back of all hydroponics are two centuries and a half of rigid scientific experimentation in the plant laboratories of the world. Let us then set down the principal steps which were taken in bringing hydroponics to its present state.

2

B. FIRST STEPS. Finding out who did what, first, is much like trying to find a needle in a haystack. Someone suggested recently, in a magazine article, that the Chinese gentleman who first discovered by accident that beans would sprout in a wet sack, started hydroponics. Unfortunately, the man ate the sprouts, thus failing to prove that the beans would reach maturity in the bag habitat. He contributed much to the bean-sprout industry and chop suey, but precisely nothing to hydroponics. No doubt Leonardo da Vinci had a hand in it, but there is no record of it, to the writer's knowledge. The first real steps in hydroponics were taken by scientists called plant physiologists. These are the things they did:

1. Showed that plants are as alive as animals.
2. Proved that water is absorbed by the roots, passes through the plant, and escapes into the air through pores in the leaves.
3. Proved that plants use oxygen in respiration, as do animals.
4. Showed that plants take up chemical salts in solution from either soil or water by means of their roots, carbon dioxide from the air by their leaves, and oxygen by means of their roots.
5. Determined what kinds of elements found in the various chemical salts are actually used by the plant to make its body and do its work. These they named "The Essential Elements."
6. Found out how to balance these elements when fed to plants in nutrient solutions of water and chemical salts.
7. Established the proper acidity of the nutrient solution.
8. Worked out formulas for making up nutrient solutions.
9. Demonstrated that plants could be grown to maturity in the nutrient solution alone, or in sand, gravel or other material flushed with the nutrient solution.

Let me repeat for emphasis, it took these scientific men and women 250 years at least to establish these few simple facts about plants. Why so long? Plant physiology is in many respects a much more difficult science than the others. Plants have no nervous mechanism for revealing their needs and their troubles. They have no circulatory system from which plant "blood" might be tested quickly for a diagnosis. Their sap is in no way comparable to blood. The plants we ordinarily eat have so short a life span that any study we make of one individual is necessarily incomplete. To argue the point is not our purpose. It is desired only to point out that to learn a few simple things about how plants live is a most difficult task. The nine items given above are not the only ones, of course, which have been worked out in plant physiology, but they are the ones which had to be done before hydroponics was possible.

The second step was also done in the laboratory. To get oxygen to the roots; to keep the water-stream going through the plants, regardless of the amounts of elements the plants might use; to keep the acidity of the solution favorable to the plants; to keep high temperatures from ruining the roots—all these problems had to be met through devising proper mechanical systems for handling a large number of plants at one time, and equally. Otherwise no proper conclusions could be drawn. Plants have to be grown in numbers, and under as like conditions as possible, for correct results. Out of all this work came the use of such things as sand, gravel and other substances into which the plants might be set, and through which the nutrient solution might be run and aerated. The second step, consisting of the mechanical details for doing all this, was, therefore, also developed in the laboratory.

The third step was to apply the findings of the laboratories to commercial growing. In 1921, Pember and Adams, at the Rhode Island Experimental Station, began applying nutrient solutions to growing carnations in sand. By 1929 Gericke in California had demonstrated the practicability of growing vegetables and flowers hydroponically, and received nation-wide recognition for his work. Two others, Biekart and Conners, at the New Jersey Experimental Station, grew flowers successfully on a commercial basis during the next ten years.

In a way, these were all epochal events. For they demonstrated that plants could be grown commercially by methods used in the laboratory. The next question was, could this be done economically? Gericke, as well as Turner and Henry, proved that it could.

C. Hydroponics remained for a long time in the hands of experts. Only well-established greenhouse firms with enough capital to maintain the expensive equipment, as well as skilled personnel, could hope to operate the systems developed in the laboratory. It should be emphasized that in a laboratory, expense is not the first consideration. There, it is the scientific result which comes first. But in growing things commercially, expense is of first importance, both in construction and in operation. The next significant step would be, therefore, that of bringing hydroponics into general use by reducing its present complexities.

If we go on the principle that after a certain point is reached, precision becomes a luxury, it becomes a practical necessity to eliminate in hydroponics all machinery which does not pay its way. The problem then resolves itself into one of doing away with the non-essentials without destroying the advantages obtained by hydroponics. It was this problem which the writer assigned himself some years ago. The technique developed, and the system adopted as a consequence of this study, are here reported for the first time. It is hoped that in this system we now have a practical method for growing plants hydroponically, the world over.

II. The Hydroponic Problems

These may be grouped conveniently under two general headings. The first are those fixed by the nature of the plant's way of life. The second are those of the operator, and arise because he is trying to induce the plant to do its work under a set of conditions not entirely natural to it.

Of the odd million kinds of plants growing on this earth, only a few hundred are cultivated for use. Left to themselves, they rarely grow in sufficient abundance at any one place to provide a dependable food supply for man. But man has been cultivating the choicest ones for so long, both by agricultural and breeding methods, that they respond fairly well to intelligent care. Since hydroponics is supposed to be the most intelligent way, so far devised, for growing plants, the one who attempts to master the technique of this method should first acquaint himself with the plant's problems, like any good gardener would. For, unless he first understands what the plant is trying to do, he is more than likely to get in its way. In such cases, the plant invariably gives up whatever ghost a plant may have.

A. THE PLANT'S PROBLEMS. In general, these are the same as yours; namely, to grow up, protect itself against its enemies, and to leave offspring. It has no way of enjoying itself, or of being concerned about its own welfare. What it does is done automatically, precisely as you do, with respect to purely bodily processes. If you do certain things a plant never does, so a plant does at least one thing you never do. Before a plant can grow, it must make its own food. You appropriate food either from animals or from plants. But a plant cannot do this. This fact fixes certain problems which one who grows plants must recognize. Let us now list the plant's specific problems which we may help it solve hydroponically:

1. A living green plant does work. This requires that energy be available to be used up or transformed.
2. The only source of energy available is sunlight.
3. To capture the sunlight the plant has to "pickle" it inside a chemical particle, called sugar.
4. To be able to lock up sunlight requires that the plant first have water, carbon dioxide gas, a suitable temperature, and the green-colored substance, called chlorophyll. Any plant that does not have this material cannot lock up sunlight.
5. It frees this locked-up energy by bringing in oxygen for burning the elements, carbon and hydrogen, in the sugar particle, thus turning these back again into carbon dioxide and water. The energy, thus liberated, is heat.
6. This heat is then used by the plant in various ways.
7. To furnish the oxygen for burning, the roots must be able to absorb it, precisely as your lungs take it in during respiration. This is a very important thing to remember in hydroponics.
8. To build its body, the plant must also absorb mineral and nitrogen-bearing chemical salts in solution, through its roots.
9. To distribute these to the parts needed an extra supply of water must be absorbed through the roots, and in sufficient quantity to provide an unbroken water-mass from roots to leaves.
10. The plant's food is the same as yours, namely, sugar or carbohydrate, fats, proteins, minerals and vitamins. But before it can "eat" it must first take in the things named above, and from them manufacture its "food." Thus, strictly speaking, we do not actually feed plants. They feed themselves from the food they manufacture. Our problem is merely to make it possible for them to do this.

This distinction is not merely an academic one. It has practical significance. A considerable amount of literature is going the rounds, charging that plants "naturally" do not require "minerals." It is stated that plants grown on land enriched with "mineral fertilizers, produce puffy and tasteless fruits." Such statements are entirely misleading. The fact is that very little "organic" matter is absorbed and used directly by green plants, and tastelessness has been shown to be due, in some instances at least, to a lack of certain elements rather than to their presence, as alleged. If minerals are categorically "harmful" to plants and humans alike, then the human race has been making an awful mistake in its eating habits for the past million years.

In hydroponics we use minerals exclusively, with the normal supply of nitrogen included. The so-called special benefits of "organic farming," which the average objectors worry about so inconsistently, are provided happily in carbon dioxide, water, and nitrates in a hydroponicum. Plants seem to be unable to prejudice themselves against the carbon, hydrogen and nitrogen found in these substances. They hold the same attraction for hydroponically-grown plants as if they had been born and bred in a manure or compost heap.

B. THE OPERATOR'S PROBLEMS. These are, of course, to provide temperature, light, water, oxygen, carbon dioxide, and minerals, together with nitrogen-containing salts, to the plant as it needs them. These are precisely the problems, in general, of any good gardener. The problems peculiar to hydroponics are:

1. Keeping the roots constantly supplied with oxygen.

2. Keeping the roots constantly supplied with water and chemicals in solution.
3. Keeping the concentration and acidity of the nutrient favorable for plant growth.

The problem of what to feed plants in a hydroponicum is like that of any other type of gardening. Plants use the same kind of materials for food making, whether grown in an ordinary garden, the field, or a hydroponicum.

Hydroponic "farming" differs from other kinds of farming only in the mechanics of operation. Instead of plowing or spading, you flood the tank with water or sterilizing solution and stir the sand. Instead of cultivating with a tractor and shovel, you may use a frog-gig for light stirring; and if you are really good at the thing, you omit the frog-gig. Instead of hauling and spreading manure or other "fertilizer" you dump a pound of clean salts into a barrel, let it sit a while, test for acidity, open a faucet or pull a wooden plug, and let the sand soak the solution up.

Since the problems of hydroponics are essentially the same as those in ordinary gardening or farming, it is strange to find that so many are frightened at the idea of attempting it. After all, is there so much difference between the expression 4-12-4 on a bag of "fertilizer" and the expression KNO_3? If one has to learn a few simple things in hydroponics to be successful, does he not also have to learn more things to garden successfully? Give the same intelligent care to a hydroponicum that you do to a good garden; get accustomed to opening a faucet instead of dragging a plow; get into the habit of saying "essential element" instead of "fertilizer," and the imaginary difficulties of hydroponics disappear. Actually, the number of people who try to raise a garden and fail each year is enormous. Yet these same dupes will persist through half a lifetime of semi-failure without once trying to eliminate failure by learning hydroponics.

Another problem must be mentioned at this point. There is an impression that insect and fungus diseases are eliminated in hydroponics. This is not the case. However, such pests are much more easily controlled in a hydroponicum, and at lower cost in labor and materials. If heavy spraying is necessary, the excess may be washed from the roots quickly, thus avoiding poisoning from this source. All in all, the crop-care, required in ordinary gardening, remains in a hydroponicum. But (and this is most important), the heavy labor and expense of plowing and cultivating are eliminated. The problems of too much or too little rain are, of course, practically eliminated.

The most acute problem in hydroponics is that of securing food-grade chemicals at a reasonable cost. Earlier writers painted a rather rosy picture. They speak of buying chemicals in carload lots. Now anyone is perfectly aware that only very large operators could possibly afford to buy in this manner. The "little fellow" has either to buy at "drug-store" prices or use a combination of better grade "fertilizers." In the first case, the cost is too high, and in the second, his formula becomes rather cumbersome. This in turn makes it impossible to be as precise in feeding as desirable for best results. "Fertilizer," "chemical,' and "essential elements" are not identical terms, as the reader must learn. See Chapters 3, 5, and 7.

It is hoped that by the time this book is ready for press, positive steps will have been taken to improve the present facilities for distributing food-grade chemicals to operators of hydroponica.

The reader should be informed, however, that "fertilizer" companies and "chemical" companies operate under different legal requirements. He should, therefore, not throw blame on either one if he finds them hesitant to supply his particular request. The fact is, up until now, hydroponics has been either in possession of a few experts, large-scale operators, or the armed forces. Chemicals are available to these groups. The "fertilizer" companies, on the other hand, have had their hands full, trying to make up stuff that could be applied to soil-growing exclusively, and be distributed legally. There simply has been no comparable demand, so far, for food-grade chemicals, because there are too few hydroponica in operation. Therefore, those who should and will be interested in this trade have not yet appreciated the problem. They will in time, as hydroponics grow, you may be sure. There are a few distributors who buy up food materials for growing pet household plants. But they sell them at prices too high to be considered in hydroponica except those used as hobbies, and where costs are not a consideration. In short, the small operator of a hydroponicum has been left out in the cold, with respect to buying his chemicals easily and reasonably.

Another problem, and an important one in tropical and sub-tropical areas, is that of keeping mosquito larva, dysentery amoeba and typhoid bacteria out of the tanks. This is the same problem encountered in soil gardening. But in operating a hydroponicum these organisms are easily controlled, thus making fresh vegetables available anywhere on earth, provided the proper type of hydroponicum is selected.

Let us now consider the various systems which have been devised to meet the plant's problems by hydroponic techniques.

III. THE HYDROPONIC SYSTEMS

For practical purposes, we may group the various hydroponica types on the basis of the mechanical arrangement for getting the plant supplied with chemical salts, air and water. All of them, to be considered successful, must stand up under violent changes of temperature, light, wind movements and rainfall. The one that does this best is the one to use, provided it can be built and operated economically.

There are three basic systems, which may be conveniently named: (A) THE GERICKE SYSTEM; (B) THE "AGGREGATE" SYSTEM; (C) THE SPESSARD SYSTEM. They have in common a tank, or "basin," in which the plants to be grown, are placed. This is filled either with nutrient solution alone, or some "aggregate" such as sand, gravel, cinders, clay pellets, or even rock wool, over which the nutrient solution is passed from a storage or mixing tank.

A. THE GERICKE SYSTEM. The essential features of this system are:

1. A tank for holding the nutrient solution. This may be reinforced concrete, wood or metal. It must be waterproof and level.

2. A "litter or seed bed," made to cover the "basin" or tank. It consists of chicken wire stretched across the top of the tank, and over this, a wooden or metal frame is set.

3. Litter to fill the litter bed. This may be excelsior, sawdust, dried cornstalks or other plant material. Anything will do, in fact, provided it does not decay too quickly and will keep moist. It is in this bed that the plants to be grown are set.

4. An air space between the surface of the nutrient solution and the bottom of the litter bed.

5. Or, in addition to the air space, an automatic stirrer inserted in the solution of the "basin."

6. A means for spraying the litter bed to maintain the desired moisture conditions.

7. A means of keeping the plants from sinking through the litter bed into the solution below, as they grow older, or for keeping them in place until their roots make proper contact with the nutrient solution.

8. A means for testing changes in concentration of the solution, as well as changes in acidity. A technically trained individual for doing this.

The remarkable success attained by the author of this system deserves serious study by any operator of a hydroponicum.

Probably no one has consistently secured as high productivity with both flowers and vegetables as has Professor Gericke with this system and his special technique for operating it.

Its chief difficulty is the delicacy of operation required in maintaining the litter bed in proper condition.

The chief virtue of this system is its lack of mechanical incumbrances, and its versatility for growing a variety of crops under skilled hands.

B. THE AGGREGATE SYSTEM. This system eliminates items two to seven of the Gericke System and adds the following:

1. A storage or mixing tank of reinforced concrete, waterproofed.

2. An "aggregate," which may be either sand, gravel or similar material. This is placed in the growing-tank. The plants are set or transplated into this aggregate.

3. Either a system of containers for dropping the solution on top of the aggregate (sand), or a pumping and drainage system of pipes and tiles for flushing it at regular intervals.

4. An electrical motor for driving the pump.

5. An available electrical current.

6. A timing device for keeping the pumping system in operation at the stated intervals.

7. A technician for handling and repairing the machinery.

In short, while this system eliminates some features of the Gericke System, it adds several more, thus adding to the cost of constructing and of operating. The principal features of the system were developed at Purdue and Ohio Universities, and the New Jersey Experiment Station, for research purposes. It is in many respects the ideal set-up for a hydroponicum for greenhouses. Its chief drawback for general use is the expense and technical experience required to operate it.

Both the Aggregate and the Gericke systems have been used extensively in growing vegetables and flowers. The United States army installed one or the other of these systems at various places during the last war. The system, as well as the manual describing its operation, were designed and written by Dr. Robert Withrow, mainly. The army adopted, rather than developed hydroponics.

C. THE SPESSARD SYSTEM. The essential features of this system are:

1. A growing-tank, with sand as the aggregate. This is the same as in the Aggregate System, but the tank is constructed differently.

2. A mixing-tank, or feeding-tank. It is of small capacity, and of a unit size to provide for a unit area of growing bed. The solution is not returned to it as in the Aggregate System, but it may, if so desired. Thus, all testing and pumping systems are eliminated. This tank and the growing tank are constructed, or may be constructed, as a single structure.

The details of this system will be given in the following chapter. Its chief features are simplicity of construction and operation, flexibility in the use of aggregate, chemicals and fertilizers, adaptability to variations in weather conditions the world over, and low cost.

As far as it has been tested, it appears to be as productive of first class vegetables as the other systems.

Once constructed, it will last a century or more with little or no repair.

CHAPTER 2

A Unit-Type Hydroponicum For General Use

I. Introduction

Before describing the Unit-Type Hydroponicum and how it operates, a word should be said about what it was designed to do, what objectives were considered to be of first importance, and what of secondary importance.

A. FOR WHOM INTENDED. The system was designed for use by anyone interested first in growing food for his own use through his own efforts; second, for growing plants to be sold on the local market; third, for those who have reached that age when to be able to work at something without exhausting labor is a precious privilege.

Such people are located all over the world. There are regions where the population is greater than the land to support it. There are regions where it is too cold to bring plants to maturity because of a short season. There are other regions where tropical conditions make a garden both a difficult and a dangerous affair, because of pests and of disease-bearing organisms. If it is possible through a simple hydroponicum and technique to enable people in such regions to overcome the difficulties named, then, by proper education, a system such as the one proposed here should become an important contribution toward solving the problems mentioned.

B. PRIMARY REQUIREMENTS FOR A PRACTICAL SYSTEM. Since the system is not intended for research purposes, it should meet the following practical requirements:

16

1. It should be so simple that anyone with skill enough to grow a garden might operate it successfully.

2. It should cost a reasonably small amount of money to enable a beginner to construct a large enough unit for learning the proper technique of operation.

3. Its operating costs should be low enough to enable the owner, after learning the technique, to repay the original cost of construction in one year of operation.

4. It should be operable under all sorts of weather conditions during a normal growing season, as well as under greenhouse conditions.

5. It should allow the use of a great variety of chemicals or ordinary fertilizers, since there is no standard set of such substances available at all places. It would be expected that chemical salts of proven worth would be preferable to an assortment of readily available fertilizers.

6. The technique of operation should be precise enough to assure a good crop regularly, yet not so precise as to increase costs of operation or of construction. For precision carried too far, is a liability rather than an asset.

7. It should take into account the fact that growing plants are tolerant of rather large variations in concentrations of the nutrient solution used, and of the kinds of chemicals offered them.

8. It should provide a rapid, simple and convenient means for measuring out the chemicals.

9. It should eliminate expensive mechanical details.

10. It should reduce chemical testing to the minimum.

11. Directions for operating it should be in the simplest language possible.

17

II. Definition of Unit

A. Growing-Unit. The growing-unit is that area of the system in which the plants are grown. It consists of 200 square feet of growing space.

This is provided by a concrete (or other suitable material) bed or tank, 50 feet long and four feet wide, outside dimensions. The inside depth of the tank is eight inches. The walls are two inches thick. The bottom is also two inches thick, unless constructed in cold regions. In the latter case, it is reinforced and is three inches thick, being set on piers sunk to below the frost line, with a space between the ground surface and the tank bottom. In tropical regions also, the bottom of the tanks may be raised above the ground level to avoid insects and infestation with disease-producing organisms.

The unit may be built also as two 25-foot or five 10-foot tanks, with other dimensions as given.

The specifications for building the growing-unit are given in Figures 1-5, Section VI, page 27 of this chapter.

B. SOLUTION OR NUTRIENT UNIT. This is one 50-gallon barrel. This is chosen because it is a familiar unit to people of the United States and many other countries. It is also a simple fraction (1/5) of the physiological units commonly used, namely, 1,000 liters, or 1,000,000 grams, or five barrels of solution. Finally, one barrel of solution is the amount which will daily provide the nutrients required for one growing-unit, having 200 square feet overall area (see A), when fully planted. This was determined by expriment.

This amount of solution is calculated to give plants in one growing-unit their daily ration at the time of maximum requirements, which is near the peak of their growing period. For tomatoes, this amount would be sufficient for approximately 130 plants in the unit area given above. Smaller plants would cover the same area, but would be more in number, of course.

18

The actual construction of the solution-unit provides for three barrels rather than one, for this reason: During the early growth of plants in the growing area less nutrient solution is required than when the plants are approaching maturity. Therefore, it is convenient to make up three barrels at a time, rather than one. A greater amount than this, experience has shown with this system, is undesirable. As the season progresses and the temperature increases, more and more water is given off by the plants. Therefore, although the daily ration of chemicals remains fixed, there has to be a provision for giving the plants more water. Since the minimum of solution in the tank is one barrel, and the total capacity is three, we have two barrels of extra water which may be provided if necessary in very hot dry weather. If the tank contains two barrels of solution, there still remains one barrel capacity for providing extra water at the time of feeding.

The dimensions of this nutrient-tank are, therefore: 34 inches long, 4 feet wide, and 28 inches high, outside dimensions, with 2-inch-thick walls.

Specifications for building this unit are given in Figures 1-5, page 27-30.

The unit, therefore, from the point of view of operation, consists of a feeding-unit and a growing-unit to form a single working whole. It may be redefined as a unit of solution (one barrel) which will adequately supply the growing-unit (200 square feet) with the proper amount of nutrient solution daily, when it is filled to capacity with plants at the time of maximum growth.

The two may be constructed in one piece, with the feeding-unit at one end of the growing-unit, or with the feeding-unit placed at the midway point between the ends of the growing-unit. The essential feature consists in having a growing area no larger than the barrel of solution will provide adequately. The size of the growing-unit was determined by experiment in the region of Conway, Arkansas. There is no apparent reason to suppose that it would vary from place to place.

In later discussions it will be the unit-as-a-whole, which will be considered. Once the operator learns how to operate one unit, he may then double or treble or otherwise enlarge his plant as desired. The details remain the same whether one or a hundred or more units are built.

III. Selection of Site for One Unit

A. light. The unit may be placed anywhere that the amount of light available is sufficient for the growing needs of the particular kinds of plants to be selected. Vegetables require more light, as a rule, than do flowers. It is a common misconception that in hydroponics one may use an attic, a cellar, a closet or any sort of ill-lighted place. This is not so.

Many believe also that there is need of ultra-violet light. It is the blue and orange-red portions of what we call white light which are used in greatest amounts by green plants. The amount of light, both as to length of daylight period and intensity, is of great importance. Some plants do best when the days are short, others when they are long. Fortunately, most vegetables offer no difficulty on this score. Plants may, to a certain extent, protect themselves against too intense light and ultra-violet light.

When the light intensity is too low, the leaves tend to enlarge, as though in an effort to make the green material (chlorophyll) cover as large an area as possible. When the light is too intense, the leaves may wilt or even burn, because of internal disturbances connected with using the substances given them through their roots.

B. water supply. The unit must be placed where a constant supply of water is available. This may be near a faucet, beside a pond or stream, or below a dam through which the water may be led to the hydroponicum by pipe or other means. The ideal locations of large hydroponica would be on the hillsides below the great water-control projects throughout the world.

I estimate that the *maximal* amount of water required to operate my own system, regardless of the number of units built, is 22 gallons per square foot of growing area per 100-day growing period. Most crops mature in this time. This may be put in another way, by saying that the amount required is the equivalent of 36 inches of rainfall. If we take a region in which the annual rainfall is 10 inches, then by collecting the rainfall over an area 3.6 times the size of one unit and storing it for use as needed, enough will be available for growing one crop on one unit. Again, in a desert with an annual rainfall of six inches, the water collected and stored from an area of only 1,200 square feet should be sufficient to grow a crop on one unit. In other words, by proper water conservation, growing vegetables for home use by hydroponic methods is practicable. It is the common practice in many regions to thus conserve water for household use. An extension of this idea to include a small hydroponicum could scarcely be called a difficulty. There is hardly a site in the world, where people must live, with less than six inches of rain annually.

This estimate of the amount of water required may be lowered in regions where the rainfall is heavy. Indeed, the rainfall may so seriously dilute the nutrient solution as to bring about temporary starvation of the plants, unless proper precautions are taken.

C. shading. In hot arid regions, in order to reduce evaporation, as well as to avoid excessive sunlight, shading is necessary for some crops. Likewise, an occasional sprinkling of the surface of the growing-unit with water may be necessary to prevent accumulation of chemicals at the surface, and to wash out wastes which tend to collect in the sand, in the absence of rainfall.

D. AERATION OF PLANTS. The supply of oxygen for the roots is discussed elsewhere. But there are regions where the air is very humid. In such places the unit must be so located as to allow free circulation of the air through the leaves. Overcrowding of the plants must be avoided, or fungi will attack the plants and destroy them rapidly. There is another reason, quite as important as the first, namely, making conditions favorable for the evaporation of water (transpiration) from the under surface of the leaves. If this does not occur, the plant has difficulty in obtaining a sufficient amount of the chemicals offered them, and fail to use properly what they do get. Circulation of air, if not excessively violent, is necessary.

E. DIRECTION OF UNIT. There is no reason for believing that the unit must be placed north and south rather than in any other direction. But it should be obvious that in whatever direction it runs, it is necessary to observe that tall plants must not be allowed to shade low plants, unless specifically desirable.

IV. MATERIALS REQUIRED FOR ONE UNIT

For the convenience of those who wish to make an estimate of what it would cost to build one complete unit in 22 their particular locality, an exact list of the materials required is given here.

A. Slightly more than two cubic yards of mixed cement and four cubic yards of washed sand for filling finished growing unit.

B. Lumber: 210 linear feet of eight-inch-wide and 216 linear feet of 10-inch-wide material for forms; 100 linear feet of two-inch by four-inch material for bracing forms; 100 linear feet of one-inch by three-inch material for screeds or guides; 14 linear feet of one-inch by two-inch material for making screen to cover the nutrient-unit tank.

C. Two pounds of nails, assorted sizes; one box of carpet tacks. Metal screening, with mesh fine enough to keep out mosquitoes; one piece 48 inches by 30 inches.

D. Three 3-inch nipples; one 8-inch nipple; one elbow; two caps for nipples; two hydrant faucets. The diameter of the nipples should be small enough to accommodate the faucet thread.

E. Ten gallons of asphalt paint (not tar).

F. Ten pounds of glass wool, or some material which will allow water to seep through freely, but not allow sand to pass through. Newspaper will serve. Rock wool may be too alkaline.

G. One hundred pounds of chemicals. It may be necessary to buy this much of each major kind, used in the formula chosen.

H. One glass graduate for measuring acid. One acid tester, with color indicator and extra rolls of paper for renewal. One tin can 10 c.m. by 5.8 c.m. diameter for measuring chemicals.

I. One five-gallon bucket. One garden hose.

23

J. Ten 7-foot cedar or other posts for building a superstructure for tieing up crops like pole beans, cucumbers, and tomatoes; about 200 feet of poles or lumber for frame attached to the posts; 150 seven-foot-long pieces of wire of weight used in an ordinary fence, to provide each plant a support suspended from the cross poles or frame.

It is assumed that the operator will have the unit built by a contractor, who will know how to make forms for pouring concrete. If the operator does this work himself, he will have to know, of course, how such forms are constructed.

The materials listed provide for making one unit and operating it for one crop. Only a partial renewal of the chemical supply will be required for further operation.

The reader should be reminded that if he has to fight insects and fungi, proper spraying materials will also be required to save the crop grown, precisely as in ordinary gardening.

A greenhouse is unnecessary, unless the operator wishes to lengthen his growing season by transplanting, or wishes to grow plants early, or desires to have produce for use when the outside temperature is low. For transplanting, I use tin cans large enough to allow the plants to become sufficiently well-advanced that one month of growing time outside is gained. The capacity of such cans is about one gallon. It requires one can for each plant to be transplanted. There are several advantages to be gained through the use of this size can rather than some other. First, tomatoes may be transplanted when in full bloom, without harming the root system. Second, they may be spaced to prevent crowding, simply by removing every other can. When not used for transplanting purposes they come in handy on many occasions. The most important use is to substitute them for the large growing-unit or cement tank. Plants such as beans, 24 tomatoes, and beets may be left in this size can and brought to maturity simply by pouring the nutrient solution over the contents by means of either a dipper or a hose. See the tin-can technique for details, Chapter 4.

V. PRINCIPLES ON WHICH TOTAL UNIT WORKS

The unit is designed to meet four practical working requirements. These are: First, providing adequate air for absorption through the roots; second, providing adequate supply of chemical solution to the roots; third, meeting additional water requirements as needed; fourth, maintaining the proper acidity of the solution about the roots in the growing area.

By means of two sand-retaining walls set on the bottom of the growing-unit, there are provided two open channels, one of which may be filled with solution, which then flows under the retaining wall, while the other receives the solution as it flows from the sand area, and serves as a drain towards the end of the growing-tank and away from the feeding-unit. The flow is regulated by properly sloping the bottom of the growing-unit from the first, or feeding-channel, to the second, or drain-channel on the opposite side.

The solution is delivered into the feeding-channel from the feeding-unit by means either of a faucet set in the wall of the feeding-unit eight inches above the bottom, or by means of a nipple set in the wall of, and at the bottom of the feeding-tank. See Figures 2 and 4, pages 27 and 29. The latter is the quickest way to deliver the solution into the feeding-channel. The former allows the solution to be aerated as it falls the eight inches into the feeding-channel and the faucet is less likely to become clogged with debris from the feeding-tank.

Aeration is provided partly as described above, and partly by alternately allowing the solution to fill the spaces between the particles of sand through capillarity, then permitting air to percolate downward from the surface as the water is used up, or drains away.

The unit type of hydroponicum differs from the types mentioned in the first chapter in several important respects. First, the solution is delivered fresh to the plants each day, and is not used over again. This may seem to be a waste. However, if a solution is made up in large quantity and used repeatedly, all of it must be thrown away sooner or later and be replaced. In the unit type under consideration we throw it all away, as in the case of the other systems, but do it gradually rather than at one time. The principal advantage gained is in not having to make chemical tests. When the feeding is done skillfully, it is found that only a few gallons are discarded daily, but in doing so the effect of a constant flow of nutrient is approached. Also, the acidity of the solution in the regions of the roots is kept fairly constant, a very important point to be considered. However, over prolonged periods of extremely high temperature, it is more economical to sprinkle the sand surface with water occasionally, or with slightly acidulated solution by means of a hose attached to the faucet of the feeding tank.

Another difference to be noted is the lack of any extra provision for root aeration. No pumping at regular intervals and no air bubbling system is required. It has been found that during very hot weather the solution may be left in both the feeding and drain channels to a depth of two inches for a whole daylight period without becoming stale, and without the plants showing injury from oxygen shortage. However, this is not advisable, since the solution around the roots, lacking a flow movement, tends to become alkaline within a day or so. In periods of wet weather this trouble is not encountered.

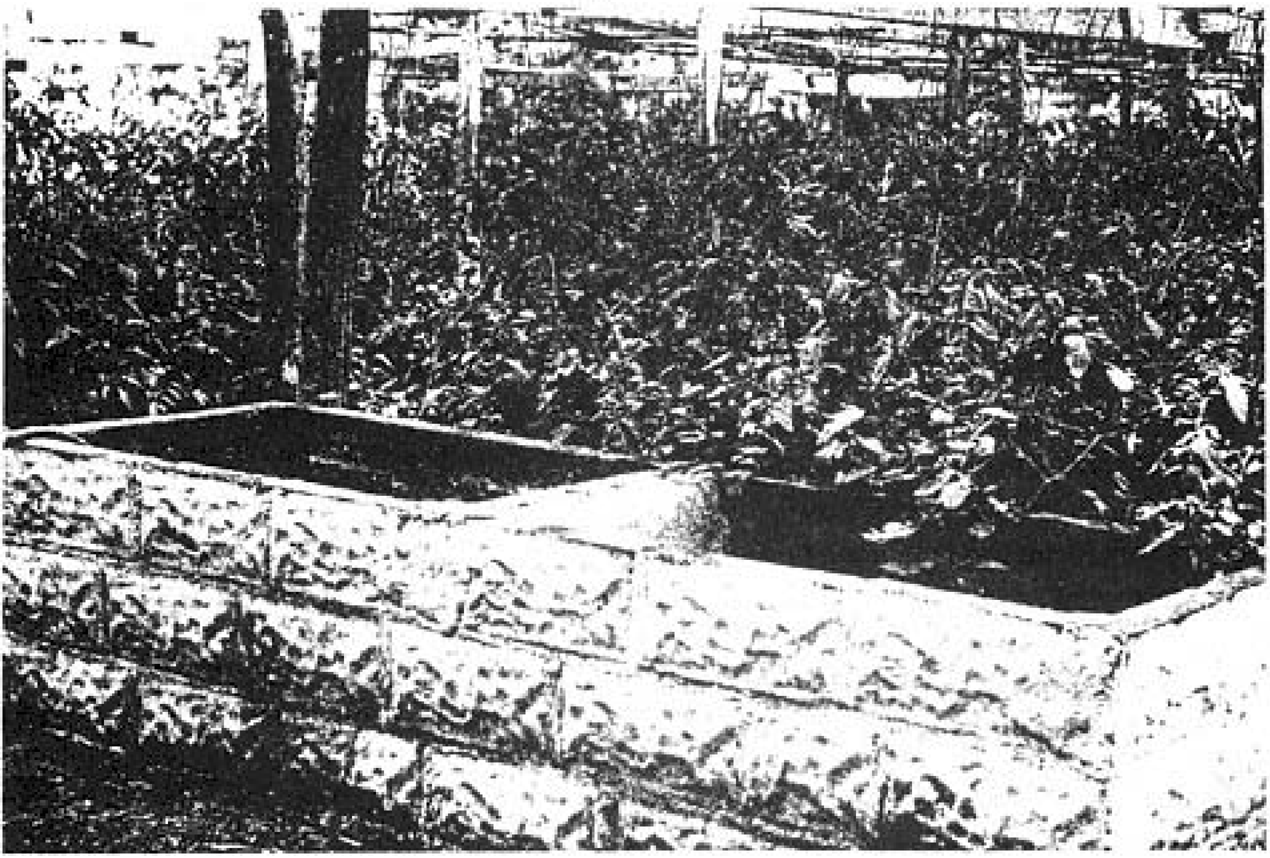

ILLUSTRATION 3. View of double feeding-tank. This shows the feeding-tanks at one end of the growing units. Photographed by Mr. Ray Bruce.

27

VI. STRUCTURAL DETAILS OF COMPLETE UNIT

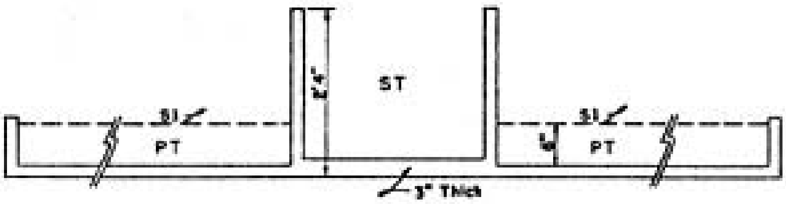

Figure 1. This shows a lengthwise section of the unit, through the middle. Each growing-unit (P.T.) is 25 feet long, with the end walls and side walls (not shown) eight inches high inside and 10 inches high outside. The solution tank (S.T.) is 34 inches long, running with the bottom of the whole unit, and 28 inches high, outside dimensions. The width is considered as running crosswise with the growing-unit, which is four feet, outside dimensions. (S.L.), sand level.

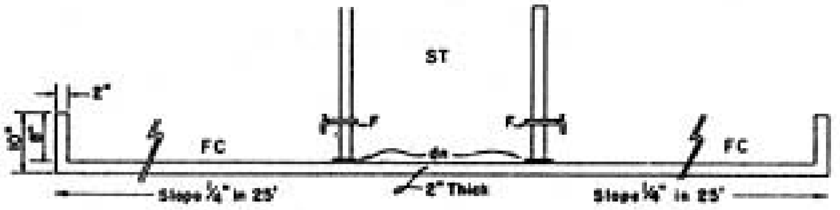

Figure 2. This shows a lengthwise section through the feeding-channel side of the unit, with a faucet (F.) and a capped nipple (D.N.) leading from the feeding-tank to each of the two feeding-channels, each 25 feet long.

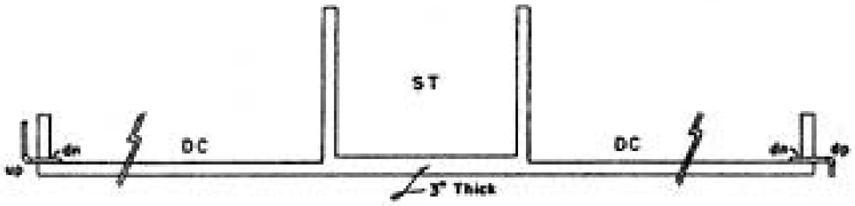

Figure 3. This shows a lengthwise section through drain-channel (D.C.) side of the growing unit, with a nipple (D.N.),

28

and an eight-inch nipple attached to this. This makes an adjustable structure which provides for both opening and closing the drain. In the upright position, (U.P.) as shown in the sketch, the drain is closed, and the tank may be filled with sterilizing solution, water, or nutrient-solution as desired. In case of continuous rainfall, the outside nipple may be lowered so that its opening is an inch or so above the inside bottom of the unit. This allows for an overflow in case of sudden rain, and also permits a certain amount of solution to remain around the roots of the plants constantly. At such times, by increasing the concentration of the solution in the feeding-unit, or by scattering some ordinary garden fertilizer over the surface of the sand, the growing plants survive very wet spells nicely. This of course conserves the water, and lowers the estimate given in (III. B).

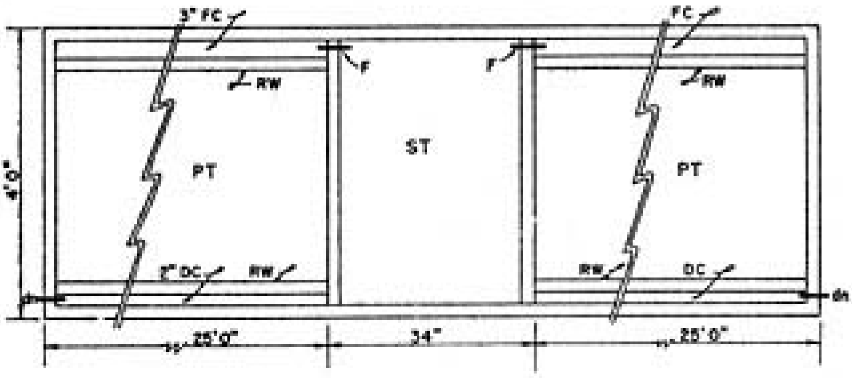

Figure 4. This shows the unit as a whole as seen looking down on it. The retaining walls (R.W.) are made of four-foot slabs of cement, one to two inches thick. These are set on the bottom of the tank and hold the sand in place, while allowing the solution to flow underneath them and over the bottom of the growing-unit. In case sand flows under them, or between the joints, glass wool, or paper, or asphalt roofing must be used to seal them loosely, being careful to permit a free flow of solution under them. See (S), Fig. 5. This is of

29

utmost importance. The retaining-wall should be so placed as to allow a feeding-channel (F.C.) three inches wide, and the drain-channel (D.C.) one inch wide. A little extra space in the feeding-channel, at the place where the feeding faucet and nipple below it come through the solution-tank wall, is very convenient. It permits free use of the hand, a pair of pliers or small wrench. The retaining-wall is held in place by the proper use of spreaders, made of any convenient material. Brickbats are excellent for this. The use of spreaders may be avoided by tilting the retaining-wall against the tank-wall. If this is done the slabs should be made 9 inches high.

Figure 5. This shows two cross-sections of the growing-unit with the bottom sloping ½-inch across from the feeding-channel (F.C.) to the drain-channel (D.C.). The space between the retaining-walls is filled with sand, which settles down about two inches after being wetted thoroughly, to its final level. This makes the sand depth six inches and allows a two-inch space above the sand for preventing splashing of the sand out of the bed during a heavy rain.

In (A) the normal arrangement of feeding and draining is given. In (C) is shown a variation of (A), in which two open-bottom troughs (T) are sunk down the length of the growing-unit. These troughs offer a very convenient method for introducing the nutrient-solution. It flows downward, increasing aeration of the roots and aids in replacing any highly concentrated solution which may accumulate near the surface. It also distributes the solution more evenly to all the plants. This arrangement is especially effective when the bottom of the growing-bed is made to slope both ways from the middle to the sides, making both channels, draining-channels. This arrangement is preferable to that in (A) in hot, dry regions. The feeding-channel is unnecessary if the troughs are used. (B), detail of draining-channel.

VII. Functional Details of Complete Unit

Let us now see how the unit works in operation. Let us assume that the growing-unit is filled with sand, is planted, and that the plants are of size requiring feeding. Let us assume also that the feeding-unit is provided with nutrient-solution, and full enough to make a feeding.

First, either the faucet or the cap on the nipple in the wall of the feeding-unit (Figure 2) is opened. If both sections of the growing-unit are to be fed, of course both faucets will be opened. The solution flows down the feeding-channel (Figures 2 and 4) until it is full, as shown in Figure 5A at F. C. The solution flows under the retaining-wall, out of the feeding-channel, into the sand-filled area of the growing-unit. Here it spreads by capillarity in all directions through the sand and comes into contact with the roots of the plants growing in the sand.

From the sand area the solution finally flows under the opposite retaining-wall and into the drain-channel, Figures 3 and 4. If the drain-nipple (D. N. Figure 3) is in the up-position, the solution will flow into the drain-channel until it is ½-inch deeper on that side of the growing-unit than on the feeding-channel side. When the drain-nipple (D. N.) is in the down-position, all excess solution not taken up by the sand and the roots will drain out of the unit.

The faucet at the feeding-unit is closed when the feeding-channel is full. or when any other desired amount has been introduced into it.

In the event that the growing-unit is provided with the troughs (T, Figure 5, C), the colution is introduced into them rather than into the feeding-channel.

In the event that the plants growing on the feeding-channel side grow more rapidly than those on the drain-channel side, it means that the slope across the growing-unit was not correct for the type of sand used. In that event, two solutions of this difficulty are possible. Either the trough (T) in Figure 5 B may be added or a cross-channel from the feeding-channel to the drain-channel may be cut through the retaining-walls and sand, straight across from where the faucet is located. Thus feeding can be done in both channels at the same time by keeping the drain-nipple (D. N.), Figure 3, closed until the amount of solution introduced is taken up by the sand and roots, and the channels then emptied of any unused solution. Care must be taken to see that the drain-nipple is then returned either to open or overflow position so that the growing-unit will not be flooded in the event of a big rain.

The feeding-unit is filled, of course, either from a water main faucet, by gravity through pipes from a pond, by pumping from a well, or by hand, according to the conveniences available.

The most economical arrangement for conserving the water supply is that shown in Figure 5, C, page 30.

This chapter ends with information on how the unit itself operates. The next chapter will tell how to operate it. In other words, we have been discussing the mechanics of the unit. Now we must deal with something which has to do with the judgment of the one who tries to make the machine work.

CHAPTER 3

How to Operate the Unit-Type Hydroponicum

In order not to frighten the beginner who is seriously interested in building and operating successfully a unit type or any other type of hydroponicum, all technical details have been reserved for later chapters. Nevertheless, such things may not be put off indefinitely, if one is to increase his understanding of what is going on and what he is really trying to do. It will be assumed that he is anxious, perhaps over-anxious, to begin growing something in the hydroponicum he has set up. Very well, let us see how one goes about growing a crop of tomatoes in a unit type of hydroponicum such as has been described in the last chapter.

I. Chemicals You May Use

In Table I, page 68, you will find a list of chemical substances which have been used by one expert or another in making up satisfactory formulas for your use. In Chart 2, page 99, you will find some of these as used in various formulas. As a test, we will choose Formula VIII for our present use: Potassium chloride, sodium nitrate, ammonium nitrate, monocalcium phosphate, magnesium sulphate, lime and nitric acid for the bulk chemicals. For the trace elements we shall use ferric ammonium citrate, manganese chloride, boric acid, molybdic acid, copper sulphate (blue vitriol), and zinc sulphate. These will give us everything the plant needs. We shall assume that you have all these on hand and have the acid testing supplies mentioned in the last chapter, page 22.

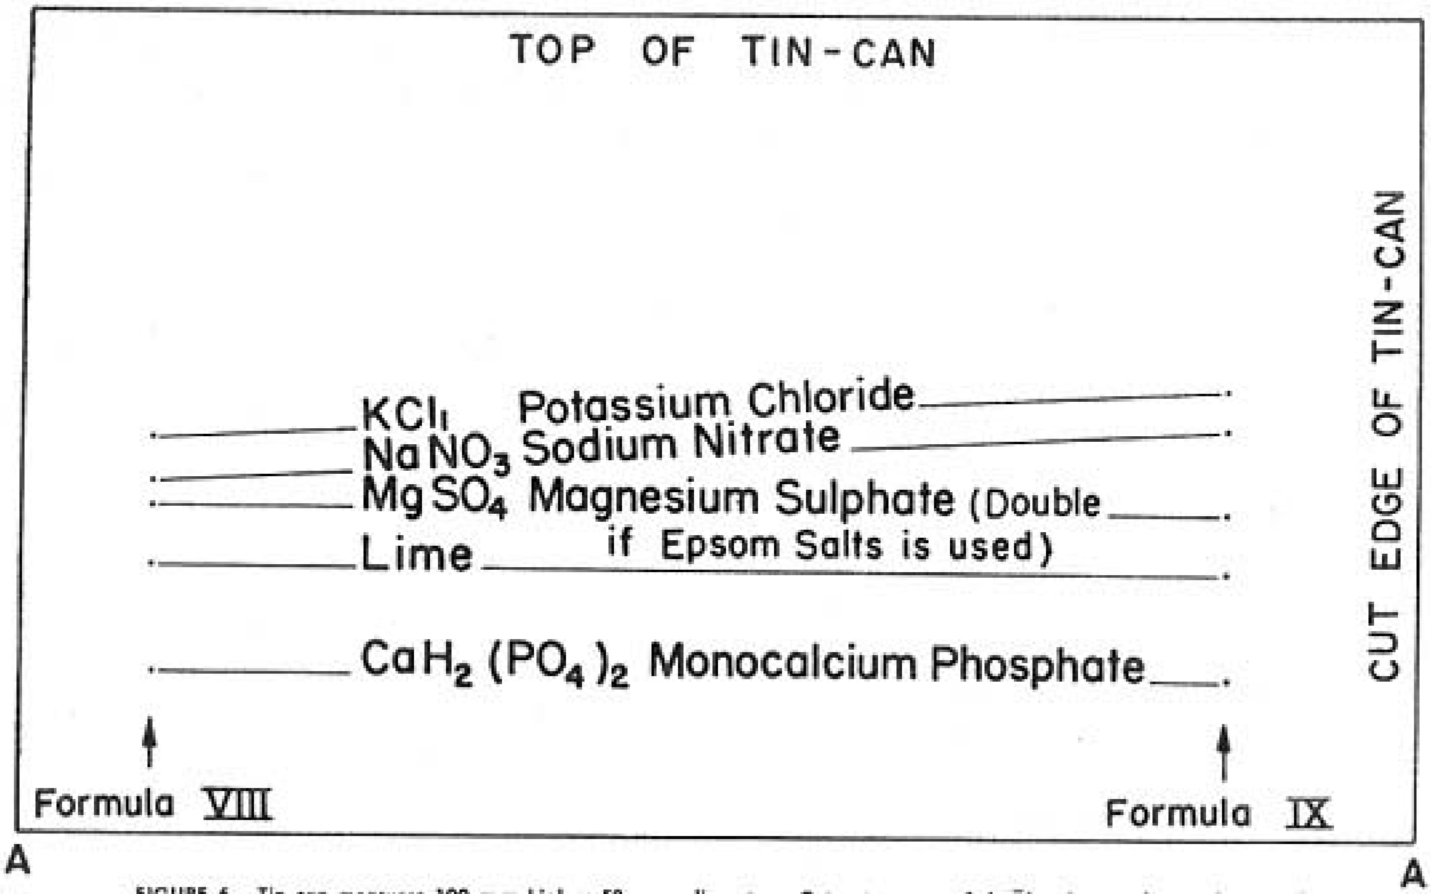

FIGURE 6. Tin can measures 100 m.m high x 58 m.m. diameter. Cut out a copy of the drawing, and wrap it around any can just large enough to allow the edges to come together. To use, punch a hole at each level indicated. For each chemical, fill the can from the bottom up to the hole, and empty. Repeat until all the salts have been measured. Dump them all into a barrel of water, stir, test for acidity (see text), and let stand six hours.

II. A Practical Method for Measuring Out Chemicals

The following method is to be used for mixing up one barrel of solution, which is the unit defined in the last chapter. It is based on the idea that a given weight of a chemical will have approximately the same volume regardless of atmospheric moisture which it picks up and loses from time to time.

I use a tin can 5.8 centimeters in diameter, and 10 c.m. high. Each chemical was weighed out according to the formula and its volume marked on the side of the can by punching a hole through the tin. Thus a chart showing the level of each volume of chemical used is easily made. The can is filled to the desired level determined for each chemical used. It is better to have a can for each formula. But the formula should be marked on the can.

[35] See Chart 2, page 99. The amount of nitric acid required to neutralize the lime would be about 20 cc.

Once the cylinder is prepared it is used as follows: It is filled to the level of the 20 mm. line with monocalcium phosphate. This is then poured out into a container of convenient size. Next, the can is filled with lime to the 33 mm. level for lime. The can is again emptied. The operation is complete when each chemical is thus measured out in its turn. The order of measuring is not important. Incidentally, one may use any size cylinder, no matter how much larger, and mix up any quantity desired so long as the levels remain as given. The whole would then have to be mixed very thoroughly, however, before using. I frequently mix up 100 pounds at a time, including trace elements, except iron. If this is done, slightly less than one pound of the mixture would be used for each barrel of solution made up. But let us proceed with making up one barrel of solution, by adding the trace elements.

For copper, use two or three drops of solution made by dissolving two pieces of copper sulphate the size of a pea in a quart of water. For molybdenum, use enough of molybdic acid powder to cover the period of this sentence. Do the same with zinc sulphate for providing the required zinc. Of, if you have an old wash tub or bucket filled with wood ashes which are covered with water, a spoonful of this will do. Or, in most cases, it might be just as well not to bother about zinc. Enough boron will be supplied if you ucover the word boron with boric acid crystals or borax. Enough manganese chloride or manganese sulphate to cover the word "acid" will be sufficient for the amount of manganese desired. For iron, enough ferric ammonium citrate or ferrous sulphate to cover the word "ammonium," would be sufficient to prevent iron deficiency in most cases.

[36] All these chemicals, *except the iron,* are now put into the barrel of water and stirred. It is perhaps best to put the acid into the water before any of the other chemicals are added, although it may be done afterwards. However, never put acid on the undissolved chemicals. Also, *never put water into the acid.* This is particularly true when sulphuric acid is used for it gets very hot when it is mixed with water. The

acid used here is to neutralize the lime. To decide exactly how much to use, make a preliminary test. Dissolve the lime you measured out, in a gallon of water. Then add acid slowly, stirring it frequently. Test with the paper after each stirring. When the paper shows a *p*H of 6.5 you are through (see III below). Note exactly how much acid was used. That is the amount to use. It should be around 20 cc. if nitric acid is used, and 10 cc. when sulphuric acid is used for Formula IX.

III. Adjusting for Acidity

You now come to a very delicate problem. You must adjust the solution to its proper acidity. Don't do this until six hours after mixing. This is called "pee-aich," *p*H, and is indicated as 4.5, 5.6, 6.0, 7.0, and so on. You are aiming to adjust the acidity to 6.5. Above 7.0 the solution is alkaline and few plants will grow in it. Below 7.0 it is acid. Most plants prefer a slightly acid solution. None will do well if the solution is at 4.0 for a very long period. It should be stated that the acidity of the solution about the roots does not remain 6.5 for very long. Whether it becomes acid or alkaline depends on several factors. However, we shall begin by giving the plants a solution reading 6.5, or slightly less, and later test it as it comes out of the growing unit or by sinking small wells down in the sand deep enough to fill with some of the solution about the roots themselves and then test this solution.

The solution in the barrel is adjusted by adding acid drop by drop until the paper reads 6.5 after thorough stirring. If too much acid has been used, the mistake may be corrected with a little lime or lye water or wood ashes. It takes practice to make this adjustment easily. In practice, the solution should be made up the evening before it is to be used. The acid adjustment may then be made the following morning. If you complete the steps given in Section II correctly, no adjustment will be necessary. But check.

The iron is added to the solution just before feeding and after the adjustment for acidity has been completed. Otherwise it will precipitate out of solution partly and the plants will show signs of iron starvation in spite of the fact that it has been used regularly. Ferric ammonium citrate is preferable to ferrous sulphate for this reason.

You now have a barrel of solution made up according to Formula VIII, which I used during the past season and which produced on one 200-square-foot growing unit 746 pounds of marketable tomatoes between April 1st, when the plants were transplanted to the growing-unit, and July 12, 1947, when the bed was replanted in Lima beans.

IV. Use Made of Ammonium Nitrate

The reader may have noted that ammonium nitrate was not included in the levels of measurement on the tin can, although it was selected to be used. This chemical will be used in our test to add nitrogen as desired. Ammonium nitrate is a liquid. The form sold in bags has a coating which rubs off easily when used on cultivated soil. In a hydroponicum one is never quite sure just when it becomes available after being put into water. It is used because the ammonium part is more quickly used by the plant than the nitrate part, when protein is being made. For this reason it is difficult to manage. It is easily possible to give too much nitrogen at once by the use of this chemical. I have found, however, that if one adds gradually increasing amounts, beginning with 5 mm. in the can or cylinder, no harm is done. The very maximum would be 100 mm. This is done only on clear days, as these grow longer, when the temperature is in the eighties or nineties. I never use it on dark days. The whole problem of feeding nitrogen is discussed in the more technical Chapter 6, Section IV, page 78.

V. Preparing the Growing-Unit for Transplanting

Before the tomatoes are transplanted to the growing-unit the sand in it must first be properly prepared. If washed sand was used, it is first made to settle down by flooding the growing-unit with tap water. It is then thoroughly drained. Properly done, this leaves the sand in a level condition. After draining, the sand is allowed to dry out at the surface.

The sand is then thoroughly wetted with nutrient-solution from the solution-tank unit. The details of this procedure are given in Chapter 2, Section VII, page 31. However, a word must be said here. You are now face to face with several problems. First, you want to supply enough water and chemicals to the roots of each plant for proper growth. Second, you want to allow enough oxygen to get to the roots so that they will not suffocate. This means that you must not allow the roots to be covered with the solution for too long a time. Remember that without oxygen a plant cannot live and everything else we may do is useless unless we provide this element.

This is accomplished by filling the feeding-channel full enough so that with the drain-nipple closed, enough will flow under the retaining-walls to soak up the sand to within a quarter-inch of the surface, and allow none to remain in the feeding-channel, and only a very little in the drain-channel. Since the bottom of the growing-unit slopes one-half-inch across, and since the sand on the feeding side has the first opportunity to soak up the solution, a little time must be allowed for the sand on the drain side to soak up its full amount. Otherwise, the plants on one side will receive more of the chemicals than on the other and will grow faster. After this time has passed what little solution remains in the drain channel may be allowed to pass out. It may be collected and returned to the solution-tank if desired. I rarely do this because it is less expensive to discard a little every day than to bother testing it, since in time all of it has to be discarded anyway if it is reused.

VI. Transplanting to the Growing Unit

If you have bought your tomato plants from a nurseryman or if you have grown them from seed yourself, the plants are transplanted as you would do in a garden. I make it a practice to grow my own plants from seed, transplant them into gallon cans three-fourths full of a mixture of compost and sand, or of dirt and sand, and transplant from these to the growing-unit. The entire contents of the can is transplanted. The roots are thus not damaged, and some time is saved. The plants are set just deep enough to have the roots, with the contents of the can, extend down to the moisture levels of the sand, but not with the stem more than an inch below the surface. I find that deeper planting causes the old roots to die, thus causing a delay until new roots are formed. I have not found that deep planting makes for sturdier and more productive plants as some growers claim.

If there is danger of the stems rotting at the surface, as sometimes happens in humid weather, it helps to wrap each stem with a small wad of rock wool soaked in a little copper sulphate, sulphur[40] and lime, at the region barely below the sand level.

The plants are set in three rows down the length of the growing unit. They are spaced about 14 inches in the row, the plant of one row alternating with that of another row. This permits the use of about 130 plants to the growing-unit.

Once the transplanting is finished, the drain-nipple is then closed, and the growing-unit thoroughly wetted again with nutrient-solution as described in Section IV above.

VII. Inducing Roots to Grow Downward

After the plants are properly set in the growing area and fed, the next problem is to induce the roots to grow as near the bottom of the sand as possible. If the sand is kept wet at the surface, the lower roots will die of suffocation and all the roots will spread out just beneath the surface of the sand. If this is allowed to occur, many difficulties will be encountered later. To avoid this situation we proceed as follows:

First, the plants are not fed again after transplanting until the surface of the sand has begun to dry out slightly. If it happens that the season turns out to be very wet at this time, it may be impossible to do anything to prevent the surface spreading of the new roots. But let us assume that the season is, at this point, reasonably favorable. As the top portion of the sand becomes less wet, the roots will tend to follow the water down and may even go as far as the bottom of the cement tank. During this period the plants are given just enough solution to keep the bottom of the two channels moist but without allowing the solution to stand in them. By running a little into the feeding-channel three times a day, the trick is accomplished. It takes at least one week to do this.

Cauliflower, for example,[41] set out in mid-summer when the temperature was 95 degrees F., and the sand surface 110 degrees F. for several hours during the day, recovered without serious wilting in 24 hours. After that time they endured full sunlight with a daily maximum temperature of 95-105 degrees F. for two months. The plants were not previously hardened but were grown in sand on the nutrient-solution used in this discussion and transplanted without the loss of roots. These plants were given Formula VIII for the first two months and brought to maturity on Formula IX. Cucumbers, grown in another unit at the same time, were similarly treated. They were given a little ammonium nitrate and some extra potassium chloride as fruit began to form. Sample plants of both the cauliflower and the cucumber showed, when pulled up, that the roots had developed nicely and toward the bottom. It should be pointed out, however, that surface roots must also be developed. The upper roots serve to absorb the oxygen, while the lower roots serve as feeding roots.

Thus we achieve a situation like that in a wet garden, where by ridging up the rows, the surface layers provide oxygen and some chemicals, while the lower and wetter layers provide water and chemicals.

VIII. Feeding Schedule

Beginners want to know first, what to feed the plant, and second, how much. Third, they want to know how often. In the Gericke system feeding is continuous. In the aggregate system, it is either continuous or every eight hours. In my own system it is once a day. In all the systems the plants are feeding continuously. It is the number of times devoted to renewing the solution that varies from system to system. To go further on this point would require that we become technical.

If the reader is prepared[42] to understand that no matter what system is used, certain changes must be made in applying the basic technique employed, because of variable factors, we may proceed. Rain dilutes the solution in the growing area. High winds and temperature cause plants to take out the water faster than the chemicals are taken out of the nutrient-solution. Dark, cloudy periods upset the plant's needs for one kind of element or another. Thus the number of feedings is linked up somewhat with a number of factors. By striking for an average and hoping for a little luck, given a sound formula and a barrel of solution properly prepared, we may expect rather fair results.

The general schedule then, keeping the above remarks in mind, is as follows:

A. FEED EACH MORNING. Use enough solution to make the sand moist to very near the sand surface after the feeding-channel becomes emptied. If this requires a whole barrel, use that amount. If it requires only a quarter of that amount, that is sufficient. The plant cannot use any more than the sand will hold. Also it cannot use what you carelessly let run out of the drain by insisting on using up the whole barrel of solution. On the other hand, don't be stingy. If for some reason the sand requires two barrels to wet it properly, give it two. (See B 4 below.) You have used enough, generally, by the time the solution reaches across to the drain channel.

B. VARIATIONS. There are several situations which require changing this daily routine which is followed, ordinarily, rain or shine.

1. *When the plants are small,* and their roots have not yet spread out to their normal extent, less water and chemicals are being taken out of the growing-unit. Therefore, you may not need to feed more than once a week during this initial period.[45]

ILLUSTRATION 4. A view of one growing-unit showing the feeding-channel to the right and the drain-channel to the left. Corn is growing as a second crop in the foreground, while the crop of eggplants, one of which is shown in Illustration 4, is growing in the background. This is not a desirable arrangement, since the food requirements for the two kinds of plants differ. The corn turned out to be a failure. Photograph by Mr. Charles A. Stuck.

2. *The weather may change,*[44] so that the temperature is in the 50's and 60's. Your plants will do nothing. Daily feeding then would not only be wasteful but it might kill the plants. Feed only enough to keep the plants from wilting.

3. *You might be faced with a week of heavy rains,* even before you have succeeded in getting the roots to grow down (see VII). You may do several things to get out of this difficulty. First, double or treble the amount of each chemical you put into one barrel and feed as usual. In this event, you would keep the opening of the drain nipple at a partial up-position, so that two or three inches of solution would remain in the bottom of the growing-unit, and at the same time allow the excess rainwater to flow out before it floods the growing-unit surface. Or you may leave the drain-nipple open at down position and sprinkle some good grade garden fertilizer, such as 4-12-4, over the surface of the sand between the plants. Since the rain dissolves this slowly, and at the same time brings oxygen into the sand, the plants are both fed and aerated. In this event, you simply omit all use of your feeding-unit until the weather clears up. Or thirdly, you may feed as usual (see A) by keeping the drain-nipple at the overflow-position. This is what I do, if the roots are fully developed, and have grown down to near the bottom of the growing-unit.

4. *Water loss.* The plant uses up water independently of the chemicals it uses. As it grows larger, and as the daily temperature rises, more and more water passes through the plant and out into the air through the leaves (transpiration). Water also evaporates from the growing-unit. At the same time, however, the plant is also taking up the chemicals more rapidly. How then are we to keep the concentration around the roots favorable? Again, a full explanation here would require that we become technical. It is enough to say that if you increase the concentration[45] suddenly, the roots will be killed. If you decrease it suddenly, the roots will not be hurt as quickly. What we try to do is to keep enough water in the solution so that the chemicals in it will not become too highly concentrated for a long period, and second, to keep enough chemicals in the water so that the concentration will not be excessively dilute. This brings us to the practical way for solving this problem.

If you note the moisture of the surface sand carefully, you will come upon a time when one barrel of solution is not enough to make it moist. Here is where the three-barrel feeding tank comes in handy. Make up two barrels in the feeding or solution tank according to directions in II and

III above. Now dilute this by filling up the tank to its three-barrel capacity. This gives you two barrels of food and one extra barrel of water. Now feed as usual. If this dilution is still not enough to satisfy the demand for extra water, make up one barrel, and fill to capacity. This makes your concentration only one-third what it would be normally. But the plants will soon take up the extra water offered them. This is, of course, a matter of using your head rather than a rule. If you had a garden you would use a hose for watering. Since you have a hydroponicum instead of soil to handle, you simply add the water at the time you give the plants their daily food ration.

5. *Change of acidity in the growing-unit.* The acidity of the solution in the region of the roots changes. This may become alkaline for several reasons. One of them may be that you have not discarded quite enough of the used solution. Another may be that not enough solution has been used to allow each spot in the growing area to be flushed with fresh solution. To test this, dig small wells in the sand deep enough to allow them to collect a little solution soon after filling the feeding-channel. Test this solution with your acid testing paper. It will show 6.5 or slightly less in all probability. By adding a little acid to the solution before it is fed into the feeding-channel, so that the paper shows a *p*H of 4.5 that is, a little more acid than what is wanted for proper growth, then, by the time the solution reaches the roots, the *p*H will be correct. It is the *p*H, or acidity, in the growing-unit that is important, rather than the *p*H in the solution-tank. Regular feeding is most important in keeping the *p*H correct, as well as proper dilution of the solution, to take care of water loss by transpiration and evaportion.

6. *High temperature and bright light.* You may have a month or more of high temperature when the thermometer hovers above the hundred mark. This will require that you not only dilute the solution to provide the extra water required, but may require that you feed morning, noon, and evening. Plants sometimes wilt, even though they have plenty of water available. But plants also wilt if not enough water is available. This is partly due to the fact that in the region of the roots, the chemicals accumulate, particularly at the surface of the sand.

Several things may be done. First, the growing-unit may be sprinkled with water in the late evening. Second, the solution may be fed over the surface of the sand between the plants by means of a sprinkling-can, a bucket or a hose. Enough would be put on in this way to have a few gallons flow out of the drain-nipple. This is also a very good way to correct the acidity in the solution of the growing-unit if this is found necessary.

7. Finally, you may be growing a plant like a cucumber, which requires more water than a tomato. In that event you would feed the unit at least twice a day, and probably three times, being careful, of course, to dilute the solution so as not to overfeed the plant with an excessive amount of the chemicals.

Let us sum up by saying that you are aiming to provide one unit, when fully planted and when the plants are growing to maturity, with between one-half pound and one pound of chemicals daily, on the average. This is less when the plants are young and small, and more when they are mature. The directions, if followed, will provide for these requirements quite satisfactorily. Or, putting it another way, a tomato plant will not use up more than a half pound of chemicals during its normal growing season. Our task is to give it not more than it can use to mature properly, but to give it enough so that it grows and bears fruit. That this schedule is satisfactory, is borne out by the production report given above in Section III of this chapter, last paragraph.

IX. USE OF YOUR TIME

The actual time and labor required to operate the unit is very small. Much more time is taken in tending the crop, and crops differ in the amount of attention needed. But a few words should be said here on how to conserve what time is needed for tending the hydroponicum itself. Following is my procedure.

First, the growing unit is examined to estimate how much solution might be required. Next, the solution is tested for acidity. Then the faucets are all opened for the six units I now have in operation. I generally use the nipple at the bottom of the solution-unit, since the feeding-trough fills in about three minutes through it. Each unit varies from the others, to some extent, in the time required for the solution to pass over to the drain side. As soon as this happens, I turn off the faucet for that unit and lift up the drain-nipple after a gallon or two have escaped into the discard. It takes about twenty minutes to go the rounds of the six units, waiting to have the solution flow into them, then closing the faucets.

During this time I generally find an opportunity to measure out, in separate containers, the chemicals for the next mixing and for each of the six units. As soon as one unit is fed, I note how much was used up. If exactly one barrel, and if no more feeding will be done that day, I turn on the water, put in the chemicals, and do something else while the tank is being filled.

Some hours later, perhaps six, I open the drain-nipple to down-position, allowing whatever solution has not been used up to escape, thereby assisting aeration of the roots. Thus, no time is wasted. Rather, the same time is used for several jobs, or for just sweet rest.

[49]

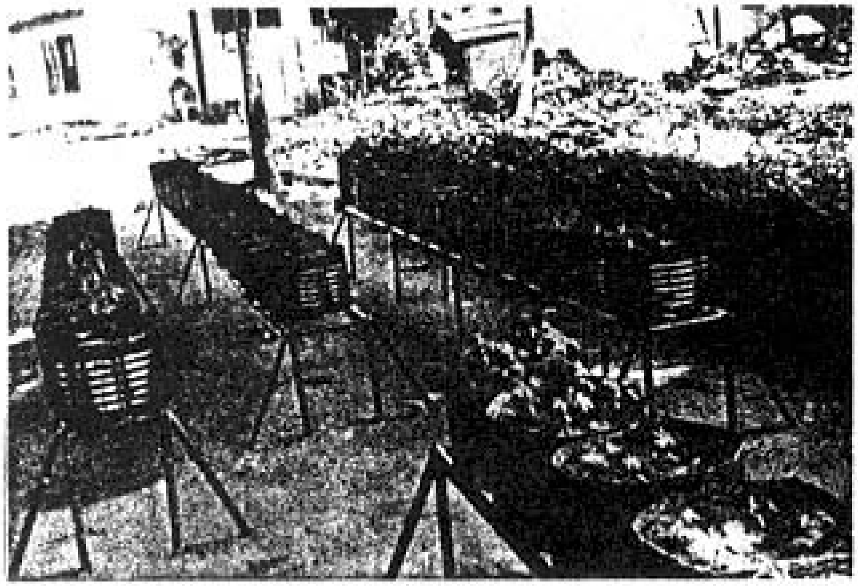

ILLUSTRATION 5. The tin-can hydroponicum of the Apolo Pipe Manufacturing Company, as constructed by Mr. A. S. Jacobsen, at Rio de Janerio, Brazil. The plants growing in the cans are soybeans. The cans are discarded carbide containers cut in half,

[50]

CHAPTER 4

The Tin Can Hydroponicum

After all, a large growing tank is little more than a glorified tin can. The main difference between the two is in having the solution offered to the plant, delivered through the bottom of the tank, while that offered to the plant growing in a tin can is delivered at the surface of the sand, or soil, in which it is growing.

Everyone is familiar with the use of flower pots and of tin cans for growing plants. But not all are familiar with the fact that nutrient-solutions, made up by any chosen formula, may be used as successfully by this means as by the use of a large hydroponicum such as has been described. In fact, it is this sort of small unit that is used quite extensively for research purposes at the New Jersey Experiment Station particularly. This method is ideal for the householder who has only room for a few plants in his back yard, on a roof, or in any other small area which is easily accessible.

This technique is described for those who would like to grow a few tomato plants, some Kentucky Wonder beans, a cucumber vine, lettuce or beets near their kitchen door. The cans may be set at any convenient place where there is adequate light. The plants themselves will cover up otherwise ugly spots about the home while doing their work of providing some food for the family. It is an ideal way to learn the first principles of hydroponics.[51]

I. Materials Needed

1. One tin can of a little less than one-gallon capacity, for each plant to be grown. Seven or eight ½-inch holes are punched through the bottoms with a road pick or other blunt instrument. The cans are then painted well with asphalt paint and allowed to dry thoroughly.

2. Materials for filling each can to within two inches of the top, after settling. This may be good garden soil which does not pack when watered, pure sand, half sand and dirt, half dirt (or sand) and well rotted compost or old plant debris, excelsior and sawdust, or even rock wool. I use some kind of rotted organic material, mixed with sand and any kind of dirt, equal parts of each. This is mixed very thoroughly with a shovel. The cans are all filled at once from the pile, which is kept renewed continuously. Filling the cans to the top, then watering them, settles the material down to about the proper level. The cans are then sterilized, if desired, and stacked for use as needed. The material used is accumulations from old weed patches, the lawn and the kitchen, piled up, sprinkled with a little lime and wood ashes, or better still, with a little fertilizer having in it some nitrogen and phosphorus. If this is allowed to rot for six months it is good for use. It should be kept wet, but the rain should not be allowed to wash it.

3. Asphalt paint, for dipping the cans or painting them as indicated in (1).

4. The chemicals as given in either Chapters 3 or 7.

5. The acid-testing equipment as given in Chapter 2, IV-H, or Chapter 9.

The only difference between this type of hydroponicum and the unit type is the use of individual cans as a substitute for the growing-unit. The solution is kept in a barrel,[52] painted with asphalt paint, and is delivered by hand to each can by means of a dipper, or a garden hose attached to the faucet set in the barrel.

II. Procedure

1. Plant the seed in the middle of the can as prepared in (I). It is best to plant two or three. When they come up, pull up all but the best one.

2. Press the dirt down with the fingers about one inch from the edge of the can, so that a shallow trench runs around the now slightly raised place where the seed was planted. Fill this trench with a dipper of water or of nutrient-solution from the barrel. Use enough so that a few drops come through the bottom.

3. Collect some of the solution that has dripped through the bottom of the can in a saucer (clean and without trace of soap). Test this for acidity as explained in the last chapter. This should be 6.5. If it is more than this, flush out the can with solution made acid to slightly below 6.5, or even as low as 4.5. Do this until the reading of the acidity of the solution coming through the bottom is 6.5.

4. Do not water any more until the plants come up. If

the cans are protected from direct sunlight the material will not dry out, and thus prevent germination of the seed.

5. Dust the place where you intend to set the cans with a little DDT powder. Dust the top of the material in the can also.

6. Now arrange the cans together and cover them as a protection from heavy rain.

7. After three days inspect for signs of germination. It may take fourteen days for some seeds to come through the soil. As soon as germination begins, space the cans as desired at the place where they are to remain. Protect them from dogs and birds by chicken wire.

8. As soon as the plants are up, begin feeding them a pint of solution once a day. Use more if necessary to keep them from wilting. Dilute with water.

9. As the plants mature, space them so that none will crowd another, or shade it. Protect the cans from becoming too hot through direct light hitting them for long periods. A little hay, straw, or newspaper will be sufficient to protect them, if laid up against the side of the can exposed to the sun.

10. Climbing plants will have to be furnished with proper support.

11. When you pull up a beet or a head of lettuce, or any other plant, stir up the contents of the can, add a little more if necessary, and plant another seed of something. In this way, you may begin your can garden inside the house two weeks to a month earlier in the spring, and carry it through the whole summer. I always have 25 cans of sweet corn ready to set outside after the danger of frost is past. These supply me with roasting ears during the month before the crop started outside comes into bearing. It is thus possible to have a continuous supply of corn, lettuce, beets and beans, with cauliflower, celery and a cucumber vine in addition.

It takes about twenty minutes a day to feed 100 such individual-can hydroponica, by means of a garden hose attached to the barrel of solution. Most people waste ten times this amount of time about the home.

If the cans are set on the lawn, they must not be moved. For the roots will fill the can and, sooner or later, find a hole through the bottom and start going down into the ground.

After the growing season is over, all the cans are emptied on the compost heap. Next spring this material is used again.

Beets and beet greens, which are particularly high in vitamin A, may be kept throughout the summer, and remain tender, if kept partially shaded. Lettuce will produce large crisp and green leaves if treated similarly. The green lettuce is richer in vitamin than is head lettuce. Care must be taken to inspect for aphids and other insect pests.

Here is a type of hydroponicum that even a child may operate and enjoy. If a constant drip is provided for adding the solution to each can individually, an added interest is furnished.

This method is recommended particularly for certain regions in the United States and Canada where mining is going on. There, gardens are frequently destroyed by a sudden shift in wind, which covers the garden with poisonous fumes sufficiently long to kill the plants. It is possible to stagger crops in such a way as to have a new one going, on a small scale of course, if such an accident occurs. Again, such plants as tomatoes, if properly supported, may be moved quickly to a safe spot until the danger from gas is over. This would be impossible, of course, for large groups of plants. But there are many householders who have an interest in only a few plants, but who would also like to save them in an emergency. This method will serve their purpose nicely. I have found it possible to move 200 cans in a half hour, to protect plants from an unexpected frost. It is worth the little trouble it takes. Incidentally, a number of families in mining regions in Canada are now trying out this method for saving their little, but precious, gardens. It was at their suggestion that the remarks above have been offered.

CHAPTER 5

Essential Elements--Their Chemical Sources

I. INTRODUCTION

Since what we are really trying to do is to supply the plant factory with raw materials for manufacturing proteins, fats, carbohydrates, vitamins and the like, it is clear that out of the many possible kinds of substances available for this purpose we must sift out those most agreeable to the plants we wish to grow. We do not select a chemical because we fancy it, but rather because the plant requires it.

The list of chemicals necessary for growing plants successfully is not large. Shive and others have used as few as three. But to do this requires much skill indeed. Generally, four or five bulk chemicals, and as many for the trace elements, are sufficient. The list given in Tables I and II is larger than required to make up one formula. The reason for this is simple. Some chemicals are available, while others, equally serviceable, are not. Therefore, if the reader masters the few technical details required, he may make up a satisfactory formula, using what chemicals are available to him, anywhere in the world.

Plants do not discriminate between substances offered them, by means of taste. To them, nitrogen is nitrogen, whether it comes from ammonia, nitrate or urine. But they do differ much, both as to chemical needs and the conditions under which the chemicals are offered to them. It is not generally appreciated that there is as much difference

56

between a tomato and a radish as there is between a man and a horse. Men occasionally eat out of a horse trough, and horses have been known to eat food off of a man's table. We are not surprised to find, however, that as a rule each gets along better on the kinds of victuals to which their bodies are, by nature, accustomed. But we are surprised to find, strangely enough, that while some plants do well planted side by side, others do not. Why? This is a complicated question, and the answer has, in all probability, little to do with the phases of the moon. One plant may want more light than another; one may require more acid than another; one may require an amount of boron that it would kill another. So it goes. Would one feed a baby pork chops, because its father, near by, required them? Would an expectant mother be allowed the same diet as a girl of six years? Let us cease this chatter in favor of something more important.

Many people have the impression that the chemicals used in hydroponics are dangerous to human health. It is human nature to fear what is not understood. In this instance, the difficulty comes partly from the inability to reconcile reports on cancer research, with human consumption of food; and partly from reports by individuals engaged in forms of what might be called fetish farming. The latter give out the impression that plants grown in certain specialized forms of compost contain no chemicals, and, therefore, cannot harm people who eat the plants so grown. The crusade against "chemical fertilizers" is on. Chemicals are supposed to be so "unnatural" as to be a positive danger. It is time that this propaganda be countered with more complete information. If a "little knowledge is a dangerous thing," it might be added that a little ignorance may be a calamity. As a matter of fact, it would be difficult to find anything more natural than a chemical. It would be impossible to have a compost heap without them.

57

Your body is made up of chemical elements. Nothing else is in it. So also is that of a plant. It matters not whether the plant is grown in a hydroponicum, a garden, or in a compost heap! Either of these may be deficient in having certain essential elements, and either may furnish the plant with too much of a given element. The consequence in either instance would be either a tasteless product or one having less health value than desirable. It is not the way you grow a plant that gives it value or makes it harmful, but rather the chemicals which that particular method is able to supply. Growing plants with the use of compost is one of the most reliable methods for growing plants ever devised. It requires a high degree of skill to practice this method successfully. But it is entirely false to say that compost-grown vegetables contain no chemicals.

This fear of "chemicals" is very real in the minds of many. A correspondent from one of our seaboard cities writes: "My goodness, Doctor, these chemicals frighten me! What if I happened to drink some of the solution in your hydroponicum?" When assured that there is nothing of an atomic-bomb nature, or poison pill, in a head of lettuce, a roasting ear, or a tomato grown in a hydroponicum, the good lady very sensibly settled down to the quiet regime of gardening the "new way."

Birds and insects drink out of a hydroponicum and appear to suffer no harm. I never do. I prefer to take my minerals and other elements in the less raw state of carbohydrates, proteins, and vitamins; and in the form of lettuce, fruit juice or tomato. The latter demand their Epsom salts. I do not.

What, then, are the elements which a plant must have in order to function as a living thing? They are: carbon, hydrogen, oxygen, nitrogen, potassium magnesium, manganese,

58

phosphorus, sulphur, calcium, iron, copper, molybdenum, boron, and zinc. The number is fifteen. Some would say more, some less. But to keep blood pressure normal, let us keep out of the argument, and stick to the fifteen. That satisfies most plants—why not us? One of the fifteen may be doubtful. It is said that the lack of molybdenum causes flower-drop. To decide the question is more difficult than pronouncing the "d" in the word. Also, it should be made clear that flower-drop may be due to a number of things. One should not jump to the conclusion, therefore, that the addition of molybdenum to his nutrient solution will stop this evil. One has to investigate, in order to decide which of a number of possibilities is the correct one. A woman may, for example, lose her teeth either through improper eating habits, decay, or simply by having them knocked out by her lover, in the light of the moon, as a sign of engagement.

This bit of humor is intended also as a mite of warning. You will be sure to have some trouble with plants if you work with them very long. So many things have been said about the elements plants need that you are likely to feel, in the face of your difficulties, some element must be missing in the diet. You will in all likelihood jump to the wrong conclusion, and proceed to kill them with an overdose of this or that. Look first, in case of trouble, for lack of oxygen about the roots, and the *p*H of the solution about them. Or, perhaps, you may be either overfeeding them or underfeeding.

We come now to the first real stumbling block for most people interested in hydroponics, and who have no knowledge of chemistry. What are "elements," "chemicals," and the like? It is said that "troubles come not singlehanded, but in battalions." So it is with elements. They come not singly, as a rule, but in those "battalions" or combinations commonly called "compounds" by chemists. We do not give plants "elements" on which to ruminate, but compounds of elements. It is their job to get the elements out of these compounds as best they can. They are experts at doing this. But they can't take out an element if it isn't in the compound we offer it. First, let us get our terms cleared up.

II. Definitions of Terms

The chemist uses the terms "chemical" and "elements." The farmer and gardener use the term "fertilizer." The plant physiologist, who is responsible for deciding what substances may be used in hydroponics, uses the term "essential element." Without being technical about it, let us attempt to make a practical distinction between them.

A. chemical. This is a loose expression, meaning either an element or a compound of several elements. Water, for example, is a compound chemical, made up of the two elements hydrogen and oxygen. Other examples, to mention only a few, are urea and carbon dioxide, which are compounds, and sulphur, nitrogen, and gold, which are elements. Perhaps the simplest way to say what is meant by an element, is to put it the way a child would, namely, one of those substances used to make a chemical compound. Since this is not intended as a treatise on chemistry, we shall let the matter stand at that.

B. fertilizer. A fertilizer, on the other hand, may be anything which has in it at least something a plant may take in and use for making its food. In other words, it contains some substance used for building the plant or enables it to do its work. It is neither a chemical compound nor a chemical element. It is a mixture of many chemicals, and is made up to satisfy the legal requirements for distributing to gardeners and farmers just three essential elements. The only essential elements ordinarily officially accounted for in "fertilizer" are nitrogen, phosphorus and potassium.

C. essential element. This term means exactly what it says. It is an element essential to the well-being of a plant or an animal. It is an element for which no other may be substituted. Not only does it have to be available but it must also be present in a definitely minimal amount. This needs explanation. Suppose, that to grow at all, a certain number of corn plants, for example, require, as determined by experiment, at least 26 pounds of nitrogen. They would grow better, obviously, if 27 pounds were made available. They would not grow at all if only 25 pounds and 15.99 ounces were available. In other words, although the essential element nitrogen is present in our hypothetical experiment, still the corn must die because it lacks 0.01 of an ounce of having just enough nitrogen to stay alive. In practice, if a plant refuses to grow, one simply puts enough "fertilizer" on the soil to make it grow. Two mistakes are possible. If too much of a good thing is added, the plant, not knowing a thing about balanced diets, may make a hog of itself, and suffer accordingly. If the rule of the minimum is ignored by the grower, the plant will die in adolescence. In either case the operator is out of luck, and the corn crop is "trumped" in the midst of a promising career.

Fortunately for the operator of a hydroponicum, the techniques involved, as well as the laboratory findings on this point, make it fairly easy to supply each plant with the minimal amounts of the elements needed. This is often extremely difficult to attain in soil farming. It is sometimes impossible.

At this point a word should be said regarding the essential elements for man. It is man and his domesticated animals that eat the plants grown. But it is probably not an exaggeration to state that more is known today about a plant's requirements for essential elements than about man's. Because a plant requires certain elements, and in certain minimal amounts, it does not follow that the same requirements hold for man. When Nebuchadnezzar took to eating grass, the silicon which is a necessary part of the vitamin-rich type of forage he ate, was of no earthly use to the king of the Babylonians. Since it is known that man does require certain essential elements, and that the soils of the world are in many cases deficient in those elements, it follows that if these may be supplied in a hydroponicum, then the food thus grown must be preferable to that grown on land deficient in such elements.

III. Chemicals vs. "Fertilizers"
Comparative Cost

It would seem to be an imposition to a respectable plant to offer it materials it cannot use. It is a helpless sort of thing, this creature we call a plant. Just as a dog cannot resist taking into its blood stream a bit of arsenic which has been mixed with its meat and swallowed, so cannot a plant keep from taking into its system the odds and ends of chemical debris thrown at it in manure, compost and "fertilizer." Much care has been exercised in the past to reduce this offensive material to a minimum. But unfortunately it cannot be entirely avoided. There is, however, another aspect to this question of useless material, namely, the cost.

Let us now reduce the cost of "fertilizer" and food-grade chemicals to common terms, and compare their values. The common term is the amount of essential element bought in each case, since that and that alone is what the plant uses.

A. ESSENTIAL ELEMENTS IN "FERTILIZER". A 100-pound bag of fertilizer is marked, let us say, 4-12-4. This means that there are 20 pounds of fertilizer and 80 pounds of other material in the bag. Of the 20 pounds of fertilizer, there are four of nitrogen, 12 of a phosphorus compound, and four of a potassium compound. Only 5.3 pounds of the phosphorus compound is actually phosphorus. The remaining 6.7 pounds is oxygen. In the case of the potassium compound there are 2.8 pounds of potassium and 1.2 pounds of oxygen. Of the total 20 pounds, therefore, four are nitrogen, 2.8 are phosphorus, 5.3 are potassium, 7.9 are oxygen.

It so happens that the plant uses very little, if any, of all this oxygen. This essential element is taken in mainly through the roots as water, or as the element itself dissolved in the water. Therefore, the amount of this element found in our bag of fertilizer must be considered as so much waste. This leaves us, then, but 12.1 pounds of essential elements which may be used by the plant.

If the 100 pounds of fertilizer cost $4.00, or four cents a pound, the 12.1 pounds of essential elements also cost $4.00, or 33 cents a pound. In other words, by buying our essential elements as fertilizer, we pay much more per pound than is generally believed.

B. ESSENTIAL ELEMENTS IN "CHEMICALS". Let us buy these in 100-pound lots as in the case of our purchase of fertilizer. A quotation for one bag, furnishing potassium and nitrogen, with only two pounds of miscellaneous waste instead of 80, and 47 pounds of useless oxygen, leaving 51 pounds of potassium and nitrogen, may be bought for $12.00. The essential elements therefore cost 21 cents a pound. To get the phosphorus for comparison, another bag containing 2 pounds of miscellaneous waste, 58 pounds of useless oxygen, and 40 pounds of the essential elements, phosphorus and calcium, may be bought for $8.50. The essential elements in the bag cost, therefore, 22 cents a pound.

Of the 200 pounds of chemicals bought, we acquired 51 pounds of potassium and nitrogen and 40 pounds of phosphorus and calcium, making 91 pounds in all of useful material, for $21.50. To buy the same amount of essential elements as fertilizer would cost $30.03. Or putting it the other way around, for the same amount of money, one would get only 45 pounds of essential elements.

Obviously, if we are intending to grow our vegetables hydroponically, it is much cheaper to buy the essential elements as chemicals rather than as fertilizers.

Two conclusions might be drawn from the result of this calculation. First, it would appear offhand that the people of the United States who use fertilizer for their farms are paying twice as much as necessary. Second, it might appear that somebody is being gypped. Now let us see to what extent this is true or untrue.

Farmers and gardeners have at their disposal all the land about them. Land is mineral matter. If it contains essential elements, and if these are suitably mixed up with humus or the dead remains of plants and animals, and if, furthermore, this mixture is inhabited by minute living organisms, the land becomes soil, fit for growing plants. In other words, in good soil all the essential elements are present. The gardener or farmer has only to do his work properly, keep his soil in condition, and his plants will thrive as well as in the best hydroponicum ever invented. But the record shows that farmers in general, the world over, have not been clever enough to do this. It is an alarming fact that soil has deteriorated throughout the world during the rapid industrial development of the past two centuries. The consequence is that while farmers and gardeners do not have to buy all of their essential elements, they do have to purchase some of the most important of them. Of the fifteen named at the beginning of this chapter, most farming areas require that the plant producer supplement his soil's essential element content with purchased nitrogen, calcium, phosphorus, potassium, boron, manganese, sulphur and copper. In some regions, magnesium and zinc must be added to this list.

We are now in a position to decide whether or not the cost of essential elements is too high for the farmer; whether or not he is being imposed upon by those who sell him fertilizer. First, if the essential elements were delivered as chemicals to him, he would almost certainly burn up his crop. This has occurred. And, as a consequence, dealers in fertilizers have been sued successfully. In other words, in order to protect both the farmer from ruining his crop, and the dealer of fertilizer from being perpetually called into court, the essential elements must be mixed with a great deal of waste material. Obviously, then, the farmer is not necessarily being gypped. He is only paying the necessary freight imposed by an unfortunate circumstance. He who buys his mineral water in a bottle over a counter must pay more for it than he whose house rests by the spring.

This rather tedious discussion seems necessary, if we are to arrive at a reasonably true comparison between the costs of farming hydroponically and the usual way. For one of the important items is the cost of essential elements. If the gardener or farmer has to pay twice as much for essential elements because of unavoidable circumstances, then it would be part of national wisdom to grow food by some method where the cost of essential elements would not be conditioned by this circumstance. Hydroponics would appear to be that method. However, if the lower cost of essential elements is offset by unnecessary mechanical and technical expense then there can be no gain by adopting hydroponics. But let us leave this point for later discussion. So far as the cost of 65 essential elements is concerned, hydroponics has the advantage over other methods of growing plants.

Not only from the cost angle would the operator of a hydroponicum use chemicals rather than fertilizers, but also from the point of view of safety. Manufacturers of fertilizers seem to feel that they are in possession of precious secrets. Actually, any second-rate chemist can determine without much trouble the kind and quantities of elements in any fertilizer ever mixed. It is to be hoped that this mediaeval attitude of imaginary secrecy may be educated out of the minds of those responsible for making available the essential elements required in all forms of agriculture.

In hydroponics, "fertilizers" may therefore be recommended only in an emergency. In a 100-pound bag of it, the 12-odd pounds of essential elements may be counted on. But it is just as likely to be chuck-full of plant poison. Any use made of it is possible only after experimenting with each "secret" kind, and long enough to determine how much of it a plant will endure before giving up the struggle. A further difficulty is encountered when one desires to double, let us say, his nitrogen without adding to his potassium. If the bag of fertilizer says 4-12-4 that is all the nitrogen which he can get out of it. If he wants eight of nitrogen, he must buy two bags. And if he does he must thereby take the potassium that goes with it. Buying chemicals gives him the chance to buy nitrogen without the potassium, if desired.

However, there are occasions when chemicals cannot be purchased. Then fertilizers must be used. It is necessary at times to make a compromise between what is desirable and what is practicable. During the war chemicals which were imported became suddenly unavailable. Those manufactured in this country became short of both nitrogen and phosphorus, since these two elements were required for 66 ammunition. Since not all types of hydroponica permit the use of ordinary fertilizer, this point must be taken into consideration before adopting one for use.

IV. Chemicals Suitable for Use in a Hydroponicum

There are two types of chemicals which may be used in a hydroponicum, "pure" grade and "food" grade. It is assumed that the bulk of the chemicals used will be of food grade, and that when these are unobtainable, the pure grade will be substituted. The calculations shown in the tables will be made for both. In those cases where minute amounts are used, only pure grade chemicals are listed. In order that the operator may have a choice of several chemicals, in case the one desired may not be purchasable, several alternatives are given.

It is assumed that the reader is not a chemist. Therefore, the tables give only the information he needs to know in order either to interpret properly the formulas given in the following chapter, or to modify them to suit his own demands. In order to make it unnecessary for him to perform them, all necessary chemical calculations have been made and the results tabulated in the tables. The tables are therefore to be used as a handy reference rather than as a source for complicated calculations.

To manage the chemical aspects of a hydroponicum one has to understand only two things. First, he must know what chemical substances (or "salts," as the chemist calls them) furnish the essential elements that plants need. Second, he must know how much of each essential element it is possible to get in a given weight of the salt. This is what the tables show. The amounts are stated in grams. To convert to ounces multiply by 0.0352. As a further convenience, in the chapter on formulas, the amounts actu- 67 ally used will be further reduced to practical volumes, in terms of a tin can. And for those in foreign countries, who have no acquaintance with this American household container of green peas and the like, drawings are made on paper for cutting out and making a container which is familiar. Everyone recognizes the rectangle and the cylinder, whether or not he knows grams or ounces. Thus, to use the formulas, the reader does not have to weigh. He needs only to take, as directed, a half can of this, a third of a can of that, a pinch of something else, and throw the amount into his barrel of water. It has been found that for all practical purposes the average plant grown has a tolerance for this variation. On the average, the operator's errors will cancel out, so far as the plant is concerned.

Since the essential elements required by plants may be available in a number of different chemical compounds or salts, the list given in Table I includes the number generally found in books on hydroponics, and in textbooks on plant physiology. The reader must now refer to Table I.

V. The Term for Measuring Concentration of Essential Elements—Parts per Million, or PPM

If, what we buy is either a fertilizer or a chemical, and if, what concerns the well-being of the plant is an essential element, then it seems sensible to agree on some easy way for deciding just how much of any essential element is to be found in a given portion of the substance we buy.

Since the earth weighs something, and since the earth is made up entirely of elements, then the elements must weigh something. But what? There is no way of knowing, except by weighing one against the other. This you won't have to do. It has been done long ago. Let us arrange

TABLE I.

CHEMICALS WHICH MAY BE USED, WITH AMOUNT OF ESSENTIAL ELEMENTS IN EACH

Column 1 Names of Chemicals and Symbols	Column 2 Relative weights in grams		Column 3 Percent pure of food-grade	Column 4 Relative weights in grams of elements in each of amounts given in column 2. (Read to right in each case.) See page 70 on how to use in calculating any formula.									
	A Pure-grade	B Corrected for Column 3		Essential								Waste	
				N	P	K	Mg	Ca	S	O	H	Na	Cl
Ammonium nitrate, NH_4NO_3	80	82	98	28						48	4

MOLYBDENUM, Mo.					
Molybdic acid	c.p.	1.58	3.16	7.90	15.80

Use this table to find the amounts of any chemical to be weighed out, if you know how many parts per million of a given element is desired in any formula.

70

the elements you will encounter in the order of their relative weights:

Chart 1. *Relative weights of chemical elements.*

Hydrogen, H	1	Magnesium, Mg	24	Manganese, Mn	55
Boron, B	11	Phosphorus, P	31	Iron, Fe	56
Carbon, C	12	Sulphur, S	32	Copper, Cu	63
Nitrogen, N	14	Chlorine, Cl	35	Zinc, Zn	65
Oxygen, O	16	Potassium, K	39	Molybdenum, Mo	96
Sodium, Na	23	Calcium, Ca	40		

Suppose, for example, we consider the chemical called nitric acid. Column 1 of Table I indicates that it consists of hydrogen, nitrogen, and oxygen. Furthermore, on observing the symbol for this compound we find that one part is H, one is N, and three are O. This means that by weight there would be 1 of hydrogen, 14 of nitrogen, and 3 × 16 or 48 of oxygen. The total would be, of course, 63. This number would then be the weight of nitric acid relative to that of any other chemical compound. For comparison, let us take potassium nitrate, found in the same column. In that compound there is no hydrogen. Instead, the element potassium occurs. The other two elements remain as in nitric acid. But, since potassium weighs 39, the relative weight of potassium nitrate is 39 for K, 14 for N, plus 3 × 16 or 48 for O, making a total of 101.

If you had 101 parts by weight of this substance, you would therefore have 39 parts of potassium, 14 parts of nitrogen, and 48 parts of oxygen. Now then, suppose you substitute the word "gram" for the word "part" in the previous sentence. Obviously, in every 101 grams of potassium nitrate you would have 39 grams of potassium, 14 grams of nitrogen, and 48 grams of oxygen.

Since we have adopted the word "gram" as synonymous with the word "part," a million parts of water would necessarily mean a million grams of water. How much are a 71 million grams of water? About five barrels, each of 50-gallon capacity.

Suppose, finally, that we fill the five barrels with water, then throw in the 101 grams of potassium nitrate and let it dissolve. What concentration have we? Precisely 39 ppm of K, 14 ppm of N, and 48 ppm of O; or, if we consider the salt as a whole, 101 ppm of potassium nitrate.

Table I gives the relative weight for each chemical listed. In column 2-A the relative weight is for pure chemicals, and in column 2-B, the same for food-grade chemicals. In column 3 the percent of purity is stated, to identify chemicals when being purchased. In column 4 the weights of the elements found in the compounds are given. Note, for example, that kieserite, Epsom salts and magnesium sulphate are three different grades of the same thing. They differ in percent of purity, the water being considered as impurity. Note again that in column 4, under Mg, the same relative amount of magnesium is found, namely, 24. To get 24 grams of magnesium one would have to use 260 grams of Epsom salts (column 2-B), or 180 of keiserite, or only 130 grams of magnesium sulphate of 92% purity.

All this means that if the latter costs twice as much per pound as Epsom salts, since you would need to use only half as much of it as of Epsom salts, your final chemical bill for magnesium would be the same in both cases. But you would have to pay twice as much freight on the Epsom salts, which would make it cheaper to buy the purer chemical. Note also that in buying 24 parts of magnesium you are also buying 32 parts of sulphur, another essential element found in Table I, column 4-S.

You may wonder why we select a million rather than a thousand or billion grams of water as the basis for mixing our chemicals. The answer is simple. The plants prefer it. 72 A little table salt (sodium chloride, NaCl) added to a glass of water improves its taste. But a tablespoon full of it would, upon being introduced to the stomach, cause that organ to assume a rebellious attitude. Experience shows that the roots of plants do their work of absorbing chemicals best when the total concentration is between 550 ppm and 2,000 ppm. In practice, formulas are made up so as to keep within these limits.

This brings up another point. All waters used in hydroponics commonly come from streams or lakes. These waters already have some salts dissolved in them. This may vary, as Gericke has pointed out, from 100 ppm to 3,000 ppm. This must therefore be taken into consideration in using a given formula. Some waters contain so much magnesium and calcium, for example, that it is unnecessary to put these essential elements into the solution. Indeed, to do so might be very harmful. If in doubt have the water tested, and make proper allowances.

73

CHAPTER 6

Conceptions and Misconceptions Regarding Formulas

I. General Considerations

Let it be emphasized at once that, contrary to general belief, a formula for growing plants is not an equation. It is more of a guide than an unalterable rule. Many beginners seem to feel that if they only had a formula to go by they could, with certainty, grow anything from mushrooms to pineapples in the same jug of nutrient solution. Unfortunately, that is not the way of life, any more for a plant than for a happy human being. The best way to kill either the spirit or the body of a human being is to feed it the same thing day after day. So it is with a plant. The plant has no spiritual needs which must be satisfied, of course, but the needs of its body require one thing at one period of its life, and something else at another period. Some things it requires all the time. Until the operator of a hydroponicum realizes that he is dealing with a living, rather than with an inanimate thing, he can never quite realize that applying a formula is not as simple a thing as applying the law of gravity.

Therefore, let us consider some matters which form the basis for constructing the formulas to be given in Chapter 7. The reader will then be in a position to comprehend why they vary as they do.

II. Requirements for Making a Formula for Growing Plants

A. THE PERFECT FORMULA. This exists only in the imagination of the novice. It implies that all plants require the same materials, and in equal amounts, throughout their whole lifetimes. Neither is true. It is only the novice who, as he approaches this business of growing plants hydroponically, makes as his first demand a formula that requires no thought in its application. He wants one that will meet the needs of any plant, at any time, in any place, whether it be spring or winter, and whether it be cloudy or sunny weather. There are those who find it profitable to have people believe this. Let it be restated, as a matter for emphasis, that there is no such thing as a perfect formula. The best we can hope to accomplish is a compromise between the plant's requirements, the kinds of chemicals available, and the climatic conditions existing where the plant is grown. For all practical purposes the best formula is the one that works.

B. PRACTICAL REQUIREMENTS FOR A GOOD FORMULA.

1. It must provide the essential elements as determined by testing in a reliable plant-physiology laboratory.
2. It must have in it the fewest possible waste elements.
3. Any unavoidable waste elements must be such that they will combine to form harmless substances, or will not prevent growth, or will not cause the solution about the roots to become acid or alkaline quickly.
4. It must be sufficiently balanced, so that one element will not interfere with another, or give the plant a chance to over-absorb a particular element it needs.
5. The number of chemicals used to provide the essential elements should be as few as possible.

6. The total concentration, after the chemical ingredients have been dissolved in water, should be between 500 parts per million and 3,000 parts per million or lower.
7. It should allow the operator to grow several kinds of plants, when used, with a minimum of alteration as the season progresses.

The first requirement mentioned provides, of course, the things a plant needs in order to grow properly. The second is an economical proposition. One hates to pay money for waste. Besides, it takes less time to handle chemicals of this nature. The third applies to such cases as, for example, the use of potassium chloride and sodium nitrate instead of potassium nitrate. The latter is expensive, and sometimes cannot be bought, while the other two can. But these two contain chlorine and sodium, both of which are not required by plants, and both are poisonous in certain concentrations. If we use them in such a way that the two unite to make common table salt, we prevent their poisonous effects. But we also make, thereby, another substance which the plant cannot endure in very high concentrations. By washing this out of the sand occasionally, or letting the rain do it, we get along very nicely. Requirement four is a technical one and will not be discussed. As for the fifth, it also is concerned with economy of operation. The final requirement is inserted for making the feeding task less troublesome in running a hydroponicum. If one can be taught to grow several things at the same time without extra bother, he will the more easily learn the trick of making the more delicate changes required to grow some specialty, later.

III. Degree of Variation in Formulas

Another question frequently asked pertains to the fact that there is considerable variation, one way or another, between formulas. The beginner has difficulty in seeing why this should be so. Let us now pause to touch on this point.

A. EXTREMES IN VARIATION OF PPM. In looking over a great number of formulas, I was myself amazed to find that in actual use experts vary the ppm considerably, for one reason or another. The formulas presented in the next chapter are presented to you because they are conservative in this respect as well as of proven value. But let us see what extremes are possible, and yet have satisfactory results. Following is the range encountered: nitrogen, 50 to 500 ppm; potassium, 70 to 1,000 ppm; phosphorus, 10-154 ppm; calcium, 80 to 3,000 ppm; magnesium, 10 to 96 ppm; and sulphur, 13 to 140 ppm.

Now this does not mean that one may be careless about selecting a formula, or that one may simply put amounts of each chemical together indiscriminately, so long as one keeps within these limits. It means only that plants vary much in their needs for specific elements, and that under some conditions show more tolerance than under others.

B. EXPLANATION. Some of the formulas to be given became famous because they were surprisingly successful. That is sufficient reason for making any formula acceptable. They were successful, however, not because they differ, but in spite of it. They were constructed after many tedious trials in the laboratory. They represent the best of those trials. They should not be changed by the beginner, without sound reasons for doing so. On the other hand, they cannot be used successfully without little changes as the season and plant demand, and as these arise and are understood.

The variations in ppm represent thus, in part, variations in seasonal and plant needs; in part, pure experimentation with respect both to tolerance, weather conditions and kinds of chemicals available for use; in part, an effort to keep the water balance as well as the balance between the sugar and nitrogen within the plant, satisfactory for best growth. Perhaps it should be added, that all these matters are concerned with the amount of oxygen available to the plant, as well as with maintaining the acidity and total concentration of the solution in which the plant is expected to grow.

In spite of recent publicity to the contrary, there is plenty of sound scientific and gardening proof that plants do differ with respect to the amounts of elements they use, their tolerance of soil or solution acidity, light requirements, temperature needs and periods of growth. While these matters may be considered as refinements, nevertheless they may not be ignored. They were all taken into consideration when the formulas to be given were constructed. This is important for the beginner to understand.

Referring back to the list of variations (see A), it will be noted that magnesium is varied least. And for a very good reason. This element, when in too high a concentration, interferes with the absorption of others. It interferes also with respiration, which, as we shall show later, is extremely important.

The greatest variation shown is in the use of calcium. This element has many uses inside the plant, among these, counteracting the poisonous effects of others. All in all, the differences between experimenters as to the ppm to be used is due not so much to a difference in opinion, I think, as to differences in conditions under which tests were made, and the kinds of plants used for investigation. For example, sand, gravel and water cultures present not quite the same conditions for growth, though they are all successful. Thus Gericke, who uses only nutrient solution around the roots (except in the litter beds), keeps the ppm lower than do most workers who use sand and gravel in addition to the solution. Another factor in the variations observed is the fact that the total concentrations of the salts or chemicals must be kept within a definite range for best results. All the formulas conform to this requirement.

There is another important fact which might best be considered here. Of the elements mentioned above, the plants use more of nitrogen than any other. The others rank, with respect to relative amounts used, as follows: potassium, calcium, phosphorus, sulphur and magnesium. Notice that the ppm decided on do not run in this order. As an example, although the plant uses more nitrogen than calcium, the variation in the ppm of calcium is much greater than the variation for nitrogen.

All this discussion is intended to have the reader, first, respect the formula he attempts to use; second, not insist on considering the formula an unchangeable thing; and third, have him become conscious of the high degree of tolerance allowable, so that he will be less afraid to make changes when they become necessary. The Purdue and the New Jersey Experiment Station tests in particular seem to indicate that successful results in growing plants hydroponically are obtainable through use of a considerable range in the ppm of the various elements, as well as in the choice of the chemical compounds which provide them.

IV. PLANT'S USE OF ELEMENTS AS A FACTOR

Probably the plant's use of a given element is the most important factor in determining a formula. This is now obvious, although it was not always so. It was thought several hundred years ago that plants live on air and water. It was a very difficult thing to prove that in addition to the four elements they get from these sources at least eleven others are obtained from the soil, or some chemical. Actually, 95 percent of the plant's body is made up of carbon, hydrogen, oxygen and nitrogen. It will be recalled that the first three are taken into the plant direct from either the air as carbon dioxide, or through the roots as water. The fourth, nitrogen, is taken in only through the roots in combination with other essential elements such as potassium and calcium. This leaves approximately only 4 percent of other elements which are all taken into the plant through the roots.

This is not the place to go into the many details of why these eleven elements, although used in such small amounts, can be so significant to plant life. There are writers who believe that we concern ourselves too much with them. But it is certain that if we try to strike a happy mean between too much and too little concern, we will in all likelihood be reasonably successful in growing plants.

One of the fascinating questions about plant life is what becomes of the elements plants take in. A little information on this point helps in deciding what to give a plant and why. Plants take in, sometimes, more than forty of the known elements. But they don't use all of them. Silicon, for example, is one element that is used by many plants, but it is not essential to all of them. Others are taken in, for example sodium, and simply tolerated. Let us now see what use is made by the more important of the essential elements, particularly of nitrogen.

A. NITROGEN. Only about one percent of the dry weight of a plant is nitrogen. But without that one percent there can be no protoplasm, the living stuff itself. Consider this as against the 44 percent of carbon, 45 percent of oxygen and the 6 percent of hydrogen in the same plant. Only five percent of the plant's needs for elements are gotten from soil water or the nutrient tank in a hydroponicum. And of these five percent only one is nitrogen. Why then, we may ask, is the giving of nitrogen to a plant to be considered so difficult? Let us spend some time on this question.

1. FROM NITRATE TO PROTEIN. Laurie calls nitrogen the "push" element, rather aptly, I think. It is given to the plant in the form of nitrate (NO_3), such as potassium nitrate, sodium nitrate, or calcium nitrate; or it may be given in the form of ammonium (NH_4), such as ammonium sulphate or ammonium chloride and urea; or as both combined, as in ammonium nitrate. To be useful, the (NO_3) must be changed by chemical processes inside the plant to (NH_4), then to (NH_2) when finally it becomes part of the protein. This in turn is the principal constituent of protoplasm. Thus its importance.

In giving the plant nitrogen we must therefore consider that it takes the plant less time to change (NH_4) to (NH_2) than it does to change (NO_3) to (NH_4) to (NH_3) to (NH_2), for one process is more direct than the other. That is why we think of ammonium containing chemicals as a quicker source of nitrogen than the nitrate containing chemicals; a practical point of importance in cloudy weather, as we shall see.

Without nitrogen there can be no protein. Without protein there can be no protoplasm; which, in turn, means no growth and in the last analysis, death.

But to make protein, nitrogen is not enough. There also has to be present a specific amount of sugar. In addition, there must be a certain amount of heat available. How are these obtained? First, as you no doubt recall, the sugar is made out of carbon dioxide and water, when the plant is in sunlight. Thus, sugar has in it, carbon, hydrogen and oxygen. Of these two, carbon and hydrogen may be burned to give the heat energy required to make the protein. Obviously, to get the job of making protein done, there must also be available an extra supply of oxygen, or the carbon and hydrogen cannot be burned. This is why it is so necessary for the operator of a hydroponicum to make sure that the roots of plants are properly aerated. After the final word has been said about growing plants in field, garden or hydroponicum, in the absence of oxygen, nothing of importance ever happens inside a plant but death. And that is highly undesirable to a grower of plants.

Proteins (and there are thousands if not millions of them) are found everywhere in the plant. If it were possible to remove everything but the proteins from the plants about your home, and keep such plants in their original places, you would still be able to recognize the lawn, the shade tree and the tomato patch. The forms of the plants would remain essentially the same. The same thing might be said with respect to the water and sugar (or carbohydrate) in the plant. It is instructive to imagine the plant body as a mass of branching water, standing alone. Indeed, the idea has been used elsewhere in this book, to help understand another point. But let us return to the nitrogen question.

2. GETTING NITROGEN INTO THE PLANTS. In giving the plant nitrogen it seems clear that we must keep in mind not only the supply of nitrogen in the solution but also the amount of light available and the oxygen supply. During this discussion we will add a fourth thing to be kept in mind, namely, the concentration of the solution.

In practical language, the plant uses its protein to grow. If the plant must make its own protein, and to do this sugar, oxygen and energy are required, it presents the grower with a very delicate problem to be solved. For on shady days there will be less sugar produced than on sunny days. If he gives the plant the same dose of nitrogen day after day, regardless of the amount of light available, he will be running into one of two difficulties. On shady days, he may be giving the plant more nitrogen than can be used up, because of a shortage of sugar, and on sunny days his plants will have more sugar than is required to use up the amount of nitrogen he is giving the plant. In other words, one day he will be building up a sugar-poor and nitrogen-rich plant, while on the other he will be producing a sugar-rich and nitrogen-poor plant. The first will be a flabby, weakly affair, the latter a hard, woody, non-edible product.

The practical point to be considered is that nitrogen must be fed in relation to the amount of sunlight available. As the daily intensity of light increases, so must a little nitrogen be added to the solution offered the plant. The opposite is done on cloudy days or when the daily amount of light decreases. There are other factors, of course, but here we must keep our minds on one thing at a time, to avoid unnecessary confusion.

3. HOW NITROGEN SHORTAGE COMES ABOUT. There are two ways in which nitrogen scarcity may be brought about. The most obvious way is to fail to put enough of it into the solution, or, if one is a "dirt" gardener, on the soil. But the

second cause is more subtle. It has to do with the total concentration of the solution into which we have put the nitrogen with other chemicals.

Everyone knows that in a concentrated solution there is less water than in a dilute one. This is the same as saying that so far as the nitrate particles in such a solution are concerned, there is a water shortage. The situation might also be put this way: since nitrogen goes into the plant's roots as nitrate (NO_3), and only arm in arm, as it were, with just so much water, obviously, if the water is crowded out by too many other things in the solution the nitrate particles will not get sufficient opportunity to enter the plant. On a beach, for example, overcrowded with many different kinds of people, the individuals of one particular kind will have much less opportunity to enjoy bathing freely and liesurely than they would have if the beach were half-deserted.

The practical consequence of this crowded condition of a concentrated solution is that one may have plenty of nitrogen in it, yet have the plant growing in it starve for lack of nitrogen. One is reminded of the "Ancient Mariner," who found that there was "Water, water everywhere, but not a drop to drink." This is one reason why the total concentration is kept well within the limits mentioned earlier.

The effect on the plant is to create an internal condition precisely like that discussed in the last section. In the event that the sunlight is normal, and the concentration is too high, more sugar will be formed than can be used up by the little nitrogen getting into the plant. Therefore, little protein will be made, growth will be slowed down, and the excess sugar will be turned into starch or into cell walls and wood. On cloudy days, such a concentration would be beneficial, since the amount of sugar produced would also be small, thus tending to balance the small intake of nitrogen. In that event, one would expect protein and cell-wall production to proceed apace.

4. PRACTICAL USES MADE OF HIGH CONCENTRATION. In transplanting young plants, it is desirable to harden them first. Some growers do this by means of increased concentrations. Suppose the concentration is raised gradually on bright sunny days, while more sugar is being formed. Since relatively less nitrogen is entering the plant, the excess sugar is used by the plant to make extra heavy cell walls; and, what is more important, sturdy, woody conducting-vessels which will stand the plant in good stead during its later life. Such plants are less easily injured, and are less subject to disease.

Mr. Turner, one of the leading growers of roses hydroponically, makes a very clever use of this method of hardening. It is very easy to oversupply roses with nitrogen. By keeping the ppm of nitrogen relatively low (between 50 and 100 ppm) and fixing the potassium also at around 100 ppm, he secures enough nitrogen to produce the protein necessary for growth. Then, by lessening the water in the solution through increasing the total concentration, he gradually hardens his plants. Since there is not enough nitrogen for making both protein and cell walls, and there is more sugar available than required to make the small amount of protein from the nitrogen available, he accomplishes his purpose nicely.

5. SUCCULENCE IN VEGETABLES. Now let us see what might be done to produce succulent vegetables, in so far as this is due to providing a plant with nitrogen.

In the springtime there is not as much light as in the summertime. Therefore there is not as much sugar made in the spring as in the summer. Part of the sugar is used to make cell walls and woody vessels for conducting materials through the plant; part is burned in the process of making protein for the growing parts. If the nitrogen supply is regulated to keep a little ahead of the sugar being made, either by putting more nitrogen into the solution or by lowering the concentration slightly, there will be less tendency to have woody plants; and a greater tendency toward succulence. But if the concentration is allowed to become excessive, or if the nitrogen level in a more dilute solution is allowed to become low, then there will be a sugar-rich condition inside the plant with consequent lack of succulence or tenderness in the vegetable.

There are only two ways to determine what is happening. One is to make chemical tests of both the plant structures and the nutrient solution frequently. The other is to gain skill by practice in observing the plant grow. The first is possibly only for those equipped to test. Most people have to rely on their experience. Since this book is intended for those who are unskilled in testing techniques, nothing will be mentioned on that point.

However, if repetition is allowable on so important a subject, obviously, to produce succulence in vegetables the nitrogen must be added to the solution with considerable care, as the daily amount of light increases. It should also be obvious that he who applies a formula blindly, rather than by use of his head, must either fail completely or have undeserved, but transitory success.

Incidentally, plants grown in greenhouses or in partial shade are sometimes more tender, for a longer period, than when grown outside. This is because in partial shade less sugar is made; and there is less danger of having an excess which might be turned into wood. Or, putting it the other way around, there is less likelihood of having a deficiency of nitrogen, and an excess of sugar.

In midsummer, the formation of sugar increases very rapidly, due to the long light periods. But high temperatures enter the picture also. If the temperature is moderate and the nights are relatively cool, the problem is simply one of adding nitrate in increasingly larger amounts without getting an excess, thus producing again a nitrogen-rich, sugar-poor plant. Also, one must avoid, of course, increasing the total concentration above the limits mentioned earlier. This problem is solved nicely by[86] changing the formula so as to give the added extra nitrogen desired without increasing the total concentration. Here is where a study of the tables given in Chapter 5 is helpful.

Actually, in so far as my own technique of feeding is concerned, there is little possibility of having an over-concentrated solution in hot weather. For the chemicals are added daily, and dilution by water is made at the time of feeding, by allowing water to enter the feeding tank before it flows out into the plant tank. Thus the concentration of solution at the plant's roots is always less than that indicated by the formula. Since the feeding tanks are filled to mark each night, and the process repeated daily, the plants get a specific amount of food daily and all the water they need. Over-concentration is avoided over a long drought, by spraying the sand surface with water.

6. HIGH TEMPERATURE. When the temperature hovers in the high nineties and over the 100 mark for long periods, and the light is intense for long stretches during the day, there arise disturbances inside the plant which may not be controlled. In fact, not all of them are known. Everyone knows that it is difficult to grow some kinds of plants in midsummer, when the temperature is excessively high. People in the desert are particularly aware of this. Here is a partial explanation. First, up to a certain point, absorption increases with temperature. Second, sugar tends to be produced faster than it can be used. Third, the respiration rate also increases with temperature rise, up to a certain point. The situation inside the plant really becomes complicated; too complicated to attempt an explanation here. Sometimes it happens that there is not enough sugar present to satisfy the respiration demands. That is when the plant starts to burn itself up.

Now then, suppose you[87] feed your plant too much NH_4. This will be used to make protein at once. But, since there is a shortage of sugar, the demand for new cell-wall material will not be satisfied. Thus the plant will seem to thrive a short while, then wilt and die. However, if you fed it NO_3, what would happen? If the oxygen supply were low the NO_3 would accumulate, and the plant would use up its body supply of oxygen. If the respiratory oxygen were sufficient some of the nitrogen would be turned into protein, and thus prevent the accumulation of NO_3. So long as there is sufficient sugar to take care of the burning process required to use up the NO_3, the plants will do well. However, this can't happen if the roots don't supply the oxygen.

7. FRUIT AND NITROGEN. Although excessive feeding of nitrogen retards or prevents fruiting, nevertheless, it is necessary to supply this element during the fruiting period. There is more to be desired in a plant than succulence and flowers. These things we like in a salad or a bouquet. But we wish, also, to have such things as beans and tomatoes. These are fruits. Before they may be formed nitrogen comes into the picture. Therefore, nitrogen must not be allowed to fall too low in the feeding schedule when the fruiting period is on.

8. SUMMARY OF NITROGEN. If the above discussion has been tedious, it is also important. Many more things might have been said had space been available. It was intended to emphasize the fact that giving nitrogen to a plant is rather difficult, if the best results are desired; particularly if one wants people to eat what he grows. The reader is urged to master the few details given. The genuine student will seek a fuller account in a standard text on plant physiology.

What has been said may be summed up under the following brief statements:[88]

a. Nitrogen is used to make the living part of the plant.

b. It is taken in either as nitrate (NO_3) or ammonia (NH_4).

c. It requires energy to turn the nitrate or ammonia into protein. This energy is secured through burning sugar, which is made only when there is light.

d. Since the amount of sugar varies, the amount of nitrogen given a plant must also vary. Otherwise we encounter either high-sugar and low-nitrogen plants, or just the opposite. Both are undesirable.

e. A high-sugar and low-nitrogen plant is produced when the concentration is excessive, or when absorbed nitrogen is not used because of low oxygen supply or high temperature. The result is that sugar tends to collect as starch or as woody hard parts; or the plant stops growing because not enough protein is made for the required protoplasm. A low-sugar and high-nitrogen plant is produced if the nitrogen is supplied too rapidly in the ammonia form when there is cloudy weather and little sunlight, or if there is a respiration upset because of prolonged high temperature. The result is that the sugar is burned almost immediately to provide the turning of nitrogen into protein, leaving none for normal cell-wall formation. The water balance inside the plant is upset, the plant continues to grow, but is too succulent, wilts, is susceptible to disease, and produces little or no fruit.

f. The amount of nitrogen given a plant is increased as the amount of daily sunshine increases, and decreased as the light decreases.

g. A plant may starve for lack of nitrogen even though its roots are supplied with much of it. This may be due to too high concentration of the solution.

h. Best fruiting results[89] are obtained with a moderate and well-balanced nitrogen feeding.

It should be obvious by now that there can be no such thing as a perfect formula, in the sense that all ingredients may be made into a cake and applied to all plants everywhere, in all seasons, under all conditions of weather, with amazing success in each instance. However, there are "merchants" of "plant food" who advertise this error as truth.

In introducing the other elements as they concern the problem of making up a formula, we must necessarily be brief. Some of them are varied as to amounts of feeding, but none so much so as in the case of nitrogen.

B. POTASSIUM. This element is used in the making of buds, leaves, root tips, sugar, starch and proteins, though it does not enter into the structure of some of these things. It provides a sort of "kick-off" to cell division. If it is not present, and in proper amounts, particularly in the early stages of growth, the plant cannot do a number of important things. Its deficiency is marked in various ways. In a tomato, for example, the lower leaves will turn grayish-green and the margins become yellow. This yellowing eventually spreads inward, the areas become brown and finally die. In a cucumber the same thing occurs, but here one notices also a bronzing effect, while the stem end of the cucumber fruit remains much smaller than the opposite end, which is the opposite of what occurs when nitrogen is deficient in this plant. A potassium-deficient radish is said to have knobby roots, with thick and leathery leaves, a characteristic some claim also for other plants.

Potassium is absorbed readily, except when there is an excess of calcium present. Thus there may be the proper amount of potassium in the solution but because there is too much calcium present the plant will be starving for it. In such a case, the usual[90] potassium-deficiency symptoms would show up unexpectedly.

The minimum amount required is about 70 ppm. But most formulas keep it around 150 ppm. Turner finds that this may be raised to as high as 1000 ppm, during winter and cloudy weather, or to offset excessive absorption of either nitrogen or calcium in certain cases for a limited time. The practical effect is one of hardening what would otherwise become a too-soft fruit, as in tomatoes, and of preventing the yellowing and withering of the lower leaves which have absorbed an excessive amount of nitrogen.

Another practical bit of information about this element is that it keeps the sugar moving from the place where it is made to the place where it is used or stored. It is thus clear that a plant like a potato requires a great deal of it, since the sugar made in the leaves is transported through the entire length of the plant down into the ground, where it is turned, presumably with the help of potassium, into starch. This is the principle substance stored in that underground stem familiarly known as a "spud," or in foreign countries, potato, or pomme de terre, according to the language.

C. PHOSPHORUS. This element actually becomes a part of the living material called protoplasm. Here again is an element which serves several purposes, making it thereby the more essential to a plant's life. Sugar is converted into the insoluble form, called starch, very quickly after it is made. In that form it is quite useless. It must be put back again into the soluble form. Phosphorus seems to be necessary in this turning-back process from starch to sugar. Since seeds are essentially infant plants lying dormant inside a wrapping of oil, protein or starch ladened tissues, it is not surprising that phosphorus must be supplied[91] to the plant particularly when it is fruiting.

If the absorption of potassium is interfered with by too much calcium, the absorption of phosphorus is interfered with by too much iron. In fact, iron and phosphorus have a mutual dislike for each other. One precipitates the other out of solution the moment its concentration is high enough to get the upper hand of the other. By keeping them both down near the minimum ppm permissible for good growth, this particular battle of the elements becomes less disturbing. By keeping the solution a little more acid than one would ordinarily, both seem to forget their chemical feud and enter the plant roots eagerly, thereafter doing what the plant expects them to do.

Incidentally, this battle of the elements is fought continuously also in a garden. In a hydroponicum we can keep it under control much more easily than in a garden or a field.

If the plant fails to get a sufficient amount of phosphorus, the deficiency shows up in stunted growth (a feature of most kinds of deficiencies), purple veins or even complete purpling on the under-side of the leaves, slender stems, and fruit that fails to set or mature. Even the roots fail to develop, a feature difficult to observe without destroying the plant. I have noticed that these symptoms are particularly noticeable in early spring when the temperature and light are low. The plants invariably come out of it when conditions are more favorable. This observation assumes that there are no apparent reasons for phosphorus shortage, through failure to keep the *p*H and iron-phosphorus balance reasonably correct.

The minimum concentration of phosphorus is 10 ppm, and it is generally unwise to allow it to exceed 100 ppm. A rose plant, for example, does well with 10 to 30 ppm, while

92

a tomato, which forms fruit, would require 60 or more ppm of this element, particularly during its flowering and fruiting period.

D. CALCIUM. This is the element which makes lime so important. Lime has been put on soil in one way or another for the past 5000 years, with little idea of why. Were words water, truly there would have been a deluge because of the prolonged debates over the use of lime. And the debate has not ended with the birth of hydroponics. Opinion among plant physiologists permits the concentration of calcium to range anywhere between 80 and 3000 ppm! Calcium is a very important element in the life of a plant. But, in general, such a high concentration of calcium would never be wisely attempted by the beginner.

By some, calcium is ranked higher in importance than is phosphorus. I prefer to consider one essential element as important as another. However, some are more difficult to handle than others, which makes them important to the operator of a hydroponicum. What makes calcium so important is the fact that it is used by the plant for several processes. For example, it neutralizes acids produced inside the plant. When a large amount of nitrogen is used by the plant a large amount of acid is produced. Since the plant has no excretory system, the only way it overcomes this acid accumulation is to neutralize it into some harmless substance. Thus calcium is used in a great amount for this purpose.

Several elements, among them magnesium, are harmful, if used in large amounts. In some way calcium helps reduce this harmful effect. Sodium, which is not used by the plant but which gets into it through the roots, harms the plant less if there is sufficient calcium present.

93

Calcium deficiency is therefore not simply a matter concerning this element alone, but is connected with toxic effects produced by other elements when there is not enough calcium to offset them.

You may recognize calcium shortage by the fact that the growing point stops developing, and dies; also, the upper leaves turn yellow while the lower remain green. If the plant is removed, the roots will be brown and poorly developed.

One tries to balance calcium with potassium. If one uses a calcium concentration of 120 ppm, the potassium would be raised to 200 ppm. These figures are not to be considered precise. The point is that for general purposes one keeps the amount of calcium between the concentrations for nitrogen and potassium. Which means that the potassium is generally kept higher than either the calcium or nitrogen. When the nitrogen is low, say at 50 ppm, the calcium would be at least 80 ppm, and the potassium at least 150 ppm. On dark cloudy days, for prolonged periods, the potassium might be raised to as high as 500 ppm. But suppose the nitrogen feeding is very high, as in summer. Then the calcium would be raised also to perhaps 400 ppm, while the potassium would be lowered to around 100 ppm. It must be remembered that these suggestions are intended as a help rather than as a set of rules to be followed blindly. Simply remember that calcium and potassium are another pair of elements which tend to interfere with each other, making it necessary for the operator to be on his guard in giving them to the plant.

If the beginner follows the formulas given, he will in all likelihood have no difficulties regarding calcium. The only conditions which he should clear up are those in which the water used is already high in calcium. In that event none at all or very little should be put into the nutrient solution.

94

Or the sand used may be high in calcium. If this is so, it must first be treated with treble superphosphate in water, until the *p*H or acidity becomes stabilized at about 6.5. By this means the sand (or gravel) is coated with insoluble phosphate, and from then on the phosphorus in the solution will not be made insoluble by the excess calcium. If you don't do this, you will have to use more and more phosphate, or your plants will show phosphorus shortage, and you will have difficulty keeping the plant bed from becoming alkaline. Adding more acid will not relieve the situation if a calcium-high aggregate is the cause.

The minimum ppm for calcium is probably 80. There are some who feel that it should be placed at 120 ppm. Probably the latter figure is the safer.

E. MAGNESIUM. Just as your blood will not be red unless there is iron to form the nucleus of the hemoglobin particle, so will plants not be green unless there is magnesium to form the heart of the chlorophyll particle. Chlorophyll makes the great majority of life on earth possible. Without it, you and I could not possibly exist, since we, like all other animals, depend on it to provide us with food. Without it there is no food. Thus the importance of magnesium also. For without magnesium no chlorophyll is possible.

The most obvious consequence of magnesium deficiency would be a yellowing of the older leaves between the veins, just as in potassium deficiency, except that there is no bronzing effect as in potassium deficiency. Also the leaves tend to curl upward. An excess of it, on the other hand, tends to increase the total concentration and to cause hardening. It has been reported that an excess of this element causes the tops of plants to wilt in hot humid weather. Minimum amount is around 10 ppm.

95

F. SULPHUR. This element becomes a part of some proteins. It also imparts flavor to some plants and aids in making chlorophyll. Leguminous plants use it for making their root nodules. A shortage of it is not likely. If so, the plants turn pale green and show tardy fruit formation. The minimum is around 10 ppm.

G. IRON. This element is used in three main ways. First, it assists in making chlorophyll, though it does not become a part of it. Thus the first sign of iron deficiency is a yellowing of the leaves, particularly the young ones. You may determine this very quickly by pouring a solution of iron citrate or iron sulphate over the sand (see formulas for the proper concentration). The plants will begin to turn green again within a few hours!

Second, it helps the plant to burn its manufactured food, thus providing heat energy for use in various processes. You may recall that sugar is burned when protein is made. Thus an iron deficiency interferes with this important process also.

Third, the living material itself, protoplasm, without which nothing happens inside a plant, has iron as a structural part of it.

Thus it seems that the plant really needs quite a bit of this element continuously. But it is rather difficult to get it served up on an acceptable platter, as it were. First, it will be recalled, an excess of phosphorus will not permit its absorption. Also, if the hydrogen ion becomes high, *p*H 7.0 or more, so that the solution becomes even slightly alkaline, it is not soluble, and is therefore not absorbed. Then, too, the concentration, if more than 10 ppm, is likely to interfere with phosphorus absorption, and, if the solution is very acid, so much of it will be absorbed as to become toxic, the roots being killed.

Another element, manganese, when too high in concentration interferes with iron absorption. Thus, iron deficiency may be the consequence of a number of things.

The practical point to be remembered is that if one feeds his plants iron regularly, but in small amounts, he will have little or no difficulty.

The minimal amount required is probably about one ppm. If one could always be sure that none of it is precipitated out of solution, feeding as little as 0.05 ppm would be sufficient. So long as the phosphorus concentration does not go high (some growers keep it at around 10 ppm), or the alkalinity side of the *p*H scale is avoided, little trouble will be experienced with iron absorption and thus iron deficiency.

H. MANGANESE. This is another element that serves to help out in several processes as a sort of activator. There is reason to believe that whatever concentration of iron is used the amount of manganese should be just half that amount. Thus, if one ppm of iron is used, then 0.5 ppm of manganese should be used. This means that the toxicity of iron is due in part to a shortage of manganese, if the manganese is lower than the relative amount stated, and iron deficiency would result if the manganese is relatively higher than the amount given as desirable. Putting it another way, the absolute amount of iron is of less importance than the relative amount of manganese used with it.

I. BORON. At the New Jersey Experiment Station work is being done to show how boron feeding is related to calcium feeding. Perhaps boron is associated with the plant's use of the other major elements. Whatever the use of it, and however other elements may later be proven to be associated with it in normal plant processes, it is known that all plants need it.

Great care must be exercised in using it. First, because it is more toxic to some plants than to others. For example, corn will not tolerate it to the amount that cauliflower and beans will. Second, because, as in the case of several other elements, its chances of harming the plant depend upon the relative amounts of other elements, particularly the other trace elements.

A shortage of boron causes different effects in different plants. In general, the growing tip of the plant first shows browning, and soon dies. The leaf stalks and veins become extremely brittle. The leaves have a tendency to burn at the tips, to become malformed and twisted, particularly the young ones. But the reader should be reminded that leaves twist for other reasons also. The margins eventually become brown and have a burned-up appearance. In strawberry this is very pronounced.

The minimal amount varies between one ppm and 0.01 ppm, according to the kinds of plants grown, the amounts of other elements present, and the condition of the nutrient-solution.

For practical purposes, using a concentration of 0.2 ppm, regularly causes neither a deficiency nor an excess.

Nothing need be said about copper, zinc and molybdenum, the remaining trace elements, except that they are very toxic in even low concentrations. It is probably best to use them in concentrations not more than 0.01 ppm, and then only infrequently.

Now that we know what elements to use, and something of what use the plant makes of them, as well as some of the consequences of their excessive use or of their deficiencies, let us next examine the formulas which have actually been used and published. None of them can be used without some changes being made as the season progresses, as the plant matures, and to satisfy specific needs of different species of plants. But they do serve as safe guides. And the earnest beginner will soon learn by experience how to make the required changes as they arise. Indeed, every time a change is made, one has a new formula. But for practical purposes the plants will tolerate a great deal of misuse of formulas, provided the required amount of aeration is kept up and the acidity or *p*H is properly maintained. When these go wrong, no formula is worth its salt.

CHART 2. FORMULAS

Chemical used	% Purity	Weights in grams to be used in making up 1,000 liters of solution. For one barrel, divide by 5.								
READ DOWN in all columns)		I*	II	III	IV	V	VI	VII	VIII	IX
Potassium nitrate, KNO_3	95	1100	286	608	949	1100	1100	440w 1100s

Sodium nitrate, $NaNO_3$	97								540	630
Potassium chloride, KCl	95								560	720
Calcium oxide, CaO (lime)	90								186	186

Note: Formulas I to VI inclusive modified from originals published in literature cited. All reduced to similar purity of chemical used, and to grams per 1,000 liters. Otherwise unchanged. Any errors in calculation noted must be charged against the present writer. *From "Complete Guide to Soilless Gardening" by W. F. Gericke, published by Prentice-Hall, Inc., 70 Fifth Avenue, New York 11, New York, at $3.00. Copyright 1940 by Prentice-Hall, Inc.

w = winter.

s = spring and summer.

CHAPTER 7

Formulas

We come at last to answering the "sixty-four-dollar question": "What formula do you use?" Here are given nine different formulas for you to try. They are put into one chart, Chart 2, and given a Roman numeral for identification. The people responsible for them are identified in the paragraphs which follow.

Formula I. This is the formula developed by Gericke. It is used for growing both flowers and vegetables. See his text for detailed directions on the technique used and the manner in which the trace elements are added.

Formula II. Mr. Wayne I. Turner, of Kankakee, Illinois, kindly furnished this formula. It was developed for growing roses commercially in greenhouses, using the aggregate system. This formula is the result of many years of practical research. The roses grown prove its worth. I have seen the roses, and can vouch for the formula. Mr. Turner, who is one of the outstanding pioneers in growing roses commercially and who has spent much time and effort trying to induce others to adopt hydroponics, writes me that in his opinion "It is a practical, scientific, commercial venture for anyone."

Since this formula is the consequence of scientific acumen and commercial experience combined, such a statement by so high an authority would not be made without genuine confidence in the formula itself. If the reader consults the text written by Turner and Henry, he will discover that the formula has been changed considerably between 1939 and the present. It is hoped that the authors will soon revise their text, and include the details which brought this formula to its present form.

Interestingly enough, the only trace elements used with this formula are iron and copper, the latter probably unnecessary, in the opinion of Mr. Turner.

Formula III. This is also a rose formula, or, better still, a flower formula. It is the famous WP formula developed by Arnold Wagner and G. H. Poesch at the Ohio Agricultural Experiment Station, and, I assume, under the direction of Professor Alex Laurie. The recent paper by Kiplinger and Laurie indicates that this formula has been tested over so long a period and covers so many questions as to the use of different substances used in the gravel or aggregate technique that it should be placed high on the list of successful formulas.

It is used either in ½WP, WP, or 2WP concentrations. The reader must consult the book by Laurie or the papers listed, for details. In general, the ½WP concentration is used during the early life of a plant, and the other concentrations follow in order, as the season progresses.

Formula IV. If one visits the New Jersey Experiment Station at New Brunswick, he will see roses growing with the use of this formula. It was developed under the direction of Dr. O. Wesley Davidson, and is to be found in its original form in a paper by him published in the July 1946 issue of *Soil Science*.

Having seen the roses growing in this solution in mid summer, I again vouch for a good formula. The reader may be surprised to find that roses may be grown equally well in solutions which vary greatly in concentration, as seen when comparing this formula with that of Turner. Professor[102] Davidson very wisely points out that "The concentration and balance of nutrients in the solution surrounding plant roots in artificial cultures vary more or less, depending upon the rate of application of the solution, or, in the case of solution cultures, upon the amount of circulation. This is particularly true of the nutrient substrata surrounding the roots of plants in gravel cultures. It is apparent, therefore, that the choice of one nutrient solution over another one varying from it slightly with respect to the concentrations of various major nutrients present is unwarranted. This statement is not intended to minimize the importance of the balance of ions in a nutrient solution. The point to be emphasized, however, is that such a balance is concerned with a suitable range of concentrations of various major nutrients rather than with the strict maintenance of given concentrations of each.

"This contention does not apply to the minor elements, or micronutrients, since small differences in the levels at which they are provided in nutrient solutions are known to effect pronounced changes in plant growth."

The reader may feel that so lengthy a quotation from so scientific a paper in a book of this sort is out of place. But let us see. Dr. Davidson has put his finger squarely on a point that has not only interest for the scientific investigators but also the commercial grower. The point is this: For a formula to be satisfactory, you don't have to insist on trying to keep the concentration of each major element in it at a given level. This means that you may choose any formula you wish, regardless of how it differs from another, so long as you choose one which has been developed on correct principles. It does not mean that you can put just any old thing into a solution and expect a good crop. Mark what Davidson says in the first sentence quoted, and be impressed[103] with the idea that the conditions under which a formula is used is also significant. There is no one in a better position to offer this advice to a beginner than is Professor Davidson.

Formula V. Here we attempt to bring in the work of the staff at the Purdue University Agricultural Experiment Station. The formula given here is one of many developed under the direction of Dr. Robert Withrow, who designed one type of growing tank used in the Gravel System, and who, together with his wife, Dr. Alice Withrow, plant physiologist, developed the formulas published in the army manual on hydroponics.

This is the now famous 2D formula, an honor which it shares with the 2E formula developed by the Purdue group. In recent years a number of new formulas were developed on the lines of these two, and for meeting specific demands during the recent war. I regret that I am not at liberty to report these here, through no fault, I am happy to say, of Dr. and Mrs. Withrow, who have been most generous with their information.

Formula VI. This is a tomato formula developed by Arnon and Hoagland, and was taken from the Davidson paper cited above. Since I have no first-hand information regarding it, the reader must consult the paper by these authors for details on how it is used.

At this point a word is necessary regarding the use of micronutrients. These have not been given with the above formulas because the authors use them differently, according to the technique of using the nutrient solution as a whole, and to the manner of mixing the trace elements themselves. They differ also in the frequency with which the trace elements are added. Space does not permit giving all these details here. Besides, most of the details may be secured[104] in the articles and books, especially the latter, listed in the bibliography section of this volume.

Formula VII. This is the original formula developed by the author and used up until the last war. A word should be said regarding its origin.

Since the entire objective of my own efforts in hydroponics was to develop a system devoid of mechanical devices and which could be operated with a technique that did not require much skill in testing, it was clear that the formulas developed for other systems might have to be modified because of a difference in the number of times the solution would be supplied to the plants, as well as the difference in the amount of flow or circulation which might be attained.

Since, also, the light intensity varies greatly in the Conway region through the growing season, an attempt was made to apply the potassium-nitrogen relationship suggested by Turner and Henry. The plants grown were tomatoes, beans, corn, lettuce and beets. The results were satisfactory in all cases. The chief difficulty encountered was an overfeeding of nitrogen to tomatoes, which resulted in the browning and drying-up of the lower leaves, when plants were grown in the greenhouse. This difficulty was not encountered when plants were grown in the outside hydroponica.

Formula VIII. This formula is the consequence of two unfortunate situations. First, the last war cut off the purchase of calcium nitrate and potassium nitrate. Second, there came a severe storm which blew down the building in which my chemicals were stored, filling the storage jars with water and debris. Since there was no possibility of getting a new supply, and to waste the diluted material would have been criminal, the only thing to do was to dip it out in a No. 1 tin can, and guess at the concentrations. The surprising result was that the crops were grown to maturity without serious difficulty. As a consequence of these two disasters, sodium nitrate, potassium chloride, lime and nitric acid were substituted for the two unavailable chemicals.

For winter use, extra potassium could be supplied by using extra amounts of potassium chloride, without serious trouble from free chlorine. For summer use, a third chemical, ammonium nitrate, was added to provide the extra nitrogen required as the season progressed. By increasing this salt gradually, and avoiding its use entirely on dark cloudy days, very satisfactory results were obtained with tomatoes particularly. One unit grown on this formula produced 746 pounds of marketable tomatoes between April 1 and July 12, 1947. It would appear that the formula is satisfactory for tomatoes when grown in a region where the daylight periods are long and the temperature, during the growing period, varies between 40 and 100 degrees F.—when used, of course, with the particular form of hydroponicum and technique described elsewhere in this book.

Formula IX. This is essentially the same as number VIII. In it sulphuric acid is substituted for nitric acid, and the potassium level is raised, while the nitrogen level is lowered. Thus, this formula may be used in winter and for starting plants, and Formula VIII substituted for it as increased nitrogen is required.

It should be noted here that there is a limit to supplying extra nitrogen through the use of ammonium nitrate. The maximum given in the two formulas is considered to be within safe limits. If more nitrogen is desired than provided by either of the last two formulas doubling the amount of lime and acid should meet requirements, or use calcium nitrate instead of lime and acid, as in Formula VII, would be satisfactory.

106

It is understood that people are frightened at the sight of tables and charts. But it is hoped that the reader will examine carefully the following Chart 3. It shows how the nine formulas vary in the concentration of the various major elements. Note that the potassium level is generally a little higher than the nitrogen, and that the calcium level is consistently kept below the nitrogen level. Compare this with the situation in Chart 4, where the formulas are compared on the basis of the relative number of absorbable particles, rather than on the basis of the concentrations of the elements in them.

CHART 3. *Ppm of each essential element in each formula*

	I	II	III	IV	V	VI	VII	VIII	IX
Nitrogen	168	50w 100s	100	250	168	252	140w 224s	168w 284s	98w 210s
Potassium	390	100	214	300	390	390	156w 390s	234	351
Calcium	80	33w 101s	320	192	184	120	160	160	160
Phosphorus	62	10	62	31	37	62	62	62	62
Magnesium	24	10	48	84	12	48	48	48	48
Sulphur	32	13	320	137	160	64	64	64	64

w = winter or early spring.
s = summer, long days of sunlight.

CHART 4. *Relative numbers of absorbable particles (ions) in the formulas*

Ions	I	II	III	IV	V	VI	VII	VIII	IX
Nitrate, NO_3	12	3.6w 6.8s	5.5	16.3	10	10	10w 16s	12w 16s	7w 11s
Ammonia, NH_4			1.6	1.6	2	2		0w 4s	0w 1s
Potassium, K	10	2.6	5.5	7.7	10	10	4w 10s	7	9
Calcium, Ca	2	1.2w 2.2s	7.2	4.8	4.8	3	4	4	4
Phosphate (H_2PO_4)	2	0.3	2.2	1.0	1.6	2	2	2	2
Magnesium, Mg	1	0.4	2.0	3.5	0.5	2	2	2	2
Sulphate, SO_4	1	0.4	8.9	4.3	5.5	2	2	2	5

w = winter or early spring.
s = summer.

107

Charts 3 and 4 are included here, not to complicate matters by a lot of technical details, but to furnish you with a sort of guide for making changes in any formula you use, if for some valid reason you deem it to be necessary. That you may understand Chart 4 a little better, let us explain it by the use of Formula VI. For every two particles of ammonia available for absorption by the plant there are 10 particles each of nitrate and K, 3 of calcium, and 2 each of the others.

Now let us note a few things. In Chart 3 the ppm of potassium is higher than the ppm of nitrogen, in all but Formula II. But in Chart 4 is revealed the fact that there are more nitrogen-bearing ions available for absorption than there are of potassium. This is because the plant uses much more ntirogen than potassium during its lifetime. In Formulas VII, VIII and IX the difference between the number of nitrogen-bearing particles and those of potassium is greater because these formulas were used in a region where there is very much sunlight.

Note also that those who use the ammonia particle (or ion) for nitrogen use it sparingly. This is because, as noted earlier in this book, the plant uses the ammonia nitrogen for making protein, while it uses the nitrate nitrogen for making both protein and cell walls. Thus if too much ammonia is used, the plant will tend to be flabby or oversucculent. It is also apparent that an attempt has been made in each formula to keep the various particles somewhat balanced against each other. This happens to be a very important matter, but entirely too technical for consumption by the average reader. It is enough, perhaps, to say that no one has yet succeeded in balancing ions perfectly, but that what balancing has been done is most important, and has been considered in making the various formulas presented. In another decade or two, you will read books giving formulas much improved in this respect. Since these formulas work, it is probably safe to say that plants are not

108

as much interested in parts per million and in grams as they are in the way one contrives to give them a balanced diet of ions.

USE OF TRACE ELEMENTS

Trace elements may not be varied as to ppm as much as may the major elements. Plants suffer from a lack of them, and may be ruined by an overdose of them. The amounts given below in Chart 5 are considered safe. Directions for using them with my particular type of hydroponicum and technique are given below.

One writer has said that plants show a deficiency trouble only when they have not had any of a particular trace element. That could scarcely be said to hold either for iron or manganese. I go on the assumption that it is safest to give plants a little of each trace element frequently, taking precautions against overfeeding them.

One writer notes that food-grade chemicals have enough of zinc, copper and molybdenum in them that adding any of these is generally not necessary. Turner writes that he has never observed signs of copper deficiency in his hydroponicum, though he uses copper very, very sparingly for no particular reason. I have found the same to be true with regard to all the trace elements with the exception of iron, in the Conway area, and with the kinds of chemicals I use.

Another writer observes that the amount of manganese used should be just half the ppm of iron used. He seems to feel that if one has added, let us say, twice as much iron as the plant can use, the toxic effect can be countered at once by adding manganese. In my own experience I have found evidence of iron deficiency in tomatoes after growing for some time in a unit which had been sterilized with potassium permanganate. Taking a tip from the above suggestion I argued that the plants were not suffering from iron deficiency so much as from manganese excess. The plants were then given a watering of iron citrate solution, and recovered in four hours. This appears to support the idea that keeping the two in proper balance is more important than the absolute ppm of either iron or manganese.

On the other hand, still other writers point out that if too much manganese is offered the plant, this element has the effect of inducing the plant to take up more calcium than is good for it. Thus, since calcium in excess interferes with iron absorption, we have a sort of merry-go-round situation: Give the plant too much manganese, it speeds up calcium absorption. When this gets too high, there is an iron shortage. Add more iron to relieve the shortage, not only does the plant fail to absorb it but the iron now begins to interfere with phosphorus absorption because of increased concentration. Please do not try to figure all this out. It is unnecessary. But it should warn you that the part of wisdom demands care in the use of the micronutrient.

Boron is another element that may not be used without caution. Some plants like beans and cauliflower use much more than corn. Thus, if you had these plants growing in the same unit and fed them enough boron to satisfy the beans, the corn would suffer toxic effects. It would take several books to review all the possible mistakes which might be made with trace elements. I think I shall end these remarks by saying that, in general, you will have little or no trouble with trace-element deficiency if you use food-grade chemicals, and, once in a while, add a pound of commercial rock fertilizer mixture such as is used for ordinary gardening. I think that much too much has been written about deficiencies, so far as practical hydroponics is concerned. The only exception to this statement would be those regarding iron.

With these remarks in mind, now turn to Chart 5, and the directions given below for the use of trace elements.

CHART 5. *Trace elements—amounts and how to use.*
Weights given for 1,000 liters, or 1,000,000 grams, or five 50-gallon barrels.

Trace element desired	*Its chemical source (see Table II)*	*Ppm used*	*Weight required*
			(grams)
IRON	Ferric ammonium citrate or ferrous sulphate	1.0	5.00
MANGANESE	Manganese chloride or manganese sulphate	0.5	1.80
BORON	Boric acid or borax	0.5	2.80
ZINC	Zinc sulphate	0.05	0.25
COPPER	Copper sulphate (blue vitriol)	0.02	0.10
MOLYBDENUM	Molybdic acid	0.01	0.02

DIRECTIONS FOR USING (not including iron):

1. Make the nutrient solution the proper acidity (*p*H) before adding.

2. Weigh out accurately ONE-FIFTH of each amount given in chart, for the chemicals selected. Use these as SAMPLES. Keep in very small containers for reference. Small glass vials are good. These are the amounts for ONE BARREL of nutrient solution. NO LUMPS.

3. Use a similar measure (vial) for determining amounts to be used. This avoids weighing repeatedly, and is accurate enough, provided extreme care in judging the volume of material is taken.

4. As an alternative to direction 3, make a stock solution as follows: (a) Weigh out 20 times amounts given in chart. (b) Dissolve in slightly acid water ONE GALLON (stock solution). (c) Use 1 cc. per quart, 4 cc. per gallon, or 200 cc. per barrel of nutrient solution ONCE A WEEK, if solution is used repeatedly.

5. If nutrient solution is renewed daily, USE ONLY 25 cc. PER BARREL DAILY, from the stock solution.

6. If nutrient solution is renewed daily, and direction 2 is followed, USE ONLY TWICE A WEEK.

DIRECTIONS FOR IRON:

7. Dissolve amount given in direction 2 (ONE-FIFTH) in acid water, if ferrous sulphate is used. Use dry if ferric ammonium citrate is used.

8. Add to nutrient tank just before feeding, stirring it up—TWICE A WEEK.

9. In case of iron deficiency (yellowing of top leaves) either use daily or water the bed with iron solution by means of sprinkling can.

CHAPTER 8

How to Use the Chemical Tables in

Making or Changing Formulas

I. The Direct Method

This is a technical chapter. It should not be read by the beginner until after he has practiced hydroponics a while, and wishes to gain some information on how to do the arithmetic involved in determining exactly how much of a given chemical is required to produce the given number of ppm asked for. So far as the beginner is concerned, all such calculations have been made for him. Table II tells exactly how much of a given chemical is required to yield one ppm of any essential element, for any chemical listed. This is a mighty handy table.

For example, if you should happen to know (see Chart 3) that a certain formula calls for 100 ppm of nitrogen, you may turn to column one, Table II, and find that you have seven different chemicals (including grades) furnishing nitrogen. In the last column of the same table you would find that it takes only 285 grams of ammonium nitrate, while it takes 643 grams of calcium nitrate to yield the 100 ppm desired. So it goes with the other five listed. But, if you happen to choose calcium nitrate, how would you know how much calcium was included with the nitrogen? Let us see.

By dropping down the table to the calcium group, and spotting the 90 percent calcium nitrate, you find that 4.50 grams of it yield one ppm of calcium (column 3). Obviously, then, one gram of it would yield 0.222 ppm (1 ÷ 4.50) of calcium. Thus, since we used 643 grams of this salt to get 100 ppm of nitrogen, we also got 643 × 0.222 or 143 ppm of calcium in the deal.

Now let us try it the other way, by finding the amount required to yield 143 ppm of calcium. There are six ppm columns already calculated for your convenience. Now, 143 is the same as 100 + 4 × 10 + 2 + 1. At the bottom of the ppm columns for 100, 10, 2, and 1, you will find the amounts of calcium nitrate required to yield the respective ppm. Thus, 450 + 180 (4 × 45) + 9 + 4.5 gives us a total of 644 grams. This is within one gram of what we determined in the previous paragraph. This is close enough agreement, for all practical purposes.

II. The Millimole Method

Now let us do the same thing by another method. Many workers, for scientific reasons, use the relative weights (molecular weights) as the unit of concentration. By taking 180 grams (see Table I, column 2-B) of calcium nitrate and dissolving it in 1,000 liters (1,000,000 grams) of water, we have what is called a millimole concentration. In columns 4N and 4Ca of the same table we find, after calcium nitrate, 28 in the N column and 30 in the Ca column. This means that in one millimole (180 grams) of calcium nitrate there are 28 ppm of nitrogen and 40 ppm of calcium. In one millimole (200 grams) of the 70% calcium nitrate there would also be 28 ppm of nitrogen and 40 ppm of calcium.

Now then, how much calcium nitrate would you need to supply 100 ppm of nitrogen called for in our example above? This is very simple. Since 180 grams yield 28 ppm of nitrogen and we want to secure 100 ppm, then 100 ÷ 28 tells us that we need 3.57 times 180 grams. This amounts to 643 grams, which is the same as we secured by the direct method.

As before, let us see, by the millimole method, how much calcium was secured in these 643 grams of calcium nitrate. Since we said above that 1 millimole (180 grams) of calcium nitrate contains 40 ppm of Ca, and since we had to use 3.57 millimoles to get the nitrogen required, evidently we also got in this deal 3.57 times 40 ppm of calcium, or 142.8 ppm. This again agrees with our calculation by the direct method.

The secret of this agreement is very simple also. The direct method depends upon the correctness of Table II. But, Table II had to be determined from Table I! If the calculations had not been made for you, you would have had to do that calculation yourself, if ever you came up against the problem of trying to decide just how much of a given chemical it takes to make one ppm of any element in it.

In the event that you ever have to add to Table II this is the rule to follow: Divide the molecular weight of the chemical by the weight of the element wanted, and point off properly. For example, if there are 28 ppm of N in 180 grams of calcium nitrate, then 180 ÷ 28 gives 6.43 grams as the amount necessary to furnish one ppm of N, when dissolved in 1,000 liters of water, of course.

III. Selecting the Chemicals

Since we have a choice of several chemicals in making a formula to provide the required ppm of the various elements, what chemicals would serve best? The following rules are helpful:

A. It is more economical to use a chemical having two essential elements in it than one that has not. For that which the plant cannot use is a waste. It costs money to ship waste material.

B. If a waste-containing element cannot be avoided, then use also a second chemical with a waste element in it and one that will combine with the first. For example, chlorine is a waste in potassium chloride, and sodium is a waste in sodium nitrate. We may use these together, because the sodium and chlorine unite to form relatively harmless sodium chloride, or table salt, which is easily washed out by rain.

C. Use the chemicals you can get, rather than insist on having precisely those called for in a formula. So long as you keep pretty close to the ppm called for, it matters little what chemical you use. But it certainly is unhandy to have to make such adjustments. For example, if you cannot get potassium nitrate but can get calcium nitrate, you would have to get your potassium from some other source. Perhaps you would have to get added nitrogen from some other source also. For, by adding more and more calcium nitrate to increase nitrogen you would soon get more calcium than would be safe. You could solve both difficulties by using potassium chloride and sodium nitrate.

D. Use as few chemicals as possible under the circumstances.

E. In an emergency, if you happen to lack a specific element in the chemicals on hand, such things as wood ashes may be used to supply some potassium and calcium. You would have to use acid, of course, to make the *p*H correct. I sometimes keep these covered with water in a galvanized tub or bucket. This dissolves zinc, and some copper from the tub. A cupful of this added to a full tank of nutrient-solution, once in a while, furnishes these elements in sufficient quantity. I have never yet noted poisoning from this source. This should be done, however, not more than once a month. The reader will think of other things which may be done in an emergency.

115

IV. Procedure in Determining Weights

Suppose that you know how many ppm of each major element are prescribed in a given formula, but do not know how much of each chemical containing them should be weighed out. After all, sooner or later one has to transform parts per million into weights. Let us illustrate the solution of this problem by an example.

We shall select Formula IX for use in this explanation. See text, Charts 2 and 3.

The ppm called for each essential element (Chart 2) are: Nitrogen (w), 98; potassium, 351; calcium, 160; phosphorus, 62; magnesium, 48; sulphur, 64.

Let us assume that we have the following chemicals available: potassium nitrate, calcium nitrate, monocalcium phosphate, magnesium sulphate (Epsom salts), potassium chloride, nitrate of soda (sodium nitrate), lime, nitric acid and sulphuric acid. You see, we have gotten hold of quite a number of chemicals in advance, simply because we wished to prepare ourselves for an emergency. We know, for instance, that the little potassium nitrate we have was hard to get. The next time we order it, we may not be successful. Therefore, we have very wisely taken advantage of an opportunity, and bought up a small supply of potassium chloride and sodium nitrate when we had the chance.

But we are not going to use all these chemicals simply because we happen to have them. We shall follow the rule of using as few as possible, to supply the essential elements in the concentrations called for.

Potassium nitrate gives us two essential elements—potassium and nitrogen. Calcium nitrate supplies another, calcium, as well as extra nitrogen. Monocalcium phosphate provides the necessary phosphorus, with some calcium. 116 Epsom salts has in it what it takes to supply sulphur and magnesium. Four chemicals are all we will need, provided we can succeed in weighing them out in proportionate amounts. That is, provided we do not get too many ppm of one element while getting the right amount of another. It is a sort of trial and error affair. But, since you are new at this, I will give you the trial without the error, to save confusion.

Rule one: If a chemical contains two essential elements, satisfy the formula by use of the heavier of the two, first. This will leave a small balance of the lighter element to be supplied by another chemical. On this basis we choose potassium nitrate, since it contains both potassium (the heavier) and nitrogen (the lighter).

We need 351 ppm of K. Table I shows that it takes 110 grams of potassium nitrate to provide 39 ppm of K. Thus, 351 ppm $\div$ 39 tells us that it will require 9×110 grams to supply 351 ppm of K. In other words, we have used 9 millimoles. But for each millimole, we also got 14 ppm of nitrogen. Thus, 14×9, or 126 ppm, is the amount of nitrogen we also have.

Obviously, we are in a jam. We only want 98 ppm of nitrogen. If we use only 7 millimoles, 7×14 will give us exactly the 98 ppm of nitrogen we need, but only 273 of K (7×39). Here is where a little head work comes in. For my own part, I would look over Chart 3, to find that Formulas II and III both use less potassium than Formula IX calls for. One of these, Formula II, is for growing roses, and the other, Formula III, is celebrated as a flower formula. But, since you insist on growing tomatoes, and Formula VI was developed by an authority for tomatoes, it would be wise, perhaps, to approach the solution of the problem by substituting potassium chloride and sodium nitrate for potassium nitrate. This upsets our desire to use 117 as few chemicals as possible, and to avoid waste, but sometimes it is necessary to make a compromise. Let us then make the substitute. But let me add this. In all probability you could go ahead with the reduced amount of potassium without much difficulty. However, don't make such reductions unless you are in a mood for experimentation and are willing to take the consequences.

Thus we make a second start. It is certain that we will have to decide the potassium amount first, since potassium chloride is our final choice of chemicals. By the same method used before, since one millimole (80 grams, Table I) of potassium chloride yields 39 ppm of K, it will require 9 (351 ÷ 39) millimoles to yield 351 ppm. This amounts to 720 (80 grams × 9) grams. But this leaves us with some chlorine waste. How shall we get rid of that? Well, it so happens that when a millimole of potassium chloride (80 grams) is put with a millimole of sodium nitrate (90 grams, see Table I), the chlorine and sodium unite. But in doing this how much nitrogen did we secure for our formula? Since one millimole (90 grams) yields 14 ppm of nitrogen, then 9 millimoles of sodium nitrate yields 9 × 14, or 126 ppm of nitrogen. Again we have too much of this element. Again we are in a jam. If, however, we use only 7 millimoles, 7 × 14 gives us exactly 98 ppm of nitrogen, the amount desired. But this allows extra chlorine, since only 7 millimoles of the 9 of potassium chloride used were neutralized by the 7 of sodium chloride. These few extra particles of free chlorine will in all probability find some stray hydrogen partners, and hook up with them to form hydrochloric acid. If this happens, the tendency for a solution to go alkaline about the roots will be counteracted somewhat. On the other hand, if they remain free they will either evaporate into the air or tie up with some dead material not wanted anyway. 118

Thus we settle on 7 millimoles of sodium nitrate instead of 9, and weigh out 7 × 90, or 630 grams.

We now come to the problem of solving the calcium requirement. This is tied in with the phosphorus needs, since they both occur in monocalcium phosphate. Table I shows that one millimole (254 grams) of this chemical furnishes exactly what we want for phosphorus (62 ppm). This amount carries with it, also, 40 ppm of calcium. Subtracting 40 from 160 ppm, the calcium requirement, there remains 120 ppm of calcium to be supplied. We cannot get this from calcium nitrate without increasing our nitrogen. We can get it from lime (CaO), by adding enough sulphuric acid to neutralize its alkaline effect. Table I shows that 62 grams of 90 percent lime will yield 40 ppm of calcium. Therefore, if we use 3 millimoles of it (120 ÷ 40, the ppm wanted, divided by the ppm in one millimole) it will require 62 grams × 3, or 186 grams of lime to provide the remaining calcium required. Likewise, since it takes one millimole of sulphuric acid (98 grams of concentrated) to neutralize one millimole of lime, it would take 98 grams × 3, or 294 grams. (Note: You would have to use 2 millimoles if nitric acid were used).

This leaves only magnesium and sulphur to be supplied. One millimole of Epsom salts (260 grams) yields 24 ppm of magnesium and 32 ppm of sulphur. Thus, 2 millimoles yield 48 ppm and 64 ppm respectively, and the job of calculating is complete for the major elements of formula IX, for the ppm required.

V. CHECKING FOR OTHER FACTORS

A. TOTAL CONCENTRATION. It was stated earlier in the text that the total concentration of salts in a solution should be kept between 500 and 3,000 ppm, as a rule. Adding up 119 the final weights determined in the last section above, we find that the total concentration is 2,170 ppm. Referring to Chart 3, and adding up the total ppm of the various essential elements, it is found that their total is only 993 ppm. This is less than for some other formulas, and more than for others. Thus, the choice of chemicals seems to be satisfactory from this point of view.

At this point a common confusion should be cleared up. It will be recalled that we have been talking of making up 1,000 liters of solution, whereas in the description of the Unit System we refer to one barrel or 250 liters as the solution unit. The 1,000 liters are used for calculation, since this has been adopted by plant physiologists as the most desirable dilution when a molecular weight of a given chemical is dissolved in it. In other words, it is the millimole that is adopted as the unit for calculation. One may use, however, any multiple or fraction of it, to secure the ppm desired. The confusion in question is this: If 2,170 grams of total salts are used to make up 1,000 liters, and we use one-fifth this amount or 434 grams to make up one 50-gallon barrel (one-fifth of 1,000 liters), will not the ppm for each element also be but one-fifth that calculated? The answer is that the ppm for each element will remain relatively the same. This holds also for the total concentration. Although you use only 434 grams to a barrel of water, you still have a concentration of 2,170 ppm total salts in the barrel. This is because you kept the relative amount of water equal to the relative amount of chemical salts used. *But*, if you diluted the solution to two barrels, after once making it up, the total concentration would be one-half that given. And if you doubled the amount of salts weighed out for one barrel, and put that into one barrel of water, then the concentration would be doubled.

120

B. CHOICE FOR SPECIAL REASONS Table I lists a number of chemicals in which desirable elements are tied up with sulphur. Such chemicals are often cheaper than others, and an excess of sulphur ordinarily does no harm. But I have found that in regions where the temperature is excessively high, and with the use of my own system, sulphur bacteria have a chance to thrive, producing not only obnoxious gasses but toxic to the plants. I have never found this with the formulas I have used. But others, who tried to use commercial fertilizers, at the suggestion of a fertilizer agent, had serious difficulty. It has always been my practice to use a minimal amount of sulphur because, quite by accident, I found that onions, radishes and lettuce grown this way seemed to have less bitterness or sting to them than those grown in the garden. Icicle radishes, in particular, were not at all "hot." I now know the reason. Dr. Davidson reports, in a personal communication, they discovered at the New Jersey Experiment Station that it is excessive sulphur which appears to be the culprit in producing "hot" radishes. It is thus apparent that the beginner has much to learn about securing best results, besides having a formula and a satisfactory method for applying it.

VI. How to Handle Variations in Purity

Throughout this discussion we have intentionally used food-grade chemicals, of the percent specified in Table I. But what would you do if the chemical you bought were of different purity? This is very likely to happen. If the purity is only a few percent lower or higher than those given, you may make a rough guess by weighing out a little more or less, and let it go at that. But if you made a mistake of 25 percent, in magnesium, or phosphorus, and perhaps nitrogen, there are times of the year or periods in the plant's life when this would be harmful. It is better to make proper calculations for corrections in purity.

All you have to do is correct column 2-B in Table I. Follow this rule: Multiply the molecular weight (column 2-A) by 100, and divide by the percent purity of the chemical you have bought. Don't forget, however, that by thus changing the amount you actually weigh out, through this correction, the ppm of the essential elements remains the same as for the pure chemical.

CHAPTER 9

Where to Buy Needed Supplies

I. Chemicals

As noted in a previous chapter, the chemical and fertilizer industries have not yet organized their sales departments to supply the needs of the hydroponicum operator. This is due to the fact that not enough hydroponica are in operation to warrant their doing so. It is therefore necessary to warn the reader that he may not be able to secure his chemicals from the sources listed, although the writer has no reason for believing that his requests will be ignored.

The Monsanto Chemical Company furnishes the *monocalcium phosphate* in several grades. The purest grade is 99 percent. The branch offices of this company are located at St. Louis, Missouri; Akron, Cleveland, and Cincinnati, Ohio; Mobile, Alabama; Houston, Texas. It is possible to send this chemical to foreign countries, through their foreign trade service.

Calcium nitrate **and** ***potassium nitrate*** **may be purchased in 200-pound barrels from the J. T. Baker Chemical Company, Phillipsburg, New Jersey. Specify food grade.**

As a substitute for calcium nitrate, one may use lime and nitric acid. I have done this since the supply of calcium nitrate was cut off. It is handier to use calcium nitrate, and it may be a little cheaper. But if one buys the nitric acid in quantity sufficient to supply the needs for one year, it is possible that this and the lime combination would be more economical. Certainly, lime may be had anywhere, and nitric acid is easily secured through any chemical house. Technical grade is the kind to buy. In using lime one should make sure that the magnesium in it is not too high, or at least take this into consideration in feeding magnesium sulphate.

W. H. Curtin and Company, P. O. Box 118, Houston 1, Texas, and Greene Bros., Inc., 1812 Griffin St., Dallas 2, Texas, will supply the trace elements. These companies are distributors, not manufacturers, of chemicals. Their quotations must therefore be a little higher for the bulk chemicals than one would expect to get from the manufacturers, since the latter sell in large lots. You will find these companies ready to give very favorable quotations on 100-pound lots, for the bulk chemicals.

Calcium sulphate, or *gypsum,* is supposed to be easily secured through local fertilizer merchants in the United States. I have not found this to be true except in limited areas. I have been informed by Mr. L. L. Coleman of the Brown-Miller Pickle Co., Texarkana, Arkansas, that the United States Gypsum Company, 300 West Adams St., Chicago, Illinois, will supply information of the shipping points for this product, upon request. They have plants at Sweetwater, Texas, and Gypsum, Ohio, among others.

Sodium nitrate (Chile), potassium chloride (muriate of of potash) and *ammonium nitrate* may be secured through local fertilizer merchants. However, the supply of these is not yet certain. The Arkansas Fertilizer Company, Little Rock, Arkansas, is in a position to supply these chemicals.

Magnesium sulphate, as Epsom salts, may be secured from any drug company. McKesson and Robbins, Inc., Chicago, Illinois, and the Baugh and Sons Company, of Baltimore, Maryland, are two companies suggested.

above, sell another type, which should be satisfactory. It is just as satisfactory to use any type available. The reader may contact any chemist in his neighborhood, and secure information regarding the use of such testing papers. Litmus paper will not do. The kind to use is one that will register the *p*H between 4.0 and 8.0.

The F. W. Berk and Co., Inc., New York City, used to handle potassium nitrate, under the trade name of Potnit.

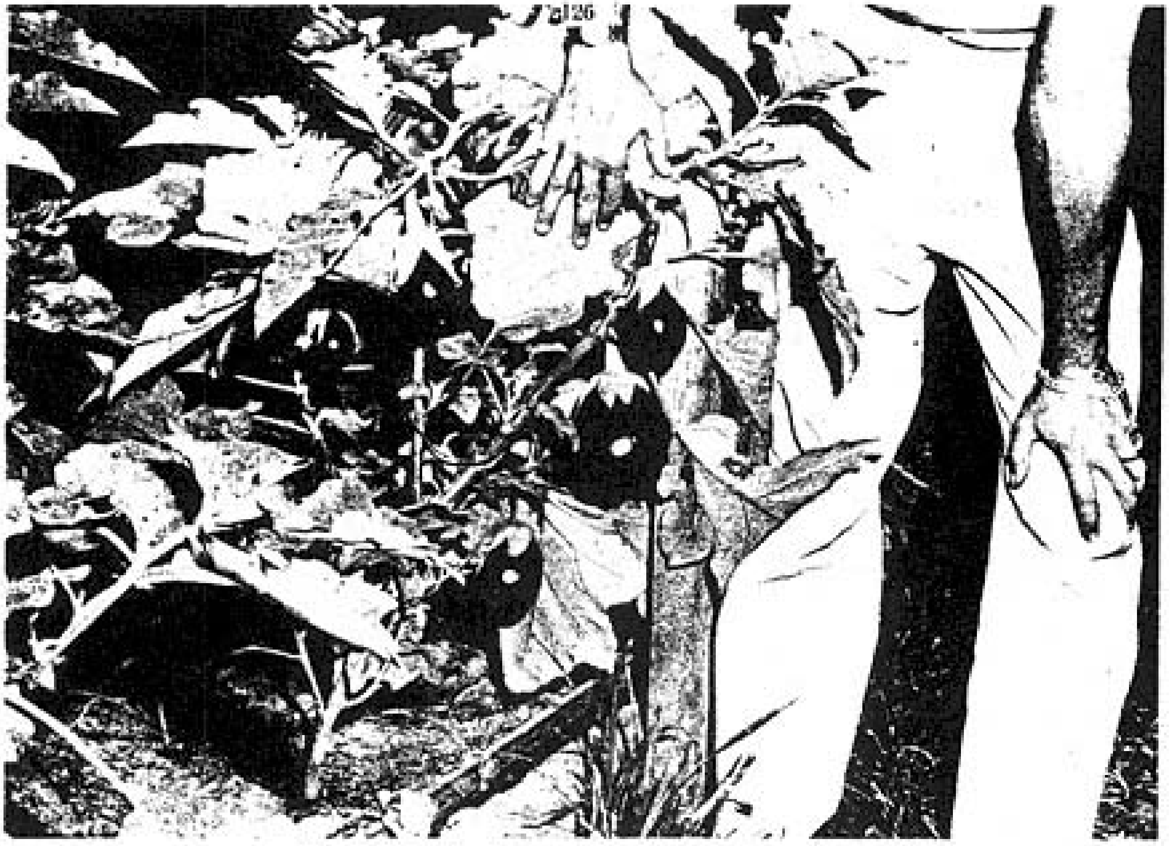

ILLUSTRATION 6. A group of five fruits on an eggplant.

It is possible that they are now in a position, since the war, to continue this service.

All in all, the distribution of fertilizer and chemical manufacturing centers has changed so much during and since the war that it is difficult to find them. The reader may uncover sources near his home, through the local Chamber of Commerce, in many instances.

The Hydroponics Distributors, Inc., P. O. Box 191, Little Rock, Arkansas, is being organized to contact manufacturers of those chemicals used in hydroponica, and to serve as distributor to operators in the United States. This will be of inestimable value to small as well as large operators, since they will be in a position to have their needs supplied in a single order. It should save considerable shipping and time loss. Fertilizer companies furnishing suitable fertilizers for hydroponica will find an outlet for their product through this same channel.

The Dow Chemical Company, Midland, Michigan, furnishes *magnesium sulphate*.

Armour and Company, Chicago, Illinois, supplies *ammonium sulphate* and *potassium sulphate*. Branch offices throughout the world.

II. Special Apparatus

Only two pieces of special apparatus are required to operate the Spessard unit type of hydroponicum. These are a glass graduate, which any druggist will supply, and an acid indicator. I use at the present the Alk-Acid Tester, sold by the Fischer Scientfic Co., of Pittsburg, Pennsylvania, and St. Louis, Missouri. Greene Brothers, Inc., mentioned

CHAPTER 10

Growing For Home-Use and Profit

Under the above caption we will consider the economic aspects of the garden crop as a whole. To grow plants profitably the operator of a hydroponicum must not only succeed in raising a crop but he must also dispose of it. Disposing of it requires in turn that he crop it carefully, grade it, clean it, transport it, have a ready buyer, a satisfied consumer, and a profit. What is required to grow the crop was covered in Chapter 6. But planning when and what to grow, in order that a profit may be had, is something many a gardener and farmer cannot figure out. So will it be with those who approach carelessly this business of hydroponics.

Then there is also the problem of costs; financial support in beginning such an enterprise. Since these are encountered first, let us take them up first.

I. Construction and Operational Gosts

I think that the best way to introduce this topic is to give an example from my own experience. My present plant consists of five full UNITS (see Chapter 5 for definition) comprising 1,000 square feet of growing area. These UNITS cost anywhere from $18 to $70 each. The difference is due to the fact that two of them I poured myself and took advantage of opportunities for buying materials cheaply, while three were contracted for. When the latter is done the contractor's profit, labor, and materials combine to make the cost high. This will of course vary similarly from place to place. There is little to go on for comparing costs of constructing tanks for the various systems used, except to say that it costs approximately twice as much to construct a V-bottom tank used in the highly mechanized systems as it does to construct the flat-bottomed tanks used in the others.

The operation costs for running the hydroponicum proper for the 1,000 square feet, from April 1st to July 15th, were:

Measuring out and mixing the chemicals, 8 hrs.	$ 8.00
Opening and closing drain nipples, 8 hrs.	8.00
190 lbs. of chemicals	15.20
12,500 gallons of water	5.00

Filling tanks is done while other things are being done, such as pruning, taking a meal or tying up tomatoes. These are not chargeable to hydroponics cost. If the operator himself will count his profits as his own labor cost, labor being considered an item when it must be bought, the $16 would be deducted from the above. If the operator is investing money only, and expects to have the hydroponicum operated by hired labor, the $16 would of course be included as overhead.

To make the illustration complete, this particular crop of tomatoes sold for $318 on the local market. In other words, the hydroponicum itself was paid for by one crop of tomatoes. This same area can be used to raise at least two other crops in one year, with outside growing weather. One of the units, operated the previous year for a full season and which cost $38 to construct, netted two crops of tomatoes and one crop of beans, $116 for the 200 square feet. This year, the same unit netted $120 for a single crop.

The first cost—the construction cost—of a UNIT is, let us say, on the average, $55. That area has the productive equivalent of 12 areas of ordinary garden space. Each year the garden has to be plowed, or spaded, and repeatedly worked until planting time, perhaps several times, and kept constantly cultivated, weeded and mulched. If all this heavy work of turning soil is considered for one growing season only, and summed up as labor of the hardest kind, it is found that it costs no more to build a UNIT which is good for a hundred years, than to do this hard work for one year. But the telling point is this: In the UNIT, you are sure of a crop. In the garden, the drought or high water may make your labor a loss.

129

130

ILLUSTRATION 7. A section of one unit showing the first clusters of tomatoes, the type of wire supports with loops suspended from the wooden frames above. Other units may be seen in the background. The tomatoes were about half grown. Photograph by Mr. Ray Bruce.

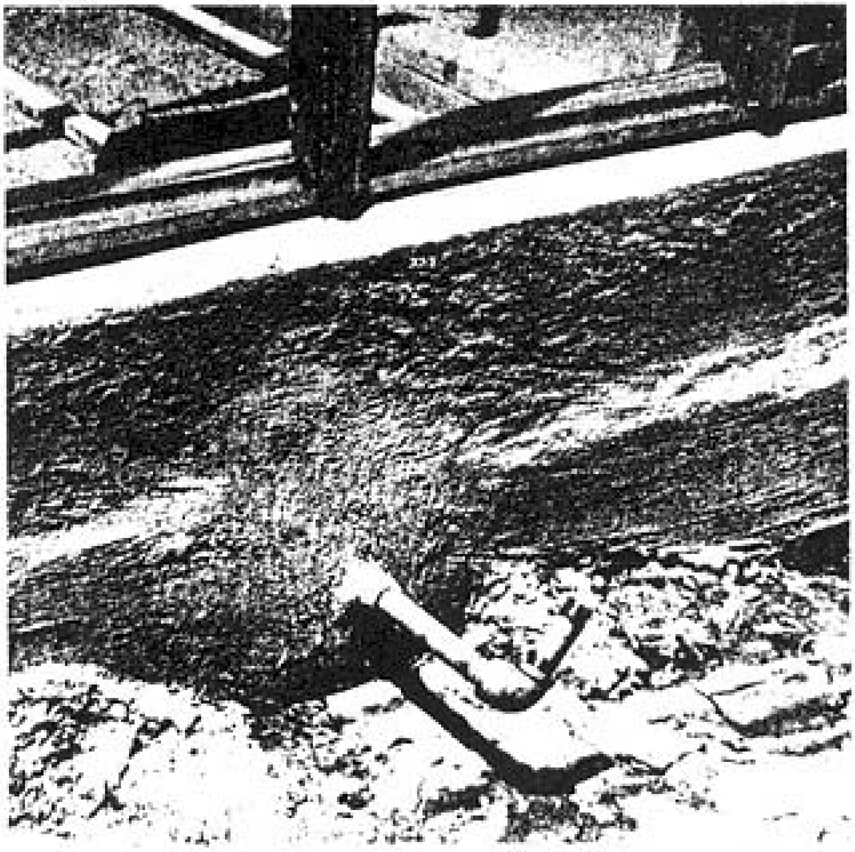

ILLUSTRATION 8. Showing the adjustable type of drain-nipple leading from the drain-channel and out through the wall of the greenhouse in which the hydroponicum was located. This adjustable feature to the Spessard-type of hydroponicum was added by Dr. Charles Deevers, who made the photograph.

131

II. Financing for the Small Operator

If we go on the principle that one should not double his UNIT until he has first learned to operate it, so that it pays for itself in one year of full operation; and if, on the contrary, he is not afraid to double it after he has achieved this success; and if he will refuse to double it after his hydroponicum gets large enough to give him a satisfactory income, or is not producing at the desired point of efficiency, then he may in confidence ask for financial support from his local banker. This would require that he first have ambition, skill, and money enough to build his first UNIT himself and settle down to the task of learning how to operate it. He need not concern himself about high cost of chemicals, if he has to buy them in small quantities during this learning period. Since during this period his one objective is to raise a crop successfully, and determine what crops are profitable in his region. Any banker knows that the larger the operation the better are the opportunities for economical buying. It costs 35 cents for a pound of Epsom salts, if you buy it one place, and 3 cents if you buy it at another, for example. Chemicals are bought generally in 100-pound lots at least, even when operating no more than a thousand square feet.

III. A Successful Way for Securing a Dealer

I operate on the principle, in so far as marketing is concerned, that there are three people concerned in this sort of transaction who must be mutually satisfied to consider the deal complete. Otherwise it is not business, but a racket. Let us illustrate the point by use of a tomato crop.

The three people concerned with a tomato are the man who produces it, the merchant who sells it, and the person who eats it. If the man cannot make a respectable 132 living producing it he is a loss to the others, for he will either quit, or complain about the unfairness of the other two. If the one that sells it cannot make a profit, or if he takes a loss, he cannot stay in business. Thus the grower and consumer are both out of luck. If the one who buys it finds he has purchased a faulty fruit, having neither taste, nor satisfactory appearance, in short has not his money's worth, he feels that he has been cheated, will complain, and go elsewhere to buy. Thus both the marketer and the producer are out of luck. It is strange how stupid people are about such a simple matter. But, since they are, the successful tomato grower will first produce a tomato that tastes well, looks well, that the merchant is happy to sell, and the consumer will buy in preference to other tomatoes, even perhaps at a higher price. People will do this if they feel that they are getting their money's worth. Since he is growing for local consumption the operator does not have to consider shipping qualities of a tomato. He can concentrate on taste and appearance.

This is the arrangement I make with my merchant. I agree to sell him tomatoes or other produce in first class condition on two conditions: first, that he suffers no loss because of poor sales or of poor fruit. I take that loss up by not delivering him more than he can sell in one day, and by delivering only fruit that is salable. I am the one that watches the market, not he. The merchant is therefore guaranteed a 20 percent profit on every dollar of my goods sold, and is not obliged to buy a dollar's worth. The other condition is that I set the price at which the goods are sold. This price is governed by the local market, plus comparative values as between other types offered for sale, and the readiness with which the fruit moves. The merchant is at liberty to buy any other tomato on the wholesale market, but is required to furnish me with separate display space.

133

In other words, the tomatoes are on their own. Experience shows that merchants are more than glad to cooperate on this basis. I have not dealt with chain stores, consequently know nothing of their response to this type of merchandising. It should not be necessary to add that I am particularly scrupulous in seeing that I keep my side of the bargain, that the merchant is to take no loss, and that the complaining customer must be given new fruit without questions asked, in case a defect is reported. In selling 1,500 pounds of tomatoes only one tomato was reported black inside, and only three pounds had to be taken back because of unsalability. This is probably a record in merchandising perishable fruit. It is this kind of merchandising that will knock out the waste which is now so enormous. In fact, it is this waste tax which the hydroponicum operator is in position to collect. No other producer is in that position.

On this basis, if we assume that one man could not operate more than one hydroponicum acre of tomatoes himself, he would have to prepare a set of merchant customers who would be able to absorb approximately 80 bushels of tomatoes daily for a period of 10 days, and from one to 50 bushels a day for two weeks before and after the high producing point. A town of 7,000 people will have about 15 stores handling fresh tomatoes. Most of these could not sell more than one bushel a day, for eating purposes, when the market is high. The largest store would not sell more than 10 bushels. Consequently, either the price would have to be cut or a market would have to be sought elsewhere, or both, if the crop is not to be a loss. In other words, the operator must be a merchant who knows his market saturation point, when it will in all likelihood hit him, and be prepared beforehand to meet it.

134

Retail merchants and growers have for a long time been the victims of what is known as the middleman difficulty. The consumer is likely to jump to the conclusion that the middleman is responsible for the high cost of food as well as its inferior quality. The farmer also complains that the middleman promises one thing, and does another. This leaves the poor middleman in an embarrassing position. He must of course be expected to look out for his own interests. If he agrees to take up a carload of tomatoes at a certain price, and at the time the tomatoes are delivered the car expected is two days away on a railroad siding, either he has to refuse the tomatoes or take a loss. Naturally, he will refuse the tomatoes. Thus the producer is left holding the bag. This sort of condition has characterized merchandising, since the writer helped ship a car of peaches as a boy, only to discover that in the transaction a widow was left holding the bag. It is therefore not without a reason that he has sought for a way to eliminate this wasteful condition which satisfies no one. The evil lies not with people

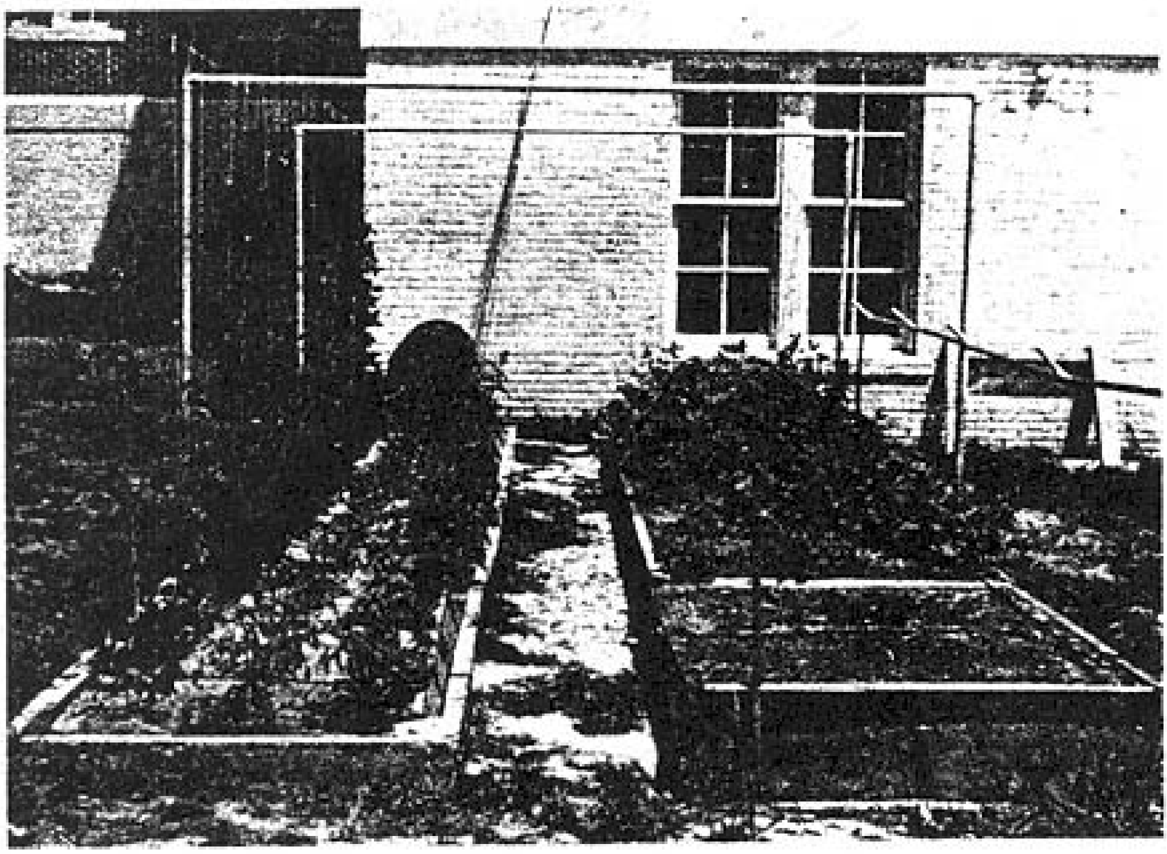

ILLUSTRATION 9. A view of Dr. Charles Deevers' Hydroponicum, located at Mississippi College. The unit on the left is the Spessard-type; that on the right, the Gericke type of hydroponicum. Photograph by Dr. Charles Deevers.

so much as with the system. Once we succeed in producing perishable food at the point where it is consumed, all over the world, the vicious system of present merchandising waste will disappear, and there will be more profit at the production end. This is not theory. It is the report of an actual performance which may and must be duplicated in every small and large town in the world.

IV. The Family Hydroponicum

To be really practical, a hydroponicum should be of the sort that can be readily adapted to the production of food for a family. In the last section it was urged that growing a garden is actually more expensive, the way gardening is done now, than operating a hydroponicum. The difference may be stated succinctly. The old way of gardening is done in sweaty overalls; the new is done in clean lounging clothes. The old confirms the barbaric belief that sweat and toil are necessary virtues to true happiness; the new subscribes to the gentlemen's philosophy that unnecessary sweat and toil are an aesthetic abomination.

All of us are gentlemen at heart. Now is the time to be one, in the home hydroponic garden.

A. size required. If the family is small (not more than three persons) the tin-can method (see Chapter 6, Sec. IV) may be used to advantage. The initial cost is low, there being no other expense involved than that for providing paint to cover the cans, and the chemicals. The chemicals, if the bulk ones are bought in 100-pound bags, will cost around $25, but will last several years for a small hydroponicum of cans.

If the family wishes to can carrots, beets, corn, tomatoes and the like, for winter use, a larger hydroponicum would be necessary, and a UNIT or more should be constructed. To be conservative, you may count on 200 square feet of tank space (actual growing space) as equal to at least 1,600 square feet of garden space; and may, according to locality and skill, be made to equal 2,400 square feet of garden space in productivity.

B. crop plans for unit. The only examples I can give are from my own hyproponic garden in a locality where three crops on the same UNIT are certain during the period from March to December (some things being kept in the sand bed over winter), and where five crops, when accurately timed and spaced, are possible. The examples follow:

A certain UNIT, let us call it No. B, had tomatoes, with flower buds showing, transplanted to it April 1st. It went through two light frosts, the support frame being covered with newspapers. The crop was 570 pounds of tomatoes of useful grade. The UNIT was cleared and sterilized July 3rd, washed July 4th, and replanted in giant Lima beans, July 5th. This crop lasted until November 13th, and yielded 58 gallons of beans in the hull. Onion sets were planted deep in the sand on November 14th, and were mulched with compost for winter, after coming up. Some were used up during the months of December and

January, during the time the sand was not frozen. In February, a second set of onions were planted in between the cross rows of those already beginning to turn green again. By the middle of March these were coming through the sand, and the winter crop was ready to sell. The second crop of onions was out of the sand on April 12th, when the UNIT was again sterilized, and tomatoes with flower buds showing or open were planted in it April 15th, after frost danger had passed. The onion crops yielded a little over 5,000 spring onions, with five-inch-long tender and sweet bodies. Thus this UNIT, as planned, grew one crop of tomatoes, one crop of Lima beans, and two crops of onions, in a 12-month period.

On another UNIT, by beginning in September, two crops of onions were raised over the autumn-winter period, a third in the spring, tomatoes in early summer, and Kentucky Wonder beans after these, making a five-crop rotation in one year on the same UNIT. These examples should be sufficient to indicate the possibilities.

Those who live in regions where to get one crop is all that is to be expected, because of limited temperature and light, will of course not be interested in rotation, but in growing several things at the same time, in the one UNIT. The following suggestions may be helpful. Any good book on gardening will give information[138] on what grows best with what. This is not a peculiarity of the hydroponicum but is inherent in the plant's nature.

Tomatoes may be grown in the same UNIT as used for potatoes, but the potatoes should be planted near the surface of the sand and covered with straw or leaf mulch and kept moist, so that the potatoes will form under this rather than in the sand, proper. Or, sand may be heaped up around the potato stems, and held in place by a wooden frame set on the sand.

Corn and eggplant do not grow well together. Celery is a special crop, requiring less phosphorus than tomatoes and more calcium, potassium and nitrogen. The *p*H for tomatoes and most other crops should be around 6.5 or lower, while that of celery would be above this. Thus celery will not do well with other plants. It will go to seed. In general, you may plant the following in the family hydroponicum: Cabbage, beans, peas, lettuce, carrots, tomatoes, beets, cauliflower, onions, potatoes, sweet corn, and strawberries, if you are in the colder regions. In the warmer regions, where growing plants separately is more easily done, because not all of the vegetables need to come in at the same time, okra, black-eyed peas, peanuts, eggplant, butterbeans and melons may be added to the list.

In all cases, of course, care must be taken that no plant shades another. Some will do better than others, when grown together, but the objective being to feed a family rather than to produce bumper crops, one must be satisfied with this limitation if only one UNIT is available. Experience alone, as in a garden of ordinary type, teaches one the really fine points of individual preferences in food by different plants.

Perhaps it should be[139] emphasized[140] once more that some plants simply will not thrive in extremely hot weather over a prolonged period. Only experience will tell you what these are. Although much sunlight is needed for good growth, when that becomes too intense, and the temperature reaches the high nineties or goes over the 100 mark, efficiency on the part of the plant stops, and in some cases drops too low for its survival. The reasons are too technical for discussing here; but knowing this is of practical importance. For it is little use to attempt to grow plants under conditions too far removed from those naturally

ILLUSTRATION 10. Another view of the bean crop shown in Illustration 2, showing in addition a portion of one feeding-tank which is placed between two 25-foot growing-units. In the foreground, one of these is seen planted in cauliflower. The temperature at the time the photograph was taken, was 110 degrees F. Neither the beans nor the cauliflower had gone through a rain. *Photograph by Dr. Charles Deevers.*

required by the plant. There is a limit, in other words, to what a plant may be expected to do.

It may be of interest to know that growing "roasting ears" in the home hydroponicum will make them cost around five cents apiece. But that is about what one has to pay for them at the store. In the frozen package they cost around 15 cents each. However, one who has once tasted a hydroponically grown ear of corn, after it has been shucked and cooked immediately in boiling water for seven minutes and no more, will be willing to grow his corn thereafter that way, even if he has to pay 25 cents a pound for his chemicals. This is admittedly comparing the incomparable.

Finally, if it is cost that bothers you, sell yourself your produce at retail prices, since that is the way you have to buy, and you will find your hydroponicum a profit to you, at almost any level of prices.

[141]

CHAPTER 11

The Tanks Are Coming

The first hydroponicum used by man was a broken fragment of coconut shell in which the juice of that fruit was fermented and sampled to the satisfaction of a primitive human palate. This may be stretching a point, since the microscopic yeast plants grown in this early form of nutrient solution were utilized incidentally, though they no doubt contained some vitamins of value.

If the first incentive to grow plants in solution was the irresponsible one of providing a jag, the last is inspired by fears of malnutrition, the high cost of living, the fear of famine, disgust with the present uncertainties and waste of food distribution, and intent on getting those elements essential to the maintenance of a sane and physically competent human race. For the first time in his history, man is genuinely concerned about the prospects for his survival as a species. And this concern derives as much from the world food situation as from concern over atomic warfare.

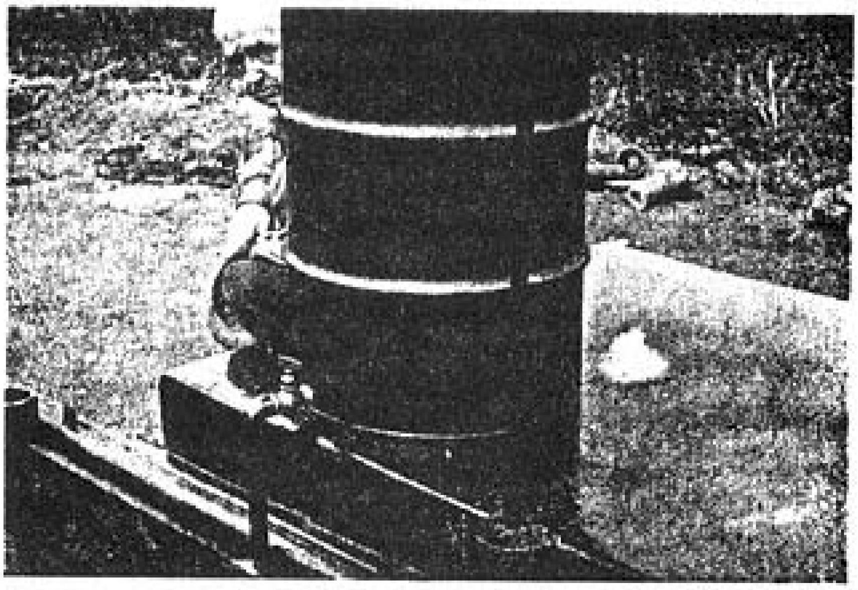
I. Present-Day Interest in Hydroponics

Among the many articles on hydroponics which have appeared in the press recently, three were responsible for bringing to my desk a flood of letters from all parts of the world. They are, in order of the articles published by their reporters, the *Log Cabin Democrat*, the *Arkansas Gazette*, and the *Magazine Digest*. A review of the interests expressed in those letters is impressive.

The foremost interest[142] is in[143] improved nutrition, both for the individual household and the world. "One loaf of bread," writes one, "and a can of condensed milk with fish-head stew for a variety, is our diet for a family of eight. I figure if I can learn this thing they call hydroponics, and I think I can if anyone can, we'll be eating better along this bayou."

Perhaps the following illustrates best the second point made: "Being farmers at heart, my brother and I are eager to take up hydroponics at our suburban home just outside the city of Damascus and, following your footsteps, get to something which might go really far, considering that hundreds here die of typhoid and almost 100 percent of the Middle East population suffer from some form of dysentery. Not counting those, who, like us, are absolutely fed up with choosing between that and a permanganate slow-poisoning diet . . . The world, Sir, is becoming smaller every day and it would be a perfect example of international cooperation if your scientific efforts could be used in far-away Arabia. It will take a lot of such efforts to make a better world."

The president of an air-lines company in Mexico looks to hydroponics as a means of providing his employes, from tropic to desert landing field, with better green food. An official invited to study the prospects for improving meat



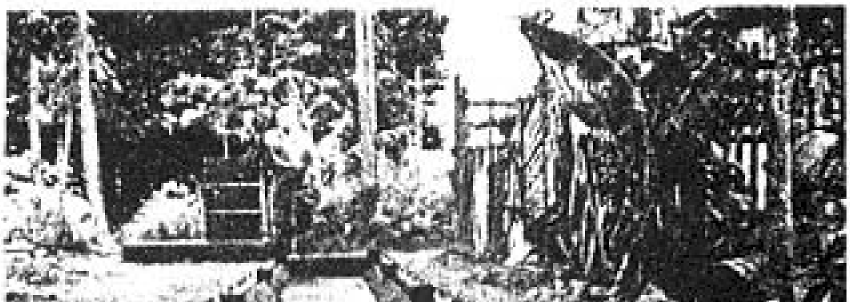


ILLUSTRATION 11. The metal barrel feeding-unit of the "Apolo Spessard-Hydroponicum" at Rio de Janeiro, Brazil, in the course of construction, as modified and constructed by Mr. A. S. Jacobsen, the ingenious gentleman shown in the photograph. Special precautions were taken in this consrtuction to avoid growing difficulties due to insect and microbe pests. (Below) The "Apolo-Spessard-Hydroponico" ready for filling with sand. The solution, in this instance is introduced at the far end, and recovered in the sump shown in the right fore-ground. Photographed by Mr. Alfred Jacobsen.

and other food supplies for the people of Peru wonders if part of the solution of his problem is to be found in incorporating hydroponics into his general plan. In Brazil, Venezuela, Cebu and Nigeria the concern is the same as in Arabia. In Palestine and Australia the interest is in getting control of drought, the great enemy to crops. In Laborador, Canadian outposts, and cold regions where the growing seasons are short it is the desire to get away from the inevitable 144 tin-can meal that causes people to look upon hydroponics as a possible relief. In farming provinces of the far North it is hoped that by this means the canning industry may be made more profitable, and more people employed.

My answer to all such inquiries has been if proper care is taken in planning, and sufficient time consumed in mastering the rather simple details, there is little doubt that each and every one of these needs may be met satisfactorily through hydroponic methods of one sort or another. I believe this to be true, though it is also true that it will take time, good will, money and intelligence. Probably the best results will be accomplished without government aid, since to be successful the economic problems must be solved through accepted economic procedure. Money is not a consideration when a scientific problem is to be solved, or when a political situation must be faced. But if one is to eat out of his own hydroponicum, or buy food from another operator, that hydroponicum which cannot operate within the all-around monetary requirements from producer to consumer must become a disappointment, a white elephant, and a thing to stay away from.

This brings us to the second interest expressed in the letters, namely, that of growing vegetables and flowers for the market. This is inspired by the glowing reports which have been achieved by isolated individuals here and there. It is encouraging to note that there is not a single genuinely crack-pot letter out of the whole. The public is quite prepared to understand the inevitable exaggerations which appear. Only one individual expected to quit his job, turn his few acres immediately into tanks, apply the "perfect formula," allow the plants to fight off their own enemies, if not prune and crop themselves, and himself become rich the first season. When informed, of course, 145 that formulas may be had for a dime a dozen, and that hydroponic perfection is not yet of the magnitude to be found only in paradise, the inquirer very sensibly gave up his premature ambitions.

If the letters represent a fair sample of public opinion, the public is definitely past the wild-eyed stage of hydroponics, and is prepared to look at the thing sensibly. People are not asking so frequently, "How much profit can I make out of it? How much does it cost?" But they are asking, "How do I go about learning how to grow plants this way?" There are two groups interested in hypdoponics from the commercial standpoint. One is the individual who wishes to build gradually in his home town, unit by unit as it pays for itself, until he has a good livelihood, and who expects to operate no more than he can handle himself. The other group consists of organizations interested in cooperating for marketing purposes, but having the individual operators work, plan and maintain their hydroponic establishments independently. In other words, it is the individual grower on his own as far as producing is concerned, but all united into a sort of union for pooling their information.

The latter groups are convinced that this can be done economically, or are at least inquiring if this is so, and that if so, believe that their community's basic wealth will, through adopting proper hydroponic methods, become gradually more stabilized than it is at present. By basic wealth they mean, I take it, individual and community health plus increased productivity of the local land area. The interest is primarily in permanent community building and against mutual community exploitation. It is as though these people have all read and hope to disprove the passage, "Each one strives against, not with, his brother. Thus each strikes a wretched bargain 'gainst himself, and knows it not." 146

The third group consists of elderly and retired people. They are the people of the world who have met up with those years when to be able to work is joy. It is their dream, a dream that also is my own, that through this simple device, this little thing we call a growing-tank, the whole world might come more quickly into possession of its daily bread; that through it we who differ so much from land to land, yet are so much alike, might find a way to help each other even as we help ourselves; that there can be small fear of war once all peoples are well fed.

He who works now for long hours over his little hydroponicum in an "old people's home" sits no more in loneliness. I do not know how well he has succeeded, but he has now the most valuable thing on earth: something to do. It is significant that he should write again to ask, "Is it all right to let some of the others here grow things this way?"

A retired sea captain, writing from a ship as it enters a Caribbean port, insists that hydroponics is "just the thing to keep me from spending my days dreaming of the many ports I've visited, and wishing I were at sea again."

A man of 85 years, who rides a hot bus 300 miles to see for himself what all this is about, finds a new way to exercise his joy in learning. And he tucks his lessons under his arm, rides back home at once, saying before he leaves, "I was once known as 'Celery Jim' up North. I will make a go of this thing. I won't make anything out of it myself, but my grandson will. For I will teach him how."

These are the people who refuse to look backward.

Then we come upon that group of people wise in human weakness–doctors, men and women old enough to earn rest, and rich enough to quit; who, as one said, "never do quite get used to seeing people die"; and who look to 147 their hydroponic garden as a place where they may for a few minutes each day, work out in the open with the lovely things of life, and forget. They have a million patients whom they wish to teach, after they have learned themselves, in order to keep those neurotics from having to spend hours on the couch of a psychiatrist.

It would be a bit impertinent to suggest that either of these groups is the more or less significant sector of the body politic. Together, they show that interest in hydroponics is worldwide. They represent significant portions of the world population. Their interests may therefore not be ignored.

But, although much publicity has been given hydroponics during the past two decades, a publicity which no doubt accounts in part for the present response, the most significant fact is that little of the vast amount of reliable information on hydroponics has been put into a form which may be consumed by the nontechnical public. The public is not stupid and is not moronic. But it is frightened at the sight of unnecessary technical verbiage. Also it is rather fed up on soft-coated hydroponic pills, and has become slightly disappointed and suspicious. Yet, in spite of this, we have the response recorded above. It was to help fill the gap between our technical achievements in hydroponics, and the common hope for using the scientific knowledge available, that this book was written.

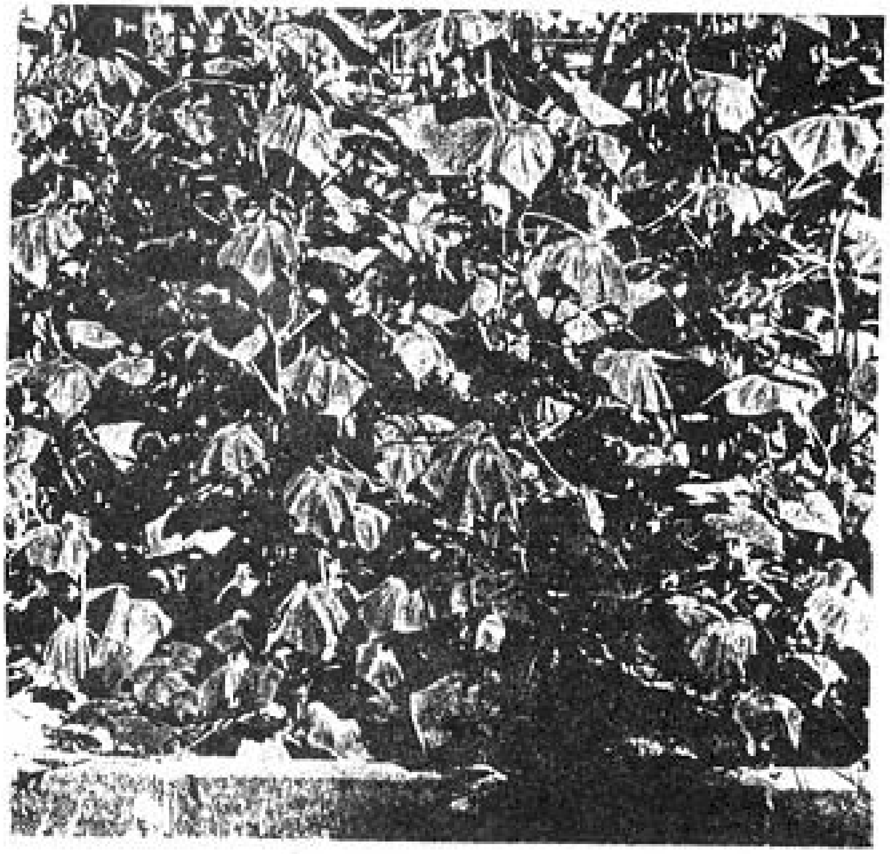

ILLUSTRATION 12. A section of one unit showing cucumber vines growing as a second crop after harvesting tomatoes. The plants had just passed two weeks of weather when the temperature reached 105 degrees F. daily. The vines were not protected from the sun, and thus the leaves show some wilting at the time the picture was taken. This set of vines produced a fine crop of cucumbers during September and October.

II. THE HYDROPONICS FUTURE

This is not a prophecy. It is a plan. It is a plan in merest outline. To fill in the details, one man would be incompetent. The plan is based on the assumptions that the first step in making hydroponics generally useful has now been successfully taken, and that people the world over are ready to adopt hydroponics as a permanent method for growing much of their food. 148

Hydroponics is here to stay. It has already been established as the sensible way to grow greenhouse produce. It has been adopted as a means for growing vegetables by the army, which is in a financial position to use the more mechanically refined techniques. Many individuals, either 149 army-trained or having the technical background and financial backing, are at present engaged in hydroponics successfully. But all this is but a drop in the bucket. It remains to teach the interested public how to equip and operate a hydroponic home garden, and also those who wish to grow plants for the local market. It might take 200 years to bring hydroponics into general use, but it may be done much sooner if we plan intelligently. It would seem that, granting the assumptions stated above, what therefore remains to be done is essentially as follows:

First, hydroponic information must be gotten to the public through our regular channels, namely, the press, radio and the schools. Second, a liaison group must be trained to translate the technical details worked out in the experiment stations and plant physiology laboratories into the practical language of truck farmers and gardeners. Let it be emphasized at this point that the public cannot in reason insist that a research man be an investigator and at the same time what he is pleased to term "practical." The most practical thing that is ever done, I submit, is what the laboratory man is doing. But, it is true that someone must act as go-between for him and the final applicator of his work. In other words, it is not a question of what is or is not practical, but one of language. It is also a matter of efficiency. With this out of the way, let us go on.

Third, young couples, interested in founding a home in the suburbs or countryside, and at the same time intelligently interested in food production as a livelihood, must be given the same chance in training as we now give to the more orthodox phases of agricultural training. I am not at all prepared to endorse the idea of giving this training below the college level at the present stage of develop- 150 ment. The course, as I see it, would include eight hours of general botany, eight of general chemistry, eight of plant physiology, and sixteen of actual work with operating a hydroponicum. This latter would mean growing two crops through two seasons successfully, after constructing the hydroponicum itself. Four hours of economics, including principles of marketing and financing, would be added. This program of education would do two things for the individual: It would give him a tool for making a living, and leave him time enough to get a real fine arts education also, which in turn would be his equipment for living. To give this training to people of high school age would in all likelihood degenerate into a system of giving easy credits, probably the most pernicious disease of our American educational system.

Fourth, the building of hydroponic tanks must now be started by interested individuals first in the home garden; next in the home-town outskirts for truck farming to produce for those without a home hydroponicum; next, large-scale hydroponica, individually controlled and operated, but associated for large-scale marketing in near-by cosmopolitan areas, and within a few hours of hauling distance.

These four steps are intended secondarily as part of the food defense of a country in case of atomic war. It will be much more difficult to destroy an enemy's food supply if that food is grown in scattered areas and at the points of consumption. Even though the main transportation system of the nation be knocked out, people will be able to feed themselves from the local larder. It is not a question any more of national or individual finance. In an emergency such as atomic warfare, money saved will have much less nutritional value than a carrot in the hydroponicum. And in those places where the people are not killed it would be stupidity par excellence to be caught alive, and without one's own hydroponicum, after a bombing disaster. It is not my intention to be facetious at this point. I am not counting on the inevitability of atomic warfare. But, if such is the inevitable, then it is now time to prepare against it. And the hydroponicum is the cheapest instrument we have for this purpose. The distribution of hydroponica would be such as to extend the present limited growing areas into mountainous and desert regions. In Chapter 5 it was shown that if the annual rainfall is properly conserved in even the driest part of the globe a definite amount of food may be grown in those regions for supporting human life. This will undoubtedly be done.

The fifth and final step would be, of course, the conversion of farm and grazing areas into hydroponica. This must be a long time in coming. But if we intend to plan at all, we might as well make our plans worldwide, and with an eye to contributing to world peace by striking at the heart of one of the causes of world war. We forget, sometimes, that the human race has never yet had three square meals a day. People, like cows, must have a full stomach regularly, to long remain contented. And contentment is a consequence of great and successful planning.

We will turn our farms eventually into hydroponica for several reasons. First, we will thereby conserve our "fertilizer" supplies. The way we now use these is a waste tax which cannot be supported indefinitely. Second, our present plans for water conservation takes into account only the prevention of floods, loss of topsoil, maintenance of recreation areas, and the water supply to large industrial population centers. As a matter of fact, except in the desert areas, practically all of this controlled water becomes river and stream again without being metered out first for plant growth. This will be corrected, once we become hydroponically built up as a nation. Third, we will insist on having our chickens and cattle fed from hydroponically produced food on the spot, because this will be done more cheaply than is now done by our roundabout methods, and because the meat, milk and eggs will be thereby more nourishing. Fourth, we will go to hydroponic farming just to get out of hard labor. Man has desired, more than any one other thing, a way to avoid sheer toil and sweat. He can stand the tears, but too much hard work gets him. Hydroponic farming wipes out most of this.

Let us see the picture as it will look to the world after we have done those five things.

Food will be available all the time, everywhere.

Cattle and chickens will eat their forage from hydroponic mangers and feeding beds, the whole year around.

Harvesting of forage crops will be eliminated. The billion dollars spent now on machinery for harvesting, curing, baling, and hauling such feed will be spent to better purpose.

The attack on insect enemies and parisitic fungi will be planned differently, and will be more successful.

Plant physiology departments will become the bureaus of food production, and will provide the basic plans for distributing and feeding people, livestock and poultry in a unified program of food defense, either for peace or war. The people, of course, may choose what they will eat and, to a certain extent, where they will eat it. But the downright independent, through-and-through individualist in such matters, the one to whom cooperation and any semblance of coordination are intolerable, that one must be permitted to go fishing, or must be driven with the sheep, cows and hogs to his segregated feeding trough.

It will not be long until the incompetent will not be allowed to grow food for other than their own consumption. To farm for profit will require proper licensing as required now for teaching, doctoring, and preaching. Farming for profit under license requirements is preferable to farming without profit, as millions now do. The high cost of ignorance is reflected in present low standards of eating throughout the world, in the malnutrition due to lack of essential elements because of improperly grown plants for food of beast and man, and in the awful waste of food transportation, food storage, and political blundering. This will be largely done away with, after the hydroponicum is established as a part of the equipment in households around the world. And it will not be difficult to do so, for once the missionary, the teacher, the county agent and, in time, others get going on this thing, people of the world will catch on quickly, and will make their own tanks out of any and everything handy.

Below and above the giant dams being built for watershed control, along the main and tributary streams large-scale hydroponic systems will cover the now unused areas, to be operated privately, in cooperatives, or under government control, for providing canning and freezing units with the food-storage requirements, which will not be as necessary then as now.

ILLUSTRATION 13. A mess of Lima pole beans, grown by Dr. Charles Deevers in his Spessard-type of hydroponicum at Clinton, Mississippi. Photograph by Dr. Deevers.

Paradoxically, more people will be engaged in growing plants than are now. Most of them will be growing for their own use, or for profit. The countryside will be more populated, and the lake resorts will be home, rather than a place to visit. For it will be more pleasant to live in the country, as well as profitable. While the hard labor and the hired labor will be eliminated largely, the delightful labor of tending the growing plant will remain. And this must in the end be of inestimable aesthetic and spiritual value to the whole nation that suceeds in going hydroponic.

The mule, the plow and harrow, the tractor, all are on their way out.

The tanks are coming.

ILLUSTRATION 14. Showing the feeding arrangement for the Spessard-Hydroponicum as used by Mr. J. M. Hammock, a successful operator in Corpus Christi, Texas. The tomaot plants shown were six weeks old at the time the photograph was taken.

GUIDE TO

Radio Control

THEORY
PRACTICE
and
OPERATION
of
RADIO
CONTROL

WINSTON PUBLISHERS Printed in U.S.A. © 1959

INTRODUCTION

There is a mistaken idea that radio control is difficult, that one must bone up on the science of electronics in order to operate an RC plane, boat, auto, or what-have-you.

The truth is that anyone can install and operate successfully the radio equipment now available at the hobby shops using just the manufacturer's directions. But for the newcomer to avoid commonly made mistakes and misunderstandings inherent to any field where written directions must be interpreted and applied, it is desirable that the beginner benefit from the advice of fellow hobbyists already successfully started, and quickly obtain a little first-hand experience with the practical fundamentals.

Unfortunately, this isn't always possible. When he finds such a course impossible, the beginner naturally turns to books and magazine articles. The books usually are written by some electronics expert who provides plenty of theory and a minimum of practice; magazine articles are scattered piece-meal over a period of years.

This booklet is intended, therefore, to give the practical kind of information that will assist the interested reader in building and operating his radio control model. While the practical side of RC modeling is emphasized, enough background information about radios and equipment is included to round out the picture.

However, the booklet is not limited to the beginner. After the thrill of the first few successful operations, the hobbyist comes up against the problem of maintaining reliability. The information herein not only will help you get into the air, but it will assure you satisfactory operations month in and month out.

Happy flying!

Chapter One

THE PICTURE

Before the Federal Communications Commission a few years ago granted, for the (among other) purposes of controlling model planes, boats, etc., by radio, the examination-free (Citizens' Radio Service) frequencies of 465 and 27.255 megacycles, this "RC" hobby was limited to licensed amateurs or "hams." The hobbyist could build his own model provided he was willing to have some radio amateur operate the controls for him. Model builders lucky enough to possess "tickets" and who, consequently, could operate their own models—such as Jim Walker, Walt Good, Joe Raspante—became famous because they were masters of something that was mysterious, presumably costly, and not available to the rest of us.

Today, radio control is simple enough for any moderately skilled builder to master and, although more expensive than other types of modeling, it is within the financial reach of many hobbyists. The combined cost of plane, engine, supplies, and complete radio equipment may be less than $50. By assembling his own transmitter and receiver from parts, the builder may realize further savings. On the other hand, elaborate equipment for operating three, five, or even more controls, may be purchased at prices from approximately $150 up.

For prices and descriptions of the various radio control outfits on the market, the reader is referred to the advertisements appearing in the current issues of the various model airplane magazines. Technical, descriptive matter about their products may be obtained by writing to the manufacturers listed in the advertisements.

While the two frequencies set aside for us modelers, as mentioned above, are loosely described as "license-free," they actually are only "examination-free" and you get your license by filling out and mailing to, or bringing to, the nearest FCC field office, the printed form 505 you found with your new radio equipment when it comes from the factory. This application form also is available from the FCC. All the transmitters and receivers currently advertised in the model plane field operate on these convenient examination-free frequencies.

In its simplest form, the typical radio control outfit consists of a transmitter, a receiver, a sensitive relay (usually part of the receiver, although it is sometimes mounted separately from the receiver), and an actuator (usually an escapement device), for moving the control surface or surfaces. A signal sent out by the transmitter is detected or picked up by the receiver; this signal causes a change in the amount of electrical current flowing through the receiver's tube. It is this current change that causes the relay to operate—either opening or closing the relay, depending on the type of receiver. The relay then closes a contact to complete a circuit that permits electrical current to flow to the actuator which moves the rudder right or left to steer the plane or boat. The most typical actuator, the escapement, is an electro-mechanical device. When energized by the electrical current, its magnet causes a revolving arm to be released to provide the physical force necessary to move the control surfaces. This force is available from a twisted or wound-up loop of model airplane rubber.

The overwhelming majority of radio control models are flown by means of a single control, the rudder. The capabilities of rudder-only control should not be underestimated. Possible maneuvers range from simple turns and stalls, to wing-overs, Immelmans, rolls, lazy eights, loops and spirals. With rudder only you can complete the standard AMA rules precision pattern used at contests. Although multi-control planes can do extra stunt maneuvers, such as vertical dives, outside loops, and inverted flight, the lighter, rudder-only jobs have often outpointed far more expensive and complex equipment, even at the National Contest. The 1953 National Contest, for example, was won by a rudder-only airplane.

Escapements may be combined in certain ways, with a single channel radio, to permit limited motor and/or elevator controls. A skilled flier, therefore, can tackle successfully such advanced maneuvers as inverted flight with the cheapest receivers on the market. Multi-channel receivers with appropriate actuating devices do provide a smoothness in elevator control not readily obtainable by other systems and allow precise trimming of the machine while in the air. Rudder only is recommended for beginners.

The usual method for moving the rudder is a self-neutralizing type of escapement. When a signal is transmitted, the rudder is moved either left or right. The rudder will remain in that position as long as signal is maintained; when the signal terminates, the self-neutralizing escapement returns to a neutral or no-control position, hence its name. So the length of the signal, determined by how long you hold shut the transmitter keying switch or button, determines the amount of turn and bank imparted to the airplane. Upon the next signal, this type of escapement will move to the opposite position. For example, if right rudder had been applied first, the next signal would produce left rudder. This sequence makes it necessary at times to pass quickly through the unwanted rudder position, to obtain or to continue turn in the desired direction. This is easily accomplished because transmitting a signal, which is instantly terminated, does not give the rudder time to affect the flight path of the airplane.

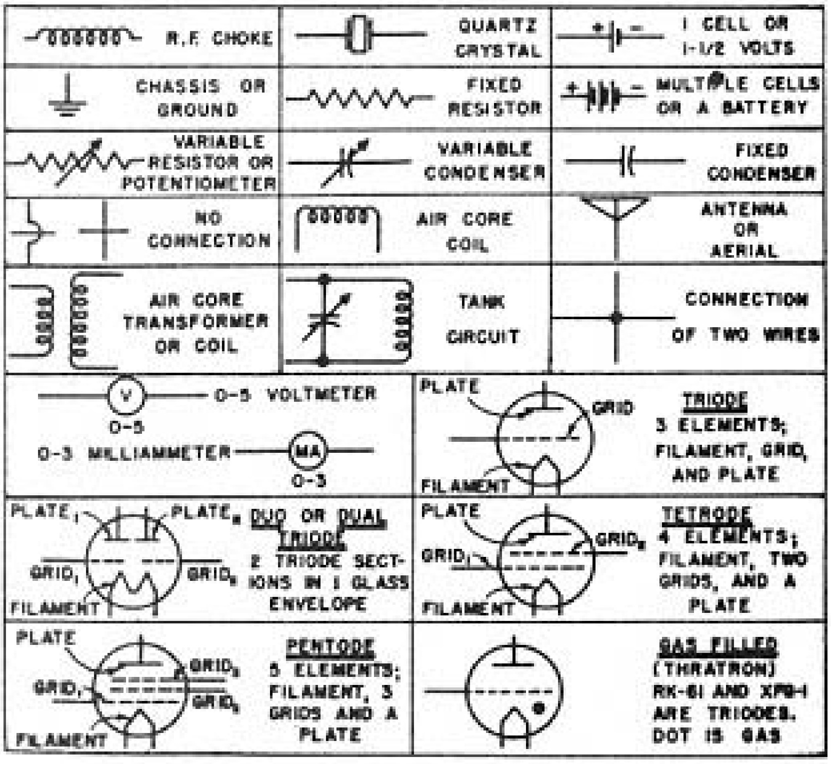
One that allows either left or right turn at will, and possible use of a second control, is the compound type of escapement. This device is designed to give one rudder position—let's say right rudder—upon one signal impulse from the transmitter, and to give opposite, or left, rudder, upon two signal impulses. Three quick signals close an electrical contact in the compound escapement, causing the auxiliary escapement to close and move the additional control. Various electric-motor driven devices or servos may be substituted for escapements. Modelers have devised variations of this basic system for obtaining precise control in the air, but always at the cost of more things that can go wrong.

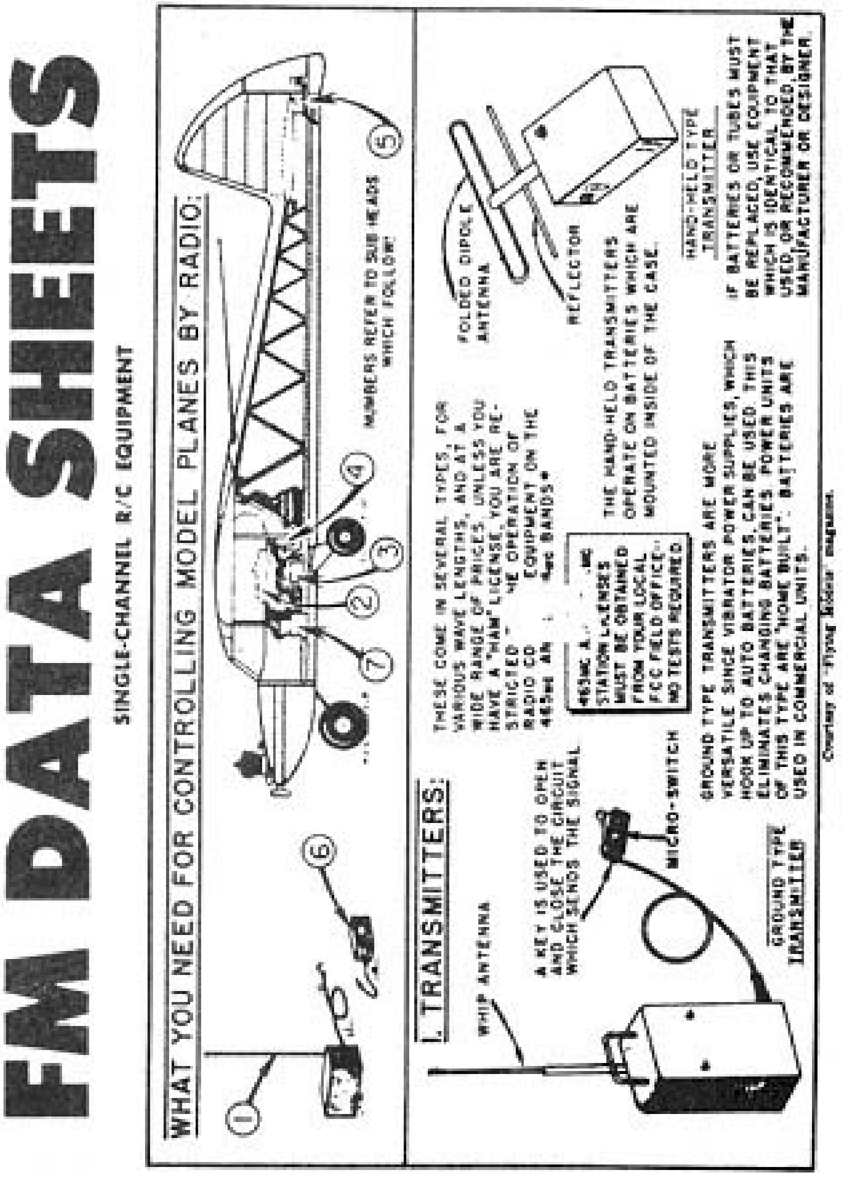
By the addition of an electronic or mechanical pulsing device—sending out a steady flow of signals, and using a magnetic type of actuator which slaves accurately following those signals—a proportionate type of control may be had. It is possible to vary the rate of the pulsing, or the length of the pulses, or both simultaneously, to obtain multi-control effects with a single-channel radio. However, such systems require much home building of equipment, although useful devices are beginning to appear on the market.

Most model radio operates on a straight carrier wave (CW). This wave is transmitted to the receiver only when the transmitter switch or button is closed. However, some equipment, particularly the multi-channel, operates by tone modulation. With these transmitters a steady carrier wave is sent out as soon as the unit is switched on. Then, when the operator closes a switch or button, a tone is imposed upon the carrier wave. A single channel receiver for tone operation responds to a rather wide range of tones but multi-channel receivers, by means of filters or reed banks, apply particular tones to particular control movements.

From one to six channels are used to work elevators, rudder, and engine. For example, one channel might be used for left rudder, another for right, one for up-elevator, one for down, and another for engine. With a compound escapement or other escapement-servo combinations, two channels adequately operate as many as five controls. Multi-channel set-ups, numerous controls, complex airplanes, gadgetry, etc., should be left to builders with a good foundation of flying experience.

Large, heavy, and powerful airplanes are not necessary in order to carry radio equipment. For the biggest and heaviest receiver, complete with batteries and actuators, a plane with approximately six feet of span, with an engine displacement of .35, grossing at the most 7½ pounds, is sufficient. Five-channel radios have been installed and flown successfully, including loops, in ships with as little power as an .09 Diesel. Spans of 4½ to 5 feet are adequate, even for most multi-channel radios.





FM DATA SHEETS

SINGLE-CHANNEL R/C EQUIPMENT

WHAT YOU NEED FOR CONTROLLING MODEL PLANES BY RADIO:

NUMBERS REFER TO SUB HEADS WHICH FOLLOW!

1. TRANSMITTERS:

THESE COME IN SEVERAL TYPES, FOR VARIOUS WAVE LENGTHS, AND AT A WIDE RANGE OF PRICES. UNLESS YOU HAVE A "HAM" LICENSE, YOU ARE RESTRICTED [illegible] HE OPERATION OF RADIO CO[illegible] EQUIPMENT ON THE 465 AR[illegible] MC BANDS*

465MC A[illegible] MC STATION LICENSES MUST BE OBTAINED FROM YOUR LOCAL FCC FIELD OFFICE; NO TESTS REQUIRED

THE HAND-HELD TRANSMITTERS OPERATE ON BATTERIES WHICH ARE MOUNTED INSIDE OF THE CASE.

GROUND TYPE TRANSMITTERS ARE MORE VERSATILE SINCE VIBRATOR POWER SUPPLIES, WHICH HOOK UP TO AUTO BATTERIES, CAN BE USED. THIS ELIMINATES CHANGING BATTERIES. POWER UNITS OF THIS TYPE ARE "HOME BUILT". BATTERIES ARE USED IN COMMERCIAL UNITS.

IF BATTERIES OR TUBES MUST BE REPLACED, USE EQUIPMENT WHICH IS IDENTICAL TO THAT USED, OR RECOMMENDED BY THE MANUFACTURER OR DESIGNER.

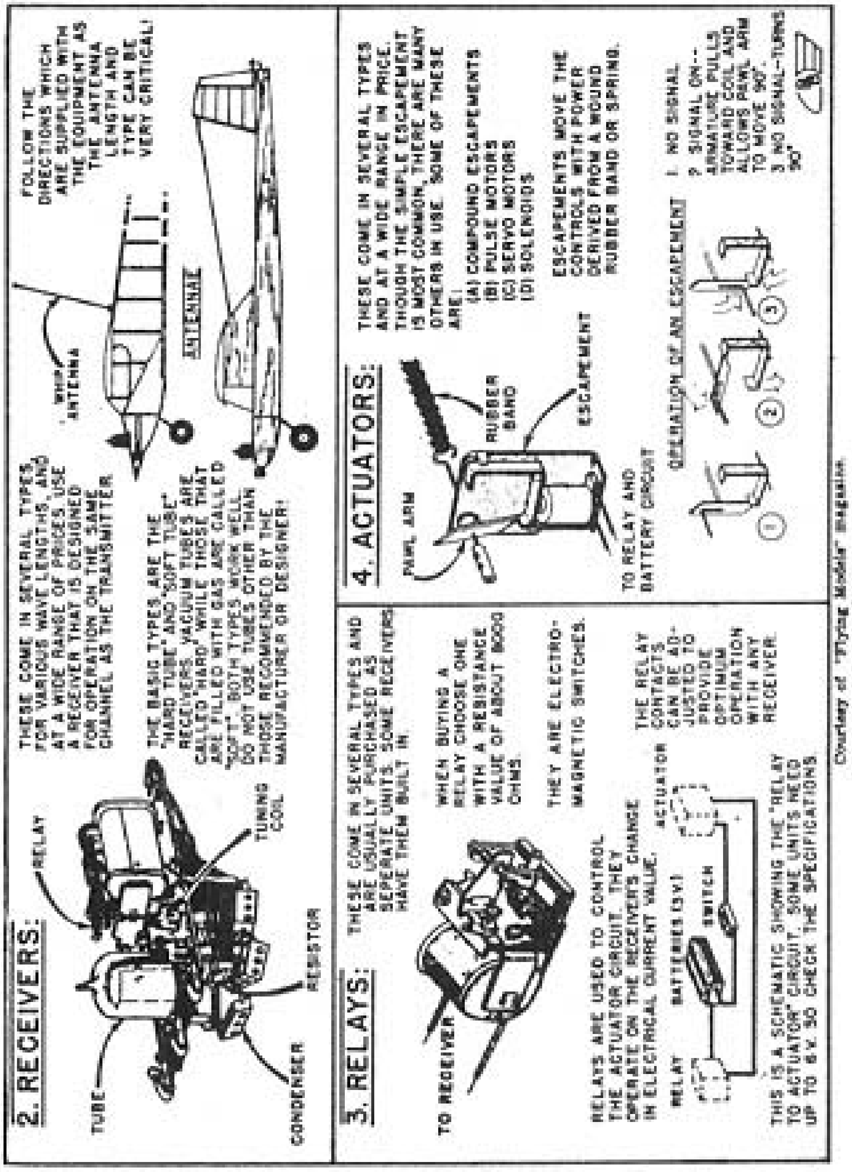
A KEY IS USED TO OPEN AND CLOSE THE CIRCUIT WHICH SENDS THE SIGNAL

Courtesy of "Flying Models" magazine.

At the other extreme, three to four foot planes with .049 Half-A class engines for power, have become very popular. The all round airplane would have between four and five feet of wing, and would be powered accordingly with an engine between .09 and .19 displacements.

Kits of all size RC models are available at your hobby shop. The model airplane magazines publish construction articles and their full size plans may be purchased from the publishers. To a smaller degree, radio-controlled model boats, kits and plans are similarly available.

Which kit you buy, or what magazine plan you work from, depends on the size of your flying area, your work bench, and your pocket book.



THESE COME IN SEVERAL TYPES, FOR VARIOUS WAVE LENGTHS, AND AT A WIDE RANGE OF PRICES. USE A RECEIVER THAT IS DESIGNED FOR OPERATION ON THE SAME CHANNEL AS THE TRANSMITTER.

THE BASIC TYPES ARE THE "HARD TUBE" AND "SOFT TUBE" RECEIVERS. VACUUM TUBES ARE CALLED "HARD" WHILE THOSE THAT ARE FILLED WITH GAS ARE CALLED "SOFT". BOTH TYPES WORK WELL. DO NOT USE TUBES OTHER THAN THOSE RECOMMENDED BY THE MANUFACTURER OR DESIGNER!

FOLLOW THE DIRECTIONS WHICH ARE SUPPLIED WITH THE EQUIPMENT AS THE ANTENNA LENGTH AND TYPE CAN BE VERY CRITICAL!

THESE COME IN SEVERAL TYPES AND ARE USUALLY PURCHASED AS SEPERATE UNITS. SOME RECEIVERS HAVE THEM BUILT IN.

WHEN BUYING A RELAY CHOOSE ONE WITH A RESISTANCE VALUE OF ABOUT 8000 OHMS.

THEY ARE ELECTRO-MAGNETIC SWITCHES.

RELAYS ARE USED TO CONTROL THE ACTUATOR CIRCUIT. THEY OPERATE ON THE RECEIVER'S CHANGE IN ELECTRICAL CURRENT VALUE.

THE RELAY CONTACTS CAN BE ADJUSTED TO PROVIDE OPTIMUM OPERATION WITH ANY RECEIVER.

THIS IS A SCHEMATIC SHOWING THE "RELAY TO ACTUATOR" CIRCUIT. SOME UNITS NEED UP TO 6 V. SO CHECK THE SPECIFICATIONS.

THESE COME IN SEVERAL TYPES AND AT A WIDE RANGE IN PRICE. THOUGH THE SIMPLE ESCAPEMENT IS MOST COMMON, THERE ARE MANY OTHERS IN USE. SOME OF THESE ARE:

(A) COMPOUND ESCAPEMENTS
(B) PULSE MOTORS
(C) SERVO MOTORS
(D) SOLENOIDS

ESCAPEMENTS MOVE THE CONTROLS WITH POWER DERIVED FROM A WOUND RUBBER BAND OR SPRING.

1. NO SIGNAL
2. SIGNAL ON--ARMATURE PULLS TOWARD COIL AND ALLOWS PAWL ARM TO MOVE 90°.
3. NO SIGNAL--TURNS 90°

Chapter Two

TRANSMITTERS

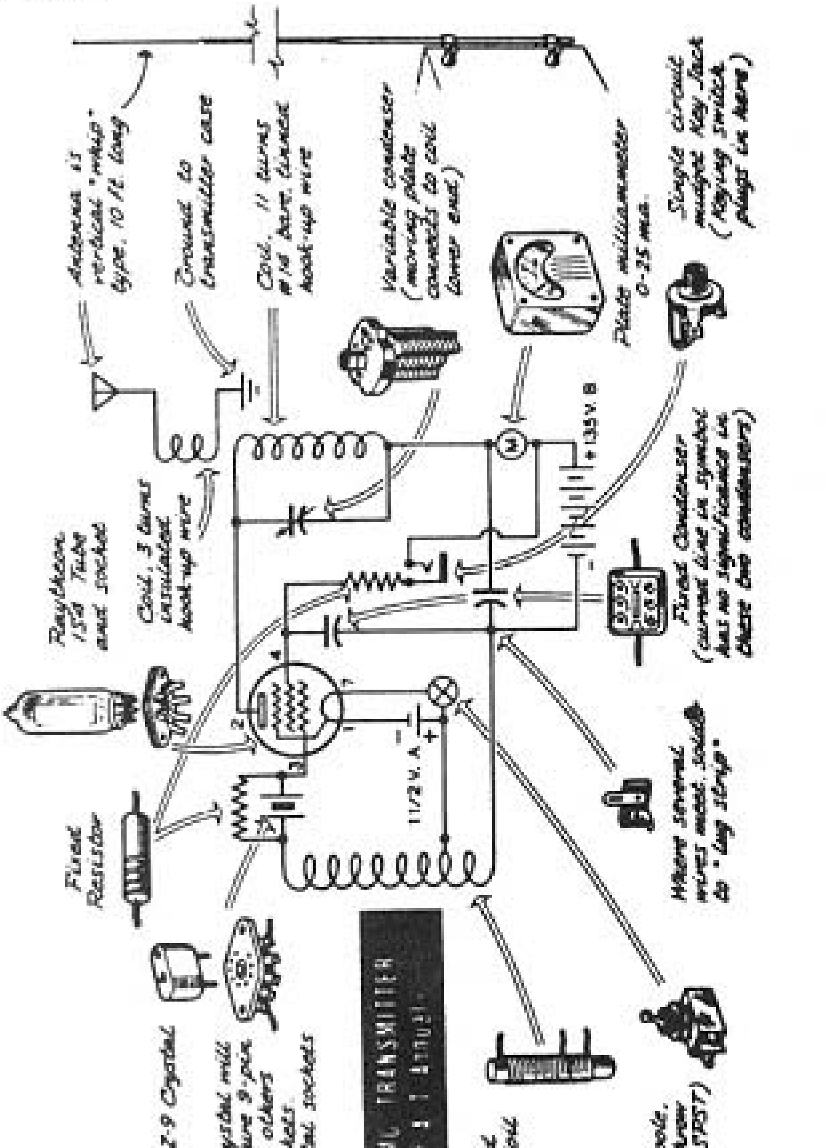
As far as external appearance is concerned, two basic types of transmitters are used: the hand-held type, and the stationary type. Each has advantages and disadvantages. For all the frequencies used for modeling purposes, a hand-held transmitter exists, but the stationary type is not suitable for 465 megacycles. The 465 transmitter is highly directional, and is aimed at the airplane, and therefore is limited to the hand-held arrangement. Another interesting fact about 465 is that the transmitter is not crystal controlled, as are the 27.255 units; but, on the other hand, only an approved factory-made transmitter may be used according to FCC regulations. So you cannot make and operate your own 465 transmitter under the law.

The main advantage of the hand-held type is its convenience on the field; the flier can walk away from cars, people, or other obstacles. He can take up a position near the landing spot, which insures a higher percentage of good close-by landings. It is difficult to hit a spot from a distance, or when standing to one side of the flight path of the airplane. Also, the transmitter may be held in any desired position, enabling the operator to place the antenna in any desired relationship to the position of the plane's antenna while it is in flight. This avoids placing the plane in a "null" or blind spot and increases reliability.

The wave pattern of the transmitted signal varies with the type of antenna used. The vertical "whip" antenna is almost standard for modelers. Each type has its areas of strong and weak signal strength and usually there is a small dead sport or null. With the whip antenna this null is directly overhead, lying within an inverted cone of approximately 15°. Actually, the model generally is responsive even overhead except at high altitudes. The plane quickly flies out of a dead area anyway. If not, have your helper tilt the transmitter to incline its antenna.

This is the reason why a hand-held whip antenna should never be pointed at the airplane. Also, the receiver's antenna should be the same type as that used on the transmitter. A light music wire vertical whip antenna may be attached to the fuselage. When a loose wire antenna is stretched from cabin to rudder top, it may be found during ground checks that range is lost when the ship is held horizontally, broadside to the transmitter, and is then rotated through 360°. With the hand-held transmitter this is not so important because the transmitter is readily tilted to maintain signal strength to the receiver.

The biggest disadvantage of the hand-held type is its inability to contain large batteries within the case; however, one set of batteries may last an occasional flier for a season, and several sets should suffice for the most active flier. The hand-held type is easily used: simply extend or insert the antenna and you are in business.



The stationary type is popular because it contains batteries large enough to last at least one season with a sustained high voltage. Since battery drain is slow to reduce the available voltage of large batteries, the flier is insured of a high average output from his transmitter. And, possibly, the sight of the large black box is reassuring, even though the "works" occupy a small portion of the barnlike interior! Placed upon a car roof, the stationary type performs most effectively, the metal roof acting as a ground plane reflector. This type of transmitter does limit the pilot to one location.

In any discussion of transmitters and receivers the subject of tubes comes up.

Although the tube may be capable of performing various functions, such as amplification, it is used in the typical single-tube transmitter to generate oscillations, as an "oscillator." The frequency of these oscillations is determined by the choice of other components. This oscillation frequency is referred to as Radio Frequency or "RF." This RF output radiates from the antenna.

When the filament in the vacuum tube is heated (by the A batteries), it throws out huge numbers of electrons. Given a positive charge of electricity (by the B batteries) a near-by metal object (the plate) will attract these electrons. They then flow toward the plate. In the oscillator tube there is a third object, the grid, which is placed between the filament and the plate. When negatively charged, the grid interrupts or stops the flow of electrons toward the plate. When positively charged the grid allows the electrons to flow. The grid, therefore, controls the oscillation of the tube. This type of tube is known as a triode. Other tubes may have two or even three grids or screen grids, are known as tetrodes or pentodes.

Most of the single channel transmitters on 27.255 megacycles employ single tubes, such as the 3A5, 3V4, and 3D6, with a 1½ volt A or filament battery, such as the Burgess 4F or its equivalent in other brands; and 135 to 180 volts (depending on the tube and make of transmitter) B or plate supply from a wide variety of batteries, choice being determined by space available in the transmitter. The A batteries may also be flashlight cells, doorbell batteries, etc. Typical B batteries range from Burgess XX-45's to M-30's, or the brand equivalents. The 465 transmitter uses a CK5703 tube and requires a six volt battery, such as the Burgess F4P1.

The technically minded reader should consult available tube charts and catalogues. Transmitter schematics and their component parts are indicated in manufacturer's directions accompanying their equipment, or may be found in various model and radio magazines.

For greatest reliability install a 50 milliammeter in the B-plus line of the transmitter in series with the keying lead. The advantages of a meter are truly important. For example, the flier will know roughly what reading his meter should show when the transmitter is in tune. He will note abnormally high readings, dangerous to tube and crystal, and indicative of bad tuning. The meter will help him tune the unit. If there is evidence of failure somewhere it is easier to determine whether it is the transmitter or receiver that is causing the trouble.

Transmitter output varies in accordance with operating conditions and, for best results, retuning may be required to suit those conditions. This is especially true of some of the stationary types: a strong signal may be sent out with the unit on top of a car but when placed on the ground, the transmitter becomes detuned and no signal is produced. Such characteristics depend on the design of the transmitter more than anything else. Multi-tube transmitters are less subject to detuning. Large rubber suction cups or "feet" may be fitted to the underside of the troublesome box to minimize tuning changes with changes in the location of the transmitter.

The output of the hand-held type varies, depending on whether it is being held firmly in the hands or placed upon a bench, etc. The body acts as a ground or reflector.

A field strength meter is not a necessity but, sooner or later, it will pay off in detecting failing output of the transmitter, as might occur from bad tuning, poor tube, bad switch, faulty leads or ailing batteries. It is most helpful when tuning the transmitter; what counts most, is what the transmitter actually puts out (as shown by this meter) more than the amount of current drain as shown by the milliammeter. The built-in milliammeter, though an important adjunct, does not necessarily prove that the transmitter is developing good signal strength.

Speaking of meters and tuning, it is important to know that the maximum signal strength of a transmitter is not always at the amount of milliamperes or "mils" drain (on the milliammeter) recommended by the manufacturer. This is why a field strength meter, giving actual output rather than drain, is the only accurate check on your output.

Most transmitters used by the examination-free fliers are one-tube affairs. Low cost is a factor. While such transmitters are adequate, some modelers, with an ability to tinker, go in for two or more tubes where the output of the oscillator tube is amplified by the second tube which actually transmits the signal. This decreases the load placed upon the first tube, increases tube and crystal life, and provides a more stable and reliable transmitter. However, the writer has made thousands of flights with single tube transmitters and the occasional failures have been traceable to faulty switches, broken battery leads, and so on.

In the audio or tone modulation, multi-channel transmitters, more elaborate circuitry is necessary. Two, three, four, even more tubes may be used. Such transmitters are a deluxe item from a modeler's point of view. But they are essential for reliable tone operation.

Hand-held transmitters for single channel use are operated by means of a conveniently placed microswitch or push button; the former gives a more-delicate feel and an audible click, helping smooth out the control of the aircraft. One multi-channel hand-held transmitter has a built-in stick for operating the ground control unit, which is a small device for determining which tone is sent out by the transmitter. This stick may be turned left, right, forward, or backward, giving left, right, down, and up movement respectively. An extra push button on this transmitter box (or on the ground control unit, if it is separate from the transmitter) is used to get a change in engine speed. The stationary type of transmitter sometimes has a built-in push button but almost invariably is equipped with an easy-to-use flexible keying lead to which the microswitch is attached.

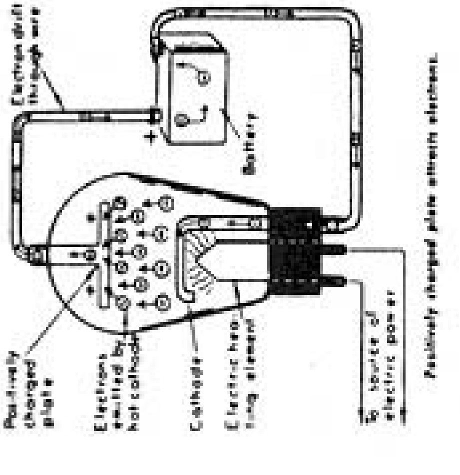
It is extremely important that no frayed ends complete a contact between the two wires of the keying lead, otherwise a steady signal could result and the plane could spiral into the ground. A routine check of the transmitter should be made before every flying session. Check voltages under load: transmitter turned on to check the A battery; button closed for signal-on to check the B batteries. Hold the button on for five or six seconds to note whether or not the voltage begins to fade. By doing this, you may detect a B battery that can't take it. Old batteries can be deceiving.

In three instances the writer observed transmitter failure caused by the internal failure of a B battery. One such failure was traced to a clerk who had dropped the battery when wrapping it. B batteries are made up of small cells stacked one on the other, and the connecting wires can be broken by rough handling.

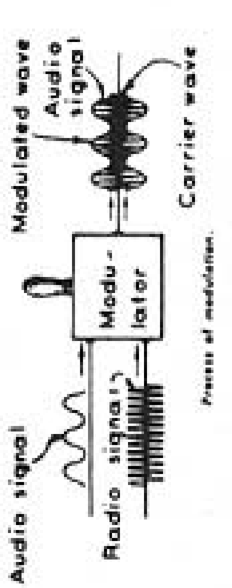
Since two, three or even more batteries are sometimes wired in series for transmitter B voltage, it is a good idea occasionally to read individual voltages, rather than just the end voltage. Sometimes one battery will be found to sag, or to read noticeably less, thus dragging down the entire set. Even a new battery cannot be taken for granted. When batteries fit loosely within the transmitter case, they should be tightly packed against movement with wadded paper or sheet balsa. Where terminal posts might come into contact with the metal case, cement thin, protective wood against the case, or cover the posts with some kind of tape. Look over the various wires and soldered joints. A nut on an antenna post may work loose, and a lead fall off.

Some advanced fliers avoid variable battery voltages by eliminating B batteries entirely. This is accomplished with a power pack which is connected by leads to the automobile battery. This unit converts the car battery voltage into the proper voltage for the B supply of the transmitter. A 22 ohm, 1 watt resistor will cut the 6V supply to 1½ volts for the A supply.

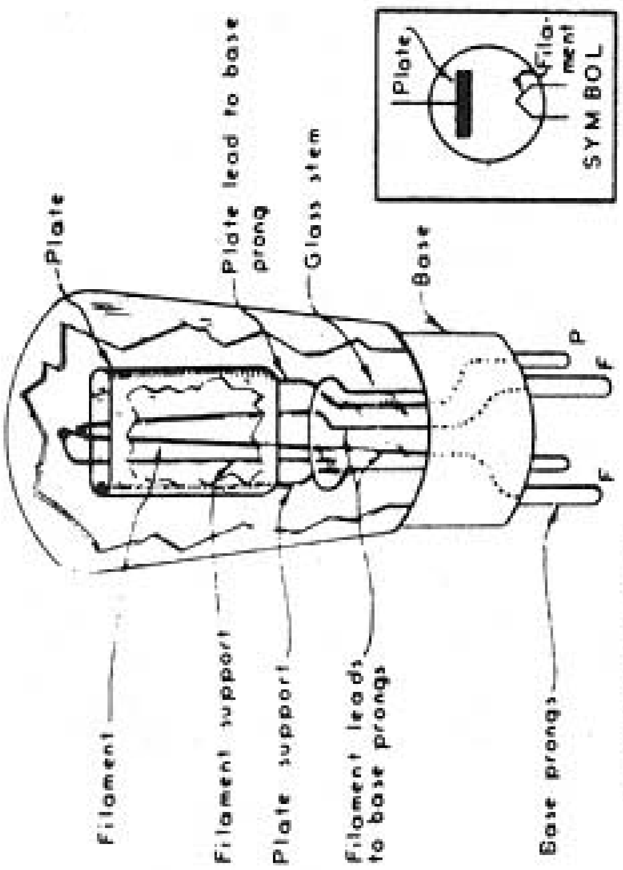
Although such a power supply eliminates all worries about batteries, or their cost, it does make the flier more immobile than ever on the field and increases the things to be done before the model can be flown. Qualified hobbyists can make such units, but finished items are available from radio suppliers who advertise in radio and model publications.

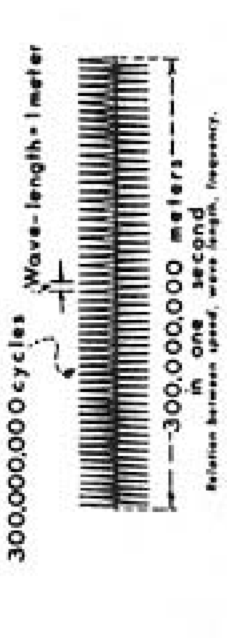


Positively charged plate attracts electrons.



Process of modulation.





Relation between speed, wave length, frequency.

The newcomer to this field frequently assumes that good range is not possible with the typical receivers and low output transmitters he sees in use. For the examination-free flier, the FCC limits the input to the final tube of the transmitter to five watts maximum. The number of watts is easily computed, one watt being equal to a current flow of one ampere at one volt. Voltage is multiplied by milliamperes. If, for instance, the voltage were 135 and the current flow 20 mils (a mil, or milliampere, being one-thousandth of an ampere) the input would be 2.7 watts. Actual output of the transmitter is less.

Good equipment, properly tuned, with good batteries, will operate reliably at a distance too great for the flier to maneuver the plane without the aid of binoculars. Licensed amateurs usually resort to much higher input on other frequencies, sometimes with less sensitive receivers, because this reduces the chances of interference. Reliability is increased with reserve output, as the signal strength may make up for some accidental deficiency in the receiver during flight.

A five-watt input transmitter may be capable of a one mile ground check with a sensitive one-tube receiver. Multi-channel equipment with as little as 1/5 watt input have ground checked up to several miles with three (or more) tube receivers.

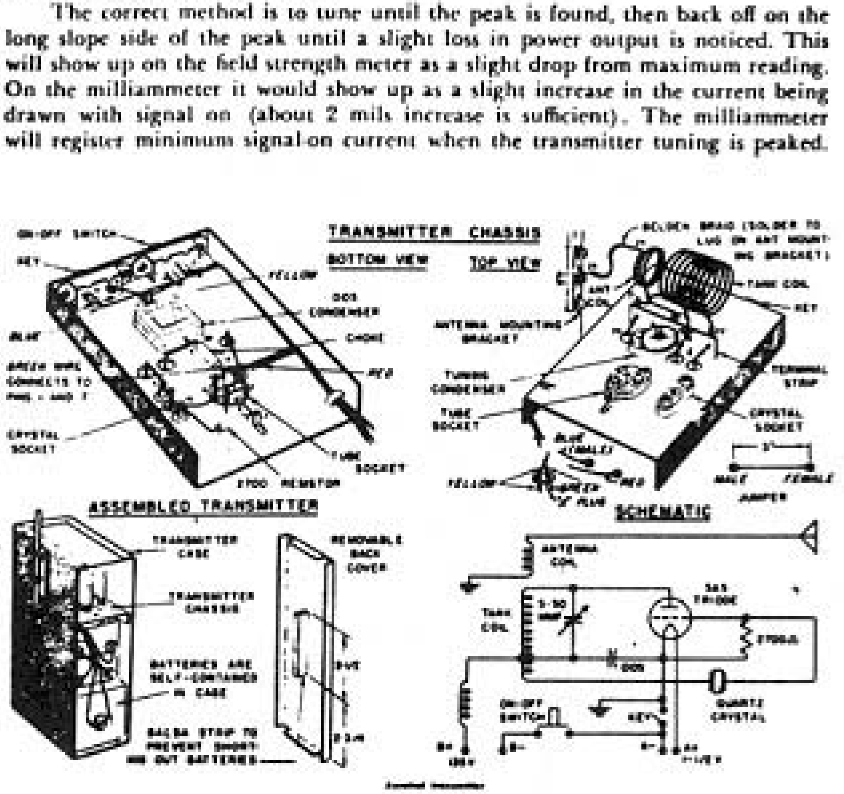
Assuming that everything is in good working order, range depends on proper tuning of the receiver to the transmitter and correct tuning of the transmitter itself for maximum output. The manufacturer builds into the transmitter a variable tuning condenser which may be turned in or out, to increase or decrease capacitance respectively. This operation is done with a tuning wand, or rod, made of non-conducting plastic, bakelite, etc. These wands are inexpensive. When tuning the transmitter keep in mind that exceptionally high currents may burn out the tube or crack the crystal. For this reason, milliammeters are an important part of every modeler's equipment. Indispensable for tuning the receiver is a 0 to 3, or 0 to 5, milliammeter. Desirable for transmitter tuning is a 0 to 50 meter. Meters vary greatly in price but any sold through the hobby shop are acceptable. A cheap meter for the transmitter serves just as well as an expensive one. The receiver meter should be calibrated against some other modeler's more expensive meter and adjusted to give corresponding readings if necessary.

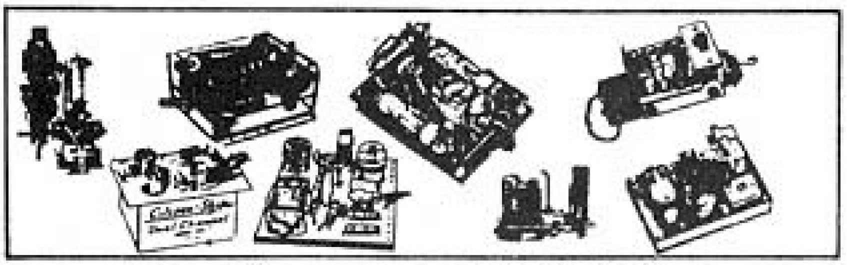
A 50 mil meter should be inserted into the transmitter B-plus lead, if there is no meter built into the box, to begin tuning. With signal on, tune to obtain the reading specified by the manufacturer or known to be approximately correct for your transmitter. If you have a field strength meter, further tuning adjustments may be made. In a pinch your receiver will substitute for the field strength meter. Once the receiver is tuned to the transmitter for maximum rise or drop, depending on the type of receiver involved, further tuning may be found to increase that rise or drop, a sure sign of higher output.

It is bad practice, however, to tune the transmitter for absolute peak output. It will be noted that when the tuning condenser is turned too far one way, the reading on the milliammeter will begin to rise slowly, too far the other way, and the reading will shoot up abruptly. If you are using a field strength meter in conjunction with the milliammeter, also note that the signal strength drops off slowly when the transmitter tuning is varied too far in one direction, or very abruptly in the other. What is happening? What should you do?

Visualize the wave as a long steep hill, followed by a near-vertical drop. As you turn in the tuning condenser, increasing the capacitance, you gradually tune the transmitter higher and higher up the long slope. If tuned at the very peak, there is a chance that the tuning may wander enough to fall off the near-vertical side, down to the valley floor, so to speak, and the transmitter is then out of tune. This is because the capacitance may be varied by movement of your body close to the transmitter or by changes in the position of the keying lead. Peaked tuning can cause loss of control in flight.

The correct method is to tune until the peak is found, then back off on the long slope side of the peak until a slight loss in power output is noticed. This will show up on the field strength meter as a slight drop from maximum reading. On the milliammeter it would show up as a slight increase in the current being drawn with signal on (about 2 mils increase is sufficient). The milliammeter will register minimum signal-on current when the transmitter tuning is peaked.





Chapter Three RECEIVERS

The most widely used receiver is the single-tube type. However, two-tube types, in which the second tube is used to step up the current available to a relay, also are popular. Several more advanced types for tone operation, utilizing three or more tubes, also are on the market, these being associated with more complex models and flying technique.

As to the less costly types in wide use, there are two distinct kinds, each with special advantages. One uses a gas tube, such as the Raytheon RK61 or the English Hivac XFG-1. Both of these tubes use 1½ volts for filament and 45 volts for B or plate supply. The other type uses the hard tube, such as a 3V4. What is the difference between a gas tube and a hard tube?

The gas tube is one in which an inert gas has been injected inside the envelope; it glows with a dim purplish light which diminishes noticeably when the current flowing through the tube is reduced, as when a signal is received. The hard tube is one from which the air has been evacuated, as in an electric light bulb. The gas tubes are said to be more sensitive but they do not last as long. Either type of receiver can be carried by an .049 engine. The hard tube almost certainly will outlive the airplane.

The gas tube receiver requires the use of a potentiometer or "pot," as it is always called on the field, built into the plane. Its purpose is to maintain a recommended idling current (which is read on the milliammeter inserted into the jack wired into the B plus lead). Hard tube owners usually install the potentiometer anyway because it is handy (on either type of receiver) for checking the relay pull-in and drop-out values. With the hard tuber, however, the potentiometer may be attached to the meter itself and does not have to be carried on the plane.

The life of the gas tube is related to the amount of current at which the receiver is operated. Usually this idling current is 1.3 to 1.5 mils. Upon signal the current will drop to .3 of a mil or less at a distance, if everything is in order. Without the potentiometer, the gas tube would idle at several mils, probably far more, and would quickly burn out. Its sensitivity becomes less as the idling current is increased, gas tubes being most sensitive at lower idling currents, particularly when new. A new tube that appears insensitive at a higher idling current may be satisfactory when the current is turned down by means of the potentiometer: for example, 1 or 1.1 mils. It is not practical in one-tube installations to reduce the idle further because a margin of safety is required above the relay setting—at least .2 mil in practice.

When new, a gas tube may show up well on bench tests but have a very limited range on the field. In this case, idle the tube for 15 minutes at 2 mils and recheck. Usually, the range improves. Sometimes several such idling periods are needed.

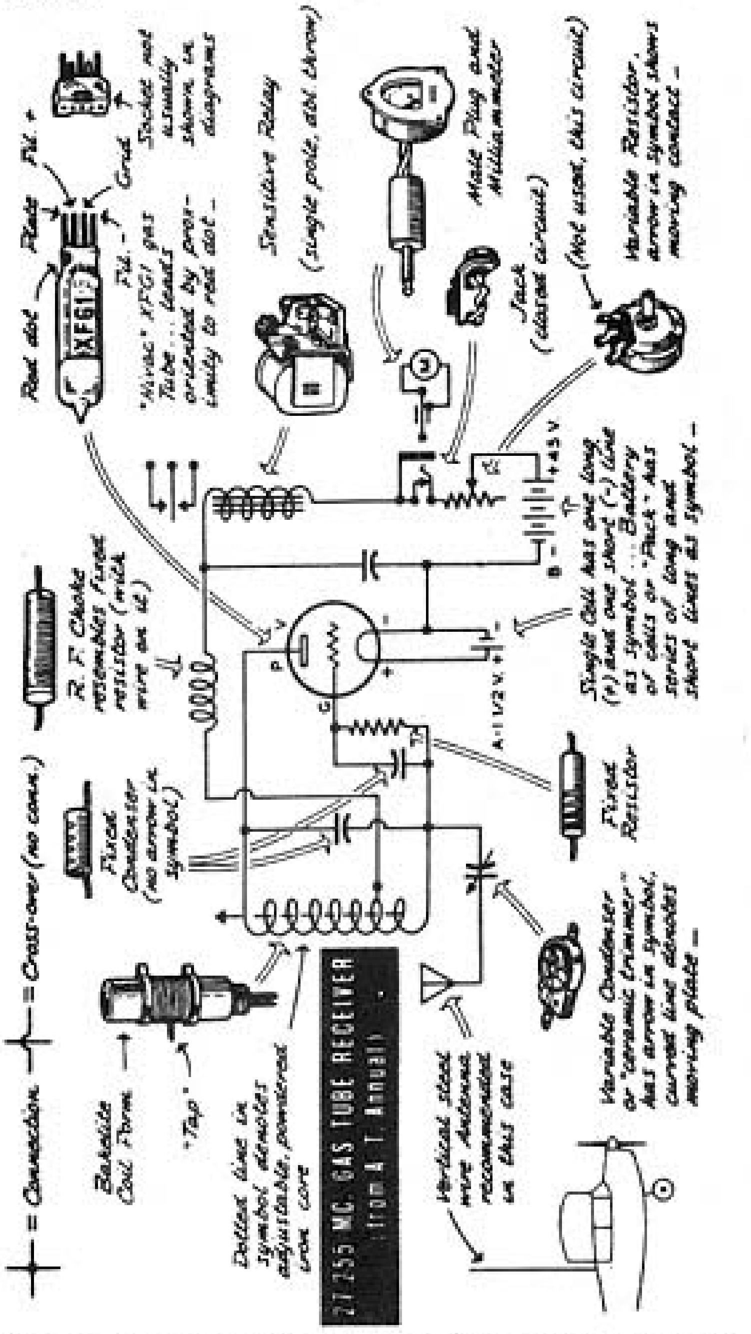
Both the RK-61 and the Hivac have long wire leads which are clipped to the desired length for mounting. Most radios using these tubes have small flea clips into which these wire leads are inserted, the tube being held firmly to the chassis by means of a rubber loop. The leads should never be soldered to the clips, nor should solder be permitted to flow up through the wire connection below to the end into which the tube leads fit. The heat from soldering can damage the gas tube. Small tube sockets, called Cinch hearing-aid sockets, may be found at radio supply stores. Never use acid core solder as corrosion and electrical leakages result. Use a good resin core solder such as Kesters.

Idling current of the hard tube, on the other hand, may be anything that results from use of recommended batteries and, depending on the tube, will vary from 1.5 to 7 or 8 mils. For practical considerations, it should be unnecessary to require more than 3, certainly 4, mils. The current, upon receipt of signal, does not drop to near zero as it does with gas tubes, but the actual amount of current drop or current change between, say, 2.2 mils idle and .8 on signal, is roughly the same as it would be with the gas tube.

The hard tube receiver sometimes has two tuning controls, one for controlling the idle current and the sensitivity of the receiver, often referred to as the sensitivity control; the second, for tuning to frequency. There is a certain amount of interplay between the two. If manufacturers' directions are followed in either case, tuning will prove easy. One odd thing that must be guarded against when tuning receivers is any condition that affects the radio, leading to detuning when those conditions are removed. For example, a type of receiver that displays sensitivity to body capacity requires careful handling. Don't lean against the antenna while tuning, etc. In general, the farther that the body and hands can be kept away from the receiver and its antenna during tuning, the less likely you are to encounter poor range in the air.

Hard tube receivers which have a sensitivity control should never be tuned for maximum sensitivity. In the air, the plane may become the victim of a fluctuating idling current. Triggering the relay and "rudder walking" would be the least of the undesirable thing that might happen. When tuned too sensitively the hard tube receiver will react with the transmitter antenna—even when the transmitter is turned off—and faulty control results when the ship is in the vicinity of the transmitter.

One check (assuming you do not have the advantage of the manufacturer's directions) is to carry the plane close to the transmitter with the receiver turned on. If the escapement is operated without a signal being sent, the receiver is adjusted with too much sensitivity. If the ship can be brought to within a foot of the transmitter without this happening, it should be safe in the air. During the ground check, be willing to sacrifice some range, perhaps a .1 mil drop, to insure stability.



27.255 MC. GAS TUBE RECEIVER (from A.T. Annual)

Hard tube receivers function as transmitters quite effectively and the more sensitive the adjustment, the more they broadcast. Under certain conditions, a hard tube receiver may spin down another airplane hundreds of feet away. For safe flying, practice keeping your receiver, as well as transmitter, dead while other planes are in the air.

In the gas two-tuber, the second tube is connected into the circuit in such a way that it idles at zero or a small fractional part of a mil but rises to 2 or even 3 mils upon signal, depending on the voltage available and the resistance of the relay. The first, or detector tube, functions precisely as it does in the normal one-tuber, but idles at .4 or .5 mil, sometimes higher. The principal advantage of the system is the large current change available for relay operation

The wide range of relay operation that results, together with greater spring tension and contact pressure, makes the relay virtually vibration free. Some fliers take advantage of this fact to install the relay without benefit of shockproof mounting. Others put such receivers in small but high powered planes or in ships with rough running powerplants.

The 465 receivers employ a 6K4 or 6AK4 tube requiring six volts on the filament. A battery drain is rather high, but small hearing aid batteries for B supply have nearly the equivalent of shelf life. The reason for the long B battery life is the low idling current of about .2 mil, which rises to 1.1 to 1.4 on signal. Fliers have found that by using 7½ volts (five pen cells), the A batteries stand up a great deal longer. No harm is done to the receiver. On medium size planes, ten pen cells, or in larger planes, five medium flashlight cells, may be carried without difficulty. A battery life then extends into weeks, or even months.

In the beginning, the 465 receiver was not tunable by the builder. Actually, it didn't require tuning, unless damaged, in which case it was to be shipped to the factory for realinement. A newer 465 receiver is tunable, like any other single hard tube receiver.

The more elaborate receivers for tone operation and multi-channel work contain many special features. In one case, hermetically sealed relays with a current change on the order of 6 mils are provided. These receivers will not respond to straight carrier signals and obey only the selected tone sent out by their own transmitters. However, a straight carrier wave transmitter, when the operator holds steady signal, will prevent, or block, the tone receiver so that it cannot respond to its own transmitter. But, on the other hand, the tone outfit, functioning as it does with a steady carrier turned on, will effectively prevent anyone ground checking, much less trying to fly, any other type of carrier wave operated equipment.

Advantages of sealed relays are that the contacts do not become dirty and do not require adjustment, the latter because of the substantial current change in this particular type of radio and resulting positive action. These receivers are not likely to be spun-in through out-side interference and will be highly resistant to vibration difficulties because of large current changes in the relays. Whereas single tube receiver uses that tube to perform several distinct functions, the typical tone receiver uses a tube for each purpose, such as detection and amplification. Therefore, it is theoretically the most reliable and stable in operation.

The multi-channel receiver requires a separate relay for each actuator (except when secondary actuators work from a compound escarpment or servo). In the case of a rudder drive servo that is moved one way by one channel, and the other way through a second channel, two relays are required for the one servo. Two to five or six relays are usually mounted on such receivers. One manufacturer uses filters to cause the proper tone to operate the correct control; at least three others use a special reed bank in which tuned reeds, vibrating at specific frequencies, respond only to their particular tone. The agitated reed then makes the contact; that closes its particular relay, and the relay energizes the proper actuator.

Receivers are installed in the airplane by various means, such as from rubber bands from the four corners of the chassis to hooks onto the cabin walls; or wrapped in foam rubber; or set upon a block of foam rubber attached to a plywood slide. Details are given in the chapter on installations.

Chapter Four

RELAYS

When your receiver comes from the manufacturer, its relay has been properly adjusted. However, it is possible for the relay to get out of adjustment, either during shipment or later, and it certainly will require readjustment from time to time during the lifetime of the model. We would like to say that you do not have to know how to adjust a relay but the unfortunate truth is that, if you expect to fly a great deal, such knowledge is essential—unless, of course, your receiver happens to have a sealed type of relay.

There are, perhaps, a dozen makes of relays that are used in radio models. Of these, the Kurmans and Sigmas are most widely used. It should be pointed out that some relays were not intended primarily for modeling purposes, despite the fact that they are advertised for such use and can, in fact, be used successfully. For example, some suppliers offer a Sigma that originally was designed for electric blankets. It mainly differs from the more familiar Sigma 4F commonly used for RC in that rigid, screw adjustable contacts are not provided. While such relays are genuine, they are not as ideal as the factory supplied job designed for our particular requirements. Whereas Kurmans have not had screw adjustable contacts until recently, the new Model BKA manufactured expressly for Berkeley does have this feature. Sigma's new 26F will supersede the 4F.

The important parts of the relay are the magnetic core or pole piece, the armature, the tension spring, and the contacts. Special directions for adjusting the relay are included with manufacturer's literature - but the purchaser of random relays does not benefit from such directions. A few handy hints will be added here.

All the single tube receivers have a steady current (the idling current) flowing through the relay. On all the single-tubes but the 465, this current is sufficiently high to cause a magnetized core piece to attract and pull in the nearest end of the armature: thus, when the receiver is turned on, the armature automatically pulls in.

When a signal is received, the current flowing through the relay is reduced, and becomes insufficient to hold in the armature because of the tension of the spring. Now being greater, this spring tension causes the relay to release the armature which then "drops out". The other end of the armature will then rest against the lower contact. All the upper contact does, in this case, is to prevent the armature from touching the magnetic pole piece when pulled in, which would magnetize the whole assembly so that it could not function properly. By adjusting the spring tension and contact gaps, the flier can set his relay to operate at any desired current value, as read upon the meter inserted in the B-plus lead of the ship's wiring.

With 465 receivers (and two-tubers) the operation is reversed. Having a low idling current (second tube, in two-tuber) not sufficient to attract and hold in the armature, spring tension holds the armature against the dropped out (lower) contact. When signal is received, the current flowing through the relay increases, the armature pulls in, and rests against the other contact. The live contact, in this case, is opposite to what it was before. It will be noted that when the relay pulls in on signal, the upper contact is wired into the escapement circuit; when it drops out on signal, the lower contact is wired in.

Anything that makes it more difficult for the relay to pull in, will raise the pull-in reading on your meter. More spring tension increases this current, but an excessive gap between the lower contact and the armature (measured when the armature is pulled in) does the same thing. If the upper contact is so set that too much gap results between the armature and pole piece when pulled in, the operation will be marginal and subject to vibration.

The drop-out current depends on spring tension only. For a quick rough adjustment of a Sigma, insert a piece of cigarette package cellophane between the core piece and the armature. Adjust the upper screw contact to maintain that gap when the relay is pulled in. Then the maximum gap between the armature and the lower contact—when pulled in—should be the thickness of a dollar bill. Changes in spring tension should be minimized because they have drastic effect. This procedure applies to both Sigmas and Kurmans operated at typical values somewhere between, say, .8 and 1.2 mils. For single tube operation it is best not to have less than .2 mil difference between pull-in and drop-out.

Narrow gaps are subject to vibration troubles because any movement induced in the armature, or contact arms, may cause touching between armature and the live contact. While higher spring tensions do increase immunity to vibration, they do not do so when the gap is too small.

When the armature is permitted to strike against the core or pole piece, it may become magnetized. Repeated pulsing of the signal may build up residual magnetism until the armature sticks to the contacts, resulting in faulty operation or a crash. Kurmans have the pole piece treated to prevent this condition.

Another relay seeing increased use is the Neomatic. Possessed of high resistance to vibration is still another relay, the polarized type. The armature is mounted vertically, moves back and forth between two screw contacts. A built-in permanent magnet replaces the spring tension feature. Drop-out and pull-in values are controlled by varying the two screw contacts.

Since you will hear the word "ohms" when relays are discussed, it would be well to understand what the term means. The amount of current that flows through a wire, relay coil, or resistor, etc., depends on the voltage applied, the thickness and length of the material, and the nature of the material itself. The resistance to the passage of current is measured in ohms. A resistance of one ohm results when one volt is needed to make one ampere of current flow through the object. Ohm's law states that the Current equals Voltage divided by Resistance. For example, an escapement having 5 ohms resistance when 3 volts are applied, would have a current of .6 ampere or 600 mils.

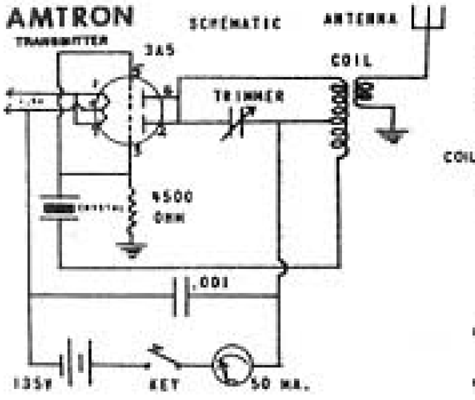
For model use a sensitive relay is desired, one that operates reliably on small amounts of current change. The relays we use have a resistance of about 4,000 to 10,000 ohms. Five to eight thousand ohms are average. Where vibration is a problem or where the relay must operate at unusually low current values, high ohmage is desired because of the resulting greater contact pressures. Low relay settings tend to pit the contacts. Clear contacts are absolutely essential in any relay. It is important that the contacts be cleaned with non-abrasive material. Use a dollar bill or clean piece of paper - never a file or sandpaper. Rough contacts lead to pitting and sticking, and finally complete failure. To prevent "arcing" between armature and live contact, place a 100 ohm resistor and a .1 mfd. condenser in series across the relay contacts.

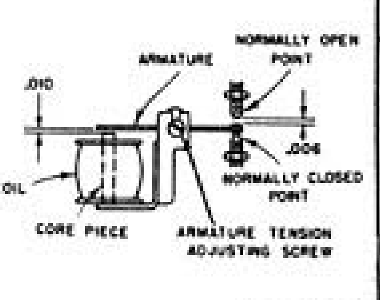
When used with two-tube receivers with a large current increase, a relay may be set with a large movement of the armature and a wide gap. Since the second tube idles at virtually nothing, the relay is dropped out regardless of whether the receiver is switched on or off. Upon signal, the large current increase imparts a slamming action to the armature. The relay may be set to operate over at least a .4 mil difference between pull-in and drop-out, such as 1 mil to 1.4 mils.

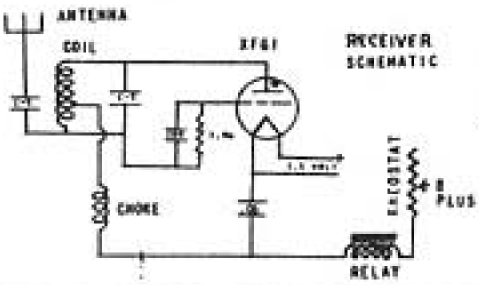
Mounted as part of the receiver, a relay automatically is shock protected against vibration. When mounted separately, it should be given such protection of its own. Some builders put the relay on a one- to two-pound Lord shock mount but must be careful that the relay so mounted does not swing through an arc large enough to strike any object. The relay also may be mounted on a small ply base and suspended in the same manner as the receiver.

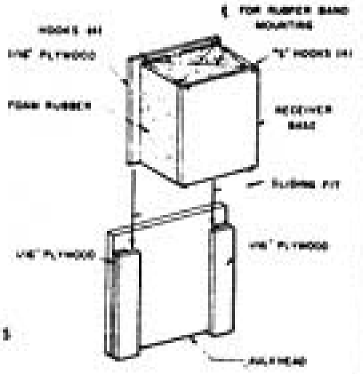
For relay adjusting a test rig may be made, consisting of a cigar box in which may be placed large batteries (as old transmitter batteries). Four pieces of dowel are inserted into holes drilled in the box top. The receiver is hung between the dowels, just as it might be in the airplane. A plug and socket arrangement enables the quick hooking up of the receiver. The jack and potentiometer are installed conveniently in the box top; use a small electric bulb to indicate relay action, instead of the escapement.

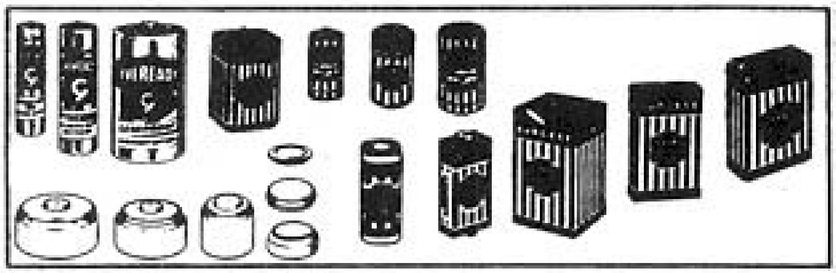
The last pre-flight check of the relay is to try the rudder by radio control with the engine working. If the rudder skips, or does not follow signals perfectly, the ship should not be flown. Sometimes the escapement is at fault but most often the relay is bothered by vibration. Changes in prop size, throttle setting, and so on, may be resorted to but these are tricky methods since engine rpm may change in the air. The relay mounting should be loose enough to avoid vibration. With the receiver properly installed, and the relay correctly adjusted, you should have no trouble with vibration.











Chapter Five

BATTERIES

Manufacturers' directions always include data on various combinations of batteries that may be used with their equipment. Therefore, we will not survey batteries required for particular receivers and transmitters, but will make some observations helpful in deciding what batteries to choose, as well as a few facts governing battery life and maintenance.

The bigger the battery that can be used, the longer its life, and the less fussing with receiver or transmitter. Bigger batteries are more reliable than small ones, especially on long flights. The smaller, optional battery arrangements should be used only when airplane size and power makes heavier, bigger batteries, impractical.

All the single-channel, straight carrier wave receivers require an A battery, usually of 1½ volts, but 6 to 7½ volts on 465; a B battery, which is 45 to 67½ volts for gas tube receivers, and usually 67½ for hard tubers.

Let's consider the .049 RC design, the smallest you'll ever want to fly. This power is adequate for either a single or two-tube receiver, with two pen cells in parallel for A, and two 22½-volt hearing aids in series for B with gas tubes, or three such batteries or two 30-volt hearing aids, as specified, for hard tubes. The escapement should take two pen cells in series for 3 volts, although English types may require 4½ volts.

Regardless of size of plane, two pen cells in parallel to give 1½ volts will suffice for A supply with single-tube receivers but, when .09 displacement is reached, four pen cells in series-parallel may be used for longer A life. If a .15 or larger engine is used, it makes good sense to switch to medium-sized flashlight cells throughout. Excepting the 465 receiver, it may be desired in bigger planes to increase B battery size, substituting, say, a 67½ volt Burgess K-45, or its equivalent, for three hearing aids, or an XX-30 or equivalent for two 22½-volt hearing aids. When using compound escapements that operate auxiliary escapements, don't use two pen cells when the plane can carry more or heavy batteries. However, two pen cells are not a touch-and-go proposition. As an example of what a small plane will carry, a good .09 engine, with a thin bladed 8 x 3½ propeller, will tote as much as 50 ounces.

Should battery boxes be used? This is a matter of personal preference. Many fliers prefer to make up battery packs, taping batteries together into conveniently sized blocks to fit compartments; the leads are soldered to the batteries. Thus, any possibility of poor battery contacts is eliminated. Also, awkward combinations, such as 5 or 10 pen cells, really require packs.

Lightweight, old style ignition battery boxes require a wrapping of rubber bands, or a spring tightener, to insure good pressure upon the batteries and to prevent the batteries from bouncing loose in crashes and hard landings. Heavier gauge boxes, especially designed for RC work, are available. Special plastic boxes for four pen cells are obtainable. The batteries fit vertically into these boxes. Each box is in two sections, held together by means of a long screw. Convenient flanges make it easy to set the boxes upon bearers cemented to the faces of adjoining bulkheads.

Connections are made in various ways. If boxes are not used, the wires are soldered directly to both A and B batteries, and escapement cells as well. Avoid overheating the batteries with an oversized iron, especially hearing aids. Some batteries have plug-in or strap-on connection features. Secure the strap (snaps on like dress snaps) with tape for safety.

For transmitters, B battery size is limited by the bulk and weight in the hand-held case, but in stationary types the largest possible batteries are recommended for long life. Sufficient space exists in any transmitter for a reasonable size A battery. Reference has already been made to checking batteries under load. When the transmitter keying switch is closed it will be found that B batteries may drop anywhere from a volt or two, to between 5 and 10 volts, depending on the size and age of the batteries. But once the battery hits the minimum voltage under load, as shown on the volt meter, watch to see if it gradually keeps on losing voltage, such as 15 or 20 volts. If so, discard it.

R.C. BATTERY DATA

(2) "PENCELL"
(3) "C" SIZE BATTERY
(4) "D" SIZE BATTERY

Wennerstrom

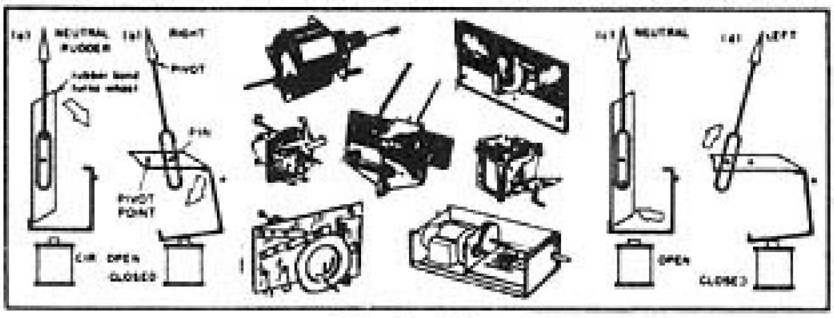
The escapement batteries may be placed under load with most single tube receivers by switching on the escapement and leaving the receiver switched off. The relay thus drops out, closing the contact to operate the escapement. Where a separate escapement switch is not provided, turn on the receiver and transmit a signal to cause the relay to drop out and work the escapement, or carefully move the armature with the finger to make contact. Measure the voltage at the escapement, not at the battery box or pack. There is a voltage loss along the line when lengthy leads separate receiver and escapement.

Some fliers may use batteries for many dozens of flights, whereas others, with the same equipment and batteries, complain about battery replacement costs. Batteries should be allowed to recuperate between flights for at least three to four times the amount of time that they were just in the air. The voltage actually rises during these rest periods.

The maneuverability and adjustment of the plane itself affects battery life in both transmitter and receiver. A slow, gently responding airplane which requires sustained application of rudder, is running down B and escapement batteries all the time control is held on. A fast responding plane reduces the length of time these batteries are under load. In cold weather battery voltage is reduced; never fly in extreme cold with batteries that are even moderately run down. However, the same batteries, when heated, will show higher readings.

Battery life charts should be disregarded as they are unduly optimistic for our purposes. We are not interested in how long a bulb can be kept lit, for example, but in how long the receiver will function reliably. Receiver voltage may be above minimum when the plane takes off but suppose it drops below minimum in the air! Also, when equipment is operated near minimum voltages, performance is reduced; the radio manufacturer really means that the minimum is where the equipment becomes marginal. It is better to allow yourself a safety margin rather than squeeze the last volt out of the batteries. Battery cost, relative to the cost of time and the materials in the plane, to say nothing of the expensive radio, is not important.

New batteries should be purchased from suppliers whose stock moves fast, such as hearing aid establishments who stock virtually any battery size needed for receiver operation—and these are fresh. Many hobby shops carry batteries.



Chapter Six

ACTUATORS

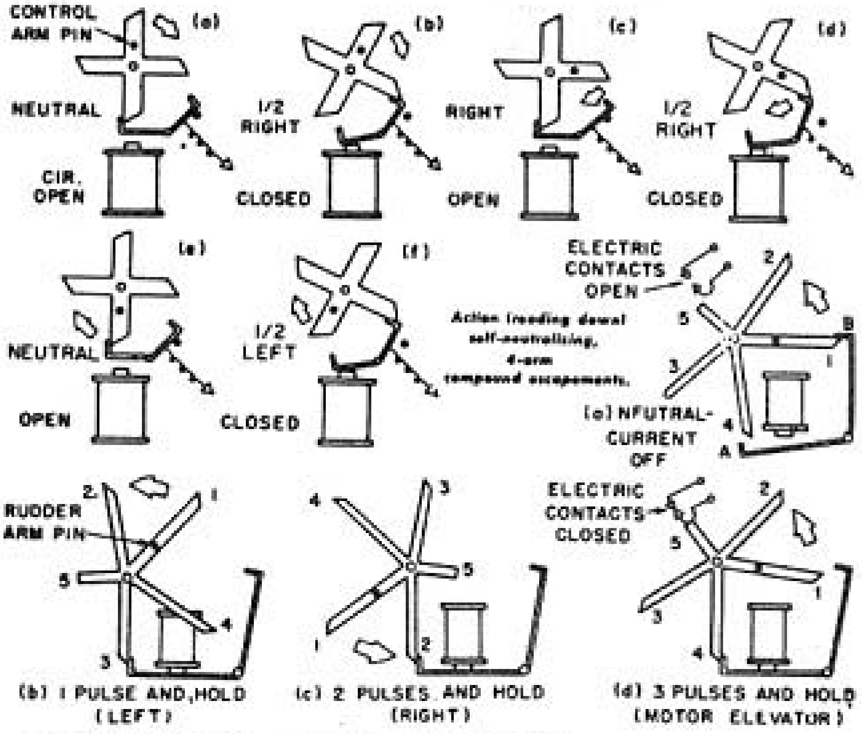
An actuator is a device for moving the rudder, elevators, or other controls. Two basic types of actuator exist: escapements and servos. An escapement is an electro-mechanical device in which a revolving arm, powered by a twisted loop of rubber, is released and allowed to turn either an eighth or a quarter revolution when its magnet is energized. The escapement moves a wire linkage, torsion rod or, by means of a bellcrank, a push rod, which, in turn, moves the control surface.

The servo is an electric motor powered device which, by means of reduction gears, works a push rod for moving control surfaces. Approximately the size of an escapement, perhaps slightly bigger and heavier than the average escapement, the servo applies stronger forces more precisely, as for trimming elevators when multi-channel receivers are used. Although escapements are more widely used, servos now are being manufactured for single-channel as well as multi-channel applications. Current may be supplied to both types of actuator with pen cell batteries.

Although escapements take many forms and shapes there are only three basic types: the two-arm self-neutralizing; the four-arm; and the compound, or single neutral type. The self-neutralizing type assumes a control position on signal, and returns to neutral when the signal terminates. The four-arm assumes a half-way position on signal, then goes to full position when the signal terminates, and does not return to neutral until moved there by an additional signal. The compound selects left or right, or the second control position, depending on the number of signals (one to three) transmitted. It remains on the selected position as long as the final pulsed signal is held, and always returns to the same neutral when the signal terminates.

Starting from neutral, the sequence for the two-arm escapement is as follows: neutral, right (or left), neutral, left (or right). For the four-arm it is: neutral, half right, full right, half right, neutral, half left, full left, half left, neutral. It, too, may be started for left rudder first, depending on what had been the last movement. The compound has no sequence, always giving the same control for the same number of pulses. When the compound is in the extra control position, it does not turn the airplane, but closes electrical contacts completing a circuit to a second escapement—which may be either two or four-arm, or a relay, or a servo or other device.

Ascertain the resistance in ohms of your escapement. This generally varies from five to about twelve ohms, with an average of about six or seven. The more or the higher the ohms, the less will be the battery drain. Low ohm escapements run down batteries more quickly, although battery drain is not a problem with any escapement on the market. But with the high ohm escapement you can use smaller batteries or get by for longer with the usual batteries.



Do not use more voltage than called for by the manufacturer. If the directions say 3 volts, use 3 volts; if 4½, use 4½. Extra voltage raises cain with some escapements. Residual magnetism is one common result, which causes malfunctioning of the escapement. This form of magnetism builds up with rapid use of the device, as when pulsing quickly. When the escapement is allowed to stand, the residual magnetism may disappear, making troubleshooting hopeless.

Examine new escapements under a magnifying glass, checking for rough edges, burrs, paint droplets, etc., that interfere with the arm's sliding free of the claw edge or altering the critical gaps. Do not file the revolving arm or pawl, as the faces may get out of alinement or the arm become too short for reliable operation. Do dress the surface of the claw end, if necessary, with a fine stone. When a burr develops, as it frequently does with service, engine vibration assists the escapement to work, but it may "hang up" during the glide for a loss of control.

Any good escapement will allow use of either 1/8 or 3/16 inch rubber. If skipping occurs and there is some doubt about the escapement, reduce the size of the rubber or place less turns upon it. This is particularly true of home made escapements. When using heavier rubber and many windings, more frequent inspection of the escapement is necessary because burrs develop more easily from the greater impact.

An essential part of the escapement system is the linkage which connects it to the control surface. Sloppy workmanship, poor design, and inadequate maintenance contribute to poor control. For instance, a long, too-thin wire torsion bar may twist so that required rudder movement does not result in the air, or, at high speed, the amount of rudder movement may be cut down.

Allow extra clearance between yokes and pins so that the pin doesn't jam within the yoke when the rudder is in the full over position. Where the linkage passes through a bushing make the bushing inside diameter a trifle larger so that rust or roughness on the wire doesn't induce friction that slows down or retards escapement action to the point of skipping or jamming. Use powdered graphite, not oil for lubrication.

Avoid excessively long yokes at the end of torsion rods because vibration may shake them hard enough to interfere with escapement action. Inertia of the long yokes may cause the revolving arm to bounce off the pawl, then to slide on by to the next rudder position. This is especially true when two yokes are bent in the same direction: the mass of the linkage is then so far off center that erratic action easily results.

Because the self-neutralizing type of escapement gives an all or nothing position to the rudder, that surface being either all the way over, or in neutral, it is generally necessary to make repeated applications of control in the one direction in order to complete a turn. If the rudder was held over continuously, the nose of the plane would drop and enter a spiral or, in the case of a good aerobatic machine, a split-S might result. A really powerful, maneuverable rudder-only job might even do a straight line roll.

Suppose, for example, that the next rudder position is right. As right rudder is applied and the plane begins to overbank and drop the nose, the operator releases the signal, allowing the escapement to return to neutral, but he instantly applies opposite, or left rudder, relaxing that signal before the airplane can respond, and then applies, and holds momentarily, right rudder. This process may have to be repeated several times to complete a 360° turn. Fliers call this technique "double blipping." With practice it can be done instinctively, quickly. There's a handy rule: "If you don't want the turn you have, give it one signal; if you want more of the same thing, give it two."

This, incidentally, is why some hobbyists are working on proportionate rudder control via various pulsing systems. However, possible to trim a properly designed plane maintains a perfectly banked turn once that turn has been begun; it's a matter of dihedral, and center of gravity position, more than anything else.

When used with a pulsing system, a magnetic actuator does provide proportionate rudder control in either direction. However, while this system allows more precise maneuvering on rudder, it adds more gadgetry and things to go wrong. It is necessary to have an electric motor driven, or electronic, pulsing device attached to the transmitter. This gadget, usually about as big as a small size cigar box, replaces the keying lead switch. The mechanical pulser consists of a revolving drum and a control stick whose inner end slides along the drum, making contact, when moved right or left. The surface of the drum at one end is entirely metallic; at the other end it is entirely of wood. At the neutral point, or midway position, where the stick is held for neutral, the surface of the drum presents an evenly spaced alternating wood and metal surface as it revolves.

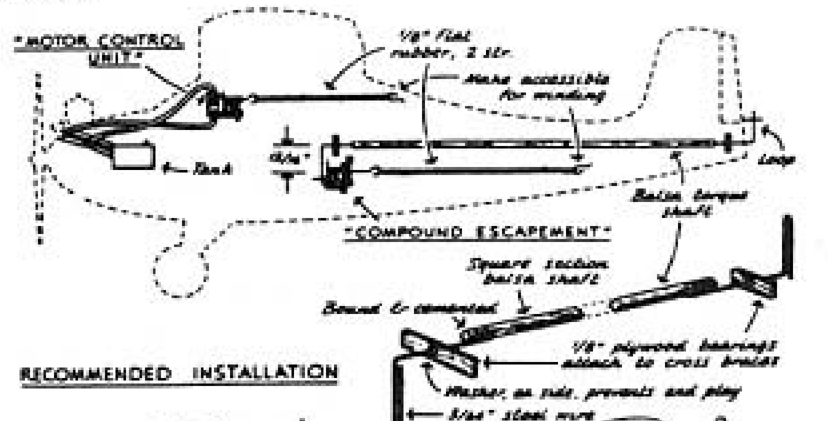
Each time the stick passes over the metal surface of the drum a signal is transmitted. The length of the signal obviously depends on the length of time the stick rests upon metal, or the percentage of metal on the circumference of the drum at the point where the stick makes contact. Thus, this is a pulse length system. At the one end of the drum, no signal would be sent; at the other end, a continuous signal would result. In neutral, the on-offs are of equal length, the rudder wiggles back and forth in response, but moves too fast for the airplane to obey and straight flight results.

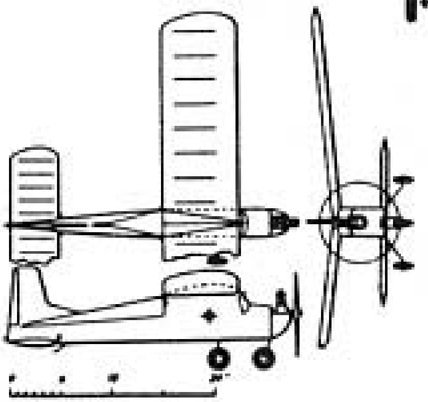
The magnetic actuator in the airplane is connected to the relay in such a way that, if the relay drops out, it moves in one direction, turning the rudder an equal amount. If the relay pulls-in, the actuator moves in the opposite direction. As the ground controller stick is moved to one side of the drum or the other, the relay in the plane tends to remain longer in the corresponding position. It is either pulled in most of the time, or dropped out most of the time, depending. The rudder, therefore, will tend to remain longer to one side imparting the exact degree of turn desired by the pilot.

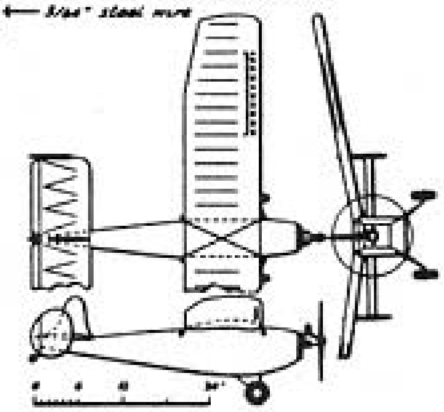
One drawback of the system is that a failure of any type, including flying out of range, results in a spin-in. The ingenious reader can devise a failure-proof system working from additional contacts that close if and when the rudder goes full over.

All manner of control switches and "beep boxes" have been devised, either to provide additional controls or to remove confusion when using any sequence escapement. The typical beep box is a variation of the revolving drum pulser; however, instead of a variable metallic surface, the drum is entirely of wood or some other non-conducting material, and has, jutting up from its surface, strategically placed pins or stops. Movements of the control stick engage the proper stops, and, during the brief interval of time consumed in moving from one stop to another, a contact arrangement at one end of the drum sends out the selected number of signals. A slipping clutch system allows the drum to resume speed as soon as the stick disengages the last stop.

When considering such systems, or multi-controls of any kind, do not write off the single-channel receiver and rudder-only control without trial. Rudder-only is a thoroughly satisfying way to fly and it takes a top notch pilot, even with the most expensive equipment, to beat out a capable rudder-only man at a contest.

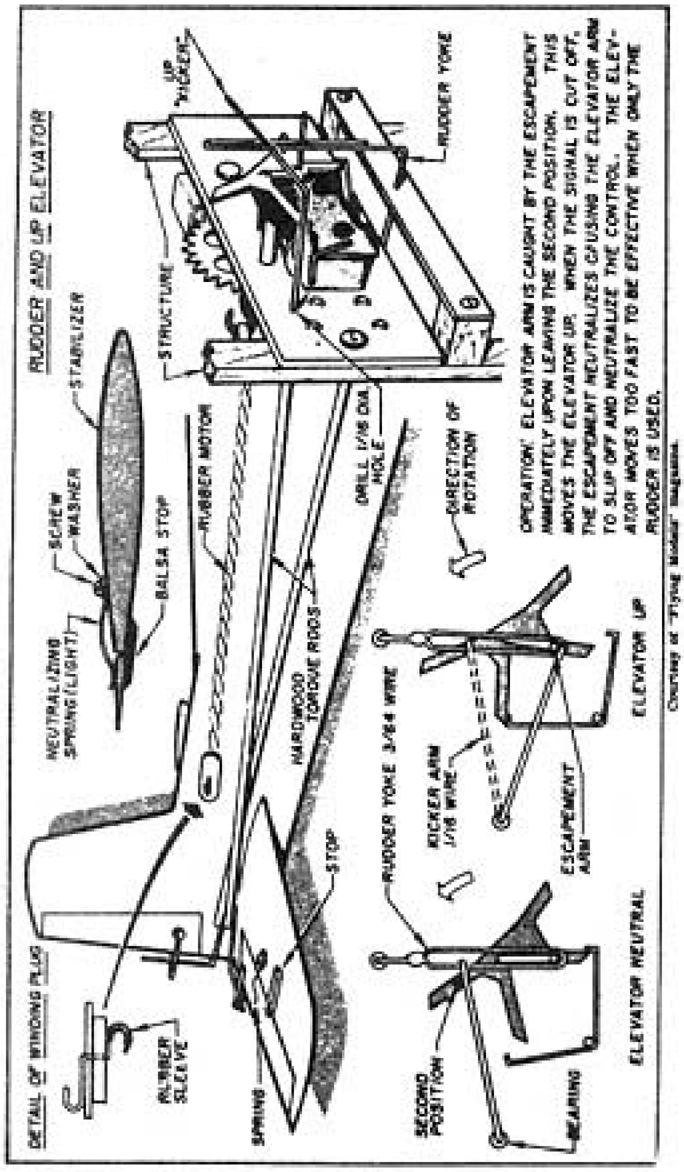






FM DATA SHEETS

R/C CONTROL SYSTEMS



OPERATION: ELEVATOR ARM IS CAUGHT BY THE ESCAPEMENT IMMEDIATELY UPON LEAVING THE SECOND POSITION. THIS MOVES THE ELEVATOR UP. WHEN THE SIGNAL IS CUT OFF, THE ESCAPEMENT NEUTRALIZES CAUSING THE ELEVATOR ARM TO SLIP OFF AND NEUTRALIZE THE CONTROL. THE ELEVATOR MOVES TOO FAST TO BE EFFECTIVE WHEN ONLY THE RUDDER IS USED.

Chapter Seven

INSTALLATIONS

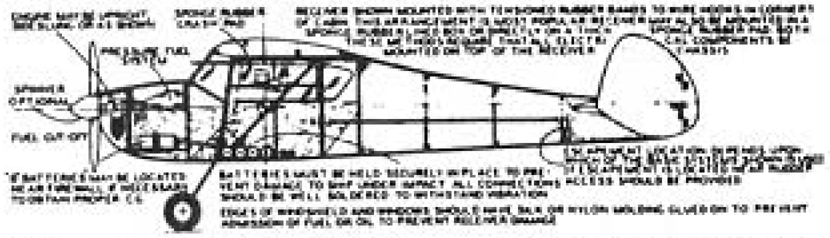
The installation of the receiver, batteries, and escapement in an airplane should provide protection to the receiver, protection to the airplane from the batteries and receiver in a crack-up, and accessibility to the receiver for tuning and to the batteries for checking and replacement. The escapement and its rubber should be accessible for servicing. The secret of a good installation is to know where everything has to go before the airplane is finished. The plane should be designed around the radio equipment.

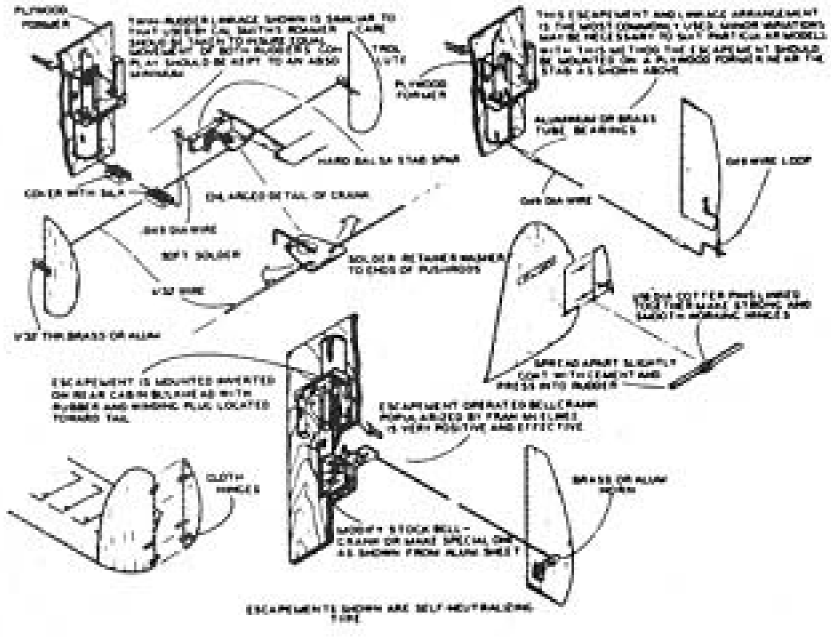
Beginning point is a cabin spacious enough to allow easy installation and removal of the receiver and of the batteries and escapement, if those units happen to be within the cabin proper. Receivers usually are mounted by two methods: suspended from rubberbands attached to hooks on the cabin walls, or on foam rubber, preferably attached to a sliding tray of plywood which fits against the front bulkhead of the cabin. The latter is the superior method because it is quickly removable and highly crash resistant. To prevent a rubberband suspended receiver from shooting back and forth in the cabin when the plane strikes an obstacle, a tether cord is tied between the rear of the chassis and some solidly mounted structural part, like the rear wing hold-down dowels. Leave only slight slack in the cord. In either method of mounting, be sure that the receiver cannot bang against potentiometers, jacks, or other objects sticking out from the cabin walls.

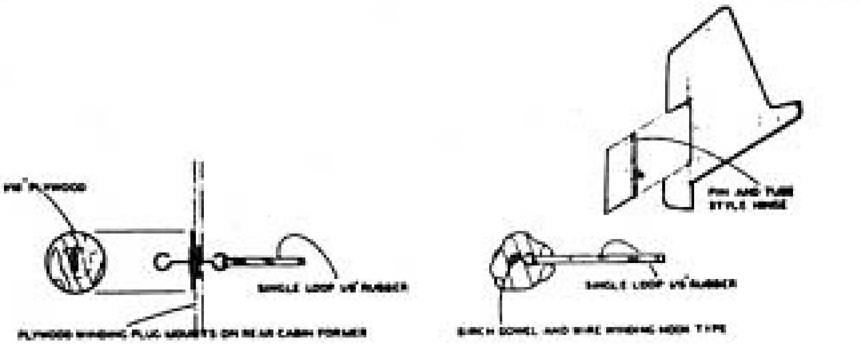
Wire leads are attached by two methods to the receiver: to fahnstock clips at the corners of the chassis (which also hold the rubber suspension bands); or as a cable terminated in a plug, the socket for which is permanently mounted in a special plywood partition, bulkhead, etc. Wires from the batteries terminate on the underside of the socket. Coat the underside of the socket with cement to prevent vibration from breaking off the soldering tabs.

Batteries may be mounted in taped-together packs in a snug fitting compartment (constructed before the fuselage is covered) with a convenient hatch either on top of the nose, under the nose, or under the cabin. The proper center of gravity position usually demands that these batteries be located forward of the leading edge. The structure should be tied together designwise so that batteries cannot knock loose the adjacent bulkhead, nor should that bulkhead be easily split. This bulkhead should be supported at the ends and in the middle. Plywood simplifies the problem.

Battery boxes must be accessible. The plastic type with vertical mounting may be reached easily from the top of the nose. On larger planes metal boxes may be installed in the nose or, if space is cramped, underneath the cabin floor, with a large removable hatch forming the bottom of the fuselage at that point. The floor should be plywood: ⅛ ply should be adequate for the largest of planes.

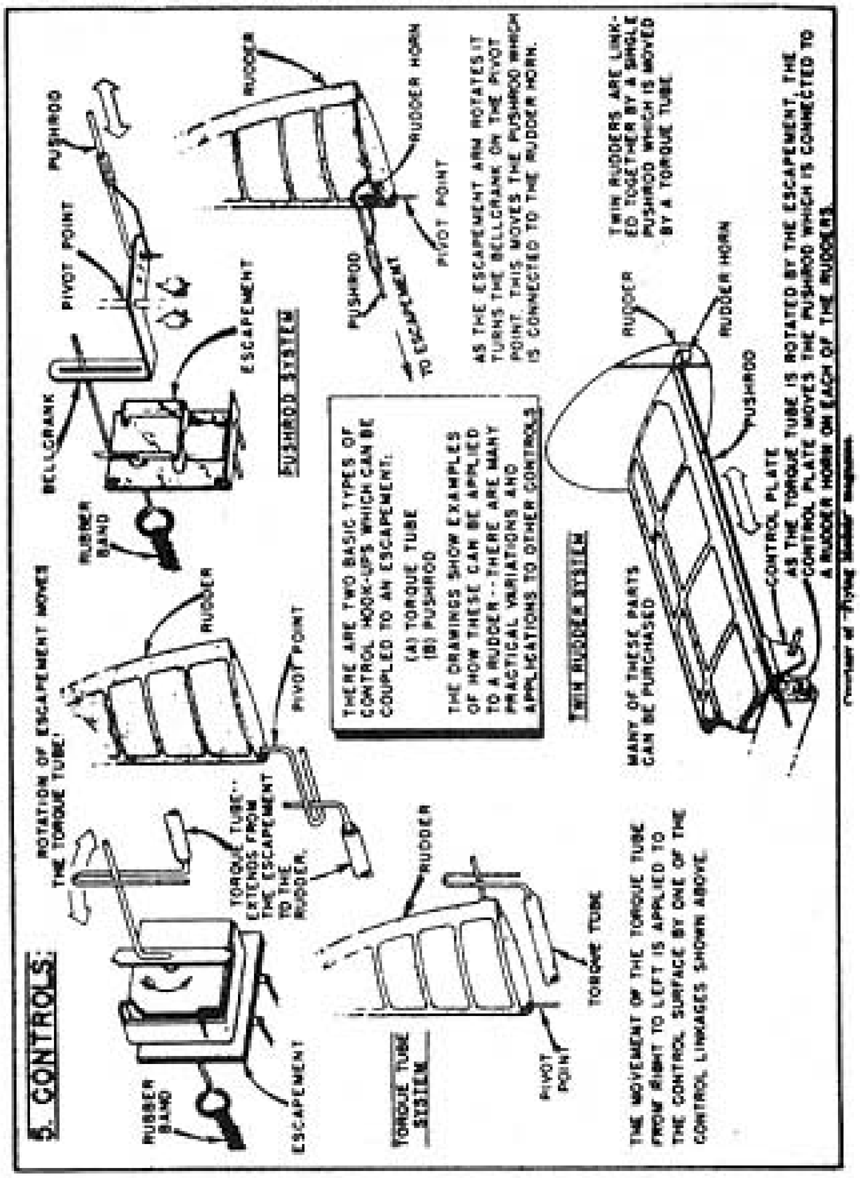






Batteries should not be located inside the cabin in such a manner that the receiver must be moved to replace them. If batteries must go inside the cabin, plan some practical arrangement.

On small planes the weight of an escapement at the rear makes proper trimming difficult; on larger planes the rear-mounted escapement requires long leads with a possible loss of battery voltage along the line. For such reasons it is desirable to mount the escapement at the rear of the cabin, accessible through the open top of the fuselage. Since an escapement should be examined periodically, it is advisable to place it on a plywood slide. Arrange convenient means for replacing and winding escapement rubber. Avoid S hooks on the escapement shaft as the hook may climb the shaft and cause jamming.



With the forward-mounted escapement, the linkage may be lengthened as necessary by means of a balsa strip or metal tubing, to the ends of which are attached the yokes. Or, if a bellcrank is employed with a push rod, the crank is attached solidly to the cabin floor. The shape of the manufactured RC bellcranks suggests obvious arrangements. Servos, of course, always are mounted within the cabin, close to the center of gravity, because of their greater weight. Magnetic actuators should be installed well forward.

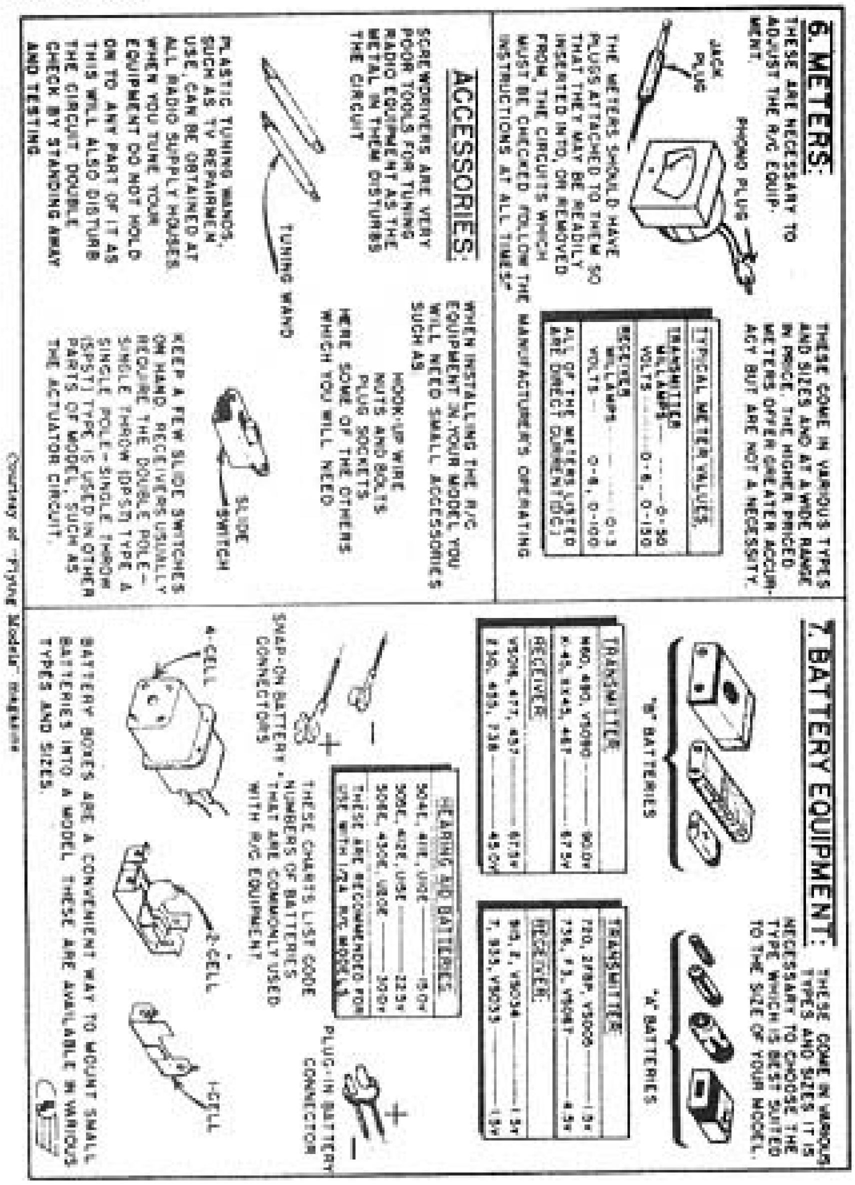
Although the bellcrank arrangement is suitable for normal use, the torsion rod is more easily moved and places no dead weight upon the escapement. When the plane is in a nose-down position, the escapement must lift the weight of the push rod. With elevators, the weight of the push rod, plus the weight of the surfaces when deflected, places heavy additional loads on the escapement which could fail or falter in a crucial position. Such additional loads transmitted to the escapement mean that it will have higher pull-in voltage: if, ordinarily, it pulls in at 2 volts it might not pull in at less than, say, 2¾ volts, when handicapped by a poorly designed control system.

Potentiometers, phone jacks, and switches also should be conveniently located, out of the way for launching (sometimes switches are accidentally flipped off during launching), and out of the way, inside the plane, for the receiver when it is bounced about by rough landings. Usually, those parts may be grouped together, perhaps in a line. The cabin wall, at the point of installation, should be reinforced with a piece of 1/16 inch thick plywood. The location of these parts varies, but most commonly is at the left of the fuselage, readily available to the launcher. Sometimes switches jut out from the fuselage bottom or from the fuselage top, back of the wing.

The milliammeter should be attached directly to the phono plug, because long leads may affect tuning. The meter can then be inserted into the phono jack during ground checks without having to hold it with the free hand, or to place the plane upon the ground because you don't have three arms. Sometimes it is desirable to slip a meter into the circuit with the engine running to help isolate trouble; therefore, place the jack so that the meter can be used without taking off a wing. If two jacks are used with a two-tube receiver, position them so that two meters may be used simultaneously if desired.

Wiring inside the plane should not run loosely from point to point, but should be brought along, and fastened to, the fuselage sides or bottom so that it does not shift about with odd effects upon the receiver. Loose wiring is vulnerable to vibration. With either battery boxes or packs it will be found that wires can be grouped together, separating only for attachment to the receiver or to the socket into which the receiver cable plugs. Individual wires may be held down by cut-off pieces of pins, bent U-shaped, and forced into the wood like staples, and finally cemented. Don't make rigid wire connections anywhere, but allow enough slack to make a small pigtail to absorb vibration. This is particularly important where wires attach to switches or enter battery boxes. Use toggle switches rather than slide types.

For the flier with more than one airplane it is a good idea to standardize installations, so that one receiver may be shifted from plane to plane. A receiver cable with plug and socket is ideal, and the receiver mounted upon a slide is most easily interchanged. If cabin interiors are held to a standard dimension, a balsa box can be built to hold the receiver, the escapement or servo, and perhaps the batteries with all the wiring. Switches, etc., would be mounted on the box and protruding parts, such as switch handles, could be dropped through holes cut in the airplane skin. The meter jack could be inserted through a hole to reach the box.



6. METERS:

THESE ARE NECESSARY TO ADJUST THE R/C EQUIPMENT.

THESE COME IN VARIOUS TYPES AND SIZES AND AT A WIDE RANGE IN PRICE. THE HIGHER PRICED METERS OFFER GREATER ACCURACY BUT ARE NOT A NECESSITY.

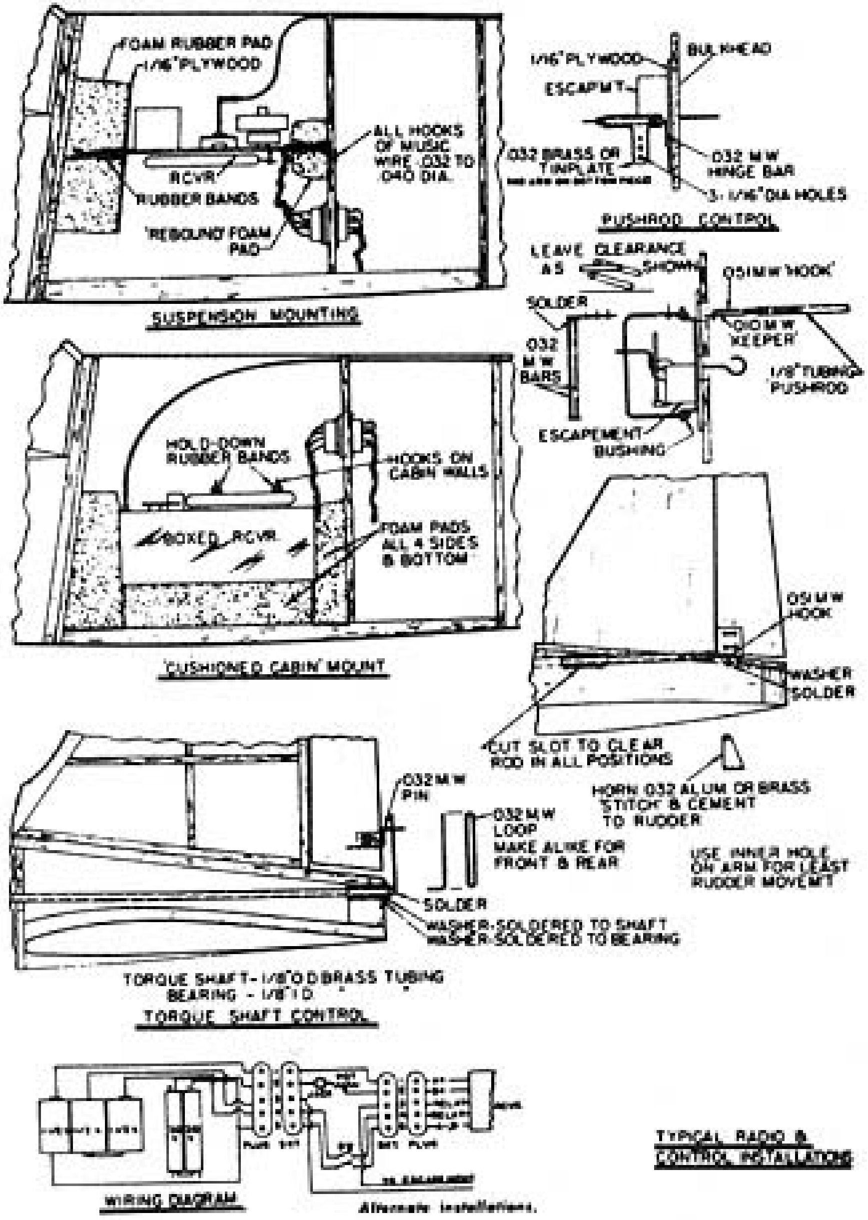
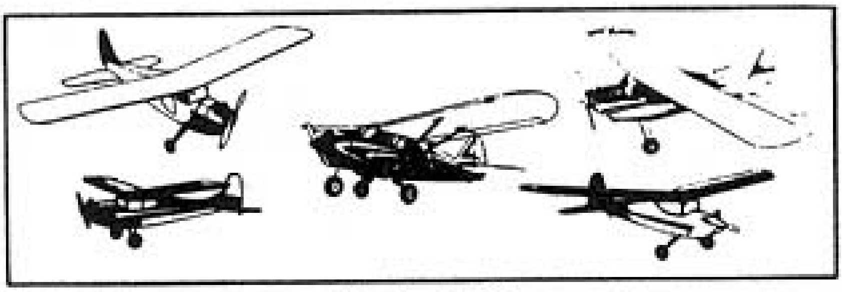
The bigger, heavier, multi-channel receivers should be mounted in accordance with the manufacturer's directions. Shock mounting these heavier, bigger units must be carefully worked out to prevent the receiver from breaking loose, and the manufacturer of such equipment has found the best means of doing so. But where simpler radios are concerned, all kinds of gimmicks have been developed by the modelers themselves. The above description represents the most typical, proven ideas.



TYPICAL RADIO & CONTROL INSTALLATIONS



Chapter Eight

THE AIRPLANE

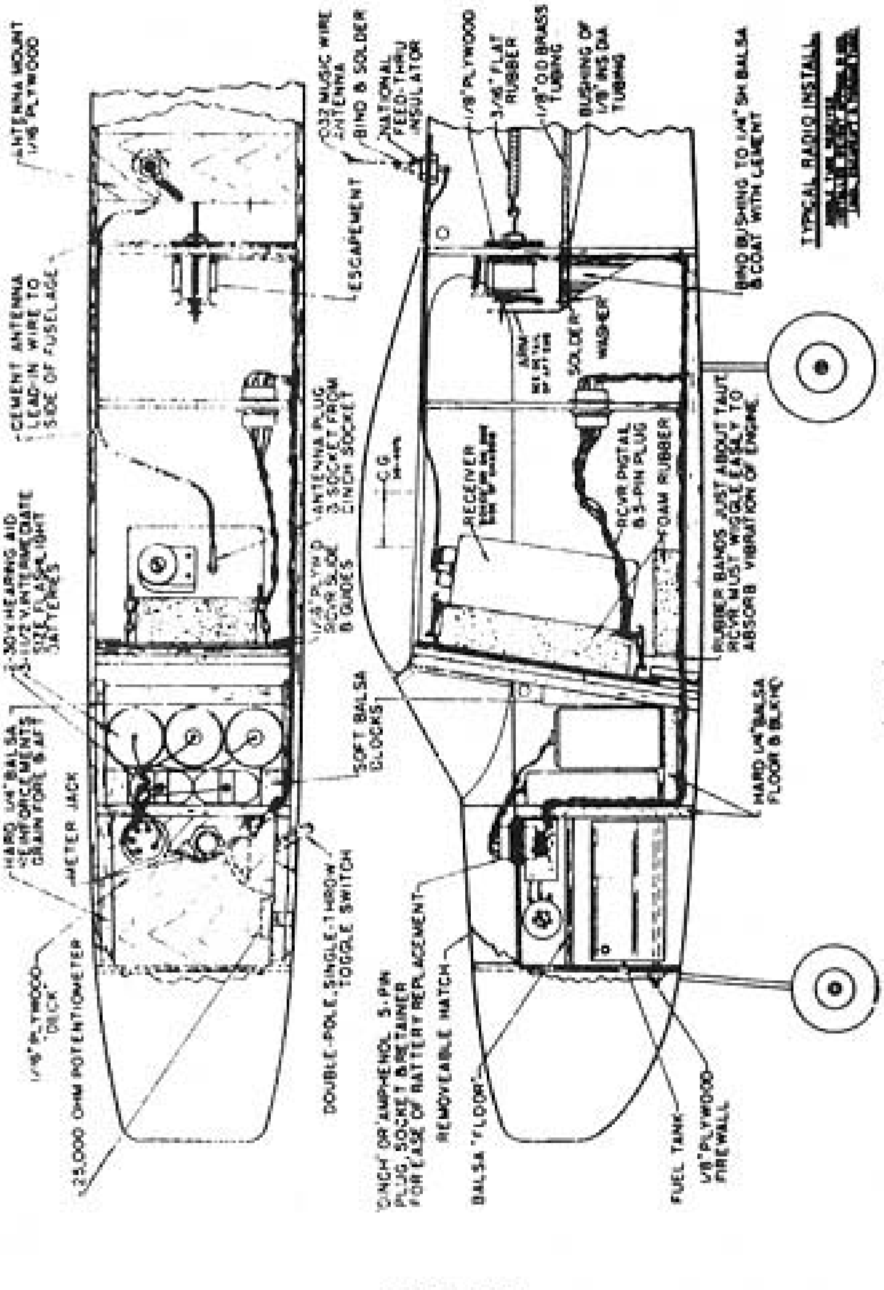
The RC airplane is as much a special design as a U-control stunter, speed model, or contest free flight. It once was considered necessary to have a high powered monster of eight or ten-foot wing span for RC, with a gross weight running as high as fifteen pounds. Its "crew" would spend most of the day tinkering with its innards and then usually crack-up along about sunset. The builder was satisfied merely to see it fly. No special attention was given to how it flew, or to the flight characteristics it should possess.

The modern RC job spans anywhere from thirty inches to six feet, though a few people always will want them big! Half-A engines are practical. A .15 to .19 engine will carry anything required, and .29's to .35's will stunt the heaviest multi-channel receiver on the market.

The newcomer to RC has misconceptions about "low power." If a U-control stunt model weighing thirty ounces is powered by a Fox .35, he reasons, how can this loaded-down RC job be expected to fly with half the power? Actually, the RC ship is trimmed to fly-flat, does not hang like a free flight, so that most of its thrust is devoted to pulling the airplane and not to lifting its dead weight vertically. A .29 in a lightly built five-foot RC job will separate the men from the boys.

At high forward speeds, control applications result in abrupt, breathtaking maneuvers. The writer has had machines which would fly inverted at 400-ounce power loading (weight in ounces divided by displacement in cubic inches): 375 ounces is a good all around figure. With a good engine and correct propeller, a plane would barely fly at 700-ounce power loading, but this is another extreme. Excess power results in very high climb, risk of loss, excessive altitudes, and the necessity of frequent spin-downs to kill that altitude, with attendant violent recoveries and zooms which may result in the airplane getting out of hand. In a wind, high power is poison.

The RC ship should not be needlessly heavy, or, on the other hand, a "floater." Good flight characteristics result from wing loadings between fourteen and eighteen ounces per square foot of wing area. These power and wing loading figures are valid for .09 to .15 engines, may be lower with smaller ships, or higher with bigger jobs. The various kits available from your dealer will fall within these limits when fitted with radio and loaded down with batteries. A rough estimate of span by classes of engines: .049–36 to 40 in.; .09–40 to 50 in.; .15–54 to 60 in.; .19–54 to 72 in. plus: .29, .32, .35 etc.–60 to 84 in. The beginner should work with the more moderate figures in all cases.



Typical installation.

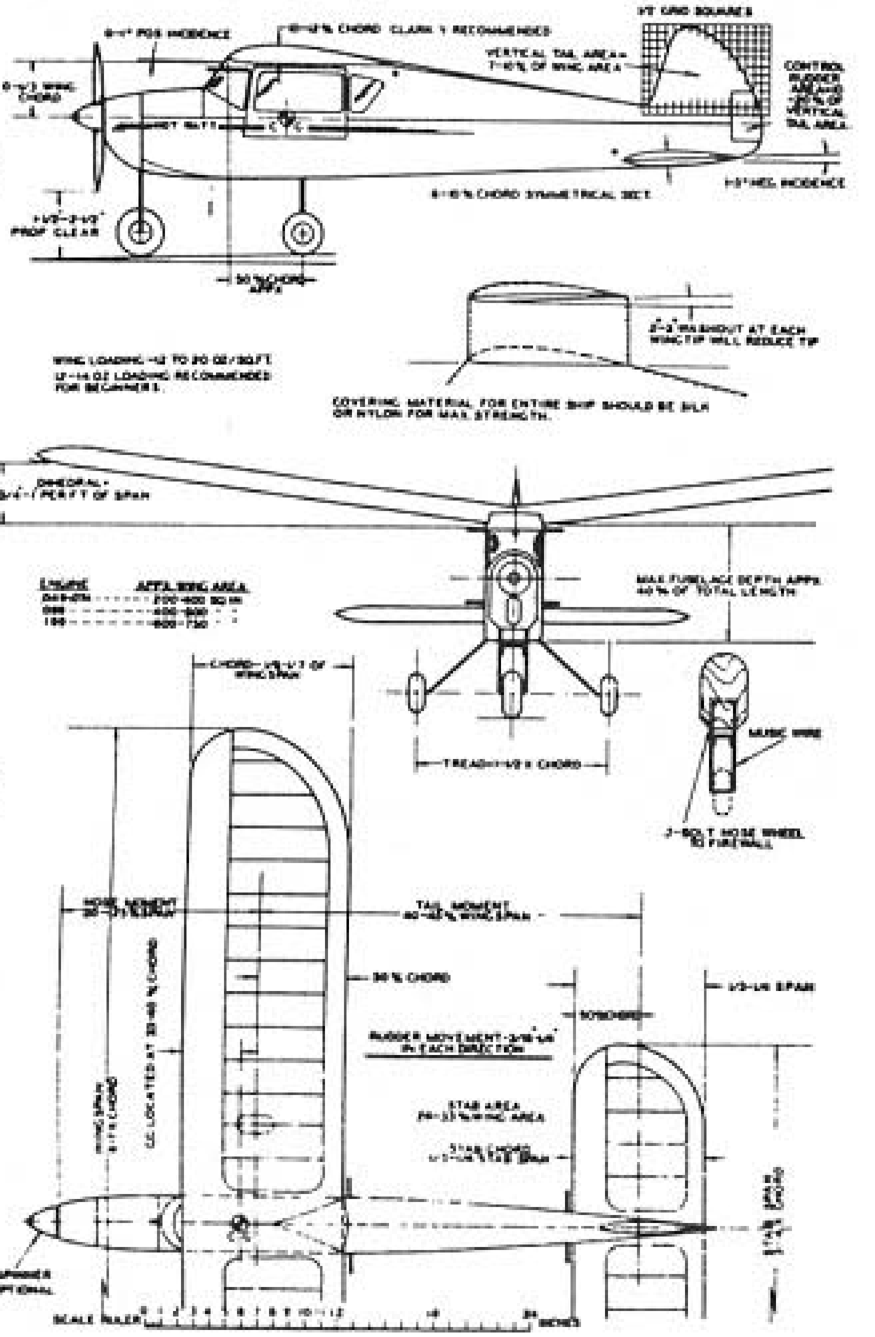
If you design your own machines, some knowledge of latest trends and proportions will be helpful. Aspect ratio, or the relation of the span to the chord, or width of the wing, is low when compared with free flight, ranging from 5½ to 1, to 6 to 1. The tail moment arm, roughly the distance between the centers of the wing and stabilizer chords, need not be longer than 40 per cent of the span. Stuntable designs are becoming shorter and shorter, with as little as two chord lengths of distance between the trailing edge of the wing and the leading edge of the stabilizer. Nose lengths, on the other hand, are becoming longer. A distance equal to about seventy five per cent of the wing chord, between rear prop washer and leading edge, is a good minimum. It is always a problem to get an RC plane nose-heavy enough when properly trimmed.

Both straight and polyhedral wings are employed. An excessive amount of either gives rough turn entries and an abrupt rocking-out recovery as soon as the signal is stopped. Too little of either, and the plane has a tendency to stay in the turn, to develop spiral dives, unless the overbanking is prevented by use of opposite rudder. Measured on straight dihedral, an angle of approximately 6-7° gives best all around performance.

Wing and stabilizer settings are important for stability, resistance to stall build-ups, and quick recovery. With a symmetrical cross-section stabilizer, the angular difference should be at least 1½° and not more than 3°. With a lifting type stabilizer, this angular difference should never be less than 3° because, in spirals, dives and other maneuvers where air speed builds up, the stabilizer may develop more lift in proportion to the wing and dive the ship into the ground. For the same reason, it is dangerous to increase the positive incidence in the tail by means of shims. Once the angular difference becomes too small the plane has poor stall resistance, may roller coaster in the wind, or dive in from a spiral.

Virtually all RC planes require varying amounts of right and downthrust. This probably averages out to about 2° right, and 5° down. Some airplanes have both wing and tail set at a positive angle so that, while the thrust line appears parallel to the ground in the take-off position, there is actually a built-in, though invisible, downthrust. Downthrust will make the plane fly faster through its effect on trim. It is imperative on slow gliding planes that seek to fly appreciably faster under power.

Two basic systems of trimming are practiced; your choice determines what you do to the fuselage during construction. With either system, the center of gravity, or CG, should be well forward, anywhere from thirty to forty per cent of the chord back of the leading edge. (Placing the CG farther to the rear invites trouble.) The resulting nose-heavy glide is compensated for by increasing the angular difference, usually by increasing the amount of negative incidence of the stabilizer. In the first system the wing is placed flat upon the fuselage top which should be parallel to the ground line. The stabilizer is then set with its leading edge at a negative angle of ½ to 1½°

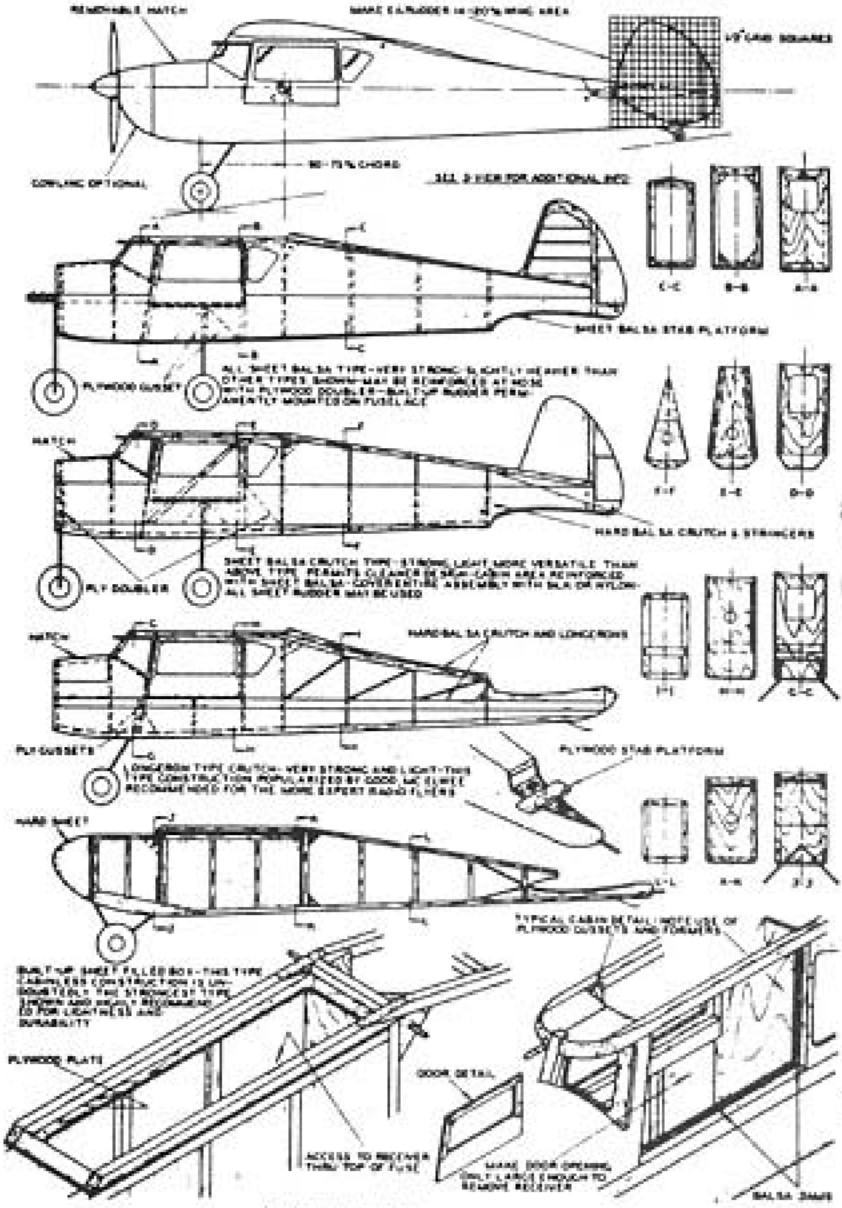


Typical proportions.

The second system involves placing both wing and stabilizer at a positive angle to a line parallel to the ground line, as much as five to 8° for the wing, and 3½ to 7½° for the tail, or some other amount depending on the necessary angular difference. This system removes unsightly downthrust as far as the eye is concerned, and tends to give a buoyant airplane in maneuvers, one that "pops" well for loops. The first system may result in a highly responsive ship on rudder and high wind penetration. Its looping ability may be reduced somewhat and downthrust is apparent to the eye.

Both tricycle and two-wheel landing gears are widely used. The former makes the surer take-offs and protects propellers better on rough fields. The latter is lighter, easier and cheaper to construct, and will take off, provided the gear is placed far enough to the rear.

Multi-control planes have begun a trend toward symmetrical wing sections, à la U-control stunters, and short coupled fuselages. Such machines will perform outside loops as easily as the inside variety and will remain on their backs more readily than those using such airfoils as the Clark Y. The symmetrical section cuts down ballooning out of turns, or zooming in a wind gust, and permits much lighter wing loadings (added area for better stunts) without ill effects on the flying characteristics of the plane. They may require a more forward CG position and, possibly, a small angular difference of ½ or 1°. With a rearward CG or large angular difference, they tend to whip into true spins when stalled. It has been found that the wedge type leading edge spoiler is superior to washout for preventing wing tip stalling. When the plane is inverted, washout becomes washin and a wing up will stall, rolling the airplane upright. Six-inch long spoilers are adequate for a 5 1/2 foot machine, with others in proportion.



Fuselage construction.

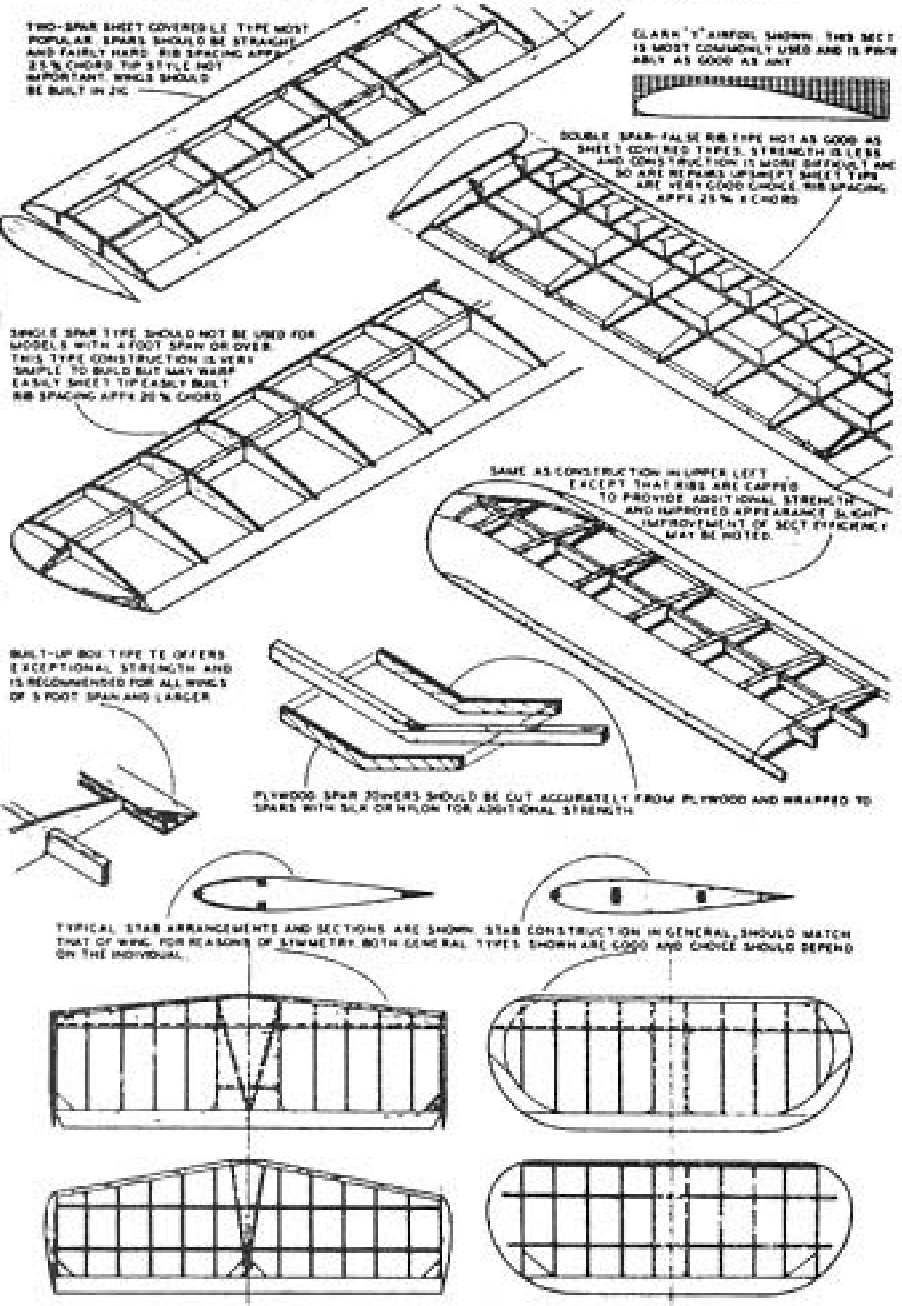
If structural design is good, a radio model will not break up even in a bad crash, unless it strikes cement or hard earth. Fuselage construction may consist of longerons and cross pieces, or of sheet balsa siding and bulkheads. The method used is up to you. If longerons, the wood should be very hard, and the forward sections of the fuselage should be filled in with sheet balsa of the same thickness. A thin facing of plywood inside the fuselage at the nose will increase strength enormously. Sheet balsa fuselages may be laminated at the nose from various thicknesses of material, sanded to match the top view contours. If one or more thicknesses end at a bulkhead station, that bulkhead may be cemented to the butt ends of the side plies, and it will then resist any forward displacement, as from battery impact.

If the material does not have to be curved, as seen on the top view, it will take much higher impact loads. Probably the strongest nose construction results from the use of light balsa blocks, carved and sanded to the proper outlines and cross-sections. Motor mounts and bulkheads that stand in the way of batteries should be anchored and reinforced. Fibreglass nose covering is becoming popular. Fibreglass patching kits may be obtained at boat supply houses and some hobby shops. The fibreglass is attached with a special resin which hardens within an hour of application. The resulting surface is impervious to hard knocks.

Most troubles resulting from wing construction come from warps. Warps create endless difficulties in adjusting and flying and must be removed. Silk and nylon coverings exert a powerful pull when drying, and may continue to pull tighter and tighter for some weeks after completion of the job. A wing or stabilizer may pick up a warp when standing in the hot sun.

Almost any wing can be given warp resistance by the addition of a top spar fairly close to the trailing edge. It is the rear corner of the wing that tends to pull up; this tendency is acute on a single spar wing. Geodetic construction, à la the Hogan type of free flight, would be excellent on radio jobs. Watch the wing panels when the first coat of dope is drying. Counter any warps as they begin to appear by holding the still-wet frame in the correct position until it is dry. Dope a half wing at a time so your attention won't be divided. Thin the dope if it appears unduly thick. Add about six drops of castor oil to the ounce of dope for the last coat or two. This prevents excessive pulling.

To remove warps in a finished wing, hold the panel over a steam kettle or other safe source of heat and, while the wing is hot, twist it in the opposite direction to the warp. Create a warp in the opposite direction as the original warping tendency will cancel it out. Or the wing may be placed flat on the bench; wipe the upper surface lightly and quickly with a rag wet with thinner. This will soften the finish. Hold the wing true until dry.



Wing and tail construction.

A common weak point in RC wing design is the leading edge; if too light, it will break on striking bushes, posts, and other objects. Leading edge sheeting is very difficult to repair after this type of failure. False ribs, or half ribs, placed between the full ribs, instead of leading edge sheeting, contribute to leading edge strength.

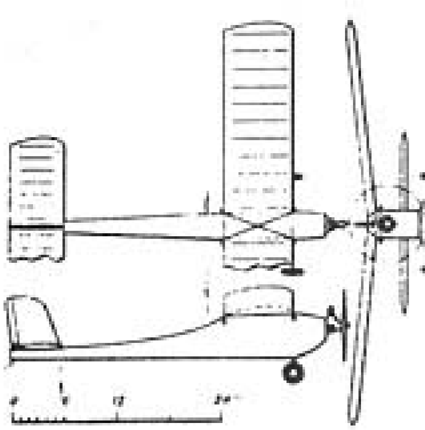
Although spar positions vary greatly, probably the ideal position is through the center of the rib, rather than on top or bottom. If the wing is cloth covered, the bottom surface is then in tension when the plane loops. Such spars will carry a surprising load and are well worth the added work. Also, their location opposes any tendency of the wing to bow upward from the pull of drying dope.

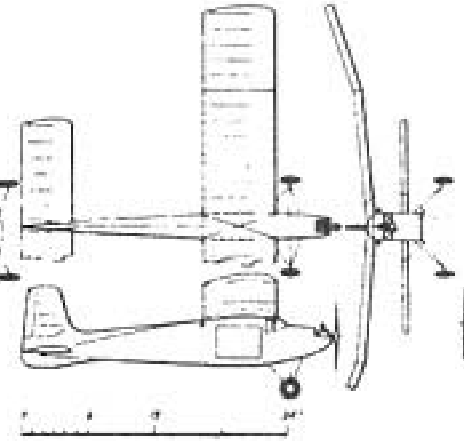
Since it is difficult to keep the rear end of the plane light enough, it is advisable to make the tail surfaces as light as possible and yet maintain warp free construction. Don't add extra material near the tail of the fuselage. Knock-off stabilizers seem to have little advantage over those permanently installed. When the plane cartwheels or snags a stabilizer tip, the rubber hold-on bands may break up the rear tip of the body. With knock-off tails, the adjoining portion of the fuselage should be reinforced with another thickness of material, and the rear dowel secured against a sideways pull. The integral stabilizer places extra stress upon the fuselage when the plane hits on the nose, as when falling from a tree. But a well-built fuselage takes this punishment. It is essential that the vertical tail be alined accurately and securely. The fin should be part of the structure of the airplane. If the fin is added after the fuselage is completed, make arrangements beforehand for its accurate placement. A fuselage that is pulled together carelessly at the rear may throw the fin out of alinement. Lay the fuselage on its side during assembly; measure from the table top to the rudder post, then turn the fuselage over and repeat the measurement. Or, measured this way, the rudder post should be off the table a distance equal to one half the fuselage width.

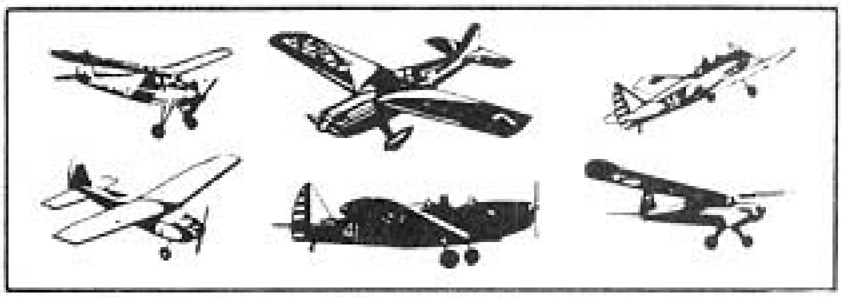
For long life, every joint on an RC model should be double cemented. That is, coat the surfaces to be mated with cement, allow to dry, then recement and press together.

Small airplanes with Half-A engines, and even some .09 jobs, may use sheet balsa stabilizers in lieu of the built-up variety. The wood should be selected for resistance to easy bending, yet not be excessively prone to split. It should be treated when finished with thinned dope plasticized with castor oil, eight drops to the ounce. Vertical fins may be made from a single thickness of balsa up to the larger size models, where thinner balsa sheeting is bent over a spar and ribs. Or, on bigger machines, built-up spar-and-rib vertical tail frames may be covered with paper or fabric.

When simple receivers are used, the tendency is to build the airplane needlessly light. But the contrary is true with complex, heavy radio equipment. Then the designer has to cut corners to hold gross weight down so that the ship may be launched easily, and not fly at excessive and dangerous speeds.







Chapter Nine

HOW TO FLY

Before considering adjustments and flying procedure, it is well to understand the effects of various design features upon the airplane's flight. To begin with, a ship that has much lift through such features as a thick or high lift airfoil, pronounced decalage (angular difference), or light weight, or any combination of these attributes, must be flown with relatively low power and at rather low speeds that are matched to the slow gliding speed. As a rule, this is a calm weather airplane, but one that loops easily when stunting is desired. A ship having any or all of the opposite attributes will fly faster and with better wind penetration.

The RC job is hand-glided like any free flight airplane and the familiar trim corrections are made to obtain a fast, straight glide, without a trace of flare at the landing. If tail heavy, the weight may be shifted forward, incidence removed from the wing, or added to the stabilizer. But if angular difference must be decreased beyond the safe limits previously described, it is necessary to change the CG position, even if some rebuilding is necessary. If the plane appears nose heavy, any or all of the required corrections are in order. If unreasonable or drastic adjustments become necessary, revise the airplane before attempting to fly it. This sometimes happens to the most expert builders. For example, a plane having a bad wing warp may fall off on the wing and slide into the ground when hand-glided. It may build up a spin under power and, despite opposite control, could hit the ground.

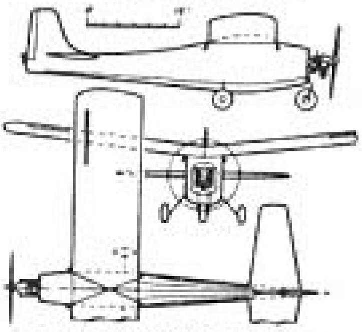
Claude McCullough, Ottumwa, Ia.



Wayne A. Schindler, Los Angeles, Calif.

Engine-on test flights are made with a moderate amount of power. Do not throttle all the way back, as with a rich mixture, because sufficient thrust is needed to pull the machine through mild stalls or mushy trim attitudes. Do not lean out the engine, on the other hand, because poor trim may result in violent zooms and turns which could give the beginner a hard time. One good system is to put the propeller on backward, then permit the engine to rev up. About one-third the thrust is lost but the engine will run reliably and develop enough thrust to climb the machine. Torque does not vary drastically when the prop is reversed.

On the first few flights use enough fuel to last thirty seconds to a minute, at the most. Try to keep the plane well out in front of you, and do not, at first, make any turn more than 45° without recovery in the opposite direction. This prevents the ship from breaking away to head downwind as the result of overcontrolling on your part. A few short, upwind flights, with a minimum of maneuvering, will give you the feel of the controls and indicate whether or not control action should be increased or decreased for reliable response.

Rudder reaction will vary with the flying speed of the airplane, differing between power-on and power-off flight. Whenever the nose rises, as when the ship hangs on a prop or mushes during normal flight, rudder response is sluggish. To eliminate periodic lapses in effective rudder action be sure the ship is trimmed properly. Try to minimize the difference between power-on and glide speeds by keeping the glide a trifle fast and the engine thrust slightly reduced. In a properly designed machine, this difference is never severe.

Rudder response should be sufficient to take the airplane out of a steep turn and to swing it into a turn in the opposite direction. Thus, if the airplane is placed inadvertently in a spiral you can be sure of making a recovery. Many a first flight has been made by holding rudder steadily against an in-built turn tendency, just because enough rudder response had not been provided. This is another reason why long motor runs should not be used with a new ship or by a beginner pilot. Poorly adjusted models, which includes most new airplanes, may build up violent maneuvers, especially when the flier is inexperienced, so it is reassuring to know the engine will not run forever, Of course, too much rudder response is possible. If you think you have extra rudder response try the control gingerly the first time, and don't hold down the button.

How much rudder movement? How much area? While this is hard to answer because of variations in design, it can be approximated, assuming CG position forward of forty per cent of the wing chord. In this case the movable rudder should be about twenty per cent of the total vertical tail area. A tall thin rudder is preferred to a short, wide one, as its action is more effective. The latter type is extremely weak on the glide, consequently forcing an excessive amount of area or movement that makes power flight too responsive. In the case of an .09 to .15 powered ship, 1/4-inch movement of the rudder to either side should be plenty to begin with, and it may be cut down to 3/16 or even 1/8-inch movement later if desired. Other size ships may be judged accordingly. This set-up should give abrupt response, enough to take care of any contingency during test flights.

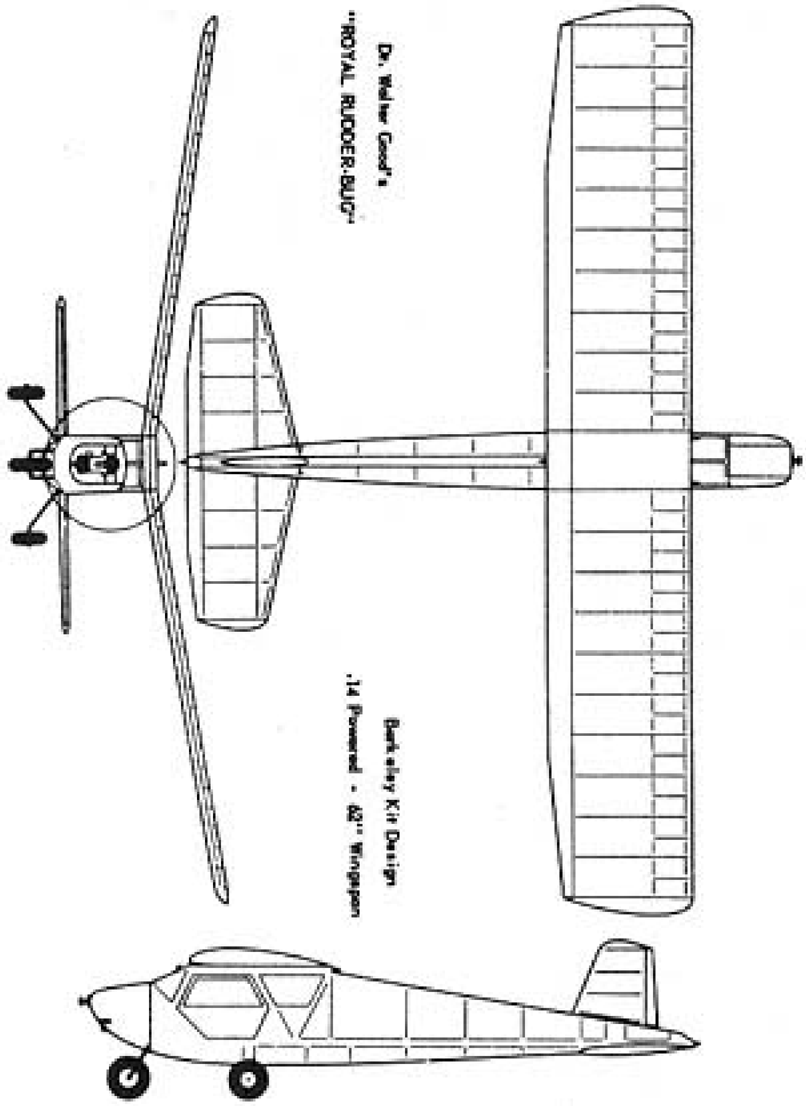
As soon as the plane becomes airborne it will be obvious immediately whether or not it is out of trim. Any tendencies to stall or turn may be corrected. It is desirable to judge these things first from the glide. If adjustments become necessary in order to make the plane fly at all, before you get chance to study the glide, remember that, ultimately, the glide should be perfected and, only then, the power portion of the flight. This is the same procedure used in free flight. Power adjustments are controlled by down and side thrust. Use side thrust to make the ship fly straight and down thrust to hold down the nose while the engine is running. It is impossible to make final power adjustments until the glide is proper.

It is smart practice to leave just a trace of a circle in the plane, both under power and in the glide so that, if anything should go wrong, the ship would cover a minimum amount of ground before coming to earth.

If it becomes impossible to hold down the nose with downthrust under power, the glide being correct, a smaller engine or less thrust is required. Thrust can be reduced by using lower pitch props, smaller diameters, and rich running. Wide blades, thick blades, with a lot of wood, will reduce rpm's by 500 or more. Sport fuels, adding castor oil to hot fuels, will help. An extra big prop often has the opposite effect to what the flier expects. Engine efficiency may drop off, true, but the propeller efficiency is so high that the combination of engine and propeller is more effective than before. The intake opening can be cut down with a wooden plug so that revolutions are less even when the engine is leaned out. Or reverse the prop.

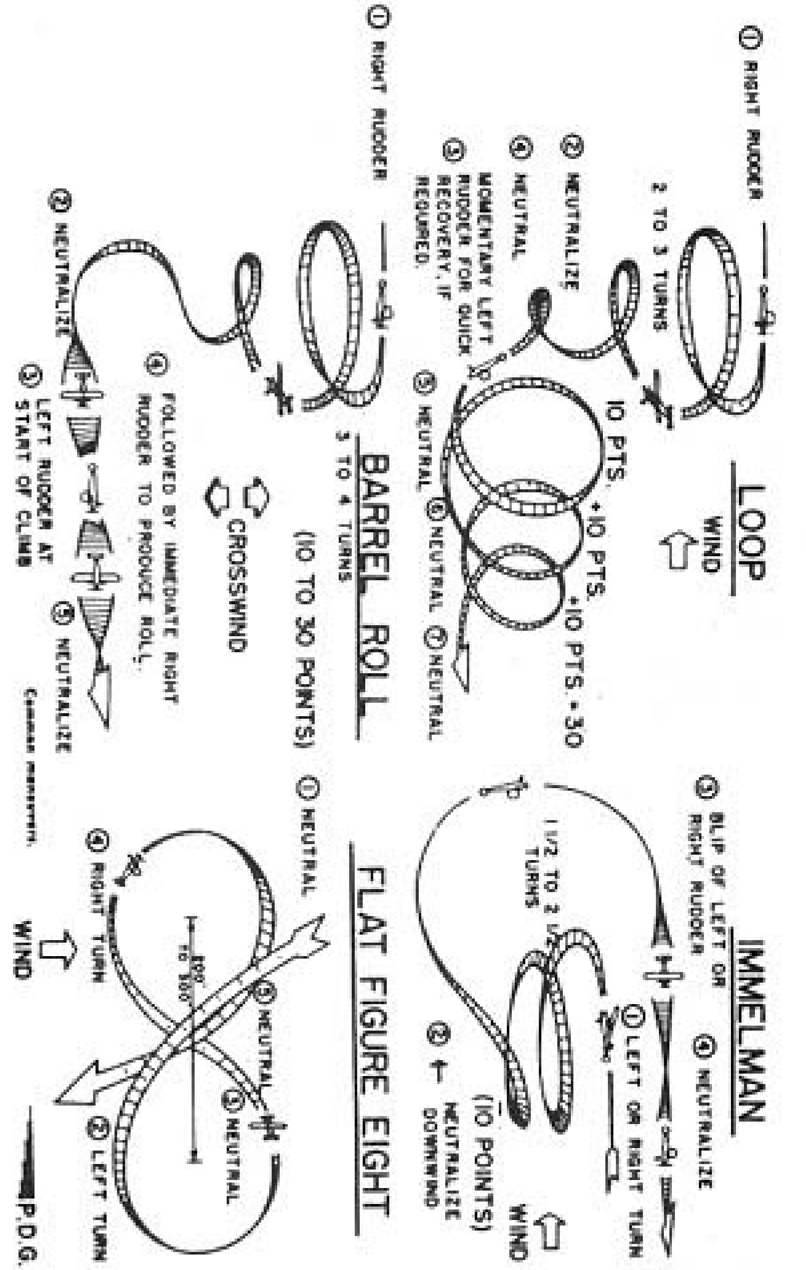
The most important trick of the trade is the killing of stalls, resulting from maneuvers during which speed builds up, by use of rudder. When the nose comes up, turn the ship with rudder, just enough to convert an incipient zoom into a climbing turn. Even a well adjusted plane sometimes stalls, as in a recovery from a spiral. Amazing things can be done with rudder. A ship that is slightly nose heavy under power, can be kept aloft by starting a turn in one direction, then abruptly reversing it, and continuing the action for as long as necessary. Properly done, the plane appears to rock from side to side. This rocking motion will get a plane into the air after a poor launch that might strike the ground, or help clear obstacles that loom ahead. It will affect a good landing when the plane comes in too steep and fast. Slowly waggling the rudder, rocking the wings, will bring up the nose and slow down the speed. Smooth three-point landings can be made by turning the nose slightly while still a few feet in the air, picking up additional speed as the nose drops farther, then using opposite rudder for recovery. The extra speed provides enough lift now to nose up the craft, flaring out for a scale type landing.

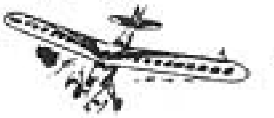
Holding steady rudder produces a spiral: break the recovery zoom-and-stall by turning. If a spiral is continued long enough and no corrective action taken as the plane begins its recovery zoom, the ship may continue over for a beautiful loop. A snap roll sometimes can be performed during the recovery from a spiral by quickly applying and instantly relaxing rudder, as left rudder after a right-hand spiral, then reversing and holding the rudder (right in this case). A slow roll may be done by holding rudder briefly until the nose starts down in a turn (beginning of spiral), then using opposite rudder until the nose again begins to drop in the other direction, and repeating the rocking action until the plane almost goes on its back. When it appears that the ship is ready to roll over, hold steady rudder to complete the job. If there is sufficient altitude, play around with spirals done after spirals, all of brief duration, and you'll discover methods of

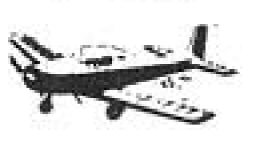


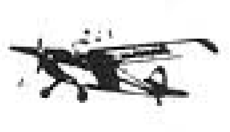
Dr. Walter Good's
"ROYAL RUDDER-BUG"

Berkeley Kit Design
.14 Powered - 62" Wingspan









performing many advanced maneuvers.

Wind affects flight. A job that is trimmed for a slow glide in calm weather may stall in the wind or, if trimmed for windy weather flying, it may glide too fast in a calm. Since modelers are plagued with wind, it is better to trim for moderate breeze. Control response may become sluggish especially when flying cross wind. The green pilot may be fooled by the delayed action into thinking he has no control at all. It is necessary to hold signals longer. Rudder response that permits only a gentle turn in the calm probably won't turn the ship at all in the wind. Reserve control action is required. It is advisable to employ more control action than actually needed at all times. Linkages, control horns, and bellcranks always permit adjustment for more or less control action.

The way to maintain control on blustery days is to keep the ship well upwind: always avoid letting the plane get behind you, or downwind. Stay far enough up-wind so that all turns may be completed with the ship still in front of you. For some strange reason, a radio job is much more difficult to fly back against the wind, looking at it nose on, than it is to control it when it is going away from you into the wind. Avoid all violent turns and acrobatics in strong wind. Anticipate maneuvers. If, for example, you wish to recover from a turn on a 90° heading, apply opposite rudder well in advance of 90°, otherwise the ship may end up with a 180° turn! If things get too hot, let the ship fly itself for a few seconds until it smooths out its flight path. This is a good rule, too, when performing stunts when the ship gets into some awkward position. It will fly itself out of trouble.

Consistent, accurate spot landings can be made by standing on or as near the spot as possible and by following a standard procedure or landing pattern, as is done with full scale aircraft. If a standard pattern is followed, it should be possible to get the airplane into an identical key position for every approach, provided, of course, that enough altitude remains after the engine quits. The writer prefers the plane to pass on the left, gliding downwind, then to swing around 90° into a base leg (crosswind), and finally turn another 90° into the final approach. The length of time on the downwind and base legs can be varied with practice, according to the wind, going farther downwind when the wind velocity is small, and vice versa. By setting up a base leg, you provide yourself with a multiple number of points from which the ship can finally be turned into the final approach. With practice, it becomes possible to round the corners of this pattern, making a 180° turn from the downwind leg into the spot. Big and small, heavy and light models will vary greatly, but a standard pattern minimizes errors.

When high up, it is better to maneuver overhead than it is to glide far away in order to make an approach. The long approach is very hard to judge, especially with a fast, shallow gliding plane. Excess altitude can be dissipated by gliding back and forth from side to side overhead, finally swinging out to begin the landing pattern. Greater propeller diameters and lower pitches assist climb, especially in combination. Low pitches make for worse stalls since thrust is maintained well despite a nose-high altitude: the plane hangs on the prop and may whip stall. High pitch props slip enough to take the edge off stalls. But in a spiral or other high speed maneuver, the high pitch props really shift gears and very high air speeds result.

The most suitable props for all around performance: 9 x 4 to 9 x 6 on .15's; 8 x 3½ to 8 x 6 on .09's; 9 x 6, 10 x 6, 11 x 4, on .19's; 11 x 5, 11 x 6, 11 x 8, 12 x 5 on .29's Props should be matched to the plane. For example, a small, fast flying .19 job would use a 9 x 6, but a slower, bigger ship would get maximum thrust from the 11 x 4.

When downthrust is present, or when wing and stabilizer both are set at a positive angle to the thrust line (that also is downthrust), a low pitch, fast turning prop, will increase thrust at low airplane speeds, as after the launch, tending to pull the nose down until forward speed becomes high enough to develop the necessary lift, when the ship noses up. This accounts for the tendency of some RC's to dive toward the ground on launch. But this low pitch will make the plane "drop dead" in the air, just as low pitches do in U-control. The higher pitch will climb smoothly but, developing lower thrust at low airplane speeds, as in launching, requires harder running to get the plane airborne.

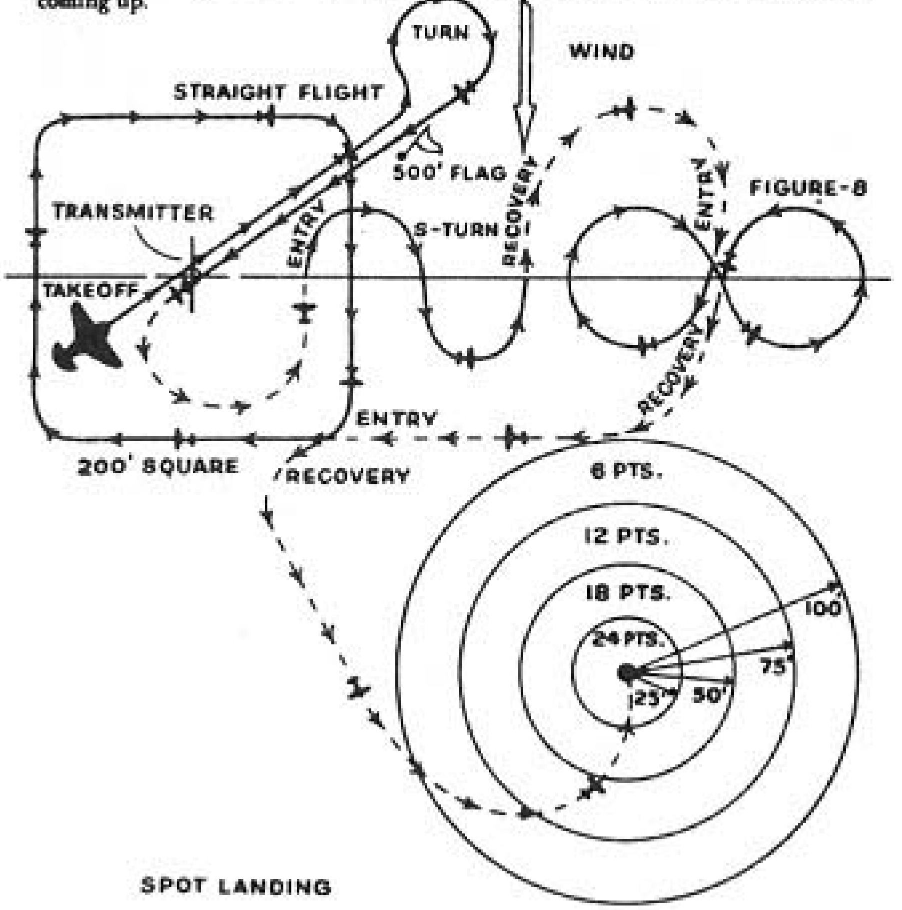
Marginal performance resulting from overweight may be improved by experiments with propellers. A sluggish .09 ship sometimes will compare with an equivalent .15 airplane by the use of a thin blade 8 x 3½ prop. A .15 job will perk up with a thin blade 9 x 5. Go to narrow, thin, light blades for higher rpm's and additional thrust.

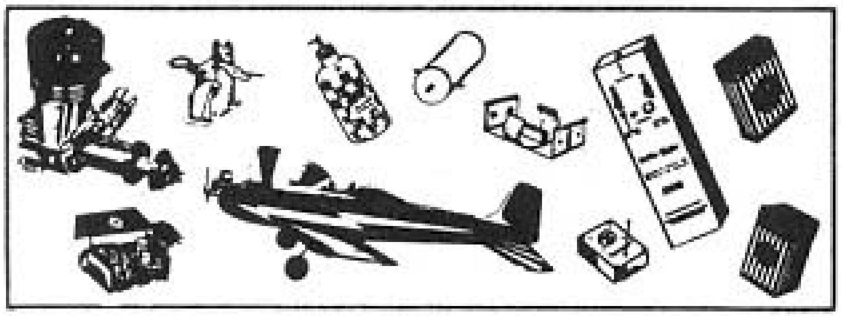
If, despite proper mounting of the radio and adjustment of the relay, you encounter vibration troubles, make sure that the propellers are carefully balanced and that the engine is turning within some smooth range of rpm's. A Torp .19, for instance, turns as smooth as silk at high rpm, as on a 9 x 5, or even an 11 x 4, but throttled back and richened up it can shake a seven-pound airplane hard enough to make the rudder skip. Many engines have rough spots in the rpm range: the designer simply did not intend them to be used with oversized props, or at medium rpm's. Persistent overheating, even of broken-in engines, can result from overly big props, high pitches, hot fuels, and hot plugs, and this almost certainly results when all these factors are present on a hot day. The engine will seem to lean out persistently—but it may be a bad case of overheating.

For normal flying, once experience has been gained, three minutes is an adequate motor run. The time seems much longer in the air. Short motor runs conserve batteries. Unless you require a full tank of fuel for contest work, there is small justification to risking a valuable plane with ten-minute motor runs, particularly on windy days. Even the heaviest RC job can ride a thermal.

Full stuntability depends on good fuel feed. Do as you would do in free flight; check the engine running with the nose of the plane up, but get the engine to run nose-down as well as nose-up! It may be necessary to plug the venturi to achieve this happy condition. A good tank installation will feed fuel steadily to any engine in good condition, if the feed line isn't too long, in any maneuver on a rudder-only airplane. Any oversized free flight tank is suitable but one of the best arrangements is a short U-control wedge tank, with the wedge down. Mount the top of the tank about one-third the tank depth above the needle valve level. A combination gravity-suction feed results. Over-elevatored planes which go through abrupt changes in direction may compel the use of a pressure type of tank, such as the Walker balloon tank with regulator.

Sooner or later every flier likes to make a long cross-country flight. In the distance, the plane is little more than a black dot. It is difficult to tell which way it is turning. Suppose, for example, it was flying broadside to you, and you used rudder to turn it back. How can you be positive which way it turned—did it come toward you, or did it go the other way? If you forgot the sequence, this can happen easily. Such tricks as painting one-half the plane one color, and the other half another, in order to check turns, is impractical, because the ship is opaque at a distance. Good technique for distance flying is to work the rudder at regular, frequent intervals, turning the ship just enough to detect a change of heading. By always doing something with the ship, you always know what control is coming up.





Chapter Ten

OPERATION

Satisfaction from making numerous flights with a minimum of fuss results from a clear-cut operations procedure. There is inevitable chore work, such as checking batteries, relay operation, inspecting escapements, making ground checks, etc., but these duties are rendered painless if incorporated into a standard procedure. Begin by putting both the ship and equipment into order before the flying session. Don't expect to do it on the field. Unexpected problems, however trivial, may ruin a flying session. A pre-flight check should include an inspection of wiring, replacement of weak batteries (receiver or transmitter), a check of the relay and escapement, linkage, etc., and finally operating everything with the transmitter.

Arriving at the field, decide upon the best location, according to wind direction, open area, nearby housing, etc. (Why is it that modelers tend to group under the only tree within a quarter mile?) If you have a stationary type of transmitter set it up before doing anything else. Check the airplane batteries and see that the transmitter operates the receiver before walking out on your ground check. This check should be simple and quick, not a Four Power Conference. Assuming you have a helper, work out an easy system of signals: you can't talk back and forth with, say, 800 feet between you and the helper while other engines are running.

When ready to begin tuning, hold up the arm; the helper switches on the transmitter in response (why wear out batteries while walking back and forth?) Make a circular motion with the upheld hand, indicating that you want a steady signal held on, while you tune the receiver. Then, as you note the signal on the meter plugged into the plane, begin to tune for maximum drop or rise, as the case may be. When tuned, raise the hand again, helper still holding signal, then drop the hand. He cuts off the signal. By up and down movement of the hand you can call for any speed or duration of signal you want. Idea is, that whenever the hand is up, the helper holds signal; when the hand drops, he releases signal. The circular wave in the beginning is to signify that you don't want the signal cut off when the hand is dropped in order to tune. Later, you can dispense with the rotary signal, for the helper will know that you intend to tune. For long ground checks wave a white cloth to clarify signals.

It is surprising how mixed up two people can become during a ground check. Suppose you call for a signal and the meter indicates nothing. So you glare at the helper for stupidity in not turning on the transmitter. But he can't see this. You wave frantically to wake him up. Meanwhile he has been sending a steady signal, and wonders if the transmitter is on the blink. Confusion can be avoided by having the helper follow your hand signals. When the receiver does not work and you have your hand raised steadily, he holds his hand up to signify obedience. You know then that the transmitter probably is working.

A commonly made error during ground checks is to walk out a goodly distance before calling for a signal. Although the receiver seemed in tune next to the transmitter it may be far enough out of tune at a medium distance not to pick up the signal. This can lead to futile and protracted tuning if the adjustment is lost, while batteries run down merrily and other fliers on the field grow grumpy. It is better to try the ground check quickly at, say, 50 or even 200 feet, and only then at progressively greater distances. After you know your equipment you will find that a certain rise or drop takes place at a certain distance and super ground checks are no longer necessary.

When ready to fly, assemble the ship—don't forget any of the wing or tail hold-on rubbers. (And who hasn't seen a wing come off in the air?) When you see that you can safely fly, allowing for other fellows whose planes may be gliding silently overhead, start the engine; have the helper hold the ship tail toward you, fifteen or twenty feet away, and check the rudder operation by sending a number of quick signals. The rudder should follow exactly. If it misses even once do not fly until the reason is found. If everything checks out, wave the launcher the release signal. Always, when checking the rudder, have a known position coming up. Make it the same position on every flight. Most fliers choose "right next" because it is opposite to a left turn tendency caused by torque. If correction must be made for a poor launch, one signal would give right turn, and two left, on self-neutralizing escapements.

If you own a hand-held transmitter, you may have a big advantage in being able to launch the ship yourself while holding the transmitter. Cradle the transmitter in the crook of one arm and launch the plane with the other. The rudder check, motor running, can be made by standing the plane against some object to prevent its rolling. If the plane becomes slippery from exhausted fuel, wipe it off before someone makes a bad launch.

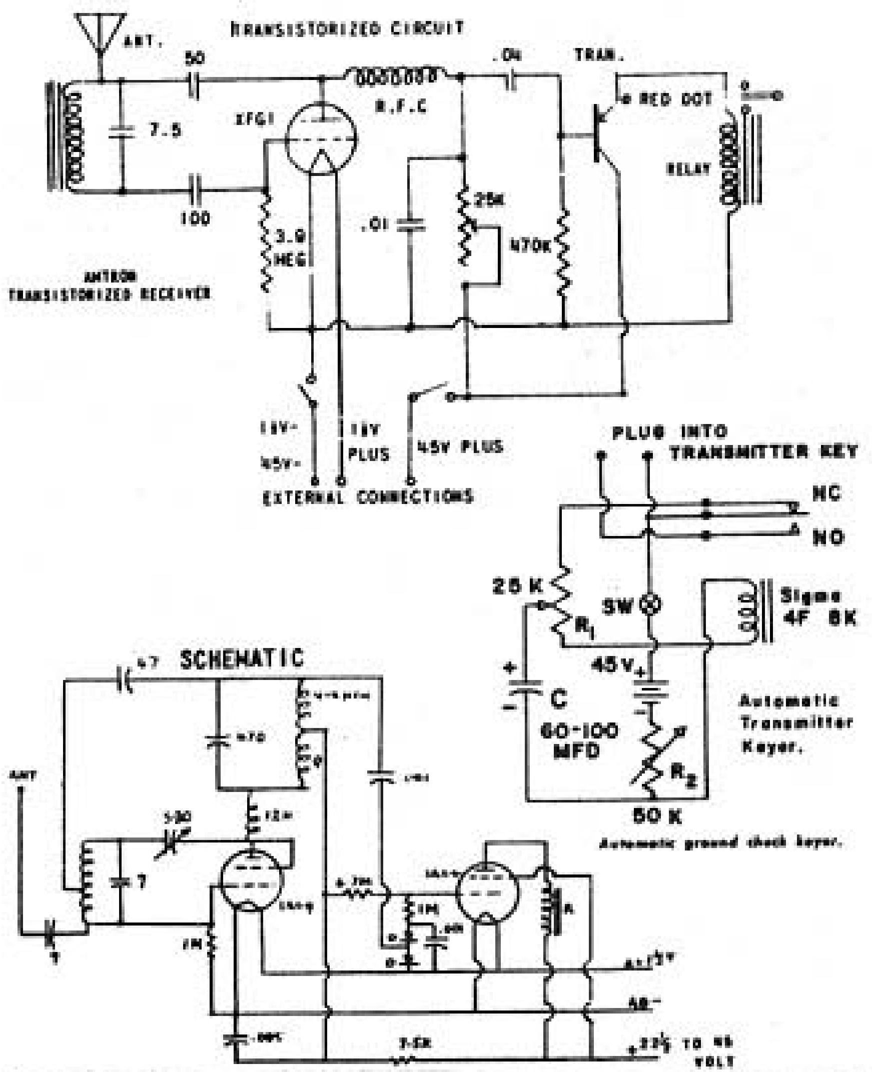
If a long flight is made, allow the batteries to recuperate for a similar period. Check the escapement rubber windings for a long, active flight can run off a double row of knots on the rubber. Otherwise, after every three flights, wind the escapement as routine and, after a half dozen flights, check the airplane batteries. Should the wind be blowing, stand the model on the ground, tail to the wind, to prevent the ship's being blown over. In the hot sun, place a rag over the wing hold-down rubbers which otherwise might snap, perhaps in flight.

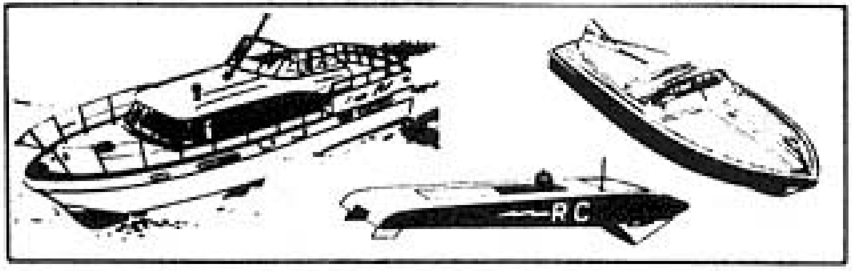
One of the most annoying aspects of radio control is the aerial traffic jam on 27.255 megacycles. Field etiquette is essential. People must cooperate with each other if everyone is to get in his fair share of flights—and how about the oaf who fills up his ten-minute tank when a dozen guys are watching that sinking sun! It is recommended that a common take-off point be established. If many fliers are present, they should line up planes ready for take-off. Anyone with engine trouble should step aside to the next man up. Who doesn't know a character who jams up such a line for fifteen minutes until he discovers the glow plug is burned out?

Some groups use flags: green for the air is clear, red for someone on the air. Trouble is that flags can't yell and everyone forgets to look at them. People paint planes various colors to designate frequencies, or use nifty signs and decals, and no one appears to pay any attention. A blast on a police whistle just before launching wakes up the dreamers but once a ship is high in the air, they forget about it. Noisy engines help—you can't hear an .049 at 500 feet while bigger engines run near-by. When many fliers are out, keep your flying near-by and at low altitude; don't let them forget you!

But people who fly a great deal together find it possible to operate without talking, if they have to. Listen for engines starting. The chap who walks out to the firing line, with engine running, should be given the air. If you do this, tarry long enough before launching to make sure that random transmitters are not working your rudder.

It is imperative that RC fliers group together on the field. Rugged individualists and lone wolves are certain to wreck someone's plane. A cooperative group of fliers always seems to know when a ship is in the air and don't hesitate to yell when a second plane makes ready for a launch before the air is free.





Chapter Eleven

BOATS

Radio control boats have become popular and their number increases daily. Boats have many desirable features. When compared with aircraft, there is no danger of loss, an out-of-sight flight being impossible. Damage rarely results from equipment failure or operational error and then usually only when a largish, fast boat strikes a concrete wall or other solid obstacle. Wind is less of a handicap. In warm weather a boat fits in better with family activity, since it can be taken more readily on swimming trips, picnics, etc., and requires less space in the car. A boat is ideal for experimenting with radio equipment.

Most boats are built from kits. Excellent construction kits, some being scale models and others of original design, are available from your dealer. Engine manufacturers are following through with various lines of marine engines, from Hall-A's to .29's or so. Many of these are genuine marine engines, not just airplane engines with special attachments. At least two manufacturers make small outboard type internal combustion engines. It takes a critical eye to tell them from the real thing. These engines clamp unto the boat transom, just like a big outboard, and are adjustable for angle, and have pull cord starting. Other engines are produced with an awareness of the heat problem from enclosed running. Water cooled marine engines are found in at least the .049 and .09 categories.

Several complete lines of marine hardware are available, such as beautifully machined propellers, stuffing boxes, drive shafts, universals, and so on. There is little than can be added here in the way of information because the boats, the necessary hardware, and suitable powerplants are abundantly available; all are of top quality and it is practically impossible to bungle the job.

Boats do have noticeable difference from planes. Battery weight is relatively unimportant so that big, dependable batteries can be used for long life and steady operation. Equipment can be made accessible by means of decks that lift off, removable pilot houses, and so on. Powerplant and escapement or servo installations require special attention. Internally mounted engines, adapted from airplane designs, sometimes have given cooling problems in the past, this being aggravated by poor ventilation.

Some hobbyists, especially ex-airplane modelers, go in for air boats in which an airplane-type engine and propeller are mounted on a pylon at the stern. The prop may be either a tractor or a pusher. Claimed advantages are simpler installations, elimination of boat hardware, such as stuffing boxes and shafts, positive cooling and easy starting. But to the purist such a boat may be an eyesore, especially when some beautifully built craft, otherwise to scale, is marred by the unsightly pylon with its engine and massive air prop. Moreover, air boats are said to be tricky on rough water or when traveling crosswind.

Boats offer many possibilities unthought of in aircraft. For example, it is quite practical to install a milliammeter in the boat and to read it by means of binoculars while the craft is in action. One well know radio equipment designer has just such a rig. His boat is powered by an electric motor and batteries. Its quiet running allows the owner to mystify flocks of ducks at rest on the water.

Escapements may be a problem on bigger, heavier, faster boats because the loads upon the rudder are greater than those on an airplane rudder. When the rudder swings over in a plane, it encounters small resistance, but water is incompressible. Water must be pushed out of the way, and this delays escapement action. More rubber on the escapement is called for. In a boat of any consequence electric motor driven servos with gear drive would greatly enhance the flexibility of performance. Some special servos for boats are on the market and more will be available soon.

Although radio control is a booming activity, the surface hardly has been scratched. Fascinating possibilities are ahead. A radio controlled model boat has successfully sailed the English Channel. Under International Rules governing plane size, weight, and so on, radio model aircraft have established duration records. Point-to-point flights with landings and take-offs at different air fields, closed course racing (for planes or boats), aerial picture taking, are among the feats already accomplished. Rapid technical progress toward multi-controls means that in a few years true proportionate, multi-control systems will become available. The sky is the limit—or is it?

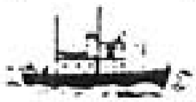
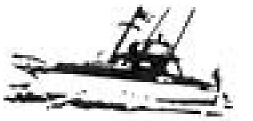
POOR 40 "





GLOSSARY

A Supply—Battery or power source used to heat the filament.

Actuator — Electro-mechanical device for moving controls.

Ampere—Unit of current flow (resistance of 1 ohm at 1 volt).

Amplifier—Usually a vacuum tube circuit used to amplify or build up the transmitter or receiver energy.

Anode—Plate of the vacuum tube.

Antenna—Conductor, as long wire, rod, etc., to intercept (as on receiver) or radiate (as on transmitter) energy, in radio wave form.

Armature—That part of the relay which is movable under influence of changing magnetic strength.

Audio frequency—Frequency heard by ear, between 20 and 20,000 cycles per second.

B Supply—Voltage applied to the plate of a tube to produce an electron flow from the filament to the plate. Usually 45 to 67½ volts for receivers and 67½ to 180 volts for transmitters.

Battery—Power source for portable electrical or electronic devise.

Capacity—Ability to store electrical charges.

Carrier—Short for carrier-wave, current or frequency of radio wave.

Cathode — Electrode in tube from which electrons flow.

Channel—Single, particular frequency of carrier wave.

Choke—High inductance coil opposing passage of pulsing current, but allowing direct current to flow.

Circuit—Path of electrical current, returning to source.

Coil—Wire winding.

Condenser—Two conductors divided by non-conducting medium.

Contact—Metal parts brought together to complete a circuit, as in switch, relay, etc.

Coupling—A means of transferring energy from circuit to circuit.

Crystal—Quartz or Rochelle salt crystal cut in small thin disc or square for maintaining a given frequency.

C W—Abbreviation for carrier wave.

Diode—Tube containing cathode and plate for passage of current in one direction.

Electron—Smallest charge of negative electricity.

Escapement—Actuator driven by power of spring or twisted rubber.

Filament—Heater in a tube, similar to the filament wire in light bulb.

Filter—Combination of resistances, inductances, etc., to allow passage of certain frequencies intended to operate more than one actuator. Replaces function of reed bank.

Flea clips—Small metal clamps to hold wire leads of tubes; replaces tube socket.

Grid—Electrode in tube that allows, or shuts off, passage of electron stream.

Ground—The A-Plus or B-Minus side of a battery and the joint to which all connections common to these points are made.

Idling current—Amount of current drawn by receiver as indicated by milliammeter inserted into B-Plus lead (no signal).

Inductance—Characteristic of circuit to oppose change of current flow.

Jack—Holder for contacts that close, change, or open circuit connections on insertion of plug.

Kilocycles—One thousand cycles.

Megohm—One million ohms.

Megacycle—One million cycles per second.

Meter—Device to indicate measured electrical quantity of current, resistance, etc.

Milliampere—One-thousandth part of an ampere.

Mils—Abbreviation of milliamperes.

Milliammeter—Meter reading milliamperes.

Modulation—Controlled variation of amplitude or frequency of carrier wave according to transmitted signals.

Ohm—Amount of resistance at 1 volt and 1 ampere.

Pentode—Five-element vacuum tube.

Plate—Output element, or anode, in vacuum tube.

Plug—Machined metal end for wire, inserted in jack to connect external units into existing wiring. Plug may have provision for one or more wires to match circuit of jack.

Polarity—Indication of which terminal is positive and which negative.

Potentiometer—Device for varying amount of current flowing through a lead. Called "pot" for short.

Power input—Wattage fed into a radio tube, determined by voltage times current consumed.

Power output—Power delivered into the tank circuit of a tube. Always less than the power input through losses in the tube and circuit components.

Pulse—In modeling terminology, a system by which repeated signals are transmitted, varying as to length and/or rate.

Receiver—A radio receiving set.

Relay—Device which operates a second circuit from current changes in the first circuit.

Resistance—Opposition to current flow.

Resistor—Unit of known, desired resistance placed in circuit to reduce or limit current flow.

RF—Abbreviation for radio frequency.

RFC—Radio frequency choke.

Servo—Electric motor-driven actuator.

Socket—Tube socket.

Tank circuit—Coil and condenser combination placed in the plate circuit of a tube.

Tone—Sound, having particular pitch, superimposed on carrier wave, to operate controls by means of modulated or audio receiver. An audio modulated transmitter-receiver system.

Transmitter—Radio transmitter for broadcasting the signals.

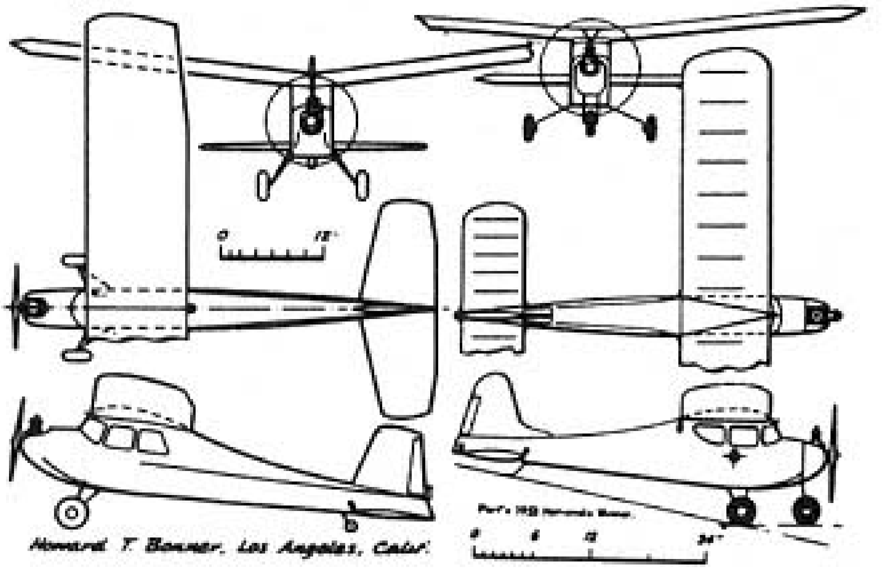
Triode—Three-element tube.

Tube—Number of electrodes packaged in an evacuated envelope.

Volts—The "force" in a battery or power source which pushes the current through the circuit.

Watt—Current flow, 1 ampere and 1 volt.

Wave length—Distance between peaks of same polarity; equal to velocity over frequency.



MICROPHONE BUTTON

As in the preceeding work on remote controls, the tubes and some other components may be impossible to get as they are obsolete. Even so, your Radio Shack salesperson should be able to tell you what modern components have replaced them.

General Instructions on the Microphone Button

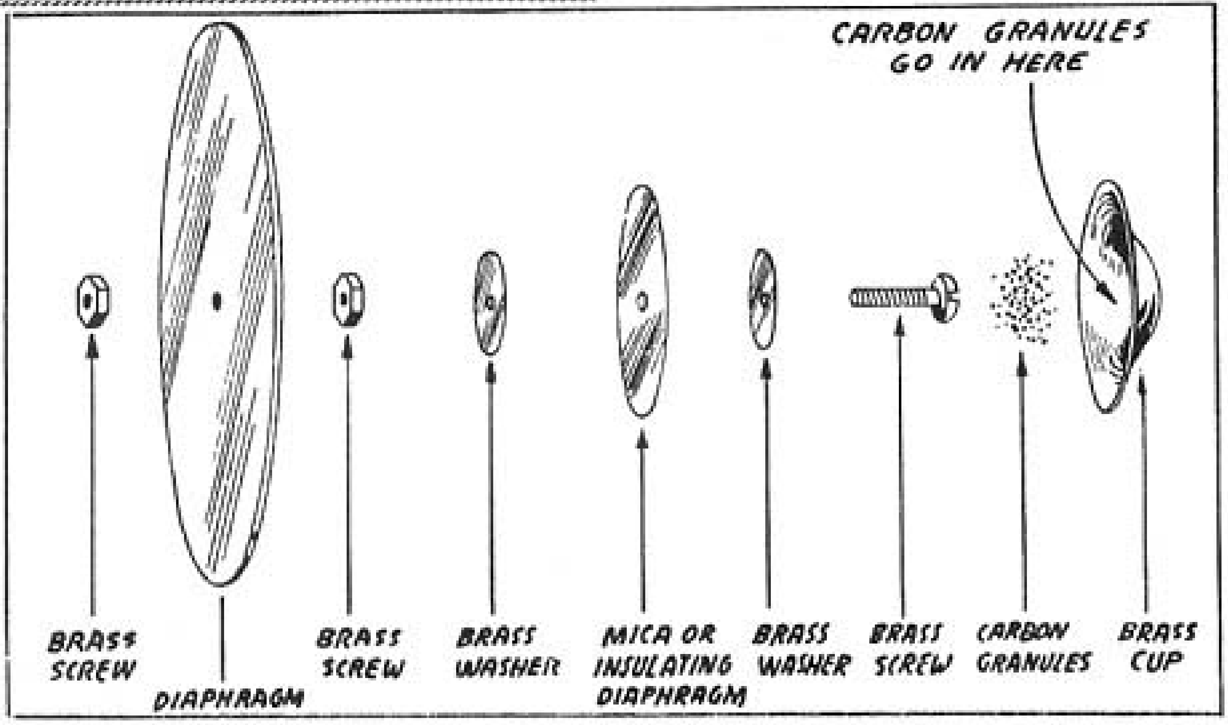
You will find it easy to build a Microphone Transmitter Button. This particular device lends itself admirably for use in radio and electrical circuits, and in view of the fact that many do not realize to what important uses such a button can be put, it is advisable to cover the use of this little transmitter in its various fields so that one will easily see how each and every one of the systems are applicable to radio uses. In the illustration a transmitter button has been taken



apart so as to show its internal construction.

For those who want to build their own Microphone Transmitter Button, it will be seen from the exploded view of the button, that it really is quite simple. The one illustration shows all the parts necessary for the complete construction of the button. The assembly of the button is illustrated in the smaller drawing.

The large DIAPHRAGM is made of either light copper or tin sheet metal, about the thickness of the metal used in a tin can. This makes it sensitive to picking up noises. The small or INSULATING DIAPHRAGM is made of either a stiff cardboard, but very thin, or a thin sheet of mica. A thin sheet of mica is the best, but if this is not available, use a thin sheet of rigid cardboard, something similar to post card weight.

The assembly of the button is quite easy, and the only difficulty you may have is inserting the carbon granules and cementing the insulating diaphragm to the brass cup. The cup should be about HALF FILLED WITH GRANULES. (Do not fill up.) These should be loosely packed, so they can move freely. Before you cement the insulating diaphragm to the brass cup, remember to assemble the button up to the first brass nut. Once you cement the parts together, you will not be able to get at the screw to tighten.

When you have finished the button, you are ready to proceed to experiment with the button. Read all of the booklet carefully before beginning your experiments.

The remarkable thing about this transmitter button is that it can be made to transmit in any position, either horizontal or vertical. It is so small that it can be readily concealed in any of a dozen or more places, and thus serves as an admirable detectophone. For instance, it can be placed in a watch case; an old watch case is used and a tiny hole drilled in the center of the back of the case. The screw of the transmitter button is then pushed through the hole and the nut is tightened on the screw. This watch case may be concealed behind a group of books or may be placed in view on the table, and there is very little possibility that anyone will pick it up to investigate. The wires leading from the transmitter can then be hooked to a regular amplifier, or else may be connected in series with a battery and a low resistance phone.

If the transmitter button is held up against the throat it will be possible to transmit speech without actually talking at the button. Experiments in talking through the throat and also talking through chest, have been numerous, and at the present time most of the airplane transmitters for communication between observer and pilot employ throat microphones. These microphones are strapped to the throat of the user who talks just as though he were talking to a friend alongside of him. In this way the noise of the engine is overcome and successful transmission is possible. If a tiny hole is drilled into the side of a glass and a person should talk towards the glass, it will be found that speech can easily be transmitted in this manner. This makes a very nice little experiment for electrical clubs.

Music from a phonograph can be transmitted to distant places by employing the hook-up wherein a small hole is drilled in the side of the tone arm of the phonograph, and the screw of the transmitter button is inserted in that hole. There are several other means for doing this perhaps a little more efficiently than indicated here, and these will be described elsewhere in the article.

These transmitter buttons can be used as detectophones for conveying speech to detectives or operatives stationed elsewhere in a hotel or in the house. In the one case a microphone button is mounted in the back of the picture. The tiny screw on the surface of the picture is not noticeable to the casual observer and any plot could not easily be detected. It is advisable, however, in placing microphones in suspected positions, to locate several of them in the same room and use different sets of wires for each, running each pair out of the room through different exits. In event then that one of these detectophones is discovered, there are still two or three of them in the room which remain to be discovered. Most criminals will assume that when they have once destroyed one detectophone that they are free from further interference on the part of this silent watchman. If several detectophones are placed in the room a complete transcription can readily be taken by the reporting stenographer.

In event that a minister should have several sick members belonging to his parish who are unable to attend Sunday services, it is possible for him to place one of these small microphone buttons in front of him in the pulpit. In this way he would be able to transmit the complete text of his sermon to any of those who care to listen and who are interested enough in going to the expense of stringing a few wires from the point at which the talk takes place to their homes.

For those hard of hearing such a device would be of particular benefit, as the church could be fitted with several sets of earphones and the speech, greatly amplified, would be impressed upon the diaphragm of the ear, and thus transmitted to the inner ear and brain in a much stronger manner than if the voice were merely heard in the usual manner. For transmitting the sound of a violin to persons hard of hearing and also for the production of various stage effects, the microphone button can be screwed fast to the body of the violin, or preferably to the bridge, as this latter position in no way damages a valuable instrument. In this manner all the tones of the violin are faithfully reproduced in the distant receiver, or they may be amplified by means of a regular vacuum tube amplifier such as you have in your radio set, and then transmitted to the crowds in the dance hall. Several of these microphone buttons attached to the various instruments in the band and all connected to a good amplifier could be made to fill the largest hall with music. The band itself need not necessarily be very large.

Sounds from a telephone receiver can be made to travel to a distant receiver. Here the microphone button is mounted inside of a cigar box and the receiver is then placed right on top of the position of the button.

The microphone button can be used to transmit the sound of a piano to a distant room. The button is preferably fastened to the sounding board in a piano, but it may be fastened to any convenient place on the piano to accomplish this work. This is of value where there may be a sick patient in a home on the second or third floor far remote from the piano, and who would like to listen to any music played on the piano by some of his friends.

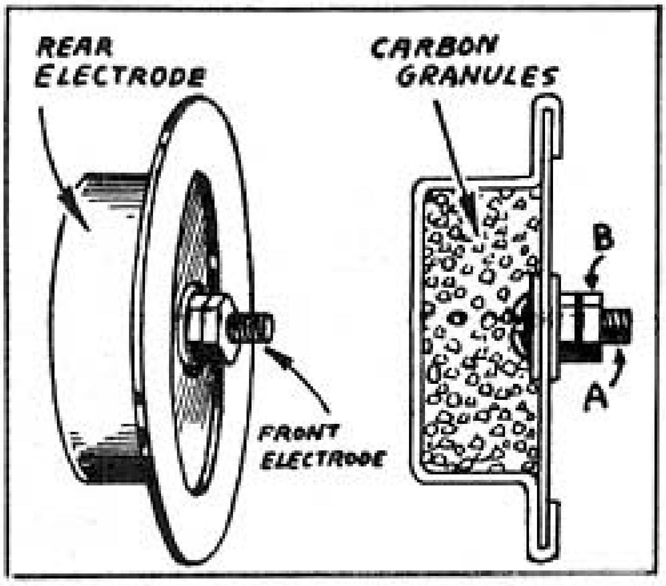
Radio music can be transmitted to distant points and incidentally amplified at the same time. Here the microphone button is soldered to the diaphragm of the receiver as indicated, and then the leads connected in series with several dry cells and a low resistance phone.

For experimenters desiring to get greater sensitivity and volume for either radiophone transmitting stations or for ordinary phone transmission. Here five or six microphones are mounted upon a thin metal or a heavy card-board disk. The screws projecting through the cardboard are then all connected by means of flexible copper wires, or in event that a metal disk is used, the metal disk itself will serve as the means for making connections between the screws and one thin lead soldered to the disk will suffice. In order to make a more classy job of the device, an old molded variometer makes a fine microphone case. The wire is removed from the variometer and then the case is packed with felt lining which should be glued to it. The disk with the five microphone buttons mounted thereon is then supported in the center of the variometer case by means of three rubber bands. The front and back of the case are then attractively covered with fine silk gauze. This makes a very presentable instrument which looks very much like those microphones used in our broadcasting stations.

Numerous questions have been asked as to why the transmitter button does not work properly. In each and every case, the answer is simple: "The button has not been hooked up in accordance with directions." There is no electrical circuit that is simpler to couple than an ordinary transmitter button and a receiver. The experimenter should remember that every transmitter button requires a diaphragm of some sort or a substitute therefore. The size of this diaphragm depends entirely upon the work which is to be accomplished or the nature of the matter to be broadcast or amplified.

For ordinary speech, a diaphragm approximately 2½ inches in diameter is better suited than one 14 or 18 inches in diameter. The smaller diaphragm enables the listener to recognize the voice of the person transmitting, whereas the larger diaphragm has a tendency to decrease the pitch of the transmitted voice. But when doing detective work, it might become necessary to attach a transmitter button directly to a large canvas picture. In this particular case, the conversation that is picked up is the all-important consideration and one does not care about the quality of the sound just as long as the speech can be recorded.

Now as to the quantity of carbon granules in this button. Slightly more than half is a splendid proportion. For more sensitive work, the quantity should be decreased and for very crude work, the button can practically be filled up. Therefore, the fewer carbon granules in the button (of course within limits) the more sensitive will be the nature of a pick-up. Coincidentally a frying noise might be produced when there is not a sufficient amount of carbon granules to properly distribute the current (frying being also due to too much current.) At no time should the current through these buttons be so high that it will produce a frying noise. While many experimenters advocate the use of a 4½ to a 6 volt battery, the use of telephone transformers was likewise suggested, but for those readers desiring to use the standard radio transformers (audio frequency types) the voltage on the button can be increased to from 22 to 45 volts, dependent upon the resistance in the primary of the transformer. If the reproduced voice develops a frying sound, the button is being overloaded; if not, then the voltage should be increased until it is just below this frying point.



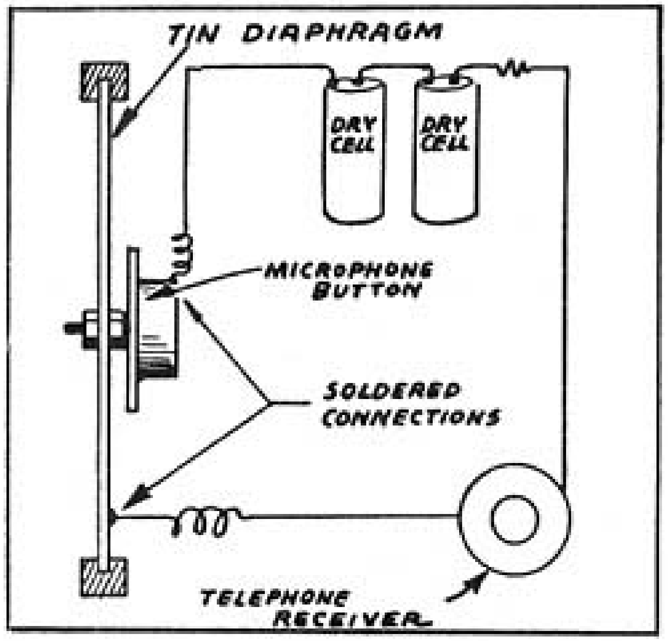
Amazing Microphone Transmitter Button

One of the most interesting little pieces of electrical apparatus is the **Microphone Transmitter Button.** The above illustration shows the construction of the button. The brass cup is the rear electrode. The front electrode is a brass screw mounted on an insulating disc. The inner chamber of the button is filled with carbon granules.

In all of its uses, the Microphone Button is attached to a diaphragm. Usually this diaphragm is made of metal, but any stiff, resonant material is satisfactory. When sound waves strike the diaphragm, the vibrations cause the carbon granules to be alternately compressed and released. A pressure wave is exerted upon them corresponding to the sound wave that is striking the diaphragm.

Carbon granules conduct electricity more readily when compressed, so that each sound wave striking the diaphragm is converted into a fluctuating electrical current wave in the circuit that passes between the rear electrode and the front electrode. It is this electric current wave that transmits sound wave to receiver or amplifier.

All the uses of the Microphone Button are based upon this ability to pick up sound waves and convert them into electrical impulses. It is a miniature telephone transmitter.

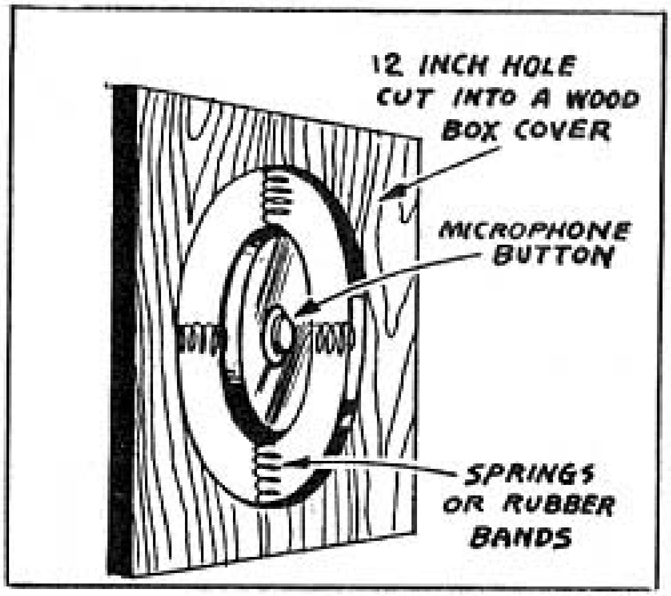


Electric Telephone

The simplest and most basic use of the Microphone Button is the Telephone Hook-up. This is illustrated above and is self-explanatory. For best results, the microphone button should be kept in a vertical position. The carbon granules should be loosely packed in the button, so that they are sensitive to the vibration of the diaphragm. If button fails to operate satisfactorily when first tested, it should be tapped firmly but gently to loosen up the granules.

In the Telephone Hook-up, ordinary 1½ volt flashlight batteries (or No. 6 dry batteries for longer life) are used. Two cells are satisfactory for good performance up to 100 feet, but for longer circuits, additional batteries should be added.

NOTE: .The Transmitter Button circuit works best with a low resistance earphone. A 6 ohm earphone is ideal, if available.

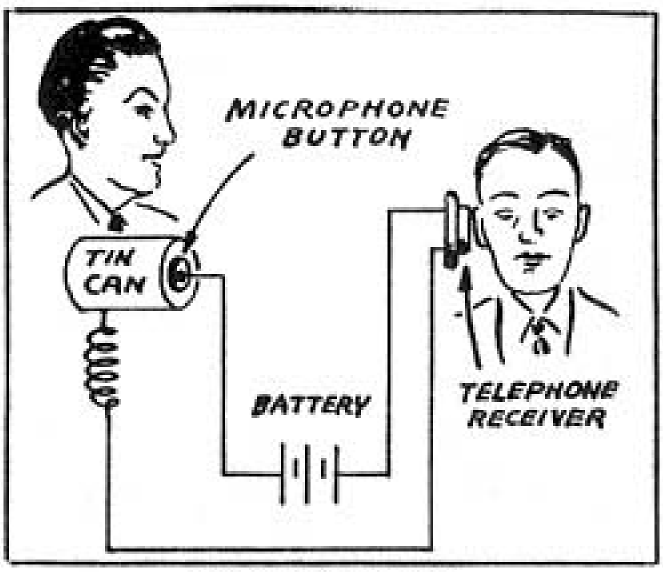


Suspension Microphone

In order to increase the sensitivity of the microphone, the suspension arrangement illustrated above is convenient to use. An ordinary 6-inch tin pie plate suspended in a wooden frame is quite satisfactory. This serves two important advantages. **One:** the suspension prevents diaphragm from picking up other extraneous vibrations. **Two:** the increased size of the diaphragm picks up more sound waves.

"Frying Noise" in the Circuit

While it is essential to have sufficient current in the circuit to obtain maximum results, a "frying noise" in the circuit indicates too much current. Ordinary dry cells work very well, but you can also use a telephone transformer. If a standard radio transformer or radio batteries are used, the voltage can be increased up to 22 or 45 volts. Remember, radio batteries deliver high voltage, but little current. Standard flashlight or No. 6 dry cells deliver 1½ volts, but a fairly strong current. Use as much current as possible, but just below the level that produces a "frying noise" in the receiver.

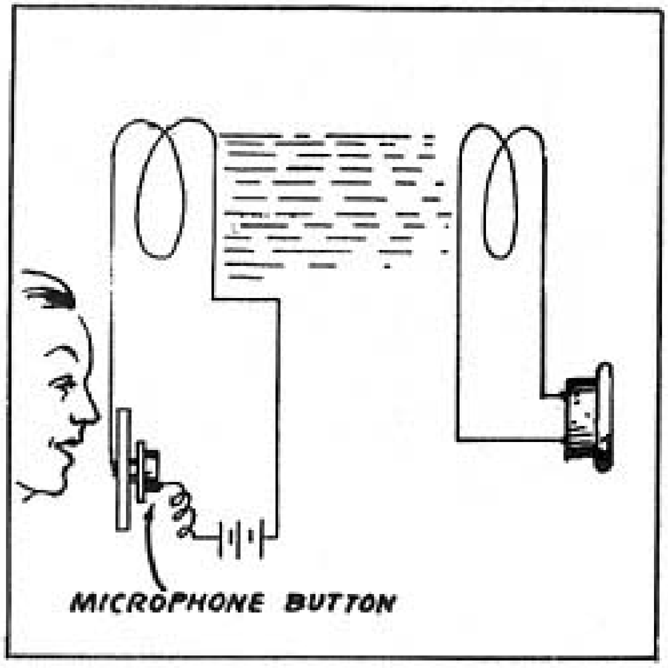


Electrical Stethoscope

A stethoscope is a "sound magnifier." It picks up and magnifies noises. A doctor uses the stethoscope to listen to body noises---the heart, the lungs, etc. A mechanic uses a stethoscope to detect unusual noises which reveal faulty machinery. A jeweler uses a stethoscope to overhear irregular watch noises. It is a general rule that in well run machinery, there is a certain rhythm. Once you become familiar with that rhythm, any discordant sound will instantly reveal trouble.

If the sounds are loud enough, the ordinary ear is capable of detecting these discordant notes. A pilot of a plane, for example, can usually tell from the sound of his motor whether it is functioning satisfactorily.

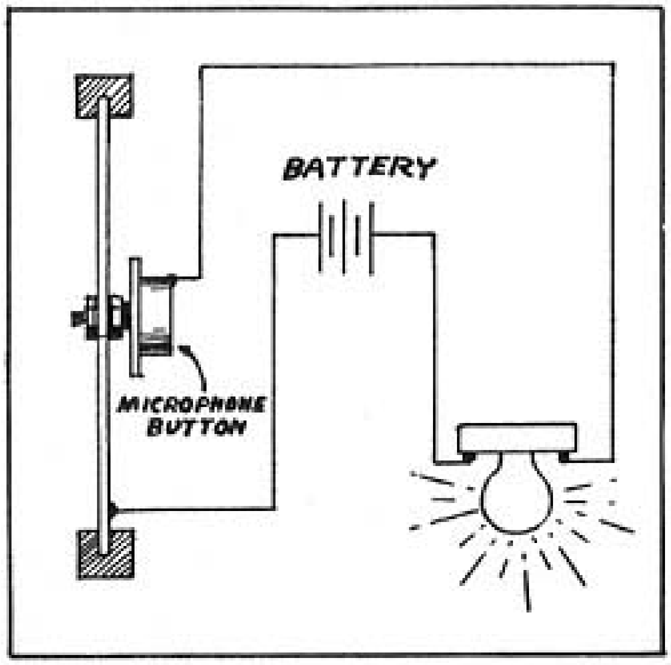
A tin can is used to pick up and collect sounds for greater sensitivity. Two or more microphones can be used. They are connected in parallel and are mounted to the same tin can or diaphragm. By "parallel" we mean that all the rear electrodes are connected together and all the front electrodes are wired together.



Induction Telephone

A Microphone Button is connected in series with a coil of wire and batteries. Several feet away another coil of wire is mounted parallel to the first coil. This second coil is connected to a low resistance receiver. Thus, you are really "broadcasting" the voice through the air. This is essentially the principle of radio.

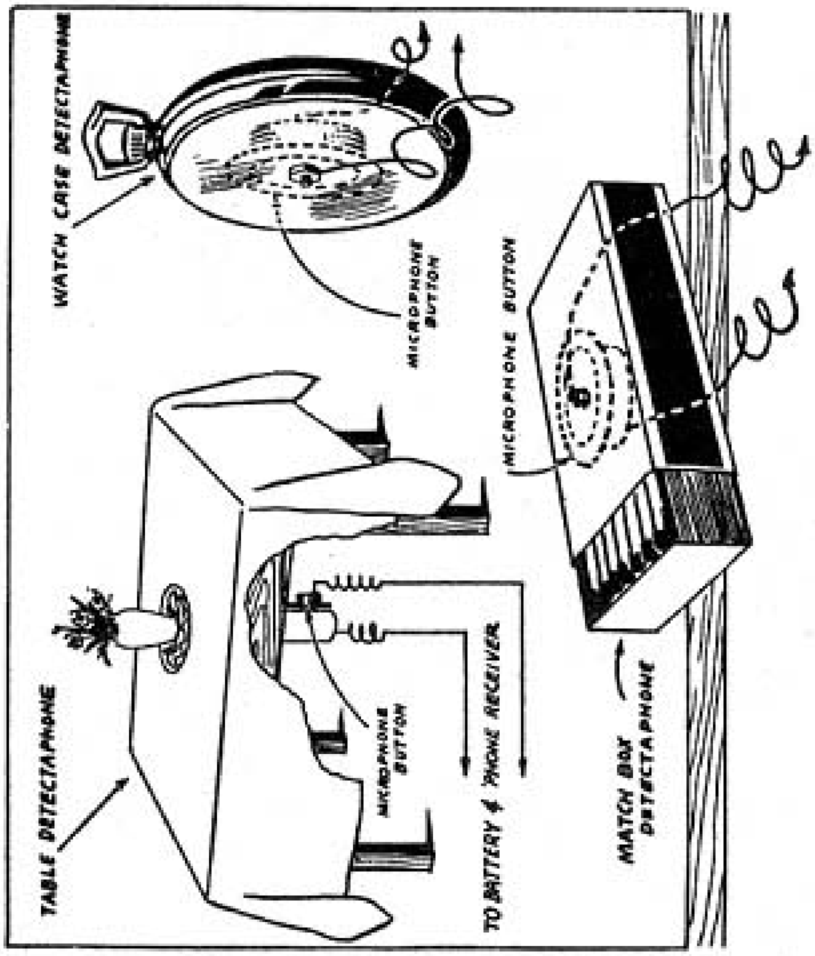
This same principle can be used in magical or mystical acts. In one case, a coil of wire was wound into a carpet. The second coil was placed around the waist of a medium. A tiny receiver was fitted into the ear of the medium (similar to those used in hearing aids) and concealed by a Hindu head-dress. An assistant telephoned the secret, written questions to the medium via a Microphone Button connected with the coil in the carpet.

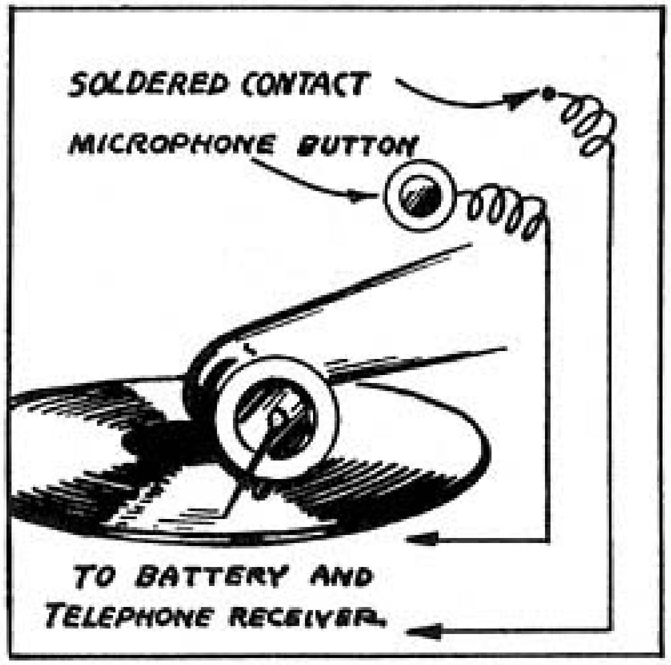


Talking Light

A simple experiment to show how impulses may be transformed into different media. The sound waves are transformed to electrical waves by the Microphone Button. The electrical waves are transformed to light waves by the bulb. If you had a Photoelectric Cell (or Electric Eye), the fluctuations in the amount of light given off by the bulb could be used to actuate another circuit. Thus, by a spoken command you could have a door open or a window shut or a bell ring. (See also Relay Circuit).

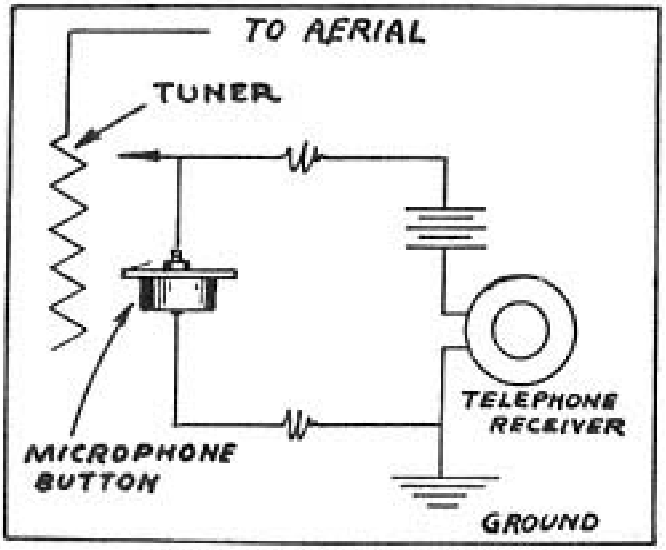
If ordinary flashlight cells are used, a 3 volt flashlight bulb is sufficient.





Phonograph Pick Up

The music or talking from a phonograph can be readily picked up by means of a Microphone Button attached to the tone-arm of the phonograph. The front electrode of the button must be soldered or firmly attached to the arm. Ordinary telephone hook-up circuit is used. Or, the button can be wired directly to an amplifying circuit (see the Radio Hook-up) and played over loudspeaker, or even broadcast.



The Button As a Radio Detector

The Microphone Button can be used as a Radio Detector to pick up broadcast programs when used in the manner illustrated above. For loudspeaker volume, a more elaborate circuit has been devised which is described elsewhere.

Secret Detectaphone

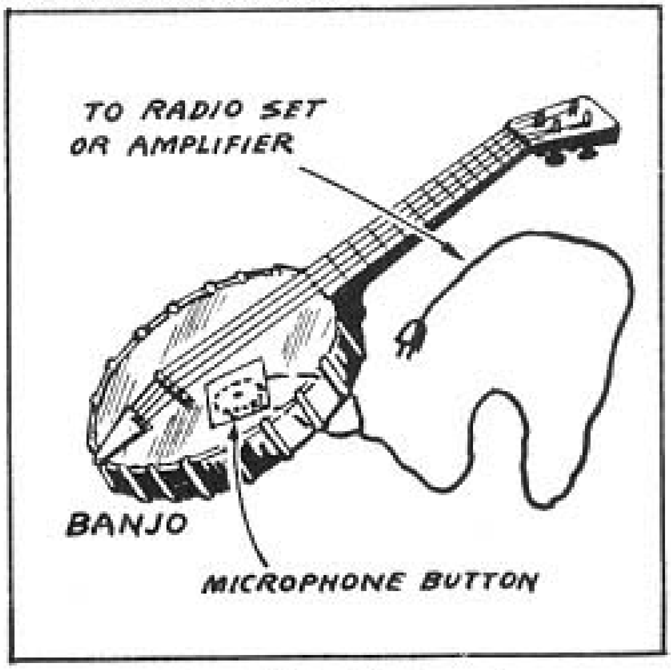
Perhaps the most difficult application of the Microphone Button, yet one of its best uses, is as a Detectaphone. It requires maximum sensistivity and complete freedom from external interruptions.

The standard Telephone Hook-up is used, but an additional battery should be added, to make certain that strong current supply is fed into the circuit.

Where possible the largest sized diaphragm or sounding board should be used. The Microphone Button mounted in a tin can (see Stethoscope) and placed firmly against a table gives a good pick up. The table acts as a sounding board, and the tin can is a very receptive shape for picking up sound waves.

There are many other ways in which the button can be concealed, two of which are illustrated here. Oftentimes a framed picture offers the best location. It must be kept in mind, however, that the button should be located as close to the source of the talking or noise as possible in order to get maximum results.

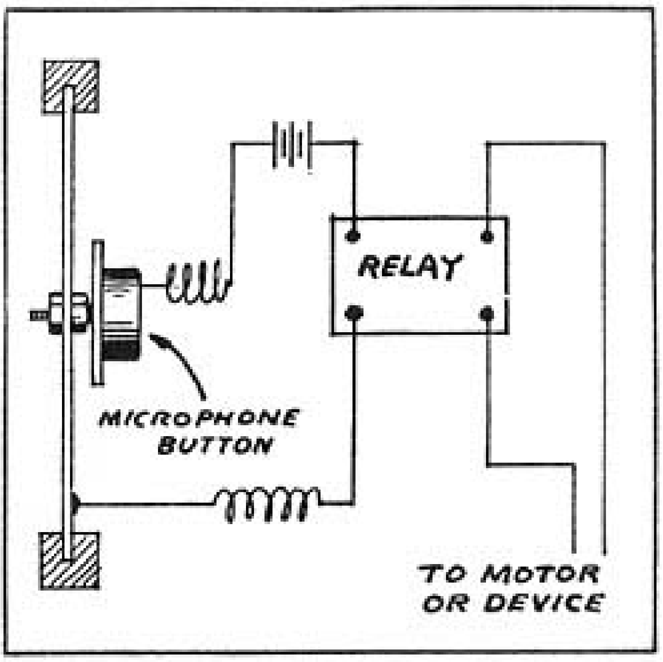
IMPORTANT: Good, continuous wire should be used. Any splices or connections should be soldered.



Electric Musical Instruments

Most people have heard the "electric" guitar and other novelty electric musical effects. These are all created the same way. A microphone pick-up unit is connected to the sounding board of the instrument and wired to an amplifying unit or radio. Almost any musical instrument can be used.

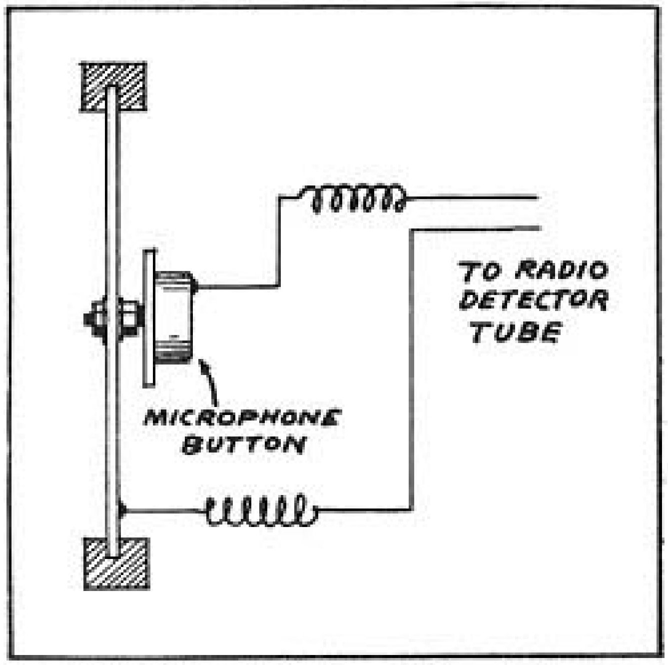
When using your radio for amplifying circuit, the button is connected directly to radio detector tube. (See Radio Mike). For best results, it will be necessary to try out the microphone button in several places on the musical instrument.



Doors Open and Mysterious Things Happen At Your Spoken Command

When use of a relay circuit, you can by means of a spoken command, make a window open, doors close, lights go on or off and many other things. You are only limited by your imagination and facilities as to what you can do.

The circuit is quite simple. It merely consists of connecting the button to one side of a relay. A spoken command causes the amount of electricity in the button circuit to change, which in turn operates the relay. This closes or opens a second circuit which contains the motor or mechanism which opens doors, etc. If a light bulb is connected in this second circuit, it is turned on or off.



Radio Mike---Talk Through Your Radio

Microphone Button is connected directly to detector tube of radio. Locate detector tube from tubes listed here or with help of radio serviceman. Shut off set. Remove detector tube. Hold tube in hand with prongs pointing up. This corresponds to base of tubes illustrated here. Twist wires tightly around correct prongs as designated in diagram. Insert tube in set. Be sure that bare part of wire does not touch any other prong or any metal of set. If mike fails to operate reverse wires. Before using any tubes not listed here, consult your radio serviceman.

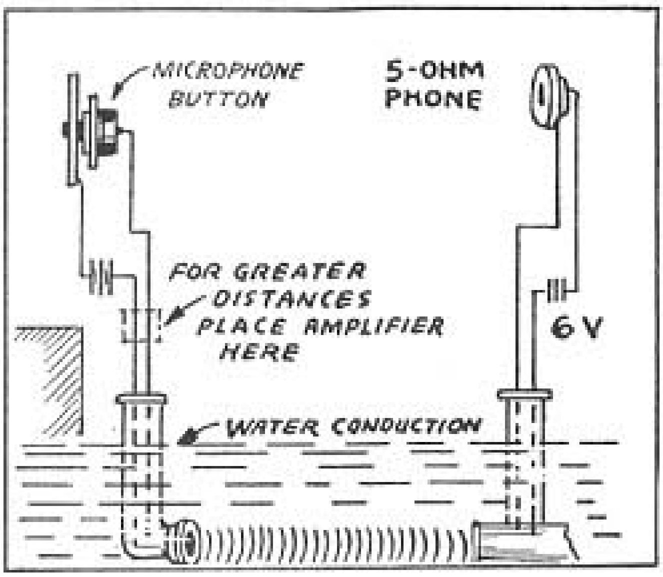
Loud Speaker Volume Radio Using Microphone Button and Crystal

This is an unusual type of radio that produces loud speaker volume, yet uses no radio tubes or "B" batteries. The diagram shows the essential features of its construction.

The Microphone Button is secured to the center of the earphone diaphragm. It is preferable to use a low resistance speaker, but if this is not available, a standard speaker can be used with additional batteries.



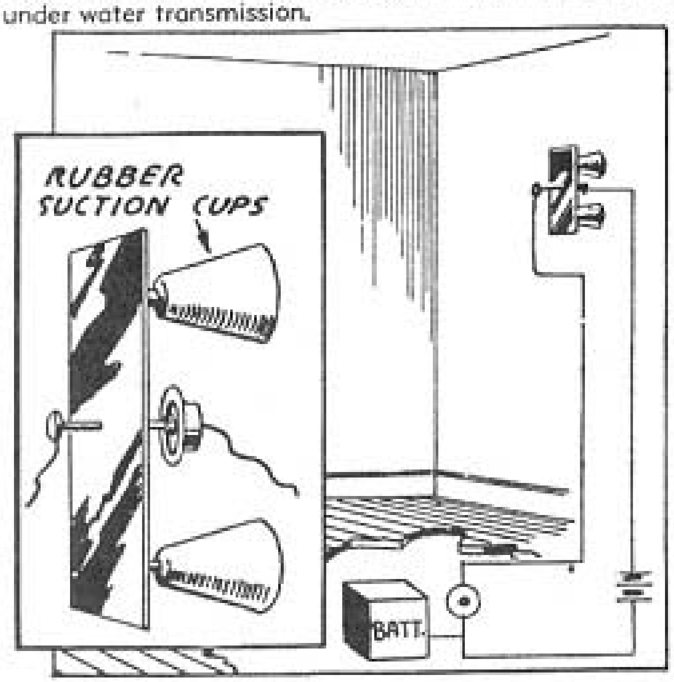
Sound Through Water---Submarine Telephones

This consists of two units. The transmitter (or broadcasting) and the receiver (or the sub-sea ear). Each unit uses a microphone button and a receiver.

The transmitter consists of an ordinary telephone hook up, with the receiver under water. The receiver must be protected from the water by wax, yet the diaphragm must be exposed to the water in order to transmit the sound waves.

The receiver also consists of an ordinary telephone hook up, with the microphone button under water. It is protected from the water by soldering it to the bottom of the inside of a tin can. The leads to the button should be protected from water.

This unit is only suitable for short distances. Longer distances--- up to about 100 feet--- can be set up if an amplifying unit is used in the transmitter along with a loudspeaker instead of an earphone for the under water transmission.



Listening Through Walls

It is well known that when a person places his ear against the partition, he can hear the entire conversation in an adjoining room; provided that the conversation is loud enough and that the wall itself is not sound-proof. This position is tiresome both for the listener and unpractical for detective work. The apparatus consists of a small plate of metal, brass or the like, to which two rubber suction cups are affixed as indicated. The transmitter button itself is mounted at the end of a long screw with a thumb or knurled nut for adjustment. In operation, the rubber suction cups are moistened with a little glycerine to make them adhere more firmly to the rather porous wall to which they are to be attached. After the suction cups are firmly in place, the thumb nut is turned to the right until the button just touches the wall. The receiver, which in this case is a 5 to 75 ohm receiver, reproduces the sounds with the proper degree of accuracy. A 4 to 6 volt battery is placed in the circuit and the detective operating the device can sit at a desk and copy down the entire conversation in the otherwise protected room. This form of eaves-dropping is more legitimate than installing detectophones in suspect's room.

Chambers' Encyclopaedia 1891

There have been several comments on the Chamber's Encyclopedia section; mostly uncomplimentary. The most common complaint is that the same information can be obtained from more modern encyclopedias in a more comprehensive and updated version. For the layman's purpose, this is simply not so. Modern encyclopedias are written mainly as introductory reference material. It is supposed that one with an interest in various chemical compounds and technical subjects need only the basic introductory material and so will go elsewhere for the working details. For this reason, the modern encyclopedias are sketchy in their descriptions or so technical that one must already be well grounded on a subject to profit from the modern encyclopedia's description.

The writers of the older encyclopedias, however, operated on the principal that theirs were the only descriptions of the subject the reader would have access to. So their entries were far more comprehensive than are the modern texts. Further, they operated on the principal that although the interested reader might be ignorant of the subject, he ought to be able to understand it if he could read at all. Therefore, entries were written so that any literate reader could duplicate the compound described whether he had any former familiarity with the compound or not.

You have but to compare a subject written in Chambers' 1891 Encyclopedia with a modern encyclopedia to see that the former was written for someone like you, rather than for one who was considering the subject for further study or already had some education in it.

In short, the older version is simpler, more complete and more applicable to the needs of the layman who may never see another reference to the subject.

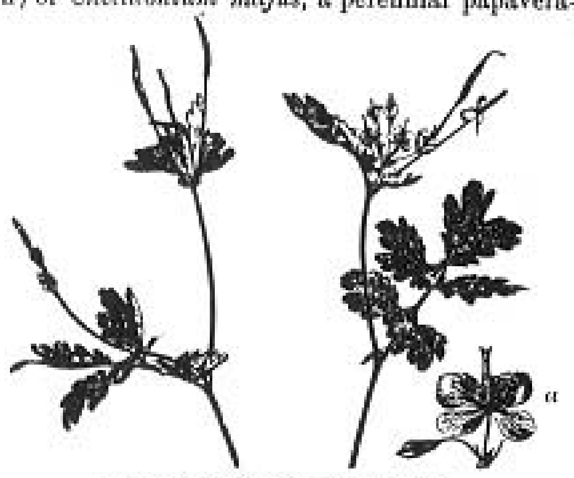
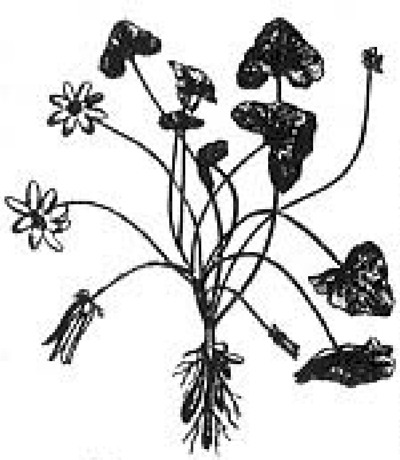
Cautery (Gr. *kaio*, 'I burn'), in Medicine, is used of any substance which burns the tissues. (The term 'potential cautery,' as applied to caustic substances, is becoming obsolete.) The *actual cautery* is an instrument with a head or blade of steel, iron, or platinum, which is heated in a fire or spirit-lamp. In the *thermo-cautery* (or Paquelin's cautery, from its inventor), the head or blade is made of hollow platinum, so arranged that a flame of benzole can be kept burning in its interior. The *galvano-cautery* consists essentially of a platinum wire which can be heated to any required degree by passing a strong galvanic current through it. The cautery is used for three main purposes in surgery: to *produce counter-irritation* over an inflamed part (see BLISTER) (actual cautery); to *check bleeding* (actual or thermo-cautery), by slowly destroying the tissues at the bleeding point or surface; to *perform operations*, where the tissues to be divided are either very vascular (thermo-cautery), or very difficult of access (galvano-cautery). See CAUSTIC.

Cel'andine is the popular name (and corruption) of *Chelidonium majus*, a perennial papaveraceous herb, which, although not uncommon in Britain, is doubtfully indigenous. Its pretty foliage and umbels of small yellow flowers, which bloom from May to August, might alone attract attention, but its ancient repute among herbalists is due to its yellow milky juice, which is very acrid and poisonous. Ex-



Celandine (*Chelidonium majus*): a, a flower.



Lesser Celandine (*Ranunculus Ficaria*).

ternally it was applied to warts and ulcers, and internally administered, it was supposed to be a specific for jaundice, apparently on no better warrant, however, than that drawn from its colour by the 'doctrine of signatures.' Its old English name Swallow-wort, which appears to be almost a translation of the botanical one, seems founded on a supposed association between the beginning and ending of its flowering time and the arrival and departure of the swallows.—It is, however, the LESSER CELANDINE which is more familiar to general readers, at least since Wordsworth devoted no fewer than three poems to its honour. This is *Ranunculus Ficaria*, also known as the common fig-wort or pile-wort, a quite unrelated ranunculaceous plant, which grows in abundant patches in fields and coppices, and brightens them in early spring with its plentiful golden flowers. Its tuberous roots and swollen separable buds give it additional botanical interest, while it is also noteworthy that these results of peculiarly vegetative habit are associated with a frequent imperfect maturity of the pollen.

Celluloid, or PARKESINE. This substance was first made by Mr A. Parkes of Birmingham in 1855 or 1856. It chiefly consists of a dried solution of gun-cotton (pyroxylin), or of what is nearly the same thing, and oil. A variety of it can be made with pyroxylin and camphor. It resembles ivory, horn, tortoiseshell, and hardened india-rubber, as regards certain properties.

The pyroxylin is prepared by treating Cellulose (q.v.) from such vegetable materials as cotton or flax waste, rags, paper-makers' half-stuff, or paper itself, with a mixture of one part of strong nitric acid and four parts of strong sulphuric acid. It is convenient to call the product so obtained pyroxylin, although the two things are not quite identical. The distillate obtained by distilling wood naphtha with chloride of lime is used as a solvent for the pyroxylin, but other solvents, such as nitrobenzol or aniline, and some camphor are added with advantage. When the excess of solvent is removed from the pyroxylin, it is mixed with a considerable quantity of castor-oil or cotton-seed oil, and made into a dough or paste between heated rollers. For a hard compound the quantity of oil should be less than the pyroxylin, for a soft one it should be greater. Chloride of sulphur is sometimes added to the oil. When articles made of celluloid are in a partially manufactured state, they are soaked in bisulphide of carbon or chloride of lime to remove any trace of solvent, which would render them apt to shrink if allowed to remain. Celluloid is of a somewhat combustible nature unless the substances used to colour it are such as will neutralise this, or unless some non-combustible chemical, tungstate of soda for example, is added to it.

Properties and Uses.—Celluloid has many valuable properties. It is buff or pale brown in colour, but it can be made as white as ivory, which it much resembles, or manufactured in a transparent state. It can be moulded or pressed into any form, and turned, planed, or carved. Neither the atmosphere nor water affects it. It is elastic and can be united by its own cement. In a plastic condition celluloid can be spread on textile fabrics, or it may be made as hard as ivory, for which it is largely used as a substitute. Billiard-balls, piano-keys, and combs are made of it, the latter two articles extensively. It can be coloured to represent amber, tortoiseshell, or malachite. In imitation of red coral it has been a good deal used for jewelry. Like vulcanite, which it excels in durability but exceeds in price, it has very numerous applications. We need only mention brush-backs, knife-handles, buttons, napkin-rings, card-cases, thimbles, and dolls. It is useful for optical instruments and for some surgical instruments. One of the most recent applications of it is for shirt fronts and collars. The manufacture of celluloid, although an English invention, has been most largely developed in the United States, where it is mostly, if not entirely, made by one firm, the Celluloid Manufacturing Co., Newark, New Jersey, who use this word as a trade-mark.

Cellulose is the substance secreted by the living protoplasm of a vegetable cell to form its investing membrane or cell-wall. (See CELL, and HISTOLOGY, VEGETABLE, for account of its mode of formation, its ligneous, corky and colloid change, its mode of arrangement and union in cell-walls, &c.). It is obtained in a pure state by treating any unaltered cellular tissue with alkalies and acids to remove mineral matter and protoplasm, and successive washings with water, alcohol, and ether to remove soluble substances. Cotton-pith or vegetable-ivory, although much contrasted in histological properties, are alike remarkably pure cellulose.

Cellulose has the chemical composition $C_6H_{10}O_5$, and spec. grav. 1·52. Among its familiar natural modifications gum is an isomer, and starch-dextrin and grape-sugar are all of similar ultimate composition, while its woody and corky modifications (lignin and suberin) possess an increasing proportion of carbon. Iodine alone stains cellulose yellow or brown, but blue when strong sulphuric acid has been previously added. Strong hot sulphuric acid chars it, while brief immersion in the cold converts it into a tough and dense modification, well known in parchment paper, and prolonged treatment dissolves it altogether. Dextrin may thus be prepared and next transmuted, by boiling the watery solution, into grape-sugar (see DEXTRINE, GLUCOSE). By immersion in a mixture of strong nitric and sulphuric acid we obtain Gun-cotton (q.v.), while dilute nitric acid or potash oxidises it into oxalic acid. Ammoniacal oxide of copper dissolves it without change, as is shown by its reprecipitation on dilution. By heating in closed vessels under pressure a dense coal-like mass is formed, while in ordinary dry distillation, gas, tar, and acetic acid are given off, processes which throw light on the formation of coal in nature and on the chemistry of gas-making. In natural decomposition cellulose turns yellow and brown with gradual formation of humus.

Although so constant and characteristic a product of vegetable life, the conditions and mode of its formation are still very obscure. From that cell-cycle or rhythm of change between the passive and cellulose-walled state and an active and wall-less one, which is so characteristic of the lowest forms of life, and of which we find surviving traces (e.g. the rejuvenescence of the pollen-grain) in the reproductive processes of even the highest plants (see CELL), it would appear that there is some relation between this increased passivity and the formation of cellulose. And in this way arises the speculation that cellulose may be viewed essentially as a (mechanically coherent and thus useful) excretion, an incompletely utilised waste product corresponding to the carbonic acid and water given off by the completer respiratory oxidation and larger evolution of energy of the active phase. Once formed by the plant, it may be again absorbed, as is well seen in the union of a row of cells into a continuous vessel, or in the consumption of endosperm of a seed during germination. Many seeds, such as vegetable-ivory or date, have a great proportion of their reserve material in this form; and this must be digested into glucose by the growing embryo, and again worked up into new protoplasm, which deposits cellulose as before. Like the plant itself, the similar digestive ferments of the animal might thus be naturally expected to digest cellulose; and this is actually, to some extent, the case with the delicate young cell-walls of many green vegetables, as can be experimentally verified, even in man; while in herbivorous animals this power is much developed, and the nutritive utilisation of their fodder is thus increased to an important extent.

The cysts of amœbæ and other protozoa appear to be at least largely composed of cellulose, and the external tunic of ascidians (see TUNICATA) is of identical, or at least isomeric, composition. Cellulose has been described as a pathological product, even in brain-tissue; and Chitin (q.v.), a very characteristic and in many respects comparable animal product, has been sometimes viewed as cellulose in association with a proteid substance.

Cements. These may be roughly divided into three classes: (1) The stone cements, including Roman and Portland cements, and ordinary mortar, which are used in thickish layers for uniting stone and brick work, and for protective coverings to buildings; (2) substances which form binding joints of much less but still appreciable thickness, such as white lead, red lead, and putty; and (3) cements which require to be used in extremely thin coatings, such as glue, isinglass, and dissolved caoutchouc.

Ordinary Mortar is a mixture of slaked lime (*calcium hydroxide*) and sand, made into a paste with water. Generally one part of lime to three or four parts of sand are used, but the proportions vary according to the purity of the lime employed. Very pure or fat lime, such as that made by burning white chalk or white marble does not make so good a mortar as lime obtained from less pure limestones, which are by far the most abundant. The more thoroughly the ingredients are intermixed, the more complete will be the subsequent hardening of the mortar. As commonly laid in the joints of brick or stone work, mortar sets sufficiently fast to allow building operations to proceed from day to day with occasional longer intervals, but it takes years—perhaps in many cases centuries—to reach its maximum hardness. The setting and subsequent slow hardening of mortar are usually considered to be due, in the first instance, simply to the loss of water, and afterwards to the absorption by the lime of carbonic acid from the atmosphere, the carbonate of lime thus formed binding together the sand and stone. It is doubtful, however, if this is an altogether satisfactory explanation. The mortar used in many medieval buildings is largely mixed with small pebbles. In a number of cases this has proved to be of a more durable nature than the stone used along with it.

Puzzolana or *Pozzuolana*, a loosely coherent volcanic sand found at Pozzuoli, near Naples, has been long celebrated for its property of forming a hydraulic cement when mixed with ordinary lime. It is composed of silica, with a little magnesia and potash or soda, alumina, lime, and oxide of iron.

Roman Cement.—Certain natural mixtures of lime and clay are called cement-stones. The clays of some of the newer geological formations in the south of England, for example, contain courses of septarian nodules (see SEPTARIA), which have been in great request for making the best kinds of Roman cement. They are concretions of impure calcareous matter, many of them having this analysis: Carbonate of lime, 66; silica, 18; alumina, 7; and protoxide of iron, 6; or consist of these substances in nearly that proportion. Cement-stones are carefully calcined in kilns, and afterwards ground and sifted. Good Roman cement should set in about 15 minutes, and this quick-setting property makes it valuable for work which requires to be executed between tides and for other purposes where the cement used must harden quickly. It is at best of but medium strength. Some natural cements are slow-setting, and these do not contain more than 22 per cent. of clay. They set under water when half their weight consists of clay. The proportion of sand used with Roman cement should not much exceed that of the cement. When employed for external coatings of buildings it is apt to effloresce and become unsightly.

Portland Cement.—This is considered by far the most important of the stone cements. It is an artificial product, named from its resemblance to Portland Stone, but is much more largely used than Roman cement. In the manufacture of Portland cement on the banks of the Thames and the Medway by the wet process, three parts of white chalk are mixed with one part of clay or mud from the lower reaches of these rivers. The two substances, along with water, are placed in a 'wash mill' in which strong revolving knives or cutters reduce the whole to a creamy 'slurry' or slip. The slurry then passes by gravitation to backs or reservoirs. There it is allowed to settle for some weeks, when the superfluous water is removed by decantation. The mixture is next dried on heated iron plates or on the floor of a heated chamber, and then burned in kilns. Finally it is ground to a fine powder. Modifications of the wet process by which the large reservoirs are dispensed with have been introduced in recent years. In other parts of the country Portland cement is manufactured by the dry process from the hard limestones of other formations than the chalk, along with clay or shale. These limestones are crushed small, mixed in the proper proportion with clay or shale, then roughly burned, and ground to powder. This powder slightly moistened is passed through a pug-mill, and then made into bricks, which are afterwards burned in kilns and reduced to powder.

Since Portland cement is hardly ever employed in the pure or neat state, its strength is perhaps best tested when it is mixed with an equal weight of sand. The best cement so mixed and moulded in the state of a stiff mortar, into any convenient shape, when tested after the lapse of seven days, during six of which it is customary to keep it immersed in water, exceeds in tensile strength 200 lb. per square inch, and in crushing strength, tested by 1½-inch cubes, 1000 lb. for the same area. Its strength in the unmixed state is much greater. Much of the Portland cement made is, however, little more than half as strong as the best kind. Roman cement of good quality mixed to the same extent with sand as the above, and tested under the same conditions, has on an average a tensile strength of 30 lb., and a crushing strength of 200 lb. in each case per square inch. Portland cement is slow in setting compared with most varieties of Roman cement. Both Portland and Roman cement form *hydraulic mortars*—that is, they set under water. No mortar will do this which contains less than 10 per cent. of silica.

Till close on 1840 Portland cement was hardly known, but the use of it has extended rapidly, especially in recent years. Its most important application is in the construction of docks and harbours, many of which are partly or wholly built of it, mixed with sand and broken stones, in the form of a concrete. In this state, or simply mixed with sand, it is also much employed for other purposes where strength and durability are required. Owing to the nature of some of the extensive engineering works in which Portland cement is largely used, it is plainly of great consequence that its properties should be thoroughly understood. Numerous failures with it have taken place. The chemical investigation into the case of the Aberdeen docks in 1887 distinctly showed the deleterious action of sea-water upon this substance. But it is also known that objects made of unmixed Portland cement from the works of some of the best makers will sometimes keep good for nearly twenty years, and then crumble to pieces even when not exposed out of doors at all. Of course explanations of these failures are forthcoming. They are generally attributed to carelessness in the manufacture of the cement, or in the selection of the materials for it. But if they occur, as they have done, with cements that have stood very well the ordinary mechanical tests, how can any cement of this kind be entirely depended upon for durability? Twenty, thirty, or even fifty years is far too short a time to test the lasting property of a building material of this nature. The use of Portland cement in pavements and for architectural ornaments is not attended with much risk, and for such purposes it is very suitable. The capital employed in the manufacture in Great Britain is probably near two millions sterling. For American cements, see ROSENDALE.

Scott's Selenic Cement consists of burnt limestone mixed with about 5 per cent. of sulphate of lime in the form of plaster of Paris, and ground to powder. The presence of the sulphate arrests the slaking action of the lime, causes the cement to set more quickly, and admits of more sand being used with it than ordinary lime does. This cement has been a good deal used for plastering, and to some extent also for mortar.

Plaster of Paris (see ALABASTER and GYPSUM).—This material is used for cementing marble and alabaster in much the same way as mortar is in brick-work. It is also employed for uniting the separately moulded pieces of any large object cast in the same material. Sometimes it is selected for fixing metal mounts to glass.

Keene's Cement is made by saturating plaster of Paris in small lumps with alum and recalcining it. It then forms a hard plaster for the projecting portions of halls and rooms, such as pilasters, columns, and skirtings. It is capable of taking a high polish.

Parian or Keating's Cement somewhat resembles Keene's. In its manufacture borax as well as alum is added to the plaster of Paris.

Martin's Cement is another kind, with plaster of Paris for its basis, but instead of borax, carbonate of potash is added, and sometimes hydrochloric acid as well. With the exception of Scott's, these plaster of Paris cements are only used in plastering or other internal work—not for mortars.

Mastic Cement, consisting of a mixture of burnt clay or limestone in a powdered state, with boiled oil and litharge, was more in use formerly than now; but though expensive, it is an excellent material for preventing the admission of rain-water at certain joints about buildings, such as where wood and stone work come together at windows. It was also used for covering external mouldings.

Rust or Iron Cement.—Joints in iron-work, such as those for hot-water pipes, are filled up with a cement of iron borings or turnings, mixed with at least 2 per cent. of sal-ammoniac. Sometimes sulphur in powder is added. The iron oxidises and forms a firm joint.

Sulphur Cement.—For jointing earthenware pipes, and occasionally for fixing bars of iron into stone, a cement is made of sulphur, resin, and brick-dust. It is a cheap but not a strong cement where metal is concerned.

Water-glass Cements.—For furnaces one kind consists of burnt and unburnt fireclay made plastic with silicate of soda or water-glass. Another cement, capable of standing a high heat, is formed of asbestos powder made into a paste with silicate of soda. The same silicate mixed with ground glass makes an acid-proof cement.

White and Red Lead Cements.—Either white lead or red lead by itself, or a mixture of both, is much in request as a cement for the joints of slate or glass cisterns, such as aquariums. These are also employed for the joints of gas-pipes, for cementing metal mounts to glass tubes, and other chemical and electrical purposes. White and red lead cements are made up with boiled linseed-oil, and sometimes gold size is added. Mixed white and red lead make a very hard and firm cement. A cement of these two substances and ground plumbago in equal parts, mixed with oil, is said to stand a great heat in steam-joints.

Shell-lac Cements.—An excellent cement is made by digesting 4 oz. of the finest shell-lac in 3 oz. of methylated spirit in a warm place. It should be made into a consistency like thick syrup. This makes a firm cement for mending pieces of glass, china, ornamental stones, and ivory. It is not soluble in water. A cheaper, but still very serviceable cement can be formed by dissolving shell-lac in wood naphtha. For some purposes shell-lac itself is used as cement by simply melting it.

Marine Glue is a mixture of shell-lac in a solution of india-rubber. It is made into thin sheets, and melted when required for use in shipbuilding, &c.

Gelatin and Isinglass Cements.—Fish-glue, gelatin, or Isinglass (q.v.), made up with dilute acetic acid and other bodies into a jelly or thick liquid, produces a cement slightly varying in its nature, for mending china, glass, ivory, bone, and other substances. Foulke's cement and liquid fish-glue are cements of this class. These can be obtained in a convenient form for use in hardware or druggists' shops. They are more or less soluble in water, so that articles mended with them must be quickly washed. Cement of mixed glue and glycerine, sometimes with tannin added, is occasionally used for leather and cloth.

Armenian or Diamond Cement.—The following is the reputed formula for preparing the cement used by the Armenian jewellers for attaching diamonds, &c., without any metallic setting: 'Dissolve five or six bits of gum-mastic, each the size of a large pea, in as much rectified spirit of wine as will suffice to render it liquid; and in another vessel dissolve as much isinglass, previously a little softened in water—though none of the water must be used—in French brandy, or good rum, as will make a 2-ounce phial of very strong glue, adding two very small bits of galbanum or ammoniacum, which must be rubbed or ground till they are dissolved. Then mix the whole with a sufficient heat. Keep the glue in a phial closely stopped, and when it is to be used, set the phial in boiling water.'

Elastic Cements.—One part of caoutchouc dissolved in 3 parts of chloroform; also, 5 parts of caoutchouc in 3 parts of chloroform, with 1 part of powdered gum-mastic added. Benzole is sometimes used instead of chloroform as the solvent. Another elastic cement can be made by a mixture of gutta-percha and caoutchouc dissolved in bisulphide of carbon. The solvents of these cements must not be exposed to any but a gentle heat.

Resin Cements.—There are a great number of cements partly formed of ordinary resin. One kind consists of resin 4, beeswax 1, and whiting 1 part. The proportions of these ingredients in the same order for another are 15, 1, and 4. Another is made from resin 4, and plaster of Paris 1 part. These cements are used to fix pieces of stone, glass, &c. to handles when grinding them. Resin, pitch, beeswax, and plaster of Paris or brick-dust are made up in various proportions into cements.

Cutlers' Cement, used for fixing knives and forks in handles, is made of equal weights of resin and brick-dust melted together; or, for a superior quality, 4 parts of resin, 1 of beeswax, and 1 of brick-dust.

Copal varnish, mastic varnish, Canada balsam, and gold size are each useful occasionally for cementing substances like two pieces of glass together.

Cerebro-spinal Fluid is a clear, almost colourless, slightly alkaline fluid, closely resembling lymph in its composition, but containing less albumen. It is contained partly within the ventricular system of the brain, and in part in the loose connective tissue (subarachnoid meshwork), which lies between the Arachnoid and Pia Mater (q.v.), being continued from this latter situation along the lymphatic sheaths, which closely invest all the blood-vessels in the substance of the brain and spinal cord. The spaces which contain it communicate with the lymphatics of the head and of the nerves, and with the venous sinuses in the dura mater. Its main function, besides that of removing waste products, is to equalise the pressure within the skull. As the blood pressure increases that of the cerebro-spinal fluid diminishes, and *vice versâ*. As the brain atrophies it is replaced by a proportionate increase in the fluid. In some diseases, such as acute and chronic Hydrocephalus (q.v.), it is greatly increased, and then it becomes a cause of atrophy of the brain. Its value as a water-cushion in diminishing the violence of shock from external injury has been already referred to at BRAIN. *Cerebro-spinal* means pertaining to the brain and spinal cord together, to the cerebro-spinal system.

Cerium (sym. Ce, eq. 92) is a rare metal found in cerite and a few other minerals. It is a white metal, has not been obtained in any quantity, is not therefore employed in any manufacture, and forms two basic oxides and a numerous class of salts. The nitrate and oxalate of cerium have been employed in the vomiting of pregnancy, their action being somewhat similar to that of the subnitrate of bismuth. Cerium biscuits are biscuits containing a small proportion of the oxalate, and they form a very convenient medium for the administration of the salt. *Cerite* or *Ochröite* is the silicate of cerium, and is found as a mineral in gneiss, near Riddarhytta, in Westmanland in Sweden.

Ceru'men is ear-wax, the yellow waxy matter which is secreted by certain glands lying in the passage that leads from the external opening of the ear to the membrane of the tympanum. It lubricates the passage and entangles particles of dust and small insects, preventing them from getting farther in.

Chalaza. The first layer of albumen deposited upon the yolk of an egg as it descends the bird's oviduct, is peculiarly viscous, and thus becomes twisted into two strands which keep the yolk in the middle of the more fluid albumen. These cords are also called *chalazæ*.

Chalk, a soft earthy variety of limestone or carbonate of lime, forming great strata, and claiming the attention of the geologist even more than of the mineralogist (see CRETACEOUS SYSTEM). It is generally of a yellowish-white colour, but sometimes snow-white. It is easily broken, and has an earthy fracture, is rough and very meagre to the touch, and adheres slightly to the tongue. It generally contains a little silica, alumina, or magnesia, sometimes all of these. Although often very soft and earthy, it is sometimes so compact that it can be used as a building-stone; and it is used for this purpose either in a rough state, or sawn into blocks of proper shape and size. It is burned into quicklime, and nearly all the houses in London are cemented with mortar so procured. The siliceous particles being separated by pounding and diffusing in water, it becomes whiting, of which the domestic uses are familiar to every one. Carpenters and others use it for making marks, which are easily effaced: the *blackboard* and piece of chalk are now common equally in the lecture-rooms of universities and in the humblest village-schools. Chalk, perfectly purified, is mixed with vegetable colouring matters, such as turmeric, litmus, saffron, and sap-green, to form pastel colours or coloured chalks; but vegetable colours which contain an acid are changed by it (see CRAYON). The *Vienna white* of artists is simply purified chalk. In a perfectly purified state it is administered as a medicine to correct acidity in the stomach. Chalk is also extensively used as a manure. See Lime, Manure.

Black Chalk is a mineral quite different from common chalk, and apparently receives its name from resembling it in meagreness to the touch, in soiling the fingers, and in being used for drawing, writing, &c. It is also called Drawing-slate. It is of a slaty structure, of a bluish or grayish-black colour, easily cut and broken, and makes a perfectly black mark on paper. It is used for drawing and as a black colour in painting. It becomes red by exposure to heat. It is essentially a kind of Clay (q.v.), and derives its colour from carbon, which it contains. It is found associated with schists, &c. in Spain, France, Italy, &c., also in the coal formation in Scotland.—Briançon Chalk and French Chalk are popular names for Soapstone (q.v.).—Red Chalk is *ochry red clay-iron ore*, consisting of clay and much peroxide of iron. It is of a brownish-red colour, and a somewhat slaty structure, the cross fracture earthy. The coarser varieties are used chiefly by carpenters for making marks on wood; the finer, by painters. It occurs in thin beds in clay-slate and graywacke-slate in some parts of Germany.

Chara. The Characeæ or Stoneworts are a small group of common aquatic plants found growing in large tufts, or even covering large expanses on the bottoms of fresh-water ponds and shallow lakes, brackish or even salt-water lagoons, &c., and of which the systematic position has undergone the most extraordinary and instructive vicissitudes. The early botanists, with K. Bauhin, had no hesitation in describing them as horsetails (Equisetum). In 1719 Vaillant proposed for them a separate genus (Chara), while Linnæus, although at first disposed to regard them as Algæ, as their habitat suggests, decided that the small red male reproductive body must be a stamen; and the larger green female one a pistil, and accordingly placed them as flowering plants among the *Monœcia Monandria*. His pupils at most ventured to remove these to the *Monandria Monogynia*, while De Jussieu regarded them as a genus of Naiadaceæ (q.v.), an order of monocotyledonous aquatics with much reduced flowers. In similar opinions he was followed by De Candolle and other eminent systematists; and it was not until 1851 that a careful re-examination of their structure and mode of reproduction by Thuret finally disproved the phanerogamous view, and established their cryptogamic nature. Since that time the group has attracted great attention, and is now on grounds of peculiar instructiveness, both morphological and physiological, one of the classical forms usually presented to the beginner, not only in cryptogamic botany, but general biology.

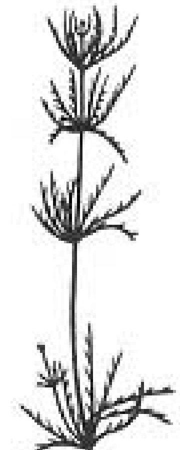


Fig. 1.
Shoot of Chara.

Commencing with the vegetative system, we find this apparently consisting of a stem with regular whorls of leaves arising at definite points (nodes) of the stem. The internodes, or distances between these, are at first considerable; but as we approach the apex these are shorter and shorter, and at length we lose sight of them in the crowded terminal bud. The resemblance to a young shoot of Equisetum is so far satisfactory, and the mineral incrustation (in some species so abundant as to lead to the substitution of the plant for scouring metal) appears to confirm this. The incrustation, however, is calcareous, not siliceous. Even under microscopic examination we may at first sympathise with the old observers, and seem to see in the stem a multicellular structure, even a cortex; nay, to see under our very eyes the actual circulation of the sap. More careful scrutiny, however, enables us to repeat the work of later and more accurate observers. We see that this movement is not the circulation of the sap in a stem, but a streaming of the protoplasm within what is simply a single enormous cell stretching from one node to the next (see Cell). The apparent cortex is a single layer of cells covering this internodal cell; and the whole vegetative structure is unravelled when we roughly dissect out the terminal bud, harden, stain and imbed this in paraffin, and thus cut a fine longitudinal section (fig. 2). An apical cell is seen which continually segments off a lower one; this divides (still transversely to the axis) into two new ones; and the lower of these henceforth steadily lengthens as the internodal cell, while the upper undergoes repeated division, until a plate of nodal cells is formed. In the simpler family (Nitella) the internode thus consists of a single naked cell: in the higher (Chara), this is inclosed by the so-called cortex, a layer of smaller cells proceeding from those of the upper and lower nodes; and itself showing a minor nodal and internodal arrangement. In all cases, from the nodal cells there divide off, parallel to the outer surface of the stem, a new set of apical cells, which proceed, like the parent one, to form the 'leaves,' reproducing, that is to say, the stem structure, until they lose the power of division, and end in a single enlarged vegetative cell. A branch may arise from a new formed apical cell cut off in the axil of the oldest leaf of any whorl, while the so-called roots, which fix the plant in the mud, are simply unicellular hairs, lengthenings produced from the superficial cells of buried nodes.

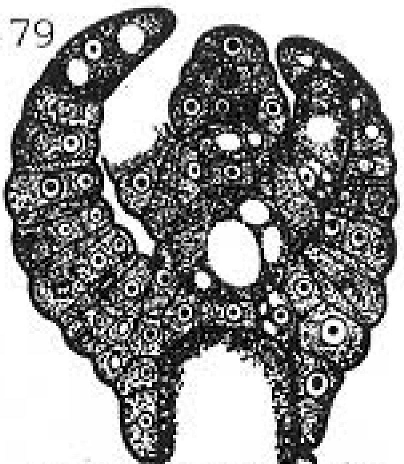

Fig. 2.—Longitudinal Section of the apical bud of Chara.

The apparently very complex and characteristic reproductive organs arise also at the nodes of the stem or leaves, in positions and numbers varying with the species. Commencing with the female (fig. 3*a*), which arises in the position of a branch, we find this to be obviously a shortened and modified one. Its apical cell forms only an internode and node, then ceases division, and becomes enlarged and filled with a store of starch and other reserve material to form an egg-cell; while the cover or archegonium inclosing this is readily seen to be a mere modification of the familiar cortex. In the male apparatus, or antheridium, the branch structure is further modified: its apical cell similarly remains all but sessile, forming only a short node and internode; but segmentation now begins, thus recalling the behaviour of a nodal cell—with which, in having below it an internodal, and not as in the case of the egg-cell, a nodal cell (fig. 3*b*), it so far corresponds. Eight quadrant-like cells are formed, but these now segment off new cells in the interior of the spherical mass, and in the growth and development of these the nodal and internodal alternation of ordinary vegetative growth can still be traced. Soon, however, a number of long segmented filaments are developed, and the protoplasm of these undergoes rejuvenescence, and becomes modified into a ciliated spermatozoid. When the reproductive organs are ripe, this archegonium is easily broken, and its filaments spread free in the water; the spermatozoids escape in a myriad, and some reach the egg-cell of the archegonium by means of a small opening, which is left by the all but incomplete upgrowth of the cortical cells which form the wall of the archegonium. After a period of rest, the fertilised ovum germinates, producing, however, not directly a new Chara plant, but a simple filament of cells called a pro-embryo, of which one cell segments into a node, and the oldest cell of this becomes the growing point of the new plant.

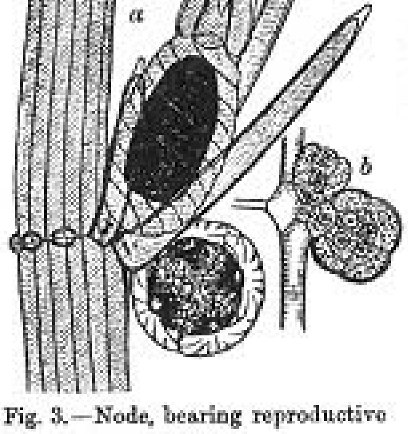

Fig. 3.—Node, bearing reproductive organs:
a, Mature; b, developing. The upper in each case is the female.

The affinities and systematic position of the group thus still afford ground for discussion, although now within narrower limits than formerly; some systematists regarding them as a somewhat aberrant group of Algæ, while others insist on their resemblance to the archegoniate cryptogams (see Vegetable Kingdom). The fruits of what seem to have been gigantic Characeæ (Spirangium) occur from the Carboniferous to the Wealden, and ordinary Characeæ are abundant in the Tertiary strata.

Charcoal is a term most frequently applied to charred wood, or coal produced by charring wood. Formerly, charcoal was the name for charred sea-coal or mineral coal; and the word is popularly used for the carbonaceous residue of vegetable, animal, or mineral substances when they have undergone smothered combustion.

Animal Charcoal, Bone-black, or Ivory-black, is prepared from bones by heating them in close retorts till they undergo the process of destructive distillation, when combustible gases and water, together with the vapours of various salts of ammonia, and oil, are given off, and bone-black is left in the retort. It is generally reduced to coarse grains from about the size of small peas down to large pin-heads, and is extensively used in the arts for decolourising liquids, such as the syrup of sugar, and solutions of argol (impure cream of tartar) and of the alkaloids, as also in Filters (q.v.) for separating chemical impurities from water. The general mode of using the bone-black is to allow the coloured liquid to percolate through a layer of the charcoal, when all colour is arrested, and the syrup or water runs clear and colourless from under the stratum of charcoal. This power of absorbing colouring matters is also observable in vegetable (peat or wood) charcoal, but not to such an extent as in bone-black. The application of heat to the liquids before filtration greatly facilitates the decolourisation, and where the volume of liquid to be operated upon is not great, the most expeditious method is to boil the liquid and bone-black together, and then strain through filtering-paper or cloth. The composition of bone-black in 100 parts is 10 of pure charcoal, associated with 90 of earthy salts—i.e. in the proportion of one of pure charcoal in 10 of the commercial bone-black. The power of absorbing colours appears to be due to the porosity of the substance, and is not resident simply in the pure charcoal; indeed, the earthy matters (principally phosphate of lime and carbonate of lime) can be dissolved out of the bone-black by dilute hydrochloric acid, and the pure charcoal thus obtained only possesses about one-third the decolourising power of the total amount of bone-black it was obtained from. Thus, if 100 parts of ordinary bone-black have the power of arresting the colour from *ten* volumes of a given coloured liquid, then the 10 parts of pure charcoal which can be obtained from the 100 parts of bone-black will be found to decolourise only *three* volumes of the same coloured liquid; so that it is apparent the earthy matters in the bone-black influence and increase the absorption of the colouring matter, and thus render a given weight of the charcoal of greater commercial value. When syrup of sugar and other liquids have been run through bone-black for some time, the pores of the latter appear to get clogged with the colour, and the clarifying influence ceases, and then the bone-black requires to undergo the process of *revivification*, which consists in reheating it carefully in ovens, or iron pipes inclosed in a furnace, when the absorbed colour is charred, and the bone-black can be of service once again as an arrester of colour. After several re-burnings, the bone-black becomes of very inferior absorptive quality, and is then disposed of for the manufacture of bone-ash and dissolved bones (see Bone Manures). Bone-black has likewise a great power of absorbing odours, especially those of a disagreeable nature, and can thus be employed to deodorise apartments, clothing, outhouses, &c., or wherever animal matter may be passing into a state of active putrefaction.

Wood Charcoal is the most important, though not the purest kind of Carbon (q.v.). Wood consists of carbon, hydrogen, and oxygen, the last two being in the proportion to form water. When heated in the open air, it burns completely away, with the exception of a small white ash; but if the supply of air be limited, only the more volatile matters burn away, and most of the carbon remains. This is the principle of the process of charcoal-burning in countries where wood is abundant.

Billets of wood are built up vertically in two or three rows into a large conical heap, which is covered over with turf or moistened charcoal-ash, and holes left at the bottom for the air to get in. An open space is also left in the middle of the heap to serve as a flue. The heap is set on fire by putting burning wood into the top of the central opening. The combustion proceeds gradually from the top to the bottom, and from the centre to the outside of the heap; and as the central portions burn away, fresh wood is continually thrown in at the top, so as to keep the heap quite full. The smoke is thick and white when the process is going on properly; if it becomes thin, and especially if a blue flame appears, the wood is burning away too fast, and the combustion must be checked by closing the holes at the bottom, or by heaping fresh ashes on the top and sides. As soon as the combustion is completed, the heap is completely covered with turf or ashes, and left to cool for two or three days. It is then taken to pieces, and the portions still hot are cooled by throwing water or sand upon them. It is found that 100 parts of wood yield on the average from 61 to 65 parts by measure, or 24 parts by weight, of charcoal. The charcoal thus prepared is the best suited for fuel. In England a large quantity of charcoal is obtained in the dry distillation of wood in cast-iron cylinders, for the preparation of crude acetic acid. The charcoal thus prepared is preferable for making gunpowder, but is inferior for other purposes. A peculiar kind of charcoal of a reddish-brown colour, and hence termed *charbon roux* or *red charcoal*, is frequently prepared for the manufacture of the gunpowder used for sporting purposes, by subjecting wood in iron cylinders to the action of superheated steam under a pressure of two atmospheres. Powder made with this charcoal absorbs moisture more rapidly than ordinary gunpowder.

The general properties of wood-charcoal are, that it is black and brittle, and retains the form of the wood from which it is derived; it is insoluble in water, infusible and non-volatile in the most intense heat; its power of condensing gases is noticed under Carbon (q.v.); and from its power of destroying bad smells it has been regarded as possessing considerable antiseptic properties. It is frequently stated that charcoal is a bad conductor of heat, but a good conductor of electricity. These properties depend upon the nature of the charcoal, the lighter wood, such as willow, yielding a porous charcoal, with little power of conducting heat or electricity; while boxwood yields a very compact charcoal, which is a good conductor of heat and electricity, and is admirably adapted for the exhibition of the electric light. Charcoal never consists entirely of pure carbon, the degree of purity varying directly with the temperature at which it is formed; thus, charcoal charred at 480° (249° C.) contains 65 per cent. of carbon, while that charred at 750° (399° C.) contains 80, and that charred at 2730° (1499° C.) contains 96; but the loss of charcoal occasioned by these high temperatures is very great, the percentage yield of charcoal corresponding to these temperatures being 50, 20, and 15.

The uses of wood-charcoal are numerous and extensive. It is very largely employed as a fuel, taking the same place in many countries that coal occupies here. From its being proof against all ordinary chemical agencies, superficial charring is often employed to protect wood from decay, as in the case of fence-posts, of telegraph poles, or of piles which are driven into mud or into the beds of rivers to serve as foundations. With the same design it is not unusual to char the interior of tubs and casks destined to hold liquids. In a finely-divided state it is commonly regarded, as has been already stated, as an antiseptic; and there is no doubt that the offensive effluvia from animal matter in an advanced stage of putrefaction disappear when the putrefying substance is covered with a layer of charcoal; but in reality the decay goes on, without the emission of any odour, till at length the whole of the carbon is dissipated as carbonic acid gas, and the hydrogen as water, while the nitrogen remains as nitric acid. It has been shown that the action consists in a rapid process of oxidation, dependent upon the power which finely-divided charcoal possesses of condensing oxygen. In a finely-divided state, charcoal not only condenses gases to a marvellous extent, but has the power of absorbing colouring matters, bitter principles, &c.; and hence it is of extensive use in the laboratory. From the rapidity of its absorbing action, the use of a respirator filled with charcoal has been suggested to protect the mouth and nostrils in an infected atmosphere; trays of powdered wood-charcoal in dissecting-rooms, in the wards of hospitals, and in situations where putrescent animal matter is present, exert a most beneficial influence in sweetening the atmosphere, by absorbing and decomposing the offensive gases. Charcoal is accordingly valuable in filters, not only for decolourising purposes, but likewise for assisting in purifying water for domestic use. It is also successfully used to prevent the escape of noxious vapours at the ventilating openings of sewers, as it allows the free passage of air, but condenses the offensive effluvia in its pores, where they are destroyed by a process of oxidation. Besides its employment in the manufacture of gunpowder it has many applications in the arts. In medicine it is at present chiefly used to destroy fetor; for which purpose it is applied in the form of powder or poultice to gangrenous sores, phagedenic ulcers, &c.; it is also largely employed in tooth-powders, as by its mechanical action it removes incrustations, while by its chemical action it destroys fetor of the breath. In indigestion accompanied by much flatulence it may be given in doses of two or three teaspoonfuls suspended in water, or may be administered in the form of charcoal-biscuits (see BISCUITS). Very finely-divided poplar charcoal is regarded as the best for medicinal uses.

Cheese is a highly nutritious food substance made from milk by elaborate processes which can only be explained in the light of a knowledge of science, chiefly chemistry. Cheeses may be roughly divided into two great classes—*hard* and *soft*. The various English, Scotch, and American cheeses belong to the first class, and are made so that they will generally keep for months, and often continue to improve in quality. Soft cheeses are those which prevail in some parts of the Continent. Many of them require to be consumed immediately after they are manufactured. Their rapid decomposition is associated with a strong and to most people an objectionable smell. Cheese is made from the solids of milk—viz. the casein or chief albuminoid constituent, along with the greater part of the cream or butter-fat, and much of the mineral ash. In fresh milk, which is slightly alkaline, these substances maintain a sort of indescribable union with the watery portion and the milk-sugar—the whole, as is well known, being liquid. The presence of an acid, or of Rennet (q.v.), counteracts the natural affinity of the substances for each other, and the bulk of the solids separate out, forming a soft jelly in the early stages, leaving the bulk of the water containing the sugar as a greenish liquid called Whey (q.v.). The chemical processes involved are as yet only very imperfectly understood.

Milk in decomposing, as it rapidly does in hot and sultry weather, becomes sour in virtue of a natural process of fermentation. Rennet induces another form of fermentation which does not end when the product ceases to be milk, but is carried on in the cheese during the period of its ripening or mellowing. In the early stages of the process of hard cheese-making, the incipient acidity which induces that condition in milk termed 'ripeness,' aids and hastens the action of the rennet. As the work proceeds, and the acidity intensifies, it hardens and contracts the curd, giving it a leathery character, thereby aiding in the expulsion of the whey. One of the most important matters in cheese-making is to watch the development of acidity both in the milk and its first product, the curd. If this is allowed to go too far, the quality of the cheese is seriously injured, and its keeping power is reduced. It cracks through becoming too dry and brittle. The delicate flavouring oils seem to be expelled, and the smell becomes high and the taste 'acrid' or 'biting.' The formation of the acid is one of the great helps in cheese-making so long as it is kept in due control. If the acid develops rapidly, as in hot weather, in a temperature which suits the germs producing it, the whole process of manufacture has to be pushed on quickly, whereas in cold weather acidity comes slowly, and the operator must wait until it has come sufficiently. There are several methods adopted in inducing acidity. Acid used to be largely added, as sour whey or buttermilk, but greater uniformity is got by delaying until natural acidity develops. This it does most quickly when the temperature of the material is kept up near to blood-heat. Chilly draughts paralyse the active organisms producing acidity.

Heat is communicated to milk or to its products in the early stages of cheese-making by two methods—either by warming a portion of the milk or whey (though not allowing it to rise much above 100° F.—say a limit of 150° F.—as to boil it would do injury by changing its constitution), and putting it into the main bulk, or by having an outer shell of wood to the tin or iron cheese-tub, with a space between into which steam or hot water can be injected. This arrangement possesses the additional advantage of being clean and of saving labour, although the cost of the apparatus is greater. When the temperature of the evening's milk requires to be reduced to insure its keeping overnight, as in hot weather, cold water can be employed in the same manner as hot water or steam.

It would be misleading to fix definite temperatures or assume definite rules of any kind in speaking of the broad principles and practices of British cheese-making, because there are so many systems which differ materially in important particulars.

A thermometer should be used at all times and in all systems. The old method of testing by the hand hardly now exists, and certainly not among good cheesemakers. The ordinary temperatures at which milk is set or steeped vary with the system adopted and the temperature of the atmosphere—from 80° to 90°, *more* or *less*, is the nearest indication that it is safe to make. High temperatures are used in making *deep* cheeses, such as Cheddars; low temperatures in making *shallow* cheeses, as the old-fashioned Dunlops. The Gloucester is a well-known variety set at a temperature nearer to 80° than 90° F. By setting at too high a temperature the curd gets hard and tough, though it needs a considerable amount of consistency if it is to retain a symmetrical form in a deep cheese. If worked too cold, the curd is soft and the whey difficult to get out of it, the processes of rennet fermentation and acid fermentation do not go on sufficiently, and their work is imperfect. In all cases the greatest regularity in method should be maintained from day to day.

After heating, the colouring matter (now almost invariably Annatto, q.v.) is put in. This is not considered an adulteration, as it is innocuous. It in no way improves the quality of the cheese, the effect being only upon the colour. All cheeses are not coloured, though the practice is widespread. Rennet is put in about the same time, and after thorough stirring for the purpose of mixing these added ingredients, as well as for keeping down the cream, it is left for 40 or 60 minutes.

Breaking the curd to let out the whey is the next process. Networks of thin wire, or series of thin knives, are passed through it in various directions with great caution, to prevent the curd substance being carried off with the whey, which would give it a white rather than its natural green hue. As the curd hardens it is more quickly worked and finally broken into small particles, so as to allow the whey to escape. The expulsion of the latter is helped on by the contraction of the curd, due to the gradual increase of acidity. Acidity develops naturally if time is allowed, but it is judicious to hasten it by the addition of warm whey during the process of working. Another method of bringing about the necessary amount of acidity is to expose the curd to the air for a time before it is salted. Salt, besides giving a flavour, stops the action of the acidity in cheese after it has done its work of expelling the whey. If allowed to go on, the acidity would destroy the cheese by curtailing the ripening action of rennet. Excess of salt retards the latter process.

After the curd has been broken thoroughly, on being allowed to settle so as to drain off the whey, it adheres together into an india-rubber-like mass; this is cut and broken up into small pieces by its passage through a 'curd-mill.' The finest quality of dairy salt should be used; the crystals being large is an indication of its purity, especially from magnesia salts, which give a bitter taste and otherwise injure all dairy products. The quantity employed is, more or less, about 1 lb. of salt to 56 lb. of curd dry enough to be made up and put into the cheese-press. Its amount should vary with the degree of acidity and the amount of moisture present. In some cases salt is applied wholly or in part dry, or as a brine, to the outside of the cheese after it has been so far pressed. In very rare cases salt is put into the milk before coagulation.

The curd is finally packed into a 'chesset' or press vat, which has as a temporary lining a cloth of open texture called a 'cheese-cloth.' The vat, which is a strong wooden or tinned-iron vessel with perforations in the sides and bottom to allow of the escape of any little surplus moisture, is placed in a press, and the cheese subjected gradually to a pressure of about one ton. The curd soon assumes the form in which it is to remain as a cheese. For a few days the cloths are taken off regularly and changed; the cheese being turned over each time to make it keep its shape. Ripening is the next process of importance. Deep cheeses are bandaged, and some are covered with cotton cloths (caps) made to fit tightly. They are then placed in the curing or ripening room, which should be dry, well ventilated, and maintained at an even temperature of about 70° F. There the green indigestible and insipid curd changes naturally into the sweet, mellow, nutty, and full-flavoured product cheese, which, if taken in moderation, and especially towards the end of a meal, is an aid to digestion. The ripening process, which is also associated with drying and shrinkage of about 10 per cent. in weight, varies in length from a few weeks to a few months. Acid cheeses are soon ready for market, and spoil if kept for a long time. Sweet cheeses are slow in maturing, and continue to improve even if kept for years. The tendency in cheese-making both in Great Britain and in America has recently been to early maturity, the strong inducement being that of early returns.

The Cheddar system of cheese-making, which first originated in Somersetshire, is, if we embrace Great Britain, Canada, and the United States of America, the most widely practised system of all. The old methods have been much altered in recent times to suit the tendency in the market for early maturity. The following is an account of the system as now practised, with improvements suggested by American and Canadian experience.

The cream is removed from the evening's milk after standing overnight, and is only returned to the full bulk immediately before putting in the rennet; the object is to prevent the cream being made oily by heating to a high temperature. The rennet is added at a temperature ranging from 82° to 88° F., but the milk is heated a few degrees above the point fixed upon for steeping, and left to ripen. The temperature falls to the required point meanwhile. The higher range of temperature is adopted when the milk is sweet and recently drawn from the cow. Low temperatures suit old milk or warm weather. If the cheese is to be marketed within twenty days, enough rennet should be added to induce the initial stages of coagulation within eight to twelve minutes. After this it should be left for twelve to eighteen minutes, then breaking begins with the perpendicular and horizontal cutting knives. It is stirred for about fifteen minutes with a hand-rake, and the temperature afterwards raised to 96°–98° F., or even by some up to 102° F. The whole is allowed to settle and remain nearly an hour to 'cook' the curd. As soon as the latter is elastic enough for the particles to retain their independent shapes on being grasped and squeezed by hand, the bulk of the whey is run off. What remains and the curd, still in small pieces, are removed bodily from the steep-tub or vat, and placed in a flat cooler with an inner movable, sparred, false bottom, to secure drainage. The vessel is lined with a cheese-cloth. On this the curd is exposed to the air and well worked by hand, so as to press out the whey and keep the particles from adhering to one another at too early a stage. After being well worked and exposed it is left to run together, being covered up to preserve heat. It is subsequently cut, piled, and left covered with a cloth for perhaps half an hour. The curd then smells and tastes slightly acid. It is either milled or put through Harris's stamp lever breaker, which cuts it into pieces like fingers. It is subsequently weighed, and should amount to fully 1 lb. to the gallon of milk, and is again exposed to the air to get quit of taints, and to toughen before salting, which should be done when a velvety feeling is noticeable. The salt is added dry at three separate times, and well mixed. The curd is then left to cool down to about 70° F. before being put into the vat. Pressure for about two and a half days is followed by ripening or seasoning. The whole operation of making up the curd may be over in five hours, or may take six or seven hours, according to circumstances. A good Cheddar cheese contains when ripe about 28 per cent. of casein, and nearly 34 per cent. both of butter and of moisture.

Cheshire Cheeses are manufactured in Cheshire, Staffordshire, and Shropshire. In their deep shape and also in many details of their working they resemble Cheddars. Setting is done in a square covered vat, and after making up they are often put into an oven to cook for a night before going to press. In the latter they remain for nearly a week. *Derbyshire Cheeses* are steeped and worked in a manner which closely corresponds to the Cheshire system. The salt, however, is applied externally. *Gloucester Cheeses* are made by a sweet process very much the same as the Derbyshire process. *Double and Single Gloucesters* are identical, with the exception of the thickness and the consequent rate at which they ripen. After a time they are scraped clean and painted with Spanish brown. *Leicester Cheeses* are small and flat, and made by a sweet process. They are at first lightly salted, but salt continues to be added externally. They take a long time to mature.

Stilton Cheeses are made mostly in Leicester. They used to be double cream cheeses, but are now successfully made of the milk as it comes from the cow. The curd is not subjected to pressure like that used in making the previously mentioned forms. While on the shelves ripening it is supported by a bandage, and during that time the characteristic blue mould should form throughout its substance.

Gruyère Cheese, made in the canton of Fribourg, Switzerland, is a whole-milk cheese, as are also the Dutch cheeses of *Gouda* and *Edam*. The fancy cheeses of the Continent, as *Camembert*, *Brie*, *Roquefort*, *Limburg*, *Gorgonzola*, &c., command a high retail price in Britain because of their perishable nature and because their consumption is restricted to a limited and wealthy class. Imitations have been made, but of a spurious and imperfect kind, owing to the impossibility of securing the secrets of their manufacture. The broad facts are known, but not the details. For example, it is quite understood that some soft cheeses are made by mixing old and new curd together. The quality of the natural pastures also affects some, notably the *Parmesan* cheeses from northern Italy.

The American system of cheese-making has been reduced by improved mechanism and association in the form of the factory method to the most economical point. This method of manufacture was a growth by necessity rather than a discovery. A large dairy was divided by the death of the owner, who left three sons. The sons united and manufactured their milk at the old dairy, and in time neighbours joined, and the first factory was established in 1851 under the management of the oldest of the three brothers. In course of time the business increased and became reduced to a most economical basis, while by the employment of skilful operatives the quality of the product was gradually raised. The factories were gradually enlarged until the milk of 1200 cows could be worked up in the largest, and an average factory received the milk of about 400 cows. One Canadian factory makes 216,000 lb. of cheese yearly from the milk of 1300 cows.

The curing occupies about three months, the temperature of the curing-room being kept at 65° F. Gang presses are used, in which a large number of cheeses laid on their sides are pressed at once by turning one screw. A common test by which the ripeness of the curd for pressure is determined is by touching it with a hot iron, and when long strings are drawn from the curd by the iron, the curd is ripe.

Milk is brought to the factory twice daily, and is weighed and run into the vat from the delivery window. The milk is either bought by the factory, or is worked up at a stated charge, or the factory is managed on the co-operative plan in which the net proceeds are divided periodically. Under this factory system the quality of the cheese is uniform and as high as is secured in any well-managed private dairy. About one-fifth of the cheese produced in America is made in private dairies in which the same system prevails.

There are several other kinds of cheese made in both factories and private dairies, as Edam (the round Dutch cheese), a small cylindrical cheese similar to the English Wiltshire, weighing 10 to 14 lb.; a flat cheese called English dairy cheese, similar to the double Gloucester cheese and coloured as highly; a few Stilton cheese; cream cheeses for immediate use; and very good imitations of the European Limburger, Schweizer, Neufchatel, Brié, Gouda, Camembert; and some other fancy makes to supply the French, German, and other immigrant population.

The cows used in the cheese dairies in the United States and Canada are mostly 'grade' shorthorns, or native cows improved by crosses of shorthorn, Devon, Ayrshire, and Dutch breeds. Jersey and Guernsey cows, and the best of the higher bred animals, are used for the highest class of cheese of the fancy kinds. The profitable exploitation of the dairy in America has raised the value of lands suitable for grazing cows to an average value of nearly $100 (£20) per acre for the fee simple, which is twice as much as that of grain farms. The cheese-dairy business prevails mostly in the states of New York, Pennsylvania, Ohio, Iowa, and Wisconsin, and in the province of Ontario, Canada. The cows are chiefly fed upon pasturage aided in the latter part of the summer by soiling crops, of which maize is almost universally chiefly depended upon. The cheese-making season begins in April and continues until November. See X. A. Willard's *Practical Dairy Husbandry* (1875), L. B. Arnold's *American Dairying* (1877), and Henry Stewart's *American Dairyman's Manual*.

CHEESE-PRESS.—The most common form is the *lever* press. A powerful steel coil or spring is sometimes substituted for the lever. In large factories the *gang* press is employed to press a large number of cheeses at one time by means of a powerful horizontal screw. The old method was by placing a heavy stone (hence the name stoning cheese) on the lid of the chesset, or by hanging it by a ring fixed to its upper side from the end of a wooden beam which acted as a lever and passed over the lid of the cheese-press vat.

Chemical Affinity is the name given to the tendency to combine with one another which is exhibited by many substances; or to the force by which the substances constituting a compound are held together. The tendency of any given element to unite with a number of other elements varies greatly. Chlorine, for instance, unites with great readiness with most metals and with many non-metallic elements, much heat being produced during the union; but it has little or no affinity for, or tendency to combine with, oxygen, so that compounds of chlorine with oxygen can only be obtained by roundabout methods, and are very liable to sudden and explosive decomposition into chlorine and oxygen. Where the affinity of elements for each other is great, the compounds produced by their union are decomposed with difficulty, and where the affinity is feeble, decomposition is easily effected. See also CHEMISTRY.

Chemistry. Although chemistry has only taken its place as an exact science based upon accurate experimental investigation within a comparatively recent period, yet its origin dates back to the earliest times of philosophical study. It will be convenient to give in the first place a short sketch of the history of chemistry, and then to state some of the principles of the science, illustrating these from the simplest facts. When possible, such illustrations will be chosen as are likely to be not altogether unfamiliar to non-scientific readers.

Historical Sketch.—The word *chemistry* has come to us from the Greek through the Arabic, as shown in our article ALCHEMY. With regard to the chemistry of the ancients, we know that the ancient Egyptians, Phœnicians, Greeks, and Romans were acquainted with a very considerable number of useful substances, and that their processes for preparing some of these did not differ in any essential particular from those now in use. It does not appear, however, that they have left any chemical records behind them, or that they knew anything of the science of chemistry. Several metals were known to, and employed by, these ancient peoples, who were acquainted with processes for reducing them from their ores. Amongst these metals were gold, silver, mercury, copper, tin, lead, and iron; whilst they also knew and worked with brass, although they were not aware that it was an alloy of copper and zinc. Various alloys were employed for bronzes for statues, and these usually contained copper, lead, and tin. The processes for manufacturing soap, starch, glass, leather, various mineral and vegetable pigments, stoneware, and other useful substances, were all known and carried on in very early times; and wine and beer appear likewise to have been prepared and used as beverages long before the process of distillation, which was unknown to the ancients, had been introduced. Vinegar, sulphur, and carbonate of soda were also known.

We find the application in medicine of many chemical products at a comparatively early period, and the Arabians appear to have been the first who tried to prepare new medicines by chemical methods. Geber, who lived in the 8th century A.D., is the most noted of the Arabian chemists, and he has left some writings which show us what was the state of chemistry at that early date. Geber knew, for instance, how to make and distil vinegar and nitric acid, and even sulphuric acid was made and used as a solvent by him. He knew, amongst other substances, white arsenic, borax, common salt, alum, sal-ammoniac (ammonium chloride), copperas (ferrous sulphate), nitre (potassium nitrate), and corrosive sublimate (mercuric chloride), and was acquainted with a number of their properties. He used almost all the kinds of apparatus that were commonly in use down till the 18th century, and understood the processes of distillation, filtration, sublimation, and crystallisation. In one of his works he describes the construction of furnaces for chemical purposes.

From the 8th till the 17th century but little real progress was made in chemistry as a science. The new knowledge that was gained during this period was mainly due to the assiduity of the alchemists, who, in their vain search for the philosopher's stone, necessarily made useful discoveries from time to time. Many of the alchemists so called were mere tricksters who deceived their dupes by more or less clumsy experiments, which appeared to demonstrate the production of gold from baser metal. Others, however, were really earnest and untiring in their labours, and held the fullest belief in the prospects of the ultimate success of some fortunate worker. The new substances obtained by the alchemists were frequently used in medicine, and it is to these infatuated workers, therefore, that we owe our first knowledge of many potent medicines. The writings of many of the alchemists are preserved, but numbers of them are entirely worthless from a scientific point of view, as the descriptions of processes are mixed up with so much of mystery and extravagance that they present a wholly unintelligible jargon. For more detail, however, regarding this remarkable period in the history of chemistry, see the article ALCHEMY.

As Geber has been called the patriarch of chemistry, so Robert Boyle (1627-91) has been called the father of modern chemistry, since it was Boyle who first tried to free chemistry from the trammels of alchemy and to place it upon a true scientific basis. Boyle in his *Sceptical Chemist* tried to discredit the salt, sulphur, and mercury of the alchemists (as well as the Aristotelian earth, air, fire, and water) as elements or ultimate constituents of substances, and he gave a scientific definition of an element. Boyle was an experimental investigator of considerable skill, and to him we owe the introduction of the air-pump and the thermometer into this country. His experiments upon the physical properties of gases led to the formulation of the law concerning the relation of the volume of a gas to the pressure, which is commonly known as Boyle's Law.

Theory in modern chemistry begins with Becher (1635-82) and Stahl (1660-1734). The latter adopted, with some modifications, a theory propounded by the former concerning elements and compounds, and formulated the phlogiston theory of combustion. The views of Becher and Stahl regarding elements were not so enlightened as those of Boyle, and must be considered as retrograde. Stahl's phlogiston theory (1697) was at once adopted almost universally by chemists, and for fifty years it was held to give the full explanation of the phenomena of combustion. According to this theory phlogiston was a constituent of all combustible substances. When a substance burned, the phlogiston made its escape, and the product of combustion was regarded as the other substance with which the phlogiston had been previously united. When a metal such as lead was heated in the air, it lost its phlogiston, and the oxide formed was looked upon as the other constituent of lead besides phlogiston. The process of reduction of lead from its oxide by means of charcoal was the transfer of phlogiston from the charcoal to the lead. It did not present itself to the adherents of the theory as an absurdity that a metal, in losing its phlogiston on oxidation, gained weight, although some of them at least were aware of the fact. The idea of gain of matter being a necessary accompaniment of gain of weight is so familiar to us that we can scarcely realise that it was not always so regarded. To this may fairly be attributed the persistence with which the phlogiston theory held its ground for so long a period.

The Dutch chemist Boerhaave (1668-1738), who did not accept Stahl's theory, published in 1732 his system of chemistry, which was a compilation of practically all that was known up till that date, collected with great labour from a large variety of alchemical and other writings.

The interval between the introduction of the phlogiston theory and its overthrow by Lavoisier in 1772-85 was one of great advance in chemical knowledge, and a number of very eminent chemists preceded and were contemporaries of Lavoisier.

In Germany, Marggraf (1709-82) studied the properties of the almost unknown alumina and magnesia, and made considerable advances in the qualitative analysis of substances in solution.

Amongst British chemists of note may be mentioned Hales (1677-1761), who was amongst the first to experiment on gases; Black (1728-99), who in 1756 published his research on *Magnesia Alba*, showing the nature of fixed air or carbonic acid gas, and of the difference between caustic and mild (or carbonated) alkalies; Priestley (1733-1804), who, in addition to his discovery of oxygen in 1774, investigated nitric oxide, nitrous oxide, sulphurous acid, carbonic oxide, hydrochloric acid, and ammonia gases, being specially attracted to the study of gaseous substances and their properties; and Cavendish (1731-1810), who investigated the nature and properties of hydrogen, analysed atmospheric air, and discovered the compound nature and composition of water and of nitric acid.

Lavoisier (1743-94) was one of the ablest chemists of his time, and his labours include a vast variety of subjects. His attack upon, and eventual demolition of the phlogiston theory, and his experiments in connection with his new theory of combustion, occupied him for a considerable number of years. He taught that combustion was the union of the combustible substance with atmospheric oxygen; he was the first to introduce system into chemistry and chemical research; he determined the constituents of a large number of substances, including sulphuric, phosphoric, and carbonic acids, numerous metallic oxides, and many animal and vegetable substances; and he, along with Berthollet, Fourcroy, and Morveau (1737-1816), introduced a new and consistent system of chemical nomenclature. Two contemporary Swedish chemists, Bergman (1735-84) and Scheele (1742-86), must be mentioned before leaving the phlogiston age. Bergman investigated, amongst other things, carbonic acid gas, studied the phenomena of affinity, and made advances in the processes and reagents used in qualitative analysis. Scheele was one of the most laborious chemists of his time. He discovered citric, malic, tartaric, oxalic, lactic, hydrocyanic, arsenic and other acids, and chlorine, besides investigating the nature of a large number of other bodies and independently discovering oxygen.

It was towards the end of the 18th century that the value of quantitative analysis of substances began to be generally recognised. The question as to whether the quantitative composition of a given substance was always the same gave rise to a discussion which lasted for several years, and was at length decided in favour of constant composition.

The researches of Richter (1762-1807) on the quantities of various acids neutralised by a given quantity of a base, and of various bases neutralised by a given quantity of an acid, led him to the general conclusion that the quantities of two acids, a and a', which form neutral salts, $a\ b$, and $a'\ b'$, with the quantities of two bases, b and b', are just the quantities required to form two other neutral salts, $a\ b'$ and $a'\ b$. This fundamental discovery was erroneously attributed to Wenzel by Berzelius in 1819, and the error has been carefully perpetuated in a considerable number of text-books since that time (Kopp, *Entwickelung der Chemie in der neueren Zeit*, p. 251).

Berthollet (1748-1822), who was one of the most active opponents of the theory of the constant composition of chemical substances, contributed valuable researches into the laws of chemical affinity, and applied chlorine to processes of bleaching. The processes of chemical analysis were improved, and large numbers of analyses, especially of minerals, were carried out by Klaproth (1743-1817), Vauquelin (1763-1829), Fourcroy (1755-1809), and others; and many quantitative observations of all kinds were made about the end of the 18th century, all preparing the way for Dalton's statement of the Atomic Theory (q.v.) in 1803-4.

The progress of chemistry during the present century has been immense, and it is not possible to do much more than mention the names of some of the most prominent workers. A stimulus was given to research by the publication of Dalton's atomic theory; and the labours of Gay-Lussac (1778-1850), who experimented with gases, of Dulong (1785-1838), and Petit (1791-1820), who pointed out the relation between specific heats and atomic weights of elements, and of others, supported and amplified Dalton's views.

Wollaston (1767-1829) discovered palladium in 1803, and rhodium in 1804. The first alkaloid (morphine) was obtained pure by Sertürner in 1816, and this led to the discovery of a number of others in a short time.

The decomposition by electricity of the bases potash and soda by Davy (1778-1829) in 1807, and the separation from these of the metals potassium and sodium, threw an entirely new light on the nature of these substances. The metals were more fully investigated by Gay-Lussac and Thénard (1777-1857). Davy is noted also as the inventor of the miners' safety-lamp, and for experiments on the respiration of nitrous oxide and other gases.

Amongst the foremost chemists of the earlier part of the 19th century was the Swede Berzelius (1779-1848), whose careful and exact analyses of mineral substances contributed a good deal to the confirmation of the law of constant proportions and to the fixing of the atomic weights (see ATOMIC THEORY) of the elements. Berzelius was very conservative with regard to new theories, which he declined to accept without putting them to the strictest experimental tests. He formulated the electro-chemical theory of the constitution of salts, introduced great improvements into the methods of quantitative analysis, increased the value of the blowpipe as an aid in mineral analysis, discovered many new substances, and further examined and elucidated points concerning many already known, both inorganic and organic.

The artificial production of urea in 1828 by Wöhler (1800-82) marks the beginning of a new era in the branch of organic chemistry, and enormous strides have been made in this department since that time by Dumas (1800-84), Liebig (1803-73), Laurent (1807-53), Gerhardt (1816-56), Wurtz (1817-84), Kolbe (1818-84), Baeyer, Cannizzaro, Frankland, Hofmann, Kekulé, Williamson, and many others. Advances in general inorganic chemistry and analysis have been made by Leopold Gmelin (1788-1853), H. Rose (1795-1864), Sainte-Claire Deville (1818-81), and Bunsen; whilst in connection with advances in chemical physics may be mentioned Faraday (1791-1867), Mitscherlich (1794-1863), Graham (1805-69), Regnault (1810-78), Andrews (1813-85), and Berthelot. These lists do not include all of even the most prominent names that might be mentioned in connection with each department.

The most striking feature of modern chemistry is the extraordinary development of organic chemistry, the account of one branch of it—the chemistry of the coal-tar products—constituting of itself quite a literature which receives additions every day.

Amongst the most recent triumphs of chemical research may be mentioned the artificial production of indigo and grape-sugar, and the isolation, in sufficient quantities to study its properties, of the hitherto all but unknown element fluorine.

Of the greatest possible interest from a theoretical point of view is the fact that since 1870 three new elements have been discovered—gallium, scandium, and germanium—the existence of all of which had been predicted, and the properties of which had to a certain extent been described beforehand by Mendeleëff. (See periodic law in article ATOMIC THEORY.)

Of late much attention has been given to measurements of the quantity of heat produced in various chemical changes, notably by Berthelot and Thomsen.

Elementary Principles of Chemistry.—The science of chemistry deals with a certain class of changes which matter undergoes when subjected to particular conditions. Similar treatment may produce very different effects upon different substances, as, for instance, the effect of strong heat upon a piece of quartz, a piece of limestone, and a piece of sugar. The quartz does not suffer any *permanent* change, that is, it has the same properties after it is cold again as it had before the action of heat. The limestone, although not necessarily much altered in appearance, has its properties entirely changed, and what remains is a new kind of matter—quicklime. The sugar melts, darkens, and chars, and becomes quite manifestly changed into more than one new kind of matter, for gaseous products, having the smell characteristic of 'burnt sugar,' go off, whilst a black coaly mass remains.

The first of the above changes is merely a *physical* change, from cold to hot; the other two are *chemical* changes, which result in the production of new kinds of matter having properties entirely different from those of the kinds of matter from which they were obtained. The existence of chemistry depends upon the existence of different kinds of matter, and it is with such different kinds of matter and the change from one kind to another that chemistry has to do.

When the properties of matter are studied, it is found that for chemical purposes all kinds of matter may be divided into two great classes, which are called respectively *elements* and *compounds*. The name element is applied to any kind of matter that has not been proved to be composed of more than one simpler kind of matter. This conception of an elementary substance we owe to Boyle, and it will be noted that some of those substances which are now looked upon as elements (see article ATOMIC THEORY for a list of the 68 known elements) may hereafter be proved to be *compounds*, or kinds of matter composed of more than one simpler kind, just as some substances which were at one time rightly classed as elements (according to Boyle's definition) are now known to be compounds of two or more elements.

The compound nature of a specimen of matter may be proved in one or other (or both) of two ways. One of these methods is called *Synthesis* (q.v.), and consists in building up the compound from the component simpler kinds; the other is called *Analysis* (q.v.), and consists in separating more than one simpler kind from the compound kind.

The distinction between chemical compounds and mere mechanical mixtures is a fundamental one, and must be fully understood. The substance gunpowder, for instance, is an intimate mixture of finely powdered sulphur, charcoal, and saltpetre (potassium nitrate), certain precautions being observed during the mixing in order to avoid explosion. These substances are not combined together chemically in gunpowder, but are only mixed, a fact as to which we can easily satisfy ourselves in various ways. We may examine the gunpowder under the microscope and identify the separate particles of the ingredients; or, by the use of appropriate solvents, we may dissolve out first the saltpetre and then the sulphur, and thus recover all three ingredients separately. The explosion of gunpowder when heated to a sufficiently high temperature is due to the occurrence of a series of changes of the kind we call chemical, for these changes result in the production of new kinds of matter, gaseous and solid, which possess properties in no way resembling those of sulphur, charcoal, or saltpetre, and from which these substances cannot now be dissolved out.

A mixture possesses to a greater or less extent the properties of its respective ingredients; a compound, on the other hand, has not as a rule any properties resembling those of its constituents. A piece of magnesium wire heated in the air to a sufficiently high temperature takes fire and burns. This is a chemical change in which the metal magnesium combines with the oxygen of the air to form a white, brittle, solid compound called magnesia or magnesium oxide. This magnesia does not in the least resemble either magnesium or oxygen in its properties, and the most powerful microscope fails to reveal particles of either of these substances to our vision.

The Atomic Theory (q.v.) is based upon the assumption that matter of every kind is made up of extremely minute indivisible particles called *atoms*. The atoms which exist in a substance may be all of the same kind, as in elements, or of different kinds, as in compounds. Chemists believe that the element hydrogen consists of *molecules* or aggregates of atoms—each molecule consisting of two atoms; further, that the compound substance water consists of molecules, each composed of two atoms of hydrogen and an atom of oxygen united to each other by that force which is called *Chemical Affinity* (q.v.); and that similarly every other compound substance is composed of molecules, each molecule consisting of two or more different kinds of atoms united by chemical affinity. The weight of a new compound formed by the union of two or more substances is in every case equal to the sum of the weights of its constituents. In chemical actions it is only the *kind* of matter which is changed, whilst, as in every physical change, the *quantity* of matter concerned remains constant and unalterable.

It has already been seen that one of the characteristics of the chemical combination of two substances is that the properties of both disappear and are not observable in the compound. Another and a most important characteristic is the evolution of heat, which is a very frequent although not an invariable accompaniment of chemical action. The best examples of this may be seen in the ordinary phenomena of Combustion (q.v.). All combustion, whether it be of magnesium wire, coal, phosphorus, paraffin oil, or a candle, is nothing more than a chemical action accompanied by the evolution of heat and light, oxygen gas of the atmosphere being almost invariably one of the substances taking part in such action.

The conditions under which substances act chemically upon each other are very various for different substances. In the first place, certain substances cannot be got to act upon each other at all. Such substances may have little affinity for each other, as chlorine and oxygen, or no affinity, as fluorine and oxygen. Other substances, again, only act upon each other with difficulty. The main conditions upon which action of one substance upon another depends are the state of physical aggregation and the temperature. Certain chemical actions take place at ordinary temperatures, as, for instance, the combination of chlorine with metallic antimony or copper, or the spontaneous ignition of one of the compounds of phosphorus and hydrogen when brought into contact with oxygen. Other actions only take place when the temperature of the substances which are to take part in them has been sufficiently raised. Thus magnesium requires to be strongly heated in air before it takes fire; once the action is started, however, the heat given out by the combustion of one part of the magnesium is sufficient to raise another part to the temperature necessary for combustion to go on, and so the change is propagated. Coal-gas only burns in air when it is raised to a bright-red heat. A jet of coal-gas escaping into the air may be easily ignited by applying a brightly red-hot poker, but when the poker cools to dull redness it will no longer ignite the jet. A bar of metallic iron does not undergo any chemical change on exposure to dry air at ordinary temperature, but if iron in the state of very fine powder (a form in which it can easily be obtained by appropriate methods) be thrown into the air, combination at once takes place with the evolution of heat and light. When a piece of iron (say a moderately fine iron wire) is heated to redness in air, combination with the oxygen of the air takes place with the formation of a scale composed of a black oxide of iron, but the quantity of heat given out during the combination is not sufficient to propagate the combustion from particle to particle of the iron after removal of the source of heat. If, however, iron wire be raised to a red heat in an atmosphere of oxygen, it takes fire and burns with great brilliancy. The difference noticed here is due to the presence in the one case, and the absence in the other, of the diluting nitrogen which forms nearly four-fifths of the air by volume.

There are certain chemical actions which in taking place are accompanied, not with evolution, but with absorption of heat. In such cases heat has to be supplied throughout the action, and not merely to start it. This is frequently noticed in the combination of substances which have feeble affinity for each other, and the compounds produced are less stable, or more readily break up into their constituents, than those which are produced with the evolution of heat. In general terms it may be stated that the quantity of heat given out in the formation of a compound is a measure of the stability of the compound. When a given weight of magnesium unites with oxygen to form magnesia, a quite definite and measurable quantity of heat is given out. In order to separate the magnesium from the oxygen again, exactly the same quantity of heat must be supplied. In the case of those substances in the formation of which heat is absorbed, we find, as we should expect, that heat is given out during their decomposition, and that its quantity is exactly that which was absorbed during their formation.

Chemical Notation.—For the purpose of shortly expressing the composition of chemical substances, and for representing chemical changes, chemists employ a system of notation which is in extremely common use. In the table of Atomic Weights (see ATOMIC THEORY) it will be noticed that after the name of each element is placed its *symbol*, which usually consists of the first, or of the first and another letter of the Latin name of the element. Each symbol distinctly indicates the element which it is intended to represent, but it must always be borne in mind that the symbol for an element is not merely a contracted form of its name, but that it stands for a definite quantity of that element, this quantity being the atomic weight expressed in terms of the unit of weight employed.

The unit of weight almost universally employed by chemists and scientific men in general is the gramme (see METRIC SYSTEM), and that unit will be adopted for illustrations throughout this article. With the gramme as unit, H stands for 1 gramme of hydrogen, Cl for 35·4 grammes of chlorine, O for 16 grammes of oxygen, Mg for 24 grammes of magnesium, and so on. In order to represent the composition of a compound, the symbols of the various elements which occur in the compound are written side by side, and this collection of symbols is called a *formula*. Thus, MgO represents 40 (= 24 + 16) grammes of magnesium oxide, and HCl is 36·4 (= 1 + 35·4) grammes of hydrogen chloride. When a compound contains more than one atom of the same element the symbol for that element is not repeated, but the number of atoms is indicated by a subscribed numeral. Thus the formula for water is written H_2O, which indicates that the molecule of water contains two atoms of hydrogen and one of oxygen; and the formula for sulphuric acid is written H_2SO_4, which indicates that the molecule of sulphuric acid contains two atoms of hydrogen, one of sulphur, and four of oxygen (besides the quantitative signification of these formulæ already mentioned). A number subscribed to a portion of a formula inclosed in brackets multiplies the portion so inclosed. Thus the formula $Ba(NO_3)_2$ represents one atom of barium united to twice the quantity of the group NO_3, which is represented as united to one atom of potassium in the formula KNO_3. A number prefixed to a formula multiplies the whole of the formula that follows. Thus $2H_2O$ represents twice the quantity of water represented by H_2O.

Chemical symbols and formulæ are used to represent shortly chemical changes. A simple illustration of the method of using them may be given to represent the case of the burning of magnesium. The symbols for the magnesium and the oxygen entering into combination (connected by the sign +) are written on one side of what is called a chemical equation, whilst the product is written on the other side, thus:

$$2Mg + O_2 = 2MgO.$$

The formula for free (or uncombined) oxygen is written O_2, because a molecule of oxygen is believed to consist of two atoms (see ATOMIC THEORY). In order to represent the element magnesium, the simplest possible formula (Mg) is employed because there is no evidence for writing a more complicated one. 2Mg simply represents twice as much magnesium as Mg does.

The above equation when fully interpreted gives a great deal of information about the change which it is intended to represent. It shows that magnesium and oxygen unite with each other (under conditions which are not expressed) to form an oxide of magnesium, and that these elements are united in the compound in the proportions by weight of 24 of magnesium to 16 of oxygen; and, further, it enables us, by applying a simple and easily remembered rule, to calculate the *volume* of oxygen taking part in the action as well as its weight. This rule for ascertaining the volume may be conveniently stated here. From certain theoretical considerations, as well as for convenience in calculations concerning the volumes of gases, chemists write the formulæ of gaseous substances in such a way that the quantity of a gas represented by its formula, in terms of any unit of weight, shall occupy, under similar conditions of temperature and pressure, the same volume as two units weight of hydrogen. Thus, the unit being the gramme, H_2 represents 2 grammes of hydrogen, and 2 grammes of hydrogen at *standard* temperature (0° C.) and pressure (760 millimetres of mercury) occupy a volume of

22·33 litres (see **Metric System**). Similarly, the quantities in grammes of oxygen, carbonic anhydride, and nitrous oxide, represented by their respective formulæ, O_2 ($16 \times 2 = 32$ grammes), CO_2 ($12 + 32 = 44$ grammes), and N_2O ($28 + 16 = 44$ grammes), each occupy, when measured at 0° C. and 760 mm. pressure, 22·33 litres. This rule holds for other gases, and also, with a certain qualification, for the vapours of volatile liquids. In the case of the latter, of course, conditions of temperature and pressure must be chosen such that the substance is in the state of vapour; and the quantity in grammes which, as a vapour, occupies the same volume as 2 grammes of hydrogen under the same conditions, is the quantity which the formula is chosen to represent. Thus, the formula H_2O informs us that 18 ($= 2 + 16$) grammes of water occupy, in the form of steam, the same volume as 2 grammes of hydrogen when both are measured at the same temperature and pressure. It must, of course, be understood that the formula for a substance is chosen so as to represent the observed facts. The formula of a volatile liquid is deduced from the determination of the *vapour density* of the liquid; this determination is made by ascertaining the weight of that quantity of the liquid which, when converted into the state of vapour, occupies the same volume as a given weight of hydrogen, both being measured at the same temperature and pressure.

Returning to the equation already given, it will be seen that from it we learn that 48 ($= 2 \times 24$) grammes of magnesium unite to form magnesium oxide with a quantity of oxygen (32 grammes) which at 0° C. and 760 mm. occupies 22·33 litres. What volume this quantity of oxygen would occupy under other conditions of temperature and pressure can be calculated from formulæ deduced from the laws of Charles (relation of the volume of a gas to the temperature) and Boyle (relation of the volume of a gas to the pressure). See further in article **Gases**.

As there are certain conditions under which chemical combination takes place, so there are definite laws which regulate combination. The first of these has been called the *law of constant proportions*, and it states that any chemical compound always contains the same constituents and in the same proportions. Thus magnesium oxide, MgO, always consists of magnesium and oxygen in the proportions by weight of 24 to 16—one atom of magnesium weighing 24, being combined with one atom of oxygen weighing 16. No compound of magnesium and oxygen containing these elements in any other proportion has ever been obtained. If in preparing magnesium oxide quantities of magnesium and oxygen were employed differing from this proportion, then some either of the magnesium or of the oxygen would remain over after the action, according as the former or the latter had been employed in excess of the right quantity.

Intimately connected with the foregoing law is the *law of multiple proportions*. Whilst certain elements combine with each other in only one proportion by weight, others combine in two, and sometimes more than two different proportions. The law of multiple proportions states that when elements combine in two or more proportions these various proportions can be expressed by simple multiples of the atomic weights of the elements concerned. Thus carbon and oxygen unite with each other to form two different compounds: 12 parts by weight of carbon unite with 16 parts by weight of oxygen to form carbonic oxide, CO; 12 parts by weight of carbon unite with 32 parts by weight of oxygen to form carbonic anhydride, CO_2. Here the relation is of the simplest kind, for the one compound contains exactly twice as much oxygen for the same quantity of carbon as the other. Again, iron and oxygen unite with each other to form three different compounds: 56 parts by weight of iron unite with 16 parts by weight of oxygen to form ferrous oxide, FeO; 112 parts by weight of iron unite with 48 parts by weight of oxygen to form ferric oxide, Fe_2O_3; 168 parts by weight of iron unite with 64 parts by weight of oxygen to form ferroso-ferric oxide, Fe_3O_4. This case is not quite so simple as that of the oxides of carbon, for here it is necessary to employ multiples of the atomic weights of both elements concerned in order to see the simplicity of the quantitative relations existing amongst these oxides of iron. The law of multiple proportions is, however, fully illustrated by both series of oxides.

It may be useful to call attention here to the simple explanation furnished by the Atomic Theory (q.v.) for the occurrence of compounds illustrating this law of multiple proportions. There is no compound intermediate in composition between carbonic oxide and carbonic anhydride. The atomic theory explains this very simply. Under one set of conditions we can obtain a compound of one atom of carbon with one atom of oxygen, whilst under other conditions we obtain a compound of one atom of carbon with two atoms of oxygen, or exactly twice as much. This is why we find such marked intervals in composition between two or more compounds of the same elements. The molecule of one compound cannot differ from that of the other by less than an atom, and the addition of an atom to a molecule necessarily forms a new molecule differing in weight from the old one by the weight of the added atom.

The last law of combination has been called the *law of volumes*. It states that when gases combine to form new compounds, the volumes taking part in the action bear a very simple relation to each other and to the volume of the product if gaseous when all the volumes are measured at the same temperature and pressure. Thus, one volume of hydrogen combines with one volume of chlorine to form two volumes of hydrochloric acid gas; two volumes of hydrogen combine with one volume of oxygen to form two volumes of water vapour; two volumes of carbonic oxide combine with one volume of oxygen to form two volumes of carbonic anhydride, and so forth. The very simple relations of the volumes concerned in these examples are sufficiently manifest, and much greater complexity is not frequently met with.

Chemists divide the elements into two great classes, the typical members of which are very different in their physical and chemical characters. These are *metals* and *non-metals*, and as representative of each class may be mentioned copper and sulphur. The more prominent physical characteristics of metals are the metallic lustre, malleability, ductility, and the property of conducting heat and electricity, all of which are possessed to a more or less marked degree; whilst non-metallic elements as a rule possess these properties to a very limited extent, if at all. Differences in chemical behaviour are also very striking in typical representatives of each group. It must be borne in mind, however, that all the members of each group are not typical, but that there is a gradual transition from one group to the other, and certain of the transition elements possess some of the properties of both groups, as in the cases, for instance, of arsenic and antimony.

With the exception of bromine and fluorine, all the elements enter into combination directly or indirectly with oxygen to form oxides. The oxides produced from metallic elements are quite different in chemical character from those produced from non-metallic elements. We shall look first at the oxides of the metals. Every metal forms one or more oxides, and at least one oxide of every metal is a *basic* oxide—i.e. an oxide which has the properties of a Base (q.v.). A distinction is made between what are called *anhydrous bases* and *hydrated bases* or *hydroxides*. The oxide of lead, PbO, is an anhydrous base (or basic oxide), whilst the compound obtained by the action of water upon calcium oxide, CaO (a basic oxide, and the only compound of calcium and oxygen known), is called a hydrated base (or hydroxide). The formation of the latter is represented by the equation

$$CaO + H_2O = Ca(HO)_2.$$

The oxides produced from non-metallic elements are very frequently *acid* oxides—i.e. oxides which unite with water to form the class of bodies called *Acids* (q.v.). The oxides themselves are often called *acid anhydrides*, whilst the compounds produced by the action of water upon them are called acids, or *hydrogen salts*. When phosphorus burns in air, phosphoric anhydride, P_2O_5, is obtained. This is a white solid substance which unites with water with the evolution of much heat to form a solution of metaphosphoric acid, or hydrogen metaphosphate:

$$P_2O_5 + H_2O = 2HPO_3.$$

There are a few acids known which do not contain oxygen, and are not obtainable by the combination of an oxide with water. Examples are hydrochloric acid, HCl, hydrobromic acid, HBr, and hydrocyanic acid, HCN. These are also called hydrogen chloride, bromide, and cyanide respectively.

The two classes of substances, bases and acids, are nearly related to the very large class of *salts*. A salt is a compound which can be obtained, amongst other ways, by the action of an acid upon a base, water being almost invariably eliminated at the same time; and just as we saw that the properties of two elements are totally different from those of the compound formed by their combination, so we find that in the formation of a salt the properties of both acid and base to a great extent or altogether become neutralised and disappear.

If to a solution in water of potassium hydroxide, KHO (which is a powerful base), we add a sufficient quantity of nitric acid, HNO_3, that is until the liquid on thoroughly mixing does not possess either the acid or the alkaline reaction, we obtain a solution in water of potassium nitrate (saltpetre), and nothing else—the water eliminated in the action simply mixing with that which is already present:

$$KHO + HNO_3 = KNO_3 + H_2O.$$

Acids have already been mentioned as hydrogen salts. The above equation shows how hydrogen nitrate is exactly comparable with potassium nitrate—an atom of potassium taking the place of an atom of hydrogen—and a characteristic of all hydrogen salts, or acids, is that they contain hydrogen, which is capable of removal and of having its place thus taken by an equivalent quantity of another metal. In the example above mentioned every 1 part by weight of hydrogen has its place taken by 39 parts by weight of potassium. These quantities of hydrogen and of potassium are equivalent, both being capable of uniting with the group NO_3. This group is an example of what is called a *compound radical*—i.e. a group of elements which is capable of going as a whole through a series of changes. Acids which contain in their molecule one atom of hydrogen replaceable by another metal are called *monobasic* acids. Nitric acid is thus a monobasic acid, whilst sulphuric acid, H_2SO_4, is *dibasic*, orthophosphoric acid, H_3PO_4, is *tribasic*, and so on.

Bases, likewise, are sometimes spoken of as *monacid*, *diacid*, *triacid*, and so on, according as one molecule of the base requires one, two, three, &c. molecules of a monobasic acid (as nitric acid) to form what is called a *normal* salt, that is, a salt in which all the replaceable hydrogen has been replaced by another metal. Thus potassium hydroxide, KHO, is a monacid base; calcium hydroxide, or slaked lime, $Ca(HO)_2$, is diacid; bismuth hydroxide, $Bi(HO)_3$, is triacid, and so on. Equations may make this clearer (see the equation above for a monacid base):

$$Ca(HO)_2 + 2HNO_3 = Ca(NO_3)_2 + 2H_2O:$$
$$Bi(HO)_3 + 3HNO_3 = Bi(NO_3)_3 + 3H_2O.$$

Salts are formed in many cases by the replacement of only a *part* of the replaceable hydrogen of a hydrogen salt by another metal. Such are called *acid salts*, and $KHSO_4$ is an example. This salt, $KHSO_4$, may be looked upon as intermediate between the acid, H_2SO_4, and the normal salt, K_2SO_4.

Many salts are known which may be looked upon as bases which have their basic character only partially neutralised by an acid. Such salts are called *basic salts*, and as examples may be mentioned $BiONO_3$ and $Pb(OH)NO_3$. The former is intermediate between the normal nitrate, $Bi(NO_3)_3$, and the oxide, Bi_2O_3, the latter between the normal nitrate, $Pb(NO_3)_2$, and the hydrate, $Pb(OH)_2$. Such basic salts are often produced by the action of water upon the normal salts, as, for instance, in the case of the basic bismuth nitrate:

$$Bi(NO_3)_3 + H_2O = 2HNO_3 + BiONO_3.$$

Salts are looked upon as being composed of metal and *salt radical*, the latter name being given to all of the salt that is not metal. Thus SO_4 is the salt radical of the sulphates, NO_3 the salt radical of the nitrates, &c. This way of looking at salts arises from the phenomena observed when salts are decomposed by Electrolysis (q.v.), metal and salt radical being the primary products of decomposition.

Chemical Nomenclature.—Chemists endeavour to make the nomenclature of compound substances as systematic as possible, and a certain amount of system has even been introduced into the nomenclature of the elements themselves. The oxides of the metals are named after the metal which they contain, as magnesium oxide, MgO; aluminium oxide, Al_2O_3; and the series of salts derivable from these oxides are similarly named after the metal. Thus $MgCl_2$ is magnesium chloride, and $Al_2(SO_4)_3$ is aluminium sulphate. When a metal forms more than one basic oxide, adjectival terminations are employed to distinguish these; thus the two basic oxides of iron are named ferrous and ferric oxides (FeO and Fe_2O_3) respectively, and correspondingly there are ferrous and ferric salts. $FeSO_4$ is ferrous sulphate; Fe_2Cl_6 is ferric chloride. Acid salts and in general salts which contain more than one metal are named after the metals which they contain, the compound radical NH_4 (ammonium; see AMMONIA) being regarded as a metal for purposes of nomenclature. Thus, $KHSO_4$ is potassium hydrogen sulphate, whilst $HNaNH_4PO_4$ is hydrogen sodium ammonium orthophosphate.

The nomenclature of non-basic metallic oxides has been rendered systematic by the use of names descriptive of the number of atoms of metal and of oxygen contained in the oxide, as, for instance, trimanganic tetroxide for Mn_3O_4. A considerable number of non-basic oxides, as BaO_2, PbO_2, MnO_2, &c., are somewhat less systematically called *peroxides*.

The acid anhydrides, which, as has already been stated, are oxygen compounds or oxides of the non-metallic elements, are named after the elements of which they are oxides. As there are frequently two or more such acid anhydrides derived from one element, different terminations and, where necessary, other devices of nomenclature are employed to distinguish amongst these. Thus there are two acid anhydrides derived from sulphur—sulphurous anhydride, SO_2, and sulphuric anhydride, SO_3. The latter unites with water to form sulphuric acid, H_2SO_4, and it is believed by some chemists that the solution in water of sulphurous anhydride (a gaseous substance) contains at least some of the corresponding sulphurous acid, H_2SO_3. From sulphuric acid there is derived the series of salts called sulph*ates*, from sulphurous acid the series called sulph*ites*. It sometimes happens that an acid and series of salts are known of which the corresponding anhydride is unknown, just as the existence of certain acids is doubtful although the corresponding anhydride is known. In other cases series of salts are known, although both the corresponding anhydride and acid are unknown. Certain of these peculiarities, as well as some further forms of nomenclature, are illustrated by the table given below of the compounds corresponding to known or unknown oxides of chlorine:

Oxide.	Acid.	Salt.	Name of salt.
Cl_2O	$HClO$	$KClO$	Potassium Hypochlorite.
—	$HClO_2$	$KClO_2$	„ Chlorite.
[ClO_2, not an acid anhydride].			
—	$HClO_3$	$KClO_3$	„ Chlorate.
—	$HClO_4$	$KClO_4$	„ Perchlorate.

It has recently been proved that the substance described in most text-books as chlorous anhydride, Cl_2O_3, is really a mixture, and that as yet Cl_2O_3 has not been prepared. The hypothetical chloric and perchloric anhydrides would have the composition Cl_2O_5 and Cl_2O_7 respectively.

A very large number of salts and other chemical compounds are commonly known by popular names, the latter being frequently of extremely ancient origin. The popular name as a rule conveys no information as to the composition of the substance. For instance, copperas (ferrous sulphate, $FeSO_4$) is not recognised by its name as an iron compound, nor calomel (mercurous chloride, $HgCl$) as a mercury compound, nor litharge (lead oxide, PbO) as a lead compound. It is the aim to convey, by the systematic name of a substance, the greatest possible amount of information as to its composition. It is not possible to attain to a perfect system of nomenclature, as new discoveries render changes necessary from time to time.

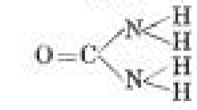
Graphic Formulæ.—In addition to representing the composition of a substance by means of formulæ, chemists endeavour to express certain ideas as to the *constitution*, or arrangement of the atoms in the molecule of substances by means of *graphic* formulæ. It must not be supposed (as has sometimes erroneously been done) that graphic formulæ are intended to represent the shape of molecules or the arrangement in space of the atoms constituting such molecules, but simply as a short method of expressing on paper certain facts. No one supposes that a printed word in any modern language is an attempt to draw the object spoken of, or that it is more than a method of representing on paper a given series of sounds, and yet criticism based upon assumption scarcely less absurd, has been directed against graphic formulæ. In a graphic formula we have the symbols for the different elements grouped in a particular way, so as (1) to indicate the *valency* (see the article ATOMIC THEORY) of each element, and (2) to express ideas based upon observed facts as to the most likely arrangement of the atoms in a molecule, when various arrangements are conceivable.

The following may be given as simple illustrations of (1):

$H-Cl$, hydrochloric acid; $H-S-H$, sulphuretted hydrogen; $Mg=O$, magnesium oxide;  $N\begin{matrix}H\\H\\H\end{matrix}$, ammonia;  $H-\underset{H}{\overset{H}{C}}-H$, marsh-gas;  $H-\underset{Cl}{\overset{Cl}{C}}-Cl$, chloroform;  $O=C\begin{matrix}Cl\\Cl\end{matrix}$, phosgene; $O=C=O$, carbonic anhydride; $S=C=S$, carbon bisulphide, &c. The letters representing monovalent atoms are written with one stroke proceeding from them, those representing divalent, trivalent, and tetravalent atoms being written with two, three, and four such strokes respectively.

Illustrations of (2) are:

Urea.



and

Ammonium cyanate.

These two substances illustrate two other points of importance. One of these is the occurrence of the nitrogen atom sometimes *trivalent*, as in ammonia, NH_3, sometimes *pentavalent*, as in the ammonium salts—e.g. ammonium chloride, NH_4Cl. In ammonium cyanate one atom of nitrogen is represented as trivalent and the other as pentavalent. The two substances, moreover, illustrate *Isomerism* (q.v.), or the existence of two or more compounds containing exactly the same elements and in the same proportions, and yet differing from one another in chemical and physical properties.

Chemical Changes.—There are several kinds of chemical changes which are of very frequent occurrence, and may conveniently be classified. The simple union of one element with another has already been mentioned, and closely related to this kind of change is the union of a compound with an element or with another compound. Along with these changes may be classed those in which a compound breaks up into two or more elements or simpler compounds, or into one or more of each. All these variations are illustrated by the following equations:

$$\left.\begin{array}{l} C + O_2 = CO_2 \\ CO + Cl_2 = COCl_2 \\ CaO + CO_2 = CaCO_3 \end{array}\right\}\text{direct union.}$$

$$\left.\begin{array}{l} 2HgO = 2Hg + O_2 \\ (NH_4)_2Cr_2O_7 = Cr_2O_3 + 4H_2O + N_2 \\ Ca(HO)_2 = CaO + H_2O \end{array}\right\}\begin{array}{l}\text{decomposition}\\\text{(by heating).}\end{array}$$

One of the most important kinds of chemical change is that called *double decomposition*. This occurs perhaps most frequently when solutions of salts are mixed with each other, and it is characterised by a mutual exchange of metal and salt radical. If an aqueous solution of sodium chloride be mixed with one of potassium bromide, although no visible change takes place, we have reason to believe that double decomposition goes on to a certain extent, with formation of some sodium bromide and some potassium chloride, whilst some of each of the original salts also remains, a state of equilibrium being eventually established amongst the four salts. If, however, one of the new products formed by double decomposition be insoluble or practically insoluble in water, as soon as any of it is formed it will appear as a *precipitate*, and be thus removed from solution, so that no condition of equilibrium can be established until formation of a precipitate no longer occurs—i.e. until the double decomposition is complete. Thus, if solutions of sodium chloride and silver nitrate be mixed in the proper proportions, the extremely insoluble silver chloride will be precipitated, and only sodium nitrate will remain in solution. The action may be represented by an equation:

$$NaCl + AgNO_3 = NaNO_3 + AgCl \text{ (precipitate).}$$

The action of sulphuretted hydrogen on many metallic solutions illustrates double decompositions in which the action is complete, as,

$$HgCl_2 + H_2S = HgS + 2HCl,$$

where the mercuric sulphide formed is insoluble in water, and is consequently obtained as a precipitate.

In connection with the subject of double decomposition the bearing of the law of Richter (already mentioned in the historical sketch) may be illustrated. Looking at the quantitative signification of the following equations,

$$KCl + AgNO_3 = AgCl + KNO_3,$$
$$NaCl + AgNO_3 = AgCl + NaNO_3,$$

we see that the quantity of chlorine which was united with 39 parts by weight of potassium or 23 of sodium to form a salt is exactly the quantity required to form a salt with 108 parts by weight of silver, whilst, similarly, the quantity of the group NO_3 which was united to these 108 parts by weight of silver is exactly the quantity required to form a salt with 39 parts by weight of potassium or 23 of sodium. The same holds good generally for double decompositions.

Another very important kind of chemical change is the displacement of one element in a compound by another. Chlorine, for instance, displaces the iodine in potassium iodide and takes its place:

$$2KI + Cl_2 = 2KCl + I_2.$$

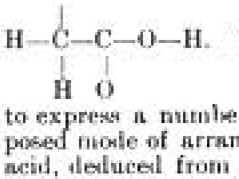
The greater affinity of potassium for chlorine than for iodine is the explanation given of this displacement. Displacement of one metal by another is a familiar phenomenon, although the chemistry of what is taking place may not be familiar to all who have seen it. When a piece of bright iron or steel, as a key or the blade of a knife, is dipped into an acidulated solution of cupric sulphate (blue vitriol), a reddish deposit of metallic copper is formed almost immediately upon the surface of the metal. This copper is derived from the cupric sulphate solution; but what is not manifest from observation alone, is that at the same time an equivalent quantity of iron is dissolved away and goes into solution as ferrous sulphate. The action is,

$$CuSO_4 + Fe = FeSO_4 + Cu.$$

The whole of the copper would eventually be separated from the solution in the metallic state if enough iron were present, and for every 63 parts of copper precipitated 56 parts of iron would go into solution.

Inorganic and Organic Chemistry.—The whole subject of chemistry has been divided into two great divisions, named respectively *inorganic* and *organic*. Made originally to separate from each other the chemistry of purely mineral substances, and that of substances of animal or vegetable origin, which were at the time supposed to be capable of formation only as products of vital processes, this subdivision is retained still mainly as a matter of convenience. The division of organic chemistry is sometimes spoken of now as the chemistry of the compounds of carbon; but this is not a very strict definition, as many carbon compounds occur in nature as purely mineral substances, and having really no connection with organic chemistry, such as numerous mineral carbonates. As has been already stated, it is mainly for convenience that the consideration of the majority of the compounds of carbon is taken as a separate branch, not because of any difference in the chemical principles involved, but really on account of the very great number of these compounds, and of the great complexity of many of them.

It is in the domain of organic chemistry that the study of the constitution of substances has been most diligently prosecuted, and with the greatest amount of apparent success. The graphic formula which chemists assign to acetic acid (to take a simple example) is,



$H-\underset{H}{\overset{H}{C}}-\underset{O}{C}-O-H.$ This formula is adopted in order to express a number of ideas concerning the supposed mode of arrangement of the atoms in acetic acid, deduced from the study of its formation, its decompositions, and the action upon it of various substances. The known facts find suitable expression in the formula, and there is no observation yet made as to the chemical relations of acetic acid which is at variance with the constitution indicated by it. It would not be possible here to quote evidence in favour of a particular constitution for any substance, but it may be stated generally that chemists endeavour to fix the constitution of the simplest compounds on the firmest possible basis, and, in passing from the simple to the more complex, to make secure every step.

The tetravalent character of the carbon atom, and the great facility with which carbon atoms enter into combination with other carbon atoms and with the atoms of other elements, give their impress to the whole of organic chemistry. The graphic formulæ of organic substances amply illustrate the former, whilst the syntheses of a long array of simple and complex organic compounds as amply illustrate the latter.

A certain amount of knowledge of chemistry is eminently useful in almost every walk of life. An intelligent knowledge of the chemistry involved in the processes of the kitchen, the dairy, the dye-house, the farm, or the manufactory, places the possessor engaged in any of these processes on a different level from the rule-of-thumb worker, who is as ignorant of the reason for adopting a particular method as he is of the properties of the materials he employs. Technical chemistry deals especially with the application of the principles and processes of chemistry to the arts and manufactures, and it is to those who are engaged in manufactures of almost every kind that a knowledge of chemistry is a particular advantage. It is not a question of expediency alone, but one of absolute necessity that a technical education, including chemistry as one of its principal subjects, should form not the least important part of the equipment for his work of any artisan who is to excel in his employment in intelligence and skill.

In connection with this article should be read the article ATOMIC THEORY, which is to a certain extent supplementary to this. ANIMAL CHEMISTRY and VEGETABLE CHEMISTRY are separately treated. The reader is also referred to the description of each element under its name, to those of the acids under their names, and to the following as amongst the most important of the large number of chemical articles throughout this work:

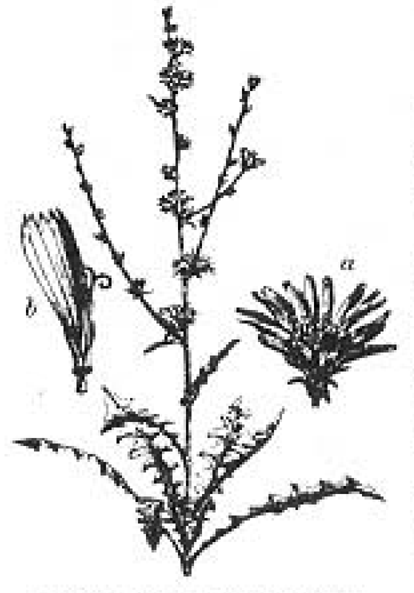
Chemists and Druggists. Up to the passing of the Pharmacy Act of 1868 the term chemist and druggist was merely a title descriptive of certain branches of trade, just as 'tailor and clothier,' or any other such combination. Any one was free so to describe himself and to prosecute that calling to the best of his ability, untouched by any special legislation, either regulative or protective. The class, like the Apothecary (q.v.), was in its beginnings closely allied to, if indeed at all distinguishable from, that of merchants and grocers, and never formed a distinct guild, and, until the Pharmaceutical Society was founded, was without permanent organisation. And owing to the absence in Scotland of the apothecaries, as a class distinguishable from druggists, the history of the latter class in that country does not, at least up to the passing of the Pharmacy Act of 1882, correspond accurately with that of their English brethren. The policy these latter pursued for a long period of their history may be described as purely defensive, and any organisation they formed was in response to some attack from one of the other orders. As early as 1802 such a defensive association was formed, and from 1812 to 1815 engaged in very active opposition to the bill promoted by the 'Associated Apothecaries.' One of the objects of that bill was to bring the chemists and druggists under the control and surveillance of a body consisting chiefly of apothecaries, on which the chemist and druggist was not represented at all. The upshot was that the promoters of the bill introduced a clause into the Act of 1815, which it was understood at the time would completely exempt the chemist and druggist from the operation of the bill. In spite, however, of this understanding, which seems to have been respected for twenty-six years, the bill was in 1841 made use of to punish a chemist and druggist for prescribing medicine, although that was a function which, rightly or wrongly, he had exercised previous to 1815. In 1841 a bill again threatened to subject the chemist and druggist to the control of the apothecaries, but was at length defeated. It now became evident, not only that a permanent society to protect the interests of the craft was necessary, but that the only wise policy was to educate and organise themselves in such a way as would deprive the physicians and apothecaries of any excuse for further interference. This led to the formation of the Pharmaceutical Society of Great Britain, which was founded in 1841 and incorporated by Royal Charter in 1843. As declared in the charter, the main objects of the society were those of 'advancing chemistry and pharmacy and promoting a uniform system of education of those who should practise the same; and also for the protection of those who carry on the business of chemists and druggists;' and to enable it to carry these out successfully the society appointed professors and examiners, and afterwards proceeded to promote a bill in parliament for the recognition and protection of the titles they proposed to confer on those who passed the examinations. This was naturally a work of time, and in the meanwhile an important act in relation to the sale of poisons—viz. the Sale of Arsenic Act (1851)—was passed, and drew the attention of government to the absence of a definite class of persons qualified by training and education to have the custody and sale of poisonous substances intrusted to them; so that this to some extent led up to the passing of the first Pharmacy Act of 1852. The main result of this act was to create a class of 'Pharmaceutical Chemists,' alone empowered to use and exhibit that or any equivalent title, and consisting, 1st, of those already members of the society; and 2dly, of such persons as should pass the examinations, as conducted by its two Boards in England and Scotland. The bill, as passed, involved no compulsion on any persons to go through these examinations, nor did it confer any privilege or monopoly on the pharmaceutical chemist except the exclusive right to that title. The dispensing of medicines and sale of poisons was still left open to any one who chose to engage in it. Nor was it till the Act of 1868 that the term chemist and druggist came to signify a specially qualified person or one possessing exclusive rights. By that act all persons not in business on their own account prior to 1st August 1868, had (except some who for a time were allowed to pass a 'modified examination') to pass two Preliminary and the Minor Examinations, and after that were entitled to have their names placed on the 'Register of Chemists and Druggists for the United Kingdom;' and no person who was not on that register could legally use the title, or (with certain exceptions in favour of physicians, apothecaries, veterinary surgeons, &c.) sell or dispense certain poisons specified in schedules to the act. Any person wishing to use the style 'Pharmaceutical Chemist,' had to pass a further examination called the 'Major,' and thus arose the two grades in what we may now call, in view of its educational qualification, the profession of pharmacy.

Chick Pea (*Cicer*), a genus of the vetch tribe of Leguminosæ. The common chick pea (*C. arietinum*) is an annual, 1½ to 2 feet high, of a stiff upright habit, covered with glandular hairs, with inflated pods containing a few angular and wrinkled peas. It is largely cultivated in southern Europe and in many parts of the East, and hence occurs frequently also as a weed in cornfields. It is also grown in Spanish America. Large quantities of the peas are exported from British India under the name of *gram*, now well known in commerce; but the name is extended to other East Indian kinds of pulse. The peas are used as food, either boiled or roasted, and are the most common *parched pulse* of the East. They are a notable article of Spanish and French cookery; while their importance in Roman times is evidenced by the phrase, *fricti ciceris emptor* ('buyer of roasted chick peas'), as a conversational equivalent for a poor fellow. Its cultivation extends as far as southern Germany; but in the climate of Britain it is found too tender to be profitable. The herbage affords fodder, and the seeds are one of the occasional substitutes for coffee. In summer weather drops exude from this plant, which, on drying, leave crystals of almost pure oxalic acid. The too free and prolonged use of chick peas as food is believed to be liable to become the cause of dangerous and obstinate forms of disease.

Chickweed (*Stellaria media*), one of the most common weeds of gardens and cultivated fields, is a species of Stitchwort (q.v.). It is a native of most parts of Europe and of Asia, appearing during the colder months even on the plains of India; an annual, with a weak procumbent stem and ovate leaves, very variable; some of the smaller varieties in dry sunny situations sometimes puzzling young botanists from having no petals or only five or three instead of ten stamens; but always characterised by having the stem curiously marked with a line of hairs, which at each pair of leaves changes from one side to another, and in four changes completes the circuit of the stem. The leaves of chickweed afford a fine instance of the *sleep of plants*, closing up on the young shoots at night. Chickweed is a good substitute for spinach or greens, although generally little regarded except as a troublesome weed, or gathered only by the poor to make poultices, for which it is very useful, or for feeding cage-birds, which are very fond of its leaves and seeds. A number of species of a nearly allied genus, Cerastium, also bear the name of Chickweed, or Mouse-ear Chickweed, and the name is occasionally given to other plants, either botanically allied, or of somewhat similar appearance.

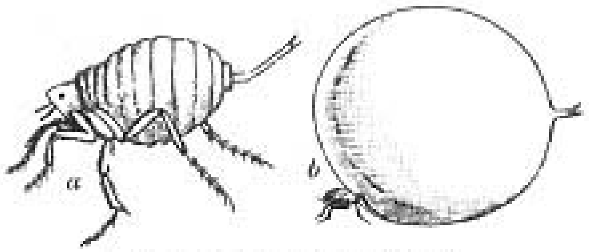
Chicory, or SUCCORY (*Cichorium*), a genus of Compositæ (sub-order Ligulifloræ), with few species, all herbaceous perennials, with spreading branches and milky juice, natives of Europe and West Asia. The Common Chicory or Succory (*C. Intybus*) is wild in England and most parts of Europe, growing in waysides, borders of fields, &c. It has a long carrot-like root, externally of a dirty or brownish-yellow colour, and white within. The stem rises 1 to 3 feet, the leaves resembling those of the dandelion; the flower-heads are sessile, axillary, large (1 to 1½ inch), and beautiful, generally blue, more rarely pink or white. Chicory is pretty extensively cultivated, both in England and on the continent of Europe, as also in California, for its roots, while its herbage is good food for cattle. The blanched leaves are sometimes used as a salad, and are readily procured in winter by placing the roots in a box with a little earth in a cellar. To this genus belongs also the Endive (q.v.).



Chicory (*Cichorium Intybus*):
a, single flower; *b*, a separate floret.

Chicory has been used as a substitute for coffee, or to mix with coffee, for at least a century. The roots are pulled up, washed, cut into small pieces, and dried on a kiln, which leaves a shrivelled mass not more than one-fourth the weight of the original root. It is then roasted in heated iron cylinders, which are kept revolving as in coffee-roasting, during which it loses 25 to 30 per cent. of its weight, and evolves at the same time a disagreeable odour, resembling burned gingerbread. An improvement to the chicory during roasting is the addition of 2 lb. of lard or butter for every cwt. of chicory, which communicates to it much of the lustre and general appearance of coffee. It is then hand-picked, to remove chips of wood, stones, &c., and is reduced to powder, and sold separately as *chicory powder*, or is added to ordinary ground-coffee, and is sold as a mixture. Chicory contains a good deal of sugar, but otherwise does not serve to supply the animal economy with any useful ingredient. It gives off a deep brown colour to water when an infusion is made, and hence its main use in coffee. Some people dislike the taste of chicory, and when largely used, it has a tendency to produce diarrhœa; but many people prefer to use coffee mixed with chicory owing partly to the taste it communicates, but mainly to the appearance of strength which it gives to the coffee.

Chigoe, or JIGGER (*Sarcopsylla penetrans*), a genus of flea, somewhat smaller than the familiar Pulex, and without its jumping legs. It is an American pest, found for about 30 degrees on each side of the equator, but especially abundant in the West Indies and in the north of South America. It is found also in the West African coast region. One of its many names—the 'sand-flea'—indicates its favourite haunt among sand. It seems always to keep near the abodes of men. The males and immature females live like other fleas on chance bites, and relish of course the blood of animals as well as of man. It is the impregnated female which is the chief trouble. Like many other animals it seeks a safe and quiet breeding-place. This is found under the skin of animals, on the feet or



Chigoe (*Sarcopsylla penetrans*):
a, male; b, gravid female.

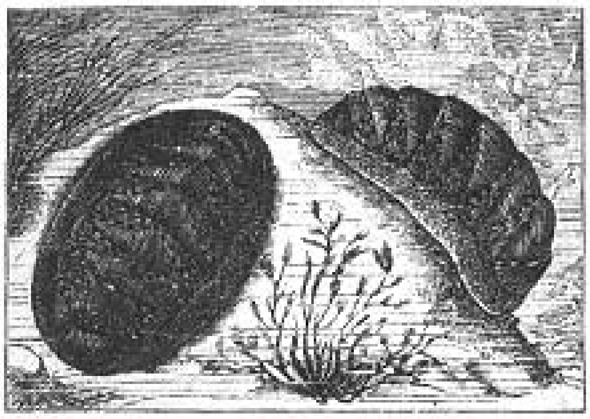
under the toe-nails of man. There the minute creature swells up enormously, attaining under the pressure of the growing eggs the size of a pea. Respiratory communication with the outer world is kept up by an air-hole at the posterior end. In less than a week the eggs are ready to be liberated, for the larvæ are not parasitic. The mother-animal has meanwhile undergone a marked degeneration, the internal organs being much squeezed and atrophied by the growth of the ova. The entrance of the female chigoe is marked by a tingling and itching sensation, but if the development be allowed quietly to proceed no evil results seem to follow. Pressure and premature attempts to isolate the intruder may, however, lead to ulceration. Its evil effects seem to have been exaggerated. When the development of eggs has been completed, the entire animal with its progeny may be gently removed, and in this operation the West Indian negresses are experts. Washing with tobacco-juice is also resorted to, and the leaves are sometimes pressed on the feet as a preventive.

Chilblains are localised inflammations of the skin which occur in cold weather, and affect the parts farthest from the centre of the circulation—viz. the hands and feet, more rarely the ears or nose. They are at first bright red, but as they disappear assume a purplish tinge. Sometimes they break and give rise to ulcers, which are slow to heal. They occur most frequently in young people, affect women more often than men, and are generally associated with weak health and a sluggish circulation. They are often extremely irritable and painful, especially when the affected part has been chilled, and is quickly warmed again. In their treatment, regard must be had to the general health; good feeding, exercise, and tonics should be prescribed. It is very important that tight shoes, gloves, garters, and bracelets should be avoided; and that the affected parts should be warmly covered when exposed to the open air. Locally, when the skin is whole, some stimulating agent answers best; tincture of iodine, spirit of camphor, or mustard applied moist and rubbed till it dries. If the skin be very tender, collodion painted over it is useful. Broken chilblains should be dressed with resin ointment or Peruvian balsam on lint.

Chitin, the substance which forms most of the hard parts of jointed-footed animals (arthropods), such as crustaceans, insects, and spiders. It was discovered by Odier in 1823, but regarded erroneously as free from nitrogen; rediscovered by Lassaigne in 1843; and since then recognised in all the four chief classes of arthropods and in some other types. Huxley has given an account of its formation in the crayfish. Chitin has been demonstrated in many arthropods, also in the pen of cuttle-fishes (Mollusca), and in the stalk and shell of *Lingula anatina*, a brachiopod. Its presence is at least probable in many other cases. In arthropods it is not confined to forming the firm and often very hard exoskeleton, but occurs internally in supporting plates, &c. among the tissues. In the crayfish it seems even to form the sheath of the strong ventral nerves. In arthropods the greater portion of the gut is formed as an intucking of the outer skin (ectoderm) from in front and behind, and the resulting portions known as fore- and hind-gut are also lined by this chitin, which frequently exhibit special internal thickenings for food-grinding purposes. The chitinous coating or cuticle is formed from underlying skin cells. In some cases the epidermic cells probably sweat it off after the manner of other secretions; but Huxley has shown in regard to the crayfish that the superficial portion of the cells undergoes a chitinous modification, being literally turned into chitin. The outer coat of crustacea is hardened by the addition of calcium carbonate or phosphate, especially the former; such calcareous hardening is very rare in insects, but copper has been demonstrated in some beetle cuticles.

Chitin is an amorphous white substance. It contains nitrogen, but is free from sulphur. Its resistance to acids and alkalies is very great; it is unaffected by digestive ferments, by water, hot or cold, by alcohol or ether. It may be dissolved by strong mineral acids (hydrochloric or sulphuric), and prepared from the cleaned exoskeleton of a lobster, or better still from the pen of a squid. Chemically it is regarded as a derivative of carbohydrates, and may be split up into sugar and glycosamin. According to Ledderhose, its formula is $C_{15}H_{26}N_2O_{10}$; according to Sundwik, $C_{60}H_{100}N_8O_{38} + nH_2O$.

Chiton, a genus of marine molluscs, type of an important sub-class which may be regarded as introductory to gasteropods. Unlike the lop-sided snails, the chitons are bilaterally symmetrical. The head is at the anterior end, the anus posterior; the 'foot' occupies the whole of the ventral surface; the heart, the gills, the excretory tubes, the genital ducts, all exhibit the same symmetry. This marked contrast to the gasteropods proper is further supported by the disposition of the two important nerve cords (pedal and visceral) which run parallel to one another along the body. In some forms there are numerous eyes, which occur, however, not on the head, but on the body. Another striking feature is the presence of a series of eight shell-plates along the back. On these and other grounds the chitons are separated from gasteropods proper, and established as a separate order, on which the name *Polyplacophora*, alluding to the multiple shell-plates, has been bestowed. Nor is the order a small one. Of the genus Chiton alone over 400 species have been recorded, and other smaller genera are also distinguished. The British species are small; those from warmer climates sometimes measure 3 to 4 inches in length. They are undoubtedly representatives of a primitive type, and include numerous fossil forms from the Silurian onwards. They are not, however, the simplest gasteropods, for a few other forms, known it is true with less fullness, exhibit the same essential features in even simpler expression. These are (*a*) the Neomeniæ, including the genera Neomenia and Proneomenia, and (*b*) the single genus Chætoderma.



Chiton elegans.

Chloral (*trichloraldehyde*) is a limpid, colourless, oily liquid, with a peculiar penetrating odour, and is formed when anhydrous alcohol is acted on by dry chlorine gas. It dissolves sulphur, phosphorus, bromine, and iodine, and is closely allied to Aldehyde (q.v.). Chloral combined with one equivalent of water forms chloral hydrate, a white crystalline substance, with a pungent odour and a bitter taste, to which the name chloral is commonly though incorrectly applied. Chloral was discovered by Liebig in 1831, and investigated by Dumas; the chloral hydrate was first used as an anæsthetic and hypnotic by Liebreich in 1869. The chief action of a moderate dose of chloral (15 to 30 grains) is the production of sleep, closely resembling natural sleep, and usually sound and refreshing. It has also a marked effect in quieting excitement, as in insanity or delirium; and in relaxing spasm, and checking convulsions and allied conditions. Its action as an anæsthetic is very capricious and uncertain; medicinal doses sometimes relieve pain completely, but much more often fail to do so. It lessens the force of the heart's action, and in large doses greatly reduces the temperature of the body; and to these effects the fatal results that sometimes follow its administration are chiefly due. As a hypnotic it is most valuable in cases where opium or morphia is dangerous or undesirable (in children, in disease of the kidneys), and where sleeplessness is combined with excitement (delirium of fevers, delirium tremens, insanity); but it may be employed in many other cases with advantage. In tetanus (lockjaw), and other diseases attended by convulsions, it is often of great value. It acts as an antidote in poisoning by strychnia and Calabar bean. It must be employed with the greatest caution, or not at all where there is any reason to suspect weakness of the heart, or embarrassment of the circulation from any other cause; in such cases dangerous symptoms are very readily produced by it. When habitually employed to procure sleep, it is generally less hurtful than opium; but sometimes 'profound melancholy and enfeeblement of the will, muscular lassitude, inability to sleep without the drug,' and other untoward symptoms (called collectively *chloralism*) result, and only disappear when its use is discontinued. Moreover, fatal accidents from its indiscriminate use are far from uncommon. Poisoning by chloral should be treated by keeping the patient warm, attempting to rouse him, administering coffee and small doses of strychnia or atropia.

When chloral hydrate is treated with caustic potash, pure chloroform is obtained; but owing to the expense, this process has not come into use in Great Britain. It has been supposed that its anæsthetic property is the result of a similar formation of chloroform in the blood, but no evidence of this is forthcoming.

Chlorantha'ceæ, a small group, chiefly tropical, allied to the peppers, aromatic and stimulant. *Chloranthus inconspicuus* is the Chu-lan of the Chinese, who use it for perfuming teas.

Chloric Acid, $HClO_3$, is the acid corresponding to the hypothetical oxide of chlorine, represented by the formula Cl_2O_5. It is a syrupy liquid, with faint chlorine odour and acid reaction. A piece of paper dipped into it becomes charred and takes fire, and it is instantly decomposed by contact with organic matter. In itself it is not of much importance, but it forms a class of salts called *chlorates*, one of which at least is well known. *Chlorate of potash*, $KClO_3$, is an article of commercial value, and may be prepared by passing chlorine into a solution of caustic potash, heating the liquid, and crystallising out the salt. It forms pearly plates, which, when heated, melt and give off oxygen in abundance. So also when thrown on red-hot charcoal, oxygen is given off, and violent deflagration ensues. On account of this property it is used in the preparation of coloured fires, but its use is not unattended with danger, owing to their tendency to spontaneous combustion and its explosive properties when triturated with sulphur. Mixed cautiously with amorphous phosphorus, previously moistened with alcohol, it forms a mixture which, when dry, explodes if tapped with a pencil. This mixture is employed in the manufacture of some kinds of matches, which give a slight explosion when struck. If a crystal of chlorate of potash be placed on a piece of paper saturated with turpentine, and a drop of sulphuric acid added, it causes the inflaming of the turpentine with explosive rapidity. The chlorate is also used in medicine, and in a compressed form has become a popular remedy in certain forms of sore throat.

Chlorimetry is the process of estimating the proportion of 'available chlorine' in Bleaching Powder (q.v.), which may vary from 20 to 40 per cent. The term *available* applies only to that portion of the chlorine which is easily liberated, and which takes part in the bleaching process. Chlorine, which is present as chloride, as in chloride of calcium, $CaCl_2$, has no bleaching power, and is not estimated by chlorimetry.

The process is one of volumetric analysis, and the apparatus used is similar to that described in the article on Analysis (q.v.). There are several practical methods of chlorimetry, all based on the principle of measuring the oxidising power of the bleaching powder. This is arrived at by making a solution containing a definite amount of pure sulphate of iron, arsenious acid, or other substance capable of being oxidised, running in the solution of bleaching powder very slowly, and then by suitable tests determining the exact point when oxidation has taken place. By calculation the amount of 'available chlorine' is at once obtained. Where substances other than bleaching powder are under examination, slight modifications of the process may be necessary.

Chlorine (sym. Cl; atom. wt. 35·5; Gr. *chlōros*, 'pale green') is a non-metallic element discovered by Scheele in 1774, and named by him *dephlogisticated marine air*. Afterwards, in 1810, Davy proved it to be an elementary body, and gave it the name which it now bears. In nature it is always found in a state of combination. United with sodium, Na, it occurs very largely as the chloride of sodium, NaCl—common salt—in the ocean; in large beds, as rock-salt; in all natural waters, including even rain-water; in clays, soils, limestone; in volcanic incrustations; and in the vegetable and animal kingdoms. The preparation of gaseous chlorine by its liberation, directly or indirectly, from common salt, has been fully described under BLEACHING POWDER, which is the form in which chlorine is prepared and employed commercially. For experimental purposes the gas may be received in jars filled with warm water at the pneumatic trough, when the chlorine rises into the jar, and displaces the water. When thus obtained it is a yellowish-green gas with a peculiar and suffocating odour, is not combustible, and is a very feeble supporter of ordinary combustion. A lighted candle placed in it burns with a very smoky flame, owing to the hydrogen of the oil alone burning, while the carbon is liberated. Several of the metals, such as antimony, copper, and arsenic, in a fine state of division, or in the condition of thin leaves, at once become red hot, and burn when introduced into the gas. A piece of thin paper soaked in turpentine likewise bursts into flame. Chlorine is a very heavy gas, nearly 2½ times heavier than air, its specific gravity being 2·470 (air = 1·000); it is soluble in cold water to the extent of two volumes of chlorine in one of water, and yields a solution resembling the gas in colour, odour, and other properties. The principal properties of chlorine are those of a bleacher of cotton and linen (see BLEACHING) and a most powerful Disinfectant (q.v.). The gas can be condensed by pressure and cold into a transparent dark greenish-yellow limpid liquid, with a specific gravity of 1·330 (water = 1·000), which also possesses bleaching properties and a most powerful odour. On the animal system chlorine acts, in very minute quantity, by producing a sensation of warmth in the respiratory passages, and increasing the expectoration; in large quantity, by causing spasm of the glottis, violent cough, and a feeling of suffocation. The workmen in chemical manufactories, who get accustomed to the chlorine in small quantities, are generally stout—at least, lay on fat—but complain of acidity in the stomach, which they correct by taking chalk, and also suffer from the corrosion of their teeth, which are eaten away to stumps. The antidotes to the evil effects of the introduction of chlorine into the lungs are the inhalation of the vapour of water, alcohol, ether, or chloroform; but the latter two should never be resorted to except under medical supervision.

Chlorine forms with other substances a very large number of chemical compounds. Mixed with hydrogen in equal volumes, and exposed to sunlight or flame, union takes place with explosive energy, and hydrochloric acid, HCl, is produced. This acid forms an extensive class of salts called *chlorides* (see HYDROCHLORIC ACID), but many of these may be produced by the direct combination of chlorine with the metals, as in the experiments described above. Chlorine replaces other elements or groups of atoms in organic compounds, forming chloro-derivatives. In combination with carbon and hydrogen it forms many substances, among which Chloroform (q.v.) is perhaps chief. Chlorine forms with oxygen a series of oxygen acids—viz. Hypochlorous, HClO; Chlorous, $HClO_2$; Chloric, $HClO_3$; and Perchloric Acid, $HClO_4$; the more important of which are referred to under separate heads.

Chlorodyne is a patent medicine of considerable popularity, invented by Dr James Collis Browne (1819-84), but largely imitated by various chemists. It contains opium, chloroform, prussic acid, and probably Indian hemp, and is flavoured with sugar and peppermint. As it is apt to separate into two liquids on standing, it should never be taken unless it has previously been well shaken; and as, in taking a dose of chlorodyne, the patient swallows an unknown quantity of three or four of the deadliest poisons with which we are acquainted, it is always advisable to begin with small doses. It is unquestionably a compound which sometimes succeeds in allaying pain and inducing sleep when opiates have failed; but whether a physician is justified in recommending a remedy with the composition of which he is unacquainted is a doubtful question. To meet this difficulty the Medical Council, in the 1885 edition of the British Pharmacopœia, have introduced the tincture of chloroform and morphia, which practically represents chlorodyne. Five to fifteen drops is the average dose.

Chloroform, $CHCl_3$, was discovered as a chemical curiosity about the same time (1831) by Guthrie in America, Liebig in Germany, and Soubeiran in France. Soon, however, its properties as a stimulant when taken internally attracted attention, and when in 1847 it was brought into prominent notice as an anæsthetic by Sir James Simpson, it was at once recognised as one of the most valuable contributions of chemical science to suffering humanity. See ANÆSTHESIA.

Chloroform is composed of 12 parts of carbon, 1 part of hydrogen, and 106½ parts of chlorine. It may be produced in several ways, but in this country at least the process by which it is obtained from bleaching powder is the only one adopted on the large scale. The materials employed are bleaching powder, alcohol, and water. The bleaching powder and water are mixed together to form a thin cream, the alcohol added, and the whole placed in a capacious still, connected with suitable condensing apparatus. On the application of heat the contents rapidly froth up, and even though the external application of heat be stopped, the chemical action is so violent that the chloroform distils over rapidly along with water and any excess of alcohol. As so obtained it is very impure, and requires to be carefully treated with sulphuric acid, and then redistilled before it is fit for anæsthetic purposes. Pure chloroform is a limpid, mobile, colourless, volatile liquid, with a characteristic odour, and a powerful sweetish taste. When diluted with alcohol it enters into the composition of artificial fruit-essences, to which it gives a flavour akin to that of ripe apples. It is a very heavy liquid, its specific gravity being about 1·500 (water = 1·000), and as it does not readily mix with or dissolve in water, it falls to the bottom when poured into a vessel of that liquid, forming a distinct layer. Chloroform is readily miscible with alcohol and ether, and it dissolves camphor, amber, gutta-percha, wax, black and red sealing-wax, iodine, and bromine, as well as strychnine and other alkaloids. It dissolves a small proportion of water, being also slightly soluble in that liquid. Chloroform is not combustible in the ordinary sense of the term, but when its vapour is brought in contact with flame it burns, imparting a green tint to it, and irritating fumes are produced. Pure chloroform is not met with in commerce owing to the readiness with which it decomposes when exposed to light. In order to prevent this a small proportion of alcohol is added, the specific gravity being thus reduced from 1·500 to 1·497. When evaporated on the hand no disagreeable odour should be noticeable, and when shaken with sulphuric acid only a very slight discoloration of the acid (due to the small proportion of alcohol) should result. Besides its anæsthetic properties, which are elsewhere discussed (see ANÆSTHESIA), chloroform is used in medicine both externally and internally. When applied to the skin or any of the mucous membranes it acts as a powerful irritant, producing a burning sensation, and on this account it is of value as an application in rheumatism, lumbago, and neuralgia. As an application to a decayed tooth its action is twofold, as a stimulant and counter-irritant locally, and also to a partial extent as an anæsthetic. Taken internally, diluted with alcohol, it is a powerful stimulant, and readily produces a species of intoxication. It is by some habitually taken as a narcotic luxury. As chloric ether, a product distilled from bleaching powder, and containing chloroform, it enters into the composition of cough mixtures, pick-me-ups, &c.

Chlorophyll, as its name implies, is *leaf-green*, the ordinary colouring matter of vegetation. Microscopic examination of plant tissues shows it sometimes to tinge the whole protoplasm of the cell (though never the cell sap). Much more generally, however, it is collected into definite bodies, the so-called chlorophyll granules, or less frequently, as in some of the lower algæ, arranged in starlike masses (Zygnema) or spiral bands (Spirogyra). A brief immersion of the specimen in alcohol suffices to dissolve out the chlorophyll, and leave the form of the chlorophyll bodies unaltered; and the solution may then be conveniently studied in a fresh state, as it gradually fades on keeping. It is of a deep rich green by transmitted, but of characteristic deep red colour by reflected light; in a word, is highly fluorescent. The absorption-spectrum is quite characteristic; yet the complex nature of the substance is strongly argued for on the ground of the following experiment. Shake up the alcoholic solution with benzol, and when the two fluids have had time to separate, we find the green to have disappeared. The lighter alcohol above is now of a strongly yellow hue, while the subjacent benzol is of a distinctly bluish green. To these colouring matters the names *Xanthophyll* and *Cyanophyll* are commonly given. While their separate spectra are quite characteristic, their combined spectrum seems to restore that of chlorophyll. The latter substance resembles the blue-green colouring matter of some of the lowest algæ (Oscillatoria, &c.), while the yellow substance recalls that of many buds and flowers. Others, however, maintain that these substances are really the result of a destructive decomposition of true chlorophyll; while Gautier has even prepared green needle-like crystals which he regards as chlorophyll in a pure state. The chemical composition of chlorophyll is also a matter of considerable difficulty, both on account of its own easy decomposability, and its being necessarily accompanied by other extractive substances; thus the question of the presence or absence of iron has been much debated, a matter which seems to indicate variability of composition. This is further borne out by the labours of spectroscopists. Thus in addition to the familiar well-defined analogous colouring matters which characterise respectively the blue-green algæ, the brown and the red (see SEAWEEDS), researches such as those of Sorby and others seem to indicate a number of varieties too numerous even for enumeration. This varietal range, however, may best be approached after considering the conditions in which chlorophyll is formed. Of the chemical factors little can be said save that the presence of iron in the soil seems to be quite indispensable; the physical conditions are, however, simpler.

A sufficient temperature is necessary to the formation of chlorophyll; for seedlings from 4° to 8° C. being a minimum, while the process is said to take place most rapidly, on the average, at about 35° C. The most important condition is, however, the presence of light; with rare exceptions, plants cannot form any chlorophyll in darkness. The blanching of celery or leeks is a familiar instance of this, or conversely, the green coating acquired by a potato-tuber where it happens to have been denuded of its covering of earth. Shoots formed in darkness form colouring matter indeed, but only of a pale-yellow hue, the so-called *etiolin*; after a very brief exposure to light, especially if direct sunshine, chlorophyll appears, apparently by direct transformation of the former. The other colouring matters of plants are sometimes in protoplasm granules (chromoplasts), but more frequently also in solution in the sap; and these frequently are present in such abundance, especially in the epidermis, &c., as to mask the chlorophyll altogether, as happens especially in so many of our hothouse plants with decorative leaves. The general tendency of research is to indicate that all the phenomena of plant colour seem intimately connected with what we may term the general life-history of chlorophyll. Thus the yellows and reds of young shoots and leaves in spring may be interpreted as having some relation to the development of chlorophyll, if not absolutely stages of the process; while the same suggestion arises with regard to the colouring matters of flowers, which are similarly to be regarded as imperfectly vegetative shoots, although in this case through the onset of the reproductive function, instead of merely by reason of immaturity. Finally also with regard to the autumnal hues, in which the chlorophyll pigment seems to be disintegrating through colour-stages analogous to those of its evolution in spring, or of its arrestment in the flower. In favour of such a view evidence is forthcoming from either end of the vegetable kingdom. Thus Cienkowsky has shown that in the case of certain unicellular algæ, which like the common Protococcus of rain-water, possess red pigment as well as green when passing into the resting stage, the quantity of red may be increased in proportion as autumnal conditions are reproduced by artificially lowering the temperature, and *vice versâ*. The same experiment may be made with the common Sempervivums, Sedums, &c., whose leaves become more or less red in autumn or winter; those of Thuja (*Arbor Vitæ*) similarly become brownish, but recover themselves in spring. Among almost all cultivated plants, *variegated* varieties tend to arise, that is to say, we have certain cell-areas of the leaf-parenchyma destitute of chlorophyll. The conditions of this are obscure (see VARIEGATED PLANTS); but it is noteworthy that this loss of chlorophyll may also take place in lower plants, so that there is considerable ground for regarding at least many apparent fungi as simply algæ which have degenerated in this respect through parasitism. Phanerogamous parasites like Toothwort (q.v.) or Dodder (q.v.) similarly become almost completely blanched.

Chlorophyll apparently identical with that of green parts of plants, can be experimentally demonstrated in the tissues of certain animals; and although this has in many cases been shown to be due to the presence of symbiotic algæ (see SYMBIOSIS), there remain cases—e.g. *Hydra viridis*, &c., and at the very least *Paramœcium viride*, in which we have undeniably intrinsic chloropnyll, and this of truly vegetable function.

The development of our knowledge with respect to the functions of chlorophyll is still far from complete, and may in any case be more conveniently treated under LEAF and VEGETABLE PHYSIOLOGY (q.v.); suffice it therefore to state here the elementary and essential fact that its presence is in every case constantly associated with the process of *assimilation*, or elaboration of new products by help of the energy of sunlight, upon which the continued nutrition of the green plant depends; and of which the formation of starch with decomposition of carbonic anhydride and disengagement of oxygen are the most obvious chemical results.

Choke-damp, also called *after-damp* or *foul-damp*, is the carbonic acid gas given off by coal which accumulates in coal-mines, and may suffocate those exposed to it. It is distinguished from *fire-damp*, the marsh-gas or light carburetted hydrogen which causes the explosions.

Cholesterin, $C_{26}H_{44}O$, is a fatty substance, originally found in gall-stones, but now known to be present in the yolk of egg, the blood-corpuscles, milk, and other animal fluids, as well as in peas, barley, rye, &c. It is soluble in alcohol and ether, and separates from its solutions in glistening nacreous scales.

Chromium (sym. Cr, atom. weight, 52·5) is a metal, so called (*chrōma*, 'colour') from the many-coloured compounds it produces. It was discovered by Vauquelin in 1797, in the chromate of lead, $PbCrO_4$, one of its rarer ores. As chrome iron ore, $FeOCr_2O_3$, it is extensively distributed in America, Sweden, Hungary, &c.

The metal has been obtained in several modifications, one of which is so refractory as to be infusible at a temperature sufficient to volatilise platinum, while it may be heated to redness without oxidation, and resists the action of most acids. Another variety is a powder which burns brilliantly when heated in air, and is readily dissolved by acids. The metal itself has not been employed in the arts, but many of the chromates are much used in painting and colouring. Chromium forms four compounds with oxygen, of which the chief are chromic oxide, Cr_2O_3, and chromic acid, CrO_3.

Chromic oxide (chrome green) possesses a bright-green colour, and is the colouring ingredient in the emerald. Owing to its indestructibility by heat, it is used in porcelain-painting; while, being non-poisonous, it is now introduced as a substitute for the dangerous arsenical green pigments which were formerly universally employed in the manufacture of wall-papers.

Chromic acid or anhydride, CrO_3, forms dark-red crystals, containing no water. When strongly heated it becomes incandescent, and is converted into chromic oxide. It forms several classes of salts: the *Chromates*, such as chromate of lead, $PbCrO_4$; the *Bichromates*, of which bichromate of potash, $K_2Cr_2O_7$, or K_2O2CrO_3, is an example; and the trichromates and tetrachromates, which are unimportant.

Chromate of Lead, $PbCrO_4$, is well known to artists as 'chrome yellow.' It is readily prepared by mixing a solution of acetate of lead with one of chromate of potash. When boiled with lime, its bright-yellow colour disappears, and a scarlet basic chromate is obtained, which is used in the dyeing of calico.

Bichromate of Potash, $K_2Cr_2O_7$, is prepared from chrome ironstone, by calcination with chalk and carbonate of potash, and subsequent treatment with nitric acid. It forms large red crystals, and has many uses in the arts. When added to a solution of gelatine and allowed to dry, it is found that on exposure to light the gelatin becomes insoluble, and a process based on this property has been used to some extent in photography. As an oxidising agent in galvanic batteries it is very effective, while mixed with sulphuric acid it is used in the bleaching of oils.

Chromic acid and its salts are all more or less poisonous, owing to their corrosive and oxidising action on organic tissues.

Chrome Steel containing a small and variable percentage of chromium, is highly valued in America for its toughness and strength.

Churns are machines used for the production of butter from cream or from whole milk. By agitation the butter globules are thrown against each other until after a period which varies in length with the quality of the butter-fat, the temperature, and the condition of 'ripeness,' or incipient acidity of the cream. Churns are of great variety in form and dimensions, from the ladies' glass hand churn producing a few ounces of butter at a time, to one driven by water, steam, or horse-power, and churning the whole milk of a dairy at one operation. The *plunge* churn or *thump* churn is one of the oldest and most simple varieties. The common *upright hand* churn seen in country places is perhaps the best known form of it, but the principle is equally applicable to larger churns. The *box* churn, either oblong or cubical, is stationary like the latter, the action being brought about by 'dashers' or 'works' made to revolve on a horizontal spindle passing through its centre.

Revolving churns, taking the shape of a box or barrel, are supported from two points on a rigid framework, so that the whole body of the churn is turned round at the rate of forty to fifty revolutions per minute by a crank handle after the fashion of an ordinary grindstone. Sometimes the motion is a simple rotatory one, as when the barrel is supported from the centre of both ends, giving it the position of a barrel rolling on the ground. It may also be hung from two corresponding points, one on each side, and occupy an upright position while at rest. The action is then called 'end over end.' An eccentric motion is given by hanging the body unevenly. These churns also contain 'dashers' or 'diaphragms' which increase the agitation of the cream. Their great advantage is the ease with which they can be worked—a matter of first importance where hand labour is employed. *Swinging* or 'cradle' churns are increasing in favour, because they are so extremely easily worked, inexpensive, and simple, and because they contain no movable 'dashers,' which demand much care and labour in keeping them sweet and clean. The body, consisting of an elongated box, may be suspended by four chains or thin iron rods, or it may be carried on four flat, flexible iron supports. It is pushed so that it swings backwards and forwards, giving the cream within a course which assumes the form of the figure 8. The *Holstein* churn is upright and rigid. Its dashers, which are attached to a perpendicular shaft, are worked at high speed. This enables the operator to reduce the temperature of the cream by nearly 10° F., as compared with the temperature at which it is put into an ordinary churn. Churning is then done in summer at 50° F., which gives the resulting butter-product much greater firmness and a better texture.

Chutney, an East Indian condiment, very largely used in India, and to a considerable extent in Britain. Indian chutney is a compound of mangoes, chillies or Capsicum (q.v.), and lime-juice, with some portion of other native fruits, such as tamarinds, &c., the flavour being heightened by garlic. It is sometimes manufactured for sale in England. Families occasionally make it for their own use, and employ the following ingredients: Chillies, 1 to 1½ lb.; apples, 1 lb.; red tamarinds, 2 lb.; sugar-candy, 1 lb.; fresh ginger root, 1½ lb.; garlic, ½ to ¾ lb.; sultana raisins, 1½ lb.; fine salt, 1 lb.; distilled vinegar, 5 bottles.

Chyle, CHYME. Food, having been partially digested and absorbed in the stomach, is then passed on into the small intestine. It is of a pulpy consistency, and is termed *chyme*. Both digestion and absorption continue in the small intestine (see DIGESTION). Of the digested chyme a portion finds its way directly into the blood-vessels of the intestine. Nearly all the fat, however, passes into a special system of Lymphatics (q.v.) termed *lacteals*. These lacteal vessels lie in the walls of the intestine, and, during the fasting condition, are filled with a watery-looking fluid called lymph, which exudes from the neighbouring blood-vessels. During absorption, however, the lacteals, in addition, become filled with the absorbed fat which is in a state of minute subdivision. This gives the *chyle*, as it is now termed, a milky appearance. The lacteals convey the chyle into a large vessel, the thoracic duct, which finally conducts it into the large veins at the root of the neck, where it mixes with the blood. One may observe the lacteals on opening the abdomen of an animal killed some few hours after a full meal containing fat. When filled with chyle they resemble white threads branching in the substance of the mesentery—a membrane stretching between the intestine and the back of the abdomen. Microscopically chyle consists of a fluid containing minute fat-globules and a few corpuscles, similar to white blood-corpuscles. Chyle is alkaline in reaction, and coagulates when withdrawn from the body. It may be looked upon as lymph plus the fat which has been absorbed. It contains (1) Proteids, such as serum-albumen, serum-globulin, and fibrinogen. Fibrin is formed during the process of coagulation. (2) Fats—palmitin, stearin, olein, and also cholesterin and lecithin. (3) Extractives, notably urea and grape-sugar. (4) Salts, especially sodium-chloride.

Cicatrisation (Lat. *cicatrix*, 'a scar'), the process of healing or skinning over of an ulcer or broken surface in the skin or in a mucous membrane, by which a fibrous material of a dense resisting character, covered by a protecting layer of epithelium, is substituted for the lost texture. The new tissue in such a case is called the cicatrix, and usually resembles to a considerable extent the structure which it replaces; it is, however, less elastic, and from its shrinking in volume may produce an appearance of puckering. This shrinking sometimes leads to serious results, especially after extensive Burns (q.v.). The glands and other special structures of the original tissue are wanting in the cicatrix, which, however, performs perfectly well, in most instances, the office of protection to the parts below the surface. See INFLAMMATION and ULCERATION.

Cinnabar, an ore of mercury, from which almost all the mercury of commerce is obtained. Chemically it is a sulphide of mercury containing 86·2 parts of mercury and 13·8 of sulphur. It occurs both crystallised and massive, not unfrequently disseminated. Its crystals are six-sided prisms. It varies from perfectly opaque to almost transparent; has an adamantine, almost metallic lustre, and a carmine colour, with a bright scarlet streak. Its specific gravity is 8 to 8·2. *Hepatic Cinnabar*, so called from its liver-brown colour, is a variety containing a little carbon. Cinnabar sometimes occurs in primitive rocks, but more frequently in those of the coal formation. The cinnabar mines of Almaden, in Spain, have been worked for about 2300 years, and have been surpassed in productiveness by those of New Almaden in California. Cinnabar mines exist also in Idria, Germany, Hungary, Peru, China, and Japan. Cinnabar is used as a pigment under the name of *Vermilion*.

Cinnamic Acid, $C_6H_5CH = CHCOOH$, exists in the free state in the balsams of Tolu and Peru, in liquid storax, and in gum benzoin. When oil of cinnamon (see below) is exposed to the air, it absorbs oxygen and deposits crystals of cinnamic acid. Cinnamic acid forms colourless crystals readily soluble in alcohol, ether, and boiling water, but sparingly soluble in cold water. It is not of any importance in the arts, and is chiefly interesting as being the acid corresponding to oil of cinnamon. This oil is the aldehyde of cinnamic acid, and is represented by the formula $C_6H_5CH = CHCOH$. Although isomeric with oil of cassia, it has a slightly different flavour, and is much more expensive. Both of these oils are employed in medicine as aromatic stimulants, but chiefly as pleasant adjuncts to disguise the taste of nauseous drugs. From a chemical point of view, the cinnamic acid and oil of cinnamon are related to Benzoic Acid (q.v.) and Oil of Bitter Almonds (q.v.). Benzoic acid is regarded as C_6H_5COOH, while the oil of bitter almonds is the corresponding aldehyde C_6H_5COH. On oxidation cinnamic acid is changed into benzoic acid.

Circle, MAGIC, a space in which sorcerers were wont to protect themselves from the fury of the evil spirits they had raised. This circle was usually formed on a piece of ground about nine feet square (in the East seven feet appears to have been considered sufficient), in the midst of some dark forest, churchyard, vault, or other lonely and dismal spot. It was described at midnight in certain conditions of the moon and weather. Inside the outer circle was another somewhat less, in the centre of which the sorcerer had his seat. The spaces between the circles, as well as between the parallel lines which inclosed the larger one, were filled 'with all the holy names of God,' and a variety of other characters supposed to be potent against the powers of evil. Without the protection of this circle, the magician, it was believed, would have been carried off by the spirits, as he would have been had he by chance got out of the charmed space. Another figure which, described upon the ground, could bar the passage of a demon, was the *pentagram*. Readers of *Faust* will remember its effect upon Mephistopheles.

Circulation, in Anatomy and Physiology, is the term used to designate the course of the blood from the heart to the most minute blood-vessels (the Capillaries, q.v.), and from these back to the heart. To simplify the consideration of the subject, we shall consider—(I.) the General Anatomy, (II.) the Comparative Anatomy, (III.) the Physiology, and (IV.) the History.

I. The organs of circulation consist of the heart, arteries, veins, and capillaries. The course of the blood through these organs will be best elucidated by the aid of a diagram, which is equally applicable for all other mammals as well as for man, and for birds. The dark parts of fig. 1 represent the course of the impure or venous blood, while the lighter portions represent the course of the pure or arterial blood. Two of the four chambers of the heart (A and C) receive the inflowing blood, and are termed the *auricles;* while the other two chambers (B and D) drive the blood to the lungs and to the general system respectively, and are termed the *ventricles.* The vessels that bring blood to the auricles are termed *veins,* and the vessels through which the blood is driven from the ventricles are known as Arteries (q.v.). We will now trace the course of the blood, as indicated by the arrows of the diagram, commencing with the right auricle, A. The right auricle contracting upon the venous or impure blood with which we suppose it to be filled, drives this into the right ventricle, B, through an opening guarded by a triple (or tricuspid) valve, which almost entirely prevents the regurgitation of the blood from the ventricle into the auricle. The ventricle, B, being now filled, contracts, and as the blood cannot return into the auricle, it is driven along the dark vessel, *c*, which is the pulmonary artery, conveying the blood *to* the lungs. At its commencement it is guarded by crescent-shaped (semilunar) valves, which entirely prevent the blood which has once been propelled into the pulmonary artery from re-entering the ventricle. The pulmonary artery gradually divides into smaller and smaller branches, which ultimately emerge into capillaries freely distributed over the interior of the air-cells of the lungs. There the blood gives off carbonic acid gas, and absorbs oxygen, becoming thereby 'pure.' The capillaries, in which the blood is purified, gradually unite to form larger vessels, and finally the blood is collected into the pulmonary veins, which pour their contents into the left auricle, C. Thence it is propelled into the left ventricle, D, through an opening guarded by a double (mitral or bicuspid) valve, which entirely prevents the reflux of the blood. The left ventricle contracts and drives its contents into the large artery, *e*, or Aorta (q.v.), which by means of its various branches supplies the whole body with pure blood. From the aorta and its various subdividing branches the blood passes into the capillaries, J, H, which occur in every part of the system. In these capillaries it parts with its oxygen to the tissues, and becomes charged with the waste carbonic acid gas. The capillaries unite into larger veins, and these gradually unite to form two large trunks, *a*, *b*, the superior and inferior *venæ cavæ*, which pour their contents into the right auricle—the point from which we started. The diagram also shows how the venous blood from the viscera, G, instead of passing directly into the vena cava, goes through the liver, F, in what is known as the hepatic-portal system.

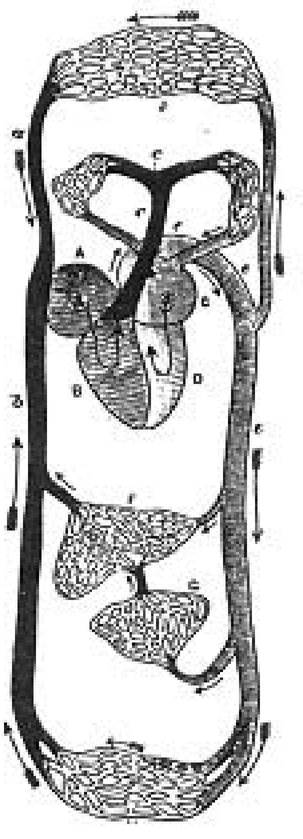


Fig. 1.—Diagram of Circulating System (from Leunis).

Before passing to the comparative study of the circulation, we must notice a few of the above facts in greater detail. The Heart (q.v.) is described in a separate article. Since all the arterial blood leaves the heart through the aorta, to trace the circulation of the pure blood involves following the branches of that great vessel. For this see AORTA. It is sufficient, without further anatomical details, to say that the ramifications of the arteries distribute the arterial blood to the Capillaries (q.v.) which pervade every part of the body. It is already evident that the pulmonary arteries from the right ventricle carry impure blood to the lungs, and that pure blood returns from the lungs to the left auricle by the pulmonary veins.

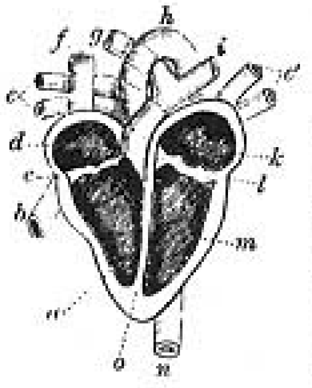

Fig. 2.—Theoretical Section of the Human Heart:

f, *b*, the two *venæ cavæ*, opening into *d*, the right auricle; *c*, the tricuspid valve; *a*, the right ventricle, from which proceeds the pulmonary artery, dividing into branches *g* and *i*, going to the right and left lung respectively; *e*, *e'*, the pulmonary veins (two from either lung), entering into the left auricle, *k*; *l*, the mitral valve; *m*, the left ventricle, from which proceeds the aorta, whose arch is indicated by *h*, and the descending portion by *n*, none of its branches being indicated in this figure; *o*, the partition, or *septum*, between the right and left hearts.

The *veins*, like the arteries, are found in nearly every tissue; they commence in minute networks which communicate with the capillaries. Branches from these networks uniting together, form veins, which, by joining, increase in size as they pass onward towards the heart. If we except certain venous structures (called *sinuses*) occurring in the interior of the skull, we may divide the veins into two sets—the *superficial* or *cutaneous*, and the *deep* veins. The deep veins accompany the arteries, and are usually inclosed in the same sheath of tissue. In the case of the smaller arteries they generally exist in pairs, one on each side of the artery, while the larger arteries have usually only one accompanying vein. The superficial veins occur immediately beneath the integument; they not only return the blood from the skin and adjacent structures, but communicate with the deep veins. All the veins finally lead by two large trunks, the *superior* and *inferior vena cava*, into the right auricle of the heart. The superior vena cava is formed by the union of the veins from the head and neck (the jugulars) with those from the arms (the subclavians), while the inferior vena cava brings back the blood from the lower extremities, the trunk, and the viscera.

We must refer to the article VEIN for the structure of the walls of this part of the circulatory system. There is only one point that imperatively requires notice here—viz. that while the arterial system presents no valves except at the points where the two great trunks leave the heart, the veins contain a great number of valves, which are formed by a doubling of their lining membrane, and resemble pocket-like folds or pouches, which allow the blood free passage toward the heart, but prevent its reflux. The veins are much less elastic than the arteries, and their total capacity is much greater.

There is one part of the venous circulation which, from its great importance, requires special notice—viz. that of the spleen, pancreas, stomach, and intestinal canal. The blood supplied to these organs by the cœliac and the two mesenteric arteries is not returned directly to the inferior vena cava, but passes by several veins into one large vessel—the portal vein, which enters the liver, and breaks up into a capillary network. There the blood undergoes important changes associated with the bile-secreting and glycogen-forming functions of the liver. The blood, entering the liver from two sources, from the portal vein and from the hepatic artery, leaves it by the hepatic veins, which join the inferior vena cava. It is also important to notice the entirely distinct set of vessels known as lymphatics, which conduct the products of digestion into the veins (see LYMPH).

The above-described double circulation (through the lungs and through the body) is exhibited by the blood from the time of birth during the whole period of life. The circulation of the blood, however, begins before birth—indeed, at a very early period of intra-uterine or fœtal existence; and the circumstance that before birth the lungs do not act as organs of respiration induces a very important modification in the course of the blood in fœtal life which will be described under FŒTUS.

II. *Comparative.*—The circulatory system in man, as above described, may serve as type of the highest development, differing but slightly from that of other mammals, or that of birds. It is convenient now to begin at the other end, and to note briefly the salient steps of progress in the gradual evolution of the system throughout the animal series. In the unicellular animals the movement of the protoplasm and the special activity of 'contractile vacuoles,' represent, to some extent at least, a circulatory function before the appearance of any system. The canals which so completely irrigate a sponge, likewise illustrate in low expression a circulatory system not yet separated off from the others. In Cœlenterates, too, the system is still unseparated: 'gastro-vascular' prolongations of the alimentary cavity penetrate the body, as may be very well seen in the disc of a common jelly-fish. In the lower worm-types also, where no distinct body-cavity is yet developed, the nutritive fluid simply diffuses through the body, and no vascular system is differentiated. But in higher worms there is generally a body-cavity, and with it the gradual appearance of a definite vascular system. In some we simply find a fluid moving in the body-cavity, occasionally clear, usually with corpuscles; in others, portions of the body-cavity are separated off as blood-spaces, or eventually as blood-vessels; these may remain in connection with the general cavity, or may at length form a closed system. The manifold worm-types afford abundant illustration of all the stages in this differentiation. In the bristle-footed worms (Chætopods, q.v.), and in some others, the perfecting of the blood-driving mechanism may be instructively traced. Often a dorsal vessel is diffusely contractile, less frequently the ventral; or there may be contractile connecting loops between dorsal and ventral vessels, as in the earthworm; or lastly, a special region in the dorsal vessel may become the main seat of the vascular contractility. Such a *dorsal* heart is found from this point onwards throughout the Arthropods and Molluscs. (The well-developed and very difficult vascular system of Echinoderms, which co-exists with an abundant body-cavity fluid with relatively few corpuscles, has no special interest for this general survey.) In crustaceans, the dorsal heart, usually inclosed in a special space or 'pericardial sinus,' drives blood by more or less well-developed arteries through the body. The rest of the system is best described as lacunar. The venous blood passes along body-cavity spaces to the gills for purification, thence returns to the pericardial sinus, and entering the heart is redistributed. In insects a chambered dorsal heart, inclosed in a sinus as before, drives the blood forward, but as one would expect from the very efficient respiratory apparatus, the general vascular system is but slightly differentiated. The blood, purified by diffusion from the everywhere present air-tubes, passes back by venous channels into the sides of the pericardium and heart. In myriapods, scorpions, and king-crab, the system is more definitely developed, but illustrates no new advance except that of more complete establishment and wider extension of vessels. In molluscs, however, some progress is observable. Except in the Elephants' Tooth Shell (Dentalium), a heart is present, and the arterial system is often very well developed, even to the extent of capillaries in some cuttle-fishes and snails. Usually, however, the venous blood travels along lacunæ, though gradual transitions occur between these and true veins. The blood purified in the gills or pulmonary chamber passes back into a special portion of the body-cavity—the pericardium, and thence into the heart. In certain worm-types, several contractile lateral vessels may often be observed to enter the dorsal vessel; in the Pearly Nautilus, which has four gills, four efferent vessels dilating into four indistinct auricles, enter the median dorsal heart or ventricle; in almost all bivalves the entrant dilatations or auricles are reduced to two, one on each side; while in most Gasteropods and Pteropods the specialisation has gone further, and the heart consists of a single auricle and a thicker muscular ventricle. The latter drives the blood through the body by a single or double aorta.

Passing now with equal brevity through the vertebrate series, we notice first that the heart arises as a dilatation no longer of a dorsal, but of a *ventral* vessel. Up to and including amphibians, the heart begins as a specialisation of the 'sub-intestinal vein' in the throat region; in most, if not all higher vertebrates, it arises from the fusion of two vessels. It always lies in a pericardial sac.

(1) Among the degenerate Tunicata there is considerable variety in the vascular system. In one case no heart is present; in several there are no definite vessels or blood-corpuscles. The main point, however, is that in most cases a tubular ventral heart drives blood to the respiratory pharynx. In all cases where the heart has been observed, the direction of its beats has been seen to undergo reversal at regular short intervals, a phenomenon which has also been noticed as a rarity in certain worm-types.

(2) The vascular system of the lancelet or amphioxus is of a peculiarly diffuse and undifferentiated nature. It has in one sense no heart, in another sense many; for while there is no main centre of contractility, there are small pulsating dilatations at the bases of the vessels passing to the gill-slits, while the portal vein and ventral vessel in the anterior pharyngeal region are both said to be contractile. In general course, the circulation is like that of a fish; the blood passes from ventral vessel to respiratory region, thence to dorsal aorta, thence to body, thence by united sub-intestinal veins to the liver cæcum, and thence to the ventral vessel from which it started.

(3) In the Round Mouths (Cyclostomata) the typical fish-circulation is established. The muscular ventricle drives the blood by a ventral vessel ('ventral aorta') to the gill-sacs; thence the purified blood is gathered into efferent dorsal vessels, which form in uniting the 'dorsal aorta.' The latter gives off branches to the greater part of the body, the head-region being directly supplied from the anterior efferent branchials. The blood returns from the anterior and posterior regions into a uniting vessel behind the heart ('the *sinus venosus*'), thence into the receiving auricle, and from that to the muscular ventricle.

(4) It is enough after the above to notice in regard to the fishes proper, that with the exception of the double-breathing mud-fish (Dipnoi), the heart never contains anything but impure blood, that it drives this wholly to the respiratory organs, and is in no direct degree 'systemic.' The 'dorsal aorta' supplying most of the body is formed from the union of efferent branchials, and does not arise, as in higher vertebrates, from the heart. It is important to notice that the five or so arches which spring from the ventral aorta are almost all quite alike, and arise (except in Dipnoi) at slight intervals from one another. A great part of the differentiation in higher vertebrates obviously concerns these aortic arches, which are seen in Cyclostomata and fishes in primitive uniformity, but become modified in higher vertebrates into the carotids, sub-clavians, aortic arches, and pulmonary arteries. The heart of a fish consists of the *sinus venosus* or general junction, running transversely behind the heart (persisting hence onwards, except in adult birds and mammals), of the auricle and ventricle, and except in Teleostei of a specialised contractile portion of the latter known as the *conus arteriosus*. A dilatation of the beginning of the ventral aorta is distinguished as the *bulbus arteriosus*. In regard to the general system, it is worth noticing that in fishes (as in amphibians and all reptiles except Chelonians) there is a renal portal, as well as an hepatic portal system. Veins from the caudal region of the fish come into the same relations with the kidneys as the portal veins do in regard to the liver. The hepatic veins returning from the liver do not unite with the other posterior veins, but enter the *sinus venosus* independently. Thus fishes have no *inferior vena cava*. (4*a*) The Dipnoi are interesting as leading on to amphibians. The heart receives pure as well as impure blood, drives blood to lungs in addition to gills, is in part systemic (driving pure blood in Protopterus and Lepidosiren through the first two pairs of arches), has the roots of the aortic arches close together, and is practically three-chambered. In these respects it reaches forward to the condition seen in those amphibians which retain their gills.

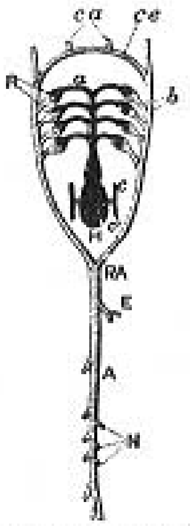

Fig. 3.—Arterial System of Fish:

H, heart; *c* and *c′*, anterior and posterior cardinal veins; *a*, branchial arteries; R, capillaries of the branchial vessels; *b*, branchial veins; *cc*, head circle; *ca*, carotids; RA, root of the aorta; A, dorsal aorta; E, artery to viscera (cœliaco-mesenteric); N, renal arteries. (After Wiedersheim.)

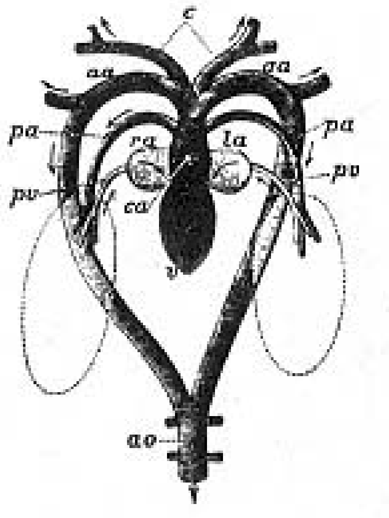

Fig. 4.—Arterial System of Amphibian:

ra, right auricle; *la*, left auricle; *v*, ventricle; *ca*, conus arteriosus; *c*, carotid arteries; *aa*, aortic arches; *ao*, dorsal aorta; *pa*, pulmonary artery; *pv*, pulmonary vein; *ra* receives venous blood from body; both the pulmonary arteries enter *la*. (After Nuhn.)

(5) The heart of amphibians is three-chambered, a right auricle receiving impure blood from the body, a left auricle receiving purified blood from the lungs or from the lungs and gills, a single ventricle which drives the blood, mingling less than might be supposed, to head or body or respiratory organs. In some cases, as one would expect, the partition between right and left auricle is imperfect. In the tadpoles at the fish-like stage there are four aortic arches, of which the first three supply gills. Where gills persist, such supply is always of course in some degree maintained. In such a metamorphosis as that of the frog, where all trace of gills is lost, the first branchial arch becomes the carotid; the second is the systemic, which forms, by uniting with its fellow, the dorsal aorta; the third dwindles away; the fourth supplies the lungs.

The same is generally true of the higher vertebrates, except that it is usually the third branchial which forms the pulmonary artery. An inferior *vena cava* is definitely established in amphibians; there is a renal portal as well as an hepatic portal system; special lymph hearts are sometimes present connecting the lymph system with the vascular.

(6) Among the reptiles, the differentiation of the heart goes a step further. In Chelonians, Lacertilia, and Ophidia, a strong muscular ridge forms an incomplete partition, dividing the ventricle into a right portion containing purely venous blood, and a left portion containing mixed and arterial blood. The pulmonary artery rising from the right cavity takes purely venous blood to the lungs; of the two aortic arches rising from the left cavity, the left aorta contains more venous than arterial blood, the right aorta more arterial than venous. In Crocodilia, however, there is a complete septum in the ventricle, and thus for the first time a four-chambered heart, though it is not certain that the division is exactly comparable to that of birds and mammals. From the right or venous ventricle rise the pulmonary artery and left aortic arch (taking venous, not mixed, blood to the viscera); from the left or arterial ventricle rises the right aorta, with pure blood to the greater part of the body. Though the division of arterial and venous chambers brings the crocodilian heart to the bird or mammal level, there are two aortic arches, one venous, the other arterial, which unite as usual, and also communicate by a foramen at their roots. In all reptiles there are two superior *venæ cavæ*, an inferior *vena cava* formed from the union of the two efferent renals, and a renal portal system except in Chelonia. In birds and mammals a single aortic arch forms the dorsal aorta, not two or more as in reptiles. In birds the aorta goes to the right, in mammals to the left, but except in this variation and in the structure of the Heart (q.v.), the circulation in Birds (q.v.) and mammals (*supra*) is practically identical.

III. *Physiology.*—The most important conditions of circulatory function are (1) a general constancy and rapidity of flow, and (2) a power of adapting this to special needs. The conditions of the former are mainly mechanical and physical—those of the latter depend upon the nervous system.

(1) *The Mechanism of Circulation* chiefly depends upon the rhythmic contractility of the heart, the elasticity of the vessels, and the friction in the small arteries and capillaries. The heart is a muscular pump contracting under the influence of its automatic nervous mechanism, but also responding in the nature of its beat to the conditions of the body. The human heart usually beats about seventy-two times a minute, and in the eight-tenths of a second occupied by each beat, three distinct events occur—the contraction (*systole*) of the ventricles, a 'passive interval' of relaxation (*diastole*) of both auricles and ventricles, and the decidedly briefer contraction of the auricles. The pumping action of the heart is thus obviously an intermittent force which drives the blood through the closed series of elastic tubes formed by the blood-vessels. To the latter attention must now be directed.

The *arteries* are surrounded by muscular tissue, and are contractile as well as highly elastic. As they break up into branches from the aorta to the capillaries, the capacity for holding blood is continually increasing. The flow of blood within them, though continuous, comes in gushes corresponding to the heart-beats. The velocity of the stream is greatest the nearer the heart. The *veins* are much less elastic than the arteries, and have a much greater total capacity for holding blood. As they unite from the capillaries to the venæ cavæ, the total capacity is continually diminishing. The flow of blood within them is continuous, but with relatively little force and small velocity. The *capillaries* have a very small calibre, but are both elastic and contractile. They are permeable by fluids, and also allow the corpuscles to pass through their walls. The velocity of the flow is here at its minimum. The resistance to the flow of blood, due to the friction of these minute passages, works back along the arterial system to the heart, and is one of the most important factors in determining the nature of the circulation.

To return now to the actual mechanism, it is only necessary to note (*a*) that the whole system is always over-filled with blood, which consequently causes a pressure on the walls; (*b*) that the cause of the circulation is the difference of pressure between the blood in the aorta and pulmonary arteries on the one hand and the venæ cavæ and pulmonary veins on the other; (*c*) that this difference of pressure is due to the contraction of the heart; and (*d*) that the interrupted current, which would naturally arise from the intermittent action of the heart, becomes continuous because of the rapidity of the beats, the resistance in the small arteries and capil-

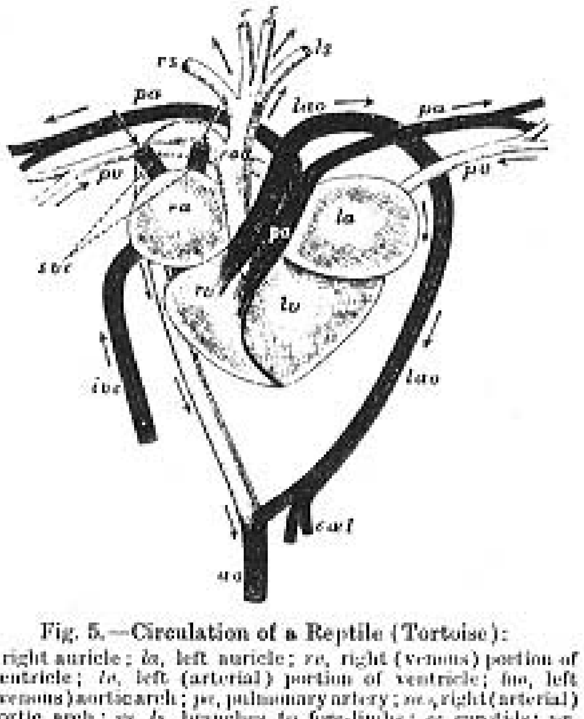

Fig. 5.—Circulation of a Reptile (Tortoise):

ra, right auricle; *la*, left auricle; *rv*, right (venous) portion of ventricle; *lv*, left (arterial) portion of ventricle; *lao*, left (venous) aortic arch; *pa*, pulmonary artery; *rao*, right (arterial) aortic arch; *rs*, *ls*, branches to fore-limbs; *c*, carotids; *pv*, pulmonary veins; *svc*, superior venæ cavæ; *ivc*, inferior vena cava; *ao*, dorsal aorta; *cœl*, cœliac artery to viscera. (After Nuhn.)

laries, and the elasticity of the arterial walls.

(2) *The Control of the Circulation.*—The phenomena referred to above are mainly physical and mechanical, and in their essential features can be readily reproduced on a model. But in a complex living organism there is a constant necessity for modifiability. The organs vary in their requirements, and the external conditions are frequently changing. Modifications in the circulation are brought about by changes in the heart's beat, and in the calibre and resistance of the small arteries. Both these changes are under the direct control of the Nervous System (q.v.). Modifications of less importance also occur in the capillary resistance and in the total quantity of blood; but the important point is simply the general fact that the requirements of the organism are met by the dominion of the nervous system over the circulation.

IV. *History.*—Aristotle and the ancients thought of the heart as a blood-fountain, but had no conception of circulation. Galen (131-201) disproved the prevalent notion that the arteries contained air, Calvin's contemporary Servetus demonstrated the pulmonary circulation, and various physiologists had a distinct notion of the centrifugal flow. In 1628 William Harvey published his *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus*, in which his discovery of the real nature of the circulation was expounded. Soon after, the use of the microscope revealed to Malpighi (1661) and Leeuwenhoek (1674) what Harvey had been unable to trace—the capillary connection between arteries and veins. Since those days the detailed problems of circulation, the hydraulic mechanism, the action of the heart and its valves, and the nervous control have been worked at by many of the greatest physiologists.

Citric Acid, $H_3C_6H_5O_7$, is the acid to which lemon and lime juice owe their sourness. It also occurs, in some cases along with tartaric acid, in oranges, cherries, currants, gooseberries, and other fruits having a subacid taste. For practical purposes it is always obtained from lemon, lime, or bergamot juice, which contain it in large quantity. The first named of these contains from 20 to 40 grains of citric acid in each fluid ounce.

Citric acid is prepared from these juices by a very simple process. The juice having been heated to the boiling-point to clarify it from albumen, mucilage, &c., is mixed with chalk, $CaCO_3$, which, combining with the citric acid, falls to the bottom as citrate of calcium. The supernatant liquid being drawn off, sulphuric acid is added to the precipitate, decomposing it, with the formation of citric acid and sulphate of lime, $CaSO_4$. By crystallisation it may be obtained pure in the form of colourless, odourless prisms, which effloresce in dry air, and possess an agreeable acid taste and an acid reaction. It is readily soluble in water and alcohol, but almost insoluble in ether and chloroform. A solution of it in water cannot be kept owing to its tendency to ferment. Dissolved in syrup it keeps much longer, and is used largely in the manufacture of lemonade and other aerated beverages, communicating an acid, fruity taste. When heated, the crystals melt, then decompose, and are finally reduced to a combustible form of charcoal. In addition to its employment as a flavouring agent it is largely used in the manufactures. Calico-printers employ it for discharging the mordant from the cloth in patterns, and it is used in dyeing silk with safflower, &c.

Citric acid may also be prepared artificially, but the process is too complex ever to come into practical use. Chemically it is of great interest as exemplifying that as soon as the chemical constitution is known there is a possibility of producing the substance artificially. There is a popular idea that some day quinine, morphia, and other natural products will be formed by the random mixing together of chemicals in the chemist's beaker, but the first step towards this result must be the knowledge of their constitution, to be followed by a series of careful experiments.

Citric acid is a powerful tribasic acid (see ACIDS), and the solution in water readily dissolves zinc and iron. It forms a class of salts called Citrates, many of which are employed in medicine.

The so-called *Citrate of Magnesia*, a granular substance, which effervesces on the addition of water, and is very popular as a gentle aperient, is not really a citrate at all, but consists of a mixture of tartaric and citric acids, bicarbonate of soda, and sugar, with perhaps a trace of some magnesium salt to justify the name. The granulating is effected by mixing the powders and placing them in a pan heated by steam, when, in proportion to the citric acid present, the powders run together into a pasty mass. This is forced through a coarse riddle, and the granules are dried by a gentle heat.

Citrate of Potash, $K_3C_6H_5O_7,H_2O$, is prepared by neutralising citric acid with bicarbonate of soda. It forms a white, granular, deliquescent powder, which acts as a cooling diaphoretic in cases of fever. Dissolved in lemon-juice it is of much value in rheumatism. It is given in doses of 20 to 30 grains.

Citrate of Ammonia can only be obtained in solution, as when this is evaporated decomposition takes place and ammonia escapes. It is employed, like the potash salt, in febrile diseases.

Citrate of Iron and *Citrate of Iron and Quinine* are but examples of a large number of compounds obtained in the form of brown or greenish-brown scales which are largely used in medicine. In these the medicinal value lies not in the citric acid, but in the iron or quinine with which it is associated, although the acid has doubtless a subsidiary action. A peculiarity about these 'scale preparations,' as they are called, is that the inky taste, so characteristic of iron in the form of steel drops, is in great measure removed. Citric acid also forms a series of organic salts called citric ethers, of which citrate of ethyl is an example. Lemon-juice, in which citric acid is the most active ingredient, is a most valuable medicine in scurvy, and when it cannot be obtained the acid may be used as a substitute. Citric acid in solution does not, however, appear to be nearly so effective as the juice itself.

Clarification is the process of clearing a fluid from a turbid condition, as in the case of Beer (q.v.), or in the action of gelatin in fining British wines. Natural waters containing much organic matter in mechanical suspension and in chemical solution are clarified by the addition of a little alum, which is precipitated with the organic matter, and the water then becomes healthy and refreshing. Liquids are often clarified by straining through several layers of cloth, or through sand or charcoal. The use of the Clearing Nut (q.v.) for clarifying water is general in India. A very interesting and useful method of clarification is that in which a 'centrifugal' is employed. This consists of a circular vessel provided with an outlet in the centre and also at the circumference, and which is so constructed as to be capable of being made to revolve at a very high speed. When the muddy liquid is placed in the vessel, and the whole caused to revolve, it is found that the particles of dust, mud, or other matter fly to the circumference, leaving the liquid in the centre practically clear. By suitable arrangements the clear liquid can be drawn off.

Coagulation, the amorphous (q.v.) solidification of a liquid, or part of a liquid, as when the casein of milk is solidified by rennet in making Cheese (q.v.); or the white of an egg by boiling. The process varies in various substances. Albumen, or the white of an egg, coagulates at a temperature of 160°. Milk is coagulated or curdled by the action of rennet or by acids. The fibrin in the blood, chyle, and lymph of animals is coagulated by the separation of these fluids from the living body.

Coal-tar, or GAS-TAR, is a thick, black, opaque liquid, which comes over and condenses in the pipes when coal or petroleum is distilled. Now usually obtained in the manufacture of gas, tar was about 1782 extracted from coal by the ninth Earl of Dundonald under a patent, expressly for the purpose of being used for protecting ships from rotting. Coal-tar is slightly heavier than water, and has a strong, disagreeable odour. The amount of tar so obtained of course varies with the nature of the coal employed, but it is also dependent on the average temperature of distillation. With a low temperature, a large quantity of tar is produced, along with a small yield of a highly illuminating gas. At first this tar was regarded as a waste product, or, at most, as a source of pitch; but it soon became apparent that as a source of Benzene (q.v.), and through it of the Aniline Dyes (q.v.), it was a commodity of great commercial value.

When coal-tar is distilled, a large number of volatile substances pass over as the temperature rises higher and higher. At first various gases, ammonia and naphtha, are obtained to the extent of about [illegible]th part of the original tar, and then distillation ceases, although the temperature gradually rises. After a period of about an hour, more oils, like the former, lighter than water, are obtained, and so on the distillation proceeds, with successive intervals, yielding what are known as Creosote oils, and finally Anthracene oils, the residue in the still being pitch.

At first, when anthracene was of little importance, distillation was not pushed so far, and the anthracene oils were allowed to remain in the pitch; but since the discovery of the process for making artificial Alizarin (q.v.), the heat is pushed as far as possible consistent with the production of a pitch that will sell. The first light oils yield chiefly benzol, carbolic acid, and naphtha. The creosote oils yield creosote and naphthaline, while the anthracene oils produce anthracene and lubricating oils.

After this enumeration of the chief coal-tar products, it will be possible to realise the great importance of this substance. The naphtha, besides being used as a solvent for india-rubber and gutta-percha, is burned to produce a fine variety of carbon for printing-ink. The benzol, including in this term many nearly allied substances, not only yields many brilliant dyes, but is used for cleaning gloves, silks, &c., and other articles which would be injured by washing. The creosote in its crude form is largely used for preserving wood, enabling it to be exposed in damp situations without rotting, while, when burned, its smoke yields lampblack. The naphthaline, besides being a source of many dyes, is employed in the Albo-carbon light to give to ordinary coal-gas very high illuminating power. Finally, the residual pitch is in constant requisition for making roofing felt and asphalt pavement. Besides these primary products of coal-tar, there are of course numerous compounds derived more or less remotely from it. Such are the aniline dyes, the quinine substitutes, antipyrin, antifebrin, &c., and the sweetening substance, Saccharine (q.v.), which may be used to replace sugar in many cases.

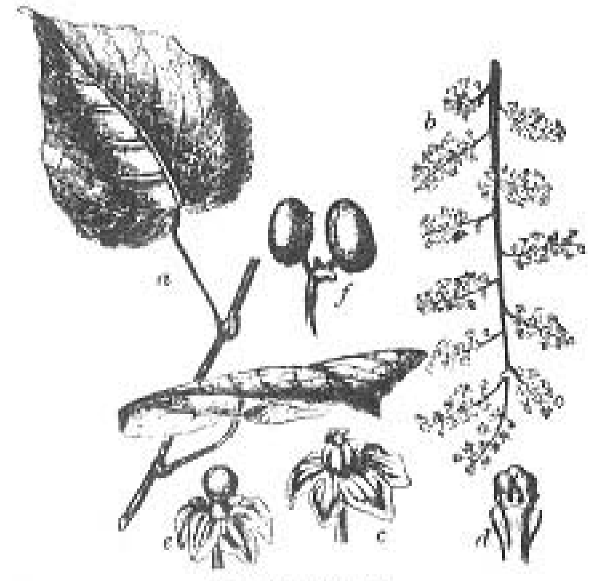
Co'ca (*Erythroxylon Coca*—which has of course no connection with Cocoa or with Cocoa-nuts), a shrub of the order Erythroxylaceæ, of which the leaves furnish an important narcotic and stimulant. The shrub is 6 or 8 feet high, and somewhat resembles a blackthorn bush; the leaves are ovate-lanceolate, simple, and with entire and slightly waved margins, and strongly marked veins, of which two on each side of the midrib run parallel to the margin. It has been in use from a very remote period among the Indians of South America, and was extensively cultivated before the Spanish conquest. Many of the Indians of the Peruvian Andes are to this day excessively addicted to it, and its use is quite general among them, besides extending to men of European race. The dried leaves are chewed with a little finely powdered unslaked lime, or with the alkaline ashes of the Quinoa (q.v.), or certain other plants. An infusion is also occasionally used. An habitual coca-chewer takes a dose about four times daily. In soothing effect it recalls tobacco, but its influence is a much more remarkable one. It greatly lessens the desire for ordinary food, and at the same time permits of much more sustained exertion, even without sleep; it affects the nervous mechanism of respiration, so that the difficulty of breathing, so common in the ascent of long and steep slopes at high elevations, is little felt. These properties readily explain its high esteem among

Coca (*Erythroxylon Coca*): *a*, a flower; *b*, fruit.

the Indians, to whom long and difficult journeys, heavy burdens, and constant privation have always been familiar.

COCAINE.—In Europe, little importance was attached to coca until the veteran pharmacologist Christison awakened interest by personally verifying in old age its sustaining powers. Investigations followed, and the alkaloid *cocaine*, upon which the active properties mainly depend, has now come into regular use as a local anæsthetic, by help of which not merely some of the operations of dentistry, but much more serious surgical operations, can be performed without chloroform. To oculists it is of special value, at once dilating the pupil and removing all sensibility. Cases of intoxication and abuse are not infrequent with the leaves, and have been already recorded in connection with the more powerful extract.

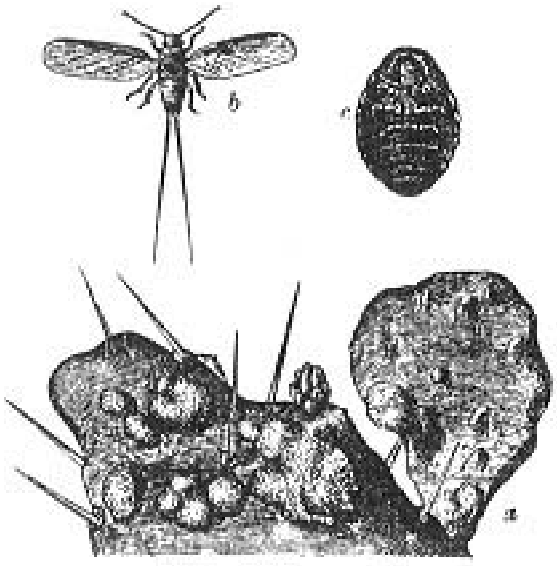
Coc'culus In'dicus (Ital. *coccola*, 'a berry') is the fruit of the *Anamirta paniculata*, a climbing shrub found in the eastern parts of India, and in the Malayan Archipelago. It was introduced into Britain in the 16th century for the purpose of stupefying fish so that they might be caught by hand. It acts as an acrid narcotic poison, and when the berries are thrown into a stream it quickly poisons any fish in the neighbourhood. It contains a crystalline principle called picrotoxine, which is very poisonous. It has often been asserted that as cocculus indicus imparts to beer a bitter taste, and at the same time a fullness and apparent richness, it is largely used in the manufacture of that beverage. As its effects are very deleterious, considerable attention was directed to the point, but no evidence is as yet forthcoming to substantiate the statement. In 1876 the report of the Laboratory Department of the Inland Revenue stated that in no case were the officers of the department able to detect it either on the brewer's premises or in the beer itself. Of the large quantity imported into England, nearly the whole is re-exported to the Continent. In Russia and elsewhere it is a popular remedy for tapeworm, lice, &c.; but when applied to the scalp it is not unattended with danger, as several deaths have occurred from its use.



Cocculus Indicus:
a, branch with leaves; *b*, panicle of female inflorescence; *c*, a female flower; *d*, the same with sepals removed; *e*, male flower; *f*, fruit. (From Bentley & Trimen.)

Cochineal, a dyestuff employed in dyeing scarlet and crimson, and in the preparation of the pigments Carmine and Lake (q.v.).

Cochineal consists simply of the bodies of the females of a species of Coccus (q.v.), called *C. cacti*, because it feeds upon plants of the Cactus family, particularly on one, therefore designated the cochineal plant, but known in Mexico as the Nopal (*Opuntia coccinellifera*), figured in the article CACTEÆ. This plant is nearly allied to the prickly pear, and assumes a somewhat tree-like form. The insect as well as the cactus are natives of Mexico and other warm parts of America, but they are now cultivated chiefly in Guatemala. This cultivation was carried on by the Mexicans long before the country was known to Europeans. The insect is not uncommon on wild cacti in Texas and Florida. Both plant and insect have been successfully introduced into the Canary Islands, Algeria, Java, and Australia. But the attempt to produce cochineal in India has been practically a failure.



Cochineal (*Coccus cacti*):
a, living on cactus (*Opuntia*); *b*, male; *c*, female.

The cochineal insect is a small creature, a pound of cochineal being calculated to contain 70,000 in a dried state. The male is of a deep-red colour, and has white wings. The female, which is wingless, is of a deep-brown colour, covered with a white waxy powder; flat beneath, convex above.

In some parts of Guatemala large plantations of Nopal exist for the cultivation of the *C. cacti*. Before the rainy season commences, branches of this cactus plant covered with these insects are cut off and stored in buildings to protect them from the weather. When the wet season is over, four or five months afterwards (October), the plantations are again stocked from these supplies. Little 'nests' of some vegetable fibre, each containing about a dozen females, are placed on the spines of the cacti. The eggs are soon deposited, and when the young females are developed, they spread over the plants, attaching themselves to the leaves, and looking more like vegetable excrescences than insects. They become covered with a cottony substance. The first crop of pregnant females, only these being valuable for cochineal, is gathered in December, and several more crops are obtained till the following May.

In the Canary Islands the insects are reared in winter and put out on the cactus leaves from May to July. Small gauze bags containing pregnant females are hung on the cactus plants, from which the young when developed spread over the leaves. In August and September, just before the females are ready to deposit their eggs, they are collected in trays, and those gathered in one day are placed in the evening in an oven heated to 150° F. They are afterwards more thoroughly dried in the sun. Hot iron and boiling water are also used in killing the insects. According to the way the insect is killed and dried, the cochineal is known in commerce as silver or black; an inferior kind being sometimes called foxy. The colouring principle of cochineal is called cochinealin or carminic acid, and the insects scarcely yield more than 10 per cent. of pure dye, although the amount is generally supposed to be much greater. Carmine has also been demonstrated in other kinds of coccus and in aphides.

The cochineal industry has suffered very much through the introduction of aniline dyes.

Codeine, an alkaloid obtained from poppy-heads. See POPPY.

Cod-liver Oil is generally obtained from the livers of the common Cod (q.v.), but likewise from allied species, as ling, dorse, coal-fish, torsk, &c. In these fish the Adipose Tissue (q.v.) containing oil is almost entirely confined to the liver, in which they agree with the shark tribe, whilst in other fish, as in the herring and salmon, the oil is diffused over the entire structure of the animal. The supplies of medicinal cod-liver oil used to be derived mainly from Newfoundland, but Norway now supplies the bulk of that used in Great Britain. The most famous of the Norwegian fishing-grounds is that of the Lofoden Islands. On the outer shores of these islands immense shoals of fish begin to arrive in December, but owing to the storms to which the coasts are liable, only a comparatively small number of boats (some 800) engage in the fishing. Later on, in the beginning of January, the fish pass in between the islands and enter the calmer waters of the Westfjord to spawn. Then the fishermen, assembling in immense numbers, catch the fish by net or baited line. A good catch for a boat, with a crew of five men and a boy, is from 600 to 1200 fish; and some idea of the importance of this industry is obtained from the fact that in a single year these fisheries alone employed 4000 vessels, with a crew of 27,000 men, the catch amounting to 25,000,000 of fish. The fishing-grounds being near the shore, the fish are at once cleaned, and the livers removed. These may be treated in different ways, the various qualities of cod-liver oil being the result. The finest oil, known as 'non-freezing pale oil,' is obtained by warming the livers by means of steam heat, when the oil separates, and is either removed by straining or by allowing it to float to the surface. It is then cooled to 14° (– 10° C.), and filtered, either by mechanical pressure or in the usual way. A white tallow-like substance remains in the flannel filter, and a bright cod-liver oil passes through, which is now capable of being exposed to frost without turning turbid.

In the case of those fisheries which are situated at some distance from the shore, the livers are placed in tanks, till a sufficient quantity has been collected, with the result that partial putrefaction takes place. The oil obtained in this way is of a dark-brown colour, and possesses a nauseous empyreumatic taste.

A still coarser variety is manufactured for use in leather-making. In it the livers of the cod, herring, haddock, &c. are indiscriminately used, a very fishy-tasted oil being the result.

It will be seen from the above that the different varieties of cod-liver oil may be produced from the same livers. Thus, that obtained by pressure or steam heat from fresh livers is the freest from taste and colour, while the oil becomes darker and darker as the livers become less fresh. It has been supposed by some authorities that the dark-brown oil is the more efficacious, but others find no difference in actual practice, while the pale oil can alone be tolerated by delicate stomachs. Cod-liver oil mainly consists of oleic, stearic, and palmitic acids, in combination with glycerine. In addition to these, *gaduin*, a substance of biliary origin, but possessing no recognised medicinal virtues, is present along with iodine and bromine. Some have ascribed the virtues of cod-liver oil to the iodine or bromine, but as the iodine is only present in the proportion of 1 part in 2000 parts of the oil, this view seems untenable. Sometimes the oil is adulterated with spurious oils, to which iodine has been added, and this may be assumed if the proportion of iodine exceeds that stated above. There are unfortunately no chemical tests that can with certainty detect the presence of other oils, although there are tests which distinguish liver-oils from those of other origin. Thus with nitric acid, cod-liver oil yields a purple colour, changing to a brown; while a drop of sulphuric acid produces a violet colour, soon changing to brownish red. In order to prevent it from becoming rancid and fishy-tasted, it is well to keep it secluded from the air.

Cod-liver oil is at present one of the most important remedies in the Materia Medica. Although possessing a high reputation on the Continent, it was not till 1841, when Professor Hughes Bennett (q.v.) of Edinburgh wrote a treatise on it, that it came into general use in Britain. It is most valued in cases of pulmonary consumption, chronic rheumatism, and gout, besides all diseases of a scrofulous nature. In all these it is, however, useless to expect good results unless the remedy has been regularly taken for several weeks. Its mode of action is uncertain. While some hold that it merely acts as a nutrient, it is certain that pork-fat, butter, and other digestible oils, do not have the same specific action that characterises cod-liver oil. It is given in doses of from half a teaspoonful to one tablespoonful three or four times a day, and it does not seem that excessive doses, such as a cupful or more, are of any real benefit, while they are a severe strain on the digestive organs.

As its peculiar flavour is very repulsive to many patients, various devices have been adopted to render it more palatable. The addition of a trace of sulphuric ether, while rendering it more easily digested, does not improve the flavour. It may, however, be made into a jelly with isinglass, or be taken floating on the surface of porter; while in the form of *Emulsion*, of which many varieties are in the market, the flavour is more or less skilfully disguised. Most druggists also keep gelatin capsules, containing from one to one and a half teaspoonful, which are easily swallowed.

Cohesion depends upon the molecular forces which keep together the parts of bodies, and are insensible at sensible distances. In the case of a small body these forces are much more efficient in keeping the parts together than are the mutual gravitational attractions of the parts. On the other hand, in the case of a large body, such as the earth, gravitation is much more powerful in preventing rupture than cohesion. The term *adhesion* is generally, though quite unnecessarily, used when the cohering particles are dissimilar—as when water clings to glass.

After the parts of a body have been separated, so as to form an incoherent mass, the force of cohesion may be again brought into action by the application of pressure sufficient to force the particles close enough together. Thus two smooth, freshly cut pieces of lead can be made to adhere by slight pressure accompanied by a screwing motion. Also two very smooth slabs of marble adhere, if pressed together, so that considerable force must be exerted to separate them. Barton made a set of cubes with surfaces so true that, if twelve of them were piled one over the other, the whole series could be lifted by raising the upper one. Lead pencils are made by applying pressure to powdered graphite, so as to make it cohere.

Coke is a form of fuel obtained by the heating of coal in confined spaces whereby its more volatile constituents are driven off. Caking coal is the most suitable for the manufacture of coke, which, in its principal qualities, is approached by the hard anthracitic coals. The process of coking is conducted (1) in heaps or mounds, or (2) in ovens; but coke is also produced in gas retorts, where, however, it is merely a secondary product. Coking in mounds—a method now little practised—is done in a way similar to that employed for preparing charcoal from wood. The coal is built up into round stacks, around a wide open chimney or column, the larger masses being placed in the centre, and small broken coal outside, the whole being covered with wet coke-dust, except at certain air-holes. The mound of coal is ignited from above, and burns gradually downwards and outwards, giving off at first much smoke and vapour, which consist mainly of tar-water and coal-gas. When the fire ceases to be smoky, the process of coking is concluded, all openings are covered over to exclude air and extinguish combustion, and cooling of the mound is aided by drenching it with water. The principle of making coke in coke-ovens is the same, but the process is much quicker and more economical, and the resulting coke is better in quality than that made in mounds. Formerly the heat and volatile gases given off in coking were allowed freely to escape, but in modern coke-ovens arrangements are made for utilising the combustion in one retort to force the heat of another, by passing the hot gases in flues around contiguous ovens. The whole of the gases pass from these flues into a common flue, by which they are carried away to heat steam-boilers. In a similar way the coal-gas is, from certain kinds of ovens, collected and burned, and the tar-water evolved is condensed and used as a source of ammonia and gas-tar products.

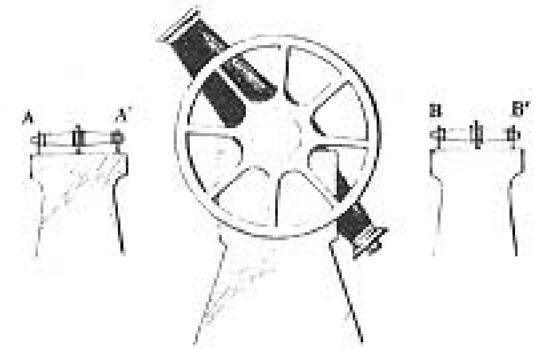
Coke is a hard, brittle, porous solid, with a steel-gray, somewhat metallic lustre, and it does not soil the fingers when being handled. It is principally valued for the intense heat which it gives off in combustion, for its freedom from smoke in burning, and because it does not become pasty and adhesive in the fire. The process of coking also drives off a good deal of the sulphur which may be present in coal, and all these properties render coke a most valuable fuel for many metallurgical operations, and for use where intense smokeless combustion is a desideratum. The higher the temperature to which coal in coking is submitted, the harder and more valuable is the resulting coke, and the heat it gives off is relatively more intense. In chemical constitution coke consists of a modified form of graphite contaminated with earthy impurities from the ash present in coal. Coal yields by weight about 70 per cent. of coke, which, however, increases in volume in the process of coking by about one-fourth. Coke will absorb about 30 per cent. of moisture from the air, a circumstance which should be borne in mind in its purchase and its use, for such moisture in being driven off greatly reduces the calorific value of the substance.

Colcothar is the name given by the alchemists to the red powder (mainly red oxide of iron) which remains in the retorts when green vitriol or the sulphate of iron is calcined. It is used for polishing glass and the like, and is called crocus by artists.

Cold Cream is the term applied to an ointment containing rose-water which is used as a mild and cooling dressing for the skin. It may be prepared by melting together almond-oil five parts, spermaceti one part, and white wax one part. Three parts of rose-water are then added with brisk stirring, which is continued till the whole is cool, and of a soft creamy consistence. As cold cream prepared in this way is liable to turn rancid, glycerine is sometimes added, or the almond-oil is replaced by white vaseline. Cold cream is a pleasant application to irritated surfaces, protecting them from the influences of the weather, and promoting the healing of wounds and chapped hands.

Colic (Gr. *colon*, 'the large intestine;' see INTESTINES), a name employed by the later Greek and the Roman physicians to denote diseases attended with severe pain and flatulent distension of the abdomen, without diarrhœa or looseness of the bowels. The disease (commonly called *gripes* or *belly-ache*) is now generally believed to be spasmodic in character, and to be dependent upon irregular contractions of the muscular coat of the intestines: its supposed particular connection with the colon, or large intestine, however, is not usually to be made out from the symptoms. Painful disorders of the bowels are very frequent in persons who are not attentive to the regular evacuations, especially when they are exposed to cold so as to experience chill or coldness of the feet, which will often suffice to bring on an attack of colic. The disease is usually attended with Constipation (q.v.), and ceases when the regular action of the bowels is restored, although often in this case the operation of medicine is attended by continued pain for a time. Warm fomentations to the abdomen may be employed with advantage, sometimes medicated with opium, or decoction of poppy-heads; and great relief is commonly experienced from friction with a warm liniment, such as opodeldoc, or the soap and opium liniment. Pressure with the hand over the painful part commonly diminishes the suffering for the time in simple colic, but increases it in more serious diseases. Warmth to the feet, and the recumbent posture, are also to be recommended. In very severe or protracted cases opium may be taken internally. A good remedy in such cases is a full dose of castor-oil (one ounce or more for an adult), with 30 or 35 drops of laudanum, or of solution of morphia. (Opiates should not be given to children except under medical advice, and in very reduced doses.) When colic resists such mild and simple remedies as the above—when it is accompanied by tenderness of the belly, or by hard swelling in any part of it—when constipation is obstinate, or vomiting is present—when there is feverishness, or tendency to exhaustion—or when there is reason to believe that it may depend on any other cause than the mere accumulation of the products of digestion in the intestines, no time should be lost in seeking the best medical assistance that can be procured; for colic is closely allied as a symptom to several very severe and dangerous diseases. One of these complicated forms of colic is termed Ileus, or iliac passion (from the idea that its seat was in the small intestine—*ileum*). It is attended with obstruction of the bowels, often from mechanical twisting or involution of one part with another (hence termed *volvulus*). This is, of course, a disease of extreme danger. The only treatment that can be attempted without medical assistance is the employment of large injections by the lower bowel, and opium in moderate and repeated doses (½ grain to 1 grain, or 12 to 20 drops of laudanum) by the mouth, carefully watched, and discontinued if there is any sign of narcotism (see OPIUM). Colic pains are also present in Peritonitis (q.v.), another most dangerous form of disease; and they form one marked symptom of the slow poisoning by lead, occasionally observed as the consequence of contamination of drinking water by leaden cisterns, &c. In this form, the treatment is different from that of simple colic, and will be treated of under LEAD-POISONING.

Collimator, a subsidiary telescope used to detect or correct errors in collimation (i.e. in directing the sight to a fixed object) when adjusting for transit observations. When the vertical thread in the field of view exactly coincides with the vertical axis of a telescope, the instrument is *collimated* vertically; and when the horizontal spider's thread just covers the horizontal axis, the instrument is correct in horizontal collimation. If three solid piers stand on the meridian, so that the telescope to be tested can be laid between the collimators and have its axis coincident with both of theirs, the principle of correction becomes almost self-obvious. Removing the great telescope, the collimators (AA′ and BB′ in fig.) are adjusted till the cross-wires in one coincide perfectly with those of the other in all possible positions. Then replacing the 'transit circle,' it is examined and tested by reference, first to one, and then the other collimator, the verification requiring that it be turned through 180° till the threads in the three fields of view absolutely coincide, and the collimation is pronounced perfect.



Practical astronomers set great value on the collimator (in the arrangement just described) for having entirely superseded the 'meridian mark.' By Rittenhouse's principle a telescope can become its own collimator, especially in determining the nadir point. When the axis is vertical over a vessel containing mercury, the telescope will be collimated when the cross-wires are brought to exact coincidence with their image seen in the mercury.

Collodion (Gr. *kollao*, 'I stick') is a solution of Gun-cotton (q.v.) or pyroxylin. Cotton itself is not soluble in alcohol or ether, but when treated, either in the form of cotton-wool, rags, or paper, with a mixture of five parts of strong nitric acid, and six of sulphuric acid, it is found that it can now be dissolved in ether, or in a mixture of ether and alcohol. To this modification the name pyroxylin is applied. There are many varieties of collodion divisible into surgical or medicated collodions, and photographic collodions. When one part of pyroxylin is dissolved in thirty-six parts of ether and twelve parts of alcohol, a thickish liquid is obtained, which evaporates rapidly, leaving a thin film of pyroxylin. As an application to wounds, where it is desired to keep the edges close together, this form of collodion is of use, owing to the contractility of the pyroxylin film which it leaves, but for general purposes a flexile or flexible collodion, as it is called, is desirable. This is produced by the addition of a little Canada balsam and castor-oil to the ordinary variety. Flexile collodion is largely used as a covering for abraded surfaces, as a remedy for burns, for sore nipples, &c., and it is also the basis for many medicated collodions, such as styptic collodion, cantharidal or blistering collodion, &c. Salicylated collodion is well known as a popular corn cure, and it is certainly most effectual in removing hard or soft corns with but slight inconvenience. It contains, in addition to salicylic acid, the active principle, a little extract of Indian hemp, which prevents the slight pain, which might otherwise prove troublesome. Collodion plays a very important part in Photography (q.v.).

Colloid is a name applied by Graham to any soluble substance which, when exposed to *Dialysis* (q.v.), does not pass through the porous membrane. Starch, gum, albumen, and gelatin are examples of colloids; and the name is used in contradistinction to *crystalloids*.

Coma, a Greek word used in medicine, to signify a state of more or less profound insensibility allied to sleep, but differing from natural sleep in its characters as well as in the circumstances under which it occurs. In coma the patient lies on his back, and is either simply insensible to external impressions, or has a confused and dull perception of them, with restlessness and low Delirium (q.v.). The former kind of coma occurs in apoplexy and epilepsy, and also in many other organic diseases of the brain and its membranes, of which, indeed, it may be said to be the natural termination. It is also seen in narcotic poisoning, and most characteristically in poisoning by Opium (q.v.). In the most fatal forms, the breathing is very slow and noisy (snoring or stertorous), accompanied with puffing of the cheeks; the pulse is at first strong and regular, afterwards feeble; there is often lividity; and the pupils are either contracted or excessively dilated, but in either case immovable, and totally insensible to light. In the second variety of coma, there is perpetual restless delirium, without enough of sensibility to lead to spontaneous and regular voluntary movements; the patient mutters slightly, and grasps feebly and without purpose at any object in his way; the pupils are commonly contracted, and the tongue is apt to be dry and brown. This kind of coma is mainly seen in many fevers, and forms one of the modes of their fatal termination. The treatment of coma is that of the disease or accident leading to it. Where there is a reasonable chance of recovery, the patient must be roused to consciousness as much as possible, either by frequent movements or strong impressions on the skin, or by the use of galvanism, so as to maintain the respiration (see OPIUM). Blistering of the head is also sometimes resorted to with good effect.

Combustion is the term commonly applied to those chemical processes which are accompanied in a marked degree by the production of heat and light. The most familiar of such processes are those in which oxygen of the atmosphere combines chemically with the constituents of what are ordinarily spoken of as combustible substances, such as wood, coal, fats, oils, &c. Chemical combination is, as a rule, accompanied by the evolution of heat and frequently of light (see CHEMISTRY); but every case of chemical combination is not called combustion, because in many cases the quantity of heat evolved is inconsiderable.

When we speak of the combustion of, for instance, coal or wood, we mean the chemical process which consists, in general terms, in the combination of the oxygen of the air with the carbon and hydrogen which constitute the greater part of the combustible portion of either of these substances, and in the production of carbonic acid and water. Many instances are known to chemists in which the oxygen required for a combustion is not derived directly from the atmosphere, but from some oxidising (or oxygen-yielding) agent, and frequently the place of the oxygen may be altogether taken by some other element, as, for instance, when metals, such as antimony in powder, burn in chlorine.

The combustion of every combustible substance is accompanied by the evolution of a quite definite quantity of heat, which is invariable for each substance, whether the combustion takes place rapidly or slowly. A piece of phosphorus, for instance, as is well known, glows in the dark. This is a process of very slow combustion, and is never accompanied by much rise of temperature. When moderately heated in air, a piece of phosphorus bursts into flame, and the combustion is rapid and is accompanied by a considerable rise of temperature; whilst if the phosphorus be burned in pure oxygen, the combustion is an extremely brilliant spectacle, and a high temperature is attained. In each case the actual quantity of heat given out is identical for the same weight of phosphorus, but the time occupied by the combustion varies, and consequently the temperature at any given instant must also vary.

The quantities of heat given out by the combustion of the same weights of *different* substances vary greatly. The measurement of quantities of heat produced by combustion and in other ways is called calorimetry (see HEAT).

The name combustion is applied to a particular process in the analysis of organic compounds. See ANALYSIS (ORGANIC). See also SPONTANEOUS COMBUSTION.

Comfrey (*Symphytum*), a common palearctic genus of Boraginaceæ, somewhat coarse perennial herbs, although occasionally to be seen in flower-borders. *S. officinale* (blue) and *S. tuberosum* (yellow) are frequent in shady and moist places. *S. officinale* was formerly much esteemed as a vulnerary. Its young leaves and its blanched shoots are still occasionally used as boiled vegetables. The Prickly Comfrey (*S. asperrimum*), a native of Siberia, 6-10 feet in height, has been recommended for feeding cattle. The stamens are covered in this genus by five awl-shaped processes pushed in from the outside of the corolla, and meeting so as to form a false bottom impassable to ants, flies, and other small honey-thieves, but which can be thrust aside by the humble-bees which alone fertilise the flower. Many bees, however (especially *B. terrestris* and one or two others), prefer to bite a hole in the side of the corolla below this cover, and the flowers may thus be seen to be visited both in the legitimate and illegitimate way.

Comfrey (*Symphytum officinale*).

Compass, MARINER'S, is a magnetic instrument used by mariners to indicate the direction of the ship with respect to the magnetic north and south line, or, in other words, to give the azimuth of the ship with respect to the magnetic meridian. That the mariner may know his direction with respect to the geographical meridian, he must know the angle between the magnetic and geographical meridians (see DECLINATION), and as this angle is different in different years and at different places on the surface of the globe, the mariner must be able at any time to determine his position, when his charts will give him the necessary data to supplement his compass reading.

The directive property of the magnet seems to have been unknown in Europe till the 12th century. It appears, however, on very good authority that it was known in China and throughout the East generally at a very remote period. The Chinese annals assign its discovery to the year 2634 B.C., when they say an instrument for indicating the south was constructed by the Emperor Ho-ang-ti. The earliest reference to the making of magnets is in a Chinese dictionary of 121 A.D., where lodestone is defined as 'a stone with which an attraction can be given to the needle;' but this property of the lodestone could not fail to have been observed at a very much earlier time. At first the Chinese would appear to have used the compass exclusively for guidance in travelling by land, and we hear of their using it by sea only somewhere about 300 A.D. According to one account, a knowledge of the compass was brought to Europe by Marco Polo on his return from his travels in Cathay; but as against this, the late Mr William Chappell, in a letter to *Nature* (June 15, 1876), produced evidence to show that we owe the appearance of the compass in Europe in the 12th century to independent discovery, and not to importation from China.

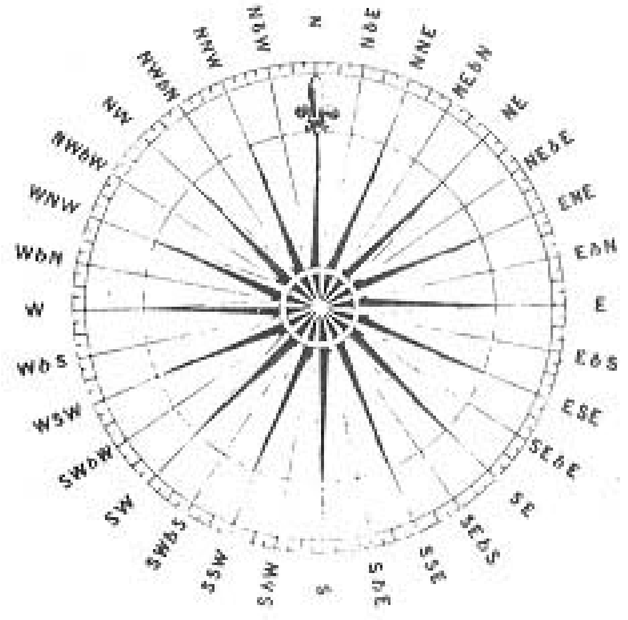


Fig. 1.

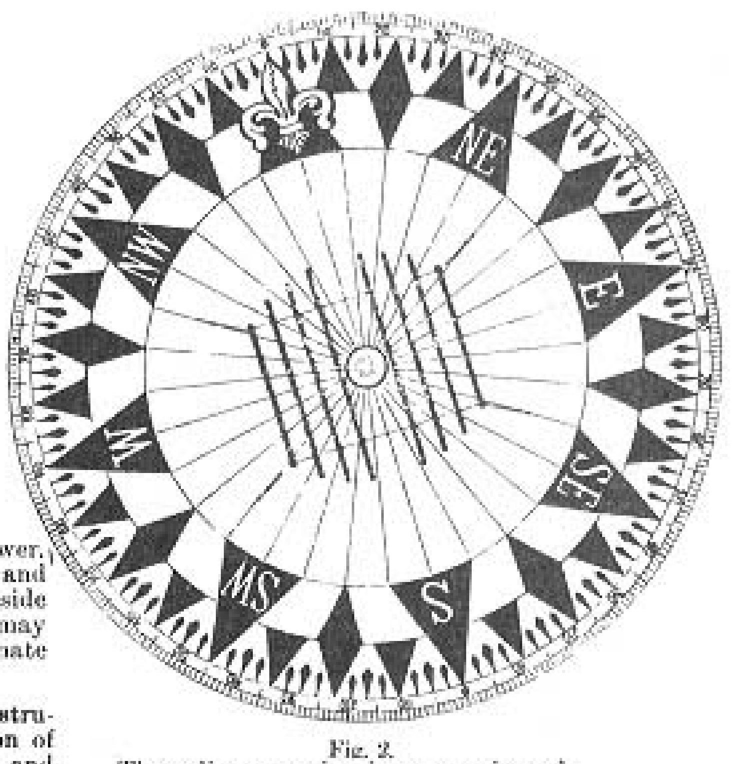

Fig. 2.

The ordinary mariner's compass is made up as follows: The needle is a magnetised strip of steel, or in the better compasses a number of thin strips magnetised separately and then bound together. This is balanced so as to swing horizontally on a fine pivot. Fastened to the upper surface of the needle and swinging with it is a circular card marked with the thirty-two 'points,' and having the point marked N immediately over the end of the needle that is attracted to the north. The pivot on which the needle swings stands up from the bottom of a copper bowl, which has a glass covering to protect the contents from wind and weather. The compass-bowl is made of copper (a good conductor of electricity) in order to damp the vibrations of the needle. For the needle in moving induces currents of electricity in the copper bowl, the electro-magnetic forces of which tend (according to Lenz's Law) to oppose the motion producing them. For the same purpose also the compass-bowl is sometimes filled with spirit, but the additional friction of the liquid interferes with the sensitiveness of the needle. The bowl is supported in Gimbals (q.v.) so as to remain horizontal in all positions of the ship. The whole arrangement is placed in the binnacle, situated when possible in the fore and aft line, and having provision for the placing of lamps to illuminate the compass-card by night.

The compass-card is represented in fig. 1. The four *cardinal* directions or 'points' are marked N. E. S. W., and there is a convenient notation for intermediate points. Thus the point midway between N. and E. is called NE., that again between N. and NE. is called NNE. (read north-north-east), and so on. The remaining sixteen points, such as

NbE. (read north by east), are named on a plan which will be readily made out by an examination of the figure. These thirty-two points are often further subdivided into halves, quarters, and even eighths, and then we have N¼E., and so on. When the ship lies in the magnetic meridian, and points to the north, the N. point on the card is directed towards a black line, called the lubber's line, marked on the inside of the compass-bowl. Boxing the compass means reading off from memory the thirty-two points in order going round either way.

Modified forms of the compass are in use on land by surveyors and miners, and need not be further alluded to here.

By way of summarising the qualifications of a good compass, we shall describe the best compass in use—Sir William Thomson's, patented in 1876: A thin aluminium ring (fig. 2) is connected by silk threads with an aluminium boss, which rests on an aluminium cup having a centre piece of sapphire poised on an iridium point (fig. 3). Instead of a single needle there are eight thin strips of steel fastened to the silk threads as shown in the figure. The thin paper rim bearing the points is divided at intervals so that the contractions and expansions due to change of temperature may not produce warping of the aluminium. The whole arrangement weighs only 200 grains or so, and thus there is very little tendency to flatten the point of the supporting needle. Hence the 'friction error' can be made very small—in fact, if it is found that a card can be made to rest even half a degree out of the magnetic meridian, the supporting point is rejected for a sharper one. The weight, such as it is, being mostly in the rim, the period of vibration of the card is long (40 seconds, or so), which makes the card very steady. The bowl is saved from violent oscillation by having in the bottom a quantity of castor-oil. The gimbals are supported on knife edges, and their being made of brass-wire-rope dispenses with the not very durable india-rubber pads otherwise used. A simple device prevents the card from jumping off the pivot when heavy guns are fired—a matter of some importance in an engagement. The binnacle has complete provision for stowing away the magnets, soft iron bars, and spheres used to counteract the magnetism of the iron of the ship.

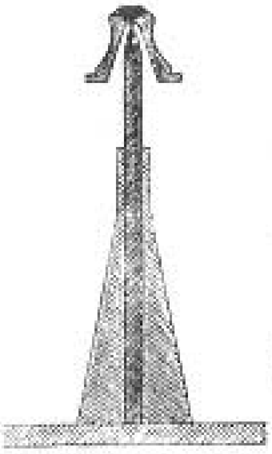

Fig. 3

Along with Thomson's compass is supplied a piece of apparatus for converting it into an azimuth compass, which is a compass for finding the angle subtended at the observer's eye by the projections of two objects on the horizontal plane.

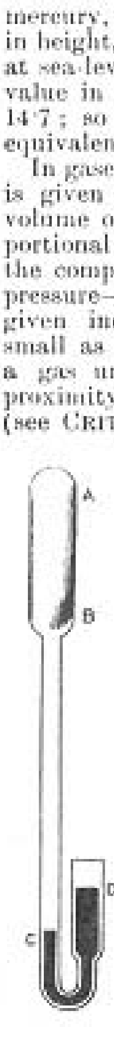
For the earth's action on a magnetised needle suspended free to move horizontally and vertically, see the articles MAGNETISM, DECLINATION.

The great difficulty connected with the use of the compass arises from the disturbing influence of the ship's magnetism, of which part is considered permanent, and part—due to the soft iron—is temporary, and varies with the position of the ship. Various methods are in use to regulate this difficulty, which in iron vessels is sometimes so great as to make an ordinary compass almost useless. The principal are (1) counteracting the permanent induced magnetism by properly placed permanent bar magnets; and (2) supplying about the compass soft iron masses in such a way that, however the ship turns, the transient induced magnetism on the left of the compass shall be exactly equivalent to that on the right. Many of the best ships carry a standard compass placed as far as possible from the iron of the ship, especially from vertical masses like iron masts and funnels. When it is mentioned that an error of one point (11¼°) in steering means an error of about one mile in five, the necessity for the various precautions will be readily recognised. For details on this subject, see the *Admiralty Manual on the Deviations of the Compass*, and the references there given.

Compressed-air Motors. One mode of employing air as a motive power has been described under AIR-ENGINE (q.v.). Another obvious way is to compress the air and then apply it in the manner of high-pressure steam. But the great loss of power, due principally to the dissipation of the heat which results from the high compression of the air, will always render the employment of such a motive power very wasteful. There are, however, many conditions under which the use of compressed air is convenient and advantageous. The air-gun, although more a toy than a useful weapon, is one of the oldest examples of a compressed-air motor. Partly by compression and partly by exhaustion of air, pneumatic tubes are worked in connection with central post-offices for the transmission of letters and messages to and from various districts in large cities. In boring in mines, and in blasting and tunnelling operations, compressed air is an exceedingly useful agent, the power being easily carried by tubes into confined areas where the air when liberated, after it performs its primary duty, is of great value for aiding the ventilation of the spaces. In the application of automatic brakes to passenger trains, compressed air has also been found to be the most convenient power. Air compressed and stored in a reservoir under the vehicle has also been proposed as a motive power for tramway cars. In a different direction the agency of compressed air is important in the artificial production of cold for chilling-houses for meat-preservation on land, and for frozen-meat chambers for preserving fresh meat on board vessels.

Compression and **Compressibility.** When a body is subjected to the action of any force which causes it to occupy less volume, it is said to be compressed, and the diminution of volume is termed *compression*. The term compressibility is frequently used to signify that property of bodies whereby they yield to that particular form of stress known as pressure; but more strictly it is employed to denote the measure of this property as possessed by different substances. Under the same pressure it is obvious that the same volume of various substances will diminish by different amounts; and, to measure this change, the *compressibility* is defined to be the ratio of the amount of compression per unit volume to the compressing force applied. It thus may be determined by measuring the amount of compression of a known volume when under a certain pressure; dividing this by the product of the original volume and the pressure gives the average compressibility (per unit pressure) of the substance throughout the range of pressure employed. The unit of pressure generally used is *one atmosphere*, which is defined in this country as being the weight of a column of mercury, one square inch in section, 29·905 inches in height, at the temperature of 0° C., and weighed at sea-level in the latitude of London. Its actual value in pounds-weight per square inch is nearly 14·7; so that 152·3 atmospheres of pressure is equivalent to a pressure of one ton per square inch.

In gases the relation between pressure and volume is given by Boyle's Law (see GASES)—viz. the volume of a given mass of gas is inversely proportional to its pressure. From this it follows that the compressibility is inversely proportional to the pressure—i.e. the diminution of volume due to a given increment of pressure is correspondingly small as the pressure is great. The behaviour of a gas under pressure is closely related to the proximity of its temperature to the critical point (see CRITICAL TEMPERATURE); for if below this temperature the gas can, and if above it, cannot be liquefied by pressure alone. It is only since 1877 that liquefaction has been effected in those gases formerly termed permanent.



From the first attempts to compress liquids it was concluded that they were incompressible, but Canton in 1762, by a comparatively simple experiment, showed that the compressibility of water though small is quite appreciable, and that it is less at higher than at lower temperatures. The measurement of the compressibility of liquids is usually made in a glass vessel (see fig.) termed a piezometer. A tube, ABCD, open at one end, D, is bent upon itself between C and D, widened at one end into a cylindrical bulb, AB, and at the other into a cistern, D. The liquid experimented on fills the bulb and stem to C, from which point to D, mercury fills the tube. On the surface of the mercury at C an index floats. The instrument is placed in a larger and much stronger vessel containing water to which pressure (measured by an attached gauge) is applied. The contents of the piezometer being thus compressed, the mercury column ascends in the stem, and when the pressure is relieved the index is left at that point to which the mercury rose under the highest pressure applied. The actual amount of compression, and the original volume, as well as the pressure, being known, the compressibility can be thereby calculated, a correction being finally added for the compression of the glass piezometer itself. From experiments made with such apparatus, the following conclusions (see *Report on some of the Physical Properties of Fresh Water and Sea-water*, by Professor P. G. Tait; *Challenger Expedition Commission Reports*, Physics and Chemistry, part iv.) seem now to be well established regarding the compressibility of liquids, more especially of water. The compressibility of water decreases as both the temperature and pressure are raised; under moderate pressures (e.g. one or two atmospheres) it has a point of minimum value about 60° C., while its actual value at 10° C. and at a pressure of one ton per square inch is very nearly $\frac{1}{20000}$. Sea-water is less compressible than fresh water; the ratio of the compressibility of the former to the latter being ·915. Solutions of common salt are less compressible as they are stronger; the compressibility falling off uniformly with increased strength. Both sea-water and salt solutions diminish in compressibility with temperature and pressure in the same manner as fresh water. It has also been proved that the maximum-density point of water is lowered by pressure; the actual amount of this lowering being 3°·1 C. per ton—i.e. water under a pressure of one ton per sq. in. has its maximum density point at 0°·9, instead of at 4°, as under ordinary atmospheric pressure.

The compressibility of solids is generally very much smaller than that of either liquids or gases. It is best measured by noting the shortening of a rod or fibre of the material tested while subjected to hydrostatic pressure; the linear compressibility thus obtained is, to a sufficient degree of approximation, one-third the cubical compressibility. For glass it is ·00000265 per atmosphere.

Concrete. There is but little difference between concrete and coarse mortar. The mortar used in the masonry of castles and churches erected during the middle ages is in fact a concrete with small pebbles instead of the larger ones used in modern concrete. Any mixture of lime, sand, and water, with broken stones or bricks, bits of slag, gravel, or other hard material, is called a concrete. The hard lumps are termed the *aggregate*, and the mortar in which they are embedded is called the *matrix*. The mixture varies with the nature and quality of the materials, but it often consists of 1 part of quicklime, 2 of sand, and 5 of gravel. It is better to use such a material as broken stone rather than water-rolled gravel, which has often too smooth a surface. Lime concrete, as the kind above described may be termed, is used principally for foundations, that is, a thick bed of it is formed below the lowest course of stones or bricks in walls, in cases where the ground itself is not sufficiently firm and solid. Not unfrequently, in some countries, walls themselves are formed of concrete, by laying a foot or two of it in height at a time between boards, and giving it some time to harden. It then forms an artificial stone. Other methods of building walls of concrete are in use.

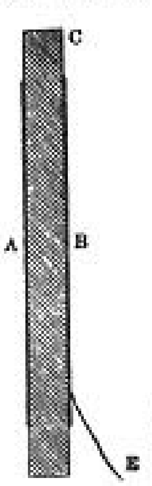
Portland cement concrete is made either by mixing it with gravel alone, or more generally by using the cement along with sand and broken stones. The concrete used at Portland Breakwater Fort and at Cork Harbour have nearly the same composition. The cubic yard of it at the former place was made by using of Portland cement 5 cubic feet, of sand 10 cubic feet, and of broken stones (not more than 3½-inch gauge) 28 cubic feet, along with 23½ gallons of water. A concrete with these materials in much the same proportion has been used at other places, but different proportions are also employed. Portland cement being the binding material in this concrete, the question arises whether there is sufficient experience of its durability, especially where it is exposed to the action of sea-water, to warrant its employment in structural works of great or even of moderate size. See CEMENTS.

Concrete made of the hydraulic lime from Teil in France, which contains 66 per cent. of silicate of lime, has been employed in the construction of breakwaters and similar works at Cherbourg, Marseilles, and other places. The Teil hydraulic lime is one of the strongest known, and the concrete made with it has resisted the action of sea-water for many years. Ordinary lime concrete does not set under water.

A concrete is made of broken stones and tar, about 12 gallons of the latter being used for every cubic yard of concrete. Bitumen or asphalt is better than gas-tar for this purpose, and either may be hardened by the introduction of dried and pounded lime, clay, or brick-dust. The materials should be heated before being mixed with the tar or bitumen. For backing armour-plates in forts a concrete of cast-iron turnings, asphalt, and pitch has been used. Gravel mixed with rather more than a thirtieth part, by bulk, of iron borings, was successfully used as a concrete at Stranraer pier.

Condenser is an apparatus in which aqueous or other water is condensed into a liquid form either by the introduction of cold water, as in the condensing Steam-engine (q.v.), or as in distillation, by placing the condenser in another vessel, through which a current of cold water passes. When the water-supply is deficient at sea or on the coast, salt water may be distilled and condensed. See DISTILLATION, GAS.

The ELECTRIC CONDENSER is an apparatus consisting essentially of two parallel conducting plates, separated by a layer of non-conducting material or dielectric, employed to receive and retain quantities of electricity greater than either or both of the plates would do alone. The simplest and typical form of condenser is that which was first used by Franklin. It is simply a sheet of glass, C (see fig.), both sides of which, excepting a margin at the edges, are covered with tinfoil, A and B. To charge such a condenser, one of the sheets of tinfoil, say B, is connected with the ground, E (either by some metallic connection or by being placed on the hand of the experimenter), while the sheet, A, remains insulated. If A be now charged with electricity, positive for example, a negative charge is induced on that side of B nearer A, while an equal quantity passes to the ground. Increasing the charge in A induces a corresponding increase in B. This process, although by means of it large quantities of electricity may be accumulated, cannot go on indefinitely; for on reaching a certain limit, depending on the dimension, &c. of the apparatus, the nature of the dielectric used, and the difference of potential of the two conducting plates, either a *disruptive discharge* (see ELECTRICITY) takes place, or the charge passes off through the insulating supports of the condenser.



All the various forms of condensers satisfy the definition given above. One useful form is that in which the two conducting plates are fixed on the ends of brass rods which pass through brass knobs on the tops of two glass pillars, the dielectric in this case being air. The more common form, however, is the Leyden Jar (q.v.). Another is made up of sheets of tinfoil and paraffined paper, placed alternately in layers; the first, third, fifth, &c. sheets of tinfoil are connected to one terminal, and the second, fourth, sixth, &c. to another.

The *capacity* of a condenser is defined to be that quantity of electricity with which one plate must be charged in order to raise its potential by one unit. It can be shown that, in the case of condensers of the Leyden jar form, the capacity is numerically equal to the product of the outer and inner radii of the coating, divided by the difference of the radii—i.e. is greater as that difference is less. Hence the thinner (within certain limits) the glass between the two coatings of such a condenser, the greater is its capacity.

Condiments, or seasoning agents, are those substances which are employed at table for the purpose of imparting a flavour or seasoning to the ordinary solid or liquid food. The principal condiments are saline substances, such as common salt; acidulous bodies, such as acetic acid or vinegar; oily condiments, such as butter and olive-oil; saccharine substances, such as sugar and honey; and aromatic and pungent condiments, such as mustard, ginger, pepper, and pickles.

Conductors and Non-conductors of Electricity. When an electrified body is placed upon a metallic stand, so that it is in metallic connection with the earth, all traces of electrification disappear; but if placed upon supports of glass or ebonite, its charge is still retained, the body then being said to be *insulated*. In the former case, the electric charge having passed to the ground through the metallic support, the metal is termed a *conductor* of electricity; in the latter, the glass or ebonite is termed a *non-conductor* or *insulator*, since by its means the charge is prevented from leaving the body. This distinction is somewhat artificial, since no substance is known to be either a perfect conductor or an absolute insulator. The substances in frequent use as conductors and non-conductors may be arranged in the following order of their conductivity, beginning with the best: Silver, copper, gold, brass, zinc, platinum, iron, tin, lead, mercury, German-silver, graphite, red phosphorus, mineral acids, saline solutions, sea-water, pure water, alcohol, wood, ice, vegetable oils, lime, chalk, camphor, porcelain, wool, hair, silk, glass, wax, sulphur, resin, amber, gutta-percha, shellac, paraffin, ebonite, air and other gases.

It is found that the efficiency of a non-conductor, when used as an insulator in electrostatic experiments, depends very largely on the state of its surface. In a damp atmosphere, glass becomes coated with a thin film of moisture which considerably lessens its insulating power. Hence these experiments succeed better in dry weather; otherwise the apparatus requires to be heated, or the glass insulators employed to be coated with shellac varnish, upon which moisture does not so readily deposit. In metals, conducting power decreases when the temperature is raised; on the other hand, glass, wax, sulphur, and some other bodies which are extremely bad conductors at ordinary temperatures, conduct very much better when raised to a sufficiently high temperature. It has been observed that a series of metals arranged in order of their electrical conducting powers, exhibits the same order as when similarly arranged for their thermal conducting powers; in other words, metals which conduct electricity well, conduct heat well. Also, that when two specimens of the same metal differ in electric conductivity, they differ in thermal conductivity, and in the same way. See LIGHTNING CONDUCTOR.

Convulsion, in Medicine, is sometimes used of any involuntary contraction of the voluntary muscles of the body; but especially of seizures in which the body is thrown into violent spasmodic contractions, the sensibility and voluntary motion being for a time suspended. In adults convulsions almost always indicate the presence of grave disease, either of the brain (particularly Epilepsy, q.v.) or of the kidneys. In children, especially before the age of three years, they are of much more common occurrence, and, though serious in themselves, may be due to temporary and comparatively trifling causes. The following description applies chiefly to the convulsions of children. A fit of convulsions may last from a few minutes to some hours, and may readily prove fatal, if not relieved within a short period. The first symptom observed is often a twitching of particular muscles or groups of muscles, and a change in the habitual expression or colour of the face, with distension of the features, and turning of the globes of the eyes suddenly upwards. The fingers are sometimes clenched in the palm, and the feet turned inwards; sometimes, however, convulsions occur absolutely without warnings of this kind, and even in the midst of perfect apparent health. Their cause is usually to be found in some source of irritation, especially in the digestive organs; as, for instance, disordered dentition, worms in the intestine, indigestible or unsuitable food, &c. Most epidemic fevers are also apt to be attended, in children, by convulsions in their early stages, and if severe, particularly in the case of whooping-cough, during their progress as well; and diseases of the brain and its membranes at every stage. Convulsions are greatly promoted by bad ventilation and injudicious feeding, with deficient exercise; and a great part of the cure consists in discovering and removing the causes of the disease.

When a child is suddenly seized with a tendency to spasm, such as twitching of the features, or contractions of the fingers and toes, it should be placed at once in a very free current of air, with its feet towards the fire; the extremities should be kept warm, and a cold lotion may be applied to the head, especially if there is much flushing of the face; a little castor-oil may be given unless the bowels are loose; and if there is flatulence, the belly may be rubbed with a warm hand, or with some simple stimulating liniment, such as camphorated oil. If an actual convulsion occur, the feet, or if possible the whole body, should at once be put in hot water to which a little mustard has been added, and cloths wrung out of cold water frequently applied to the head. If there is any suspicion that worms or undigested food may be the cause, a purgative Clyster (q.v.) should be given; and aperient medicine by the mouth as well, if the child be able to swallow. Nothing more should be attempted without medical advice. The further treatment generally consists in the administration of nerve sedatives, especially bromide of sodium or potassium and chloral, and in obstinate cases chloroform, with careful attention of course to any cause of irritation that may be present.

Convulsions are rare amongst horses and cattle. In young dogs, however, they frequently occur from intestinal worms, disordered digestion, or in connection with distemper or other debilitating diseases: they usually disappear when their special causes are removed.

Copaiba, or COPAIVA, BALSAM OF, a valuable drug, consisting chiefly of a resin (resin of copaiba) and a volatile oil (oil of copaiba). It flows from incisions in the stems of various species of copaifera trees, natives of the American tropics, which belong to the natural order Leguminosæ. When these trees become old or surcharged with copaiba, it is no unusual thing for the stems to burst with a loud booming sound. The balsam has a peculiar, aromatic, but not disagreeable odour, which, however, is highly persistent, while its taste is decidedly acrid. It has stimulant properties, is diuretic, laxative, and in large doses often an active purgative. It is, however, mostly on account of its powerful action on the mucous membrane that it is used, and it is accordingly much employed in affections of the urino-genital system, in chronic catarrhs, &c. The resin itself has been found efficacious given in the form of a cough-pill. Balsam of copaiba is sometimes adulterated with castor-oil or volatile oils. The former of these is readily detected if any milkiness is produced when the balsam is shaken with ten times its volume of petroleum benzin. The volatile oils may be recognised by shaking the balsam with a little alcohol, when, being more soluble, they are removed first.

Copal, a resinous substance used for a variety of purposes in the arts. It appears in commerce in smooth rounded masses, colourless or lemon-yellow, translucent or transparent, rather brittle, and in a cold state, almost without smell or taste. It is readily fusible and inflammable, is insoluble in water, and only partially soluble in alcohol and oil of turpentine, but becomes entirely soluble in them when it has been for a short time melted. Various useful pale-yellow or almost colourless varnishes and lacquers are made by dissolving melted copal in alcohol, oil of turpentine, or boiled linseed-oil. The chief sources of copal are the East Indies, Africa, and South America, but the varieties derived from these countries differ in their origin. The East Indian is the exudation of a large tree, *Vateria Indica*, and possibly also of different species of Hymenea, which probably yield the Brazilian variety. Much copal is obtained from West Africa, where it is found in rounded masses, embedded in sandy soil. *Gum Animé* is the name applied to a copal of this nature.

Copalchi Bark, a bark resembling Cascarilla Bark (q.v.) in its properties, and produced by a shrub of the same genus, *Croton niveus*, a native of Central America (see CROTON). The bark is in quills a foot or two in length, and has a thin corky epidermis. Copalchi Bark is much used as a substitute for cinchona in Mexico, where it goes by the name of *Quina blanca*, and is imported, although not to a large extent, into Europe. It contains a minute proportion of a bitter alkaloid resembling quinine.

Copper. This appears to have been the first metal employed by man both in war and the peaceful arts. Like gold and silver, it is found native, but, except in one or two districts, only to a small extent. It can, however, be extracted from its ores at a comparatively low heat, and it is not altered by exposure to dry air; although in moist air, in the presence of carbonic acid, it soon takes on a coating of the green carbonate of copper. The use of copper by ancient nations is well known, through the weapons and other objects of Bronze (q.v.)—that is, copper mixed with a small quantity of tin, &c.—which have been so largely collected by archæologists. Some prehistoric implements are, however, of unalloyed copper. It was obtained by the ancients from various places, but especially from Cyprus—whence the name. Copper has a characteristic fine red colour and takes a brilliant polish. It is nearly nine times heavier than water, its specific gravity being from 8·8 to 8·95. Next to silver it is the best conductor of heat and electricity, hence its many useful applications. Its point of fusion lies between silver and gold, but unlike these metals, it absorbs oxygen when strongly heated in the air, and scales of black oxide form rapidly on its surface. Copper is moderately hard, and is highly malleable, ductile, and tenacious, although not so strong as iron. When held, in the form of sheet or wire, in a flame, it communicates to it a highly characteristic green colour. Whereas steel is hardened by being heated to redness and suddenly cooled in cold water, copper is softened by the same process. Copper forms two important compounds with oxygen—cuprous and cupric oxides.

Cuprous Oxide (red oxide, sub-oxide), Cu_2O. This is obtained by heating to redness the black oxide with nearly its own weight of finely divided copper in a well-covered crucible, to protect the mixture from the oxidising action of the air. It is got as a hydroxide by adding grape-sugar to a solution of sulphate of copper, and then caustic soda, till a blue precipitate, which is first formed, is redissolved. The solution, on being gently warmed, deposits the hydroxide as a rich orange-yellow powder. On continuing the heating till the liquid has reached the boiling-point, and maintaining the ebullition for some time, the powder changes into the red anhydrous oxide. This oxide is used in colouring glass a fine ruby tint. It is not acted on by air or moisture, and for this reason is produced on copper surfaces as a bronze to keep the metal itself from becoming stained. The salts of this oxide are generally colourless, but they are liable to absorb oxygen and pass into the blue-coloured cupric salts. Cuprous chloride is the most important salt, being used for absorbing carbonic oxide in gas analysis.

Cupric Oxide (copper monoxide, black oxide), CuO, is the scale or rust of copper which peels off the surface of the metal when heated. It is got for chemical purposes by heating nitrate of copper to redness in a crucible with occasional stirring, and carefully avoiding any possible admission of coaly matter. By the use of cupric oxide Liebig established the method by which the composition of all organic substances has been determined, as it readily gives up its oxygen at a red heat to carbon and hydrogen, converting them, respectively, into carbonic acid and water, from the weight of which the composition of the organic body is calculated. This oxide is used for staining glass, to which it imparts a green colour; and its solution in ammonia has the remarkable property of dissolving cotton fibre. The *Hydroxide*, $Cu(OH)_2$, is obtained as a blue precipitate by adding caustic soda to sulphate, or other salt, of copper, which, as in the case of the cuprous oxide, becomes anhydrous on boiling, the blue precipitate becoming black and granular. The salts of cupric oxide are readily obtained by dissolving it in the necessary acids; for example, in sulphuric acid for the sulphate, and in nitric acid for the nitrate of copper.

Cupric Sulphate (sulphate of copper, blue vitriol), $CuSO_4$, occurs native in veins of copper and iron pyrites, and is manufactured on a large scale by gently roasting native copper sulphide (copper pyrites), when oxygen is absorbed from the air, the anhydrous sulphate thus obtained being dissolved in water, and from this solution the salt as found in commerce crystallises out. The crystals are large, transparent, and have a fine blue colour. They are much used by the dyer and calico-printer, in electroplating, and in the preservation of organic materials.

Cupric Nitrate, $Cu(NO_3)_2$. The crystals of this salt are of an intense blue colour and deliquescent. It is much used in calico-printing as an oxidising agent.

Cupric Cyanide, $CuCy_2$, along with cyanide of potassium, gives the solution from which copper is deposited on an iron surface. It is not, however, necessary to prepare pure cupric cyanide, as the sulphate in excess of potassium cyanide serves the purpose.

Cupric Arsenite, $CuHAsO_3$ (Scheele's green), is a well-known green pigment, got by adding an alkaline arsenite to cupric sulphate, and washing the precipitate till free from sulphate, and drying. This colour has been much used for wall-papers, but has been supposed to have insanitary effects. See ARSENIC.

Copper Acetate, $Cu(C_2H_3O_2)_2$, is got by adding copper hydroxide, or carbonate, to acetic acid. It forms dark blue prisms. If acetic acid is allowed to act on metallic copper in the presence of air and moisture, a basic acetate is slowly formed termed *verdigris*; this has less acetic acid than the previous compound, and is much less soluble. It has a bluish-green colour. Verdigris and arsenious acid boiled together in water form the fine colour termed *emerald green*—an aceto-arsenite of copper.

Copper Stearate is obtained by adding stearate of soda to sulphate of copper in hot solutions. It is a light bluish-green powder used for colouring candles.

The pigment, *Brunswick green*, used in the arts, is an oxychloride of copper.

Copper in any liquid is easily discovered by placing in it a plate of polished iron, when it will be observed coating the metal with its well-known reddish tint, making its appearance over the part of the plate immersed in the fluid. If the quantity of copper is very small, the liquid should be concentrated till it half fills a watch-glass, and a bright steel needle used in place of an iron plate. Solutions of cupric salts have a blue or greenish-blue colour, but this on addition of ammonia in excess becomes an intense purplish blue.

Native Copper, although frequently met with wherever copper ores occur, is yet rarely discovered in sufficient quantity to admit of its being systematically worked. It is found crystallised in cubes and in modifications of this form; also in arborescent pieces, in thin laminæ, and in irregular lumps or masses. Sometimes it forms a nucleus with first a layer of red oxide and then a second layer of carbonate of copper around it. The largest masses of native copper are obtained from mines in Russia and from copper-bearing strata in the neighbourhood of Lake Superior. One mass was mined at Minnesota in 1859, weighing 500 tons, which required the work of forty men for a year to extract it. The largest yet obtained was got in 1866 at the Central mines, Lake Superior, and weighed 800 tons.

The ores of copper are numerous. *Cuprite, ruby copper, cuprous oxide*, or *red oxide of copper*, is the richest ore. It contains, when pure, nearly 90 per cent. of copper. *Malachite* (q.v.), or *green carbonate of copper*, consists, when pure, of 57 per cent. of the metal. This ore occurs largely in Russia, South Australia, and in some localities in South America. *Chessylite, azurite*, or *blue carbonate of copper*, in a pure state contains 55 per cent. of copper. *Chalcopyrite, copper pyrites*, or *yellow copper ore*, a sulphide of copper and iron, is, from its abundance, the most important of copper ores. Although containing, when pure, 35 per cent. of copper, yet on account of impurities, what is mined in England does not yield, on an average, more than 8 per cent. of the metal. Some of the auriferous copper pyrites of the western states of America and elsewhere is worked as an ore of gold (see GOLD). *Erubescite*, or *purple copper ore*, is also a sulphide of copper in which the proportion of the metal varies from 60 to 70 per cent. *Tetrahedrite*, or *gray copper ore*, is a sulph-antimonite of copper of very variable composition, but often containing from 30 to 40 per cent. of copper, &c. *Atacamite* (q.v.) is an oxychloride of copper mined in Chili, and found in other countries. *Melaconite*, or *black oxide of copper*, and *Chrysocolla*, a silicate of copper, are sometimes smelted as ores of the metal.

COPPER-SMELTING.—In practice, the process of smelting copper from ore (copper pyrites) like the Cornish is somewhat complicated, but in theory it is comparatively simple. The main impurities of the ore are quartz, iron, sulphur, and very commonly arsenic. The process is conducted with the view of separating the iron and quartz as a fusible slag, and of dissipating the sulphur and arsenic, by converting them into sulphurous and arsenious acids, through oxidation in the furnace. At Swansea, which is the chief seat of copper-smelting in this country, reverberatory furnaces are used, and these are of two kinds, called respectively calciners and melting furnaces. Gas, along with Siemens' regenerative apparatus, is now to some extent used in different parts of the world for supplying heat to copper furnaces, but at some places it has been given up, after a short trial, owing to the costly repairs which it causes. There are never fewer than *six operations* in the Welsh process of copper-smelting, and when so limited, a favourable admixture of ores, such as copper pyrites and copper carbonates, is necessary. In the *first*, the ore is calcined in a furnace for at least twelve hours, by which time the greater part of the sulphide of iron is decomposed, and much sulphurous and other acids have formed and escaped in fumes—i.e. a partial oxidation of the iron and sulphur takes place. In the *second*, the calcined ore is melted along with siliceous slags obtained in later stages of the process. Here a fusible slag, consisting in great part of silicate of iron, is formed, and the sulphides of iron and copper are run off as a regulus, termed *coarse metal*, and granulated in water. A section of a melting furnace is given in fig. 1. In the *third*, the coarse metal is calcined again for twenty-four hours, during which time most of the sulphide of iron is converted into oxide. In the *fourth*, the calcined coarse metal is melted with slags rich in oxide of copper, and also with rich ores, as oxide and carbonate. These oxidise any sulphide of iron remaining, and a regulus called *white metal* is formed, consisting almost entirely of sulphide of copper, and containing about 75 per cent. of the metal. In the *fifth*, called 'roasting,' the regulus is very slowly melted, so as to allow of the gradual and thorough reduction of the sulphide by heated atmospheric air through the formation of oxide of copper. When oxide and sulphide of copper are heated together, they decompose each other, the sulphur escapes as sulphurous acid, and impure metallic copper, called *blister copper*, is produced, while other foreign bodies are for the most part removed in the slag. In the *sixth*, the copper from the previous operation is refined. To effect this, it is melted in a furnace, and exposed to the oxidising influence of the air for from fifteen to twenty hours, by which time it is full of dioxide, and this is in turn reduced by throwing pure coal on the surface of the molten metal, and then stirring it with a pole of green birch-wood.

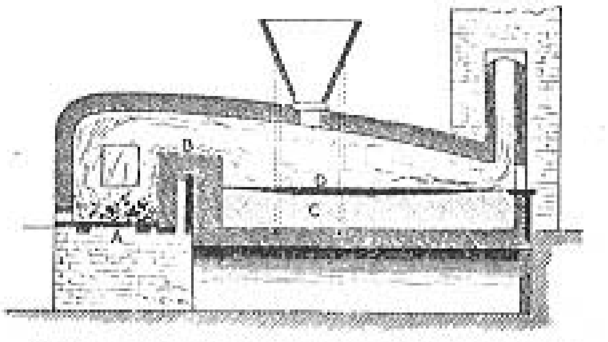


Fig. 1.—Section of a Reverberatory Copper-melting Furnace:

A, fireplace; B, fire-bridge; C, bed of sand; D, melted copper.

At those smelting works where the sulphurous acid produced in the calcining or roasting of copper pyrites is saved for the manufacture of sulphuric acid, peculiar furnaces, such as Gerstenhöfer's, Hasenclever and Helbig's, and Maletra's, are used for roasting the ore. Shaft or cupola furnaces, instead of those of a reverberatory kind, are used in some countries, for smelting copper ores where these are highly ferruginous, or oxidised, or comparatively poor. Coke, anthracite, or charcoal is used as fuel in cupola furnaces, which require a blast of air at a moderate pressure.

Wet Copper Extraction Process.—Soon after iron pyrites (sulphide of iron) began to be used about thirty years ago as the source of sulphur for the manufacture of sulphuric acid, it was thought desirable to recover the copper, amounting to a small per cent. of the pyrites used. The burnt pyrites, consisting chiefly of oxide of iron, along with 4 or 5 per cent. of copper, is mixed with from 12 to 15 per cent. of crushed rock-salt and the mixture properly calcined, when the whole of the copper is converted into a soluble chloride. The roasted mass is then lixiviated, and the copper contained in the solution thrown down as metal by scrap iron. This precipitate contains about 75 per cent. of pure copper, and is mixed with the copper of the later stages of purification got in the dry process.

APPLICATIONS OF COPPER.—The metal is used for a great variety of purposes. It is most largely consumed along with zinc in the production of Brass (q.v.). To a less, but still considerable extent, it is made into bronze and gun-metal, in which it is alloyed with tin and other metals (see BRONZE). Alone it is employed for boilers, stills, cooking vessels, seamless and other pipes, wire and wire-cloth, nails, and spikes. In the form of thin plates it has long been in demand for engraving and etching upon, and in the shape of strong rollers it is extensively employed for a like purpose by the calico-printer. Copper does not cast very well, but it is admirably adapted for producing works of art in electro-deposit instead of casting them. This process is extensively employed, and does even for objects as large as life-sized statues. In this way engravings and pages of type are also copied for the printing-press. For its use in coating other metals, see BRONZING. Copper is the metal usually chosen for lightning conductors. Writing-pens are made of an alloy consisting for the most part of copper, and for some purposes are better than those made of steel, as they do not corrode nearly so soon. These pens are usually white in colour. An alloy of copper, 'yellow metal,' is used for sheathing the bottoms of timber ships, so as to prevent molluscs and seaweeds from encumbering them. Copper, owing to its ductility, may be made into pipes, tubing, &c., by high pressure alone, without heat.

Copperas is the commercial term for the sulphate of iron, and is used extensively in dyeing black, in making ink, and has been found useful as a dressing for crops.

Coriander (*Coriandrum sativum*), an annual plant of the natural order Umbelliferæ, with branching stem, 1 to 2 feet high, the lower leaves bipinnate, the upper leaves more compound, and globose fruit. It is a native of the south of Europe and of the East, and has long been cultivated for the sake of its fruit; and has thus become naturalised in some parts of England, although its fruit (coriander seed) is much less used in Britain than in Germany and some other European countries. The whole plant, when fresh, has a very offensive smell; but the ripe and perfectly dry fruit has an agreeable aromatic smell and a sweetish aromatic taste. It is used in medicine as a carminative, and as a corrective of certain purgatives; also in domestic economy as an aromatic, being very often mixed with bread in the north of Europe; spirituous liquors are flavoured with it; and confectioners cover it with sugar to make a well-known kind of comfit. In the south of England it is common to sow coriander and caraway together, the coriander yielding a crop in the first year, and the caraway in years following. Coriander delights in a rich soil, and is much cultivated and used in India.

Corrosive Sublimate, the popular name of the highly poisonous bichloride of mercury (mercuric chloride). See MERCURY.

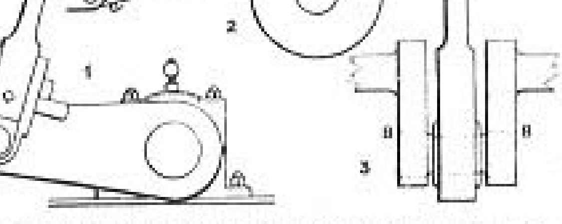
Corrugated Metal. Iron and other metals in sheets and plates have communicated to them enormously increased rigidity and power to resist buckling and collapse by being corrugated. The process is merely an application to metallic substances of the old contrivance of 'goffering' or 'piping,' by means of which frills are stiffened and kept in shape. The metal to be corrugated is passed between pairs of rollers with ridged surfaces, the ridges of one fitting into the hollows of the other, and the sheets or plates operated on are bent and compressed into the wavy outline of the rolls. Walls and roofs of light and temporary buildings are extensively made of corrugated galvanised iron—i.e. sheet-iron first corrugated and subsequently coated with zinc by dipping the sheets into a bath of the liquid metal. The most important mechanical application of corrugated metal has been for the flues of large steam-boilers. About 1878 a system of annular corrugated iron flues was introduced, which increased the resistance of the flue to collapse, and saved fuel because of the greater heating surface presented by the corrugations. A spiral corrugated flue gives the greatest amount of strength.

Counter-irritants, agents applied to the skin so as to redden (rubefacients), to vesicate (vesicatories or Blisters, q.v.), or to produce pustules, purulent issues, or even sloughs of skin and of the subcutaneous textures. The milder counter-irritants are mustard (see CATAPLASM), turpentine applied on warm cloths, and spirit or acetic acid in lotion. The stronger are blisters of Cantharis (q.v.) or of ammonia; of Croton-oil (q.v.) or Tartar Emetic (q.v.), in ointment; setons, caustic or pea-issues, and the moxa; and above all, the actual Cautery (q.v.) or hot iron. None of the stronger counter-irritants should be used without careful consideration and medical advice; great mischief is often done by their careless or improper use. Counter-irritants relieve internal pain, check inflammations, and tend to promote the absorption of morbid effusions. Their effect is probably due mainly to reflex action, produced by the impression they cause upon the nerves of the skin to which they are applied.

Amongst horses, counter-irritants are much used for strains and diseases of the joints, but should never be applied, as they too often are, in recent cases, or whilst the part is hot or inflamed. Cantharidine preparations, or ointment of biniodide of mercury, are the most convenient. For cows, use fomentations, followed by the smart infriction of mustard-paste; for dogs, soap-liniment, strengthened, if required, by ammonia or turpentine.

Cowhage, COWAGE, or COWITCH, consists of short, slender, brittle hairs, which cover the pods of species of Mucuna, a papilionaceous climber, particularly *M. pruriens* of the West Indies and *M. urens* of the East. These hairs readily stick in the skin and cause intolerable itching, and were hence formerly used (as still in their native country) as a vermifuge. They are administered in syrup, and of course act mechanically. The unripe pods are eaten like kidney-beans.

Crank, in Machinery, is a lever or arm on a shaft, driven by hand (e.g. a winch-handle), or by a connecting-rod, its object being to convert reciprocating motion into rotary motion. Engine-cranks which convert the to and fro motion of the piston into continuous rotation of crank-shaft are connected to the piston-rod end by the connecting-rod. They are, when single, of steel, wrought-iron, or cast-iron, the crank in this case being either a simple arm, enlarged at one end to fit over the shaft, and with a pin at the other end embraced by the rod end (fig. 1); or else a disc centred on the shaft, with crank-pin as before (fig. 2). This last form is well balanced. When double, as is usual in large engines (fig. 3), they are now often built up of steel, the two arms being shrunk on to the shaft, and pin on to them. In two positions during each turn, a connecting-rod exerts no power of rotation. These are when rod A and crank-arms B are parallel (as in fig. 3 and opposite position), and are the *dead centres*; all the push or pull of the rod only causes pressure on shaft-bearings. To carry the crank over these points either a heavy wheel (fly-wheel) is attached to the shaft, which stores up energy during other parts of the revolution, and gives it out at these points, or else two or more cranks are so placed on the shaft that when one is on its dead centre, the others are exerting nearly their maximum effort, which is when rod and crank are at right angles.

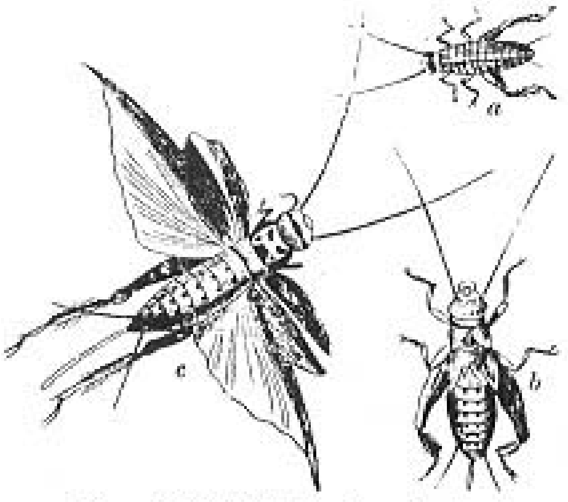


Cream of Tartar exists naturally in grape juice, but being insoluble in alcohol, it is gradually deposited, in the form of argol, as the sugar of the juice becomes converted into alcohol by fermentation. In the preparation of cream of tartar the argol is dissolved in hot water, to which charcoal or fine clay is added, to take up the colouring matter; by boiling and filtering a clear colourless solution is obtained, from which, on cooling, the cream of tartar separates as crystals. These crystals, after being exposed on linen for several days, become whiter and constitute the *crystals of tartar*, or, when ground to powder, the *cream* of tartar. Although cream of tartar is, practically speaking, the bitartrate of potash, $KHC_4H_4O_6$ (see TARTARIC ACID), yet it usually contains from 5 to 10 per cent. of tartrate of lime, while adulterants, properly speaking, may also be present. The tartrate of lime is derived from the clay added to purify it, and is more or less present in all commercial samples. In 1888, however, cream of tartar was offered in the market containing 99 per cent. of bitartrate of potash, so that it may be assumed that in future a purer article will be forthcoming. Cream of tartar is readily soluble in hot water, though it takes 60 parts of cold water to dissolve one part of it. *Soluble cream of tartar* is prepared by dissolving together 2 parts of Borax (q.v.) and 5 parts of cream of tartar, evaporating to dryness and powdering. Cream of tartar has an acid taste and gritty feel. When taken repeatedly in small doses of a scruple to a drachm, it acts as a refrigerant and diuretic; in doses of one to two drachms, it is useful as an aperient; and in larger doses of from two to three drachms it acts as a purging agent, accompanied by flatulence and griping. *Imperial liquid* is prepared by dissolving about a drachm of cream of tartar in a pint of boiling water, and adding a little lemon-peel and sugar to flavour it; when an agreeable refrigerant drink is obtained, which is highly serviceable in allaying thirst in feverish cases. Cream of tartar whey is obtained by adding two drachms of the salt to a pint of milk.

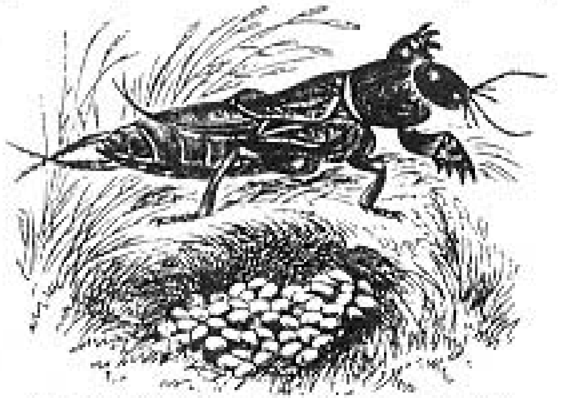
Creasote (Gr. *kreas*, 'flesh;' *sōzō*, 'I preserve') is an oily substance obtained from the tar produced by the destructive distillation of wood. When Coal-tar (q.v.) is distilled, a certain portion called creasote oils passes over, and from this much of the creasote of commerce is obtained. This, although similar in some respects to wood creasote, is quite distinct chemically. The coal product consists largely of carbolic acid, along with creasol and xylenol, while the wood product, to which alone the name creasote rightly belongs, consists of guaiacol, creasol, and phlorol. As it contains several substances, so its boiling-point ranges from 392° to 428° (200°-220° C.). The leading character of wood creasote is that it instantly coagulates albumen, but does not coagulate Collodion (q.v.), in this respect differing from carbolic acid. It has a very remarkable power of arresting the decay of meat or wood, and when meat is treated with so small a proportion as one-hundredth of its weight of creasote, and exposed to the air, it does not putrefy, but becomes hard and dry, assuming the taste and odour of smoked meat. Indeed, there can be no doubt that hams cured by means of wood smoke owe their preservation and flavour to some extent to the volatile creasote in the smoke. Railway sleepers and wood liable to be frequently wet are often saturated with the coal-tar creasote; or, where economy is not so essential, with the wood creasote, and are thereby preserved indefinitely. In toothache, where the cause of pain is a carious tooth with an exposed, inflamed nerve, a drop of creasote, carefully inserted, after previously cleansing the cavity, will often give relief. In this case it acts by coagulating the albumen and destroying the nerves. Creasote acts powerfully on the skin, producing a white stain when applied to it. A few drops added to a pint of ink preserve it from mouldiness. Medicinally, it is given in doses of one or two drops, and has been found efficacious where there is a tendency to fermentation of the contents of the stomach and bowels. Owing to its action on the skin it acts as an energetic poison when taken in large doses.—The Creasote Plant (*Larrea mexicana*), growing abundantly on the borders of the Colorado Desert, emits a strong odour of creasote. The odour arises from an exudation similar to Indian gum-lac, and is caused by the punctures of an insect, *Carteria Larreа*.

Creatin, or KREATIN (Gr. *kreas*, 'flesh'), a constant and characteristic constituent of the striped muscle of vertebrates. It was discovered by Chevreul in 1835, but little was known about it till Liebig published his researches on the *Chemistry of Food* in 1847. Its chemical formula is $C_4H_9N_3O_2$. Except in one doubtful case, it has always been found as above indicated; it is very uncertain if it ever occurs in unstriped muscles, and it has never been demonstrated in invertebrates. A dehydrated form, known as *Creatinin*, $C_4H_7N_3O$, occurs as a constant constituent of urine, and has also been demonstrated in fish muscles. Under the influence of acids, creatin becomes creatinin, and by hydration the transformation may be reversed. As these changes may readily occur during extraction, there is often doubt whether creatin or creatinin is present in a given case.

Cricket (*Gryllus*), a familiar genus of insects in the order Orthoptera, near locusts, grasshoppers, &c. A substantial body, a thick head, long feelers, a rasping organ on the wing-covers of the males, wings closely folded lengthwise, but often along with the wing-covers degenerate, great powers of leaping, and a retiring, more or less subterranean habit of life, are some of the more important characteristics of the family (Gryllidæ) of which the cricket is a type. The females are fertilised by means of peculiar spermatophores, and as in allied Orthoptera there is no marked metamorphosis in the life-history. In the genus Gryllus the head is blunt, the antennæ are long and thin, the wings are always present, the hind-legs are very broad and strong, and the females have a straight protruding egg-laying organ.—The Field Cricket (*G. campestris*) is very common throughout Europe in fields and meadows (local in England), and is very well known from the sound, by means of which the male captivates his mate. The body is compressed, the head is black and shining, the wing-covers are brown and yellow at the roots. As in other crickets, the noise of the males is made by rubbing the wing-covers against one another. The under side of one of the nervures bears over a hundred sharp transverse ridges or teeth. These insects hide in burrows in the ground, and sometimes do much damage to vegetables. The female lays numerous eggs in the burrow, and the larvæ remain as such through the winter.—The House Cricket (*G. domesticus*) has a lanker, yellowish-brown body an inch long. A recent arrival in the United States, it is common throughout Europe in houses, is said to occur in the open air in Madeira, and even in Britain occasionally wanders out of doors in summer. It hides in nooks and crevices, and loves the neighbourhood of the fire, especially in winter. Its merry note has become associated with ideas of domesticity (as in Dickens's *Cricket on the Hearth*). Without the heat of the fire, it becomes more or less dormant in winter. It remains quiet during the day, but hunts about actively at night for crumbs and other scraps both animal and vegetable. For the sake of both food and warmth it often frequents bakehouses. The larvæ are wingless, and the pupæ have only rudimentary wings. The loudest noise made by a cricket is probably that of a Sicilian species (*G. megalocephalus*), which is said to make itself heard 'at a distance of a mile.' Closely allied to the above genus is Myrmecophila, a wingless cricket with extremely strong hind-legs. Only the females are known, and these live parasitically in ants' nests. The Mole Cricket (*Gryllotalpa*) belongs to the same family, and is distinguished by the enormous burrowing fore-legs, by the large size of the anterior ring of the thorax, and by the absence of an ovipositor in the females. The only European species (*G. vulgaris*) is a large and formidable insect, sometimes attaining a length of two inches. It is of a grayish-brown colour, with a silken sheen. It burrows like a mole in fields and meadows, but is sometimes seen in flight in the evenings. Numerous eggs, inclosed in a cocoon, are laid underground. The larvæ are long in becoming adult. The mole cricket often does damage by biting at the roots of vegetable crops. Like the field cricket, however, it feeds very largely on ground insects and the like. A South American and West Indian species (*G. didactyla*) damages the sugar-canes.



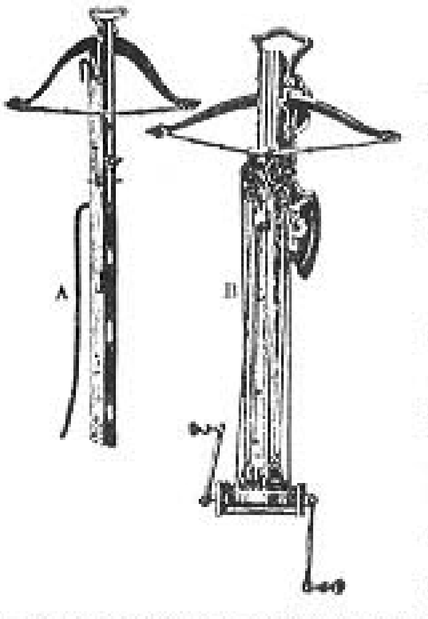
House Cricket (*Gryllus domesticus*):
a, full-grown larva; *b*, pupa; *c*, perfect insect.



Mole Cricket and eggs (*Gryllotalpa vulgaris*).

Critical Temperature is that temperature below which a substance may, and above which it cannot, be liquefied *by pressure alone*. This temperature for carbonic acid gas, for example, is 30·9° C.—i.e. below that temperature, the liquefaction of the substance may be easily effected if sufficient pressure be applied; but above it the substance cannot be liquefied, no matter how great be the pressure to which it is subjected. The discovery of the critical temperature by Dr Andrews in 1869 first gave the means of distinguishing between a true gas and a true vapour; for the former is a substance above, the latter one below, its critical temperature. When any substance is at this temperature it is in the critical state—i.e. its passage from liquid to gas, or *vice versâ*, is one in which the two parts, liquid and gaseous, so merge into one another as to render them optically indistinguishable. The critical temperatures of oxygen, hydrogen, and nitrogen (formerly termed 'permanent' gases) are all extremely low, and hence liquefaction can only be effected (as it has already been) by the application of intense cold as well as considerable pressure. On the other hand, such vaporous bodies as sulphurous anhydride, alcohol vapour, ether vapour, &c. can, provided the pressure be sufficiently great, be liquefied at ordinary air temperatures, since these are much below their critical temperatures.

Crossbow, or ARBALEST, a weapon used in war and sport in mediæval times. It consisted of a wooden stock, with a bow made of wood, iron, or steel, crossing it at right angles to the end: the bowstring was pulled down towards the other end of the stock by a lever (which in the simpler kinds was worked by hand or foot), and retained in position sometimes in a notch by a catch or trigger. The bolt or 'quarrel' was then laid in a groove on the top of the stock, and the trigger being pulled, it was shot with a considerable amount of power. The latter, of course, depended on the size of the bow, some of the weapons being comparatively small and easily handled, while others were of large dimensions, and required a machine of the nature of a windlass, called a 'moulinet' or 'gaffle,' to enable the bow to be properly bent. The crossbows of the 14th century were almost all thus equipped. The 'quarrels' employed varied with the size of the bow, but generally they were short stout shafts about 18 inches long, winged with horn or leather, and having a metal point, which was sometimes sharp, but often lozenge-shaped, obtuse, and indented at the sides. Some crossbows had a tube or barrel, with a slit for the bowstring, and discharged balls of clay, marble, or lead with such force that they were more formidable weapons than the earliest firearms. The larger crossbows were really military engines, which required several men to work them, and threw proportionally heavy missiles (see BALLISTA). The crossbow was used in England chiefly during the 13th century; after that it gave place to the longbow, which was found to be the more convenient and easily handled weapon of the two. Its use, however, was general among the continental nations of Europe after the 12th century; though the Lateran Council of 1139 forbade its use as being too murderous a weapon for Christians to employ against one another.



A, Hand Crossbow; B, Rolling-purchase Crossbow.

Croton, a genus of plants of the natural order Euphorbiaceæ, with numerous species, which are mostly tropical or subtropical trees or shrubs, a few herbaceous. The most important is the Purging Croton (*C. Tiglium*), a small tree, a native of India and the more easterly tropical parts of Asia. The leaves are extremely acrid; the wood in a fresh state is a drastic, and in a dried state, a more mild purgative; and the seeds (*Croton Seeds*, or *Tilly Seeds*) are a very powerful drastic purgative, formerly much employed in Europe, but latterly disused on account of violence and uncertainty of action, although still valuable as yielding croton-oil. They are oval or oval-oblong, about the size of field-beans. So great is their acridity, that dangerous effects have ensued from working for some hours with packages of them. The oil is obtained mostly by expression, and partly by treating the cake with alcohol. The wood and seeds of *C. Pavana* are employed in some parts of the East in the same way as those of *C. Tiglium*. Other species possess similar properties. Very different are the properties of the species which yield Cascarilla (q.v.) and Copalchi (q.v.) barks. Other species are still more aromatic, and some delightfully fragrant, containing in great abundance a thickish balsamic sap. The sap of *C. gratissimus* is employed as a perfume and cosmetic at the Cape of Good Hope; that of *C. origanifolium* is used in the West Indies as a substitute for Balsam of Copaiva; that of *C. balsamiferum*, also West Indian, furnishes *Eau de Mantes* by distillation; and the balsamic sap of some South American species is dried and used as incense. The *C. Draco* and other species yield a blood-red juice, which, when dried, forms the finest kind of dragon's-blood, and is possessed of astringent properties.

Croton.

CROTON-OIL is the oil expressed from the seeds of the *C. Tiglium*, and is a sherry-coloured, viscid liquid, with an acrid taste, a somewhat rancid smell, and a fluorescent appearance. It contains a number of oily bodies, none of which have as yet been definitely shown to be the cause of its purgative and vesicating properties. Croton-oil is a violent purgative, in most cases a single drop being sufficient to remove constipation. When rubbed upon the skin it produces rubefaction and pustular eruption, and thereby tends to relieve some affections of the internal organs. It is used either by itself in the unmixed state, or diluted with olive-oil, soap liniment, alcohol, &c. It is not to be employed except under the advice of a doctor.

Croup, a term used in Scotland from an early period to describe a certain train of laryngeal symptoms, was first applied by Dr Francis Home, in 1765, to an acute inflammatory and non-contagious affection of the Larynx (q.v.), in which there is the formation of a false membrane or fibrinous deposit on the mucous surface of the windpipe. The invasion of the disease resembles that of simple Catarrh (q.v.), and may be very insidious. The child is languid, feverish, and thirsty, and a dry, shrill cough is gradually developed, but these symptoms sooner or later give way to those of the second stage. Here the respiration becomes difficult, the drawing of each breath having a hissing and 'croupy' sound; the voice is almost inaudible or greatly modified, and accompanied by a harsh, brassy, or may be stifled cough; the face is red and swollen, and covered with sweat; and the nostrils are rapidly working. If the little patient is not relieved by coughing or vomiting up some membraneous shreds and glairy mucus, a state of greater dyspnœa ensues; the lips become livid and the nails blue; the fever is higher, the pulse quicker but weaker; and the child's efforts to relieve the increasing obstruction to the breathing are most distressing to witness. A period of extreme restlessness and suffering is (unless relieved by immediate treatment—see below) soon followed by death from increasing coma, syncope, or exhaustion.

Croup seems to be caused by a damp atmosphere of low temperature, and is got in exposed situations. It is most frequently met with between the years of two and ten, although all ages and classes are liable to suffer from it. It is commoner in boys than girls. Croup requires to be distinguished from simple catarrh of the windpipe; from so-called false croup, a spasmodic affection of the larynx—the Laryngismus Stridulus of Dr Mason Good; and from Diphtheria (q.v.), an infectious disease in which a false membrane is usually found on the pharynx or palate, as well as in the larynx. As croup is an acute and very fatal disease, the treatment requires to be active and decided. If the case is seen early, apply an ice-bag to the throat and give ice to suck, but if you suspect the presence of false membrane, give a full dose of an emetic, such as ipecacuanha, sulphate of copper, or sulphate of zinc, which should be repeated in three or four hours if necessary and effectual in relieving the breathing. The child should at intervals be placed in the hot bath, and inhalations of steam or medicated vapours administered. An inhalation of lactic acid is often of great use in the first stage. If these means fail, Tracheotomy (q.v.) must be at once resorted to, to save the life of the patient, as recommended by Trousseau.

Crucibles (Low Lat. *crucibulum*; from the root of Old Fr. *cruche*, 'a pot') are vessels made of materials capable of being exposed to high temperatures without alteration, and used for fusing substances together, such as the materials for glass-making, or metallic ores, with various fluxes to obtain the several metals they yield. Crucibles should resist the corrosive action of the substances brought into contact with them, and are generally made of fireclay, porcelain, graphite, iron, platinum, and, for some special operations, of silver. See ASSAYING.

Crucible.

Crystallography (from the Greek *krustallos*, 'ice,' an idea among the ancients being that rock-crystal, which may be taken as a type of crystalline minerals, resulted from the subjection of water to intense cold). Minerals, salts, and inorganic bodies generally (examples, rock-crystal, fluor-spar, alum, and sugar) exist in the crystalline state; and when we examine all crystals, whether occurring naturally or obtained artificially, certain laws have been discovered, and phenomena observed, and these laws and phenomena constitute the science of crystallography. The following are the more important laws and principles of the science:

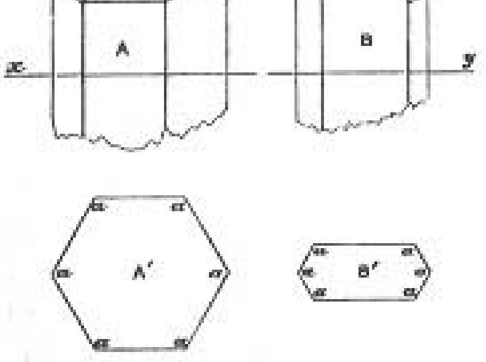


Fig. 1.

Drawings of two crystals differing much in appearance, but with angles at *a* shown to be constant when similar sections are made.

(1) *Law of Constancy of Angles.*—Crystals of the same substance may differ much in general appearance, but when the angles between their faces are measured these angles are found constant. Thus the crystals A and B (fig. 1), when cut through in the direction *xy* at right angles to the prism, give the sections shown at A′, B′; and in each section the angles *a* will be found the same—viz. 120°; or again, if the angles between the faces *ab*, *bc*, or *ac*, be measured, they will be found identical in both crystals.

(2) *Law of Symmetry.*—Suppose we cut a crystal in two, and then place the two parts with their cut surfaces on a mirror. The mirror will reflect each part, and may or may not produce the appearance of the original crystal. If the mirror will produce the appearance of the original crystal, we have severed the crystal in a plane of symmetry. Thus with a cube, if we cut it in either of the planes *abc*, *def*, *ghk*, *lmn*, *opq*, *rhm*, *nhg*, *lkn*, *gmk*, and place in each case the two severed parts on a mirror in the way described, the reflection together with the object will reproduce a cube. There are then in the cube nine planes of symmetry. The octahedron and dodecahedron similarly have nine planes of symmetry. With such a form as a common brick there are three planes of symmetry, while with other forms varying numbers of planes of symmetry may be found, until with a sphere there are an infinite number of planes of symmetry, for it is obvious that if a sphere be cut anywhere by a plane passing through its centre, and the half thus obtained be laid upon a mirror, the appearance of a complete sphere will be produced. Now examining all (holohedral) crystals, it is found that they fall into one of the following six categories or systems: (1) *Anorthic System.*—No plane of symmetry—examples, copper sulphate and anorthite. (2) *Oblique System.*—One plane of symmetry—gypsum and washing-soda. (3) *Prismatic System.*—Three planes of symmetry at right angles to each other—barytes, saltpetre, and native sulphur. (4) *Rhombohedral System.*—Three planes of symmetry at 120° to each other—calcite, quartz, and ice. (5) *Pyramidal System.*—Five planes of symmetry—cassiterite, zircon, and idocrase. (6) *Cubic System.*—Nine planes of symmetry—fluor-spar, galena, and alum.

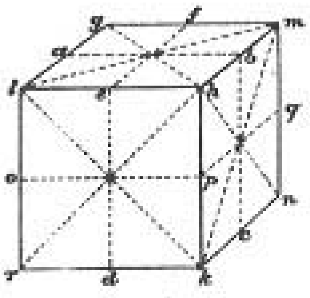

Fig. 2.

Each of the planes represented by dotted lines is a plane of symmetry.

(3) *Law of Rationality of Indices.*—The various planes of crystals, as explained below, are indicated in the Millerian system by three numbers, which together form the symbol of the plane. Thus we have planes represented by 1 2 3, by 1 1 1, by 1 1 0, &c. Now the law of rationality asserts that the symbol of a plane must be represented by numbers which are rational—i.e. numbers which can be expressed exactly, not those like $\sqrt{2}$, $\sqrt[3]{4}$, &c., which can only be obtained approximately. Thus by the law of rationality, no plane of a crystal can have such a symbol as $1\ \sqrt{3}\ 5$, $1\ \sqrt{2}\ 0$, &c.

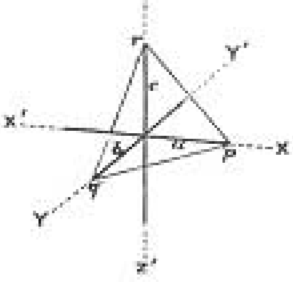

Fig. 3.

The plane 1 1 1 in Miller's notation.

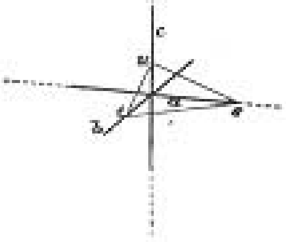

Fig. 4.

The plane 1 2 3 in Miller's notation.

Crystallographic Notation.—Several methods of representing planes of crystals by symbols are in use. Two of these only need be mentioned—viz. Miller's notation and Naumann's notation. In both systems the planes are referred to three axes corresponding in direction to three edges of the crystal.

Let *abc* (fig. 3) represent parts or parameters cut off from three axes *xyz*, then in Miller's system the plane 1 1 1 represents a plane which cuts the *x* axis at one-oneth of *a*, the *y* axis at one-oneth of *b*, and the *z* axis at one-oneth of *c*. Such a plane is indicated by *pqr*. The plane 1 2 3 means a plane which cuts the *x* axis at one-oneth of *a*, the *y* axis at one-half of *b*, and the *z* axis at one-third of *c*. Such a plane is represented by *stu*, fig. 4. The plane 1 1 0 means a plane which cuts the *x* axis at one-oneth of *a*, the *y* axis at one-oneth of *b*, and the *z* axis at one-noughth of *c*—i.e. does not cut *c* at all, or is parallel to it. Such a plane is represented by *uvxs* in fig. 5.

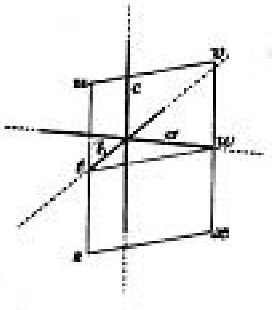

Fig. 5.

The plane 1 1 0 in Miller's notation.

In Naumann's system some form is selected as the fundamental pyramid of the crystal, and his pyramid, which corresponds to Miller's form, 1 1 1, is represented by the letter P in all systems but the cubic (in this system it is called O) and the rhombohedral (in this system it is called R). Thus the planes marked P (fig. 6) form the fundamental pyramid, the planes $\frac{1}{2}$P are those of a pyramid one-half the height, while the basal plane is represented by *o*P or a pyramid of no height, while the planes ∞ P represent a pyramid of infinite height.

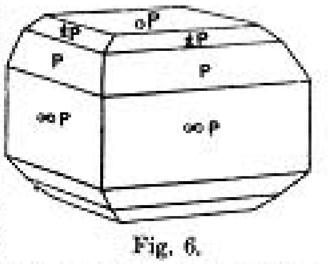

Fig. 6.

A crystal with the faces marked in Naumann's notation.

Drawing and Mapping of Crystals.—Various modes of representing crystals have been adopted. Perspective drawings are made by projecting the axes according to the rules of Projection (q.v.), then the various planes are indicated, and from these their intersections are known, and these intersections form the drawing of the crystal. Fig. 7 represents one octant of the form 2 1 1 drawn by this method. Some writers represent crystal forms by orthographic projections—that is, represent them in plan and front elevation. Of all methods, however, of representing crystals from measurements made with the goniometer, the most elegant and convenient is that of spherical projections. Two kinds of spherical projection are in use—viz. the *gnomic* and the *stereographic*. Imagine a glass sphere placed within a crystal, as in fig. 8, and suppose the faces of the crystal to move parallel to their original positions until they touch the

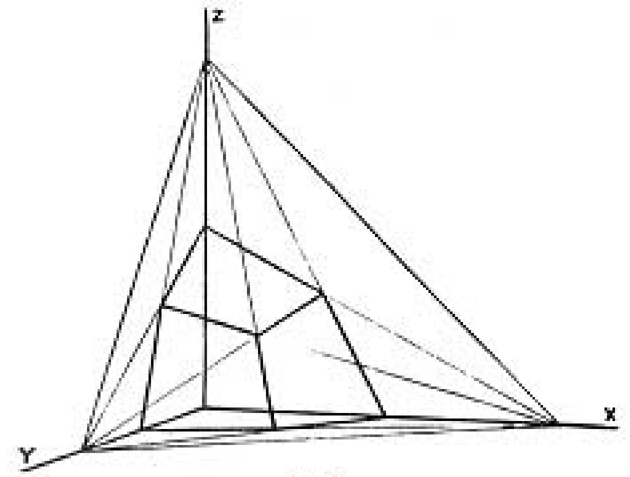

Fig. 7.

Mode of drawing a crystal from projection of axes.

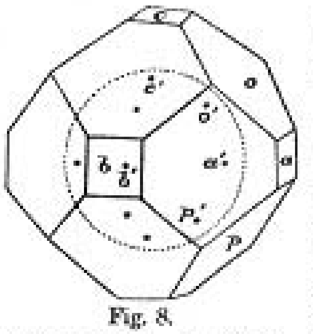

Fig. 8.

Sphere within a crystal. When planes are moved they touch the sphere where dots are marked.

sphere, and where the faces touch let dots be marked on the sphere. Thus the face *a* will produce the dot *a'*, the face *o* the dot *o'*, and so on. When the sphere is thus marked with dots corresponding to the several faces, the next thing is to make a map of the dots in their proper position. If the map is to be made on the gnomic projection, the sphere is supposed to be placed on the paper on which the map is to be made, and the eye is then placed at the centre of the sphere. The various dots when projected on to the paper as seen by the eye placed at the centre of the sphere produce the map. If the map is to be made on the stereographic projection, suppose a piece of glass to pass through the centre of the sphere as in fig. 9, and let the eye be placed touching the sphere at E, then the dots as they appear on the glass to the eye at E form the map. Such a map of the crystal of fig. 8 is given in fig. 10. In the stereographic projection all great circles on a sphere are represented on the map by either straight lines or arcs of circles, whereas in the gnomic projection they are represented by straight lines. The map (fig. 10) shows not only the position of the dots or poles, but also great circles passing through the sphere. These great circles correspond to the planes of symmetry of the cube (fig. 2) and other forms of the cubic system. These stereographic maps, as will be seen by reference to treatises on the subject, convey a good deal of information respecting the crystals they portray.

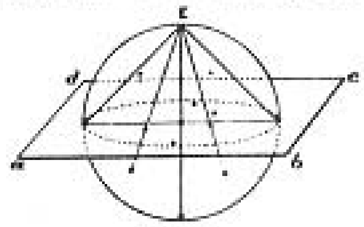

Fig. 9.

The eye placed at E sees the dots on lower part of sphere projected on the plane *a b c d*.

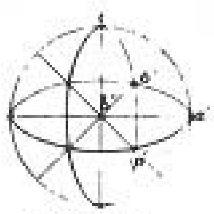

Fig. 10.

Stereographic map of the crystal of fig. 8 as obtained by method in fig. 9

Planes of crystals form a *zone* when the intersections of the planes (i.e. the edges) are parallel to each other. Thus, in fig. 6 the faces *o*P, ½P, P, and ∞P form a zone. Now in Miller's notation these forms have the indices 0 0 1, 1 1 2, 1 1 1, 1 1 0, and it will be noticed that all these symbols have a common ratio—thus, the first and second index are equal to each other. It may be shown that this is universally true; hence, knowing the indices of a plane, we can say whether it is on a particular zone, or knowing that a plane lies in two zones, we can determine its indices. Thus, the planes 1 2 3, 1 2 4, 1 2 5, &c., are all in one zone, as the symbols have the common ratio 1 : 2, and the plane 3 4 5 cannot be on this zone, because its symbol does not contain the ratio 1 : 2.

Holohedrism and Hemihedrism.—Crystals which have all faces present as required by the law of symmetry are termed holohedral. Where, as is often the case, only one-half of these faces are present, the crystal is said to be hemihedral; while if only one-fourth of the full number of faces are present, the crystal is said to be tetartohedral.

Physical Crystallography.—The physical properties of crystals have some interesting relations to the symmetry and form of the crystal, and these properties are included generally with crystallography. Thus, if in the regular system a face is striated or has any peculiarity, this striation or peculiarity will be found on each face which is present by the law of symmetry. Again, most crystals cleave (i.e. break easily) in certain directions, and the cleavage planes follow the law of symmetry. Again, when examined by polarised light, other properties of crystals in relation to symmetry are brought out. Thus, crystals of the regular system (except in a few certain cases) do not doubly refract light, no matter in what direction the light is incident. With crystals of the rhombohedral system and the pyramidal system light is not doubly refracted when it falls parallel to the vertical axis, but in other directions it is doubly refracted; while in the remaining systems two directions can be found in which the crystals of these systems do not doubly refract light, though they do so in all other directions. Again, heat is conducted differently in different systems of crystals. Suppose crystals turned in a lathe into spheres, and that the centre is made suddenly hot, then in the regular system the heat spreads equally, and after a time the surface of the sphere is uniformly raised in temperature; with other systems the effect is different; with the pyramidal and rhombohedral systems a similar experiment would result in the surface of the sphere being heated uniformly over belts corresponding to an equator and parallels of latitude, but the temperature of the different belts would be different, thus showing that heat is propagated in two directions at right angles to each other with different velocities. With other systems more complex results would be obtained owing to heat being propagated in three directions with different velocities.

When soluble crystals are placed in a solvent the faces are eaten out differently, producing figures termed by German writers 'aetzfiguren.' These figures will often indicate the symmetry of the crystal, and have been useful in such determination. As physical properties generally are related to elasticity, Groth states that the best way to define a crystal is that it is a solid body, the elasticity of which is the same in all parallel directions, but on the contrary is different in different directions.

Crystalloid is a name given by Graham to a class of substances which when in solution pass easily through membranes; as opposed to *colloids*. Metallic salts, sugar, oxalic acid, are crystalloids.

Cubebs, or CUBEB PEPPER, the dried berries of *Piper Cubeba*, a climbing shrub, a native of Sumatra, Java, and Southern Borneo. The berries are about ¼th of an inch in diameter, and are furnished with a thin stalk a little longer than the berry itself. The fruits of other species of Piper are sometimes substituted for the true cubeb, such as those of *Piper longum*, &c., but in general the stalks of these substitutes are either wanting or are less than the length of the berry. Although known to the Arabs in the middle ages, and used in medicine as well as in culinary art, cubebs fell gradually into disuse, till at the beginning of this century all reference to it was omitted in medical books, and its importation into Britain ceased entirely. It is again, however, coming into use. As a stomachic and carminative in indigestion it has a certain value, while in piles and in sore throats its administration is attended with benefit.

Cubebs contains a volatile oil, a crystalline substance called *cubebin*, and resinous bodies, one of which is *cubebic acid*. The cubebin is inactive, while the volatile oil is not believed to have the full virtue of the cubebs. It enters, however, into the composition of a well-known voice lozenge, to which it imparts highly stimulating properties. The diuretic properties are held by some to be entirely due to the resinous bodies, but on this point there is difference of opinion. The dose of powdered cubebs is from one to three drachms, that of the volatile oil ten drops, and of the oleoresin five to thirty drops.

Cudbear. The lichens from which, and the process by which, this dyestuff is obtained, are described under the head ARCHIL, cudbear being simply archil paste dried and ground. It is very useful to the wool-dyer for producing, in conjunction with indigo, logwood, fustic, and other colouring materials, rich shades of brown and chocolate. The preparation of archil, known as French purple, was used for a short time in calico-printing, and produced fine and delicate shades of purple, but its employment for this purpose ceased soon after the introduction of aniline mauve as a dyestuff. The ancient Cretan purple was probably obtained from the same source as archil. The name cudbear is a corruption of *Cuthbert*, and is derived from that of Dr Cuthbert Gordon, under whose management the manufacture of this dyestuff was begun in Leith about the year 1777, by Mr Macintosh of Glasgow.

Cudweed, the popular name of many small inconspicuous species of composite weeds of the genera Gnaphalium, Filago, and Antennaria, the stems and leaves of which are more or less covered with a whitish cottony down. The heads of the flowers consist, in great part, of dry involucral scales, and may be kept for a long time without undergoing much apparent change, so that they may be reckoned among *Everlasting Flowers* (q.v.). *Antennaria dioica* (also called Cat's-foot) is very frequent in dry mountain-pastures. All the three genera are represented in the United States, where *Gnaphalium polycephalum* has some repute in domestic medicine.

Culm, a kind of impure Anthracite (q.v.). In some districts the culm obtained from the pits in a broken and crumbling condition is used as fuel, being made up into balls, with one-third of its bulk of wet viscid clay. It burns without flame, producing a strong and steady heat, well adapted for cooking (see BRIQUETTES). The term *Culm-measures* is applied to the carboniferous strata of Devonshire, on account of the workings for culm near Bideford, and other places.

Curari, URARI, WOORALI, or WOORARA, is a celebrated poison used by some tribes of South American Indians for poisoning their arrows. It is by means of this poison that the small arrows shot from the Blowpipe (q.v.) become so deadly. It is brought to Europe as a black, brittle extract, resinous in appearance, and encrusting the sides of little gourds containing it. The source of this deadly poison was for long unknown, owing to the natives jealously guarding the secret. The process of manufacture has now, however, been witnessed and described by several travellers, and in each case some species or other of Strychnos has been recognised as the source of the poison. There seem to be four distinct varieties of curari, each characteristic of a different tract of country, and probably varying in their physiological action; but for our purpose we may confine ourselves to that kind which is used in physiological experiments. Curari is one of those poisons which have little action when taken into the stomach, owing to the difficulty with which they are absorbed, but when introduced into a wound it acts with great promptness. The symptoms caused are loss of muscular power, feeble respiration, and death by suffocation. By means of artificial respiration it is possible to sustain life for a lengthened period, although the animal is apparently insensible to pain. In this way it is employed in vivisection experiments as an anæsthetic.

At first it was supposed that curari contained strychnine, but as its action was so entirely different, this view was soon abandoned. Prolonged research has separated a special alkaloid, *Curarine*, which possesses the leading properties of the poison itself. *Curarine* differs from all other crystallisable alkaloids, save one, in containing no oxygen. It forms salts, and is said to be twenty times as strong as curari. In medicine curari is very little used. It has been proposed to employ it in lockjaw, hydrophobia, and as an antidote in poisoning by strychnia; but although it quiets the spasm, it has no direct curative effect, and it may cause an equally fatal paralysis.

Besides curari proper, there are two other arrow-poisons called Corroval and Vao. These, which are brought from New Granada, have an entirely different action on the body, as they primarily stop the beating of the heart, whereas with curari the heart continues to beat after breathing has ceased.

Currant Wine is made of the juice of red or white currants, to which is added about one pint of water for every four pints of berries employed. About a pound and a half of sugar is afterwards added to each pint of the liquor, a little spirits being generally also added, before it is set aside to ferment. A larger quantity of sugar is sometimes employed, and no water, and a stronger and sweeter currant wine is thus produced. Fermentation requires several weeks, and the wine is not fit for use for at least some months afterwards. Black currant wine is made in the same way from black currants, but the fruit is put on the fire in as small a quantity of water as possible, and heated to the boiling-point before it is bruised.

Curry Powder, or CURRY PASTE, is a compound of turmeric, coriander, pepper, ginger, and various spices; it is used to a large extent in India and elsewhere as a seasoning for a variety of dishes.

Cuticle, a sheath formed outside a layer of cells, either by their secretory activity or by a modification of their external portions. In the strict sense, a cuticle is not in itself cellular, but consists of the products or of the modified portions of underlying cells. The thin envelope which may be readily stripped off a leech or earthworm when killed in spirit supplies a convenient example. A cuticle is usually formed outside relatively passive cells, but even ciliated Epithelium (q.v.) may have its cuticular outer layer through the pores of which the cilia emerge. By continuous modifications of the cells considerable thickness of cuticle may be developed—as e.g. the hard lining of the gizzard in many birds. By chemical modification of a well-developed cuticular formation very varied protective and offensive skin-structures often result. Thus the peculiar gelatinous, cellulose-containing tunic of Ascidians is for the most part a cuticle; the shells of molluscs are cuticular formations plus lime; the raspers of snails are formed from cuticle; the hard armour of Arthropods is a cuticle associated with the formation of Chitin (q.v.); the bristles, jaws, and firm sheaths of many worms are also cuticular, and so on. For the use of the term in special connections—e.g. the cuticle of the hair or of the teeth, see special articles. The term must not be confused with *cutis*, one of the names for the under skin or *dermis*; nor should it ever be used as equivalent to skin.

Cuttings are branches or portions of branches of trees or shrubs, employed to produce new plants, by burying the lower end in the earth so that new roots may arise from the nodes. Nothing is more easy than to propagate willows, fuchsias, pinks, geraniums, currants, gooseberries, &c. in this way; but many other plants, commonly propagated by cuttings, require greater attention on the part of the gardener, warmth, a uniform damp atmosphere, and shade. The term cutting is, however, usefully extended by most horticultural writers to any part of a plant which can be separated to become an individual similar to its parent; thus some plants may be propagated most readily from simple leaves or portions of leaves, others from a segment of stem bearing a single leaf with a bud at its base, others from offshoots at the base of the parent plant, some again from the younger shoots, and others from partially ripened wood, and so on. Hence there is room for considerable experience and skill, and detailed instructions should be sought by the amateur florist in works on horticulture (e.g. Johnson's *Dictionary of Gardening*). The most convenient general method, however, is to strike cuttings in well-drained shallow pots or boxes of silver sand overlying a little sandy peat or loam; shade and water being applied with discretion, and bottom heat only in special cases, which of course include the majority of stove plants. Hardy fruit-trees may be best propagated by cuttings taken after the fall of the leaf, and planted on the north side of a wall, but not so close as to be constantly in shade.

Cyanogen, CN or Cy, although intrinsically of little importance, is one of the most interesting compounds of carbon. It was the first known compound body which was proved to be able to unite with elements in the same way as these substances unite with each other. Thus hydrogen, H, unites with chlorine, Cl, to form hydrochloric acid, and sodium, Na, unites with chlorine to form chloride of sodium, NaCl. Like these elements, H, Cl, or Na, each a single substance, the group CN, consisting of 12 parts of carbon and 14 of nitrogen, enters into combination, acting as if it also were for the time being an element; thus it forms cyanide of sodium, NaCN, or NaCy, and hydrocyanic acid, HCN, or HCy. There are now many thousands of such *radicles* known, of which the groups methyl, CH_3, ethyl, C_2H_5, &c. may be taken as other examples.

Cyanogen is a colourless, poisonous gas, which burns with a purplish flame. It is soluble in water, and can be condensed to a liquid, under a pressure of about four atmospheres (60 lb. per sq. inch). It may be obtained by heating the cyanide of mercury, $HgCy_2$, when the cyanogen passes off in the gaseous state.

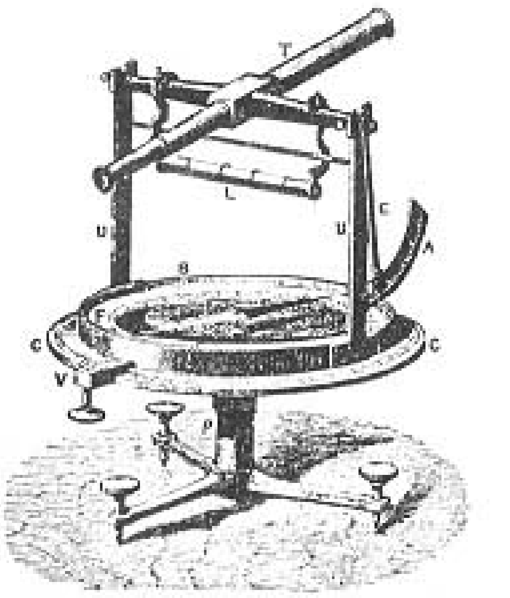
Cyanogen forms poisonous compounds with metals called *cyanides*, of which the best known is the *cyanide of potassium*, a salt of much importance in photography. With hydrogen it forms the deadly prussic or hydrocyanic acid, while it is united with oxygen in cyanic acid. For the properties of *cyanides*, see HYDROCYANIC ACID.

Cyanic Acid is a compound of cyanogen which can hardly be prepared in the free state, owing to its great tendency to decompose. It forms a class of salts called *cyanates*, of which the chief is the cyanate of potash. This salt is produced when cyanogen gas is passed into solution of potash. The formula of cyanic acid is HCyO, that of the potash salt being KCyO.

Cystin, or CYSTIC OXIDE, forms a rare variety of urinary Calculus (q.v.). Its chemical composition is $C_3H_7NSO_2$, and it forms a whitish or dirty yellow deposit consisting of six-sided crystalline tablets. It is soluble in ammonia, and is thereby distinguished from the similar crystals of uric acid.

Damascening, or DAMASKENING, is a name which is given (1) to the watered or striated structure seen in certain sword-blades and other weapons, and (2) to the ornamental incrustation with gold and silver of steel and iron surfaces. The term in both its applications originates from the city of Damascus, whence the crusaders brought into Europe swords and other weapons of remarkable strength, elasticity, and keenness of edge, the surfaces of which were beautifully striated with waved dark and light lines. The hilts of such weapons, and the whole surface of defensive armour from the same source were in many cases elaborately ornamented with incrusted gold, and hence one term came to be applied to the peculiar structure of the metal, and to its ornamental treatment. It is probable that even in the crusaders' times the making of the so-called Damascus blades and the art of damascening were Persian, and to this day they remain characteristic of that country, the practice having spread thence eastward into India, while the Persians still supply the Turks on the west with their best and most highly ornamented weapons. The production of a watered or damascened surface is illustrated by the manufacture of 'Damascus twist' barrels for sporting-guns. The metal for the barrels is prepared from rods of iron and steel, piled alternately and forged and welded together into a single solid rod of small section. Three of these composite rods are used in forming a barrel. They are separately twisted in contrary directions till each has the appearance of a fine threaded screw, then they are welded together into a solid ribbon, which in its turn is spirally wound and welded by the edges till the requisite length and bore of barrel are formed. The result of the intertwisting of fine laminæ of steel and iron is a beautifully damascened surface which shows itself when the barrel has been treated with acid. The incrustation of arms, armour, and other objects of steel and iron with gold, and more rarely with silver, is very extensively practised in the North-west Provinces of India, as well as in Persia. In India it is known as Kuft work or Kuftgari. The design to be worked out is undercut in the metal, into this the gold or silver wire is laid, and the scarp edge is beaten down with a hammer, thus securing the wire in its position. Another method consists in scratching the surface, and beating into the scratched lines the gold or silver wire, after which the whole surface is burnished to remove the incisions.

Damping off, in Horticulture, the death of plants from excess of moisture in the soil and atmosphere. Young seedlings in stoves and hot-beds are particularly liable to it. Although the cause is sufficiently obvious, prevention is not always easy; not only because some plants are very sensitive as to moisture, but also because the necessity of keeping sashes closed on account of temperature often stands in the way of the ventilation which would otherwise be desirable, and it is when a moist atmosphere stagnates around them, and the temperature is not very low, that plants are most liable to damp off.



Declination Needle.

Declination Needle, or DECLINOMETER. The magnetic meridian passing through any place on the earth's surface is a vertical plane whose direction is that in which a magnetic needle, free to move about a vertical axis, comes to rest under the influence of the earth's magnetic force. In general, the magnetic and geographical (or astronomical) meridians are not coincident; the angle between is termed the magnetic declination, or (in nautical phraseology) the variation. It is east or west, according as the magnetic is east or west of the geographical meridian. Any apparatus for the measurement of this angle is termed a declinometer, and consists essentially of a means of ascertaining the two necessary elements—viz. the directions, at the place of observation, of the two meridians. The accompanying figure represents one such instrument, the declination needle or compass. Upon a tripod, provided with levelling screws, stands the pillar P, to which is fixed the graduated circle CC. The compass-box B, with the attached vernier V, moves on the azimuthal circle by means of a pivot on the pillar P. Two uprights, U, U, are fixed to the side of the compass-box, on the tops of which rests the axis of the telescope T. A graduated arc, A, is fixed to the bottom of one of the uprights, and the angle of elevation of the telescope is marked by the vernier on the arm E, attached to the axis of the telescope, on which is hung the level L, for adjusting the instrument previous to making an observation. Inside the compass-box is another graduated circle F, the line joining the zero-points of which is parallel to the axis of the telescope. The compass-box and telescope thus move round together on an axis passing through the centre of the azimuthal circle. When an observation is made, the instrument is first of all levelled, and the telescope directed to a star which is either on the astronomical meridian or whose position with respect to it is known. The reading of the inner circle then gives the declination at once, in the former case; if the latter—i.e. if the star be not on the meridian, the reading of the inner circle has to be corrected by adding or subtracting, as the case may be, the position of the star in azimuth, in order to give the declination. In order to obviate error due to the non-coincidence of the magnetic and geometric axes of the needle, a second reading is taken with the face of the needle reversed; the mean of the two readings is taken as the true declination.

It is found, however, that this instrument only gives results approximately correct, and has in consequence been superseded in observatories and magnetic surveys by a form of the unifilar magnetometer. For an account of the determination of declination by this latter instrument, see MAGNETOMETER. Details as to the value and secular change of the declination at different places on the earth's surface will be found under MAGNETISM.

Decoction, the term applied in pharmacy to the solution procured by boiling an organic substance with water.

Decolorim'eter, an instrument for determining the power of portions of bone-black or animal charcoal to abstract colouring matter. See CHARCOAL.

Decomposition is the rather comprehensive term applied to the breaking up of complex substances, or substances of delicate stability, into others which are less complex or more stable. Such breaking up is very familiar in many chemical changes, and may result from increase of temperature, the action of light, the action of ferments and micro-organisms, and so on. The ordinary process of alcoholic fermentation is a good example of decomposition, which takes place in the presence of, and is dependent upon, the life and growth of yeast in the saccharine solution. Similarly the oxidation of nitrogenous organic matters with formation of nitrates, if not dependent upon, is greatly accelerated by the presence of a micro-organism.

The term decomposition is constantly applied in chemistry to the changes which compounds undergo in the most varied circumstances when subjected to change of conditions. See also CHEMISTRY, FERMENTATION, PUTREFACTION.

Deflagration is the term applied to the rapid combustion of ignited charcoal when a nitrate (such as nitrate of potash) or a chlorate (such as chlorate of potash) is thrown thereon. As chlorates do not occur naturally, it follows that deflagration with a natural salt indicates a nitrate; and if the deflagration be accompanied by a violet flame, it is characteristic of nitrate of potash (ordinary nitre or saltpetre); and if by a strong yellow flame, it is indicative of nitrate of soda (cubical nitre).

Deliquescence is the term applied to the property which certain substances have of absorbing moisture from the air, and becoming damp, and even running into liquid. Caustic potash, and the chlorides of calcium and magnesium, are examples of substances which undergo this change.

Delirium is a condition in which there is perversion of the mental processes. In its essential nature this symptom is analogous to insanity; insanity is, in short, a similar state, unaccompanied by the obvious conditions which are the causes of delirium.

In health the mental processes correspond to present sensory impressions or to the memory of those which are past, but in delirium this correspondence ceases, and the results of cerebral activity bear no true relation to reality. Delirium has three well-known mental phenomena, any or all of which may be present in any individual instance. The mind may be possessed by false ideas or *delusions;* sensory impressions may produce false perceptions or *illusions;* or there may be fictitious perceptions or *hallucinations*, without the presence of any sensory impressions.

The more common causes of delirium are four. (1) Local diseases of the brain or its envelopes, as in the case of inflammation of the lining membranes. (2) Toxic substances circulating in the blood, which may have their origin within the system, as in the retention of waste products during the final stages of kidney disease, or may be introduced from without, such as the specific poisons of the acute infectious diseases, or active substances like alcohol. (3) High body temperatures, which may occur apart from any blood-poison in a local inflammation of some distant organ. (4) Inanition, which may often be seen in the concluding periods of wasting diseases.

Delirium Tremens is the term employed to denote one of the acute phases arising in the course of chronic Alcoholism (q.v.). It is as a rule precipitated by a period of indulgence in excessive drinking, and shows itself at first in the form of general uneasiness and restlessness during the day, followed by sleeplessness, or disturbed sleep with distressing dreams, at night. These initial symptoms usher in the stage of delirium, always accompanied by constant muscular tremors. The delirium almost invariably presents the three main varieties of mental disturbance—illusions, hallucinations, and delusions—to which reference has been made in the preceding article. An attack generally lasts about three days, but it may exist for a period of six or seven days, and, so far as is at present known, there is no means of shortening its duration. The chief danger lies in the great tendency to exhaustion which the disease shows. One attack appears to have a power of predisposing the individual who has suffered from it to subsequent recurrence. The affection frequently induces some degree of mental weakness, and this is more likely to be the case in those who belong to families which have a hereditary tendency to insanity. As above mentioned, no means is known of cutting short an attack, and the employment of drugs in this disease is of at least doubtful utility. The only rational treatment consists in the use of every expedient which can tend to sustain the patient, and avert the great tendency to exhaustion of the vital centres.

Demand and Supply. In Political Economy demand has reference to the quantity of goods asked for in the market, and supply has reference to the quantity of goods offered. The laws of demand and supply may be thus stated: when the demand exceeds the supply, competition grows stronger among the buyers, and prices rise, and when the demand falls short of the supply, competition grows stronger among the sellers, and prices fall; or thus, falling prices tend to lessen the supply and increase the demand, while rising prices tend to increase the supply and lessen the demand. A rise in prices tends to encourage production, while a fall in prices tends to discourage it. Conversely, consumption is promoted by falling and lessened by rising prices. The result is that demand and supply continually tend to equilibrium. Under such a system it is assumed that buyers and sellers or producers and consumers are free to fix their own prices. In other words, the laws of supply and demand prevail under a system of free competition.

Demulcents (Lat. *demulceo*, 'I soften'), bland and lubricating liquid substances, taken by the mouth, for the purpose of soothing irritation of the mucous membranes, and promoting the dilution of the blood, and the increase of the secretions. Demulcents are chiefly composed of Starch (q.v.), or Gum (q.v.), or of substances containing these, dissolved in water; sometimes also of oily matters, or the white of eggs, and other albuminous or gelatinous substances largely diluted. The decoction of althæa, or marsh-mallow, is a favourite form of demulcent.

Dengue, or BREAK-BONE FEVER, also called DANDY and BUCKET FEVER, is a disease first certainly known to have occurred in 1779-80 in Egypt, parts of the East Indies, and probably in Philadelphia. Since that time there have been great epidemics in India and Further India (1824–25), America and West Indies (1826–28), Southern United States (1850), East Africa, Arabia, India, and China (1870–73), besides numerous minor outbreaks. The disease occurs almost exclusively in the tropics, in hot weather, and in towns either near the sea-coast or on large rivers. It is characterised by sudden onset, with high fever, and extremely violent pains in the bones, muscles, and joints; by a remission, usually at the end of one or two days, during which the patient feels almost well; and after one or two days more by a second period of fever, less severe than the first, which lasts for two or three days. Each attack of fever is often accompanied by a well-marked skin-eruption. Though often followed by much emaciation and loss of strength, it is very rarely fatal or succeeded by serious after-effects. It occurs almost always in well-marked epidemics; but observers are much divided upon the question whether it is communicable directly from the sick to the healthy. See Hirsch, *Geographical and Historical Pathology*, vol. i.

Deodorisers are chemical substances employed for the purpose of absorbing or destroying the odoriferous principles evolved especially from decomposing animal and vegetable matter. Thus, freshly burned charcoal is a powerful deodoriser because it absorbs sulphurous acid gas, ammonia, and other odorous gases. They belong to the classes of substances known as Antiseptics (q.v.) and Disinfectants (q.v.).

Deoxidation is the term applied to the process of withdrawing the oxygen from a compound, as in the reduction of the native peroxide of iron in the smelting-furnaces to the condition of metallic iron. On the small scale, in experimental inquiries, the process of deoxidation may be carried on before the Blowpipe (q.v.), where the inner or reducing flame is essentially a deoxidising one.

Dephlogisticated Air. See PHLOGISTON.

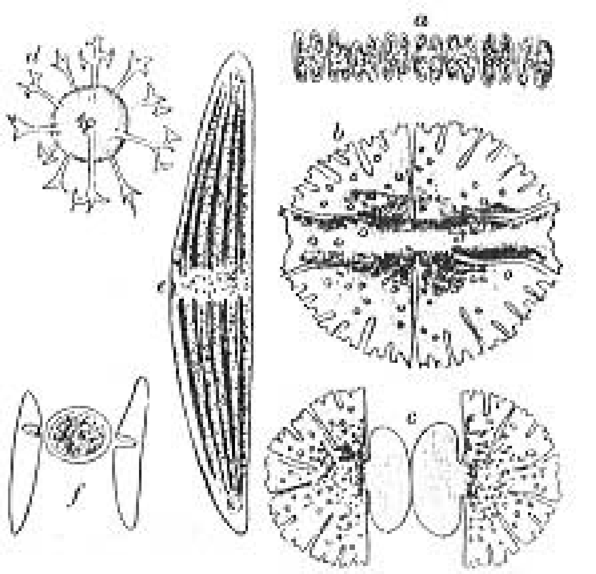
Depilatories (Lat. *depilo*, 'I pull out the hair') are chemical agents employed for removing superfluous hair from the skin. They were extensively used by the ancients, but are now restricted in their employment to the face, and to the removal of the hair from the scalp in the treatment of certain diseases. They should only be used under medical advice.

Desiccants, in Medicine, are substances with astringent properties, which are serviceable in checking secretion and exhalation.

Desiccation is the process of drying by the employment of heat, dry air, or chemical agents which have an affinity for water. Examples of the class of *desiccants* or drying substances are fused chloride of calcium, quicklime, fused carbonate of potash, and oil of vitriol. The latter is employed by being placed in a separate vessel near the substance to be dried, and under a bell jar.

Not a few of the lower animals are said to be able to endure drying up without losing the power of recovery. Some of the Protozoa form protective sheaths or cysts from which they emerge on the return of moisture. Nematodes or thread-worms (paste-eels) have been known to revive after fourteen years' desiccation, but trials beyond this limit were unsuccessful. With those animals the interesting fact has been noticed that the longer the period of desiccation, the longer the time required for recovery. Rotifers are also described as reviving after prolonged and thorough desiccation, but experiments have shown that, in the case in question at least, only the associated eggs retained their life. The eggs rapidly developed on the return of moisture, but the adult organisms proved to be really dead. The bear-animalcules or Tardigrades have been thoroughly desiccated and even heated to a high temperature without, it is said, losing power of revivification. A state of latent life is also assumed in consequence of cold, absence of stimulus, &c., and a relative quiescence occurs naturally in hibernation, or pathologically in trance. Among the lower plants, resting spores, &c., may survive desiccation; and, among the higher, seeds are well known to have a similar power.

Desmids (*Desmideæ*) are a group of conjugate Algæ (see ALGÆ) related to diatoms, but readily distinguished from these by their bright green instead of brownish-yellow colour, their cellulose instead of silicified walls, and their general form, which is usually more or less deeply constricted in the middle line. As with diatoms the lower forms are, however, united in long chains, so indicating a relationship to the lower and filamentous Conjugatæ (Spirogyra, &c.). About four hundred species have been described, but these are often variable and ill defined. All are inhabitants of fresh water, but chiefly occur in the standing pools of heaths and peat-mosses. They rarely form large aggregations; but usually occur associated with filamentous algæ, diatoms, and other forms of microscopic life. On account of the singular beauty of their general form they are much prized by the microscopist; their mode of division, too, is remarkable, yet akin to that of diatoms, the two halves of the cell being pressed apart at the median constriction by the development of two new bud-halves to complete them (see fig.), two new desmids being thus gradually formed, which become as symmetrical as the original one, yet with the two apparently similar halves of very unequal age. Conjugation also occurs, with formation of a resting spore; the cyst of which may have peculiar markings or hook-like prominences.



Desmids (mostly × 100):

a, Continuous filament of *Sphærozosma vertebratum*; *b*, *Micrasterias rotata*; *c*, *M. denticulata*, dividing; *d*, Zygospore of the same; *e*, *Closterium lunula*; *f*, Closterium in conjugation.

Dextrine (syn. 'British gum,' 'torrefied starch'). When starch is carefully heated to 392° (200° C.), or until vapours arise from it, it becomes soluble in cold and hot water, and loses its gelatinous character; it also has the property, when viewed by polarised light, of turning the plane of polarisation to the right; hence its name. It is often used as a substitute for gum-arabic in the processes of calico-printing, and for stiffening different goods; it is also applied to the back of postage-stamps. Its value as a substitute for gum consists in its being more flexible and less brittle when dry than that substance. Starch may be converted into dextrine by the long-continued action of dilute acids at a high temperature; also by the action of Diastase (q.v.). Dextrine and starch are isomeric, both being composed of $C_6H_{10}O_5$; but dextrine may be distinguished from the latter body by its not being rendered blue by iodine, which gives with it a dingy purple tint.

Diabe'tes (Gr., lit. 'a syphon,' from *diabainō*, 'I go or flow through'), a disorder of the general system, of which the principal symptom is a greatly increased flow of urine. Diabetes is of two distinct kinds: the one, *diabetes insipidus*, is a mere exaggeration of the water-excreting function of the kidneys, accompanied by extreme thirst, and hence called *polydipsia* (Gr., 'excess of thirst') by some authorities; the other is a more complex disorder of the assimilation, consequent on the formation first, and the excretion by the kidneys afterwards, of an enormous excess of animal sugar (see SUGAR), the sugar being found in excess not only in the renal excretion, but in the blood, and in nearly all the secretions which have been examined. The pathology of this disease, called *diabetes mellitus* (Lat. *mel*, 'honey'), is very obscure, notwithstanding the numerous recent physiological researches which tend to throw light on the development of sugar in the animal organism, especially in the liver, and which must undoubtedly be regarded as bearing on the solution of the problems connected with this disease. Unhappily, the cure of it is still entirely unknown, except in so far as it may be controlled or retarded by good management of the diet, drink, and clothing. The course of the disease, however, is very different at different periods of life. Before middle age it is severe, progressive, and almost invariably fatal. After that period precisely similar symptoms often appear, especially in gouty persons, but are so much less dangerous, and so much more easily controlled, that many authorities are unwilling to place them in the same class as true diabetes. All diabetics are subject to progressive emaciation, and they often become subject to a chronic disease of the lungs, closely resembling true tubercular Consumption (q.v.); it is chiefly in warding off this termination, or some other more quickly fatal, and in mitigating the symptoms of the malady, that the medical art can be of service.

The first fact observed in cases of diabetes is usually the increased flow of urine, when it becomes so great as to amount to a practical inconvenience; and also a considerable increase of the appetite, and an unquenchable thirst, which rarely fail to accompany the disease from the beginning, but often do not attract attention, or at least suggest the idea of anything wrong, till an advanced stage of the disorder. When the patient demands medical assistance he is usually somewhat thin; the pulse is quiet, the skin cool, the heat of the surface, indeed, habitually rather low and easily depressed. There is often a complete absence of perspiration, which gives a peculiar feeling of harshness to the surface, especially of the palms of the hands. With these symptoms the first approaches of pulmonary disease may concur. In the very last stages there is sometimes dropsy of the feet; and the urine may be natural in quantity, or even diminished. For the other characters of diabetic urine, see URINE. Diabetic persons bear excitement and fatigue, either mental or bodily, extremely badly; and imprudence in this respect is not unfrequently followed by sudden or rapid collapse and death. The treatment consists mainly in removing from the diet, as far as consistent with comfort and due nourishment, everything which easily turns to the formation of animal sugar in the system, especially all excess of farinaceous food. The complete suppression of sugar-forming food, however, as recommended long ago by Rollo, has not been found possible in practice in the majority of cases. Bread composed of gluten of wheat without starch, or bran-cakes baked with eggs, or biscuits made of almonds, have been strongly recommended; and in most of the great capitals, as London and Paris, bakers may be found who regularly furnish bread suitable for this unfortunate class of sufferers; indeed, any intelligent baker who will take the trouble may, under medical direction, be got to manufacture such bread when required; or it may be ordered in the form of cakes and biscuits, in quantities at a time, from London houses. It is of importance, however, that it be ascertained that the bread or flour supplied is really suitable; for Dr Pavy, one of the chief authorities on this disease, ascertained that some of the so-called foods for diabetics contain little less starch than ordinary bread. Saccharin (q.v.) has lately been of great service to diabetics, as it supplies the flavour of sugar without its objectionable properties. Medicines proper should be used only under the advice of the physician. There is no specific, and the unguarded use of strong remedies is to be condemned. Of all medicines that have been used, however, opium and morphia have been found most frequently useful in delaying the progress of the disease. Flannel should be worn next the skin, and the languid function of the cutaneous perspiration aided by the warm bath, especially, perhaps, the vapour bath—e.g. that form known as the Russian bath. The Turkish bath, which abstracts a large quantity of water through the skin, is less suitable to such cases.

Diagnosis (Gr., from *dia*, 'through,' and *gnōsis*, 'knowledge'), in Medicine, the discrimination of diseases. It includes the study of all the vital phenomena of diseases, and also of their appearances after death, in so far as this can aid their discovery during the life of the patient. It is usual to speak of rational or physiological diagnosis, or diagnosis by symptoms—i.e. changes chiefly functional, observed by the patient; and of physical diagnosis, or diagnosis by signs—i.e. objective phenomena appreciable by the senses of the observer. The latter method of diagnosis has been much enlarged in scope and increased in importance by the modern methods in medicine of Auscultation (q.v.) and Percussion (q.v.), and also by the great advances made in physiological chemistry, and by the use of the microscope. Skill in diagnosis is one of the highest gifts of the physician, and nothing distinguishes the man of long experience from the tyro more than this unerring insight into some unseen disease.

Dial and **Dialling.** A *sun-dial* is an instrument for measuring time by means of the motion of the sun's shadow cast by a stile erected on its surface. It is an instrument of very great antiquity, and before clocks and watches became common, it was in general use as a time-keeper. Some old sun-dials are very elaborate—e.g. that at Glamis Castle, Forfarshire; and many bear quaint mottoes (cf. *Leisure Hour*, 1870, p. 413; and Mrs Gatty's *Book of Sun-Dials*, new ed. 1889). Dial-making was then an important branch of mathematical study; now it is more an object of curiosity than utility. A dial consists of two parts—the *stile* or gnomon, usually the edge of a plate of metal, always made parallel to the earth's axis, and pointing towards the north pole; and the *dial-plane*, which may be of any hard substance, and on which are marked the directions of the shadow for the several hours of the day, their halves, quarters, &c. Dials receive various names, according mostly to the positions which they are constructed to occupy. When the dial-plane is on the plane of the horizon, the dial is called a horizontal dial; when perpendicular to that plane, a vertical dial. An equinoctial dial is one whose plane is parallel to the equinoctial plane. The south dial, north dial, east dial, west dial, polar dial, declining dial, are named from the position of the dial-plane. The cylindrical dial is a dial drawn on the curved surface of a cylinder. The ring dial is an ingenious small portable dial, but rather a curious toy than a philosophical instrument. A *night* or *nocturnal dial* is an instrument for showing the hour of the night by the shadow of the moon or stars. Moon-dials may be constructed relative to the moon's motion; or the hour may be found by the moon's shadow on a sun-dial. But because of the irregularity of the moon's motion, due to its varying speed at different parts of its orbit, the time so found is subject to considerable error.

Dialling.—The *stile* of a dial being parallel to the earth's axis, those familiar with spherical trigonometry will readily see that the problem of constructing a dial resolves itself into that of ascertaining where the hour-lines cut a given circle, with a view to the graduation of the dial-plane. Suppose *Pep* (fig. 1), a hollow and transparent sphere, as of glass, to represent the earth; and suppose its equator divided into 24 equal parts by the meridians *a*, *b*, *c*, *d*, &c., one of them passing through a given place, say London (see HORIZON), at the point *a*. If the hour of twelve be marked at the equator, both on the latter meridian and that opposite it, and all the rest of the hours in order on the other meridians, those meridians will be the hour-circles of London, because, as the sun appears to move round the earth in 24 hours, he will pass from one meridian to another in one hour. Then, if the sphere has an opaque axis, as *Pep*, terminating in the poles P and *p*, the shadow of this axis would fall, in the course of the day, on every particular meridian and hour, as the sun came to the plane of the opposite meridian, and would thus show the time at London, and at all other places on the same meridian as London. If the sphere were cut through the middle by a plane ABCD, in the rational horizon of London, and if straight lines were drawn from the centre, E, of the plane to the points where its circumference is cut by the hour-circles of the sphere, those lines would be the hour-lines of a horizontal dial for London; for the shadow of the axis would fall upon each particular hour-line of the dial, when it fell upon the like hour-circle of the sphere. Similarly, if we suppose the sphere cut by *any* other plane facing the meridian, the hour-circles of the sphere will cut the edge of the plane in those points to which the hour-lines must be drawn straight from the centre; and the axis of the sphere will cast a shadow on these lines at the respective hours. The like will hold of any plane, whether it face the meridian or not, provided it do not coincide with it, or do not coincide with a plane through the poles, and perpendicular to the plane of the equator. In the latter case, the axis

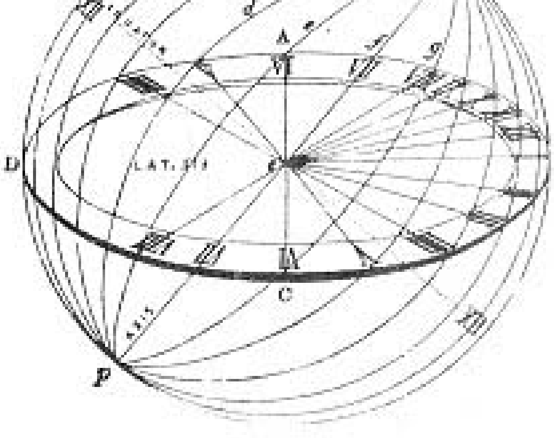


Fig. 1.

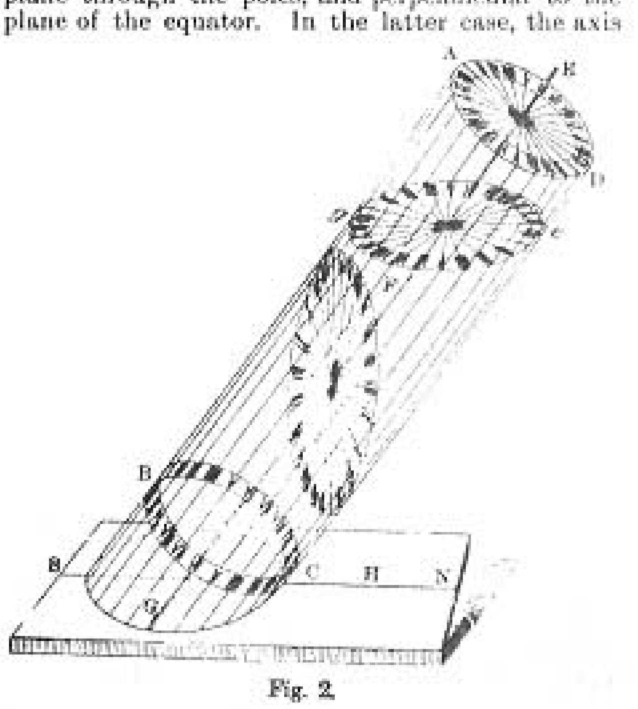

Fig. 2.

would have no elevation above the plane of the dial; in the former, the shadow would not move circularly.

The *universal dialling cylinder*, an invention of Ferguson's, is represented in fig. 2. ABCD is a glass cylindrical tube, closed at both ends with brass plates, on the centres of which a wire or axis, EFG, is fixed. The tube is either fixed to a horizontal board, H, at an angle equal to the latitude of the place, or moves on a joint, so that it may be elevated till its axis is parallel to the earth's at any latitude. The 24 hour-lines are drawn on the outside of the glass, equidistant from one another, and parallel to the axis. The XII next B stands for midnight; the XII next the board, for noon. When the axis is adjusted for the latitude, and the board levelled, with the line HN on the meridian, and the end towards the north, the axis EFG, when the sun shines, will serve as stile, and cast a shadow on the hour of the day among the parallel hour-lines. As the plate AD is parallel to the equator, and EFG perpendicular to it, right lines drawn from the centre to the extremities of the parallels will be the hour-lines of an equinoctial dial, and the axis will be the stile. A horizontal plate, *ge*, if put into the tube, with lines drawn from the centre to the several parallels cutting its edge, will be a horizontal dial for the given latitude; and similarly a vertical plate fronting the meridian, and touching the tube with its edge, with lines drawn from its centre to the parallels, will be a vertical south dial, the axis of the instrument in both cases serving for the stile; and similarly for any other plate placed in the cylinder. If, instead of being of glass, the cylinder were of wood, any of these dials might be obtained from it by simply cutting it in the planes of the plates, and drawing the lines on the surface of the section.

Dialling sometimes occurs as a term for surveying by help of a compass with sights, such as is called a 'miner's dial,' and is used especially in underground surveys and mine-surveying.

Diastase is a peculiar ferment developed during the germination of all seeds. An impure solution of diastase may be procured by adding one part of hot water to two parts of ground malt (see BEER), or freshly germinated barley, and, after standing for a short time, straining through a cloth. The proportion of diastase in malt is not more than 1 part in 500 parts, and yet it performs important functions. Thus diastase has a powerful action upon starch, and at a temperature of 150° F. one part is considered powerful enough to change 2000 parts of starch into dextrine, and then into maltose, a variety of sugar. When obtained separately, diastase is a white tasteless substance, soluble in water and in weak alcohol, and having no action on gum or sugar. A similar principle is found in the saliva of animals, the action of which on starch is identical with that of diastase. When bread is masticated, the saliva is rapidly secreted, and the animal diastase converts the starch into sugar.

Dia'thesis (Gr. *dia*, 'through,' and *tithēmi*, 'I place or arrange'), a Greek word signifying a disposition or arrangement, and applied by the old medical authors to the predisposition or constitution of the body which renders it prone to certain diseased states. By recent writers the term is applied to the general constitutional tendency of an individual, to indicate not merely the class of diseases to which he is most likely to be liable, but also in many cases the manner in which his normal functions, both bodily and mental, are carried on; and is thus opposed to Cachexia (q.v.), an unhealthy condition associated with actual disease. Though the study of diathesis apart from existing disease is very apt to lead to over-refinement and the pursuit of intangible abstractions, yet a proper appreciation of a person's constitutional proclivities or diathesis often enables a medical man to advise him how to regulate his life and habits to the best advantage—what to do and what to avoid—and may furnish important guidance as to his treatment in disease. The diatheses most usually recognised are the sanguine, the nervous or neurotic, the bilious, the lymphatic, the strumous, and the hæmorrhagic. Numerous mixed varieties are also described by some writers.

Diatoms (*Diatomaceæ*) are a group of algæ which, on account of their microscopic interest and geological importance, have acquired an unusual share of scientific and even popular attention. They were discovered by Leeuwenhoek in 1702, and their movements by O. F. Müller eighty years later; their thorough investigation, however, has only become possible with the development of the compound microscope.

The reader who wishes to view the diatoms other than as mere microscopic marvels must begin with a clear grasp of the structure and mode of life of the filamentous conjugate algæ, such as *Spirogyra*, and next observe that of those higher members of the group which we know as Desmids (see ALGÆ, DESMIDS). These simpler forms understood, let him next imagine a desmid (in which the characteristic division of the unicellular body into halves is distinctly but not too deeply marked) to become somewhat unequally developed; next let these be pressed together so that the larger half slides a little way over the smaller, much like the lid of a canister or the halves of a pill-box. Let the two halves or shells of the cell-wall now become strongly silicified, the cellulose only remaining unaltered and flexible round the narrow 'girdle band' connecting them; next let variation arise in the general shape so that the original box-shape becomes elliptical or wavy, squared, or more often pointed, or even unsymmetrically curved; finally, let the siliceous shells become covered with the most delicate striations and markings, and these characteristically varied, not only from group to group, but from species to species. A gelatinous envelope may also be developed, or this may be secreted at one pole only, forming a stalk.

The living protoplasm shows less variation than might perhaps have been expected; it lines the siliceous shell, leaving a large central sap-cavity, often traversed by protoplasmic filaments. Very commonly, however, this is divided by a large central mass of protoplasm usually containing the nucleus, while similar accumulations may be formed at the ends. The colouring matter may occur in minute granules, or be collected into one or two large 'endochrome-plates;' it consists of chlorophyll, masked by a closely allied yellow pigment (*phycoxanthin*). Starch is absent; oil is frequently present, either in minute vacuoles or collected into a single large drop.

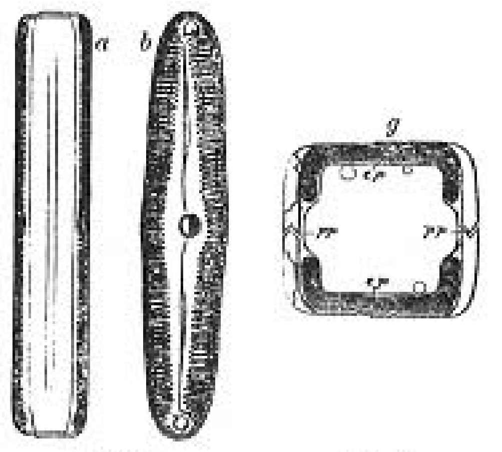

Fig. 1. Fig. 2.

Pinnularia viridis: 1. *a*, Optical section through the unequal valves; *b*, side of one valve, showing markings and longitudinal slit.
2. Diagrammatic transverse section; *pp*, protoplasm containing endochrome-plates, *cp*; *g*, girdle band. Valves left unshaded, the left showing depressions due to markings.

The mechanism of the peculiar creeping or rather gliding movements has long baffled investigators; these, however, are not due to diffusion currents as some have maintained, nor to the agency of any ordinary cilia or pseudopodia, but seem to be effected by means of a locomotor band of protoplasm which is said to be protruded through a longitudinal slit in the surface of the siliceous shells (see fig. 1).

The mode of multiplication is primarily by division, and is effected on the same principle as in Desmids (q.v.). Thus the two halves of the diatom are not only of unequal ages, but since the new half is always formed within the previous one, a continuous diminution of size takes place. At a certain limit, however, division stops, and rejuvenescence may occur, with formation of a resting spore; more frequently, however, this is preceded by conjugation as in desmids, though sometimes complete union may not take place. The resultant 'auxospore' has a continuous cellulose coat, but develops within it, by rejuvenescence, a two-shelled diatom of the largest size, which issues to divide in turn.

Of the 2000 species, 400 are fresh-water, the remainder marine. Their distribution is ubiquitous, and the genera and even species seem little dependent upon temperature or climate, many being apparently cosmopolite, and some having been described as occurring in glacier water, yet also in hot springs. Their minute size and resistance to drying favour their distribution in the form of dust: hence the calcination of the dust which falls upon ships in mid-ocean has been shown to yield an appreciable diatom residue. Every soil which is overflowed teems with them, notably, therefore, that of Egypt; harbour mud often contains one-fourth to one-half its volume of diatom shells, while in many parts of the world there occur strata of purely diatomaceous origin, which are frequently of vast area and considerable thickness. These are in all states of preservation and hardness, from the loose *Bergmehl* of Siberia and Lapland (which still contains so much undecomposed organic matter as to be mixed with flour in times of scarcity) to building stone, and even the extremely hard polishing slates of Tripoli. Diatomaceous deposits were found in Skye in 1886. The diatomite may be used for making dynamite, siliceous glazed paints, steam-pipe casings, &c. Diatoms live in enormous abundance at the surface of the sea in cold, temperate, and arctic latitudes, and the mud of the sea-bottom is hence very largely composed of the shells of dead diatoms, which are falling from the surface in a gentle but unceasing rain.

Die-sinking, the art of engraving the die or stamp used for striking the impression on coins and medals, and for stamping thin plates of metal into various shapes. The method of sinking the dies used for coins or medals will serve to illustrate the general method of die-sinking. Suppose the coin to be of the size of a shilling: a cylindrical piece of carefully selected steel, about three or four inches in length, and two in diameter, is prepared by slightly rounding one end of the cylinder, then turning and smoothing upon the middle of this a flat face equal to the size of the coin. This blank die, which is carefully softened by the process of Annealing (q.v.), is then engraved with the device of the coin in intaglio. This is a very delicate and artistic operation, and is effected by a great number of careful touches with small and very hard steel tools. The face of the die is now protected with a thin coating of lampblack and linseed-oil, and then placed with its face downwards in a crucible containing animal charcoal. In this position it is raised to a cherry-red heat, then taken out, and hardened by being plunged into water. When properly tempered, it is in a state to be used for stamping the coin; but dies of superior workmanship, from which many impressions are required, are not thus directly used, as the expense of engraving is very great, and the risk of breakage considerable. This first engraved die, called the matrix, is therefore reserved only for making other dies. An impression in relief is made from this matrix on a small block of soft steel, which is called the puncheon; this is retouched and hardened, and from it the dies directly used for striking the coins or medals are impressed. When the engraving is not very costly, a small number of impressions required, or a soft metal is to be stamped, as in livery buttons, for example, the work is stamped directly from the engraved die or matrix. See MINT.

Die-engraving is a very ancient art, and was perhaps first suggested by the closely allied art of engraving gems. Notwithstanding the great number of ancient Greek coins which have been preserved, it is stated by Mr R. S. Poole, of the British Museum, that only one of the many dies which were used for these has ever been found, or at least only one believed to be of undoubted authenticity. The Greek coins struck between the years 415 and 336 B.C. show that the art of engraving dies had then reached the highest point of excellence which it ever attained either in ancient or modern times. As works of art, the Italian medals of the 15th and 16th centuries come next in merit to Greek coins, but none of these of the 15th, and only the smaller sized ones of the 16th century time were struck from dies. All the others were cast either from wax models or from patterns made in other materials. The art of cutting dies.

in the comparatively deep intaglio required for medals, consequently dates from the beginning of the 16th century. Since then, or soon after it, Germany, France, Russia, and England, as well as Italy, have all had many more or less famous die-engravers.

The engraving of dies for medals is perhaps that branch of the art which gives the greatest scope for artistic skill, although the work on those required for coins is nearly identical in its character. Comparatively few dies of new design are, however, required for coins, while many hundreds of medal dies are annually made in England. The medals struck from these are used for such purposes as awards at exhibitions, colleges, and schools; for prizes at various games, and in commemoration of various events. Copper, bronze, and tin are the metals most commonly employed for medals, the copper being usually 'bronzed' on the surface. A copper medal with a head in moderately high relief requires half a dozen blows in the screw-press to bring up a sharp impression; but some in very bold relief require to be struck with as many as thirty blows. The medal requires to be frequently annealed during the process. Coins are finished at one blow, so that the devices upon them are only in slight relief. When a coin or a medal is being struck, a steel collar, accurately fitted to the die, is used to prevent the metal from spreading.

Dies have been extensively applied in Birmingham and other places to the manufacture of many kinds of objects in sheet-metal. These are of all sizes, from those required for parts of jewelry up to dies weighing more than a ton. Large and heavy dies are, however, cast, and only in some cases finished with the graver—those for such articles as curtain-pole and cornice ornaments being among the largest kinds worked up and finished with the die-cutter's tools. Dies have recently been used in America in the stamping or pressing of solid pieces of wood into lion's heads, rosettes, and other ornaments, in high relief, to imitate wood-carving. By the same process similar ornaments, in bas-relief, are made in pieces of wood formed of several layers of veneers.

Diffusion. The particles of all material bodies, except such as may be totally devoid of heat, are in rapid motion. In the case of solid bodies the excursions of any one particle are limited to a small space; but in fluids a particle may move more or less freely throughout the whole space occupied. This intermixture of molecules may occur also when different fluids are placed in contact with each other, but it may be prevented by the existence of tension at the common surface (see SURFACE-TENSION and CAPILLARITY). When it does occur, the fluids are said to *diffuse* into each other.

Diffusion of Liquids.—The diffusion of dissolved salts may obviously be considered under this heading. The phenomenon may be conveniently studied by introducing a strong solution of some highly-coloured salt, such as bichromate of potash, into the bottom of a tall glass cylinder nearly filled with water. The rate of diffusion varies with the nature of the liquids. Graham was the first to investigate the subject carefully. He filled a number of similar glass vessels with solutions of different salts. The mouths of these vessels were carefully ground so that they could be closed by means of glass plates. The different vessels were then placed in equal glass jars, and covered with water to a definite extent. Next the glass covers were cautiously withdrawn, and the diffusion was allowed to go on for a certain time. The rate at which each liquid diffused was thus obtained. Graham found that, for any one solution, the rate is proportional to the gradient of concentration—i.e. to the rate at which the quantity of salt dissolved per unit-volume varies per unit-length. Thus the law regulating diffusion of liquids is analogous to that which regulates the conduction of heat in a homogeneous solid. Hence the equations obtained by Fourier in his *Théorie de la Chaleur* apply to the problem under consideration.

Graham found also that rise of temperature greatly increases the effect. He divided substances into two classes, *Colloids* and *Crystalloids*, the members of the first class diffusing very much more slowly than those of the second. His investigations have been much extended by more recent observers employing various methods of observation.

If two miscible liquids be separated by a membrane of bladder or of parchment paper, &c., diffusion takes place through the septum at rates which are usually very different for different liquids. This phenomenon is known as *Osmose* (q.v.). It was first shown by Nollet that, if a vessel filled with alcohol be closed by a piece of bladder and placed in water, the diffusion of the water is so much more rapid than that of the alcohol that the bladder is burst because of the increase of the contents of the vessel which it closes. By this means the various constituents of a mixture of colloid and crystalloid substances may be separated to any desired extent. The rate at which liquids diffuse into each other through a septum depends greatly upon the molecular action between them and the septum.

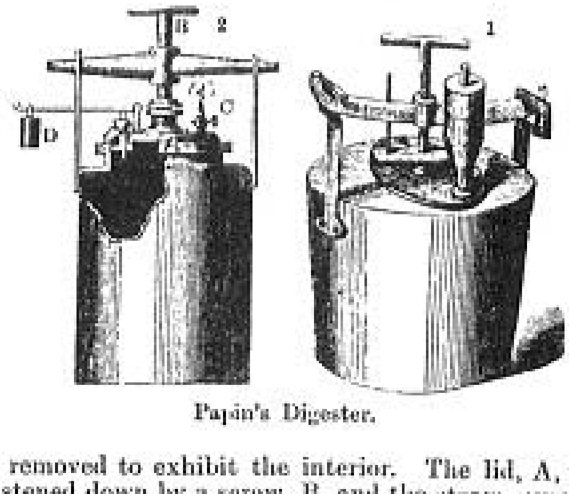
Diffusion of Gases.—If two flasks, each filled with a different gas at a given pressure and temperature, be placed in communication with each other, the gases will be found to interdiffuse. The rate of interdiffusion is shown by theory to be nearly in inverse proportion to the square root of the product of the densities of the two gases, and the experimental results are in accordance with the theory.

Effusion of Gases.—This is exhibited in the passage of a gas into vacuum under constant pressure through a small opening in a very thin plate otherwise impervious to it. The work done in the passage of a given volume of the gas is proportional to the pressure, and the equivalent kinetic energy is proportional to the product of the density and the square of the speed of effusion. Hence the speed for a given pressure varies inversely as the square root of the density. Graham showed that this result of theory is closely realised by experiment. He showed, further, that when a discrepancy exists, it is due to the finite thickness of the plate.

Transpiration of gases is the term to the passage of gases under pressure through a fine capillary tube. This subject was also investigated by Graham, who found that the rate of passage is not affected by the material of the tube. This seems to indicate that the tube becomes coated internally with a thin film of gas, so that the opposition to the flow of gas is due to Viscosity (q.v.).

The rates at which different gases pass through fine unglazed earthenware are inversely as the square roots of their densities. Hence we have a means of separating gases the densities of which are different (see ATMOLYSIS). If the septum be made of caoutchouc, which is not porous, the passage of gases still occurs. The gas seems to combine with the matter of the septum on the one side, to diffuse through it, and finally to be given off on the other side. The passage of some gases, such as carbonic oxide, through hot cast-iron is analogous.

Digester, PAPIN'S, is a strong boiler with a closely fitting cover, in which articles of food may be boiled at a higher temperature than 212° (100° C.). As its name implies, it was invented by Papin (q.v.), and a common form is the *Autoclave*, fig. 1, where the lid can be turned round under clamps or ears, and thus be rendered steam-tight. Another form is given in fig. 2, where a portion of the side is removed to exhibit the interior. The lid, A, is fastened down by a screw, B, and the steam generated in the boiler is allowed to escape at a stopcock, C, or by raising the weighted valve, D. The increased pressure to which the contents of the boiler are exposed causes the boiling-point of the water to rise to 400° (204° C.), and occasionally higher. The digester is of great value as a means of preparing soups of various kinds, and especially in the extraction of gelatin from bones.



Papin's Digester.

Digestion is the change which food undergoes in order to prepare it for the nutrition of the animal frame, and is carried on in the higher animals in the DIGESTIVE SYSTEM. In some of the lowest forms of animal life (amœbæ) particles of food may be drawn into the body (which possesses no special organs at any part of its surface), and may then be digested. In higher organisms, however, parts have become evolved, which serve more especially the function of digestion. Thus in the common sea anemone there is a simple pouch which leads inwards from the centre of the cluster of tentacles. Into this fish and other food are drawn and digested, while the undigested parts are afterwards voided through the same aperture by which they entered. In still higher organisms, man himself included, this simple pouch is changed into a complex and greatly elongated tube, which is provided with one aperture (the mouth) by which food enters, and another aperture (the anus) through which undigested matter leaves the body. The whole digestive system is lined with a soft membrane, which is richly supplied with blood-vessels. This membrane is called the mucous membrane, and from it is secreted by the glands which it contains a viscid substance called mucus. If the finger be thrust into the back of the mouth, and the mucous membrane gently scraped, the fluid which will adhere to the finger is seen to be viscid: it is secreted by the glands of the mouth. Not only mucus, but many other substances useful in digestion are formed by little glands in the mucous membrane, so that the whole digestive system is bathed during digestion with fluid having a digestive action on the food. In addition there are other glands, such as the salivary, the liver, and the pancreas, which we may look upon as glands of the mucous membrane which have enormously developed. To so great an extent have they increased in size that they have got far outside the digestive system, and have become situated in neighbouring parts of the body, only connected with the digestive system by their ducts or elongated mouths. Through these ducts their secretions, like that of the microscopic mucous gland, pour into the cavity of the digestive system. Outside the mucous coat we have the muscular coat, the function of which is to move the food onwards in its course, and to mix it with the digestive juices. In the mouth, throat, and the upper part of the gullet, the muscles which move the food onwards, as in swallowing, are, when examined by the microscope, seen to be transversely striped, and like other striped muscles their contraction is rapid. In other parts of the digestive system, however, the muscular coat consists of smooth muscle, and like all other

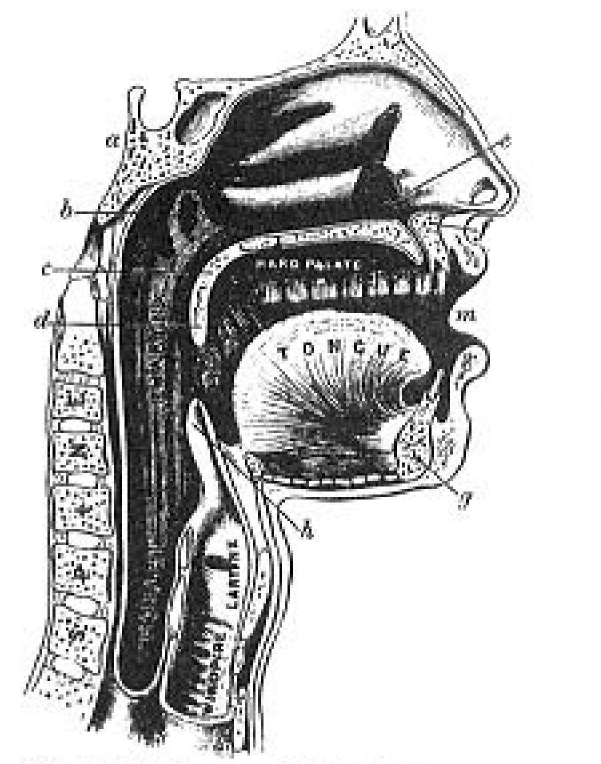


Fig. 1.—Section through Mouth, Nose, &c.: *a*, sphenoid bone; *b*, Eustachian tube; *c*, soft palate; *d*, uvula; *e*, nasal passage; *f*, upper jaw; *g*, lower jaw; *h*, epiglottis; *m*, mouth.

smooth muscles this coat contracts slowly. On this account the food rapidly swallowed passes very slowly along the rest of the digestive system.

Having shown that the digestive system is a muco-muscular tube, we may now consider it more in detail. The mouth (fig 1, *m*) is lined with mucous membrane, and into it is poured the secretion of three pairs of salivary glands—the parotids, situated in front of the ear; the submaxillary, within the angle of the lower jaw; and the sublingual, under the tongue. The mouth in most animals is provided with hard tissues—teeth, beaks—for the subdivision of food before it is swallowed. Vegetable feeders, eating tough grains, roots, and fibres, have large molar or grinding teeth, while the carnivora have these same teeth modified so as to present a cutting edge, with which and their pointed canines meat is torn and cut into pieces, which are then swallowed (see TEETH). The mucous membrane of the mouth is covered externally by the muscles of the cheek and lips. Into its cavity the muscular tongue projects. On looking into the mouth with a looking-glass, one sees back into the throat. The entrance to the throat will be observed to be bounded at the sides by two muscular curtains passing downwards obliquely to the sides of the root of the tongue. These are termed the anterior pillars of the fauces, and behind them, one on each side, are masses of lymphoid tissue, subject to enlargement, called the tonsils. Above, another curtain hangs down. It is called the soft palate, and separates the mouth from the hinder part of the nasal cavity. Projecting from its centre is a little cone called the uvula (fig. 1). The cavity of the pharynx, or the interior of the throat, is another cavity lined by mucous membrane, with muscular walls. These muscles constrict it (constrictors). Below, the cavity passes into the gullet or oesophagus, and in front of this tube runs the windpipe which communicates with the pharynx through the larynx, or organ of voice. Food will pass through the pharynx into the gullet; and air, during respiration, passes through the pharynx on into the larynx and windpipe; a valve, called the epiglottis, partly closes the aperture of the larynx. The pharynx is common, therefore, both to the digestive system and the respiratory passages. Above, the pharynx communicates, as before described, with the mouth and also with the nose. One can demonstrate this latter fact by drawing smoke into the mouth, and expelling it by the nostrils. This communication is closed during the act of swallowing, and also during the singing of pure vowel-sounds, such as *ā*, *ōō*, and the closure is effected chiefly by the elevation of the soft palate, which acts as a valve. The pharynx communicates in addition with the middle ear by the Eustachian tubes, and this may be rendered evident if the mouth and nose be closed, and a violent expiratory effort made at the same time. As the pressure of air within the throat is increased. the Eustachian tubes which previously were collapsed now become distended, and a little wave of air at high pressure is forced into the middle ear, causing a buzzing sound. Occasionally the middle ear communicates with the external air through congenital or acquired apertures in the membrana tympani. In these cases smoke may be propelled from the throat out of one or both ears.

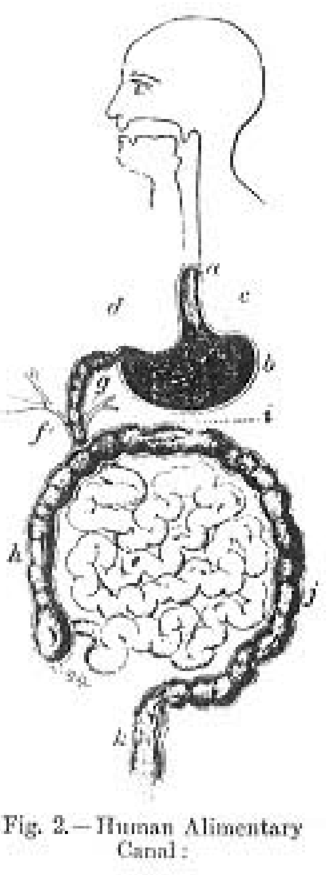

Fig. 2.—Human Alimentary Canal:

a, oesophagus; *b*, stomach; *c*, cardiac orifice; *d*, pylorus; *e*, small intestine; *f*, biliary duct; *g*, pancreatic duct; *h*, ascending colon; *i*, transverse colon; *j*, descending colon; *k*, rectum.

The gullet or oesophagus (figs. 1, 2, and 3) is a long tube passing from the pharynx to the stomach. Its mucous coat is loaded with very large mucous glands, which secrete a quantity of very viscid mucus. Its muscular walls contain striped fibres in the upper, unstriped in the lower part. The stomach itself is a greatly dilated part of the digestive system. Its shape is indicated in the fig. It may be said to consist of two parts, even in the human subject; a more complex arrangement is found in many animals, such as the ruminants. The large dilated portion into which the gullet opens is termed *cardiac*, and the opening the cardiac or oesophageal opening. The narrow part opening into the duodenum is the pyloric part, and the opening the pyloric opening. The whole is lined with mucous membrane, which, in the empty stomach, is thrown into projecting folds or rugæ, but these folds are effaced when the organ is distended with food (fig. 3). In the membrane are innumerable glands, which secrete the digestive juices of the stomach (fig. 4). If the surface of the membrane be examined with a strong pocket-lens, the apertures of these little glands may be seen. They run down from the surface into the deeper parts of the mucous membrane. They are lined by secreting cells. The greater number of glands situated in mucous membranes have the simple structure diagrammatically represented in fig. 4. Each gland has a mouth or short duct lined by cells. Below this the little tube is lined by cells which secrete the juice peculiar to the gland. This secreting part sometimes branches. Outside the gland blood-capillaries ramify, which supply the gland with nourishment, enabling it to manufacture the substances which it secretes. The gastric juice is acid, and the chief acid secreted is hydrochloric acid. This is formed at the cardiac, but not at the pyloric end. The substance called *pepsine*, which is necessary for digestion, is secreted by the whole of the glands. The cardiac glands therefore secrete both substances, and they possess two sorts of cells, those which form the hydrochloric acid being bigger and more granular than the other sort which secrete pepsine. The pyloric glands secreting pepsine have only one kind of cell similar to the pepsine-secreting cell of the cardiac end. Outside the vascular and glandular mucous coat, and united to it by a loose delicate layer—submucous coat—is the muscular coat. This is similar to that of the rest of the alimentary canal, except that there are in addition to the circular and longitudinal fibres, many oblique fibres. The circular fibres are very thick indeed at the pyloric aperture, forming a circular sphincter band, which contracts and keeps back the food in the stomach until gastric digestion is nearly completed.

The food, now called the *chyme*, passes into the small intestine, a tube some 20 feet long. This tube, besides the muscular and mucous coats, possesses in addition an external coat of loose fibrous tissue, covered by a single layer of flat epithelial cells. This coat is prolonged into, and helps to form the mesentery, a membrane connecting the intestine with the abdominal walls, which are lined with a similar fibro-epithelial coat. This membrane is called the peritoneum, and is sometimes inflamed (peritonitis) as a result of cold, injuries, &c. The small intestine is somewhat arbitrarily divided into three portions—the upper (duodenum), the middle (jejunum), and the lower (ileum). In all parts the muscular coat is similar to that of the rest of the digestive system. The mucous coat contains glands very like the pyloric glands of the stomach, called Lieberkühn's follicles. These, however, rarely branch. They secrete the intestinal juice. In the duodenum, one finds in addition highly-branched glands called Brunner's. These extend right down into the submucous coat. Little is known concerning their function. In both the mucous and submucous coats, and generally involving both layers, are found masses of tissue—lymphoid—similar to that found in a lymphatic gland (fig. 6). These are termed solitary glands, but it must be understood that they do not secrete any juice concerned in digestion. Their function is probably connected with the blood and the blood-corpuscles. Collections of these solitary glands, forming oblong patches about two inches long, are called Peyer's patches. These are affected in typhoid fever. In addition to the follicles of Lieberkühn and the glands of Brunner, there are two very important glandular structures, the liver and the pancreas, which pour their digestive juices into the small intestine (fig. 5). The bile, which is the secretion of the liver, is formed continually by that organ, but the amount thus formed is greatly influenced by the kind and quantity of food taken. It passes out of the liver by the two

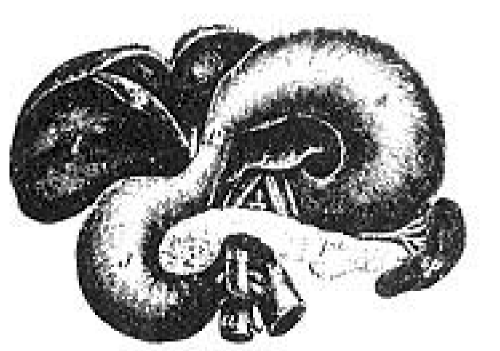

Fig. 5.—The under surface of the Stomach and Liver, which are raised to show the Duodenum and Pancreas;

hepatic ducts, and much of it passes by the cystic duct into the gall-bladder, where it is stored up.

From this the bile passes into the common bile duct, which joins the duct of the pancreas, and the two open into the duodenum by a common aperture. The bile is to be looked upon not only as a digestive juice, but as a drain or channel of excretion, whereby effete and useless matters are removed from the body. The flow of bile is easily restrained, as by inflammation of the duct, or the presence of a tumour pressing on the duct, or a gall-stone. In this case, the bile already formed is reabsorbed with the blood, through the lymphatics, and we have jaundice due to absorption of the colouring matter of the bile. The secretion of bile goes on before birth; the meconium of infants consisting chiefly of biliary matter. The pancreas is very similar in structure to a salivary gland. It secretes the pancreatic juice which pours with the bile into the digestive system. The mucous membrane of the small intestine contains, in addition to the structures already mentioned, little projections called villi (fig. 6). These are not, to any great extent at least, secretive, but they are important absorbants. This property they share with the whole of the digestive system, through any part of which, and especially through the walls of the stomach and small intestine, digested matter passes into the numerous blood-capillaries which form everywhere a dense network. The villi are peculiar, however, for each one contains, in addition to blood-vessels, a small lymph-vessel or lacteal. Nearly all the fat absorbed by the digestive system is taken up by the little cells of the villi, and passes on into the lacteals, and thence to the blood (fig. 7). If some osmic acid, which blackens fat, be poured into the intestine of a milk-rabbit, killed during active digestion, and if the villi be examined with a microscope, they will be seen to have been blackened, especially at their tips, while the rest of the intestine will have preserved its ordinary colour. On further examination it will be seen that the fat has been taken up in microscopic globules by the cells covering the villi, and that they are passing, in a way which is as yet not definitely settled, into the central lacteal.

The small intestine is a tube of great importance, and in order to increase its total area, the mucous membrane is elevated, in the upper part, into transverse folds (the valvulæ conniventes, fig. 8).

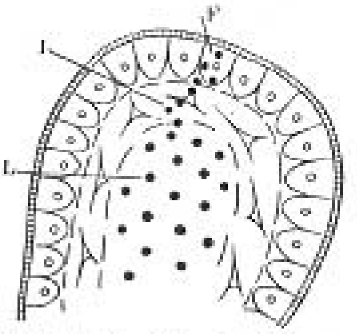

Fig. 7.—The Top of a Villus:
Fat globules are represented as passing through one of the epithelial cells, F, on through the tissue of the villus, I, into the central lacteal, L.

The unabsorbed food, mixed with the various secretions we have mentioned, now passes into the large intestine, when both digestion and absorption go on, although to a less extent. The large intestine is only 5 feet in length, but its girth is much greater than that of the small intestine. It commences with the cæcum, a dilated part, into which passes a little blind canal (the vermiform appendix), a large and important structure in some animals. The food remnant (fæcal matter) is prevented, under ordinary circumstances, from passing back into the small intestine, by a double fold of mucous membrane (the ilio-cæcal valve, fig. 9). The large intestine ascends on the right side (ascending colon), crosses over to the left side (transverse colon), and descends again (descending colon), and makes a bend (sigmoid flexure), and finally terminates in a somewhat enlarged portion (rectum).

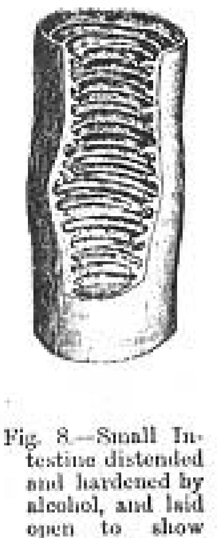

Fig. 8.—Small Intestine distended and hardened by alcohol, and laid open to show the valvulæ conniventes.

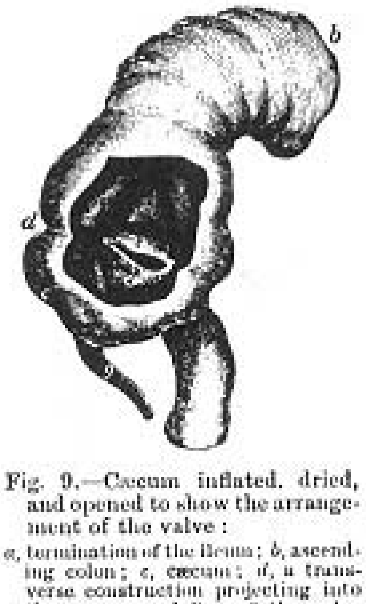

Fig. 9.—Cæcum inflated, dried, and opened to show the arrangement of the valve:
a, termination of the ileum; b, ascending colon; c, cæcum; d, a transverse construction projecting into the cæcum; ef, lips of the valve separating the small from the large intestine; g, the vermiform appendix of the cæcum.

The anal aperture is closed by muscles, an internal sphincter of non-striped, and an external of striated fibre. The mucous membrane of the large intestine differs from that of the small intestine in containing no villi, or Brunner glands. Lieberkühn's and solitary glands are present, but the aggregation of the latter into Peyer's patches is nowhere to be found.

Movements of Food in the Alimentary Canal.—When food is taken into the mouth it is at once swallowed, unless it is in the solid form. In this case it is chewed or masticated; the use of which is to divide the solid fragments taken into a convenient size for swallowing, for which purpose it, in addition, is mixed with the viscid saliva and juices of the mouth. The chewed food, moreover, is more easily digested, inasmuch as the gastric and other juices can act more readily upon finely divided than upon larger masses of food. Many animals can hardly be said to masticate; such are the carnivora (dog, cat, &c.), and they are not provided with grinding teeth. In most animals living on vegetable food, which frequently consists of hard grains, roots, and fibres, large flat grinding molars are found. In these animals, not only is the food finely divided in the mouth, but the food, largely consisting of starch, is partially digested by the saliva. In mastication, the head is firmly fixed by the powerful muscles of the neck, while the lower jaw is moved upon the upper. The lower jaw is approximated to the upper by powerful muscles (the temporal, masseter, and internal pterygoids), which pass upwards, and are attached to the side of the head and face. Their contraction may be felt by placing the hand in front of the ear and voluntarily contracting the jaws. The lower jaw is depressed by muscles which pass down the front of the neck. Most of these spring from the hyoid bone, which may be felt deep in the tissues of the neck above the 'Adam's apple.' Rotating movements and those of protrusion and retraction of the jaw are produced chiefly by the action of the pterygoid muscles. It is obvious that during mastication the food would naturally tend to escape from between the grinding surfaces of the teeth, and would collect within the mouth and outside the gums. This is prevented, however, by the muscles placed in the substance of the cheeks (buccinators) and lips (orbicularis oris). These keep the cheek and lip walls closely opposed to the outside of the teeth. On this account food will only escape from between the grinders into the interior of the mouth, from which it is collected and pushed back between the teeth by the muscular tongue.

The very complex muscular movements just described result from very perfectly co-ordinated nervous impulses, which pass from the brain to the muscles, and cause and regulate their contractions. One can masticate 'at will'—that is to say, one can consciously cause the muscles to contract. In order that the mastication may be effective, however, it is necessary not only to know the sizes, but also to be aware of the ever-changing positions of the particles of food. This is effected by sensory nerves, which pass to the brain from the mucous membrane of the mouth. Although mastication is frequently voluntary, yet, like most other voluntary actions frequently performed, it can be performed reflexly. In this case the sensory impulses pass from the mucous membrane to the brain, and initiate appropriate motor impulses which pass to the muscles, without exciting attention and special volition in their passage.

As a result of mastication, the food is gathered in the form of a round moist bolus on the upper surface of the tongue (see fig. 1). It is now ready to be swallowed. In the first place, it is pushed backwards by the tongue, and seized by muscles, many of which are attached to the hyoid bone, which can be felt to move during their contraction. According to the most recent investigation, the bolus is propelled with great rapidity through the pharynx and gullet into the stomach. If the finger be placed upon the hyoid bone, or Adam's apple, and the ear placed against the upper third of the back of a patient, the movement of the hyoid bone indicating the commencement of swallowing is almost coincident with the passage of food down the gullet, which produces a very audible sound. Following the propulsion of the food downwards, there is a wave of contraction, which, commencing in the pharynx, travels downwards through the gullet. This, however, is comparatively slow. It is seen then that swallowing is not due to the falling of liquids down the throat. A horse drinks 'up hill,' and the jugglers, or indeed any one, can drink or swallow with the head vertically downwards.

When the food has reached the back of the mouth, the rest of the act of swallowing occurs irrespective of the action of the will. The nerves, which commence in the mucous membrane of the pharynx and gullet (sensory branches of vagus), carry impressions to the brain, which disengage of themselves the appropriate muscular movements without necessarily involving either the will or consciousness. Thus, in alcoholic stupor, or fainting from drowning, in both of which conditions consciousness is suspended, food and liquid placed at the back of the mouth are at once swallowed.

There is a possibility that during swallowing the food may go the wrong way—i.e. it may pass into the larynx and windpipe. It will be seen from the diagram that the food in its passage to the gullet must actually pass over the aperture of the larynx. It is prevented from passing into it by the elevation of the larynx (this can be felt by the hand placed on the throat), which pushes its aperture against and under the back of the tongue, which at the same time is pushed backwards. In addition, there is a valve called the epiglottis, which is pushed down over the larynx by the movement just described, and by muscular fibres, which act upon it for that especial purpose. If the epiglottis be destroyed, as by ulceration, gun-shot wounds, &c., it is necessary for the patient to have the food he takes carried over the aperture of the larynx into the gullet by a feeding-tube. It is obvious that one cannot speak with the larynx shut, and with the larynx open we cannot safely swallow. Food is prevented from passing into the nose by the elevation of the soft palate which meets the constricting pharynx, and shuts off the cavity of the nose like a valve (fig. 1).

The walls of the stomach and intestine are, like the gullet, provided with muscular fibre. An external layer passes in the length of the gut, and within this is a circular layer. These muscles, unlike the muscles of the limbs, contract slowly on stimulation, and they are outside the domain of voluntary action. During digestion they contract peristaltically, urging the food towards the rectum. The peristaltic waves may begin in any part of the gut and pass slowly downwards, followed at varying intervals by other waves. It is probable that what is called antiperistaltic waves may occasionally occur, tending to bring the food back towards the mouth, for bilious matter is frequently vomited, the bile having in all probability passed upwards into the stomach by antiperistalsis from the duodenum.

Eructations are frequently caused by antiperistalsis, and by a movement of this kind food is brought back into the mouth for further chewing in the ruminants (sheep, oxen, &c.). The peristalsis is particularly active during digestion, and is produced in great part by the food stimulating the mucous membrane. If a portion of the intestine or the stomach be removed from the body, peristalsis may continue or may be produced artificially, especially by irritating the mucous membrane. In the body the canal is under the influence of additional nerves (vagus), through which fibres the digestive processes are chiefly regulated among themselves.

The peristalsis in the stomach is combined by irregular churning movements.

The act of vomiting is a reflex nervous act. It can be excited by stimulating the branches of the vagus nerve, which are distributed to the stomach, as when indigestible and irritative food is taken; or emetics, such as mustard, hot water, or a hot saline solution, tartar emetic, ipecacuanha, sulphate of zinc, and alum are administered. By tickling the back of the throat with a feather, the glossopharyngeal nerve is stimulated, and vomiting may readily be produced. It is of frequent occurrence when painful irritation of the uterine nerves in pregnancy, of the nerves of the liver and kidneys during the passage of a hepatic or renal stone, or indeed when irritation of any sensory nerves takes place. Nerve-impulses may pass to the brain through any one of these channels (fig. 10), or may be excited in the brain itself by the sight or smell or even the thought of anything disgusting, and they produce, if the person be conscious, a feeling of nausea. In any case there is a discharge of nerve-impulses, which, as a result of this stimulation, passes to the glands of the mouth through the chorda tympani nerve, and produces a rapid flow of saliva. In addition, motor nerves carry impulses to the muscular walls of the abdomen, and to the walls of the stomach itself. As a result of the muscular contraction which follows, the contents of the stomach are propelled upwards into the mouth. Just before vomiting an inspiration generally occurs, and the aperture of the larynx (glottis) is closed. The diaphragm—the muscle which separates the thorax from the abdomen—then becomes pressed down upon the abdominal contents, and assists in the act of vomiting. Cases in which irritating or poisonous substances are swallowed are so frequent, that every one should be aware that a large quantity of hot liquid, especjally if it contain much salt, or some mustard, forms a safe and speedy emetic.

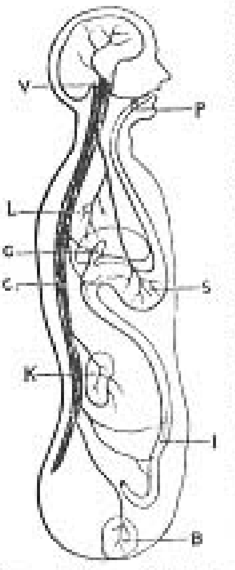

Fig. 10. — Sensory Nerves concerned in Vomiting:

Nerves come to vomiting centre V, through spinal cord SC, from pharynx P, lungs L, gall-bladder G, stomach S, kidney K, intestine I, and bladder B.

Ice is a valuable sedative, and often prevents vomiting. The undigested food when it reaches the lower part of the intestine (rectum), excites sensory nerves which carry impulses to the brain and spinal cord. A feeling of distension results, and voluntary contraction of the abdominal muscles and of the diaphragm—an inspiration usually taking place—expels the undigested matter. This voluntary effort is aided by the contraction of the bowel itself, and by the relaxation of the band of muscular fibres (sphincters) which, during the intervals between evacuations, remain contracted.

In many animals, such as the sheep, ox, and camel, the stomach consists of several cavities communicating with one another. In the ox and sheep both the cardiac and the pyloric portions are each subdivided into two compartments. The cardiac part consists of a very dilated cavity, the paunch (rumen), into which the food is passed as soon as swallowed. In addition there is a smaller part, the reticulum (honeycomb), so called from the folds of lining mucous membrane which intersect, forming a reticulum. The pyloric half is divided into two parts. The psalterium (maniplies), so called from the lamellated appearance of its mucous membrane, communicates with the last division, the rennet stomach (abomasum, fig. 11).

Fluid passes either into the first, second, or third parts of the stomach, and thence on into the fourth. Solid matter, such as grass, roots, &c., passes either into the paunch or reticulum. This is mixed with the saliva swallowed with it, and in addition it is mixed with juices formed by the mucous membrane of these cavities. When the animal has finished feeding, it lies down and rumination commences. Due in part to the contraction of the abdominal muscles and diaphragm, the food is propelled in the form of rounded pellets from the paunch and reticulum up into the mouth. The pellets are there thoroughly masticated, and are returned in a pulpy condition to the stomach. Now, however, the food passes into the psalterium, and finally into the rennet stomach. It will be seen, therefore, that the consistency of the food determines into which part of the stomach it passes. The walls of the stomach near the gullet are thrown into two folds or lips which, when in contact, form a tube leading from the gullet into the psalterium. Along this tube the masticated and fluid food can pass. The mouthfuls of grass which are first swallowed pass between their lips, and find their way at once into the paunch or reticulum.

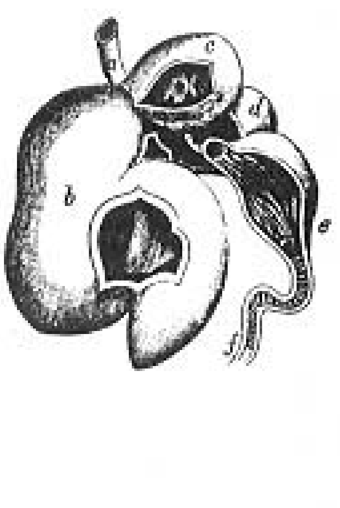

Fig 11.—Compound Stomach of Ox:

a, œsophagus; *b*, rumen, or paunch; *c*, reticulum, or second stomach; *d*, omasum, or third stomach; *e*, abomasum, or fourth stomach; *f*, the duodenum.

Fig. 12.—Alimentary Canal of Fowl:

a, œsophagus; *b*, crop; *c*, proventriculus, or secreting stomach; *d*, gizzard, or triturating stomach; *e*, intestinal canal; *f*, two long cæcal tubes indicating the theoretical commencement of large intestine.

In the bird some interesting modifications in the structure of the alimentary canal are seen (fig. 12). The gullet at about the middle of its course is provided with a pouch or crop. Into this the food passes, and is bathed by a secretion formed by its glands. It is then propelled onwards into a dilated cavity, the proventriculus, and is acted on by digestive juices. Thence it passes into the gizzard. This cavity is provided with muscular walls of enormous thickness in the case of birds that are vegetable-feeders. It is lined by thick and corneous epithelium, and in its interior are generally found pieces of stone, chalk, &c. The gizzard is a powerful mill, which grinds the food into a soft pulp, upon which the digestive juices can readily act.

The Action of the Digestive Juices.—By digestion is meant that process by which food is rendered capable of passing through the walls of the digestive system into the blood-vessels and lymphatics, in such a form that it may be of use to the economy. The most essential change which food undergoes is one of solution. Albumen, starch, fat, and other food-stuffs are quite insoluble in the circulating fluids of the body, and were they injected into the blood they would simply block up the smaller blood-vessels. During digestion these pass either into nearly allied chemical substances which are readily dissolved in water, or in the case of fat partly into a soluble soap, and partly into a state of microscopically minute subdivision. It is not sufficient, however, merely to have a soluble food-stuff in order that it may be absorbed and used by the body. Cane (table) sugar is soluble in water, but it is of no use as cane-sugar to the body. If injected into the blood-vessels, it is at once secreted by the kidneys. During digestion it is converted into another sugarless soluble, but in a form which can be used by the economy.

It must clearly be understood that food introduced into the stomach is not received into the system. It is still 'outside the body.' It is only when it has become absorbed, and has passed in a suitable form, carried by the blood, to the tissues of the brain, muscles, &c., that it is made use of in so-called vital manifestations. The relief and stay that a meal gives is chiefly due to nervous action, the result of gastric distension. Clay and other non-nutritive matter may be swallowed, and will temporarily produce the same effect.

The digestion of food is brought about by the action of juices, the saliva, the gastric, pancreatic, intestinal, &c. These are mixed with the finely divided food by the movements of the alimentary canal. The digestive juices are in all cases secreted by the microscopic cells which line the various glands opening into the digestive system. The digestive juice, whatever be its source, contains either an acid substance or an alkaline one, and in addition a substance termed an unorganised ferment. These ferments differ in many particulars from the organised ferments (bacteria, micrococci), found in putrefaction, diseases such as anthrax, scarlet fever, cholera, &c. The latter are whole living cells, having definite parts or organs. They live and multiply, consume, and excrete in the fluid they inhabit. The digestive ferments are not whole cells, they are the *products of cells.* They are not the broken-down useless substances, such as carbonic acid, water, &c., which all cells give out, and which an animal, like man (an aggregation of cells), excretes. They consist of very complex active matter, of which we know almost nothing, and which we class with some other substances of which we know little more, under the head 'albuminoids.' These ferments in fact possess many of the qualities of cells themselves. They are killed by the temperature of boiling water, like all other living things. They have a certain range of temperature, within which alone they evince activity, and within the limits of that range they are more active the higher the temperature. Then again they require the presence of water, in which fluid they are soluble. In their action they seem to be hydrolytic, that is, they produce important changes in the substances they attach by, amongst other things, adding the elements of water. These digestive ferments, together with the other constituents of the digestive juices, are secreted by the cells of the digestive glands. If we study these glands and their cells with the microscope, they all present several points of similarity. Each gland has a duct, which, as in the case say of the salivary glands, divides into several branches. The duct, or its branches in the latter case, terminate in the secreting tubules of the gland. These are little tubes, which are lined by the secreting cells, leaving only a small cavity in the centre of each tubule for the escape of the secretion into the duct. Outside the tubule there is a dense network of fine blood-capillaries, from which the liquor of the blood escapes, bathing the gland and the cells within it. These imbibe the liquor, and they have almost certainly the power of selecting such constituents of it as they require. The substances derived from the blood are used by the cells, which manufacture the juice which they excrete. The constituents of the excretion are not found, it will be observed, in the blood; they result from chemical processes which go on within the cells, which use blood as a raw material. The cells are very small, being about $\frac{1}{1500}$th to $\frac{1}{1000}$th of an inch across. They have each a very thin envelope, within which the finely granular contents of the cell are seen. In the centre is a kernel or nucleus. During digestion the cell enlarges, and granules appear in it. These are the manufactured products: they are discharged into the duct of the gland.

We have now to consider how it is that the glands are regulated in their secreting powers, how it is that at certain times, and in sufficient quantity, the secreting juice is poured into the digestive system. This is brought about by the action of the nervous system. Although in some cases—e.g. the stomach, local nerve-cells placed in the walls of the digestive system itself, seem to regulate in part the secretion, yet in all cases nerve-cells placed in the brain are chiefly concerned. It was thought at one time that the brain acted by causing the blood-vessels of the gland to enlarge, and in consequence the food-supply and secretion of the gland to become greater. That this is not the whole truth, is shown by the administration of belladonna. If a rather large dose of this drug be taken, the mouth becomes very dry and unpleasant, and it is difficult to speak and to swallow. In other words, the cells of the salivary glands are paralysed, and the customary flow of saliva is for the time being at an end. It is found, however, that during this condition the blood-vessels are by no means contracted. This experiment, together with others, suggests that although during the secretion of a digestive juice the blood-vessels dilate, the activity of the secreting cells is not always associated with the condition of the blood-vessels. The latter are undoubtedly under the influence of nerves (vaso-motor) which regulate their condition, and it is probable that the secreting cells are themselves under the influence of other nerves, which are special secreting nerves. We have already seen that in the case of the movements of the digestive system, the motor-impulses which started from the central nervous system were called into action by sensory impulses starting from the mucous membrane of the digestive system. So in like manner the nervous impulses which pass to the blood-vessels and the glands are caused, in the first instance, by sensory impulses from the mucous membrane. If food be taken into the mouth, especially if it be 'tasty,' a secretion of saliva rapidly follows, and even the tickling of the mouth by a feather, or the stimulation of the mucous membrane with electricity, will produce the same result. In this case sensory impulses pass to the brain through such nerves as the lingual and glossopharyngeal, and reflexly excite the glands through the medium of the brain, the outgoing impulses passing through nerves such as the chorda tympani (fig. 13). See BRAIN. In the case of salivary secretion, the smell or sight of food may excite a secretion. In this case the sensory impulses pass from the nose or eye along the nerves of these organs to the brain. When the thought of food produces a flow, this is due to the recalling of previous sight and smell impressions in the brain.

When food is passed into the stomach, secretion occurs. This too may result from mechanical irritation, as when through an opening (fistula) the mucous membrane is brushed with a feather. In all cases the stomach, pale before, becomes suffused with blood, and the gastric juice is poured out. The flow of the intestinal juice, the pancreatic juice, and bile, all follow the stimulation of the mucous membrane, and in all cases the blood-vessels enlarge so as to give the cells a good supply of food, although, as we have seen, they themselves actually pass into a condition of activity, as a result of the influence of special secreting nerves.

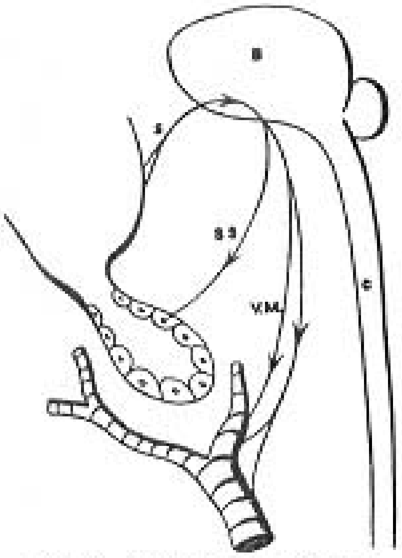

Fig. 13.—Nervous Mechanism of Secretion :

B, brain; C, spinal cord; S, nerve passing from mucous membrane of mouth to brain; SS, nerve passing to cell in salivary gland; VM, nerve passing to blood-vessels of gland.

We have now to consider the digestion of food-stuffs, and the parts that the various glands play in this important process. For our present purpose it is sufficient to speak of foods as belonging to four classes: (1) Proteids—albumens, globulins, &c.—e.g. the white of egg, the chief constituent of meat, the gluten of bread. (2) Carbohydrates—starches, sugars, gums—e.g. potato-starch, cane or grape sugar. (3) Fats and oils—e.g. suet, marrow, olive-oil. (4) Minerals—e.g. water, table-salt, iron, phosphates. See also DIET, FOOD.

Some few substances are absorbed without being digested at all; they do not need to be. Such are water and the minerals, although even many of these undergo some change or other. Grape-sugar is absorbed, and probably proteids too are often absorbed to some extent at least. Fat is profoundly modified during digestion, although not as the result of any digesting ferment. It may be said, however, that the great mass of food-stuff which is classed under the heads of proteids and carbohydrates is all digested by the action of ferment-like bodies. The saliva, of which about 30 ounces are secreted during the 24 hours, contains a ferment termed ptyalin, which is capable of turning starch into a soluble sugar called grape-sugar, or according to other observers, into another soluble sugar termed maltose. This can easily be demonstrated in the following manner: Take a tiny pinch of ordinary starch powder, and shake it up with a tablespoonful of water. It will not dissolve. Then boil it, when the starch will swell up, forming a thin starch paste. Dilute a few drops of tincture of iodine with several volumes of water, and add a drop of this to a small quantity of the starch paste. It will become of a rich blue colour. This is the test for starch. Now add to some of the original starch paste about one quarter of its volume of saliva from the mouth, and keep the mixture by the fire at a temperature pleasant to the hand. In a minute or so take out some of the starch in order to test it again. The iodine no longer gives a blue colour, but produces a beautiful mahogany brown. This shows that the starch has disappeared, the brown colour being the reaction given by erythrodextrine into which the starch has been converted. After a little time another portion tested in a similar way gives no reaction whatever, the erythrodextrine having in its turn disappeared. The starch is now converted into sugar, mixed with a little unconverted dextrine. This being an achroodextrine, uncoloured like the erythro-dextrine by tincture of iodine,

$$\overset{\text{Starch.}}{C_6H_{10}O_5} + \overset{\text{Water.}}{H_2O} = \overset{\text{Grape-sugar.}}{C_6H_{12}O_6}.$$

The ptyalin may be extracted from the saliva or from the salivary glands themselves. It does not appear to be much exhausted during its activity, and has the general characters already discussed of unorganised ferments. The saliva is alkaline, and the starchy food is no doubt partly converted into sugar during its sojourn in the mouth and gullet by its action. When the food has reached the stomach and the acid gastric juice has mixed with it, the saliva is unable to act, and is probably killed. Any undigested starch is subsequently converted into sugar when the food reaches the small intestine by the pancreatic juice.

When the food reaches the stomach it causes a reflex secretion of gastric juice. This is but slowly produced when insipid heavy food, such as coagulated white of egg, boiled meat, sago, &c., is eaten, but flows readily when soups, broths, and fluids containing salts and extractions in abundance are taken. Thus we have a scientific reason for commencing a dinner with soup, preserving the *pièce de résistance* until the stomach has secreted gastric juice for its digestion. The gastric juice, several pounds of which are secreted daily, is acid in reaction containing free hydrochloric acid. In addition lactic and butyric acids are formed during the progress of digestion. The ferment peculiar to the stomach is termed pepsine, and it requires, unlike the ptyalin of the saliva, an acid medium for its action. Pepsine and hydrochloric acid convert proteids into substances termed peptones. The latter bodies are soluble in water, and are not coagulated by boiling like many of the proteids. In addition they pass readily through an animal membrane, and are therefore easily absorbed. The proteid does not pass directly into the peptone, but like the starch is changed into at least one intermediate body. In the first case the proteid becomes converted by the hydrochloric acid into what is called syntonin, or acid protein, and it is this syntonin which alone the pepsine has power to change into peptone. The syntonin becomes a propeptone which is intermediate in its properties between a proteid and peptone itself. It is very probable that the whole change from proteid to peptone consists in some simple change in the molecular character of the proteid, together with the addition of water. A peptone may be termed therefore a hydrated proteid, and the pepsine a hydrolytic ferment. Within the stomach, and capable of being readily extracted from the stomach of a calf, is a ferment called the milk coagulating ferment (rennet). This causes milk to coagulate, and form a clot or curd. It subsequently contracts and squeezes out some fluid termed the whey. It is difficult to assign any use to this ferment, for the acid of the gastric juice would cause of itself the milk to curdle. Still more difficult is it to explain the existence of a similar ferment in the pancreatic juice, for we cannot suppose that any milk can even pass through the stomach to be subjected to its action. The milk indeed often forms dense clots which cannot afterwards be digested, and which cause considerable gastric irritation. Milk when drunk is frequently found to disagree with some stomachs; but even in such cases it may often be 'sipped' with impunity. In this case the formation of large clots is prevented. Lime-water causes the milk to coagulate in small soft clots.

The products of digestion, peptone and sugar, together with water and many soluble salts, are absorbed into the blood-vessels which ramify in the gastric mucous membrane. When gastric digestion is over, the undigested food (chyme) passes through the relaxed pyloric sphincter into the small intestine. The chyme consists of some proteid and starchy matter, together with fat and oil and indigestible substances such as vegetable fibre, pure wax, cartilage, &c. mixed with gastric juice. Intestinal digestion is an alkaline one, and all the digestive juices of this part of the digestive system are alkaline in their reaction. They soon counteract the acidity of the chyme, which now becomes alkaline. The proteids which remained undigested by the stomach are now acted upon by a ferment called trypsin found in the juice of the pancreas. This converts the proteids into peptones through an intermediate propeptone. The pancreatic juice contains other ferments which operate during digestion, notably a hydrolytic ferment, similar in its action to ptyalin, whereby the remaining starch is converted into sugar. The juice itself is thick and viscous. It is strongly alkaline and secreted in rather small quantity. It is said to possess a ferment capable of splitting oil and fat into glycerine and fatty acid, which it does by adding water to the fat, which is then decomposed. The fatty acid unites with the free alkali present, and a soap is formed which is subsequently absorbed. The alkaline contents of the alimentary canal also emulsify fat—i.e. they cause it to become very freely divided, forming a milky fluid. The minute microscopic globules which result pass readily through the walls of the alimentary canal into the lymphatics (lacteals). The emulsification of an oil can readily be shown by adding about half its volume of carbonate of soda (3 per cent.) solution to cod-liver oil. The latter becomes at once very similar to milk in its appearance.

The intestinal juice, the secretion of Lieberkühn's follicles, is strongly alkaline. It assists in the digestion of starch and of proteid matter. In addition an important ferment called 'invertin,' is found. This has the power of changing cane into grape-sugar and an allied substance, lævulose. Both these bodies have the same formula, but differ from one another in their action on polarised light,

$$\overset{\text{Cane-sugar.}}{C_{12}H_{22}O_{11}} + \overset{\text{Water.}}{H_2O} = \overset{\text{Grape-sugar.}}{C_6H_{12}O_6} + \overset{\text{Lævulose.}}{C_6H_{12}O_6}.$$

The importance of this ferment will be appreciated when we consider how large a quantity of food is taken in the form of cane-sugar, and that cane-sugar introduced into the blood is not of any use to the body, and is eliminated at once by the kidneys. The bile may be looked upon both as an excretion from the body and as a digestive juice. The colouring of the fæces and urine is due in part to a pigment hydrobilirubin (urobilin), which is an altered bile pigment. If bile is excreted rapidly, the fæces are dark in colour, and they may be white owing to deficient excretions. Many substances such as mucin, cholesterin, &c. found in the bile are excreted to form part of the fæces. On the other hand many bile constituents, such as the bile salts, are reabsorbed and used again in the economy. Bile has an important action in digestion, as may be shown by making biliary fistula in dogs, whereby the bile leaves the body at once through an aperture in the abdomen. In this case the animal loses flesh; the fat which it takes with its food passes unabsorbed through its digestive system, and its excretions are offensive. The bile seems then to assist in fat absorption, and to have some antiseptic action whereby putrefaction is prevented or lessened within the digestive system. Bile assists in the absorption of fat not only by assisting in its emulsification, but also by helping in some way or other the epithelial cells, covering the villi to take up the minute fatty particles. In addition it is supposed to stimulate minute muscular fibres within the villi, which by their contraction pump the absorbed fat on into the larger lymphatics.

Within the small intestines most of the food undigested by the stomach is rendered fit for absorption. This takes place through the tissue of the mucous membrane; much of the sugar and peptones find their way into capillary blood-vessels. Absorbed products, and notably fat globules, pass into the lacteals, and thence into the blood, circulating through the veins at the root of the neck. The contents of the lacteals during absorption are called *chyle*. The contents of the small intestine pass into the large intestine, where digestion occurs to a very slight extent. Absorption is, however, more rapid, and the contents become far more solid as they pass towards the rectum, due to the deprivation of water and soluble substances. The absorptive power of the large intestine is important to remember; for injections per rectum of liquid food, especially if it has already been artificially digested, may frequently sustain life for long periods.

Artificial Digestion.—The digestive juices are occasionally defective in amount or in quality, and in this case they may be supplied artificially. All the digestive ferments may be separated by very simple processes from the glands which secrete them, and many may readily be obtained in the market. Pepsine and hydrochloric acid, taken with or before a meal, are often of great service, the most reliable preparations of pepsine being the ordinary pepsina porci. Food may be digested *outside the body* before its administration. Beef-tea and milk-gruel may be prepared in the following way: To bring the food to the proper temperature, boil half of it, mix it with the other half, and keep warm near the fire. To this add a preparation of the pancreatic ferments in the proportion given in the directions which invariably accompany the bottle containing the substance. The food should now be kept warm for an hour or so, and then boiled in order to prevent any further action of the ferment. It may be taken by the mouth or administered as an enema. Preparations of the pancreas are alone to be used in peptonising food outside the body, as pepsine preparations produce a bitter and unpleasant taste. Pancreatic preparations on the other hand are useless when taken with the food, as they are destroyed within the stomach.

Digita'lis, a genus of Scrophulariaceæ, natives chiefly of the south of Europe and temperate parts of Asia. One only, the Common Foxglove (q.v.), (*D. purpurea*), is a native of Britain. Other species have been introduced, notably *D. lutea* and *grandiflora*, with yellow flowers. The botanical name Digitalis (late Lat. *digitale*, 'the finger of a glove') refers, like the popular English name, to the form of the flowers.

The leaves of the *Digitalis purpurea*, collected before the expansion of the flowers and dried, are largely used in medicine, either in the form of powder, or as tincture or infusion. Digitalin granules, containing minute quantities of a mixture of the active principles, are also employed. The leaves owe their activity to the presence of certain bodies, which have been named digitalin, digitalein, digitoxin, and digitonin, the three first mentioned having the characteristic digitalis action, while the fourth is entirely different, and closely resembles saponin in its effects. The leaves and their preparations have a bitter taste. When given in large doses by the mouth, they produce violent vomiting and purging; this may prevent their absorption into the blood, but if absorbed, they may cause death by paralysing the heart's action. When the leaves are administered in medicinal doses, a peculiar action is exerted on the muscular substance of the heart and blood-vessels, causing the former to beat more slowly, regularly, and powerfully, and contracting the latter. By this combined action the blood-pressure is raised, and if dropsy be present, a diuretic action is exerted. Digitalis is also used in many organic forms of heart-disease, in nervous and functional irregularity of the heart's action, in cardiac weakness from long-continued disease, in œdema of the lungs, internal hemorrhages, and other conditions. When taken for a long time it may cause nausea and other digestive disturbances, and in a very few cases sudden and serious symptoms of poisoning come on. This constitutes the so-called *cumulative* action of digitalis. In therapeutic doses digitalis should slow the pulse; if too large doses be given, the pulse becomes rapid and irregular.

Dippel's Animal Oil, a panacea invented by Johann Konrad Dippel (1673–1734), a German chemist and alchemist. It was obtained in the manufacture of ammoniacal products by the distillation of bones. A mixture of oils passes over, and these, after being repeatedly distilled, eventually yield an aromatic liquid, free from fetid odour. This obtained a great reputation as an antispasmodic, and being present in the old spirit of hartshorn, gave it properties somewhat different from those of the modern sal volatile. Owing to the careless way in which it was usually manufactured, and the consequent disgusting odour and taste which it possessed, it has been quite discarded and is no longer used in medicine.

Distemper is a typhoid inflammation affecting the mucous membranes of young dogs, and resembling in many respects the strangles of young horses, and the scarlatina and other such complaints of children. Like these, it is generally contagious, occurs only once in a lifetime, runs a definite course, is accompanied by low fever and debility, and is most successfully treated by good nursing and attention to diet and regimen. It is divided into five different forms—catarrhal, pneumonic, intestinal, hepatic (known as yellows), and nervous. The catarrhal always accompanies and frequently precedes the other forms. The eyes are red or yellow, weak, and watery; the nose dry and hot; draughts of air or movements of the animal readily excite sneezing or cough; there is dullness, fever, and loss of appetite. The thickened slimy mucus which the inflamed membrane after some days secretes, accumulates about the eyes and nostrils, and lodging in the bronchial tubes, prevents the free access of air and the proper purification of the blood. Hence ensue distressed breathing, increasing weakness, and symptoms of nervous disturbance, such as staggering gait, chorea, and fits. All dogs are liable to distemper, but the delicate and highly bred varieties suffer most severely, and amongst them the mortality is very great. Bleeding, physicking, and all irritating and reducing remedies, must be carefully avoided, and a good dry bed in a comfortable airy place provided. The stomach, which is generally overloaded, should be relieved of its contents by an emetic, which, for an ordinary sized English terrier, may consist of two grains each of tartar emetic and ipecacuanha, with eight or ten grains of common salt, given in a wine-glassful of tepid water. If no effect is produced, the dose must be repeated in twenty minutes. Constipation, if present, should be corrected by half an ounce each of castor and olive oil, to which, in large dogs, a few grains of gray powder is a useful addition. The febrile symptoms, if acute, may be alleviated by giving four times daily, in cold water, five drops of laudanum, and five grains each of nitre and hyposulphite of soda. Distressed breathing will be relieved by applying to the chest and sides, for an hour or two continuously, a thick flannel cloth, wrung at short intervals out of hot water. The throat may also be rubbed with hartshorn and oil, and the nostrils sponged and steamed occasionally. Give frequently, and in small quantities at a time, milk and bread, or any other such simple and digestible food; and when recovery is tardy, and weakness ensues, endeavour by nursing, tonics, and stimulants, to support the strength. See *Management and Diseases of the Dog*, by J. Woodroffe Hill (new ed. Lond. 1881).

The term distemper is sometimes applied to Influenza in horses, and epizootic Pleuro-pneumonia (q.v.) in cattle.

Distillation is the name given to the process of applying heat to a liquid, or, it may be, a solid, in order that certain constituents may pass away in vapour, and, by suitable arrangements, be obtained in the form of a liquid. When the vapour does not condense as a liquid, but only as a fine dust or flour, the process is called *Sublimation* (q.v.). The natural evaporation of water, by the heat of the sun, or warm air currents, the ascent of the vapour into the colder regions of the atmosphere, and the condensation there into clouds and mists, with the subsequent rain-shower, form together the grandest example of distillation. The apparatus for artificial distillation essentially consists of three parts, the Still (or RETORT, q.v.), Condenser, and Receiver. The *still* is made of glass, copper, iron, or earthenware, according to the nature of the substances to be placed in it. In experimental chemical work, glass is almost the only material admissible, while in the preparation of alcohol from grain, copper-stills are commonly employed. The *condenser* is made in an infinity of forms, the object being to condense the vapours disengaged from the still as rapidly and effectually as possible. For this purpose it is important that the condenser shall expose a large surface to the cooling medium, water or air. Owing to its rapidity in conducting heat, and the thinness of pipes made of copper, this metal is generally employed in the construction of condensers. Whatever the form, the principle is the same—viz. that the hot vapours pass through a tube or vessel surrounded with cold water, which running in a constant stream, passes away more or less warm after it has done its work. The *receiver* merely consists of a suitable vessel in which to receive the *distillate*. As the forms of apparatus are capable of infinite variety, so the conditions of distillation are innumerable; the best defined types going under the names of Fractional Distillation, Destructive Distillation, and Distillation in Vacuo.

In *Fractional Distillation* a mixture of liquids having different boiling-points is put in the still and heat is applied. If the vapours were allowed to pass over together and the distillate to be received in a single receiver, it is evident that nothing would be gained; for the different liquids would re-mingle in the receiver. If, however, the temperature be raised very slowly, and especially if the vapour requires to rise through a high *head*, or tube, before passing into the condenser, it will be found that the more volatile liquids pass over first in a state of comparative purity, and while the others follow as the heat is increased. If the receiver be frequently changed, a series of *fractions*, or portions of liquid, are obtained, corresponding to the different substances present in the still. For example, if a mixture of glycerine, water, alcohol, chloroform, and ether were distilled, the ether would distil first, then the chloroform, next the alcohol, and lastly, the water, while nearly all the glycerine would be left behind. This then is fractional distillation.

Destructive Distillation, or Dry Distillation as it is sometimes called, is best exemplified when coal is heated in an iron still or *retort*, as in the manufacture of gas. Now, in coal there are only traces of moisture capable of distillation, but when strongly heated, the coal is destroyed, or *decomposed*, and a large number of substances distil over, some of which, like lighting gas, are permanently in the gaseous state, others like Creasote (q.v.) are liquid, while others, such as naphthaline, are solid bodies at the ordinary temperature. Here no distillation takes place until the substance heated is destroyed, hence the term destructive distillation. Further examples are the distillation of wood in close vessels, at a red heat, when charcoal is left in the vessel, and wood-vinegar, wood-spirit, tar, &c. pass over in vapour, and are condensed; and the heating of bones in similar retorts, when animal charcoal is left in the retort, and Dippel's animal oil distils over. See CHARCOAL, COAL-TAR, and DIPPEL'S ANIMAL OIL.

Distillation in Vacuo.—When water is heated in a kettle it eventually boils, and if a thermometer be plunged into it, the mercury is seen to remain stationary at a temperature of about 212° (100° C.). It will be noticed, however, that when the barometer is low, the temperature of the boiling water is somewhat below 212° (100° C.), and that when the barometer is very high, the temperature is also high. On the summit of Mont Blanc, it is found that water boils at about 180° (82° C.); while in a vessel from which the air has been removed by an air-pump, it continues to boil even when the temperature falls down to the freezing-point (see BOILING.) There are many substances which are injured by heat, such as extract of malt and sugar, and when solutions of these bodies require to be evaporated on a large scale, they are always distilled *in vacuo*, so that the water may be removed without unduly heating the vessel.

There is another very interesting method of distillation whereby liquids which, alone, cannot be distilled without decomposition, are made to distil in presence of the vapour of some other liquid. Thus, glycerine is not, practically speaking, capable of being distilled, but when heated with high-pressure steam, it readily distils over, and can thus be purified. The great object of distillation is purification, and in the manufacture of the fragrant volatile oils of lemon, lavender, &c., it is necessary to distil them along with water so as to avoid overheating of the oils, and consequent injury. Not only is the flavour improved by this treatment, but they distil at a lower temperature along with water than when alone. The term distillation in excise language refers to the distillation of alcohol alone. For information on this subject, see FERMENTATION, ALCOHOL, BRANDY, GIN, SPIRITS, and especially WHISKY; under which latter head the subject of the duties payable and of illicit distillation are also treated.

Distilled Water is the condensed product obtained by the distillation of water. All natural waters, even rain-water, contain certain saline matters (common salt, &c.) in a state of solution, from which they can only be completely freed by the process of distillation. The characteristics of distilled water are, that it possesses a mawkish, insipid taste, without odour or colour, and when evaporated to dryness in a vessel, it ought to leave no residue. Unless very specially prepared, it is sure to contain traces of free ammonia, and, when this is the case, it is liable to form a green vegetable growth in any bottle containing it. The other properties of distilled water will be noticed under WATER.

Distilled Waters is the name for what is obtained by distilling water along with the parts of plants containing essential oils. Rose-water and lavender-water are familiar examples.

Diuretics, medicines having the property of increasing the secretion or excretion of urine, and on this account much employed in dropsies, as well as in a variety of other diseases. The principal diuretics are the salts of potash, especially the nitrate, acetate, and bitartrate (cream of tartar); squill, in powder, vinegar, or syrup; digitalis or foxglove, in powder or infusion; the decoction or infusion of broom-tops (*scoparium*); nitrous ether (in sweet spirit of nitre); caffeine, the active principle of coffee; the alcohols and ethers, with most of the volatile oils, especially that of juniper, as in gin; the berries of the common elder; the tincture of cantharides or Spanish flies; turpentine, &c. The last named (from the alcohols onwards in the above enumeration) are more or less irritating in their effects on the urinary organs, and should not be used without due consideration as to the requirements of the particular case. Cream of tartar and the broom-decoction form one of the safest and best diuretic mixtures which can be employed in domestic use; or cream of-tartar may be given alone, either dissolved in hot water and allowed to cool, or in substance along with syrup.

Ductility is that property of solids in virtue of which they can be drawn out so as to increase their length at the expense of their cross dimensions. Thus silver is a very ductile metal, while platinum is not so ductile. But although platinum cannot be drawn out to any very great extent by the ordinary process of wire-drawing, it may be drawn out by Wollaston's process. Wollaston fitted a platinum wire into the interior of a hollow rod of silver, and then drew out the compound rod to an extent limited only by the ductility of silver. He then dissolved off the silver, and so obtained an excessively fine platinum wire, the diameter of which was, according to Leslie, [illegible] inch. Leslie also says that, by drawing out a thickly-gilt silver rod, a film of gold only [illegible] inch in diameter could be obtained. See MALLEABILITY, WIRE.

Dulse (*Rhodymenia palmata*), a seaweed, one of the Florideæ (see SEAWEEDS), growing on rocks in the sea, and used as food by the poor on the coasts of Scotland, Ireland, and other northern countries. It is eaten raw or roasted, and with vinegar. It is an important plant to the Icelanders, and after being washed and dried, is stored in casks, to be eaten with fish or boiled with milk. In Kamchatka, a fermented liquor is made from it. Sheep are fond of it.—One or two other edible Florideæ bear the same name on different parts of the coast, and the pungent *Laurencia pinnatifida* is known as pepper dulse.

Dyeing is the art of imparting colours to textile and other materials, such as cotton, silk, wool, and leather. It has been practised among eastern nations from time immemorial; and in the Old Testament, we read of the purple-dyed vestments of the high-priests, of linen cloths dyed blue, purple, and scarlet, and of rams' skins dyed red. The famous Tyrian purple, obtained from one or two species of shell-fish, is believed to have been discovered by an inhabitant of Tyre fifteen hundred years B.C.; afterwards this purple became the badge of royalty, and cloth dyed with it commanded a princely price. Purple of various shades was dyed not only at Tyre, but at Tarsus, Alexandria, and other places on the shores of the Mediterranean, though other colours were of course employed. The Egyptians, Greeks, and Romans practised the art of dyeing. There is an ancient Roman dyer's workshop with its apparatus to be seen among the ruins of Pompeii. Gradually the art became more and more widespread as civilisation advanced. In earlier times, dyeing was much more extensively followed as a domestic art than it is at present, but in some outlying parts of Europe and even in the Highlands of Scotland, the colours imparted to home-made fabrics are still to some extent obtained from native vegetable dyes. Many of the ordinary dyestuffs and dyeing agents have been used in England for more than four centuries, and to these America added cochineal, as well as some important dyewoods and barks. Dyeing with colours obtained from natural products had reached a high state of perfection when Perkin, in 1856, introduced the first of the coal-tar colours. Since that date the progress of artificial colour making has been so rapid, and the application of the new dyes made so simple, that it now seems doubtful whether many of the older dyestuffs and processes can continue much longer in use. The experience acquired in dyeing with any colouring material must not be undervalued on account of its partial disuse; and some illustrations, though of less practical importance than they were lately, may here be given, in describing the general principles of dyeing.

Assuming that the textile material has been subjected to the cleansing and whitening operations described under BLEACHING; that the water is soft and clear, and the vessels free from rust and perfectly clean, the next point to consider is the nature of the fibre. Very often if this is of animal origin, such as silk or wool, a simple immersion in a bath containing the colour will dye the fabric; but colour so applied to a vegetable substance as cotton, linen, or jute, would be easily washed away. The fibre in the latter case requires some special preparation to make the dye adhere, and a mordant is employed for this purpose Mordants are usually mineral salts applied to the yarn or cloth, so as to leave their bases in intimate contact with the fibre. A class of mineral colours may be first described, as their production depends on simple reactions similar to those occurring in the use of mordants. One of these colours, chrome yellow, has been already noticed under CALICO-PRINTING. They are the result of an interchange of the bases and acids of two soluble salts in the material of the fibre, one of the new salts being soluble and readily washed out, the other insoluble and the substance having the colour.

Prussian blue (q.v.) may be taken as an instance of this mode of dyeing. A bath to dye 7 lb. of silk is made up as follows: 10 gallons water; 24 oz. nitrate of iron solution, specific gravity 1·6; 4 oz. stannous chloride. And another bath with 10 gallons water; 6 oz. yellow prussiate of potash; 3 oz. sulphuric acid. The first bath has a temperature of 130° F. The silk is turned through it till it is thoroughly penetrated with the liquor, then washed, and transferred to the second bath, which is also warm. The silk, without washing, is returned to the first bath, after which it is again washed and placed in the second bath. The first bath is now strengthened with 6 oz. of nitrate of iron and 2 oz. of stannous chloride, and the second bath with 3 oz. of sulphuric acid and 2 oz. of yellow prussiate of potash. Once more the silk is returned to the first bath, washed, and transferred to the second bath. After this steep, it is wrung out and left for six hours, when it is washed, raised, and dried in the air.

There are several things to be learned from this process. (1) The solutions must be dilute; (2) several operations are required to get an equal shade; (3) an acid solution is necessary to prevent iron oxide from depositing on the cloth, and this is made more certain by strengthening it in the last dipping; and (4) time is given for any action of the air before the final washing is given to the dyed silk. These or similar matters require attention in dyeing generally.

Buff is produced on cotton by a bath of nitrate of iron, followed by one of dilute and clear lime-water, washing and drying. In this case peroxide of iron is left in the fibre, and forms the colouring material; the nitrate of lime being readily soluble in water, washes out. This is an instance, however, in which the cloth has been mordanted as well as dyed, and if we wish to give it, say, a black or dark purple colour, it only requires to be immersed in a bath of logwood.

Supposing that in place of nitrate of iron we had used a solution of alum or other soluble salt of alumina, as the sulphate (alum cake) or acetate (red liquor), we should have had the hydrate of alumina deposited in the fibre. As, however, this is simply white, the appearance of the cloth would not have altered; but if placed in a logwood bath, a pink or red colour would be the result, the tint and depth varying with the strength of the solutions. In such a case the cloth is dyed with an aluminous mordant.

The mordants most largely used are the salts of iron, alumina, and tin. Acetates and sulphates of both oxides of iron, as well as of alumina, and the two chlorides of tin and stannate of soda, form the greater portion of the materials employed.

Suppose that cloth is impregnated with acetate of iron, which is a combination of the peroxide of iron with acetic acid. This oxide is a feeble base, and the acid is volatile. Consequently, when the cloth is placed in a hot chamber filled with moist air, the acetic acid is expelled, and the oxide of iron is left in the fibre, which is what the dyer requires. The application of the acetate of alumina as a mordant is explained in the same way.

In the case of salts with non-volatile acids (nitrate of iron or sulphate of alumina, for example), lime-water, caustic soda, carbonate of soda, or similar bodies are used to precipitate the mordants in the material to be dyed, as in the instances given above. But in some kinds of dyeing the assistance of an alkali is not necessary to decompose the salt, as merely boiling it with the fibre is sufficient to separate the base and liberate the acid, the cloth retaining the former, and the latter adding to the acidity of the bath. If fresh alumina were added to the bath to combine with the liberated acid, the process could go on indefinitely, but when a certain amount of free acid has accumulated, the fibre ceases to effect the decomposition of the salt. In practice this is not the method followed, but a potash salt of an organic acid is added to the bath, the potash of which neutralises the strong mineral acid; the weaker organic acid being set free, which has not the same power of preventing the absorption of alumina by the fibre. Tartar or argol (impure acid tartrate of potash) is much used along with alum for wool-mordanting, and also in silk-dyeing with tin mordants.

Several salts of tin are much used as mordants—the most important being stannous chloride or muriate of tin—also called 'tin salts' and 'tin crystals.' Stannic chloride or perchloride of tin is likewise used, and a solution of the metal in hydrochloric and nitric acids, called 'tin spirits' and 'oxymuriate of tin,' is in general use. The latter is a mixture of stannous and stannic salts, and requires very great care in its preparation. The salts of tin are decomposed readily by the fibre, and the tin spirits require to be used when freshly made, as deposits soon appear in the solutions. Stannate of soda is also much employed in dyeing. When the fibre is charged with it, the insoluble stannic acid is liberated with dilute sulphuric acid.

The mordants mentioned above are employed chiefly in cotton-dyeing with the vegetable dyes or the similar artificial alizarin colours. Wool and silk are not usually mordanted in the manner described, and the following observations apply to cotton and other vegetable fibre.

Often, in dyeing, copper boilers are used with an ordinary fireplace for heating them. The dyestuffs are used either in powder or raspings among the water, or their extracts are employed. The dye solutions are generally warm or boiling, and the goods immersed in them require to be kept in constant motion, or nearly so, to insure uniformity of absorption.

Dyeing of Cotton.—The following is a brief outline of the processes in use for a few important colours:

Black is produced by steeping the goods in a decoction of sumac; then passing them through a solution of acetate of iron. After washing, they are next passed through a decoction of logwood.

Brown is usually obtained by passing the cloth through a decoction of cutch or Catechu (q.v.), and afterwards through a solution of bichromate of potash. Logwood, fustic, or any of the red colouring stuffs, can be afterwards added according to the shade of brown wanted.

Purples and lilacs are got from logwood and alizarin with mixtures of iron and alumina. With madder colours, reds and pinks are got by the use of alumina and tin.

Reds are also got from various dyewoods, as sappan-wood, peachwood, barwood, &c., with tin or alumina, the cloth being first soaked in an astringent, as sumac or gall-nuts. The coal-tar colours, safranine, &c., have almost entirely superseded these woods in the dyeing of reds.

Yellow is got from fustic, quercitron bark, Persian berries, &c., with tin or alumina mordants. Better shades of yellow are now, however, produced by auramine and other coal-tar dyes. Blue colours are not obtained from the natural dyeing materials with the usual mordants, and green is produced by dyeing a yellow such as fustic over cloth already rendered blue.

The production of Prussian blue on silk has been fully given, and the same method is applicable to cotton. For the dyeing of indigo blue.

Turkey-red is a very bright and permanent colour on cotton, obtained till recently from madder, but now almost entirely from alizarin, by a special process in the treatment. An oil mordant, as it is termed, is employed in combination with the fibre. Formerly a coarse olive-oil was made into an emulsion with a weak solution of crude pearl-ashes, through which the cloth was passed, then wrung out and hung up in a stove. The oil absorbs oxygen, and thickens into a varnish containing free fatty acids. The operation was repeated six or eight times. A Turkey-red oil is now sold which is chiefly the oleic acid of castor-oil in combination with ammonia or soda, and of this oil the cloth requires only one or two applications. The cloth is also mordanted with alumina as usual, and then passed into the dye-bath, which is gradually raised to boiling. The bath may be charged with ground madder, natural alizarin, or the artificial product, and generally sumac or some substance containing tannin is added. The goods are brightened by boiling in soap solution, and finally in a bath of tin spirits.

In dyeing cotton with coal-tar colours (with the exception of the azo group), the goods are first mordanted by passing them through a solution of tannic acid, and then through one of tartar emetic; or they are first passed through a decoction of sumac, and afterwards through a solution of stannate of soda. The goods are usually put into the dye-beck in a cold state, and gradually raised to a heat of about 120° F. as the dyeing proceeds. With the azo group of colours (see below) no previous mordanting is required, but a little sulphate of soda or common salt is added to the dye-beck to make the colour go on more evenly. These azo colours are dyed at a boiling heat. The reds of this group are not very satisfactory on cotton.

Aniline black is produced on cotton yarn directly by the oxidation of aniline with bichromate of potash and hydrochloric acid.

Dyeing of Wool.—This fibre absorbs both colours and mordants so much more readily than cotton, that for the most part the methods of dyeing it differ from those that have been described. Sulphuric acid has little action on wool as compared with cotton, consequently many operations in wool-dyeing are conducted in acid solutions at high temperatures, where cotton would be destroyed. An instance of producing a Prussian blue on worsteds may be given: 'Worsted, 100 lb. Make cold solutions of 9 lb. red prussiate of potash, 2½ lb. tartaric acid, 2½ lb. oxaliç acid, and 2 lb. tin composition. Pour these together and add the mixture so produced to about 300 gallons of water at 100° F., and further add 12 lb. good oil of vitriol. Enter the goods, turn well, heat up slowly to the boiling-point, and boil for half an hour.'

Here it will be seen no salt with an iron base is present to form a Prussian blue, and consequently this constituent must be got from the decomposition of the red prussiate by the oil of vitriol, the wool absorbing the colour as it is formed. A blue produced in the way already given for silk would be comparatively cheap, but none of the mineral colours obtained by the mutual interchange of acids and bases in the fibre are successful with wool. Wool is dyed to a much larger extent than either cotton or silk with dark colours, and for these logwood and the astringent dyes catechu, nut-galls, sumac, &c., are chiefly used along with indigo, alizarin, and fustic for special shades. The wool is first, as a rule, boiled with bichromate of potash, sulphate of copper, and oil of vitriol, then with the dyes—for instance: 'Black. For 55 lb. wool. Boil with 17 oz. each chromate, bluestone, and oil of vitriol for 1½ hour. Dye in 22 lb. logwood and 4 lb. fustic, boiling 1 hour.' Sometimes the chromate is mixed with tartar for the first treatment of the wool, with or without sulphuric acid. Woaded blacks are the best for woollen cloths. By this method the wool or cloth is first dyed in the indigo vat a light or medium shade. It is then dyed a chrome black by a process the same or similar to that just given in which bichromate of potash and logwood are the chief ingredients used.

Generally when dyes on wool are required to stand milling (see WOOLLEN MANUFACTURE), the goods are first mordanted by boiling them for an hour in a solution of bichromate of potash and tartar. Brown, olive, drab, and similar colours are dyed with madder or alizarin, camwood, fustic, and logwood, in proportions varying with the shade required.

Until quite recently, the most important of the materials for dyeing wool, next to indigo, was cochineal. It gives with tin and alumina mordants very brilliant pinks, crimsons, and scarlets. To produce scarlet the cloth is boiled in tin spirits—generally with addition of cream of tartar—until mordanted with stannic oxide, then washed and boiled in the ground cochineal till the solution gets colourless, that is, till all the dye is absorbed. A second boiling is given with cochineal mixed with a little more mordant and tartar. Benzidine reds are now replacing cochineal.

With coal-tar dyes almost every conceivable colour can be obtained on wool. In most cases it is only necessary to add a little sulphate of soda and sulphuric acid to the dye-beck, no previous mordanting being necessary. Tin spirits and tartar brighten a number of the colours.

In dyeing wool, alizarin blue solution is said to give beautiful deep blue shades, as fast as indigo to light and milling, and is regarded as a great success as a substitute for the natural dyeware; artificial indigo is as yet too expensive a competitor.

Silk, when dyed dark colours, may be used without the same bleaching operations for the removal of the gum, required for brighter tints. The dyes and mordants for these are much the same as for wool, but the baths are usually hot soap solutions containing the dyes. Cochineal gives a poppy red with a tin or alumina mordant, and annotto in alkaline solution an orange yellow with the latter. Archil and safflower give violets and pinks without a mordant, but they are fugitive.

Silk is dyed with the coal-tar colours by a simple immersion in a solution in water or, if necessary, in spirit. Usually the soap solution of the silk gum is taken, and the colour brightened by rinsing in acetic acid. For the oxyazo dyes sulphuric acid is added to the bath.

DYESTUFFS.—The principles of the art of dyeing being already stated under the head of DYEING, it is only necessary to notice here, in the first place, the more important of the older dyestuffs of commerce, and then to give some account of the remarkable group of artificial dyes known as the 'coal-tar colours.' The first of these was introduced in 1856, and the number of them now in use is considerable. Still many of the older colouring materials to a large extent hold their ground, and it is by no means certain that they will ever be entirely displaced by purely chemically prepared dyes. Natural dyestuffs are chiefly products of the vegetable and animal kingdoms.

Vegetable dyes are obtained from all parts of plants, such as the roots, the wood, the bark, the leaves, the flowers, and the seeds or fruits. That is to say, of certain plants one or other of these is the dye-yielding part, but sometimes the whole plant is employed. The number of plants which yield colouring materials such as could be applied in the tinctorial arts is very great, and if we include those employed by savage races, the number of these dyestuffs actually used is still large. Those, however, which are well known are not very numerous. A fuller account of a few of the more important of those noticed below is given under their separate heads.

Madder (q.v.), from the root of *Rubia tinctorum*, has been used for dyeing red and for producing, along with other dyes and with certain mordants, compound colours since ancient times. Until the discovery of a process of making artificial *Alizarin* (q.v.)—the chief colouring principle of madder—it was largely cultivated in the Levant. Madder, and not artificial alizarin, is still used for dyeing calico in Persia and some parts of India, but a comparatively small quantity is now brought to western Europe. There are other two species of Rubia yielding dyes somewhat resembling madder which are employed in India. These are *R. cordifolia* and *R. sikkimensis*, the dye from the former being called 'manjit' or Indian madder.

Garancine is a red dyestuff prepared by treating spent madder with sulphuric acid. It is of less importance now than formerly.

Safflower, from the flower-heads of *Carthamus tinctorius*, yields both a red and a yellow dye, but it is only the former that is useful. The red, or rather pink, is a beautiful, though not a permanent, colour applied to the dyeing of silk, and more sparingly to cotton. It is a costly material, and before the introduction of aniline colours, the cultivation of safflower was an important industry in India.

Brazil-wood (q.v.), obtained from one or more species of Cæsalpinia, according to some authorities from *C. braziliensis*, according to others from *C. echinata*. Peachwood and Lima-wood are probably mere varieties, and the colouring matter from all three is supposed to be identical. These red-woods, as they are called, are chiefly used for cheap calico prints, and to some extent for dyeing silk.

Archil (q.v.) and *Cudbear* (q.v.) are dyes prepared from lichens. The colouring principle in each appears to be the same, and in fact there is no essential difference between the two stuffs. Archil is of a purple colour, and is most useful, along with other colouring matters, in the dyeing of wool various shades of brown and chocolate.

Panama Crimson.—This dye is used by the natives of the Isthmus of Panama for dyeing their straw-hats a fine crimson tint, which is said to withstand in a remarkable manner the action of sun and rain. It is obtained from a vine, but is scarcely known in commerce.

Chrysammic acid is a dye obtained by treating Aloes (q.v.) with nitric acid. From it a purple can be obtained on silk, black on wool, and pink on linen. It can be used with advantage along with aniline dyes.

Barwood and *Camwood* (q.v.), which are produced by the same tree, are employed in the ground state along with proper mordants for dyeing wool quiet reds and reddish browns; also for producing an imitation of Turkey-red on cotton. On wool the colours are permanent, but the dye on cotton is less so.

Quercitron.—From the bark of *Quercus tinctoria* a useful yellow dye is obtained. An extract of this bark called 'flavine' is used by woollen-dyers. Quercitron bark is most largely used as the yellow part in compound colours.

Fustic (q.v.).—There are two dyestuffs called by this name; the one is 'young fustic,' and the other 'old fustic.' The latter is the produce of *Morus tinctoria*, a large tree growing in Central America, and is the more important. The wood of this tree is ground, or an extract of it is made, and used like quercitron bark in the dyeing of compound colours on wool and cotton, for which it furnishes the yellow part.

Persian Berries, the fruit of *Rhamnus infectorius*, and perhaps other species. They are known also as Yellow Berries, French Berries, and Turkish Berries. The fruit is not much larger than a pea. The dye is employed for wool, but most largely in the printing of calico as the yellow part in such colours as green or orange. A decoction of the berries is made. The colour obtained is bright, but not very permanent.

Turmeric, the root of *Curcuma longa*, a plant largely cultivated in South Asia. It is rich in yellow colouring matter, which is, however, very fugitive. It is one of the few dyes which will fix itself on vegetable fibre without the help of mordants. Turmeric is largely used for colouring test-paper for chemical purposes, but its use as dye for textiles is falling off.

Annatto or *Arnotto* (q.v.), a preparation from the seeds of *Bixa orellana*. It produces a buff colour upon cotton, and a flesh colour upon silk, no mordants being required. The colours obtained from this dye are fugitive. The chief use of it is to improve the appearance of other dyed colours.

Indigo (q.v.) is obtained from two or three species of Indigofera, chiefly *I. tinctoria*. The indigo-plant is found wild over most parts of India, but generally near places where it has been cultivated. In that country the plant is extensively grown, there being two sowings in the year. It is cut just as the flowers begin to appear. The process of extracting the dye consists in steeping the plant for twelve hours, or rather more, in a vat with water, after which it is transferred to another vat where men agitate the liquid with sticks, thereby effecting the oxidation of the green colouring matter into blue particles of indigotin, which settle down as a sediment. This is next boiled for five hours and repeatedly passed through a strainer, by which the dye-particles are separated. After drying, the dye is pressed into slabs 3½ inches thick, from which the cubes of commerce are cut. For other plants from which indigo can be obtained, see INDIGO. This dye is one of the oldest known, and is still largely used for the dyeing of wool and cotton.

Woad.—This is believed to be the blue dye with which the ancient Britons stained or coloured their skins. It is obtained from the leaves of the cruciferous plant *Isatis tinctoria*, which has been long cultivated in Great Britain. In England woad is still used along with indigo in the dyeing of wool, but it is no longer employed in France or Germany.

Logwood (q.v.).—This well-known dyestuff consists of the heart-wood of *Hæmatoxylon campechianum*, a tree indigenous to Central America. Applied in small quantity to textile materials, the colour which logwood gives to them is a fugitive blue. At some places on the Continent it is used along with a mordant containing a large proportion of alum to dye wool a blue colour. It is employed to some extent as the blue part of compound colours in the dyeing of cotton, but the chief use of logwood is in the production of different shades of black on cotton and wool, for which suitable mordants are necessary. This dye stands best when applied in large quantities for dark colours.

The following vegetable dyes are of some importance in India, a few of them being also used in Europe: Sappan-wood (*Cæsalpinia Sappan*) yields a red colour; Sanders-wood (*Pterocarpus santalinus*), a pink; Catechu (q.v.) (an extract of *Acacia Catechu*), browns, drabs, and grays; the roots of *Morinda citrifolia*, a useful red; the twigs of *Strobilanthes flaccidifolius*, Assam indigo; the fruit-rind of the pomegranate (*Punica granatum*), a yellow; and the powder called 'kamala,' from the fruit of *Mallotus philippinensis* (otherwise called *Rottlera tinctoria*).

Several plants, either indigenous or naturalised, in Great Britain yield dyes. Among others, weld, the stalks of *Reseda luteola*, was used for dyeing yellow up to recent times. Dyer's Broom (*Genista tinctoria*) also yields a yellow colouring matter. From *Rhamnus catharticus* and *R. frangula* green and yellow dyes are obtained. The cultivation of the common yellow bedstraw (*Galium verum*) for red and yellow dyestuffs was at one time attempted.

The following are the chief dyes derived from animal substances:

Cochineal (q.v.), obtained from the insect *Coccus cacti*, is the most important red colouring matter for animal fibres. See above.

Kermes.—A colouring matter which, though not obtained from the same insect, is identical with cochineal. Several species of Coccus, of which the most common is *C. ilicis*, yield kermes. This dyestuff is chiefly employed for dyeing woollens and leather in the countries of which the insect is a native—viz. Spain, Turkey, Morocco, and the south of France.

Lac-dye.—In the washing of stick-lac (see LAC), the colouring matter secreted by the lac insect (*Coccus lacca*) is dissolved in the water, and recovered by boiling down the washings. The red dye is then made up in the form of small cakes. Lac-dye usually produces duller red colours than cochineal, but from a pure extract of it the same, or very similar, colours are obtained. It is still used as a dye in India, but very little now in Europe.

Murexide.—This beautiful and delicate purple dye, prepared by the action of dilute nitric acid upon uric acid and treatment of the product with ammonia, was largely used in 1855 and 1856 for dyeing wool and silk, and for printing upon calico. The uric acid required for its production was got from guano. Murexide had only been tried for a year or two when its manufacture was rendered unprofitable by the introduction of aniline colours.

The only mineral dyes of much importance are *Prussian Blue* and *Chrome Yellow* (q.v.). The method of producing the former is given under DYEING.

Coal-tar Colours.—The dyes now manufactured from products obtained in the distillation of coal-tar are extremely numerous, and new ones are daily added to the list. With the exception of anthracene, from which artificial alizarin is prepared, the raw materials chiefly used are the naphtha or benzene and carbolic acid; naphthalene, a crystalline solid body, has lately been coming much into use as well, more especially for dyes competing with cochineal. These substances, although not constituting a large percentage of the tar, are more than sufficient in amount for any supply that could be required, the quantity of tar from the gas-works in Great Britain alone being nearly half a million tons per annum. The total annual value of these colours produced in England, Germany, and France is about £4,000,000.

The rapid development of this industry is the result of the progress of organic chemistry, and these dyes can only be understood and classified from a chemical point of view. Leaving out artificial alizarin and indigo at present, these colours may be arranged in three divisions: (1) *Aniline Dyes.*—These are compound amines, bodies of the nature of bases. (2) *Phenol Dyes.*—These are derivatives of carbolic acid or phenol and similar chemical bodies, and have more or less acid properties. (3) *Azo Dyes.*—These are bodies containing azote or nitrogen connecting two groups, and may be neutral, but the groups may also be either of a basic or acid nature.

1. *Aniline Dyes.*—The preparation and properties of aniline have been described under that head. A base of the same series, toluidine, and another from naphthalene, are used along with it for certain colours. The method of preparation for all these bodies is nearly alike—viz. by the action of nascent hydrogen on the requisite nitro-compound and distillation of the product with soda. Iron filings and hydrochloric acid are generally taken to obtain the hydrogen.

When a mixture of aniline and toluidine is heated with arsenic acid for several hours to a temperature of about 380° F., a mass is left from which rosaniline is separated, the compounds of which chiefly form the aniline dyes. Stannic chloride can be used in place of arsenic acid, but the latter gives better results; careful attention is required in the separation of arsenic from the dyes. The residue after cooling is powdered and treated with boiling water, which dissolves arseniate and arsenite of rosaniline, and leaves a residue containing other colouring matters. When the solution has common salt mixed with it, double decomposition takes place, and the arsenical salts remain in solution, while rosaniline as hydrochloride is precipitated. This substance is not insoluble in water, but in water containing salt it is precipitated or 'salted out.'

The mixture of bases treated, called 'aniline oil,' combine with oxygen from the arsenic acid, which removes hydrogen in the form of water, the residues coalescing into the more complex molecule of the colouring matter. Another process—the one now chiefly used—for the preparation of rosaniline is heating aniline with nitrobenzine, protochloride of iron, and iron filings; in this case the oxygen is derived from the nitrobenzene. The residue is treated as in the previous process. The product is purified by crystallisation from water, and the hydrochloride of rosaniline so obtained is the colour magenta.

Rosaniline itself is colourless, and crystallises in needles or plates. It separates from magenta on adding soda to its solution, not being very soluble in water; it dissolves more readily in alcohol. It forms salts with acids, and these are the aniline red dyes. Magenta, or fuchsine, is chiefly hydrochloride, roseine the acetate, azaleine the nitrate, but pure simple salts are not usually sold. The salts have usually a green metallic lustre, and red in thin plates by transmitted light. The solutions have an intense crimson colour, and are not fluorescent.

Rosaniline is accompanied, as usually manufactured, by an almost similar substance—pararosaniline. The difference is that of homologues of the same series, and as pararosaniline is the lower, we shall use it in the following comparative formulæ, showing the replacements producing the various colours.

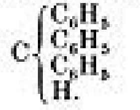
Methane (marsh-gas), CH_4, is the simplest of a series of hydrocarbons, and contains 1 atom of carbon and 4 of hydrogen. The hydrogen atoms may be replaced one after another by various elements or compound groups. In chloroform 3 are replaced by chlorine, giving the formula $CHCl_3$; and if this body, under certain conditions, acts on benzene, C_6H_6, we get hydrochloric acid and a hydrocarbon named tri-phenyl-methane.

$$CHCl_3 + 3C_6H_6 = C(C_6H_5)_3H + 3HCl.$$

The substitution products, or their compounds, derived from this hydrocarbon are the various aniline dyes.

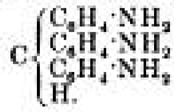
By treating tri-phenyl-methane in the same manner as benzene is treated to get aniline, we get a tri-amido base termed paraleucaniline. By the addition of an atom of oxygen to this body we get pararosaniline, which by solution in acids, as already stated, forms the aniline reds. The following are the respective formulæ:

Tri-phenyl-methane.



$$C\left\{\begin{array}{l}C_6H_5\\C_6H_5\\C_6H_5\\H.\end{array}\right.$$

Paraleucaniline.

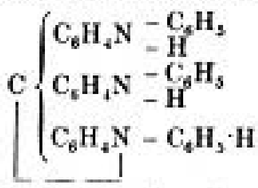


$$C\left\{\begin{array}{l}C_6H_4\cdot NH_2\\C_6H_4\cdot NH_2\\C_6H_4\cdot NH_2\\H.\end{array}\right.$$

Pararosaniline.

$$C\left\{\begin{array}{l}C_6H_4\cdot NH_2\\C_6H_4\cdot NH_2\\C_6H_4\cdot NH_2\\OH.\end{array}\right.$$

Aniline Blue.—When the hydrogen atoms in the amido groups (NH_2) become replaced in pararosaniline by phenyl, C_6H_5, methyl, CH_3, ethyl, C_2H_5, or similar groups, the aniline blue colours are produced. The ordinary spirit soluble blue has an atom in each of the amido groups replaced by phenyl, and is the hydrochloride of triphenylated pararosaniline, and has the following formula:



$$C\left\{\begin{array}{l}C_6H_4N\begin{matrix}-C_6H_5\\-H\end{matrix}\\C_6H_4N\begin{matrix}-C_6H_5\\-H\end{matrix}\\C_6H_4N-C_6H_5\cdot HCl.\end{array}\right.$$

This blue is obtained by heating rosaniline to a high temperature with a large excess of aniline along with some benzoic acid—the action of which is not understood. Ammonia is formed during the operation, and escapes along with the excess of aniline, which is distilled off. When the action ceases, the product is cooled, and excess of hydrochloric acid added, which forms an insoluble compound of the base, giving, when washed and dried, the spirit blue.

It will be seen by the formula that there are still two free atoms of hydrogen in the amido groups. These can be substituted by methyl or ethyl, and blues of a purer shade obtained. All the varieties are only soluble in spirit, and to a small extent; they give very pure blue colours.

Soluble Blue.—The spirit blue, so called from being insoluble in water, is to a large extent converted into a compound soluble in water, termed 'soluble blue,' thereby giving it a much wider range in its application. The compound is a sulphonic acid salt, and is prepared in the usual manner by mixing with sulphuric acid, gently warming, and after a time pouring the mixture into cold water, in which the free acid is insoluble. After washing, it is cautiously dissolved in soda solution, and salted out. It is then dried gently, forming a brownish cake. It dissolves readily in water. This is monosulphonate of the dye, and called alkali blue.

Water Blue or *Cotton Blue* is a trisulphonate, and is prepared by longer heating at a temperature a little over 212° F. The excess of sulphuric acid used is separated from the solution by milk of lime, this sulphonic acid being soluble in water. It is converted into a soda or ammonia salt.

Methyl Violet.—If five of the amido-hydrogen atoms in rosaniline are substituted by methyl, this colour is produced. The methyl groups are substituted in the aniline, and the process of oxidation is then nearly the same as in the preparation of magenta. Pure di-methyl-aniline is treated with chloride of copper, and some common salt is used to moderate the action. After the mass is cold it is carefully treated with water, to form a strong solution of the salt, in which the colour is insoluble. After the salt is carefully drained off, the colour is dissolved in water and any copper removed by sulphuretted hydrogen. The salt or form in which this colour is sold is often a double chloride of the colour base with chloride of zinc, which is crystalline. The double zinc salts are frequently used for a similar purpose, as they crystallise readily, giving the product a definite form and appearance, and the oxide of zinc is readily soluble in acids and in caustic alkalies, and having no colour does not interfere with the dyes.

Benzyl-rosaniline Violet.—The methyl groups in the violet described can be replaced by heating the colour with the chloride of benzyl, a body prepared with toluidine, the benzyl group, C_7H_7, producing a bluer colour.

Malachite Green.—This is a colour belonging to a class having only two amido groups in tri-phenyl-methane. The formula will best illustrate its structure. That of brilliant green is also given.

Malachite Green.

$$C\left\{\begin{array}{l}C_6H_5\\C_6H_4\cdot N(CH_3)_2\\C_6H_4\cdot N(CH_3)_2\\OH.\end{array}\right.$$

Brilliant Green.

$$C\left\{\begin{array}{l}C_6H_5\\C_6H_4\cdot N(C_2H_5)_2\\C_6H_4\cdot N(C_2H_5)_2\\OH.\end{array}\right.$$

In malachite green 4 hydrogen atoms are replaced in the amido groups by methyl, and in brilliant green by ethyl. These colours are chiefly sold as zinc double salts or oxalates. They generally have a rich metallic lustre, and are readily soluble in water.

Helvetia green and others are sulphonic acid derivatives of these colouring matters.

2. *Phenol Dyes.*—When the hydrogen atoms of benzene are replaced by hydroxyl, OH, bodies of an acid or semi-acid kind are formed, called phenols. These are mono-acid, di-acid, &c., according to the number of hydrogen atoms substituted. This is seen in the following formulæ :

Benzene..C_6H_6 ;
Phenol, carbolic acid ....$C_6H_5(HO)$;
Resorcin, di-hydroxyl-benzene..$C_6H_4(HO)_2$;
Pyrogallic acid ....$C_6H_3(HO)_3$.

Naphthalene yields the most important bodies of this class, called naphthols. A general method for their preparation is to melt the sulphonic acid of the hydrocarbons with caustic soda, and add to the solution of the residue an excess of hydrochloric acid, which separates the phenol.

Some of the important yellow dyes are nitro compounds of these bodies. They are got by cautiously mixing the phenols with strong nitric acid, and generally finishing with the aid of heat. Practically better results are got by first forming the sulphonic acid.

Picric Acid is tri-nitro-phenol. Its formula is $C_6H_2(NO_2)_3OH$. It is sparingly soluble in water, to which it gives an intensely bitter taste, recognisable in fibres which have been dyed with it. It crystallises in thin yellow laminæ. The salts form fine crystals, and are more or less explosive.

Naphthol Yellow, Martius' Yellow.—This is dinitro-naphthol, and was the first colour of value made from naphthalene. It is insoluble in water, but gives fine yellow or orange coloured salts, crystalline and soluble in water. They closely resemble the picrates. A sulphonic acid of this yellow is also used as a dye.

Rosolic Acid, Aurin.—If tri-phenyl-methane contained phenol instead of amine groups, as in rosaniline; it would represent these dyes. In fact, the rosolic acids and rosanilines are convertible into each other. These dyes are now of little importance in practice.

Phthaleins.—These form a very important class of dye-yielding materials, and are formed by the union of phenols with the anhydride of phthalic acid. Phthalic anhydride is obtained from naphthalene by first forming a chlorine addition product, and then oxidising with nitric acid. Crude phthalic acid so obtained is converted into water and the anhydride of phthalic acid (which is volatile) by heating.

Gallein was the first discovered of these colours, and was produced by heating pyrogallic acid with the anhydride. It is chiefly made into cerulein.

Cerulein is obtained from gallein by heating with sulphuric acid to 400° F. till the colour changes to brownish-green, then, on cooling, mixing with a large quantity of cold water. The treatment has removed an atom of water. The cerulein forms a blackish powder. It is insoluble in water, but dissolves in alkalies with a beautiful green colour.

Fluorescein, Eosin.—This is the resorcin phthalein, and is prepared by heating the materials to 400° F. till water ceases to be given off. The mass remaining is fluorescein. From the remarkable fluorescence of its compounds it derives its name, and an alkaline solution of it is taken as a striking example of this phenomenon. It is slightly soluble in water, with a yellow colour, and in the dry state is a reddish crystalline powder.

Fluorescein itself is scarcely used as a dye. But when part of its hydrogen is substituted by bromine, chlorine, or iodine, the beautiful dyes called *eosins* are formed. The tetrabrominated eosin, or rather its potash salt, has been most largely used. It forms red crystals with yellowish-green reflections. The solutions are rose-coloured with intense green fluorescence. One of the most beautiful colours of this group is the replacement by 2 chlorine and 4 iodine atoms, called phloxine. Methyl and ethyl ethers of this body are also dyestuffs.

3. *Azo Dyes.*—The first section of the coal-tar colours consisted of aniline and similar bodies coalesced into more complex basic forms. The second of phenols, with substitutions yielding acid compounds. The third section, now to be considered, in its simplest form is neutral, but by reactions with amines (bases) or phenols (acids) can produce colouring bodies with the chemical properties of either of the other sections. This class is obtained by a reducing action on nitro compounds, leaving two residues in combination by the mutual affinity of the *nitrogen* atoms—hence the name, from azote (nitrogen). The construction will be understood from the following equation :

$$\overset{\text{Nitrobenzene.}}{2C_6H_5NO_2} + 4H_2 \quad = \quad 4H_2O + \overset{\text{Azobenzene.}}{C_6H_5\mathbf{NN}C_6H_5}.$$

We have here, it will be seen, simple phenyl groups combined with two nitrogen atoms, and from the absence of amido or hydroxyl groups, the substance is neither basic nor acid. If in place of nitrobenzene a nitro derivative of a different hydrocarbon had been taken, a corresponding azo compound would have been produced. The principal development of the coal-tar colours of late years has been connected with this reaction. It can be seen that by manipulating the hydrocarbon groups with amido and hydroxyl groups as with the bodies in the other sections of the colours, any number of azo dyes may be obtained.

Most of these dyes from benzene and the lower members of its series are yellow or brown, but when hydrocarbons with more carbon atoms are used, such as cymol and naphthalene, reds and blues are produced; some of the scarlets having almost displaced the colours from cochineal.

Bismark Brown, Phenylene Brown, &c.—This is an example of a colour with amido derivatives, and is selected as being the first of the azo colours having a manufacturing success. It is prepared by the action of nitrous acid on the di-amine of phenylene. The reaction is shown in the equation :

$$2C_6H_4(NH_2)_2 + HNO_2 = 2H_2O + \\ NH_2{\cdot}C_6H_4NNC_6H_3 2(NH_2).$$

These colours are very easily prepared; as a rule the colour precipitates when its components are brought together. Besides the dyeing of cotton and wool, this colour is much used for dyeing leather. It is used as the hydrochloride, a dark powder.

Fast Yellow is the potassium salt of a sulphonic acid. Its construction is seen by the formula :

$$KSO_3{\cdot}C_6H_4NNC_6H_4{\cdot}NH_2.$$

Oxyazo dyes are prepared with phenols, and have become the most important of the coal-tar colours. They are nearly all sulphonic acid compounds, and used in the form of soda salts of these acids. The yellow and orange colours are sold as Tropeolins; fast red, Roccellin; claret red, Bordeaux; scarlets, Biebrich, Croceïn, &c. An example may be given of the composition of one of these colours, first known as Meister's scarlet, now sold as scarlet G :

$$C_6H_3(CH_3)_2NNC_{10}H_4(OH)(HSO_3)_2.$$

This dye is the sulphonic acid itself, but usually an alkaline salt is employed in the dyeing process, as the acids are more or less insoluble. A compound of the acids with alkaline bisulphites has lately been used with some success.

The benzidine and allied colours recently introduced belong to the tetrazo group of the oxyazo dyes. These have the valuable property of dyeing cotton without a mordant. Almost any shade of blue, green, yellow, and red can be obtained from them. They stand scouring and milling, and are considered fast to light on wool; but some, at least, are not permanent on cotton. There exists a strong belief that the benzidine colours will be those most largely made from coal-tar products in the future since they are so simply applied. See PHENYL COMPOUNDS.

Anthracene Dyes.—These are only a small group, and are regarded rather as artificial productions of the natural colours of madder than coal-tar colours. Artificial alizarin is now, however, manufactured on a large scale, and has almost completely taken the place of the natural product. In England it was first made in 1870. In the manufacture of these dyes anthracene is first converted into anthraquinone by oxidation with solution containing chromic acid, and then into sulphonic acid, or rather sulphonic acids, for there are several formed. This requires fuming sulphuric acid, and a temperature of 320° F. The acids are converted into soda salts, and may be separated by crystallisation. Mono-acid produces blue, di-acids more of the red and orange colours.

The soda salts of the sulphonic acids are now mixed with a small proportion of chlorate of potash, and heated under pressure with caustic soda to 400° F. for twenty-four hours. Water is added in sufficient quantity to keep the soda liquid, and the mixture requires to be constantly stirred, or the materials would not come together. The mass obtained is ground and dissolved in water neutralised with hydrochloric acid, when the alizarin separates. It is filtered and pressed.

Alizarin as sold contains three colouring matters—alizarin, giving blue; anthrapurpurin, red; and flavopurpurin, orange shades. They may all be produced separately from the different sulphonic acids. Their properties as dyes are similar.

Dynamo-electric Machines are machines for generating electric currents by means of the relative movement of conductors and magnets. Faraday discovered in 1831 that an electric current is induced in a conductor when it is moved across the pole of a magnet, so that it cuts the lines of magnetic force, or (more generally) whenever the number of these lines which passes through the circuit of the conductor is in any way varied. If, for example, a coil of wire, the ends of which are connected so that the whole forms a closed circuit, be suddenly withdrawn from the pole of a magnet, a transient electric current is induced in it, while the lines of magnetic force which proceed from the pole are ceasing to be present within the coil. If the coil be replaced, a current will again be induced, but in the contrary direction. Similarly, a transient current is induced if the coil be held at rest while the magnet is drawn away; or, again, if the coil be turned round so that the direction of the lines of force through it becomes reversed, in which case the effect will be twice as great as before. Any movement which causes an alteration to take place in the amount of magnetic induction through the coil produces a transient current, the electromotive force of which is proportional to the rate at which this alteration takes place. The whole amount of electricity produced is the same whether the movement be fast or slow. When the movement is slow, the current lasts longer in proportion as its strength is less. To produce the movement requires an exertion of mechanical work, which finds its equivalent in the energy of the induced current.

Faraday's discovery was immediately followed by the invention of numerous forms of magneto-electric machines, as they were then called, in most of which a steel horseshoe magnet was made to rotate over a pair of coils wound on a fixed armature, or the armature and coils were made to rotate while the magnet was held fixed. Fig. 1 is an example of one of these early forms, in which the armature, BB, with the bobbins, C, D, which consist of coils wound upon iron cores fixed to the armature, revolves in front of the magnet poles, N, S. In every half-revolution the lines of magnetic force through the bobbins have their direction reversed, and a series of transient currents are consequently produced in the coils. These pass to the external part of the circuit through the spring brushes, H, K, which make contact with a revolving collector, consisting of insulated metallic rings on the axle, to which the ends, *m*, *n*, of the coils are attached. If *m* were always in contact with H, and *n* with K, it is obvious that each successive transient current would take the direction opposite to its predecessor—the direction of the current would alternate at every half-revolution. On the other hand, it is easy, by splitting the rings, to arrange the collector so that H is in contact with *m* for

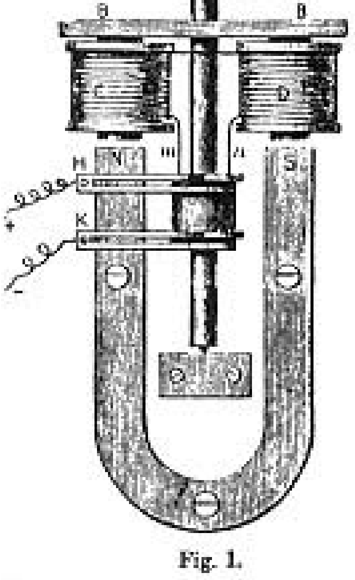


Fig. 1.

Fig. 2.

half a revolution, and then with *a* for the other half, while K is in contact first with *a*, and then with *a*, with the effect that the successive currents all have the same direction in the external portion of the circuit. The collector is then called a commutator. A common form of commutator is shown in fig. 2.

An ideally simple form of dynamo is represented diagrammatically in fig. 3, which represents a conductor consisting of a single loop of wire revolving in the magnetic field between the poles of a magnet, NS, so that at every half-revolution the lines of force have their direction of passing through the loop reversed, and a series of transient currents is consequently induced in the loop. Here, again, a commutator is required if the currents are to have one continuous direction in the external portion of the circuit. In the position sketched (by full lines), the side, *a*, of the rectangular loop is cutting the lines of force in one direction, and the side, *b*, is cutting them in the other, and both these movements are contributing to produce electromotive force in one direction round the loop; the other two sides (i.e. the front and the back) of the loop do not cut lines of force, and therefore do not contribute to the production of electromotive force. As the loop approaches the vertical position (shown by dotted lines), the component motion of the sides across the lines of magnetic force becomes reduced, and the electromotive force diminishes, till, at the vertical position, it disappears entirely, for there the sides of the loop are moving (at the instant) along the lines of force. After that they begin to cut the lines of force again, but in the reverse direction, and an electromotive force opposite to the last begins to act, which reaches its maximum when the coil is again horizontal. The same variations are repeated as the coil turns through the remaining half of its revolution. The strength of the current follows similar fluctuations, being determined by the electromotive force and by the resistance of the circuit, including the resistance of the revolving loop itself.

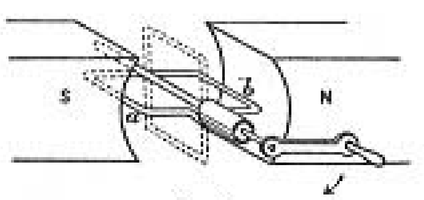

Fig. 3.

The effect of the revolving conductor in producing electromotive force may be increased (1) by increasing the speed of rotation; (2) by forming the loop with more than one turn of wire so as to make a coil, the whole effect is then the sum of the effects due to the individual turns; (3) by strengthening the magnetic field. One very important method of doing this is to furnish the revolving coil with an iron core, the effect of which is to increase the magnetic induction through the loop, across the space from pole to pole, by providing an easier path for the lines of magnetic force to cross this gap. In early dynamos the armature (as the revolving-piece is called) frequently consisted of a coil of many turns wound on an iron core, in the manner illustrated by fig. 4, which shows in section the simple shuttle-wound armature introduced by Siemens in 1856. The ends of the coil were brought to a commutator like that of fig. 2, and the effect was to produce currents which were uniform in direction. They were, however, very far from uniform in strength, varying from zero to a maximum twice in every revolution of the shaft.

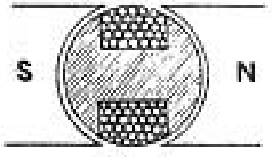

Fig. 4.

In the early dynamos permanent steel magnets were used to produce the field in which the armature moved, but it was soon recognised that electro-magnets might be employed instead, and in 1863 Mr Wilde introduced a machine with large electro-magnets, which were excited by a small auxiliary armature revolving between the poles of a permanent magnet. Before this it had been proposed in machines with permanent magnets to supplement the magnetism when the machine was in action, by having coils wound upon the magnets, and by allowing the current produced in the machine itself to pass through these coils. It was not till 1867, however, that it became known that steel magnets were wholly unnecessary, and that dynamos with electro-magnets might be made entirely self-exciting. Even when the cores of the electro-magnets are of soft iron, there is enough residual magnetism to initiate a feeble current; this develops more magnetism, which in its turn develops more current, and so the process goes on until full magnetisation is reached. The principle of self-excitation was enunciated independently, and almost simultaneously, by Wheatstone, Werner Siemens, and S. A. Varley; it is now made use of in all except the smallest machines. The term 'dynamo-electric' was at first applied to distinguish those machines which were self-exciting from 'magneto-electric' machines, which had permanent magnets to give the field; but this distinction is no longer maintained, and the name 'dynamo' is now used in the wider sense defined above.

An extremely important step in the development of the dynamo was taken in 1870 by Gramme, who introduced a form of armature which, for the first time, gave a current not merely continuous in direction, but also sensibly uniform in strength. The Gramme ring armature is shown diagrammatically in fig. 5. It consists of a ring-shaped iron core, revolving in the magnetic field, and having a series of coils, A, B, C, &c., wound upon it. These are joined to one another in a continuous series, and also to the insulated segments of a commutator, *a*, *b*, *c*, which revolves with the ring, and from which the current is taken by brushes, H, K. Consider now the action of the field in producing electromotive force in any one of the coils, such as A. Near the place in which it is sketched, the coil A is moving in a direction parallel, or nearly parallel, to the lines of force, and, therefore, is having little or no electromotive force induced in it. But by the time the ring has made half a revolution, the same coil will have the lines of force within it reversed. Between these two positions, therefore, there must have been a generation of electromotive force, and this will in fact be going on most actively half-way between the two places. The coil C is at present the most active contributor of electromotive force, but B and D, the coils lying in front of and behind it, are also contributing a share, and the whole electromotive force between A and E, so far as that side of the ring is concerned, will be the sum of the several effects due to all the coils from A to E. A little consideration will show that the same action is going on on the other side of the ring, so that if the brushes be applied at *a* and *e* they will take off to the external portion of the circuit a current, half of which is contributed by one side, and half by the other side of the ring, the two sides acting like two groups of battery cells arranged in parallel and of equal resistance and equal electromotive force. The whole electromotive force in the armature is the same as that produced by the coils on one side alone, but the internal resistance is halved by the division of the current between the two sides. In actual Gramme armatures, the number of coils on the ring is very much greater than the number shown in the sketch, and each brush is made wide enough where it presses on the commutator to touch two of the segments at once. Hence the current is never interrupted, and the fluctuations in its strength, which occur as one segment passes out of contact and another comes in, may be made almost indefinitely small. As each coil passes, it is for the instant short-circuited through the brush, and this would give rise to a waste of energy in the coil and to sparking at the brushes, were it not that the brushes are set to bear on the commutator at the points where the development of electromotive force in the corresponding pair of coils is a minimum. These neutral points, as they are called, are not exactly midway between S and N, but are in advance of that position in consequence of the magnetic field within the ring being distorted through the action of the currents in the armature coils. Hence the brushes require to have what is called 'lead,' and this lead has in general to be adjusted whenever the output of the machine is considerably varied, more lead being needed if it happen that the armature current is increased while the field magnets remain of constant, or nearly constant, strength. The adjustment of the brushes is a matter of much practical importance in the management of a dynamo, for the sparking to which faulty adjustment gives rise speedily wears away the commutator bars as well as the brushes themselves.

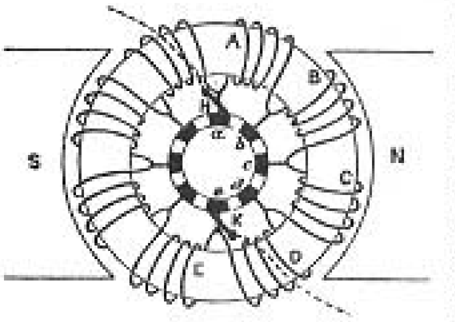

Fig. 5.

A small practical Gramme dynamo of an early form is shown in fig. 6. In this example two field-magnets conspire to produce a north pole at N, and other two to produce a south pole at S. The commutator is a series of copper bars mounted on an insulating hub fixed to the shaft, and separated from one another by thin stripes of mica or other insulating material; these bars have radial projections, which are soldered to the junctions of successive armature coils. Each brush consists of a flat bundle of copper wires pressed lightly against the commutator by a spring. The core of the armature is a ring made up of many turns of soft iron wire, on which insulated copper wire is wound to form the coils. It is essential that the core of the armature should not be solid, for in that case currents would be developed in the substance of the moving iron itself to such an extent as very seriously to impair the efficiency of the machine. Hence the core of dynamo armatures is always subdivided, by being made up either of wire, or more usually of thin plates more or less carefully insulated from one another. Fig. 7 shows the armature of a small Gramme dynamo, removed from its place between the pole-pieces.

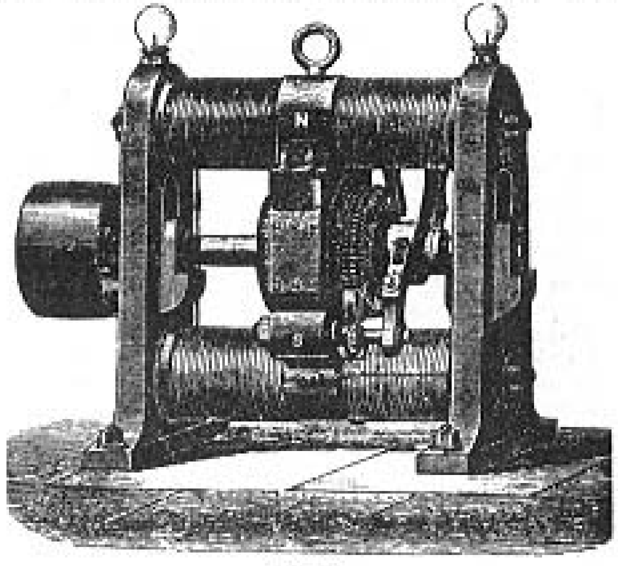

Fig. 6.

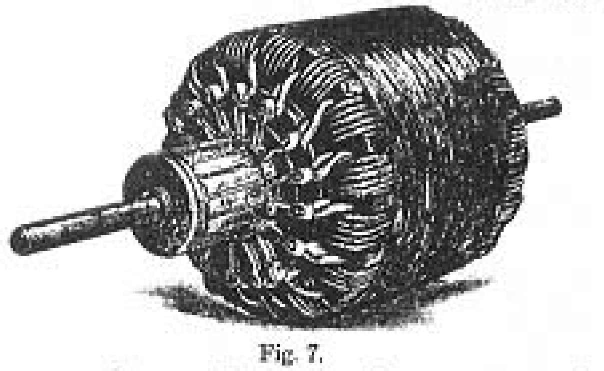

Fig. 7.

Two years after the introduction of the ring armature by Gramme, it was shown by Von Hefner Alteneck that the Siemens armature (fig. 4) might be modified so that it also should give continuous currents of practically constant strength. In the original Siemens armature there was but one coil, all wound parallel to one plane, and the current fluctuated from nothing to a maximum in every half-revolution. In the modified form the coil is divided into many parts, which are wound over the same core, but in a series of different planes, the plane of each successive coil being a little inclined to the plane of the coil before it. The coils are all joined in series, and their junctions are connected to the bars of a commutator just as in the Gramme ring. The Siemens-Alteneck or drum armature may, in fact, be compared to a Gramme armature, in which the coils, instead of being wound on successive portions of a ring, are all wound on one piece of core, preserving, however, the angular position they would have in the ring. Their action depends on their angular motion, and is therefore the same in both cases. As the drum revolves, that coil which is passing the neutral plane (viz. the plane perpendicular to the lines of force) is for the moment inoperative, and the brushes are set to touch those bars of the commutator that are connected with it. The other coils are more or less operative, the most active contributor of electromotive force being that one which is for the moment perpendicular to the neutral plane. The electrical effects in drum and in ring armatures are the same. Nearly all continuous current dynamos have one or the other; most makers prefer the ring type, mainly from considerations of convenience in construction; but the drum type holds its place in some of the best modern machines.

An important element in the classification of dynamos is the manner in which magnetism is induced in the field-magnets. These may of course be excited from an independent source of electricity; but when the machine is self-exciting, there are three important alternative methods. In the early machines the coils on the field-magnets were connected in series with the external part of the circuit, and consequently the whole current produced by the machine passed through both. This arrangement is distinguished as *series winding*, and is shown diagrammatically in fig. 8. It was first pointed out by Wheatstone, in 1867, that the magnet coils, instead of being put in series with the external conductor, might be arranged as a shunt to it, thereby forming an alternative path through which a portion only of the current would pass. In this arrangement, which is called *shunt winding* (fig. 9), the magnet coils consist of many turns of comparatively fine wire, so that they may not divert an excessive quantity of current from the external circuit. Finally, in *compound winding* (fig. 10) the two previous methods are combined. The field-magnets are wound with two coils; one of these (which is short and thick) is connected in series with the external circuit, and the other (which is long and fine) is connected as a shunt to it. This plan appears to have been first used by Varley in 1876, and afterwards by Brush, who pointed out that it, along with simple shunt winding, has the advantage of maintaining the magnetic field even when the external circuit is interrupted. It has, however, when properly applied, another and more important merit, as will appear below.

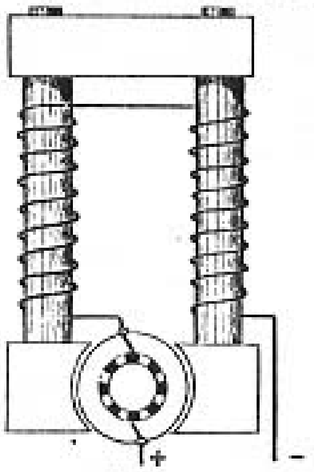

Fig. 8.

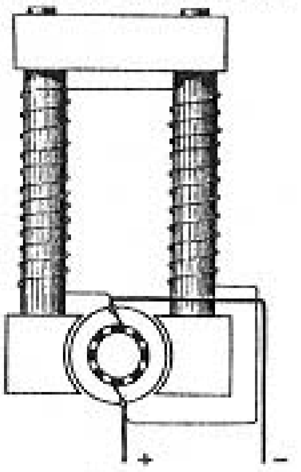

Fig. 9.

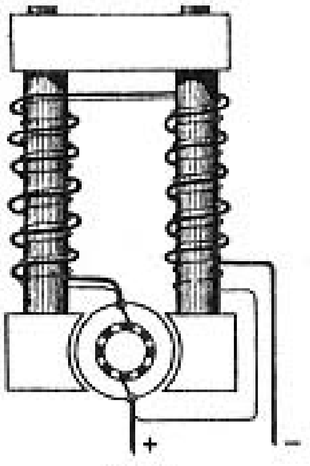

Fig. 10.

In a series-wound dynamo the magnets do not become excited if the external circuit is open, and become only feebly excited when the external resistance is high. Let the external resistance be reduced, while the armature is forced to turn at the same speed. The current will now increase, producing a stronger magnetic field; the electromotive force is therefore greater than before. A curve drawn to show the relation between the current and the difference of potential between the terminals of the machine (which is a little short of the full electromotive force, in consequence of the resistance of that part of the circuit which is within the machine itself) will in its early portion rise fast as the current increases, in consequence of the rapid augmentation of the magnetic field. Such a curve is called the characteristic curve of the machine, and is shown at AA in fig. 11.

If we continue to increase the current by further reducing the external resistance, the magnets tend to become saturated, and finally even have their magnetism somewhat weakened on account of the influence of the currents in the armature coils. Further, the loss of potential, through internal resistance, becomes more considerable. The difference of potential between the terminals accordingly passes a maximum, and becomes considerably reduced when the current is much augmented, as appears in fig. 11. The characteristic curve for a shunt-wound dynamo is shown at BB in the same figure. Here the strength of the magnetic field is nearly constant, but decreases a little when the machine is giving much current, partly because the current in the shunt circuit is then somewhat reduced, and partly because the current in the armature coils tends to oppose the magnetisation. Hence the potential falls off as the current increases. This fall will, however, be slight if the resistance of the armature is very low and if the field-magnets are very strong, and under these conditions a shunt-wound dynamo will give a nearly constant difference of potential whether much or little current be taken from it, provided, of course, that the speed remain unchanged. To make the difference of potential more exactly constant, it is necessary that the magnetic field should become stronger when the machine is giving much current, and compound winding achieves this. A compound-wound dynamo may be regarded as a shunt machine in which the action of the shunt winding is supplemented by that of a series coil on the magnets. When the machine is running on open circuit, the shunt coil alone is operative; as the current taken from the machine is increased, the series coil produces a larger and larger supplementary effect on the magnets, and by choosing a proper number of series windings, their effect may be made to neutralise with great exactness the droop in the characteristic curve which would occur if the shunt coil were the only source of magnetism.

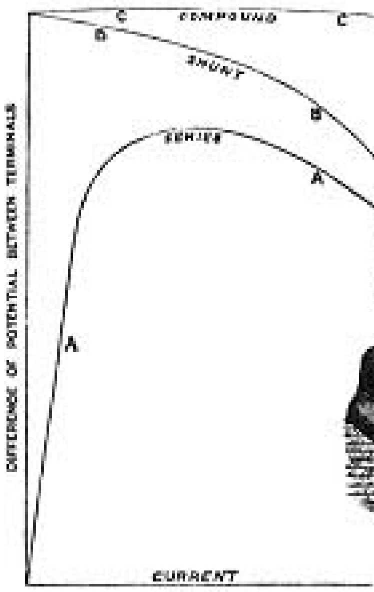

Fig. 11.

Compound machines wound for constant potential give a nearly straight horizontal line for their characteristic; CC in fig. 11 is an actual example. By making the series coil more influential, so that the potential at the terminals rises slightly as the current increases, the machine may be compound-wound to give constant potential at the ends of long leading-wires by which the current is conducted to a distance.

Series-wound dynamos are largely employed for electric lighting by arc lamps. Compound-wound machines are especially suitable for incandescent lighting, where the lamps are connected in parallel, and where it is important that the potential shall not vary when more or fewer lamps are in action. Shunt-wound machines are also largely used for incandescent lighting, the potential being adjusted to a constant value by varying the speed of the machine, or by throwing resistance into or out of the magnet shunt circuit. Shunt machines are the most suitable for charging storage batteries and for electro-plating, because of their not being liable to have their polarity reversed by a back current from the battery or bath.

Fig. 12 illustrates the Edison-Hopkinson dynamo, which may be cited as an excellent instance of modern construction. Here a drum armature is used, not a ring: and in this instance the armature coils, instead of being of wire as they are in smaller machines, are formed of copper bars insulated with mica, each pair of opposite bars being joined to form a loop, the ends of which are connected to opposite segments of the commutator, as well as to the loops which come next in order. The field-magnets are shunt-wound, and are set vertically with the pole-pieces at the bottom. Machines of this class are made of sufficient size to give a current of 660 ampères, with a potential of 105 volts: the output of electrical energy is therefore at the rate of 69,300 watts, or over 92 horse-power. There are five brushes on either side of the commutator, giving a large area of contact, and these are separately removable to allow of their being trimmed or cleaned while the machine is running.

In most dynamos the field-magnets are designed to form as simple a magnetic circuit as possible, with two poles which stand at opposite ends of one diameter of the commutator. In some cases four or more poles are used, spaced at equal intervals round the armature, which then takes more or less the form of a disc, in which the similarly affected coils may be connected together, so that a single pair of brushes still serves to take off the current. In some cases the coils are connected to commutators of special design, which have the effect that each coil is entirely cut out of circuit for a time, during that part of its movement in which there is little or no electromotive force induced in it. The Brush dynamo, which took a prominent place in the early industrial development of electric lighting, and the Thomson-Houston dynamo, are instances in point.

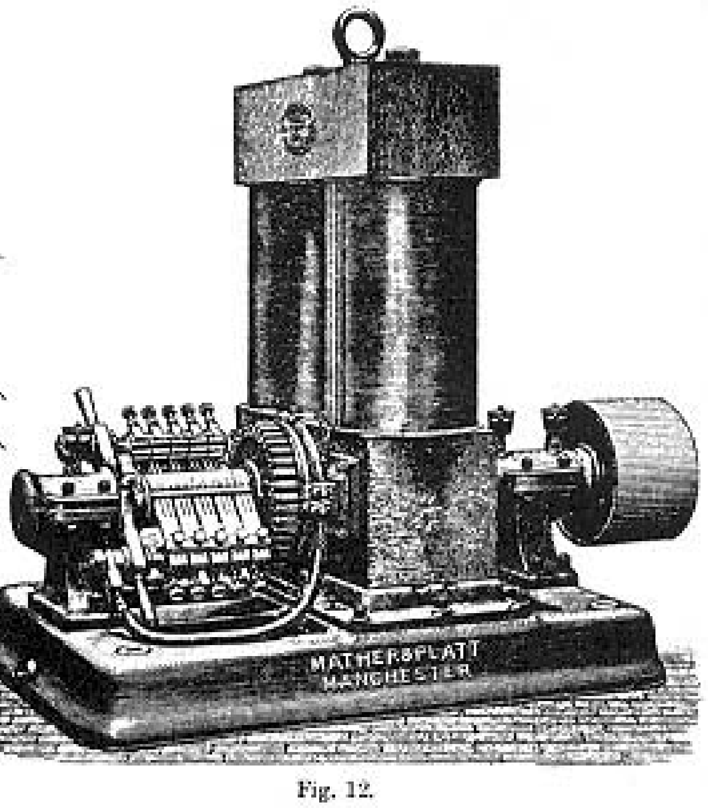

Fig. 12.

In *alternate current dynamos* the armature consists usually of a group of coils, joined in parallel or series, attached to a disc which revolves in the space between a corresponding group of pairs of magnet-poles, so that rapidly alternating transient currents are induced as the coils pass the successive poles, and these currents pass to the external circuit through a simple collector which is not a commutator. In some cases the armature is stationary, and the field-magnets revolve. The field is usually excited by an auxiliary dynamo of the continuous current type. It is impossible in the space at our disposal to describe the great variety of forms which alternate current machines have taken in the hands of Siemens, Gordon, Ferranti, Westinghouse, Mordey, and others. Dynamos of this class are now acquiring a special importance from their use in connection with transformers in Electric Lighting (q.v.), and are being made for this purpose of very great size and power. In alternate current dynamos, the relation between the strength of the current and electromotive force induced in the moving coils depends not merely on the resistance of the circuit, but also on its coefficient of self-induction, which has the effect of making the maximum of strength in each transient current lag behind the maximum of electromotive force. It has been shown experimentally and theoretically, by Adams and Hopkinson, that in consequence of self-induction two similar alternate current machines driven independently, but started at the same speed, and connected in parallel, will control one another, so that the phases of the currents will continue to agree.

Dynamos, of whatever type, may be regarded as machines for converting energy from a mechanical into an electrical form, and from this point of view a matter of prime importance is what is called the efficiency of the machine, which is the ratio of the electrical power the dynamo gives off, available for use outside the machine, to the power used to drive the machine. The electrical energy given off falls short of the mechanical energy absorbed, in consequence of (1) mechanical friction; (2) the generation of eddy currents, to be prevented as much as possible by laminating the iron core of the armature; (3) magnetic friction or 'hysteresis,' by which every reversal of magnetism in the iron causes dissipation of energy, apart from the production of eddy currents; (4) the energy consumed in maintaining the magnetic field; and (5) the heating of the armature in consequence of the resistance of its own coils. The aggregate effect of these sources of loss is that in a good machine about 90 per cent. of the driving power is available as electric energy in the external circuit. Dr Hopkinson has shown by careful measurements that machines of the type illustrated in fig. 12 may attain an efficiency of over 93 per cent.

The Dynamo as a Motor.—Just as a conductor when made to move across the lines of magnetic force has a current generated in it, so when a current is made to pass along a conductor placed in a magnetic field, the conductor tends to move across the field in the direction which would reduce the current by inducing an opposing electromotive force. Even before Faraday's discovery of the induction of current in a conductor by its movement in a magnetic field, he had shown (in 1821) that the reverse process was possible, and soon afterwards various forms of magneto-electric engines were devised by Barlow and Sturgeon, and later by Ritchie, Henry, Dal Negro, Joule, and others, which employed electric currents to do mechanical work on a small scale. In 1838 Jacobi constructed an electric motor of sufficient power to propel a small boat, using a group of electro-magnets, which revolved on a disc between opposite groups of other electro-magnets, which were fixed. Some time before the application of the ring-armature to dynamos by Gramme, it had been used in a motor by Pacinotti, and the principle had been explicitly stated that any electric motor might be used to produce currents, but it was not until Gramme's time that the full significance of this principle was generally recognised. The action of the dynamo is in fact reversible; the same machine which converts mechanical into electrical energy will serve the opposite function equally well. Power may therefore be conveyed to any distance by using a dynamo to produce currents, conducting these to the distant spot, and utilising them there to produce mechanical effect by means of another dynamo acting as a motor. The second dynamo may be a counterpart of the first; in some cases, however, it may be desirable, for the sake of lightness or for other special reasons, to adopt a different construction in the motor. In general, however, the most efficient generator is also the most efficient motor. The experiments of Hopkinson, in a case where some 50 horse-power was being transmitted in this way, show that the double conversion of energy from the mechanical to the electrical, and back again to the mechanical form, may be accomplished with a total loss of no more than 13 per cent.; the efficiency of the motor and that of the generator being each above 93 per cent.

Alternate current dynamos form fairly efficient motors when driven by alternate currents; they require, however, to be started in synchronism with the impulses received from the generating machine, but once started they tend to remain in synchronism. Special forms of motor for alternate currents have been designed by several inventors, but these have scarcely as yet passed the experimental stage.

Ear. The apparatus of hearing, as it exists in man and the mammalia, is composed of three parts—the external ear, the middle ear or tympanum, and the internal ear or labyrinth.

The *external ear* consists of two portions, the *auricle* or *pinna* (the part popularly recognised as the ear), and the *auditory canal* or *external meatus*.

In man, the auricle, on its outer or more exposed surface, presents various eminences and depressions, resulting from the form of its cartilaginous framework. These have received special anatomical names, to which it is unnecessary to advert further than to mention that the deep capacious central space to which several grooves converge is termed the *concha*, and that the lowest and pendulous portion of the ear is termed the *lobe*. The cartilage forming the basis of the external ear consists of one principal piece, in which there are several fissures, which are filled up by fibrous membrane. Several muscles are described as passing from one part of the auricle to another, but they are so little developed in man that they do not require notice; there are additionally three muscles—the *attollens aurem* (or *superior auris*), the *attrahens aurem* (or *anterior auris*), and the *retrahens aurem* (or *posterior auris*), which pass from adjacent parts of the scalp to the ear, and which, though more developed than the previous group, are of little or no real importance in man (at least in his civilised state), but are of considerable use in many mammals. Their actions are sufficiently indicated by their names.

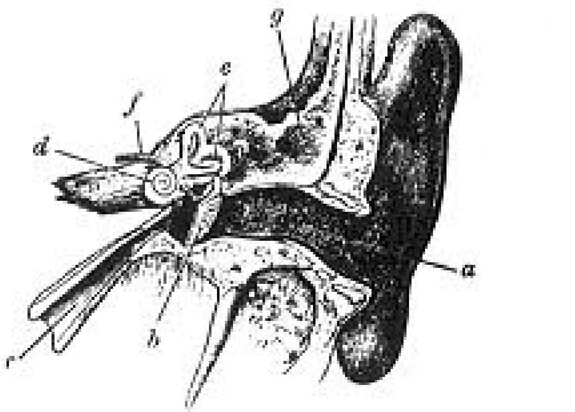

Fig. 1.—Sectional view of the external, middle, and internal Ear, showing the interior of the Auditory Canal, Tympanic Cavity, and Eustachian Tube:

a, the auditory canal; *b*, the tympanum; *c*, the Eustachian tube, leading to the pharynx; *d*, the cochlea; and *e*, the semicircular canals and vestibule, seen on their exterior by the removal of the surrounding bony tissue; *f*, auditory nerve; *g*, temporal bone.

The auditory canal passes from the concha inwards, and a little forwards, for rather more than an inch. It is narrower at the middle than at either extremity; and on this account there is often considerable difficulty in extracting foreign bodies that have been inserted into it. The membrane of the tympanum which terminates it is placed obliquely, in consequence of the lower surface of the meatus being longer than the upper. The canal is partly cartilaginous and partly osseous; the osseous portion consisting in the fœtus of a ring of bone, across which the membrane is stretched, and in many animals remaining persistently as a separate bone. The orifice of the meatus is concealed by a pointed process, which projects from the facial direction over it like a valve, and which is called the *tragus*, probably from being sometimes covered with bristly hair like that of a goat (*tragos*); and it is further defended by an abundance of ceruminous glands, which furnish an adhesive, yellow, and bitter secretion, the cerumen or wax, which entangles small insects, particles of dust, and other small foreign bodies, and prevents their further passage into the meatus.

The *middle ear*, or *cavity of the tympanum*, is a space filled with air which is received from the Pharynx (q.v.) through the Eustachian tube (see fig. 1, *b*, *c*), and traversed by a chain of very small movable bones (fig. 2), which connect the membrane of the tympanum with the internal ear. It lies, as its name implies, between the external meatus and the labyrinth or internal ear, and opens posteriorly into the cells contained in the mastoid portion of the temporal bone, and anteriorly into the Eustachian tube. The cavity is of an irregular shape, and is lined by a very delicate ciliated epithelium, which is a prolongation of that of the pharynx through the Eustachian tube.

Its external wall is in great part formed by the membrane of the tympanum, which is nearly oval, and placed in a direction slanting inwards, so as to form an angle of about 45 degrees with the floor of the auditory canal (see fig. 1). The handle of the malleus (or hammer), the first of the chain of ossicles (see fig. 2), is firmly attached to the inner side of this membrane in a vertical direction as far downwards as the centre, and by drawing it inwards, renders its external surface concave.

Its internal wall has two openings communicating with the internal ear, each of which is closed by a delicate membrane. These openings are termed, from their respective shapes, the *fenestra ovalis*, and the *fenestra rotunda*; the former leads to the vestibule, and is connected by its membrane with the base of the stapes (or stirrup-bone), the last of the chain of ossicles; while the latter opens into the cochlea.

The ossicles of the tympanum are three—viz. the *malleus*, the *incus* (or anvil), and the *stapes*. We have already explained how the malleus is connected with the membrane of the tympanum by means of its handle. Through this connection, the tension of that membrane may be modified by the agency of a muscle which is attached to this ossicle. This muscle is the *tensor tympani*, which arises from the under surface of the petrous portion of the temporal bone, and is inserted into the handle of the malleus immediately below the commencement of the *processus gracilis*. The mode in which the malleus articulates with the incus is sufficiently explained by the figure. The *incus* much more closely resembles a molar tooth with two fangs than the anvil from which it derives its name. Of the two processes which it gives off (see fig. 2), the short one, *sc*, runs backwards, and is attached to the posterior wall of the tympanum near the entrance to the mastoid cells; while the long one, *lc*, inclines downwards, and terminates in the lenticular or orbicular process, *a*, to which the head of the stapes is attached. The *stapes* is almost sufficiently described by the figure. It has a head, neck, two branches, and a base, which, as has been already mentioned, fits into the *fenestra ovalis*. A minute muscle, the *stapedius*, takes its origin from a hollow conical eminence termed the *pyramid*, which lies behind the *fenestra ovalis*, and is inserted into the neck of the stapes; its function is probably to act as an antagonist to the *tensor tympani*.

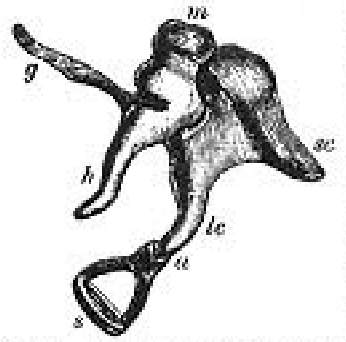

Fig. 2.—Ossicles of the left Ear, as seen from the outside and below:

m, head of the malleus; *g*, the slender process, or *processus gracilis*; *h*, the manubrium or handle; *sc*, the short crus, and *lc*, the long crus of the incus; *a*, the position of the lenticular process, through the medium of which it articulates with the head of the stapes; *s*, the base of the stapes. Magnified three diameters.

The Eustachian tube, into which the tympanic cavity opens anteriorly, is about an inch and a half in length, and passes downwards, forwards, and inwards to its opening in the pharynx. It is partly osseous, but chiefly cartilaginous. Its chief use is to allow the free passage of air in and out of the tympanum.

The *internal ear* or *labyrinth* is the essential part of the organ of hearing, being the portion to which the ultimate filaments of the auditory nerve (see BRAIN, NERVOUS SYSTEM) are distributed. It is composed of three parts—viz. the *vestibule*, the *semicircular canals*, and the *cochlea*, which form a series of cavities presenting a very complicated arrangement, and lying imbedded in the hardest part of the petrous portion of the temporal bone. They communicate externally with the tympanum by the two openings already described—the *fenestra ovalis*, and the *fenestra rotunda*; and internally with the internal auditory canal, which conveys the auditory nerve from the cranial cavity to the internal ear. The very dense bone immediately bounding these cavities is termed the *osseous labyrinth*, to distinguish it from the *membranous labyrinth*, which lies within a portion of it.

The *vestibule* is a common central cavity into which the semicircular canals and the cochlea open (see fig. 3, V). It is about a fifth of an inch in height and in length from before backwards, its transverse diameter (from side to side) being somewhat less. On its posterior wall are five orifices for the semicircular canals, one of the orifices being common to two of the canals. Anteriorly, the cochlea enters it by a single opening, partially divided by an osseous partition—the *lamina spiralis ossea*. On its outer wall is the *fenestra ovalis*, and on its inner are the *maculæ cribrosæ*, containing several minute orifices for the entrance of filaments of the auditory nerve.

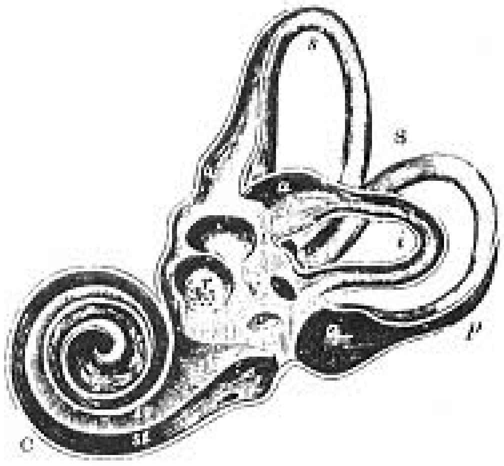

Fig. 3.—Interior of the Osseous Labyrinth:

V, vestibule; ar, aqueduct of the vestibule; r, maculæ cribrosæ; S, semicircular canals; s, superior; p, posterior; i, inferior; a, a, a, the ampullar extremity of each; C, the cochlea; sv, osseous zone of the lamina spiralis, above which is the scala vestibuli, communicating with the vestibule; st, scala tympani, below the spiral lamina. Magnified 3½ diameters.

The *semicircular canals* are three in number, and open into the vestibule by means of five orifices, the two vertical canals having at their non-ampullate extremities a common orifice. They vary in length, and notwithstanding their name, each is considerably more than a semicircle, the superior vertical canal being the longest. The average diameter is about a twentieth of an inch, one extremity of each canal exhibiting a dilatation or *ampulla*. Each canal lies in a different plane, very nearly at right angles to the planes of the other two, hence their names of the *superior vertical*, the *inferior vertical*, and the *horizontal* canals.

The *cochlea*, which derives its name from its resemblance to a common snail-shell, forms the anterior portion of the labyrinth. It consists of an osseous and gradually tapering canal, about an inch and a half in length, which makes two turns and a half spirally around a central axis, termed the *modiolus*, which is perforated at its base for the entrance of the filaments of the cochlear portion of the auditory nerve. This spiral canal gradually diminishes towards the apex of the cochlea. At its base it presents an opening into the vestibule, partially divided into two. In the recent state, one of these openings (*scala tympani*) does not communicate with the vestibule, but is closed by the membrane of the *fenestra rotunda*. Its interior is subdivided into two passages (*scalæ*) by an osseous lamina. This is the *lamina spiralis*, which incompletely divides the cochlea into an upper passage, the *scala vestibuli*, and a lower one, the *scala tympani*—i.e. the division is incomplete so far as the skeleton goes, but is completed during life by soft parts afterwards to be described. At the apex these two passages communicate by an opening to which the term *helicotrema* has been applied.

We now return to the *membranous labyrinth*. The membranous and osseous labyrinths have the same shape, but

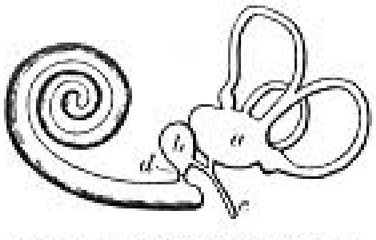

Fig. 4.—Scheme of Mammalian Labyrinth:

a, utricle; b, saccule; c, aquæductus vestibuli, dividing into two branches, going to saccule and utricle respectively; d, canalis or ductus reuniens.

the former is considerably smaller than the latter, a fluid, termed the *perilymph*, intervening in some quantity between them. At certain points recent investigations have shown that the membranous is firmly adherent to the inner surface of the osseous labyrinth. The vestibular portion consists of two sacs, an upper and larger one, of an oval shape, termed the *utriculus*, and a lower and smaller one, of a globular shape, called the *sacculus*. The membranous semicircular canals resemble in form and arrangement the osseous canals which inclose them, but are only one-third of the diameter of the latter.

It will be remembered that the osseous structure of the cochlea is that of a tube almost but not quite divided into two by the lamina spiralis ossea. The division is completed by the lamina spiralis membranacea (or basilar membrane). From near the junction of the osseous with the membranous lamina springs the membrane of Reissner, which, stretching across to the wall of the osseous cochlea, shuts off a third space known as the *ductus cochleæ*. The cochlear duct terminates blindly at both ends, but near its lower extremity is connected with the saccule through a delicate membranous channel known as the *ductus reuniens*. Upon the basilar membrane is situated the organ of Corti, which consists of the following parts (to name only those of most importance) from within outwards: (1) a single row of so-called inner hair-cells; (2) the two rods of Corti (known as inner and outer); (3) four or five rows of outer hair-cells. These are again protected by the curtain-like *membrana tectatoria*.

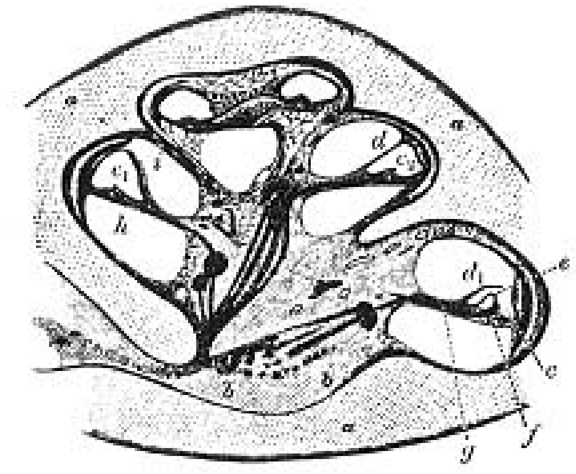

Fig. 5.—Section through the Cochlea of a Human Embryo:

a, a, a, cartilage, which afterwards ossifies; b, b, tissue, which afterwards becomes the modiolus; c-c_2, duct of the cochlea; d, d_1, membrane of Reissner; e, membrana tectatoria, rather elevated from its proper position; f, position afterwards occupied by organ of Corti; g, lamina spiralis; h, scala tympani; i, scala vestibuli.

The auditory nerve leaves the medulla oblongata together with the facial, and passing into the internal auditory meatus, divides into two branches, which pass respectively to the vestibule and the cochlea. The former ends in a peculiarly modified epithelium with projecting processes situated in the ampullæ of the semicircular canals and on certain spots within the saccule and utricle, known as the *maculæ acusticæ*. In the latter situation are also found small crystalline bodies, called otoliths, which are suspended around the maculæ: by exactly what means this suspension is effected is at present unknown. The cochlear branch of the auditory nerve probably terminates in the inner and outer hair-cells of the organ of Corti (see fig. 6). The saccule and utricle communicate with each other and with the interior of the skull through the *aquæductus vestibuli*, while the *aquæductus cochleæ* connects the perilymph of the scala tympani with the arachnoid space.

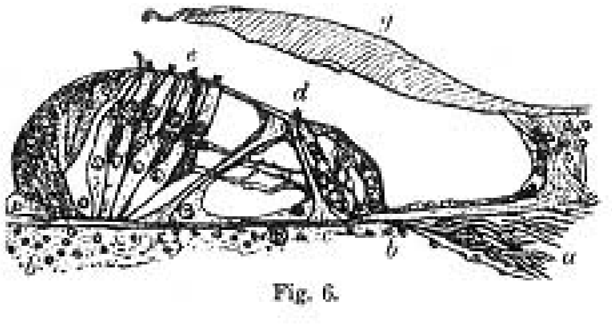

Fig. 6.

a, lamina spiralis ossea, with nerve bundles from cochlear nerve; b, b, lamina spiralis membranacea; c, inner rod or pillar of Corti; c_1, outer rod or pillar of Corti; d, inner hair-cell; e, outer hair-cells; f, nerve fibres; g, membrana tectatoria.

Physiology.—(1) *Of the External Ear.*—A true auricle only exists in the mammalia, and in this class it varies from little more than an irregularly shaped cartilaginous disc with little or no motion, as in man and the quadrumana, to an elongated funnel-shaped ear-trumpet movable in all directions by numerous large muscles, as in the horse, the ass, and the bat. The mode in which we see it employed by those animals in which it is highly developed sufficiently indicates that its main function is to collect and concentrate the sounds which fall upon it. But the experimental investigations of Savart, with an apparatus constructed to resemble the tympanic membrane and the external auditory apparatus, show that these parts are also adapted to enter into vibrations in unison with those of the air; and he suggested that the human auricle, by the various directions of different parts of its surface, could always present to the air a certain number of parts whose direction is at right angles with that of the molecular movement of the air, and therefore is the most favourable position for having the vibrations communicated.

(2) *Of the Tympanum and its Contents.*—Savart's experiments show that the membrane of the tympanum is thrown into vibration by the air, and that it always executes vibrations equal in number to those of the sonorous body which excites the oscillations in the air. He further ascertained that the malleus participates in the oscillations of the tympanic membrane, and that these vibrations are propagated to the incus and stapes, and thus to the membrane of the *fenestra ovalis*. The malleus has further the office of regulating, through the *tensor tympani* muscle, the tension of the tympanic membrane; and to allow of the motion necessary for this purpose, we find movable joints between it and the incus, and again between the latter bone and the stapes. The contraction of the stapedius muscle similarly modifies the tension of the membrane of the *fenestra ovalis*; and as compression or the reverse exercised on this membrane extends to the perilymph, and is propagated through it to the *fenestra rotunda*, the tension of the membrane of the latter opening is also influenced by the muscle in question. The incus is much more limited in its motions than either of the other bones, and its use seems to be to complete the chain of ossicles in such a manner as to prevent any sudden or violent tension of the membranes, such as we can easily conceive might occur if the conductor between the membranes were a single bone. The presence of air in the tympanic cavity serves a double purpose: in the first place, it preserves a uniform temperature on the outer surfaces of the fenestral membranes, and thus supports a fixed elasticity in them, which would not be the case if they were freely exposed to ordinary atmospheric changes; and secondly, the action of the chain of ossicles as conductors of sound is materially increased by their being completely surrounded by air, as is obvious from the first principles of acoustics; further, were it not for the presence of air within the tympanum, the drum membrane would be arched inwards, and the resulting displacement and change of tension would produce deafness.

(3) *Of the Labyrinth.*—Sonorous vibrations may be conducted to the labyrinth through the bones of the skull; but during the ordinary act of hearing, the movements of the tympanic membrane are propagated through the chain of ossicles and the labyrinth, and thus perceived by the auditory nerve. A considerable amount of mystery surrounds the functions of the saccule and utricle; indeed, on this subject so little is at present accurately known that no good purpose would be served by discussing it further. The view, until recently accepted, that these parts were concerned in the perception of sounds as distinguished from

tones (i.e. notes), has been rendered doubtful by recent researches.

The semicircular canals have been of late years made objects of study by many physiologists. It has now been conclusively demonstrated that they are intimately associated with the maintenance of the body in the erect position. Injury of a semicircular canal tends to produce rotatory movements of the body and eyes, and it has therefore been suggested that the functions of these organs may be connected with the reflex act of listening, as exemplified in the lower animals by pricking the ears and rotation of the head. From experiments on animals, and observations on the human subject in disease, it has now been proved that a lesion of the semicircular canals is followed by giddiness or vertigo, which manifests itself either in involuntary falling, rotation, or in a subjective condition, during the continuance of which surrounding objects seem to revolve round the patient. It is generally believed by physiologists that the cochlea has the special function of analysing sounds. It has been found that the basilar membrane is not equally broad throughout, but that it increases gradually from base to apex. It therefore presents a series of strings of different lengths, and the short ones are assumed to vibrate in the perception of high notes, while the long ones are stimulated to motion by low tones. The lower part of the cochlea is therefore chiefly concerned in the perception of sounds of high pitch, while the upper parts respond to those of low pitch. Some observers, however, do not accept this view—e.g. Voltolini and Rutherford, but believe that sounds are analysed in the auditory centre, which, according to the investigations of Munk and Ferrier, is located in the temporal lobe. For the hearing of birds, reptiles, &c., see Bird, Reptiles, &c.

The Diseases of the Ear.—It is manifestly impossible to attempt any account of the various individual ear diseases in an article like the present. Since aural surgery has become an exact science, the medical profession have come to realise that such phrases as a 'cure for deafness,' or a 'treatment for earache,' are not only inexact but absurd. Deafness—varying in degree from a slight impairment of hearing up to total inability to perceive sounds—may be due to a great variety of causes, and any of these causes may produce not only deafness, but noises in the head. Thus the auditory canal may be blocked by wax, the products of skin eruptions affecting its lining membrane, tumours, masses of fungus, the results of inflammation, &c. The tympanic membrane may be displaced or thickened, the ossicles may be impeded in their movements by the presence of exudation, or by fibrous adhesions or swelling of the mucous membrane within the tympanum. Then again these parts may be injured either by disease or by violence. The auditory nerve may be affected in any part of its course from the auditory centre to the labyrinth, and thus deafness may result.

We have only indicated some of the pathological causes of ,impaired hearing, but enough has been said to show that before deafness can be prescribed for with any hope of success, an examination of the ear must be made by a competent medical man.

Turning now to earache, let us consider some of its causes. Sometimes it is due to the presence of boils in the auditory canal, or the whole lining membrane of the passage, including the outer layer of the membrana tympani, may become inflamed. Perhaps the most common cause of earache is inflammation of the drum-cavity. Such inflammation often stops before the inflammatory products have taken on a purulent character. This mild form is very common in children, and often sows the seeds of deafness in after-life if appropriate treatment be not applied. Occasionally earache is altogether due to the presence of a diseased tooth, which need not necessarily be tender or painful. By far the most dangerous form, however, is that which arises in connection with a so-called 'running ear.' The general meaning of this symptom in such cases is an accumulation of decomposing matter and sometimes diseased bone in close proximity to the brain, and a fatal result is by no means uncommon. Vertigo, or giddiness, is a very frequent symptom of ear disease, and can often be relieved or cured by attention to this organ.

A feeling of fullness in the head, and disinclination for mental effort, is far from uncommon. Rarer or less important symptoms of aural affections are (1) anomalies of taste, owing to involvement of the chorda tympani nerve on its way through the drum-cavity; (2) paroxysmal cough and sneezing; (3) neuralgia of the head; and (4) epilepsy; the last named being fortunately extremely uncommon. We should not be justified in omitting to mention that nasal diseases, especially in children, are often the causes of deafness. This is all the more important, because such cases when taken early can almost always be cured.

From what has been said, it will be obvious that any remarks we could, without unduly extending this article, make with regard to treatment would be useless. We feel it, however, to be our duty to warn those who suffer from ear disease from consulting unqualified quacks. This resort to empirics is all the more uncalled for as there are now numbers of respectable highly-qualified practitioners who devote attention to aural maladies.

There are, however, a few points of general interest and of great importance which may be touched upon.

It is a common delusion that it is a dangerous thing to cure a discharge from the ear. Now this is by no means true; indeed it may be at once stated that life is never safe so long as a chronic putrid discharge issues from the ear. In all such cases it is not only safe but necessary to syringe the meatus with a warm disinfecting solution, such as boracic lotion, or water to which some Condy's fluid has been added. The ear should then be dried by carefully introducing a wick of absorbent cotton-wool. The origin of the superstition anent the danger of stopping a discharge is easily explained. If the putrid matter be present, it is better that it should find its way out. Now, if in such a case some physical obstacle prevents its exit, a fatal result is apt to supervene. It had thus been noticed that in many cases the 'running from the ear' stopped before dangerous symptoms set in, and hence the delusion. Another point as to which much misapprehension exists, is the danger caused by the presence of a foreign body in the ear. It has been observed by a noted specialist that 'the point of a dagger in the meatus is less likely to do harm than unskilled efforts to remove it.' No endeavour should ever be made to remove a foreign body which is not seen, and all probing in the dark is to be absolutely avoided. Most extraneous objects can be removed simply by means of warm water and a syringe used by a skilled hand. If the object be a pea, bean, or any other body which is likely to swell from absorbing moisture, it is better not even to attempt syringing, and to wait until skilled advice can be obtained.

Should an insect get into the ear, it can almost invariably be syringed out with warm water, or if a syringe be not at hand, the ear may be filled with warm oil or even water.

Deafness occasionally runs in families, and the symptom is then usually due to chronic thickening of the tympanic structures. Persons in whom this hereditary tendency exists should, on the first indication of ear trouble, seek advice.

It need hardly be said that picking the ears ought to be avoided. This habit may lead to the 'ear pick' being driven through the drum membrane. Should the ear be made to bleed, and should there be any doubt as to whether the drum membrane be wounded, scrupulous care should be taken to prevent the entrance of fluid. If the tympanic membrane be accidentally perforated, syringing, or instilling ear drops is almost certain to be followed by inflammation. After fifty the hearing tends to fall off a little, but except possibly in extreme old age, marked deafness for conversation is always abnormal. It is a curious fact that elderly people who require a watch to be put quite close to the ear, can often hear conversation well. This is explained by the fact that after middle life the auditory nerve is less sensitive, and the power of-readily perceiving high-pitched tones is then less acute.

According to the writer's experience, almost complete deafness in one ear, while the other is perfect, does not necessarily endanger the sound organ. Others, however, take the opposite view. It must be remembered that in most cases, impairment of hearing is bilateral, and this is always the case when deaf persons have to be addressed in an elevated voice.

The instruction and training of children who have been born deaf is dealt with in the article Deaf and Dumb.

Ear-trumpets, &c.—The number of ear-trumpets now advertised makes any detailed account of them impossible. The application of one of three principles exists in most, if not all, to wit: (1) a tube with a suitable ear-piece at one extremity, and a more or less conical mouthpiece at the other; (2) a bell-shaped sound-collector, with an ear-piece for insertion into the auditory canal; (3) appliances for tilting the auricle forwards. There can be no doubt that a person who desires to purchase an ear-trumpet will best gain his end by carefully testing a large number of instruments, and choosing that which suits him best.

As a rule small invisible instruments are useless. Politzer has constructed a small tube made of vulcanite and flesh-tinted, the object of which is to prolong the tragus backwards; in a very few cases this is found to be an exception to the above rule. The same authority has attempted, by a special appliance, to conduct the vibrations of the auricle directly to the tympanic membrane. The Audiphone (q.v.) and dentiphone are only useful in a few cases; in both the object is to convey sonorous vibrations through the teeth and the auditory nerve. The so-called fonifero is a rod for connecting the larynx of the speaker with the teeth of the auditor. In some cases—those in which the drum membrane is destroyed—the introduction of an artificial drum is useful. This fact has been taken advantage of by unscrupulous quacks, who sell for several pounds an appliance not differing in its essentials from 'Toynbee's artificial tympanum,' which can be had for a shilling or two.

Earths, the name applied by the alchemists and earlier chemists to certain substances now known to be oxides of metals, which were distinguished by being infusible, and by insolubility in water. The term was made to include the oxides of calcium, strontium, and barium, which undergo chemical change by contact with water, and yield alkaline solutions. On account of this property these oxides were called the alkaline earths. The term earth is now disappearing from modern text-books of chemistry. See Soils.

Eau de Cologne, a celebrated perfume, the reputed inventor of which is Johann Maria Farina (1685–1766), a native of Piedmont, who settled in Cologne in 1709, though his claim to be the inventor is not undisputed. The secret of the process of its manufacture is claimed by from thirty to forty firms, bearing the name of Farina, now existing in Cologne. The recipe is said to be twelve drops of each of the essential oils neroli, citron, bergamot, orange, and rosemary, along with one drachm of Malabar cardamoms and one gallon of rectified spirit. The whole is distilled together, and the condensed liquid constitutes Eau de Cologne. In Great Britain, where chemists and others make an article little, if at all, inferior to the imported one, the oils are usually mixed with a highly purified spirit, and the subsequent distillation dispensed with.

Effervescence. Nearly all gases are more or less soluble in water, the amount of solubility depending on various conditions of pressure and temperature. As a rule, the lower the temperature and the greater the pressure, the greater is the solubility of a gas, so that when the temperature of such a solution is raised, or the pressure lowered, the gas escapes in small bubbles, giving rise to the phenomenon of effervescence. The most familiar instance of effervescence is when a bottle of soda-water is uncorked, the excess of carbonic acid gas over what can remain in solution escaping with effervescence. Again, when a seidlitz powder is mixed with water, effervescence occurs, owing to the inability of the water to retain the gas in solution. Many slight circumstances affect effervescence. Most people know that by stirring a glass of soda-water, or by dropping into it a fragment of cork or a crumb of bread, greater effervescence occurs. Sometimes the liquid is rather viscid, and a persistent froth is produced, as when a siphon of lemonade is discharged into a tumbler. In such a case, the addition of a few drops of milk or of a little alcohol causes more rapid effervescence and settling of the froth. In the former of these cases, the bread crumb or the stirring acts by making it more easy for the gas to form bubbles and escape. In the latter case, the effect of milk may have a twofold cause, one similar to that of the crumb, the milk globules acting as nuclei; the other similar to the calming influence of oil on sea foam,

the natural oil, butter, here coming into play. The alcohol merely acts by thinning the liquid.

Efflorescence, in Chemistry, is the term applied to the appearance of a white incrustation on the surface of certain bodies, as when a salt loses its water of crystallisation, and presents a white powdery appearance on the surface. Common washing-soda exposed to the air affords a good illustration of this phenomenon.

Electricity.* If a stick of sealing-wax is rubbed vigorously with woollen cloth it will be found capable of attracting small shreds of paper. This is the simplest experiment in electricity. Many other substances, such as resin, vulcanite, glass, &c., can be made to show the same phenomenon. To obtain the best effect with any given substance, a particular rubber must be chosen. For example, a cat's fur, slightly warmed, is very efficient in electrifying vulcanite or resin; while silk, amongst simple substances, should be used to excite glass. It is now known, however, that any two different substances, which can be rubbed together, become electrified by the friction. Thus, if wax and glass are rubbed together, they will both become electrified—i.e. capable of attracting light objects. And so, in the other instances, it can be shown by experiment that the cloth is electrified as well as the wax, the cat's fur as well as the vulcanite, the silk as well as the glass. Moreover, the two substances so electrified by mutual rubbing are found to attract one another, being indeed *oppositely* electrified—a term which the following experiment will elucidate.

Let two pieces of glass be electrified by rubbing each with a distinct piece of resin. The pieces of resin will also be electrified, and it will be found (1) that the pieces of glass repel each other; (2) that the pieces of resin repel each other; (3) that each piece of glass attracts each piece of resin. Exactly the same phenomena of attraction and repulsion will be shown—only much more powerfully because of the greater efficiency of the rubbing—if the pieces of resin are rubbed with cat's fur and the pieces of glass with silk.

Again, let a small light body, a pith-ball for example, be suspended at the end of a silk thread. This will be attracted by either the resin or the glass. But if it is allowed to come into contact with, say, the resin, it will immediately be repelled by the resin and strongly attracted by the glass. And if it should be allowed to touch the glass, it will at once be repelled by the glass and strongly attracted by the resin. By such contact the pith-ball itself becomes electrified; for it will repel a second pith-ball similarly treated. We are thus led to the following conclusions. Repulsion exists between bodies which are similarly electrified, and attraction between bodies which are oppositely electrified. Bodies, electrified by mutual rubbing, become oppositely electrified. A body, electrified by contact with an electrified body, becomes electrified similarly to that body. Substances which like silk-rubbed glass repel silk-rubbed glass and attract wool-rubbed resin are vitreously or *positively* electrified, while bodies which attract silk-rubbed glass and repel wool-rubbed resin are resinously or *negatively* electrified. The indication of the two kinds of electrification by opposite signs is very appropriate, but the application of the positive sign to one rather than to the other is a matter of convention and purely arbitrary.

To study electrical phenomena by means of metallic substances, it is necessary first of all to *insulate* them—i.e. to support them on glass, vulcanite, paraffin, &c., or to hang them by silk threads. The significance of the term insulation will appear from the following experiment. Hang two metal balls, one by a silk thread and the other by a wire, and touch them with a piece of wax strongly electrified by friction. On trial, the silk-suspended ball will be found electrified; but not so the wire-suspended ball. Or, again, set a metal ball on a glass support, but let a wire connect it with the table or the hand. It will be found impossible to electrify it by contact with an electrified body. But remove the connecting wire, and immediately a single contact will suffice to electrify the ball. Thus we recognise two kinds of substances—viz. *insulators* and *non-insulators*. The latter are usually called *conductors*, and include all ordinary metals. Such conductors can be electrified only when they are insulated.

When a body is sufficiently strongly electrified and brought very near another body originally unelectrified, a spark will pass between them even before they are made to touch. If this second body is the finger or knuckle, the spark will be accompanied by a peculiar sensation called an electric shock. Now let us take such a highly electrified conductor A, and bring pretty near to it a second insulated conductor B, but not so near as to cause a spark to pass. If, then, the finger be brought near enough to B a shock will be felt, a spark will pass between B and the finger, although B was originally not electrified. Thus B has become electrified by being brought into the neighbourhood of A. This mode of electrification is called electrification by *induction*. As Faraday clearly pointed out, it 'has the character of a first, essential, and fundamental principle,' and its thorough comprehension is of prime importance.

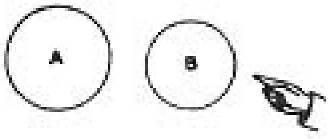

Fig. 1.

As it is our purpose to regard the whole subject from the Faraday point of view, it will be convenient to define certain useful terms. The *electric field* is any region of air, glass, vulcanite, or other non-conducting substance surrounding or containing electrified bodies. In it and through it the electric forces act; hence it is convenient to call such insulating substances *dielectrics*, especially when attention is being drawn to the rôle they play as transmitters of electric action. To investigate the properties of an electric field it is generally necessary to bring into it a conductor, as in the experiment just described. In that experiment the induced electrical condition of B was studied by means of a physiological sensation, partly optical, partly muscular. A far better way, however, of studying the phenomena of induction is to make use of the fundamental laws of attraction and repulsion between electrified bodies, as they are mechanically applied in such instruments as the gold-leaf electroscope, Coulomb's torsion balance, Thomson's quadrant electrometer, &c.

In the gold-leaf electroscope (invented by Bennet in 1787), two light strips of gold-leaf hang from the lower end of a metal rod, which passes vertically through an opening in the top of a glass bottle and expands above into a plate. If a piece of rubbed sealing-wax or other electrified body be brought near the plate, the gold leaves will repel each other and diverge. In other words, the conductor, consisting of the plate, rod, and gold leaves, has been introduced into an electric field, and has in consequence become electrified by induction. This is shown by the repulsion between the similarly electrified gold leaves. The nearer the electrified body is brought, the stronger is the electric field surrounding the electroscope, the wider do the gold leaves diverge. Here evidently the repulsion tends to lift the centre of gravity of each gold leaf, and is finally balanced by the action of gravity. A cylinder of wire gauze, placed just inside the glass case, improves the action of the instrument. The other two instruments mentioned above depend for their action upon the same general principle—viz. the equilibrium of a body under the action of the electrical and what, for distinction, might be called the material forces.

Fig. 2.

Coulomb's torsion balance is historically the first true electrometer—i.e. the first instrument whose indications were capable of quantitative interpretation. In it the force with which one small charged sphere is repelled by another similarly charged is balanced by the torsion of a wire, which acts as suspension to a horizontal insulating rod bearing the one sphere at one of its ends. By rotation of the upper end of the wire this sphere can be made to move in a horizontal circle; and at some point in the circumference of the circle the other sphere is fixed. If the spheres are charged, **the rod bearing the movable sphere will take up a position of equilibrium under the combined action of the electrical force and the torsion of the suspension; and these, as regards their rotatory effect upon the rod, must be equal. But by the laws of elasticity, the force of torsion is proportional to the twist of the wire, and the twist itself is as easily measured as the distance between the spheres. Hence to the degree of accuracy to which the geometrical configuration of the system is known, the electric force can be calculated in terms of the elastic constants of the wire. In this way Coulomb proved, in 1785, that two small charged balls repelled each other with a force which diminished as the square of the distance increased.**

Sir William Thomson's quadrant electrometer is, in a certain sense, a development of Coulomb's torsion balance. Its many nice electrical and mechanical devices render it a peculiarly delicate and accurate instrument for measuring minute differences in electrification. Essentially it consists of four hollow brass quadrants, which when fitted close together form a squat hollow cylinder bounded above and below by parallel plane faces. For electrical purposes they must, however, be drawn a little apart, so that when looked at from above or from below they have the appearance as shown in the figure—viz. that of a circular disc with two mutually perpendicular diametral clefts. Each quadrant is insulated on its own glass support; but each is joined to its opposite by a wire, so that electrically they go in pairs. From one of each pair a vertical rod leads to the outside of the case in which the whole is inclosed. These rods are called the *electrodes*, and their function is to bring the pairs of quadrants into electrical connection with external bodies. The inside corner of the top and bottom of each quadrant is cut away, so that at the centre a small circular space is left concentric with the external cylindrical surface of the quadrants. In the hollow space inclosed by the quadrants a light charged body (E in fig. 3, *e* in fig. 4) of a convenient shape hangs, its axis of suspension passing up through the circular central space just mentioned. The light body can rotate about this vertical axis only, and its motion is controlled by the torsion of the suspension. If the four quadrants are all connected together, the suspension makes the light body hang so as to lie with its longer axis of symmetry parallel to one of the diametral clefts separating the quadrants. If, however, the pairs of quadrants are disconnected, and by connection with external bodies brought into different electric conditions, electrical forces will at once act upon the charged body and rotate it until they are balanced by the resisting torsion of the suspension. Thus let the charged body *e* (fig. 4) be positively charged; and let the pairs of quadrants be charged differently, so that the ones marked AA' have a higher positive charge than the ones marked BB'. Then the charged **body will move so as to come more within the quadrants BB'. If the relative electrifications of the pairs of quadrants is reversed, the charged body will move the other way. The motion is shown and measured by means of a beam of light reflected from a small mirror fixed to the vertical axis of suspension of the body and moving with it.**

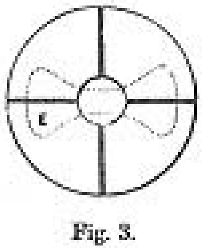

Fig. 3.

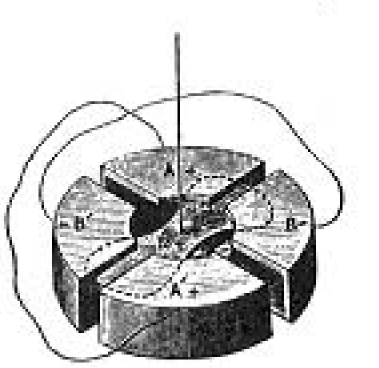

Fig. 4.

Henceforth we shall use the unqualified words electroscope and electrometer as meaning the gold-leaf electroscope and quadrant electrometer respectively.

We are now in a position to make an accurate study of the phenomena of induction. We shall

---

* For the plan and distribution of the following article, see the epitome in the concluding paragraph. The word *electric* was coined in the 16th century by William Gilbert from the Gr. *ēlektron*, 'amber.' See AMBER.

suppose, when nothing is said to the contrary, that all our conductors are of one metal, say brass; that they are at the beginning of every experiment insulated and unelectrified; that the electroscope and electrometer quadrants are likewise unelectrified at the beginning of each experiment; and that the dielectric is air.

Experiment I.—Set a cylindrical brass vessel on the electroscope; and let down into it, without coming into contact with it, a positively charged conductor A. It is convenient to hang this charged ball at the end of a short silk thread from the lid of the vessel, the lid itself being lowered or raised by means of a silk thread. As soon as the ball is brought inside the vessel the gold leaves will diverge, as shown in fig. 5; and the vessel B, as regards outside objects, will behave as if positively electrified. Now touch B with the hand or with any non-insulating material connected to earth—in technical language, put the vessel to earth—and the gold leaves will fall together, and all appearance of electrification will be destroyed. Remove the earth connection so as to insulate B once more, and lift away the lid and the attached ball, care being taken to prevent A coming in contact with B. The gold leaves will again diverge, and the vessel B will be found to be negatively electrified.

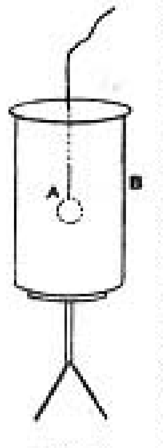

Fig. 5.

The nature of the charge on the vessel and gold leaves is indicated at once by the approach of an electrified body. If a piece of rubbed sealing-wax or any negatively charged body is brought near, the gold leaves, if negatively electrified, will diverge still more; if positively electrified, will tend to fall together.

In thus charging the vessel B negatively by induction, we have in no way diminished the original positive charge on A; and we may use this same charge an indefinite number of times in charging negatively other bodies like B. No doubt in each body so charged by induction we have a new-formed source of energy; but this has been derived, not from the energy spent in originally charging the ball, but from the energy spent in separating against their mutual attraction the positively charged ball and the negatively charged vessel.

Experiment II.—Begin again as in Experiment I., introducing the charged ball A into B, and putting B to earth, so that the gold leaves fall together. Now connect A with B. No effect will be observed on the electroscope, even though, as in the former experiment, A should be removed. Thus the charge on A has been completely destroyed; hence, there must have been on B, just before the contact was made, an equal but opposite charge. This is, in fact, the very charge which made its presence evident when, in Experiment I., the ball A was removed.

Thus, if a charged body A be completely surrounded by a closed vessel B, which is put to earth and then insulated, the charge induced on B is equal and opposite to the charge on A. To make this induced charge apparent we must remove A.

Experiment III.—Repeat Experiment I., and after having charged B negatively by induction, introduce A into another conductor C, initially without charge and insulated. If C is resting on a gold-leaf electroscope, the gold leaves will diverge with positive electrification as in the earlier stage of Experiment I. Bring now A into metallic connection with C. If C *completely* surrounds A, no change will be observed on the electroscope, although a spark may be heard at the instant the contact is made. The ball A, if removed without again coming in contact with C, will be found to have lost all its charge; and if B and C are brought into metallic connection, all appearance of electrification on them also will be destroyed. In other words, the negative charge induced on B has been quite destroyed by union with the positive charge transferred to C. These charges therefore must be equal and opposite. Thus, the charge originally on A has been wholly transferred to C.

We conclude, then, that when a conductor is electrified, its electrification resides wholly on the surface. Any portion of it removed from the inside will be found unelectrified if taken quite out of the influence of other electrified bodies.

This experiment, or one very similar to it, was first performed in 1772 by Henry Cavendish, who deduced from it by rigorous mathematical reasoning that 'electric attraction and repulsion must be inversely as the square of the distance.' He inclosed a metal globe within a hollow conducting shell which was built up of two hemispheres. The globe and shell were connected by a wire and charged. The globe was then disconnected from the shell, and immediately thereafter the hemispheres forming the shell were drawn asunder. The globe, now left exposed, was tested for electrification; and, to the degree of accuracy of the experiment, none was found.

Maxwell repeated the experiment in a much more delicate manner than was possible before the invention of the quadrant electrometer. During the charging of the shell and inclosed globe, these were connected by a short wire 'fastened to a small metal disc hinged to the shell, and acting as a lid to a small hole in it.' After the charging, this lid was lifted up by means of a silk thread, and the communication between the shell and the globe done away with. The shell was then discharged and kept connected to earth. Through the small hole in the shell a wire was led connecting the globe with one electrode of the quadrant electrometer. Not the slightest deflection could be observed.

It is impossible then to charge a body by placing it inside a charged conductor. In other words, there is no electric field within any region bounded by a conducting surface, however much that surface may itself be charged, unless there be within that region other insulated and independently charged bodies. It matters not what electrical phenomena may be taking place in the region outside such a conducting surface, such external electrical phenomena have absolutely no internal electrical effect; and *vice versâ*, any purely internal electrical change can produce no external electric effect. In short, any closed conducting surface divides space into two regions, which are electrically independent the one of the other—i.e. so far as electrical action through either is concerned. This principle is taken advantage of in the construction of the quadrant electrometer, the essential internal arrangements of the instrument being inclosed as far as possible within a conducting vessel, the quadrants communicating with external space only by means of their electrodes.

Experiment IV.—The conclusions just stated may be easily illustrated by use of the quadrant electrometer. Thus, as in Experiment I., let the positively charged body A be introduced into an insulated and initially unelectrified closed conductor B. Then, as we know, B becomes electrified, and the region round B becomes an electric field. The condition of this electric field may be studied by means of a small sphere C, joined by a long thin wire to one electrode—i.e. to one pair of quadrants—of the electrometer E. The other electrode is supposed to be kept connected to earth. Before A was introduced into B, the electrometer showed no sign of electrification. But as soon as A is introduced into B, C and its connected quadrants become electrified. The deflection produced on the electrometer will depend upon the position of C with regard to B and upon the original charge of A. It is quite independent, however, of the particular position of A, which may be moved about inside B without in any way affecting the deflection on the electrometer. A may even be brought into contact with B (as in Experiment III.) so as completely to lose its charge; and yet the electrification of C, as shown on the electrometer, is in no way altered—in other words, the electric field outside B is independent altogether of any purely internal changes which may take place inside B.

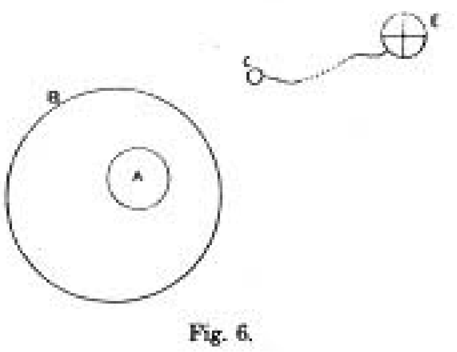

Fig. 6.

Suppose, now, that when A has been introduced into B, and a corresponding deflection obtained on the electrometer, B is put to earth. At once the electric field around B is destroyed, C and its connected quadrants recover their original unelectrified condition, and the electrometer gives zero deflection on its scale. Thus the charge on A is completely masked by being surrounded by a closed conductor put to earth.

Further, let B be insulated again and A removed with its charge—then, as we already know, B will be left negatively electrified. The region round B will again become an electric field, and C and its connected quadrants once more electrified. But the deflection on the electrometer, though equal to that first obtained, will be in the opposite direction, opposite because of the opposite character of B's electrification.

This experiment may be taken as an illustration of one of the most fundamental facts in electrostatics—viz. that the generation of so much positive electrification implies the generation of as much negative electrification. Here is a conductor B apparently without charge. Remove from it by any process a positive charge, and an equal negative charge is left behind. The same is true when bodies are electrified by friction, as may be proved by operating inside a closed insulated conductor joined to one electrode of the electrometer. The most energetic rubbing of the two bodies, and their subsequent separation, each in a highly electrified condition, produce no effect whatever on the electrometer—thus showing that their inductive effects on the inclosing conductor are equal and opposite—i.e. their charges are equal and opposite.

Experiment V.—To study in greater detail the properties of the electric field around a given charged conductor B, take two small insulated spheres and connect them by thin wires to the electrodes of the electrometer, each to one. Suppose these spheres to be at first in close contact at some part of the field; then, since the pairs of quadrants are in the same electrical condition, the electrometer will show zero deflection. Now gently separate the spheres, both insulated of course, and in general a deflection to the right or to the left will be obtained on the electrometer. By trial we may find the unique direction of separation which, for a given distance of separation, gives the maximum deflection. This will be to the right or to the left according to the relative position of the two spheres. It will be found, however, that a separation of the spheres in directions at right angles to this unique direction does not cause any deflection on the electrometer. It is far easier indeed to find these directions of separation for which there is no deflection than to find the direction of maximum deflection for a given separation. Suppose in fact that the one small sphere is fixed in position, and that the other, which we may call the exploring sphere, is moved away from contact with it in such a manner that the electrometer always shows zero deflection. The centre of the exploring sphere will describe a curve, and can be made by successive trials to describe an infinity of curves, all lying on a certain surface which passes through the centre of the fixed sphere. We shall call this the surface S. Now with the exploring sphere lying anywhere on this surface, let the fixed sphere be shifted in towards B till the electrometer deflection is unity. Then shift the exploring sphere correspondingly until the deflection is brought back to zero again, and proceed as in the first position to trace out a second surface, which we shall call S + 1, and which will pass through the centre of the fixed sphere in its second position. Shift the fixed sphere once more till unit deflection is obtained, follow up with the exploring sphere, and trace out the third surface S + 2. In this way, step by step, the electric field may be supposed to be mapped out by a series of surfaces, differing in value by unity as measured on the electrometer scale. We may pass out to the surfaces S − 1,

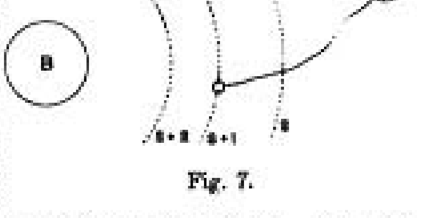

Fig. 7.

S − 2, S − 3, &c., as well as in to the surfaces S + 1, S + 2, S + 3, &c. These surfaces are all closed, and cannot cut each other. For suppose two did cut each other; then, by putting the fixed sphere in the supposed line of intersection, we could move the exploring sphere from the position S to the position S + 1, and produce no change on the electrometer; which is a manifest absurdity, as S + 1 is defined in terms of S *and a change*. If the electrodes of the electrometer terminate on any one of these surfaces there is no deflection; if they terminate on different surfaces the deflection is the difference of the name-values of the surfaces. Evidently the conductor B is such a surface, for if the electrodes terminate on it, all the quadrants, being in metallic connection, will be in the same electrical condition, and the electrometer will show no deflection.

The surfaces we have just described are called *equipotential* surfaces, the term potential having in electricity much the same import as temperature has in heat or pressure in hydrodynamics. When a channel exists between two masses of fluid at different pressures, fluid will flow from where the pressure is higher to where it is lower. Similarly if we have two charged conductors whose electrical conditions as tested by electroscope or electrometer become changed after they have been connected by a wire and disconnected again, these two conductors are said to have been at first at different potentials. If they had been connected to the electrodes of the electrometer, each to one, the electrometer would have shown a deflection; and this deflection would have been a measure of the difference of potential. If the difference of potential is great, then the contact of the two conductors is evidenced by an obvious electrical discharge in the form of a visible audible spark.

If we directed our attention to conductors only, we should not find any special advantage in using the phrase 'difference of potential' instead of 'differently electrified;' but when we follow Faraday in regarding the dielectric as of at least equal importance as the conductor, the conception of the potential is found to be one of peculiar value. Thus any conductor or any system of connected conductors must have all points at the same potential;' whereas, in a dielectric, the potential may vary from point to point, and indeed must vary if the dielectric is separating two conductors at different potentials.

Within such a dielectric we may suppose traced out, after the manner of the last experiment, a series of equipotential surfaces. To fix our ideas, let the one conductor be completely inclosed within the other—say, a spherical globe within a concentric spherical shell—and let this outer shell be put to earth, and let us call its potential zero. Then we know by Experiments II. and IV. that the electric field exists only in the region between the shell and the globe, which we shall suppose to be at a high potential V. The symmetry of the system requires that the other equipotential surfaces will all be spheres concentric with the globe and shell. Now we may compare this electrical system of globe, shell, and intermediate equipotential surfaces to a system of Contour (q.v.) lines representing a hill with a flat top rising up from the sea-level—the successive equipotential surfaces in the electrical system corresponding to successive equal-level lines in the geographical system. If the substance of the hill were to become fluid, the whole would be reduced to the sea-level, and the contour lines would be effaced.

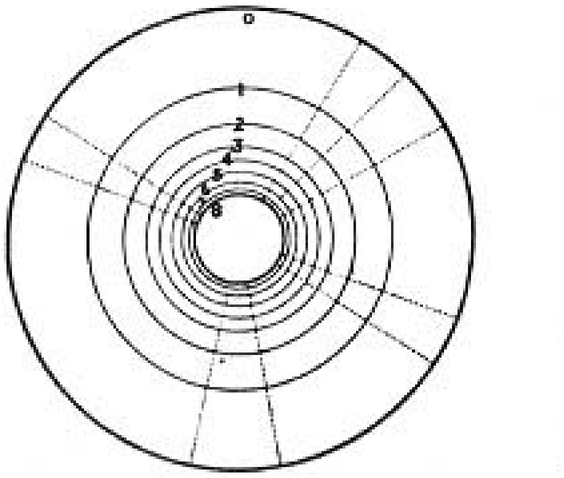

Fig. 8.

So, if the dielectric were to become conducting, the equal and opposite charges (see Experiments II. and IV.) on the globe and shell would combine and destroy each other, and the electric field with its imaginary equipotential surfaces would cease to exist. Again, to carry one pound of matter from the sea-level up to the top of the hill requires so much work to be done against gravity (see ENERGY), and this amount of work is proportional to the height lifted through—i.e. to the number of contours crossed. So, in the electrical system, to carry a small positive charge from the shell to the globe will require so much work to be done against the electrical forces, and this amount of work will be proportional to the number of equipotential surfaces crossed. Further, exactly as the pound of matter taken to the top of the hill will add to the height of the hill, so will the addition of this small extra charge to the globe increase its potential. We must not, however, push the analogy too far, since in the one case the force of gravity overcome is constant and acts downwards, whereas in the other the electric force varies inversely as the square of the distance from the centre and acts outwards.

We have assumed in the above discussion that the successive equipotential surfaces, experimentally determined by means of the quadrant electrometer, are really such that the work done in carrying a given small charge over the interval separating any two contiguous surfaces is the same. It is usual in treatises on the subject to begin with the dynamical definition of the potential at a point as the work done in carrying a unit of positive electricity from infinity to that point. It is then shown that the quadrant electrometer is an instrument so constructed as to fit in to this definition.

Assuming then that our equipotential surfaces have the property just mentioned, we are in a position to study the energy relations of the electric field.

Coulomb established by experiment that the force of repulsion between two similarly charged bodies was directly as the product of the charges. Hence, as the charge of the globe inclosed in the shell is increased, the electric forces in the field increase in the same proportion. Hence the work done in carrying a given charge from the shell to the globe against the electric forces increases in the same ratio. In other words, the number of equipotential surfaces in the field grows uniformly with the charge. If the potential of the globe is V, we may write the charge CV, C being a constant so long as the geometrical dimensions of the system remain unchanged. Since the shell is always kept connected to earth—i.e. at zero potential, there is a charge − CV distributed over the inside of the shell. To add a small extra charge to the globe may be regarded as equivalent to taking this small charge from the shell, carrying it across the dielectric, and distributing it over the globe. The work done in effecting this is evidently proportional to the charge taken and to the number of equipotential surfaces crossed. But as the extra charge is added, let us suppose, at a steady rate, the potential of the globe is increased at a proportional steady rate. Hence the whole work done in adding a given charge is equal to the product of the charge and the mean potential of the globe during the operation. Thus, in charging the globe from zero potential to potential V, we do an amount of work equal to half the product of the final potential V into the final charge CV—in symbols $\frac{1}{2}CV^2$ or $\frac{1}{2}QV$ or $\frac{1}{2}Q^2/C$, where Q is the charge, and C the constant which depends on the geometrical dimensions of the system.

We have already seen that positive and negative electrifications always co-exist—that it is impossible to generate so much positive charge without at the same time generating as much negative charge. Faraday took implicit account of this truth in his conception of lines of electric force traversing the dielectric. Since no work is done against the electric forces in passing along an equipotential surface, we readily see that the electric force at any point is perpendicular to the equipotential surface there. This direction is, in fact, the unique direction of separation of the two terminal spheres in Experiment V., which, for a given distance of separation, gave the maximum deflection. If, starting from any point, we move always perpendicular to the equipotential surface through which we are for the moment passing, we shall describe a curve which at every point of it is tangential to the direction of the electric force there. Such a curve is called a Line of Force. Take any small area on an equipotential surface, and draw lines of force through its perimeter. These lines of force will form a so-called Tube of Force, whose section in general will vary as we pass along it. Following this tube of force backwards to its source, we shall finally come to a positively charged conductor; and following it forwards we shall ultimately come to a negatively charged conductor. Every such tube of force has, in short, two ends. It springs perpendicularly from a positively charged area, and terminates, also perpendicularly, on a negatively charged area. According to Faraday's view, and to the view now generally accepted, it is along these tubes of force that electric induction takes place; so that the negative charge on the terminal area is exactly equal to the positive charge on the area from which the tube springs.

In the symmetrical system of globe and shell the lines of force are obviously straight radial lines, the tubes of force portions of cones terminated by the spherical surfaces. Some of them are indicated by the dotted lines in fig. 8. If we take each tube as springing from an area bearing unit charge, then there will be in the region as many tubes of force as there are units of charge—i.e. there will be Q(= CV) unit tubes of force. These Q unit tubes of force with the V equipotential surfaces will cut up the dielectric into QV imaginary cells, each of which may be regarded as containing half a unit of energy. In fact, exactly as a stretched piece of india-rubber contains in every element of it so much energy in virtue of the elastic stresses acting throughout it, so we are to regard an electric field as a kind of strain existing in the dielectric, so that in every element of the dielectric so much electrical energy is stored up in virtue of the electric stresses. Every complete unit tube of force contains $\frac{1}{2}V$ units of energy; and between any two complete equipotential surfaces differing by unity there are $\frac{1}{2}Q$ units of energy stored up. Clearly the electric strain will be greatest where the unit tubes of force are narrowest and where the equipotential surfaces are closest.

Suppose, now, that in the region between the globe and shell an insulated conductor originally unelectrified is introduced; or, what comes to the same thing, suppose a marked off region in the electric field to become conducting, this region will at once be reduced throughout to the same potential, and its surface will form part of an equipotential surface. But, since originally the potential in this region fell steadily as we passed outwards from the globe, a transference of charge must have taken place also outwards in order that the potential should become equalised throughout. The introduced conductor in fact acts as a channel along which electrification is transferred; so that, if tested, the end facing the globe will be found negatively electrified, and the farther end positively electrified.

Now it is evident that the introduction of this conductor into the field has very much changed the configuration of the equipotential surfaces in its vicinity, the new configuration being something like what is indicated in the diagram (fig. 9). As a consequence, the tubes of force, which are necessarily perpendicular to the equipotential surfaces, must also suffer a corresponding change of configuration. A certain number, springing from the globe, will fall perpendicularly on the nearer part of the introduced conductor, while from the farther part an equal number of tubes of force will spring and continue outwards to the shell. Where the tube ends on a conducting surface, there we find unit negative charge; and where it springs from a conducting surface, there we find unit positive charge. Thus, by consideration of the equipotential surfaces and tubes of force, we are led to a conclusion in strict accordance with the experimental truth that an uncharged conductor brought near a charged conductor becomes electrified by induction, so that the nearer end shows an opposite charge, and the farther end shows a similar charge, to that which

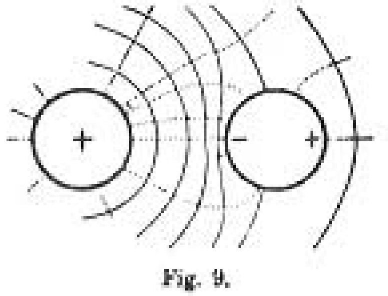

Fig. 9.

exists on the charged conductor.

Generally speaking, the effect of the presence of the introduced conductor is to crush the tubes of force in the neighbourhood closer together, and therefore (since this number remains constant) to compel an expansion of them elsewhere. The terminals of the tubes on the globe will obey the same tendency towards concentration and expansion. In other words, the charge Q, at first distributed uniformly over the globe, becomes redistributed and tends to accumulate on the side facing the conductor. The nearer the conductor and globe are brought, the greater will this tendency be; and at last, when they are near enough, the dielectric is unable to sustain the high electric tension along the ever-shrinking tube of force. It yields, a more or less sudden transference of charge takes place in the form usually of a spark, the potentials of the globe and conductor are practically equalised, and the tubes of force between them are annihilated. This is the phenomenon which is exhibited on a large scale in every lightning-flash, and on a small scale in every spark between electrified bodies.

Suppose, however, that before this catastrophe has taken place, the conductor is joined by a wire to the surrounding shell, and consequently brought to zero potential. All those equipotential surfaces which at first inclosed the conductor—i.e. lay between, it and the inclosing shell, will be shifted so as to lie between it and the globe. The tubes of force will shift correspondingly; and as no tube can now pass from the conductor to the shell, none will spring from it. Hence the charge on the conductor will be wholly negative. Now experiment shows that when the conductor is brought to zero potential in the way just described, a spark always passes at the instant the connection is made. This spark means so much energy in the form of light, sound, and heat, and must therefore mean a disappearance of energy in some other form. This cannot be other than electrical energy. Consequently the number of unit cells in the dielectric must be diminished. But the charge on A has not changed, so that the number of tubes of force is exactly as before. The change must therefore be in the number of equipotential surfaces; and since the shell and the conductor are at zero potential, the diminution must take place in the potential of A. Thus we see that the potential of a positively charged body is diminished if a conductor at zero potential is brought near it.

This result leads naturally to the discussion of *capacity*. The capacity of a conductor is measured by the ratio of its charge to its potential. Hence if, as in the experiment just described, we have a diminution of potential with constant charge, this is equivalent to an increase of capacity. The greater the capacity of a conductor, the greater the charge it can hold at a given potential. Hence if a number of conductors are at the same potential, the charges must be distributed amongst them directly as the capacities. The experiment just described shows how we may arrange matters so as greatly to increase the capacity of a given conductor. It is sufficient to have close to it another conductor at zero potential. Such an arrangement of conductors is called an *accumulator* or *condenser*; and the most familiar form of accumulator used in electrostatic experiments is the Leyden jar, so called from the city where, in 1745, its properties were accidentally discovered by Cunæus. About the same time, possibly a month or two earlier, almost exactly the same discovery was made by Kleist at Kammin in Pomerania. In its modern form, a Leyden jar is a cylindrical glass bottle, lined inside and outside with metal foil up to within a short distance from the top. A brass rod connected below with the inside coating passes upward through the cork or stopper, and terminates generally in a ball or knob. A Leyden jar then consists essentially of two conductors, the one almost completely inclosed in the other, and separated from it only by the thickness of the dielectric. If either conductor is put to earth, and the other insulated and charged, an opposite and nearly equal charge is induced on the former. If we could completely surround the one conductor by the other, the induced charge would, as we have seen, be exactly equal but opposite to the inducing charge. Leyden jars are indispensable for carrying out illustrative experiments in electricity. When used in combination, they are said to form an electric battery.

Fig. 10.

The essential nature of the mode of action of an accumulator or condenser may be illustrated as follows: Take any charged conductor with its associated electric field. Let Q be its charge, V_0 its potential, so that $\frac{1}{2}QV_0$ is the measure of the electric energy stored up in the field. Having fixed our attention upon any equipotential surface V_1 inclosing the conductor, let us suppose this surface to become conducting. There will be no transference of charge over this surface, because it is from the very beginning an equipotential surface. There will be no change of the electric field either inside or outside the surface V_1; but these two regions will now be separated by a conducting surface. So far as the outside region is concerned, we may regard the charge Q as distributed over a conductor co-extensive with the conducting surface V_1 (see Experiments III. and IV.), and may quite disregard the existence of the original conductor at potential V_0. The electrical energy stored up in this outside region is therefore a $\frac{1}{2}QV_1$. Let us now connect this new-formed conductor to earth so as to reduce it to zero potential. By so doing, we discharge the conductor, completely destroying the electric field outside of it and the $\frac{1}{2}QV_1$ units of electric energy stored up in it. This therefore is energy lost to the original system; and the energy stored up in the dielectric separating the two conductors becomes a $\frac{1}{2}Q(V_0 - V_1)$. Now, since the inclosing conductor has been reduced to zero potential, the quantity $(V_0 - V_1)$ must represent the new potential of the inclosed conductor.

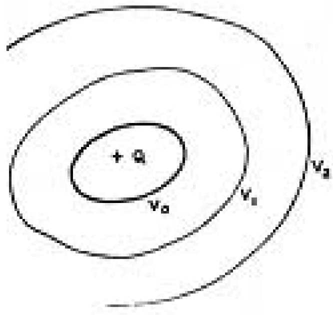

Fig. 11.

In short, the bringing of the inclosing conductor to zero potential, being a purely external electrical change, has in no way altered the *configuration* of the equipotential surfaces and tubes of force inside; it has simply *reduced the potential values* throughout by the same amount—viz. the potential of the inclosing conductor before it was put to earth. The potential of the inclosed conductor has fallen from V_0 to $V_0 - V_1$; and hence, as the charge Q has remained unchanged, the capacity has increased in the ratio $V_0 - V_1 : V_0$. Thus, with either conductor fixed in size, the capacity of the system grows greater and greater as the thickness of the separating dielectric is diminished. If, as in almost all practical cases, the dielectric is very thin compared to the size of the conductors, we may assume that the successive equipotential surfaces come at sensibly equal intervals, so that the surface halfway between the conducting surfaces will have approximately a potential value half-way between the potentials of the conductors. Thus it is easily seen that for a condenser built up of closely opposed surfaces, whether plates or cylinders, separated by a given dielectric, the capacity varies inversely as the thickness of the dielectric.

Take, for example, two concentric spheres, one slightly larger than the other, and let the inner one have a charge Q, and the outer one be at zero potential. The negative charge on the outer sphere will, by a well-known proposition in attractions, exert no electric force throughout its interior. Hence, if a is the mean of the radii of the spheres, we may write Q/a^2 as a very approximate value for the mean electric force acting in the region separating the spheres. If t is the small distance between the two surfaces, the work done in carrying unit charge from the outer to the inner surface is Qt/a^2, the product of the distance into the mean force. This therefore measures the difference of potential of the two spheres, so that a^2/t is the capacity. Now, we shall suppose that t is kept constant, and that a is made to grow indefinitely; then if we write $Q = 4\pi a^2\sigma$, the quantity σ will be the charge on unit area of the inner surface. Hence, ultimately, when the concentric spheres become two parallel planes, the difference of potential between them is measured by the quantity $4\pi\sigma t$, where σ is the charge on unit surface of the one plane, $-\sigma$ the charge on the opposing surface of the other, t the distance between the planes, and π = the ratio of the circumference of a circle to its diameter. The force is measured by the rate at which the potential changes, in this case simply $4\pi\sigma$, and is therefore the same not only at every point between the planes, but also for all values of t.

Now we may calculate the electric force very close to any charged surface on the supposition that the contiguous surface element is part of an infinite plane having the same charge per unit area—in other words, the same surface density. By surface density at any point of a charged conductor we mean the limit of the ratio of the charge on a small element containing the point to the area of the element, as the element is taken smaller and smaller. Such is the quantity σ just discussed.

Thus the electric force just outside a charged conductor is equal to $4\pi\sigma$, where σ is the surface density at the contiguous point of the conductor. It is a repulsion when σ is positive, an attraction when σ is negative.

We may use the result just obtained for finding the force acting on an element of the charged surface itself. Consider the two parallel planes at distance t and difference of potential $4\pi\sigma t$, σ being as above the charge on unit area. Hence the energy stored up in a tube of force stretching from the unit area on B to that on A is $\frac{1}{2}\sigma \times 4\pi\sigma t = 2\pi\sigma^2 t$. Now, with A at zero potential, let B be moved away to double its original distance from A—i.e. through a distance t to B'. If the charge on unit area remains constant, the energy stored up in the corresponding tube of force has become simply doubled, so that there has been an increase in electrical energy represented by the quantity $2\pi\sigma^2 t$. But this must be equivalent to the work done in removing the charge σ through the distance t against the electrical force; hence, the value of this force estimated per unit charge must be $2\pi\sigma$. Thus the force per unit charge acting *on the surface* is just half the electric force acting on unit charge at a point in the field just outside the surface. Otherwise, if F is the electric force at a point just outside a charged surface, $F/4\pi$ is the measure of the surface density at the contiguous surface element, and $\frac{1}{2}F$ is the force per unit charge acting on the surface.

Fig. 12.

The importance of this result is that it gives us a simple method of measuring electric force in terms of weight. It is the principle of Thomson's absolute electrometer, which is essentially two parallel plates at different potentials, one of which is made so that a small area at its centre is movable under the action of the electrical force. Where this small area is, the electrical system does not differ appreciably from what would be the case if the plates were really infinite. We may suppose the small area suspended by a spiral spring, and that, when the plates are at the same potential, W grammes must be laid on the small area to bring it so that its lower surface is flush with the lower surface of the rest of the upper plate. Let the weight W be removed, and the lower plate be put in connection with the conductor whose potential is to be measured. Now raise or lower this plate until the small area, which with the rest of the upper plate is kept at zero potential, is brought again to be flush with the upper plate. Then we know that the suspension is stretched by a force equal to the weight of W grammes. Now, if the potential of the lower plate is V, and t the distance between the opposed surfaces, V/t is the electric force in the region between the surfaces, and $V/4\pi t$ the measure of the charge on unit area. Hence the force acting on unit area is $\frac{1}{2}V/t \times V/4\pi t$; and finally, if A be the area of the small suspended portion, we have

$$W = \frac{V^2A}{8\pi t^2}.$$

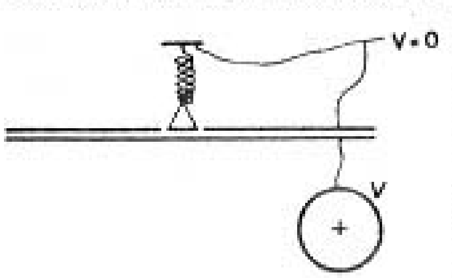

Fig. 13.

In this equation W, A, t are all known, hence V is measured in terms of definite units. In the universally adopted system of scientific dynamic units, we must multiply W by the quantity g, which measures the number of units of force equivalent to the weight of one gramme. Then we find

$$V = t\sqrt{\frac{8\pi g W}{A}}.$$

As a special case, suppose that W is 50 grammes, and A one square centimetre; then, with $g = 981$, we find $V = 1110\,t$, and 88·3 units of charge on the unit area. The unit of charge here referred to is that quantity which when placed at 1 centimetre from an equal quantity will repel it with a force of 1 dyne—i.e. a force which, acting on 1 gramme for 1 second, will increase its velocity by 1 centimetre per second. This quantity is called the electrostatic unit of quantity; and the electrostatic unit of potential is the potential of a sphere of radius 1 centimetre, and charged with this unit quantity.

Generally speaking, except in such obviously symmetrical cases as concentric spheres, infinite co-axial right cylinders, and infinite planes, the surface density will vary from point to point of a conductor, and where it is numerically greatest there also will the electric force close to the surface be greatest. In the case of a simple elongated conductor, the surface density is greatest at the ends. This may be proved very easily by experiment, by, for example, measuring the charge which a very small disc carries away after contact with the conductor. The following reasoning will lead to the same conclusion. Take a uniformly charged sphere in wide space, so that the equipotential surfaces are concentric spheres, and the tubes of force radial cones. If this sphere, by appropriate expansion at right angles to a given diameter, becomes changed into an oblate spheroid, what is the nature of the accompanying change in the surrounding electric field? Let OY be the given diameter, and consider a tube of force symmetrical about any axis OX perpendicular to OY. Let APQB represent this tube of force for the sphere. Along this tube induction takes place, so that the positive charge on PQ would induce an equal negative charge on AXB, if the equipotential surface, of which AXB is a part, were to become a conducting surface. We may express this by saying that the electric displacement across any section AXB of a tube of force is equal to the charge on PQ, the area from which the tube springs. Now let the sphere change form in the manner described, but to such a small extent that no appreciable change is produced at the distance OA. The electric displacement across AXB is therefore the same as before; and, if we follow back the tube of force to the conductor, we shall find the corresponding charge distributed over the area from which the tube springs. But, the conductor being itself an equipotential surface, the lines of force must meet it perpendicularly. Hence, near the deformed conductor, each line of force will suffer a displacement as shown in the figure, where AP' represents the new position of what was originally the line of force AP. Similarly the line BQ will bend inwards to the position BQ'. In other words, the tube of force as it springs from the spheroidal surface P'Q' lies wholly within the tube of equal strength which sprang at first from the spherical area PQ. The unit tubes of force which compose the tube which passes through AB are, therefore, more concentrated in the region P'Q' than they were in the region PQ. Hence, the remaining unit tubes of force which spring from the rest of the conducting surface are, taken as a whole, more expanded over the rest of the spheroid than they were over the rest of the sphere. Thus, the average density over P'Q' is greater than the average density over the rest of the spheroid. Now we may suppose this almost spherical spheroid to become elongated little by little. At every step a readjustment of the lines of force will take place, until at length for a pronounced ellipticity they come into the positions P"A", Q"B". At a far enough distance, however, these lines of force will be indistinguishable from the original positions PA, QB. Hence, the electric displacement across a far-away section of the tube being as before, the charge on P"Q" will be the same as that originally borne by PQ. Thus, the more elongated the ellipsoid becomes, the greater is the relative concentration of charge towards the ends. It may be easily shown that the lines of force springing from P"Q" are branches of a hyperbola confocal with the spheroid, and having PA, QB for asymptotes.

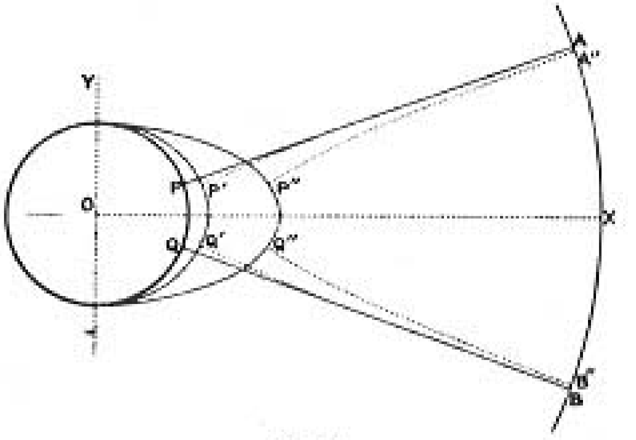

Fig. 14.

This accumulation of electric charge towards the ends of a pointed conductor is well exemplified in the lightning-conductor, which is simply a very elongated piece of metal in contact with the earth. A charged body of air, such as we have accompanying a thunder-cloud, passes near it. The tubes of inductive force are at once concentrated on the elongated conductor; the electric force at the point becomes so intense that the air can no longer act as a perfect insulator; electrical discharge takes place along these very tense tubes of force; and in a more or less gradual manner the cloud is robbed of its charge, and the evil effects of a sudden lightning-flash minimised. On the same principle, electric discharge through air is facilitated by the use of pointed conductors, such as the combs which are so important a detail in machines for generating electricity by means of friction.

We have seen that the capacity of a condenser depends upon the distance between the surfaces or plates which compose it; it also, however, depends very materially on the nature of the dielectric. Suppose, for example, that we have a series of condensers, made of the same conducting material, and all exactly equal as regards their geometrical and space relations, but all differing as regards the dielectric which separates their plates. Thus let one have air as its dielectric, another plate-glass, another paraffin, another mica, and so on. Let them now all be brought to the same potential, then disconnected and tested as to charge. The charges will be found to be all different—being, in the four cases we have mentioned, approximately proportional to the numbers 1, 6, 2, 6·6. These four numbers are the values of what is termed the *specific inductive capacity* of air, glass, paraffin, and mica. Thus by merely inserting a plate of mica between two plates of an air condenser, we increase the capacity by as much as if we had approached the plates in air through a distance equal to ·85 (= 5·6/6·6) of the thickness of the mica. Otherwise, let there be two metal plates, A, B, separated by a thin plate of mica, and on the other side of A let a third equal-sized plate C be so adjusted that when A is charged, the potentials of B and C shall be equal. This can be readily done by severally connecting B and C to the electrodes of the electrometer, as indicated in the figure. Then it will be found necessary to adjust C so that the distance between A and B is about 6·6 times the distance between A and C.

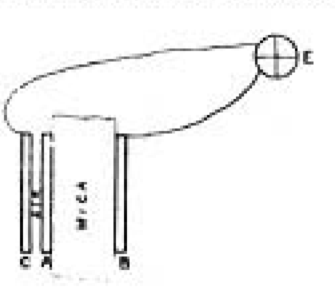

Fig. 15.

We may now fitly consider the principles of action of the various machines that are used for generating electricity. The rubbed pieces of resin, sulphur, glass, &c. were gradually succeeded by spheres, cylinders, and circular plates of these materials, which, as they revolved against prepared rubbers, were kept in a constant state of electrification. Any insulated conductor brought near enough to a portion of such a cylinder or plate at a distance from the rubber will become charged, the dielectric strength of the air breaking down exactly as in the case of the lightning-conductor and the thunder-cloud. Such is the action of the ordinary frictional machine; obviously the conductor acquires a charge similar to that on the revolving cylinder or plate. The opposite charge on the rubber may be transferred to another conductor, which is usually put to earth. Le Roy's or Winter's plate machine is shown in the diagram (fig. 16).

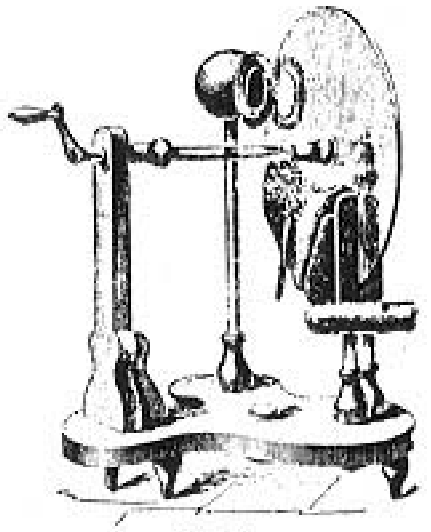

Fig. 16.

Essentially different in its action is the electrophorus, invented by Volta in 1771. In its most improved modern form it consists of two plates, one of metal, and the other of resin, vulcanite, or ebonite backed with metal. Insulating handles can be screwed on to the backs of the plates; and one plate at least must be so insulated. The surface of the ebonite is first electrified by friction, and the metal plate is brought into close contact with it. The metal plate, from its greater proximity to the negatively charged surface of the ebonite, will be at a lower potential than the metal back to the ebonite. If these are then brought into contact—conveniently effected by means of a metal pin passing through the ebonite—a transference of charge will take place, so that the metal plate when lifted away will be found positively charged, while the metal back is left negatively charged. In this machine, the original negative electrification on the rubbed surface of the solid dielectric is used again and again, in accordance with the principles of electrostatic induction and convection, to produce a practically unlimited amount of either kind of electrification.

In Nicholson's 'revolving doubler' we have the parent form of a number of rotatory machines which, like the electrophorus, depend for their action upon induction and convection. They make direct use of the principle of 'doubling' discovered by Bennet, by which the difference of potential between two conductors is indefinitely increased. Thomson's replenisher, which is an important part of the quadrant electrometer in its perfected form, is perhaps the simplest and most compact of these machines. In it, a turning vertical shaft of ebonite bears, at the ends of a horizontal cross-piece of ebonite, two metal pieces called carriers (cc in the diagram, which represents a horizontal section). These carriers rotate in the region between two insulated metal inductors (a, b) in the form of cylindrical segments. When the carriers are in position AB, they come into momentary contact with delicate springs attached to the neighbouring inductors; and when they are in position CD, they come into momentary contact with delicate springs connected by a metallic arc which is quite insulated from the inductors. Suppose a to be at a higher potential than b, and consider what takes place as cc rotates counter-clockwise, as shown by the arrows in the figure. In the position AB, the carriers are well surrounded by the metal shields, and will part with nearly all the charge that may chance to be upon them. Just before they come into contact with the springs in position CD, the two carriers are at different potentials. Hence at the moment of contact with the connecting springs, a transference of charge will take place from the carrier near a to the carrier near b. The former will thus acquire a negative charge, and

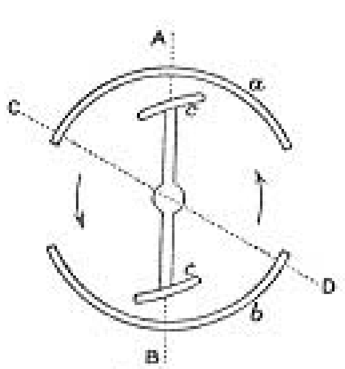

Fig. 17.

will move on till it comes within the inductor *b*, to which it will give up nearly all its negative charge; while the latter will simultaneously give up nearly all its positive charge to *a*. Thus every complete revolution each carrier becomes once negatively charged and once positively charged, giving up its negative charge to the one inductor, and its positive charge to the other. The inductors therefore steadily increase in positive and negative charges, or in other words, their difference of potential steadily grows. If the carriers are rotated clockwise, the opposite effect will take place, *a* acquiring so much negative charge every revolution, and *b* so much positive charge. In the electrometer, *a* is in connection with the charged body, which is suspended inside the quadrants. A very elegant contrivance enables the operator at once to tell if this body is charged to its normal condition. If it is undercharged, a few turns of the replenisher in the proper direction will bring the potential up to its proper magnitude; if it is overcharged, a few turns in the reverse direction will bring the potential down to its required value.

The same principles of induction and convection are made use of in the so-called influence machines, which in recent years have quite eclipsed the older frictional machine. These are generally known by the name of their inventors, such as Töpler, Holtz, Bertsch, Voss, and Wimshurst. Of these, the Wimshurst is the latest, and apparently the most satisfactory. It consists of two circular glass plates, mounted on a common spindle, and capable of rotation in opposite directions with equal speeds. Each plate carries twelve or sixteen strips of thin sheet-metal, fixed radially at regular intervals apart. These strips lie on the outside of the closely opposed glass plates. At the extremities of the horizontal diameter of the plates the main conductors are placed, insulated on glass or vulcanite pillars. Horizontal arms with the usual combs project inwards, embracing both plates as far as the inner ends of the metal strips. In front is fixed a diagonal conductor, called a 'neutralising rod;' and a similar rod is fixed behind at right angles to the one in front. These neutralising rods terminate at both ends in a small metal brush, which touches the metal strips or carriers as they pass. By this contact of brushes and strips, every strip on either plate is, very soon after it has passed under the collecting combs, brought into metallic connection for a moment with the strip diametrically opposite it on the same plate.

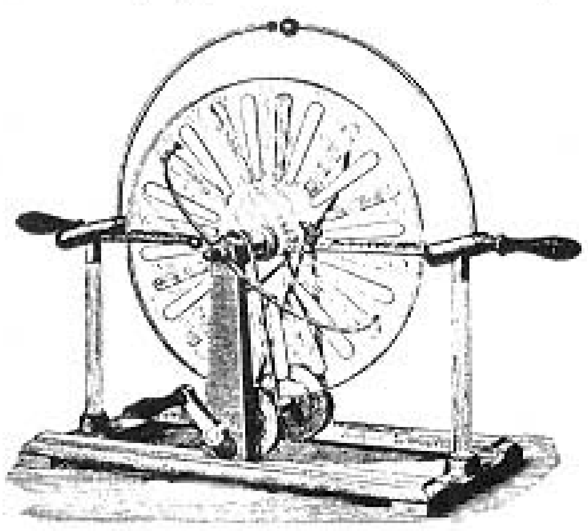

Fig 18.

Suppose the principal conductors to be at different potentials, then—exactly as in Thomson's replenisher—the carriers as they leave the brushes of the neutralising rod will acquire a charge, negative or positive, according as they are nearer the positively or negatively charged main conductor. But, evidently, each carrier on the one plate will act as inductor to the carriers on the other plate; and a moment's consideration will show that this inductive action will everywhere accentuate the inductive action of the main conductors. Thus the positive conductor is being fed by the positive charges brought by the strips on the upper half of the one plate and on the lower half of the other; while the negative conductor is being fed by the negative charges brought by the strips on the lower half of the one plate and the upper half of the other. The main conductors are provided with arms, which reach out towards each other, and between whose terminal knobs discharge takes place. Sparks, 3 to 5 inches in length, can easily be obtained with this machine.

So far we have confined our attention almost entirely to electrostatic phenomena—i.e. to phenomena connected with the existence of a steady electric strain in dielectrics. When compelled to deal with the transference of so-called charge from conductor to conductor, we had regard rather to the initial and final equilibrium conditions than to the intermediate condition of change. This condition of change, however, has clearly very important energy relations. In all cases of electrical discharge there is, in the language of Faraday, a concentration of the lines of force in a certain region of the dielectric, until that becomes, as it were, overstrained, and yields with a more or less evident appearance of part of the energy of strain in the form of light, sound, and heat. The particular manner of transformation into these commoner forms of energy depends on a variety of circumstances, such as the pressure and temperature of the dielectric, the form and relative size of the conductors, and so on. Even if there be no such energy transformations apparent to our senses, it can be shown that any equalisation of potential without increase of total charge necessarily results in a loss of electric energy to the system.

Thus, let there be two insulated conductors of capacities C and C′, originally at different potentials. If they are brought to the same potential V by being connected by a thin wire of comparatively insignificant capacity, the original charges on the conductors will become redistributed, and the final charges will be CV and C′V. Whatever charge the one conductor has lost, the other has gained. Hence we may write the original charges as CV + *q*, C′V − *q*, where *q* is the charge which has been transferred from C to C′. Now the energy of any charged conductor is measured by half the charge into the potential or half the square of the charge divided by the capacity. Thus the final energy, after equalisation of potentials, is:

$$\tfrac{1}{2}CV^2 + \tfrac{1}{2}C'V^2,$$

while the initial energy was

$$\tfrac{1}{2}\frac{(CV+q)^2}{C} + \tfrac{1}{2}\frac{(C'V-q)^2}{C'} = \tfrac{1}{2}CV^2 + \tfrac{1}{2}C'V^2 + \tfrac{1}{2}q^2\left(\frac{1}{C}+\frac{1}{C'}\right)$$

Hence, since $\tfrac{1}{2}q^2\left(\frac{1}{C}+\frac{1}{C'}\right)$ is always positive, we see that the initial energy is necessarily greater than the final energy. The loss of energy is represented by a quantity which is proportional to the square of the charge that has been transferred. If we look more closely into the significance of this quantity, we see that it represents the electrical energy of the system of two conductors of capacities C and C′ when they are charged each with *q* units of either positive or negative electricity; or, more particularly, it represents the work which must be done in carrying *q* units from the one to the other. This is an example of the general principle that the work done by the electric field in compelling a transference or flow of electricity from one region to another is exactly equal to the work which must be done against the electrical forces in carrying an equal quantity of electricity back again.

It is convenient, especially when the flow of electricity is the subject of consideration, to use the term Electromotive Force instead of Difference of Potential. We may suppose it measured by means of the quadrant electrometer. Thus if the regions A and B are connected severally to the electrodes of the electrometer, the deflection will measure the electromotive force acting along any conducting channel which may be supposed to bring A and B into communication. The flow of electricity which this electromotive force compels will tend to bring A and B to the same potential; and in the ultimate vanishing of the deflection on the electrometer we have the evidence of such a flow having taken place. But we may suppose that, by some means, notwithstanding the conducting channel between A and B, their difference of potential is sustained, so that the electromotive force acting along the channel is kept constant. Then the electrometer will show a steady deflection; while at the same time a steady flow of electricity will take place along the channel. This flow, whose existence is indicated only indirectly by the electrometer, must be measured by some one of its direct effects.

These effects are conveniently grouped into physiological, thermal, chemical, and magnetic.

The electric 'shock,' experienced when the experimenter uses himself as a discharging conductor, is a familiar example of the physiological effect of an electric current. The electric discharge causes a muscular contraction. In 1790 Galvani observed that the limb of a frog, when touched simultaneously by two different metals in contact, was convulsed exactly as if subjected to an electric shock; and Volta, following up this observation, discovered in 1800 a new source of electromotive force which could sustain an electric current through a conductor for a lengthened period of time. From this dates the development of Galvanic or Voltaic electricity, or, as it is now more commonly called, current electricity. The electric shock, however, depends upon *variations* in the amount of flow; a steady current produces no shock, except when it is beginning or ending.

In the electric spark there are of course thermal effects; and generally, since, as we have seen, a transference of charge or flow of electricity means a loss of electric energy, an evolution of heat is a necessary consequence.

Towards the close of last century the decomposition of water by an electric discharge was observed by Van Troostwijk and Deiman; while with Volta's electrical discoveries a new era in chemistry as well as in electricity was inaugurated.

None of these effects, however, give a ready method for measuring a steady electric current—i.e. the amount of electricity which is transferred across any section of the conductor in a second, or in any other chosen unit of time. For this we must go to the fourth group—viz. the magnetic effects of currents. This branch of the subject, which includes electro-magnetism, and as a consequence much of electro-dynamics, dates from 1820, when Oersted of Copenhagen discovered the action of a current upon a magnet suspended near it. As a matter of history, the discovery was made by means of voltaic electricity; but that there was some close relation between magnetism and electricity had long been recognised by experimentalists. Lightning had been known to destroy and even reverse the polarity of ships' compasses. Steel and iron had been magnetised by discharging electricity through them; but the effects of such sudden discharges were extremely capricious, and quite baffled all attempts to co-ordinate them. We may, however, by discharging a Leyden jar through a carefully insulated wire suitably coiled round a magnet, show that at the instant of discharge the magnet is displaced.

The broad fact established by Oersted was that every electric current tends to make a magnet set itself perpendicular to the direction of the current. To make the effect specially apparent, the wire conveying the current should be coiled again and again round the region in which the magnet is placed. The same current is thus brought again and again into the vicinity of the magnet, and has a proportionately greater effect. An instrument consisting in this way of a coil of wire surrounding a magnet, free to rotate in some plane passing through the axis of the coil, is called a *galvanometer*. The coiled wire must be covered with gutta-percha, silk, or cotton thread, so that the contiguous coils may be insulated from each other; and, for ordinary purposes, the plane of the coil should contain the magnet when no current is flowing. We may suppose the magnet to be suspended horizontally under the influence of the earth's magnetic field; then the plane of the coil should contain the magnetic meridian (see MAGNETISM). The ends of the coiled wire are called the terminals of the galvanometer. When they are connected to conductors at different potentials, a current will flow round the coil of wire, and will indicate its presence by compelling the magnet to move out of its normal position of equilibrium. The tendency of the current in the coil is to make the magnet turn itself at right angles to the plane of the coil—i.e. to set itself along the axis of the coil, magnetic east and west. But this is resisted by the steady action of the earth's magnetic field. The result is a compromise, and the magnet is deflected from its normal position in the magnetic meridian through an angle which depends on the relative values of the current and the earth's magnetic force. Since the latter is practically constant, the angle of deflection will depend on the value of the current, being greater for the greater current. It is not our purpose under this heading to enter into the magnetic relations of currents. For that we refer to MAGNETISM. It is sufficient at present to know that in the galvanometer we have an instrument which can measure current, exactly as in the electrometer we have an instrument which can measure difference of potential or electromotive force.

In discussing the equalisation of potential in electrostatics, we purposely confined our attention to one metal only. The reason was simply because, in general, two different metals, or in fact any two different conductors, can never when in direct contact be at the same potential. The discovery of this fact we owe to Volta. Take, for instance, any four conductors BAXB, put them in series as in the figure, and connect the terminal members, which are of the same material, to the electrometer. According to the character of the conductors AXB, there may be, or there may not be, a deflection on the electrometer.

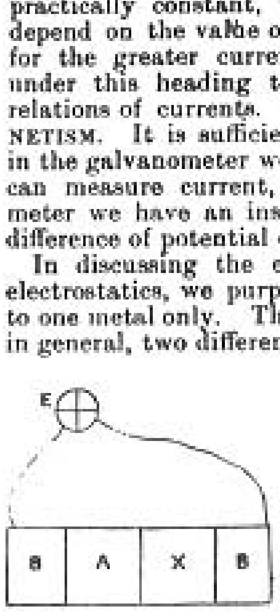

Fig. 19.

(1) If there is no deflection, the two B's are at the same potential; and yet, according to Volta's discovery, the three different substances are at different potentials. This may be shown at once by breaking the chain at any of the separating surfaces, when a deflection on the electrometer will be observed. During this act of separation, the separating surfaces, one of which must of course be kept insulated, act like a condenser with a constant charge, the difference of potential changing because the capacity is changing. The reason why the B's are at the same potential is that, whatever be the differences of potential between B and A and between A and X, the difference of potential between X and B is always such as to restore B to its original value. Thus if the separation of B and A gives a deflection of 20 to the right on the electrometer, and the separation of A and X gives a deflection of 8 to the left, the separation of X and B is found to give a deflection of 12 to the left.

(2) If, however, there is a deflection produced on the electrometer, then we know that the two B's must be at different potentials, so that, if we connect them by wires to the terminals of the galvanometer, a current will be observed to flow. Such a combination of materials, in which two conductors of the same material are kept at different potentials by being linked together by at least two other and different materials, is called a voltaic or galvanic cell. If we join the two terminals either directly or by means of any other simple conductor, a current will necessarily flow round the circuit. But this current means a transference of charge from one conductor to another at a lower potential —i.e. a loss of electrical energy which is proportional to the square of the quantity transferred. Hence, if, as is practically the case, the electromotive force or difference of potential remains fairly steady, it must be because electrical energy is supplied as fast as it is being lost. Consequently there must be in the circuit somewhere an original source of energy. In fact it is found that a permanent electromotive force of the kind just described is always associated with a tendency to chemical action between two at least of the members of the chain; and that, when the circuit is complete and the current is flowing, chemical changes are going on within the cell. In this case, also, we may, by separating the chain at its various surfaces, show that at every surface there is an electromotive force of contact sustaining a difference of potential. But whereas, in the former case, the algebraic sum of all the differences of potential between the successive pairs of materials as we pass along the chain from B to B vanishes identically, in the present case it has a finite value, which is the total electromotive force of the combination as measured on the electrometer. A combination of two or more voltaic cells is commonly called a voltaic or galvanic battery.

There are innumerable forms of voltaic cells, built up in different ways of different materials. Copper and zinc dipping into dilute sulphuric acid is one of the simplest forms. When the cell is *closed*—i.e. when the copper and zinc are joined externally by a wire, a current will be obtained flowing in the wire from the copper to the zinc. At the same time the zinc will be dissolved in the acid; and it is from the energy set free by this chemical action that the electrical energy is derived. Such a single fluid cell is not, however, very steady in its action. We shall therefore take as a type of a good cell one of the class known as two-fluid cells; and of these we shall choose the Daniell cell. In its best form, the Daniell cell consists of copper and zinc plates dipping into saturated solution of sulphate of copper and semi-saturated solution of sulphate of zinc respectively—the liquids being also in contact but prevented from mixing by a porous septum. Connect the copper and zinc plates, or *poles* as they are technically called, to the electrometer. A deflection will be produced which will measure the electromotive force of a Daniell cell when it is not being used for the production of currents—i.e. when it is *open*. We shall take this, provisionally, as our unit electromotive force, and we may suppose the electrometer scale graduated so as to show unit deflection when the poles of a Daniell cell are connected to the electrodes of the electrometer. The deflection is such as to indicate that the electrode connected to the copper is at the higher potential. Hence the copper is spoken of as the positive pole, and the zinc as the negative pole.

Take now a second Daniell cell, connect its zinc to the copper of the first one, and connect the free poles to the electrometer. The electromotive force of the two cells so joined will be double that of one —i.e. equal to 2. And generally, when a number of cells are arranged in series (i.e. with the zinc of the first joined to the copper of the second, the zinc of the second to the copper of the third, and so on), the electromotive force of this battery, in terms of the electromotive force of one cell, is just the number of cells composing it. Theoretically there is no limit to the electromotive force obtainable by means of cells; practically the difficulty consists in keeping a large number of cells in good condition. With a large enough battery we can obtain effects in every way analogous to the effects produced with frictional electricity. The electric light in its earliest form was obtained between carbon terminals joined to the poles of a large battery of cells. Generally speaking, however, the differences of potential in electrostatic experiments are much greater than the electromotive forces commonly used in experiments with electric currents. Thus, the electromotive force of a Daniell cell is very much smaller than the electrostatic unit of potential as measured on Thomson's absolute electrometer in the manner previously described. It would require a battery of about 278 Daniell cells set in series before the electrostatic unit of potential could be obtained; and it would require the use of about 10,400 cells in series to compel a spark to pass directly between two parallel plates connected to the poles and distant one-third of a centimetre from each other. With such comparatively small electromotive forces many substances can be used as insulators in current electricity which are fairly good conductors in electrostatics.

If, at the same time that the poles of a cell are connected to the electrometer, they are connected by stout short wires to the terminals of the galvanometer, the galvanometer needle will be deflected, while the electrometer deflection will be unchanged, or at the most diminished slightly. If thin long wires are substituted for the thick short connections, a very great diminution will be observed in the galvanometer reading, and perhaps a very slight increase in the electrometer reading, the apparent electromotive force of the closed cell approximating more closely to the electromotive force of the open cell. Thus, we may alter the current at will by employing different lengths and different thicknesses of wires for transmitting the current; and yet the electromotive force between the poles of the cell is but slightly if at all affected. In other words, the current, as measured on a galvanometer, depends not only on the electromotive force acting along the channel, but upon some property of the channel itself—some property independent altogether of electromotive force.

This property we may indicate by either of two words—viz. Conductivity or Resistance. These words denote contraries. Thus, a body of small conductivity has a great resistance; and a body of low resistance has a high conductivity. Quantitatively, the one is the reciprocal of the other; and they are measured in terms of current and electromotive force by what is known as Ohm's Law. We now know (see *The Electrical Researches of the Hon. Henry Cavendish*, edited by Maxwell, 1879) that Cavendish had in 1781 established this law, and compared the resistances of iron wire and various saline solutions to electric discharge through them. He acted as his own galvanometer, and compared discharges by their 'shocks.' As regards the historical development of the science, however, it is to Ohm that we owe the full statement of the Law (1827). Since his day it has been subjected to the severest experimental tests that the scientific mind could imagine, and has stood them all. It is really the basis of our whole system of electrical measurements; and is to electric currents what the law of gravitation is to planetary motions. Ohm's Law asserts that the resistance of a conductor is measured by the ratio of the electromotive force between its two ends to the current flowing through it. Thus, if E is the electromotive force as measured on the electrometer, and I the current as measured on the galvanometer, and if K, R measure the conductivity and resistance respectively, Ohm's Law gives us these relations:

$$EK = I, \quad E = IR.$$

The Law is purely empirical. Assuming its truth, we shall here deduce from it certain relations, which experiment accurately verifies.

The peculiar value of Ohm's Law lies in the fact that the property designated resistance, though measured in terms of electromotive force and current, is absolutely independent of them. Hence so long as the physical condition, and therefore the resistance, of each conductor remains unaltered, the currents in any system of conductors are proportional to the electromotive forces; steady currents imply steady electromotive forces; steady electromotive forces imply steady currents. And thus, if the potential at one point is steady, the potentials at all other points will be steady; and this means that whatever quantity of electricity flows into a point must flow out again—for otherwise there would be a gain or loss of charge at that point, and therefore a change of potential, which is not contemplated. In the particular case of a single circuit, it follows that the current is the same at every part of it, and must therefore be regarded as flowing through the Daniell cell from the zinc to the copper, as well as through the rest of the circuit from the copper to the zinc.

If a steady current is flowing along a conductor of one kind of material, say a copper wire, the potential will fall off continuously as we pass along in the direction of the current. Let AB be the wire, and suppose the current to be flowing from A to B. Join B to one electrode of the electrometer; and let a wire from the other electrode be led to any point P on the wire. Then as the point of contact P is moved up towards A, the electrometer deflection will increase continuously. Even though AB is not all of one material, the same steady growth of the electrometer deflection will be shown as the point P is made to travel from B to A. Thus suppose AC to be zinc, and CB to be copper, and no current to be flowing; then according to Volta's discovery the potential, otherwise constant, will undergo an abrupt change at the surface of separation at C. But, as we have seen, the brass quadrants of the electrometer will not on this account be at different potentials, even though P lies in AC. Hence, if any difference of potential *shows itself on the electrometer*, it must be because a current is flowing along AB. Thus we may extend Ohm's Law to heterogeneous circuits.

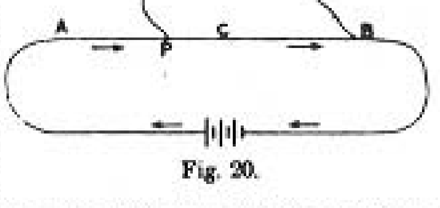

Fig. 20.

The measurement or, more strictly, comparison of resistances is one of the most important operations in the modern science of electricity. For this purpose we first choose a certain standard, say a particular length of a particular piece of wire at a certain temperature. It is obviously convenient to have a standard which can be exactly reproduced should the first standard be lost or in any way damaged. Hence scientific men of all nations have agreed to use as the unit of resistance the resistance of a column of pure mercury 106 millimetres long, 1 square millimetre in cross-section, at the temperature of melting ice. This is called the *legal ohm*. It differs very slightly from the theoretic ohm, which is defined in terms of what are called the electro-magnetic units of current and electromotive force. See MAGNETISM.

Such a mercury standard, though fulfilling the very necessary condition of accurate reproduction, is not convenient for practical use. For this purpose copies of the ohm must be made in solid wires of some metal or alloy. German silver has long been a favourite substance for making such practical standards; and of late a somewhat similar alloy called *platinoid* has come into use. Ohm's Law at once suggests a method for copying the standard mercury ohm. First, let the mercury column be included in a circuit with a given battery and galvanometer, and the deflection on the galvanometer noted. Second, let the mercury column be replaced by a wire, and the length of the wire adjusted till the galvanometer shows the same current. Then, provided that the electromotive force of the battery is the same in the two cases, the resistance of the substituted length of wire is 1 ohm. We may obviously construct an indefinite number of such copied standards.

If we put any number of these single ohms end to end in series, we shall get a whole resistance equal to as many ohms as there are conductors. This is an immediate consequence of Ohm's Law. For since it is the same current that is flowing through all the single ohms, the fall of potential as we pass from beginning to end of any one is the same for all; hence, the fall of potential as we pass along, say, three is three times the fall as we pass along one; hence, the current being the same for the three as for the one, the resistance of the three must be 3 ohms. A special case of this is that the resistance of a wire, otherwise constant in its physical relations, is directly as the length. The completely general statement is that the resistance of any single continuous channel is the sum of the resistances of its parts.

Suppose, however, that the single ohms are so arranged that they all begin at one point, A, in the circuit, and end at another point, B. Then it is clear that they must all be traversed not by the same current, but by equal currents. Hence, there will flow into A and out of B a current equal to the sum of all these equal currents. Thus, if there are, say, three single ohms connecting A and B, the total current flowing into A and out of B must be three times the current flowing in any one of the branches. But for constant electromotive force the current is directly as the conductivity, or inversely as the resistance. Hence, the conductivity of the threefold conductor between A and B is three times the conductivity of any one of its components; or, otherwise, the resistance between A and B is one-third of an ohm. Here, again, as a special case, we find that the resistance of a wire, otherwise constant in its physical relations, is inversely as the area of its cross-section. The completely general statement is that the conductivity of a multiple channel whose branches all begin at one point and end at another, is the sum of the conductivities of the branches. These multiple-arc arrangements, as they are technically called, are of peculiar value in all electrical investigations and applications. Cavendish, who states the law of the double-branch circuit with particular accuracy, was the first experimenter who used the arrangement. By discharging a Leyden jar through a branch circuit consisting of an iron wire and his own body he obtained a certain sensation, which he compared with the sensation produced when a column of salt water was substituted for the iron wire. By adjusting the length of the salt-water column until the two shocks felt equally intense, he had data from which a comparison of the resistances of iron and salt water could be made. This comparison Cavendish gave in a paper published in 1776, without, however, giving his method of experiment, which lay hidden in the unpublished manuscripts for fully a century. His result was that iron conducts 555,555 times better than saturated solution of salt, a result in remarkable agreement with modern galvanometer measurements. In comparing resistances of *materials*, we must find the resistances of portions which have the same length and the same cross-section. The results given above, connecting the measured resistance of a conductor with its dimensions, enable us to effect this comparison without difficulty. Thus, if r is the resistance of a wire of length l, and cross-section s, the quantity rs/l evidently measures the resistance of a wire of unit length and unit cross-section. If the unit length is a centimetre, and the unit area a square centimetre, the quantity which measures this resistance is called the *specific resistance* of the material. The substance which has the smallest specific resistance is the best conductor of electricity. The best conductor is silver; but copper is nearly as good. The specific resistance of iron is nearly six times that of copper, and that of mercury nearly sixty times.

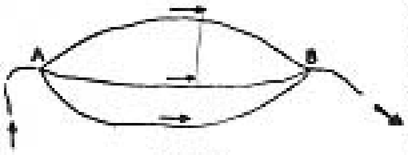

Fig. 21.

In Cavendish's experiment just described, the iron wire acted as a *shunt* in the circuit of jar and body; for the resistance of the iron wire was much less than the resistance of the body. Hence, the discharge through the wire was proportionately greater than the discharge through the body. In a double-branch circuit the current divides itself into two parts, which by Ohm's Law must be directly as the conductivities of the branches. If we put the galvanometer in one of the branches, we may, by adjusting the resistance in the other branch, vary the current in the galvanometer through a very large range, while the total current supplied by the battery remains constant. Let AB be a wire of unit resistance, forming part of a circuit; and let the points AB be connected to the terminals of the galvanometer, whose resistance we shall suppose to be very great compared to the resistance of the wire AB, say, 5000 ohms. If i is the current as measured on the galvanometer, 5000 i is the electromotive force acting along AB; and this multiplied by the conductivity of the double-branch portion lying between A and B will give the total current entering at A and leaving at B. The conductivities are 1 and $\frac{1}{5000}$ respectively, so that $\frac{5001}{5000}$ is the conductivity of the whole; and, hence, 5001 i is the total current supplied by the battery. Suppose, now, that instead of connecting the galvanometer terminal with B, we connect it with B′, where BB′ represents another ohm of resistance. Then if i' is the current in the galvanometer, we have 5000 i' as the electromotive force between A and B′. The conductivity of the double-branch portion is now $\frac{1}{2} + \frac{1}{5000}$, i.e. $\frac{2501}{5000}$; hence, the current supplied by the battery is 2501 i'. But in almost all cases of importance—except when extremely accurate results are wanted—the fourth significant figure in any number is negligible. Indeed, very few galvanometers can be trusted to measure currents to such an extreme of accuracy. Hence, the resistance of the whole circuit is practically the same so far as the possible measurement of current is concerned—i.e. the currents 5001 i and 2501 i' are equal; and, hence, to the degree of approximation stated $i' = 2i$. In short, the galvanometer of high resistance used in the way just described, in which the main current is shunted through a comparatively small resistance, really measures the electromotive force between the ends of the shunt. For many purposes we may use such a high-resistance galvanometer instead of the electrometer.

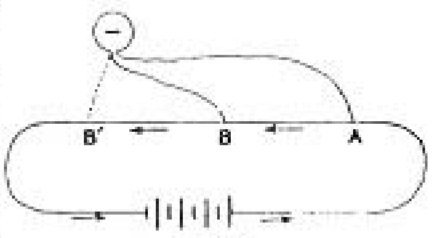

Fig. 22.

From what has just been said regarding the accuracy to which a galvanometer deflection may be read, it is evident that if the comparison of resistances depended on the *measurement* of current, it would be impossible to compare resistances to any very great degree of accuracy. The comparison of resistances may, however, be effected by the method known as the Wheatstone bridge, without so much as a single measurement of either electromotive force or current.

Consider the case represented in fig. 23, in which the current from a battery is made to flow along two distinct channels from A to B. Along each the potential falls from its value a at A to its value b at B. Hence, for any point P in the one branch there must be a corresponding point Q in the other which has the same potential, v, say. Let the points P and Q be joined to the terminals of the galvanometer, G. Because of the equality of the potentials at P and Q, no current will flow through the galvanometer, however strong the currents may be in APB and AQB. Thus, as no current flows between P and Q, the current in AP must be the same as the current in PB, and the current in AQ must be the same as the current in QB. Hence, by Ohm's Law, the resistances of AP and PB must be proportional to the electromotive forces acting along them—i.e. in the ratio $(a - v)/(v - b)$. Similarly the same ratio expresses the ratio of the resistances of AQ and QB. Thus the existence of no current in the galvanometer circuit—a condition which admits of the most delicate of tests—implies that the resistances of the four branches AP, AQ, PB, QB form a simple proportion, any one forming the fourth proportional to the other three properly taken. Two equal lengths cut off from a fairly uniform wire may be assumed to have approximately equal resistances. Let them be the branches AP, AQ. Let PB be the standard ohm. Then, by adjusting the length QB of a given wire till no current flows through the galvanometer, we obtain a copy of the ohm, accurate if the resistances AP and AQ are really equal to each other. Suppose, however, that they are not quite equal, but that AP/AQ is equal to $1 + \omega$, where ω is usually a small quantity, and that therefore AQ/AP $= 1/(1 + \omega)$. Let l be the length of wire required in QB when the standard ohm is in PB, so as to satisfy the condition of no current in PQ; and let l' be the length of the same wire required in PB when the standard ohm is in QB, so as to fulfil the same condition. The lengths l and l' will differ so slightly that we may assume them to be accurately proportional to their resistances. If L is the length of wire whose resistance is accurately 1 ohm, then evidently

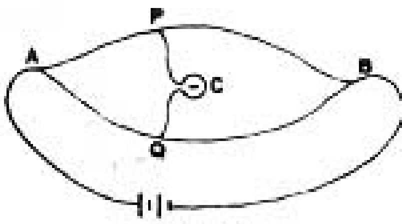

Fig. 23.

$$l = \mathrm{L}\,(1 + \omega)^{-1},\; l' = \mathrm{L}\,(1 + \omega);$$

and hence, multiplying we find

$$ll' = \mathrm{L}^2;$$

or the length of wire whose resistance is 1 ohm is the geometric mean between the lengths whose resistances balanced the standard ohm in the two cases described. This discussion is an illustration how, from a first approximation, a second and much closer approximation can be obtained.

To facilitate operations in the measurement of resistance, it is expedient to construct a series of graded resistances, which are multiples and occasionally submultiples of the chosen unit of resistance. We may obtain, in the manner just described, any number of copies of the ohm. Then, by putting two in series in the one arm of the Wheatstone bridge, we can measure off a piece of wire having a resistance of 2 ohms; and so on, step by step, we can measure off lengths of suitable wires whose resistances will be any imaginable number of ohms. Again, by putting in the arms AP, AQ very different resistances, say 10 ohms and 1 ohm, we can construct resistances of fractions of an ohm—e.g. if PB is 1 ohm, QB will be the tenth of an ohm. For such fractional resistances thick wires or many strands of thin wires in multiple arc must be used. For the higher resistances thin wires are convenient. Suppose we have, in this way, constructed resistances having the values 1, 2, 3, 4, 10, 20, 30, 40, 100, 200, 300, 400, 1000, 2000, 3000, 4000, 10,000, 20,000, 30,000, 40,000; then we may by proper combination express any integral number of ohms from 1 up to 100,000. Thus, the resistance 7956 is built up of 4000, 3000, 400, 300, 200, 40, 10, 4, 2. There are several ways in which these twenty resistances can be arranged so as to admit of rapid combination of any required number. Such an arrangement is called a box of resistance coils, or simply a resistance box. It is an indispensable part of the apparatus of a physical laboratory.

We have already seen that the passage of an electric current means a loss of electric energy. What becomes of this energy—i.e. into what other form is it transformed—is a question which requires to be answered. The answer was fully given by Joule of Manchester in a magnificent series of experiments on the heating effects of electric currents. It was early recognised that the electric current and electric discharge had a heating effect on the conductor along which the current flowed or the discharge took place. As early as 1801, very soon after the discovery of voltaic electricity, Wollaston exhibited before the Royal Society the glowing of a thin wire joining the poles of a cell. To Joule, however, we owe the complete statement of the irreversible heating effects of currents. In 1840 he published the important result that 'when a current of voltaic electricity is propagated along a metallic conductor, the heat evolved in a given time is proportional to the resistance of the conductor multiplied by the square of the electric intensity.' The heat so evolved fully accounts for the electric energy lost. Suppose we have an electromotive force E driving a current I through a resistance R. E is the measure of the work done in transferring unit of electricity along the channel. Now I is the amount of electricity transferred in a second of time. Hence the product EI measures the work done per second by the electromotive force in driving the current I. But by Ohm's Law

$$EI = RI^2;$$

and this is the very quantity which Joule showed appeared as heat in the wire. Here evidently we have a thermal method for comparing resistances. Set the various conductors in series, so that they are traversed by the same current. Then the resistances are proportional to the heats developed in them. To measure the heats so evolved we must know the rise of temperature and the thermal capacity of each conductor.

If a very thin wire forms a part of a circuit, it is there that we shall best observe the effect of the heating. For the heat evolved per unit length of any conductor is directly as the resistance—i.e. inversely as the cross-section. But, with the circuit all of one material, the rise of temperature is directly as the heat evolved and inversely as the mass heated; and the mass per unit length is directly as the cross-section. Thus the rise of temperature is inversely as the square of the cross-section—i.e. inversely as the fourth power of the diameter.

This is the principle of construction of the incandescent electric lamp, now so common a source of illumination (see ELECTRIC LIGHT). A thin filament of carbon is made to glow by the passage of a powerful current along it. To prevent the 'burning' away of the carbon in air, it is inclosed in a hermetically sealed glass vessel quite empty of oxygen.

As an example of the magnitude of the Joule effect in a conductor of given resistance traversed by a given current, let us take a resistance of 10 ohms, along which the electromotive force is equal to that of one Daniell cell, then the heat evolved in an hour will be about 100 gramme-degree units of heat—i.e. an amount of heat capable of raising the temperature of 100 grammes of water by 1° centigrade.

So long as we are dealing with metals or simple conductors like carbon, the currents derived from the Daniell cells in the circuit do not appreciably change in value from the first instant onwards for several hours. If the currents are powerful enough, there will be slight diminution during the first few minutes, due to the heating of the conductors; for the resistance of nearly all metals increases with rise of temperature. But this effect will not in general be appreciable.

A very different set of phenomena confronts us when we introduce into the circuit a conductor like a solution of sulphuric acid, or of any sulphate, or indeed any ordinary chemical compound, either in solution or in a state of fusion. Such conductors can transmit currents only at the expense of their constitution; or, in the words of Faraday, in them 'the power of transmitting the electricity across the substance is dependent upon their capability of suffering decomposition.' Such substances—the whole terminology of the subject was introduced in 1834 by Faraday—are called *electrolytes*; the conductors by which the current enters and leaves the electrolyte, the *electrodes*; and the whole process by which chemical compounds are decomposed by means of electric currents is named *electrolysis*.

Take, for example, a dilute solution of sulphuric acid nearly filling a glass vessel. Dip into this electrolyte two platinum strips, some little distance apart and not touching. These are the electrodes; and it is important in such an experiment to choose as electrodes materials for which the electrolyte has no chemical affinity. In this respect platinum is, over all, by far the most satisfactory. Now connect the one platinum strip to one pole of a Daniell cell, and the other to one of the terminals of the galvanometer. The other terminal of the galvanometer and the other pole of the cell may be connected at will, so as to complete the circuit. When in this way the circuit is completed, a current will be observed flowing through the galvanometer; but this current will very soon become extremely feeble, and, even though it may not altogether vanish, will produce no continuous decomposition of the fluid. Let now a second Daniell cell be added as shown in fig. 24, where B is the battery of two Daniell cells, G is the galvanometer, and C is the electrolyte. Then the galvanometer will indicate the existence of a pronounced current, which during the first few moments will fall considerably below its original intensity, but will ultimately reach a steady value. At the same time small bubbles of gas will appear at the surfaces of both electrodes, and will form steady ascending streams in the electrolyte. These products, or *ions* as Faraday called them, may be collected in separate vessels, as shown in fig. 27, where the gases accumulate at the top of test-tubes inverted over the electrodes, gradually pushing out the liquid which at first filled these tubes. It will be noticed that the volume of gas given off from the one electrode is twice that given off from the other; so that if the test-tubes are exactly the same size, the one will become quite emptied of liquid when the other is only half-emptied. The greater volume of gas accumulates over the electrode by which the current leaves the electrolyte. When tested, the gas which comes off in greater quantity will be found to be hydrogen, and the other oxygen. In fact we have here separated from one another the constituents of water—H_2O. We may therefore say that, whatever the intermediate stages of the process may be, the final result of passing a current through dilute sulphuric acid is to decompose water.

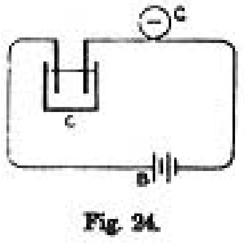

Fig. 24.

The characteristic points to be noticed here are that one Daniell cell cannot decompose water; that when two or more are used, the current markedly falls off in intensity during the first few moments; and that, when the current has become constant, steady streams of bubbles of gas ascend through the liquid from the surfaces of the electrodes, and from them only. These are some of the characteristics peculiar to electrolytic conduction; and, when present, any one of them is sufficient to distinguish an electrolyte from a simple conductor. We shall discuss them more fully in order.

(1) Exactly as one Daniell cell cannot decompose one electrolytic cell of dilute acid, so two Daniell cells cannot decompose two electrolytic cells. Take, for example, a trough filled with dilute acid, and forming with its platinum electrodes one long electrolytic cell, C, which is traversed by a current from two Daniell cells, B. A distinct deflection will be observed on the galvanometer, G, and the ions will be given off at the electrodes. Now, let a platinum plate, P (shown dotted in fig. 25), of exactly the breadth of the trough be inserted somewhere between the electrodes, and pushed down till it comes into close contact with the bottom of the cell. Very soon the current will die away, or only a very feeble one will remain, which Von Helmholtz has shown to be due to the presence of free gases dissolved in the electrolyte. There will, however, be no continuous production of ions at the electrodes, even in cases in which this feeble current has not been eliminated. The reason is simply that by so partitioning an electrolytic cell we really make it into two. To obtain distinct decomposition in these two cells we must use four Daniell cells in series; and then we should observe the ions given off not only at the terminal platinum plates, but on both sides of the partition plate. Thus it appears that the process of electrolysis is not merely a question of current, but also a question of electromotive force.

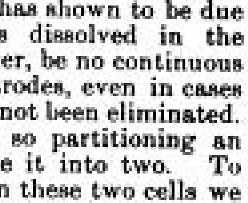

Fig. 25.

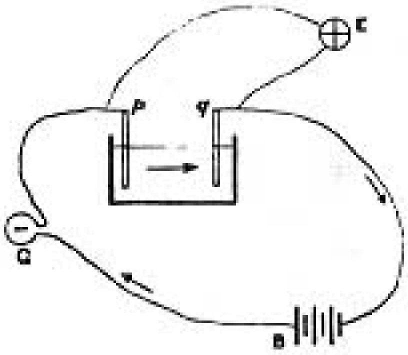

Fig 26.

(2) To study more closely the second point indicated, take two platinum strips *p*, *q*, thoroughly cleaned by heating in a flame to bright redness, dip them into the electrolyte, and connect them to the electrometer. The electrodes being both clean, platinum will have the same contact electromotive force with the electrolyte, so that they will be at the same potential. Hence the electrometer will show zero deflection. Now put the electrolytic cell in circuit with the galvanometer and a battery of two or more Daniell cells; and suppose the current to flow from *p* to *q* through the electrolyte. Then it may be observed that, as the current through the galvanometer falls off during the first stages, the difference of potential between *p* and *q* as measured on the electrometer increases. If we apply Ohm's Law to the portion between *p* and *q*, we see at once that the ratio E/I has considerably increased. This ratio, which for simple conductors measures the resistance, we shall speak of as measuring the Impedance. Impedance in fact is a more general term, synonymous with resistance for steady currents through metals and simple conductors, but including other quite distinguishable properties when electrolytes are the conductors, or when the current is variable. It should be mentioned that during these early changes in current and distribution of potential the temperature of the circuit has not appreciably altered, so that we are precluded from explaining the effect as due to increase of resistance in virtue of rise of temperature.

After the current has become steady, let the circuit be broken. The galvanometer needle will swing back to zero; but the electrometer needle will swing back only a certain distance, and then continue slowly and more slowly back towards zero. Thus, after the current from the battery has ceased to flow, the electrodes in the electrolytic cell remain at different potentials, and will remain so for an indefinite period. This phenomenon is called the Polarisation of the Electrodes. From being in a state of electrical identity these electrodes have been brought, simply through the agency of a current, into a condition of electrical dissimilarity. In other words, the electrolytic cell has virtually become a voltaic cell; the electrodes have become poles at different potentials.

Let now the polarised cell be joined up in circuit with the galvanometer—i.e. let a wire be set in where the battery at first was. The electrode *p* being at a higher potential than the electrode *q*, a current will flow from *p* to *q* through the galvanometer, and from *q* to *p* through the cell—i.e. in a direction contrary to the direction of the current which first circulated in the circuit. As this current flows, the deflection on the electrometer will rapidly fall off, until very soon the potentials of *p* and *q* will be practically equalised, and the current will disappear. Thus although, because of the polarisation of the electrodes, the electrolytic cell has at first all the virtue of a voltaic cell, this virtue is rapidly lost when it is used as a source of current, for there is nothing to sustain it.

In this polarisation of the electrodes we have one explanation of the increased impedance of the cell. As soon as the current from an external source begins to pass through, decomposition begins in the electrolyte. The ions accumulate on the platinum electrodes, which become coated with oxygen and hydrogen gases. They are no longer platinum, platinum, dipping in an electrolyte; but oxygenised platinum, hydrogenised platinum, dipping in the same. Of these the latter is eminently oxidisable, just as the zinc is in, say, a simple platinum zinc voltaic cell. Hence the hydrogenised platinum, which is that by which the original current left the electrolyte (*q* in fig. 26), behaves like the zinc in an ordinary cell, but behaves like the zinc only so long as it is hydrogenised. When, then, the polarised electrolytic cell is included in a circuit otherwise free of electromotive force, a short-lived current will flow at the expense of the electromotive force of polarisation, its energy being derived from the reunion with their appropriate associates in the water molecule of the oxygen and hydrogen clinging to the platinum electrodes. We may express the result very simply in symbols, thus: Let E be the electromotive force acting round the circuit, r the resistance of the electrolytic cell *when there is no polarisation*, s the resistance of the rest of the circuit (galvanometer, battery, and connections). Then if I be the initial value of the current before polarisation sets in, we have, by Ohm's Law,

$$I(r + s) = E.$$

But at once polarisation begins, and the reversed electromotive force due to it more or less quickly attains its maximum value e. If J is the final value of the current, we have, by Ohm's Law,

$$J(r + s) = E - e,$$

in which E and r are supposed to be the same as before. Evidently J is less than I. Again, if we write the quantity e in the form Jk, where k measures something of the nature of resistance, we may at once transform the equation thus:

$$J(k + r + s) = E.$$

The quantity $(k + r)$ measures the impedance.

The unavoidable production of this reversed electromotive force due to the polarisation of the electrodes is a great hindrance in the way of measuring the true resistance of electrolytes. If we put an electrolytic cell into one arm of a Wheatstone bridge, and operate as we do in the case of simple conductors, we should measure the impedance, not the resistance. Suppose, however, that we have in some thoroughly satisfactory manner measured the true resistance, which perhaps might be best defined by Joule's Law in terms of the heating effect of a given current in a portion of the electrolyte far removed from the electrodes, even then we should be in doubt as to the true significance of the rest of the so-called impedance. We see that the electromotive force of polarisation explains a part; but does it explain all? Its existence depends on the accumulation of the ions at the electrodes, and it is quite conceivable that the existence of such accumulations may mean an extra resistance in the true sense of the word.

(3) We pass now to the consideration of the ions themselves. As we have seen, the electrolysis of dilute sulphuric acid results in the appearance at the electrodes of oxygen and hydrogen. The oxygen is given off where the current enters the electrolyte, and the hydrogen is given off where the current leaves the electrolyte. A very simple experiment will show that the amount of water decomposed in a given time is proportional to the current as measured on the galvanometer. Suppose, for instance, that with two Daniell cells in the circuit, the test-tube over the negative electrode in the electrolyte fills with hydrogen in 20 minutes. Then, if four Daniell cells are put in circuit, and the external resistances slightly adjusted so as to make the galvanometer indicate double the former current, the test-tube will be filled with hydrogen in 10 minutes. With six cells, and three times the original current, the tube will be filled in 6⅔ minutes, and so on. Thus we may compare currents by the quantities of a given electrolyte which they decompose in a given time. Faraday's voltameter, as shown in fig. 27, is intended for this purpose. As compared with a galvanometer, the voltameter has the obvious disadvantage that it cannot measure a current at once, but only after the current has been flowing for some time. Hence it measures only the average current during this time; so that unless we know the current to be very constant we cannot draw sure conclusions from the indications of the voltameter. Then, again, there are other sources of error which must be guarded against if anything like accurate results are desired. Thus, in Faraday's voltameter, the gases, as they collect in the test-tubes, are at somewhat diminished pressures in the early stages, so that their volumes do not grow quite proportionately with their masses. But a greater source of error lies in the fact that all the gas given off does not collect in the tubes. Some remains dissolved in the fluid, and this is specially true of the oxygen, which, besides, comes off partly in the denser form of ozone; and some (as the phenomenon of polarisation shows) remains clinging to the electrodes. For ordinary purposes, however, the volume of hydrogen given off in a given tube is a fairly accurate measure of the current effecting the decomposition, and may be used for gauging galvanometers—i.e. for finding what deflection corresponds to the chosen unit of current. For that purpose we must know how much water a unit current can decompose. Now, as proved by Faraday, equal currents decompose equal quantities of a given electrolyte in equal times—i.e. wherever and whenever one milligramme of water is decomposed in one minute by a particular current, that current has a definite absolute value. The numerical measure of it will depend of course on the particular units of length, time, and mass which are adopted as the fundamental units (see UNITS). It is evident, then, that electrolysis gives us a means of measuring a current in terms of a quantity of matter decomposed. To obtain absolute measurements of currents with a galvanometer we require to know the magnetic field in which the galvanometer needle hangs, and the dimensions and arrangement of the coils of wire constituting the galvanometer; but for absolute measurements of currents by means of electrolysis we have to do only with measurements of mass.

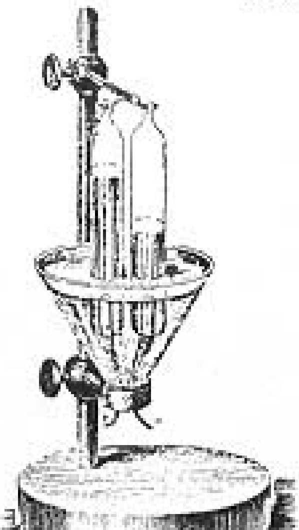

Fig. 27.

Now, not only is the amount of any electrolyte decomposed proportional to the strength of current used, but the amounts of different electrolytes decomposed by the same current have a definite numerical relation to one another—a relation which Faraday showed to have a most essential connection with the known laws of chemical combination.

Let us take, for example, three electrolytic cells—the first, an ordinary voltameter with dilute sulphuric acid as electrolyte; the second, a V-shaped tube containing fused silver chloride with a silver wire for negative electrode and a piece of carbon for positive electrode; and the third, a solution of sulphate of copper with copper electrodes. Let these electrolytic cells be put in series, and a sufficiently strong current passed through them. In the first—the voltameter—oxygen and hydrogen will collect; in the second, chlorine will appear at the carbon, and may be collected, while silver will be deposited on the silver wire; and in the third, copper will be deposited on the negative electrode, while the positive electrode will gradually dissolve away. After the current has flowed for some time, measure the amounts of gases collected, and the amounts of silver and copper deposited. The last two are easily measured by simply weighing the electrodes before and after the process—the increments of mass of the silver and copper which acted as the negative electrodes in the silver and copper salts respectively giving at once the amounts deposited on them. Suppose, for example, that 2 milligrammes of hydrogen and 16 milligrammes of oxygen have collected in the voltameter; then it will be found that 70·8 milligrammes of chlorine have collected over and on the carbon, 216 milligrammes of silver have been deposited on the silver, and 63 milligrammes of copper on the copper electrode. Now these numbers measure what are called the chemical equivalents of these substances—they are proportional to the quantities which enter into similar combinations. Thus, in hydrochloric acid, for every 2 grammes of hydrogen there are 70·8 grammes of chlorine; in cupric chloride, for every 70·8 grammes of chlorine there are 63 grammes of copper; and so on, right through all the related compounds of these substances. See ATOMIC THEORY.

Maxwell has thrown Faraday's fundamental laws of electrolysis into a suggestive form by first defining the electro-chemical equivalent of a substance as that quantity 'which is electrolysed by a unit of current passing through the substance for a unit of time, or, in other words, by the passage of a unit of electricity.' Then the law of electrolysis is that 'the number of electro-chemical equivalents of an electrolyte which are decomposed by the passage of an electric current during a given time is equal to the number of units of electricity which are transferred by the current in the same time.' Now during electrolysis the products of decomposition appear only at the electrodes, and nowhere else. The electrolyte consists in fact of two groups of components, chemically bound together everywhere throughout the liquid. But the steady appearance of the ions at the electrodes shows that the two groups of components must be steadily travelling in opposite directions through the electrolyte. Hence it follows that although these molecular groups are chemically bound together everywhere throughout the liquid, the individual component groups are constantly changing their associates. For example, in the case of the electrolysis of fused silver chloride any individual silver molecule is handed on, so to speak, from chlorine molecule to chlorine molecule till it reaches the negative electrode and is deposited there. At the same time, each individual chlorine molecule passes in the other direction from union with one silver molecule to union with the next, until finally it reaches the positive electrode and becomes free—i.e. there is constant dissociation and recombination going on in the substance of the electrolyte. Clausius (1857) supposes that this process is going on in the liquid at all times; but that, when an electromotive force acts upon it, a direction of motion is given to the component molecules in their momentarily free condition, so that they drift, the one set of components with the electric current, the other set against it. The feeblest electromotive force is sufficient to compel a certain drift of ions, which we may suppose to be conveying the current of electricity by a kind of convection through the liquid. When the ions reach the electrodes, they no longer find ions of the opposite kind to combine with, and begin to accumulate on the electrodes. But for this a finite electromotive force is necessary; for with the accumulation of ions on the electrodes a reversed electromotive force—the so-called electromotive force of polarisation—begins to show itself. This grows with the accumulation of the ions up to a certain point; and if the external electromotive force is not greater than the electromotive force of polarisation so produced, the current will cease to flow, or at least be so enfeebled as to be practically useless in causing electrolysis.

The ions, as they appear at the electrodes, may not be the real components of the electrolyte which are being urged in opposite directions through the liquid. In the case of fused silver chloride, the ions are no doubt these very components; but, in the case of dilute sulphuric acid, we have no right to regard hydrogen and oxygen as the real original products of electrolysis. Indeed, we know by experiment that the purer the water the greater its resistance; so that we have every reason to believe that absolutely pure water is a non-conductor and cannot be electrolysed. Probably the secondary actions which in the case of dilute acid transform the real original ions into oxygen and hydrogen may be somewhat similar to what is certainly part of the action when a solution of sulphate of soda is electrolysed. The components of the molecule Na_2SO_4 are Na_2 and SO_4—i.e. sodium and what is called sulphion. The sodium molecules drift with the current, the sulphion molecules against it. But the sodium, when it appears at the negative electrode, at once acts chemically on the water, forming soda, Na_2O, and liberating hydrogen, H_2. Again at the positive electrode, the sulphion not being able to exist in the free state, breaks up into SO_3 and O; and then the sulphuric acid is dissolved up in the water, and oxygen is given off. Thus, again, the constituents of water, H_2O, appear as the ions, exactly as in the case of the dilute acid. Here, however, the molecule of the electrolyte is not really Na_2SO_4, but has so much water united with it. Thus there may be a direct decomposition of water, as well as of the sulphate of soda. Whatever the real process of electrolysis, it is certain that in many cases secondary chemical actions quite mask it. These secondary actions do not, however, affect the accuracy of the law of electrolysis. Whatever be the apparent products of decomposition, these, if they can be caught and measured, will appear in quantities proportional to their chemical equivalents. It is further evident that if one electro-chemical equivalent of an electrolyte is decomposed, it must be decomposed into components chemically equivalent to one another and to it.

Hence it is enough to measure carefully the electro-chemical equivalent of one of the ions or products of decomposition. By means of a table of chemical equivalents we shall then be able to calculate the electro-chemical equivalents of given electrolytes. So many are the causes, both physical and chemical, which tend to disturb the perfect accumulation of the ions on or over the electrodes, that the accurate experimental determination of the electro-chemical equivalent is a matter of great difficulty. Large copper electrodes in copper sulphate yield fairly good results; but the only completely satisfactory combination is a particular solution of nitrate of silver with pure silver electrodes. The electrolysis of this electrolyte by means of a current, whose strength should be adjusted to the size of the electrodes, so as to give a particular amount of current per unit area, is accompanied by an accurate transference of so much silver from one electrode to the other. In other words, the one electrode loses as much as the other gains, a degree of perfection which is hardly ever attained in other cases. Recent independent determinations by Kohlrausch and Rayleigh agree to the fourth significant figure; so that we may safely say that the unit of current known as the ampère will reduce out of a solution of nitrate of silver 1·118 milligrammes of silver per second. This therefore is the electro-chemical equivalent of silver. Now in chemical combinations 216 grammes of silver correspond to 18 grammes of water and to 65 grammes of zinc. Hence a simple calculation gives ·0932 milligrammes as the electro-chemical equivalent of water, and ·336 milligrammes as the electro-chemical equivalent of zinc.

The unit of current which has just been mentioned, the ampère namely, is one-tenth of the electro-magnetic unit of current, which may be defined in several ways (see MAGNETISM). For our present purpose, however, it will be sufficient to indicate experimentally what magnitude of current the ampère is. If an ampère is passing along a conductor of 1 ohm resistance—say, a column of mercury 106 centimetres long and 1 square millimetre cross-section—the electromotive force along the conductor—i.e. the difference of potential of its ends—will be the quantity known as 1 volt; and the volt is such that the electromotive force of a Daniell cell is about 1·08 volts. In connection with electric lighting, these units—the volt, the ampère, and the ohm—are in universal use.

Intimately connected with electrolysis is the theory of action of the ordinary galvanic or voltaic cell. For, whenever such cells are being used for the production of electric currents, there is going on within them chemical actions essentially electrolytic. Take, for example, the Daniell cell with its copper and zinc plates dipping respectively in solutions of copper and zinc sulphates. When the cell is closed, the current flows externally from the copper to the zinc, and internally from the zinc through the zinc and copper sulphates to the copper. The electrolysis of these electrolytes is a necessity, with the result that the zinc is gradually dissolved away, and copper deposited on the copper electrode. The net chemical result is the removal of copper from the sulphate and the substitution of an equivalent of zinc. But this chemical reaction is accompanied by the evolution of heat—i.e. the liberation of so much energy available for transformations. It is this energy which is the source of the electric energy when the replacement of copper by zinc in the sulphate is effected in the particular arrangement known as the Daniell cell. Now, according to Thomson's determinations of heats of combination, the consumption of 1 gramme of zinc in a Daniell cell means the evolution of 8053 gramme-degrees, that is, an amount of heat that would raise 8053 grammes of water 1° C. in temperature. Hence the consumption of an electro-chemical equivalent of zinc—i.e. ·336 milligrammes—means the evolution of 2·706 gramme-degrees of heat. This then is the energy which is associated with the production of one unit of electricity. To reduce it to dynamic units we must multiply by the factor $4{\cdot}2 \times 10^7$, which is the number of units of energy equivalent to the heat required to raise the temperature of 1 gramme of water 1° C. Thus we find $1{\cdot}14 \times 10^8$ as the energy which a Daniell cell liberates per second when it produces a current of 1 ampère. If E is the electromotive force associated with this unit current, then E measures the work done per second by the current; and assuming that this is the energy liberated in the cell, we find $E = 1{\cdot}14 \times 10^8$ electro-magnetic (C. G. S.) units of electromotive force—i.e. 1·14 volts, according to the definition of a volt. This is slightly higher than the real value of the electromotive force of a Daniell cell, but it is close enough to warrant the conclusion, first enunciated by Sir William Thomson (1851), that the electromotive force of any electro-chemical apparatus is, in absolute measure, equal to the dynamical equivalent of the chemical action that takes place during the passage of unit current for unit time. There are many cases of galvanic combinations for which this principle fails to a degree which cannot be even approximately referred to errors of experiment. Some other principles, either chemical or physical, must be involved. There is no question, however, as to the general application of the law enunciated by Thomson.*

We are now able to see why it is that one Daniell cell cannot effect an electrolysis in which the constituents of water appear as the ions. It is simply because the heat developed in the formation of an equivalent of water by direct union of its constituents is about half as great again as the heat evolved in the combustion of an equivalent of zinc in a Daniell cell. Hence to decompose an electro-chemical equivalent of water requires more energy than is supplied by the combustion of an electro-chemical equivalent of zinc in the cell.

The general principle here indicated may be stated thus: A current i flowing through a given electrolyte decomposes i electro-chemical equivalents in unit time. But this requires a definite amount of work done, which we may write ie, where e measures the work which must be done to decompose one electro-chemical equivalent. Hence the energy of the current must be *at least* ei, or in other words, e measures in absolute measure the smallest electromotive force with which distinct electrolysis can be effected.

All the phenomena which accompany simple electrolysis are encountered in the action of galvanic cells. The poles, like the electrodes, become, or tend to become, polarised. This is especially the case in single fluid cells, in which the apparent electromotive force very markedly diminishes during the first few moments of action, due to the reversed electromotive force of polarisation produced by the accumulation of the ions on the poles. In the so-called constant elements, such as the Daniell, the Bunsen, or the Grove, all of which are double-fluid cells, the ion is either of the same nature as the pole at which it appears, or is dissolved in the fluid so as not to accumulate. By such means the electromotive force is kept fairly constant so long as the strengths or characters of the solutions do not greatly alter. The chief conditions to be fulfilled by cells which are to yield strong steady currents are (1) small polarisation, (2) a plentiful supply of electrolyte, (3) a small resistance. This last condition is obtained by using large surfaces for the electrodes, which are opposed to each other as closely as the arrangements of the cell will permit.

The difficulties of measuring the true resistance of electrolytes, and therefore of galvanic cells, have already been touched upon. We must here confine ourselves to the chief results which experiment has established. As compared with metallic conductors, the specific resistance of electrolytes is very great. Then, again, rise of temperature diminishes the resistance of electrolytes, whereas, except for selenium, phosphorus, and carbon, it increases the resistance of simple conductors. Finally, in the case of solutions in water of such compounds as sulphuric acid, nitric acid, sulphates, chlorides, nitrates, and so on, there is in general a definite solution which conducts better than any other solution of the same substance—i.e. a definite percentage composition which is associated with a minimum specific resistance. In all cases a condition of infinite resistance is approximated to as the solution is taken weaker and weaker; and in some instances (sulphuric acid, for example) the same condition of infinite resistance is hinted at for infinitely strong solutions—i.e. for the pure non-hydrated substance. Kohlrausch, who has probably worked most extensively at this subject, speculates upon the necessity of solution or of mixture of stable chemical compounds before conduction can take place. In other words, such compounds, if absolutely pure, would be non-conductors.

We cannot hope to understand the true nature of resistance till we know what an electric current really is. The fact that electrolytes obey Ohm's Law as accurately as simple conductors suggests that the process of conduction is essentially the same in both, notwithstanding the many differences that exist in the accompanying phenomena. The view that an electric current is intermittent—i.e. is a succession of distinct discharges at extremely short intervals of time, is one which seems to be involved in all the best theories of electrolysis that have been elaborated. Maxwell has shown that a rapid intermittent charging and discharging can give rise to all the effects of a true resistance. Suppose we have a condenser of capacity C, whose plates are, by means of a tuning-fork interrupter, alternately brought into contact with the poles of a battery and with each other, so that the condenser is charged and discharged n times a second. If E is the electromotive force of the battery, EC is the electricity which passes at each discharge. Hence in one second ECn units of electricity pass; and this is the current I. Thus

$$I = ECn,$$

so that Cn measures the conductivity. The greater n is, the greater the conductivity, the less the resistance. Hence, if the electric current is of the nature of intermolecular discharge, we see that greater closeness of the molecules, being in all probability associated with more rapid charging and discharging, will give rise to less resistance. This would so far explain the much greater resistance of electrolytes as compared with metallic conductors. For a very complete statement of this view, consult Professor J. J. Thomson's *Applications of Dynamics to Physics and Chemistry* (1888).

The hypothesis just given of the intermittent character of electric conduction obviously suggests that the mode by which electric transference takes place in simple conductors, electrolytes, and dielectrics is fundamentally the same. In many dielectrics the phenomenon of 'leakage'—the name given to the gradual loss in charge of a conductor in contact with the dielectric—presents characteristics very similar to true ohmic conduction. Then dry glass, although a very good insulator at ordinary temperatures, becomes distinctly conducting at temperatures above 200° C.—a fact first noticed by Cavendish. Later experiments indicate that the conduction of hot glass is electrolytic, the electrodes becoming polarised. In the case of gases, electrical discharge seems always to be of an intermittent character. A certain electromotive force, depending on the shape and size of the electrodes, on their distance apart, and on the density, temperature, and nature of the gas, is necessary before discharge takes place. For smaller electromotive forces, the gas, if free from convection currents, seems to insulate perfectly. The insulating power of the gas under given conditions is measured by its dielectric strength, which varies as the square of the electric force. The dielectric strength increases markedly for very small distances between the electrodes, a very remarkable fact which may possibly be due to a greater density of gas close to the surfaces of the electrodes. For smaller and smaller distances such condensed layers would of course play a more pronounced rôle. This explanation agrees with the fact that the dielectric strength of gases diminishes as the density is diminished. This, however, does not go on indefinitely, but it reaches a minimum for a certain low density, which has a different value for each gas, and which is also a function of the diameter of the tube in which the rarefied gas is contained. A pressure of 2 or 3 millimetres of mercury gives the density for which the dielectric strength of air reaches its minimum. Further rarefaction beyond the point of minimum dielectric strength is accompanied by a rapid increase of insulating power, until at length it is impossible to make a discharge pass through the extremely attenuated gas. It thus appears that electricity cannot pass from electrode to electrode in a perfect vacuum—i.e. a region void of ordinary matter. Whether this is due to an infinite passage resistance between the electrodes and the so-called vacuum, or to the absolute non-conducting power of the vacuum, is a point not yet settled. Electric discharge through rarefied gases is accompanied by very beautiful luminous effects, which are often enhanced by the phosphorescence of the glass forming the vacuum tubes. These tubes are usually called Geissler tubes, after the first great maker of them (the glass-blower and mechanician, Heinrich Geissler, 1814–79). Into their many curious properties we cannot here enter.

The polarisation of the electrodes during electrolysis has within the last ten years acquired a great practical importance in connection with the construction of secondary batteries or accumulators. An accumulator is simply a polarised electrolytic cell capable of supplying a steady current for a lengthened time. Theoretically of course, all polarised electrolytic cells are accumulators; but usually the currents they supply are short-lived and feeble. It was not till 1860 that Planté constructed an accumulator which could supply a really efficient current. The Planté secondary cell is formed by the electrolysis of dilute acid with lead electrodes. With sufficiently strong currents, the result of the electrolysis is that the positive electrode becomes covered with peroxide of lead (PbO_2), while lead accumulates in a spongy form on the negative electrode. When the polarisation has been carried on to a sufficient extent, the cell is said to be charged, and it will be found to have all the properties of a true galvanic cell of low resistance and fairly high electromotive force (about 2 volts). On being closed, it will supply a current sufficient to keep a thin wire glowing for several hours. At the same time, the peroxide of lead will become reduced to a lower oxide, and the spongy lead will be oxidised, while the sulphuric acid present gives rise to other reactions. During the greater part of the discharge of the cell, the electromotive force remains very constant, and only begins to diminish as the depolarisation approaches completion. When the charged cell has thus, through use, lost nearly all its accumulated electrical energy, it is put into circuit with a primary source of current energy and re-charged. The modifications of construction introduced by Faure in 1881 gave a great impulse to the development of accumulators as a practical source of electrical energy. Instead of using merely lead sheets as electrodes, Faure covers them first with a layer of minium or red lead. With these as electrodes the electrolysis of dilute sulphuric acid is effected, the result being, as before, the formation of peroxide of lead at the positive electrode and spongy lead at the negative electrode. What chemical reactions take place as the accumulator discharges itself are not fully understood. The final result, however, seems to be the formation of sulphate of lead on both electrodes. Re-charging from a prime source restores the peroxide of lead and the spongy lead as in the first charging. As part of the recent development in electric lighting, the efficiency of accumulators has been greatly increased; and they are now largely used as the direct source of power. They must, of course, be charged and re-charged at intervals depending upon the particular rate at which they are made to give off their stored-up energy. A battery of Bunsen or other cells may be used for charging purposes; but if the wasteful voltaic cell had been our only prime source of electric energy, the secondary cell could never have assumed the practical importance it has. It is because we can generate electric energy dynamically and economically (see MAGNETISM) that we find a use for the accumulator, which is simply an arrangement for the storage of so much electrical energy in a form convenient for future purposes.

Of all the thermal effects produced by currents, the Joule Effect is the most conspicuous and by far the most important. But there are other thermal effects which are associated with the transference of electricity, and which are readily distinguished from the Joule effect by what is known as their reversible character. Thus the Joule effect always means a rise of temperature in the conductor whatever the direction of the current through it; whereas these so-called reversible effects mean a rise of temperature when the current passes in the one direction, and a fall when it passes in the other. If at any part of a circuit, in which a current is flowing, a fall of temperature is observed, we are probably safe in regarding this cooling effect as one of these reversible effects. We may test this directly by reversing the current; but occasionally the conditions of the experiment may prevent the application of this test. Thus, in some cases, a galvanic cell, in circuit with a large external resistance, is found to cool. Since the current due to a given galvanic combination must always flow in the same direction through the cell, it is impossible of course to apply the test of reversal. Other galvanic cells, again, when similarly joined up with a high external resistance, are found to rise in temperature under conditions in which the true Joule effect is inappreciable. Such thermal effects seem to be true reversible effects; and upon them Von Helmholtz bases his explanation of the apparent failure, in many instances, of Thomson's dynamical theory of the electromotive force of a battery (see above). In most cases, the electromotive force is smaller than what the chemical reactions imply; but in some it is greater. In the former there is intrinsic heating in the cell; in the latter there is cooling—exactly the relations which the principles of energy require. For, as in the latter case, if the electrical energy generated is greater than the *chemical* energy supplied, it must borrow heat from the surrounding substances to make up its surplus energy. The further fact that those cells, which either heat or cool of themselves, have electromotive forces which vary with temperature, points to these being truly reversible thermal effects. An electromotive force which grows with temperature is associated with a cooling effect in the cell as the current is flowing, while an electromotive force which diminishes with rise of temperature is associated with a heating effect. This must be so; for in all cases of transformations of energy, the final effects react so as to resist the changes that lead to them. In the present case, if a heating effect coexisted with an electromotive force which increased with temperature, this heating effect would raise the temperature still further, increase the electromotive force still more, and cause a stronger current to flow, which in its turn would cause a further rise of temperature, and so on indefinitely—an obvious contradiction of all experience. We shall find some simple applications of the same dynamic principle of reaction in the other reversible thermal effects of electric currents. These are intimately connected with the whole subject of thermo-electricity, which we shall now discuss.

Thermo-electricity dates from 1821, when Seebeck discovered that a current was generated in a circuit composed of copper and antimony, when the junctions were at different temperatures. With a sufficiently delicate galvanometer, the same phenomenon may be shown not only with any two different metals, but also with the same metal in two different conditions. Thus, a stretched, twisted, or (if possible) magnetised wire will give thermo-electric currents with a piece of the same wire which has not been so treated. Slight impurities cause distinct changes in thermo-electric properties; indeed, thermo-electric currents may often be obtained in a circuit of two wires, which no other physical test can differentiate. The fundamental fact of thermo-electricity is that, in a circuit built of two or more different conductors, a current is in general generated when one junction at least differs in temperature from the others. For the sake of definiteness, consider a circuit of the two metals iron and copper, with their junctions at A and B, and with a delicate galvanometer included for the measurement of current. If A and B are at different temperatures, a current will in general be set up in the circuit; and for moderate temperatures up to 250° C. or so, this current will flow from copper to iron through the warmer junction, and from iron to copper through the colder junction. Now this current i must derive its energy, ei, from some source; and the only source that exists is the heat which is available in virtue of the unequal distribution of temperature. In virtue of thermal conduction and radiation, the tendency is towards an equalisation of temperature, the warmer junction losing heat, and perhaps the colder junction gaining heat. But if this heat is also being partly drawn upon to sustain an electric current, the equalisation of temperature will be hastened because of this transformation into electric energy. Hence, we should expect the thermo-electric current to be associated with, at anyrate, a cooling effect at the warmer junction. That such an effect really does exist was established experimentally in 1834 by Peltier—hence the name Peltier Effect. He showed that heat is absorbed or evolved at the junction of two different metals, across which any current is made to pass; and that if the direction of this current is the same as that of the thermo-electric current that would be produced by heating the junction, the effect is absorption of heat—i.e. cooling; and *vice versâ*. Thus, in a copper-iron circuit at moderate temperatures, the thermo-electric current is associated with a cooling effect at the warmer junction, and a heating effect at the colder junction. Icilius proved by experiment (1853) that the Peltier effect is proportional to the strength of the current. It is also known to vary with the temperature, sometimes increasing with rise of temperature, sometimes diminishing, according to the particular kinds of metals used.

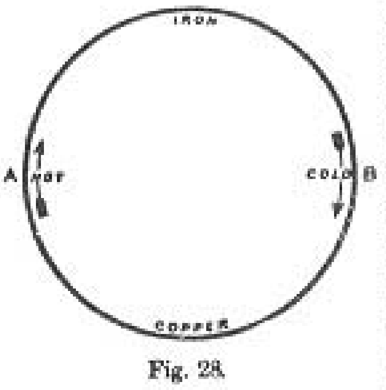

Fig. 28.

The Peltier effect is defined as the heat absorbed by the passage of unit of electricity in the proper direction across the junction; or otherwise, the heat absorbed per second by the passage of unit current. Let p be the Peltier effect at the warmer junction of a thermo-electric circuit, and p' its value at the other junction. Assuming that the Joule and Peltier effects are the only thermal accompaniments of a thermo-electric current i, we find for the whole amount of heat absorbed the quantity pi, and for the whole amount of heat evolved $p'i + ri^2$, where r is the resistance of the circuit, and where the heats are estimated in dynamic units. If we suppose these to be the only transformations of energy involved, we have at once

$$pi = p'i + ri^2 \text{ or } p - p' = ri.$$

In the latter equation, the difference of the Peltier effects appears as the electromotive force associated with the current i. From this point of view the Peltier effect is to be regarded as an abrupt change of potential at the junction of the two metals. It must not be confused, however, with the electromotive force of contact discovered by Volta, compared with which it is extremely small, and frequently of opposite sign.

Thus we may suppose thermo-electric currents to be explained in terms of the Peltier effects, regarded as electromotive forces at the junctions. But the striking phenomenon of thermo-electric inversion, discovered by Cumming in 1823, necessitates the supposition of other than Peltier effects for a satisfactory explanation of thermo-electric currents. Take, for example, the copper-iron circuit, keep the one junction B at a steady temperature of, say, 10° C., and raise the temperature of the other junction A steadily and indefinitely from 10° C. to about a dull red heat. As the temperature of A rises, the current setting from copper to iron through A will increase to a maximum, then decrease to zero, and finally become reversed. The temperature at which this maximum current is obtained is a definite temperature for a given pair of metals, being quite independent of the temperature of the other junction. It is called the Neutral Point. If the temperature of the one junction is as much above the neutral temperature as the temperature of the other junction is below it, there is no current; and the mean of these two temperatures is the neutral temperature. For copper-iron the neutral point is about 275° C.; for zinc-iron, about 210° C.; for cadmium-iron, about 160° C.; and so on. In the majority of cases, the neutral point, occurring either above or below ordinary ranges of temperature, cannot be easily observed directly; but its position is usually indicated by the manner in which the electromotive force is found to vary with temperature. Now suppose that the one junction A in the copper-iron circuit is kept at the neutral temperature (275° say); then whatever be the temperature of the other junction, whether it is higher or lower than 275°, the direction of the current will always be the same—viz. from copper to iron through the junction A. Consider the two cases: (1) B at temperature 270°; (2) B at temperature 280°. In the first case, if the only reversible thermal effects existing are the Peltier effects at the junctions, then there must be absorption of heat at A (copper to iron), and (if anything) evolution of heat at B (iron to copper).

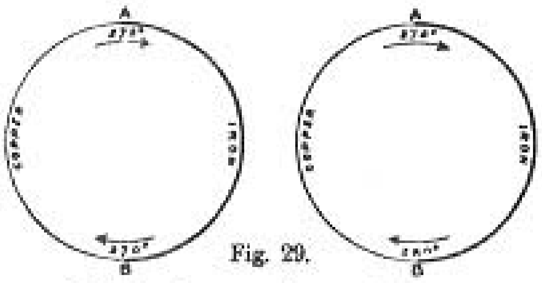

Fig. 29.

But in the second case, the same assumption requires that there must be absorption of heat at B (iron to copper), and (if anything) evolution of heat at A (copper to iron). Now these two statements are incompatible unless there be neither absorption nor evolution of heat at A—i.e. unless the Peltier effect vanish at the neutral point. But this being so, it is at once evident that in the first case there is no absorption of heat at all. Heat is evolved at B, and heat is evolved because of the Joule effect; but there is no evidence of any absorption of heat to account for the energy of the current. Hence the original assumption must be wrong—i.e. there must be other reversible effects in the circuit besides the Peltier effects at the junctions. There must be a cooling effect either in the copper wire, or in the iron wire, or possibly in both. This theoretical conclusion was first obtained by Sir William Thomson (1851), who proceeded at once to test it by an appeal to experiment. It was found that both of these predicted effects take place. A current passing from cold to hot in copper is associated with an absorption of heat; while heat is evolved if the current passes from hot to cold. On the other hand, for iron, things are just reversed; cooling is associated with the current that flows from hot to cold, and heating with the current that flows from cold to hot. This reversible thermal effect which accompanies the passage of a current in an unequally heated conductor is called the Thomson Effect. It is said to be positive in copper; and is therefore negative in iron. Cadmium, zinc, silver, gold, nickel between the temperatures of 250° C. and 310° C., and iron above a dull red heat, have, according to Professor Tait's experiments, their Thomson effects also positive. Platinum, palladium, potassium, sodium, cobalt, nickel below 200° and above 320°, and probably iron again above a bright red heat, are examples of metals having negative Thomson effects. The Thomson effect has been measured directly in a very few cases; but it may be calculated from thermo-electric constants, if Tait's hypothesis be true (and recent direct experiments go far to verify it) that the Thomson effect is for most metals directly as the mean absolute temperature. The extraordinary change of sign in the Thomson effect, which Tait discovered to exist both in nickel and iron at certain temperatures, is an extremely interesting phenomenon, and seems to be connected with other properties peculiar to these magnetic metals—such as their loss of magnetic susceptibility and the manner in which their electrical resistances change with temperature.

In comparison with the electromotive forces of voltaic cells, the electromotive forces that can be obtained with thermo-electric circuits are usually very small. Thus copper-iron with one junction at 275° C., and the other at 0° C., has an electromotive force of only ·0022 volts. The electromotive force of an iron-nickel pair with junctions at temperatures 0° C. and 200° C. is ·008 volts; and the electromotive force of a bismuth-antimony pair with a difference of temperature of 50° C. is about ·005 volts. Bismuth and antimony are, because of their high mutual thermo-electromotive force, ordinarily employed in the construction of the thermopile, a valuable instrument for indicating and measuring small variations of temperature. It consists of alternate strips of bismuth and antimony forming a continuous zigzag chain, as indicated in fig. 30. They are arranged in compact form so that the successive junctions alternate, now on this side, now on that side, forming two plane faces looking opposite ways. If a source of heat is brought opposite to the one face, the junctions ending there are heated by radiation, while the alternating junctions on the other face remain at the temperature of the air. Each pair of junctions gives rise to a thermo-electromotive force e, and therefore the n pairs to ne. If s is the resistance of each pair of strips, and r the resistance of the galvanometer and connecting wires, the current i is given by the equation

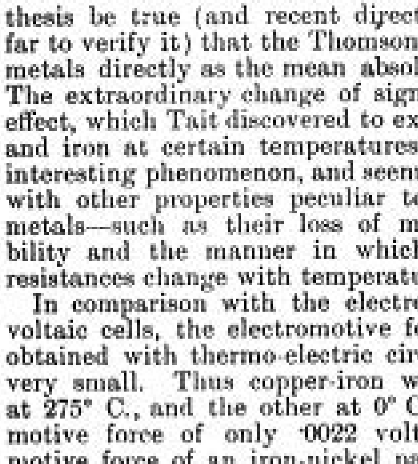

Fig. 30.

$$i\,(r + ns) = ne.$$

Thus r is always greater the greater n is; and if, as is usually the case, the resistance of the thermopile (ns) is small compared with the resistance of the galvanometer, the current due to the n pairs is very nearly n times the current that one pair would give. Thus a thermopile of thirty-six pairs of junctions will give an electromotive of nearly one-tenth of a volt for a difference of temperature between the faces of 25° C.

The Peltier effect between bismuth and antimony at the ordinary temperature of the air is about $3{\cdot}14 \times 10^6$ per ampère per second, estimated in dynamic units—i.e. about ·0075 in gramme-degree units of heat. Hence in one minute, a current of one ampère passing from antimony to bismuth will evolve a quantity of heat sufficient to raise a gramme of water nearly half a degree centigrade in temperature. For other ordinary pairs of metals, the Peltier effect is considerably smaller than that just given. Thus for iron-copper at the ordinary temperature of the air, the Peltier effect is about one-seventh of its value for bismuth and antimony.

The Thomson effects are extremely difficult to measure directly. We may, however, get an idea of their magnitudes by calculating them according to Tait's theory from the thermo-electric constants. Suppose, for example, that a current of ten ampères is flowing along an iron or copper wire, whose ends are at 0° C. and 100° C. Then the amounts of heat in gramme-degrees evolved or absorbed per minute are, in iron ·224, in copper ·044. These numbers are calculated on the assumption that the Thomson effect in lead is nil, an assumption based on the direct experiments of Le Roux.

Electric Light. The electric light, like light from most other sources, is produced by raising a body to a temperature so high that some of the radiations it throws out have a wave-length short enough to affect the retina. A slightly heated body gives radiations of long wave-length only; they may be detected, as any radiations may, by their heating effect when they fall on an absorbent surface, but the eye is not sensitive to them. When the body is made hotter the whole energy of the radiations increases, but the short waves increase in greater proportion than the long waves, and when the temperature is sufficiently raised the body begins to give out light. So long as the source is just hot enough to be luminous the light is nearly all red; as the temperature rises there are added more and more of the other colours, of shorter wave-length, towards the violet end of the spectrum. In the flame of a candle or of a gas-jet particles of solid carbon form the luminous source: their temperature, which is determined by the condition that they radiate energy as fast as work is done upon them by the process of combustion, is so low as to make the red and yellow constituents of the light preponderate. A higher temperature has the double advantage of giving whiter light, and of giving it accompanied by a smaller proportion of non-luminous infra-red rays, and therefore with less expenditure of energy in proportion to the amount of light produced.

One way of heating a body to a high temperature is by forcing a strong current of electricity to pass through it. The energy expended depends on the strength of the current and on the electromotive force which is required to make it pass, and this energy takes the form of heat. By selecting a conductor which offers considerable resistance to the passage of the current, it is practicable to produce so much heat in a small space that the temperature reached is only limited by the melting or volatilising of the heated body. In all actual electric lamps carbon is used, first and mainly because of its great infusibility, and second, because of its emissive power. Carbon is in fact the luminous body in nearly all sources of artificial light.

Arc Lighting.—The earliest means of applying the electrical current to the production of light was discovered in 1810 by Sir Humphry Davy, who found that when the points of two carbon-rods, to which the terminals of a powerful battery were connected, were brought into contact and then drawn a little way apart, the current continued to pass across the gap, forming what is known as the electric arc. The electric arc (fig. 1) is brilliantly luminous. The points of the carbon-rods become highly incandescent, and in addition the space between them is filled by a sort of flame, or cloud of particles of white-hot carbon. As the temperature of the arc is much higher than that of any ordinary flame, its efficiency as a source of light is exceptionally great, and it is specially rich in highly refrangible (or short wave-length) rays. The carbon-points being exposed to the air gradually burn away, and in addition to this there is a transfer of carbon particles across the arc from the positive to the negative rod, which has the effect of making the positive rod waste about twice as fast as the negative rod. The end of the negative rod becomes somewhat pointed, and a crater-like hollow forms on the end of the positive rod. As the points waste away the arc lengthens, and would presently break and the current would cease to pass if the rods were not pushed nearer together. Should the arc break it can be re-established by bringing the rods again into contact, and again drawing them a little way apart. Arc lamps are devices for holding the carbon-rods, so that they are first brought into contact and drawn apart, to establish or 'strike' the arc, and are then 'fed' together, continuously or at short intervals, to prevent the distance between the points from growing too long.

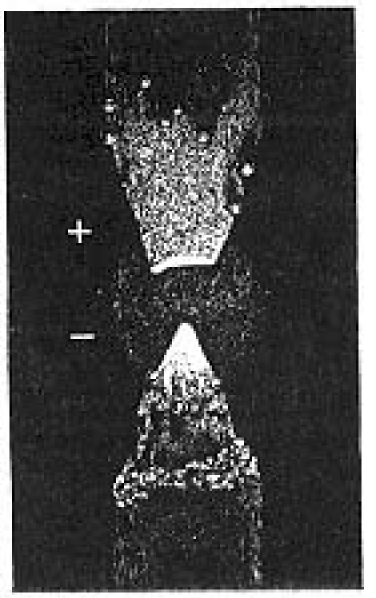

Fig. 1.

It was not until the development of the Dynamo-electric Machine (q.v.) as a means of producing the electric current economically on a large scale, that the electric light came to be of commercial importance. Before that, however, various contrivances had been devised for automatically striking the arc and regulating its length. As early as 1847 a lamp was patented by W. E. Staite, in which the carbon-rods were set vertically one over the other, the upper one being held fixed, while the lower rod was fed upwards by the intermittent action of clockwork, which came into gear whenever the current across the arc became reduced below a certain limit of strength through the lengthening of the distance between the carbon-points. Similar devices were proposed by Foucault and others; but the first really successful arc lamp was Serrin's, patented in 1857, which has not only itself survived, but has had its main features reproduced in many later forms. In 1858 a lamp designed by Dubosq was used to show the electric light, for the first time at sea, from the South Foreland Lighthouse, where the current to feed the lamp was generated by the large magneto-electric machine of Holmes; and this experiment was followed a few years later by the permanent establishment of electric lighting there and at Dungeness and other lighthouses. The invention of the self-exciting dynamo in 1867 paved the way for the development of electric lighting on a commercial scale. The Jablochkoff candle (1876), in which the arc was formed between the ends of a pair of parallel carbon-rods separated by a layer of insulating material which was slowly consumed as the carbon burned down, did good service in accustoming the public to the new illuminant, and the invention of simple and effective arc lamps by Brush and others, brought about its wide adoption in 1878–79 for lighting large rooms, streets, and spaces out of doors. In the following year the future of domestic electric lighting was secured by the introduction of the incandescent lamp.

In modern arc lamps, of which there are so many forms that it would be impossible even to classify them in the space at our disposal, the arc is generally struck by the action of the current in an electro-magnet or solenoid, which is connected in series with the carbons, so that when the current passes the armature of this magnet is attracted, and its motion is caused to separate the carbons. This sets the lamp in action, and then, as the carbon-points are consumed, the resistance to the passage of the current gradually increases. If the source of electricity is such as to maintain a constant, or nearly constant, difference of potential between the terminals of the lamp, the effect will be that the current will gradually become reduced. On the other hand, if the source is such as to maintain a constant or nearly constant current through the lamp, the effect will be that the difference of potential will increase. Either of these effects may be made use of to regulate the length of the arc. Generally the carbons (which are round rods formed by making powdered coke into a paste and baking it) stand in a vertical line, and the upper one is fixed in a heavy holder, which tends to slide down until the points touch. But its motion downwards is checked by a clutch or brake of some kind, which allows it to descend little by little, and only when the length of the arc has become unduly great. Fig. 2 is a skeleton diagram showing the mechanism of Serrin's arc lamp, which was one of the earliest successful forms. Here the upper carbon-holder, A, has rack teeth on it, which gear into the first of a train of toothed wheels, BC, so that the train must revolve as the carbon descends. The last wheel in the train, C (which moves much for a very small movement of the holder), is a star-wheel, whose projecting limbs hit or miss a detent, E, the position of which is controlled by an electro-magnet, G, pulling against a spring, F. When the arc is struck the star-wheel is locked, so that the upper carbon-holder is fixed. As the arc lengthens, the current in the controlling electro-magnet becomes weakened, and this goes on until the detent rises far enough to release the star-wheel. The holder, A, then descends until the current is again strong enough to make the electro-magnet draw the detent down and lock the wheel. Here the control depends on variations in the strength of the current passing across the arc, and the controlling electro-magnet is in series with the carbons (being in fact the magnet which also strikes the arc); if, however, the lamp were to be used with a constant current, the control could easily be effected by variations in the difference of potential between the carbons. The controlling magnet must then form a shunt to the arc itself, and be set so that when the shunt current in it is weak the star-wheel is locked, and when the shunt current exceeds a certain limit the detent is raised and the star-wheel is released. The lamp shown in fig. 2 has this peculiarity, that the descent of the upper carbon-holder makes the lower holder rise, through half the distance, by means of the pulley D, and chain H. The effect is to keep the arc burning always at one and the same place, the lower carbon being the negative one, which consumes half as fast as the other. Lamps with this feature are called 'focussing' lamps, and are useful in lanterns where the luminous centre must be maintained in the focus of a lens. For ordinary uses the focussing arrangement is not necessary, and is omitted.

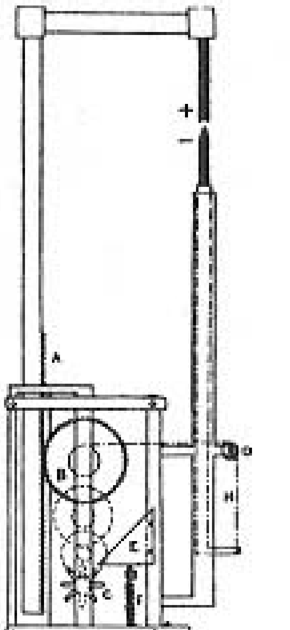

Fig. 2.

In many modern lamps the controlling electro-magnet is double, consisting of a series and a shunt portion, combined in such a way that the holder is released, and the carbons are caused to approach by either a weakening of the current or an increase of the potential, or both. Such lamps may be used either with constant current or with constant potential.

In place of the train of wheels in Serrin's lamp, a single brake-wheel has been used, turned by a rack on the upper carbon-holder, and stopped or checked by a brake-lever which is pressed against or withdrawn from its circumference by the controlling electro-magnet. Some very successful modern lamps, such as those of Brush and Thomson-Houston, use a still simpler device. The upper carbon-holder slides through a loose collar or ring, which can be tilted by the controlling magnet, so that it clutches the holder. When the current falls or the potential rises this clutch collar is untilted, so that the holder slips through it and shortens the arc. A dash pot is employed to prevent the fall of the holder from being too rapid.

When a number of arc lamps are to be used together they are generally connected in series; a constant current is sent through the group, and the control of the carbons is effected by shunt electro-magnets, taking advantage of variations in the difference of potential between the carbons. To prevent the whole group from being extinguished should the feeding mechanism in any one lamp fail to act, a device is added by which any lamp that fails is short-circuited—i.e. the current passes through it by another path. They may, however, be grouped in parallel, if the control is arranged to depend on variations in the strength of the current. Parallel grouping is usual when the lamps are to be served with alternating electric currents.

The rate at which energy is expended in the electric arc is measured by the product of the current and the electromotive force required to maintain it passing across the gap. If the current be measured in ampères and the electromotive force in volts, their product gives the rate of expenditure of energy in watts, and may be reduced to horse-power by dividing by 746. It is found that the electromotive force between the points is nearly constant whether much or little current is passing, which shows that the opposition to the passage of the electric current across the gap is different in kind from the resistance of an ordinary conductor. However short the arc be it requires an electromotive force of from 30 to 40 volts to maintain it; when the arc is lengthened the electromotive force necessary to keep up the same current is increased, but not in proportion to the length. It is not found practicable to maintain the arc with less than a certain strength of current. Hence the power consumed in an arc lamp is necessarily considerable, and the lamp can be employed to advantage only where a large amount of light will be serviceable. The arc lamps which are most extensively used take from three-quarters to one horse-power, and have an illuminating effect equivalent to something like 1000 candles. It is impossible to speak with any precision of the candle power of an arc lamp, because its light differs enormously in colour from that of a standard candle. A comparison of the blue rays of the arc with the blue rays of the candle will give a figure nearly three times more favourable to the arc than if the comparison be made between the red rays.

Incandescent Lighting.—In early attempts to produce light by the incandescence of a heated conductor, wire of platinum and of other refractory metals was employed; but these become melted or disintegrated at too low a temperature to let them serve as efficient sources of light. Carbon rods also had been used, but the matter was not brought to a practical issue till 1879, when Mr Edison (and, almost at the same time, Mr Swan) made lamps in which the incandescent conductor was a fine thread or filament of carbon, inclosed in a glass globe, from which the air was exhausted as completely as possible. The filament was originally formed by carbonising a thread of paper, cotton, bamboo, or other vegetable fibre: it is now more usually made by forcing a semi-fluid preparation of cellulose through a die, bending and drying the thread, and heating it to a very high temperature, surrounded with plumbago, in a crucible. The ends of the filament are attached to short conducting wires of platinum, which are sealed into the globe. By making the filament longer or shorter, thicker or thinner, the lamp is adapted to be used with more or less electromotive force, and to give more or less light. The lamp has a limited life, for the filament undergoes a slow process of disintegration, which finally breaks it. As in the case of an arc lamp the power consumed is measured by the product of the current and the electromotive force or difference of potential between the terminal. In ordinary use incandescent lamps consume from three to four watts per candle of light, and last for some 1500 hours. One may force them to a higher efficiency by increasing the electromotive force, so that the temperature of the filament is further raised, and the light is much increased with the expenditure of but little additional power. But this shortens the life of the lamp, and tends also to make a deposit of carbon particles form on the inside of the glass. The temperature of the filament is in no case so high as that of the electric arc; hence incandescent lighting is less efficient than arc lighting as regards the proportion of light to power, and the colour of the light is more yellow. But in point of steadiness and pleasantness, facility for distributing light, and convenience in placing and management, incandescent lamps have many claims to be preferred for indoor use.

An interesting part of the manufacture of lamps is the process of 'flashing' invented by Messrs Sawyer and Mann, which means the electric heating of the filament for a short time in a hydrocarbon atmosphere. The high temperature of the filament causes the dissociation of the gas in contact with it, and the carbon of the dissociated gas is deposited on the filament. This forms a convenient means of adjusting its thickness and resistance; it also tends to make the filament more uniform, for the process of dissociation and deposit goes on most actively at those places which are thinnest to begin with, and therefore hottest. Incandescent lamps work well with either continuous or alternating currents. They are now made of all sizes, from the miniature lamps of one candle power or less which are employed in surgery, up to two or three thousand candle power. When a number of them are used together they are almost always grouped in parallel. In the electric lighting of a house, for instance, positive and negative main conductors, consisting of insulated copper wire, are led from the dynamo, and to these the positive and negative branches are respectively connected, whose ramifications extend to every room. Wherever a lamp is to be placed a positive and a negative leading wire must come, and each lamp forms as it were a bridge between the positive and the negative side of the system. The difference of potential is nearly the same for all; it is a little less in the case of the more distant lamps, because a certain fall in the difference of potential is incurred through the resistance which the leading wires themselves offer to the passage of the current. This loss has to be kept within reasonable limits by making the sectional area of the leading wires great enough, and no serious difficulty is experienced in doing this when the lamps all lie within a few hundred feet of the source. But the difficulty becomes serious when distribution is attempted on a large scale. Not only is the loss of energy in the conductors then a large part of the whole energy supplied, but it may give rise to wider variations in the potential than can be tolerated. If the number of lamps in use in any district were nearly constant, so that a nearly constant current would flow through the mains leading to that district, it would be easy to allow for the fall of potential in those mains. But this fall is itself a variable quantity, depending on amount of the local demand; and to keep the potential sufficiently constant requires mains of large size, the cost of which becomes prohibitory when the area of distribution is much extended.

In such cases it is necessary to resort to other methods of distribution than by a simple system of parallel mains and branches. A sufficient number of sub-centres may be taken over the area to be lighted, and each of these made the starting-point of a system of parallel conductors, the sub-centres themselves being fed from the central source, through independent mains, with currents which are regulated to produce the necessary potential at each sub-centre. Even then, however, if the sub-centres are widely distant from the source the loss of energy in the mains will be serious. In distribution over a large area there is an obvious advantage in very high potential, for the same amount of electrical energy is then conveyed by a smaller volume of current, and consequently with less loss in the conductors. This advantage may be secured if we convey the electric energy to sub-centres in the form of small currents at a high potential, and convert it there into low-potential currents suitable for domestic use. Two plans of doing this have been put in practice—one, by means of storage batteries, is suitable for continuous currents; the other, by means of transformers, is suitable for alternating currents.

Storage Batteries are cells consisting of large sheets or grids of lead, superficially coated with oxide, which are immersed in dilute sulphuric acid, and are polarised by the passage of the current. Peroxide of lead is formed on the positive plates, and spongy metallic lead on the negative. After being charged by the passage of the current the cells will act for a time as electric generators, giving a current in the opposite direction until the plates again become inactive, when they may be again charged. The electric energy given out when the cells are discharging is somewhat less, but need not, if the cells are slowly charged, be very much less than the energy expended in charging them. Each cell has an electromotive force of about two volts, and its internal resistance is made low by grouping a number of pairs of plates in parallel within a single cell (fig. 3). When such cells are used to convert an electrical supply from high to low potential, they are grouped in series while they are being charged, and the groups are then broken up into sections which may be discharged separately or connected in parallel for discharge. Apart from this use of storage batteries in electric lighting, they form a most valuable, but unfortunately very costly adjunct in domestic and other installations for steadying the electromotive force of the supply when used as a shunt across the terminals of the dynamo, and for storing electricity for use during intervals when the dynamo is not running. Small storage batteries have been successfully employed as a means of providing portable electric lamps for use in houses, carriages, and especially in mines. The miner's lamp is a small storage battery weighing a few pounds, and is inclosed in a watertight case no bigger than an ordinary lantern, in the front of which is fitted a small incandescent lamp protected by a stout glass cover. Primary batteries have also been used, in place of storage batteries, to supply electricity to portable lamps.

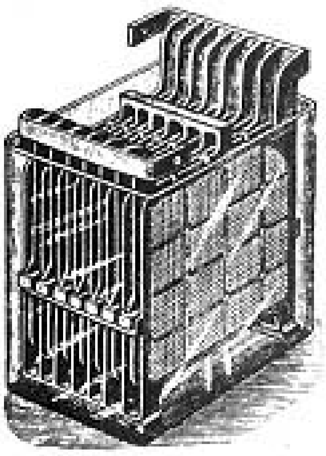

Fig. 3.

Transformers are induction coils, consisting of a core of soft iron on which two coils of insulated copper-wire are wound. When alternating currents are made to pass through one of these, called the primary coil, they produce corresponding periodic alternations of magnetism in the iron, and induce alternating currents of corresponding period in the other or secondary coil. The effect of the iron is to increase the coefficient of mutual induction between the two coils. When the number of windings in the secondary coil is small compared with the number of windings in the primary coil, the electromotive force induced in it is correspondingly smaller than the electromotive force impressed upon the primary; and this is taken advantage of in practice in the conversion of a high-potential into a low-potential supply for electric lighting. In order that the iron core should have as much magnetic susceptibility as possible, it is made in the shape of a ring or some other closed (poleless) magnetic circuit, and to prevent waste of energy by the induction of currents in the substance of the iron, the core is laminated by being built up of thin plates or of wire. Even then, however, there is some waste of energy in the core on account of what is called magnetic hysteresis in the periodic changes of magnetism it undergoes, and some further waste occurs through the heating of both the primary and secondary coils in consequence of the resistance they offer to the conduction of the currents. Notwithstanding these sources of loss the efficiency of a transformer working under favourable conditions is very high, as much as 90 and even 95 per cent. of the energy expended in the primary coil being given off in the converted currents from the secondary. In practice the direction of the current is reversed about 150 or 200 times per second.

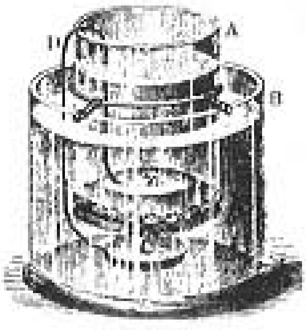
Distribution of electricity for the purpose of lighting by means of transformers, high potential being used in the conveyance of the currents from the distant source, with conversion to low potential before use, has been effected on a fairly large scale in many places, especially in America, where the system has later taken practical shape in the hands of Mr Westinghouse. In London the same method has been successfully employed for some years over a pretty wide area by the Grosvenor Gallery Company, and now (1889) preparations are far advanced for its being applied on a hitherto unprecedented scale by the Electric Supply Corporation, from whose central station at Deptford alternating currents are to be conveyed to all parts of London at a potential of 10,000 volts, to be reduced to 100 volts or so by two successive conversions in transformers before they reach the lamps of the consumers.

Among the minor adjuncts in electric lighting, an important part in guarding against possible risk of fire is played by the 'cut-outs,' whose function is to interrupt the current in any main or branch conductor should it ever exceed a safe strength—as might happen in the event of an accidental cross-connection or short-circuit being formed between the wires. The usual form of cut-out is a safety fuse, consisting of a short piece of foil or wire made of lead or of some fusible alloy which any dangerous excess of current will melt, and so interrupt the current, in that portion of the system which is guarded by the cut-out, before any damage is done. Cut-outs are generally put at the junction of branch with main wires, as well as in the mains themselves. Where the amount of current to be passed is large, an electro-magnetic cut-out is often preferred to a fuse.

Numerous forms of *meter* have been devised for measuring and recording the quantity of electricity supplied to consumers, some suited for continuous currents only, and others for alternating as well as continuous currents. Space does not admit of any description of the ingenious meters invented by Ferranti, Aron, and others. In Edison's meter for continuous currents, which has done good service in central station lighting on the parallel system in New York, the amount of electricity which passes is measured by the deposit of metal in an electrolytic cell. In Forbes's meter, which acts equally well with continuous or alternating currents, the current heats a small coil of wire so that a stream of warm air rises from it; this is made to turn a little windmill, whose number of revolutions is registered, and is found to be a good index of the amount of current which has passed.

Electro-metallurgy is the art of depositing, electro-chemically, a coating of metal on a surface prepared to receive it. It may be divided into two great divisions—electrotype and electroplating, gilding, &c., the former including all cases where the coating of metal has to be removed from the surface on which it is deposited, and the latter all cases where the coating remains permanently fixed. Gold, platinum, silver, copper, zinc, tin, lead, cobalt, nickel, can be deposited electrolytically.

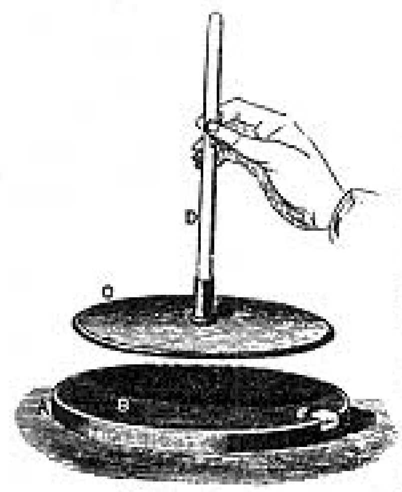
Electrotype is the art of copying printing type, woodcuts, seals, medals, engraved plates, ornaments, &c. by means of the galvanic current in metal, more especially copper. Suppose we wish to copy a seal in copper; an impression of it is first taken in gutta-percha, sealing-wax, fusible metal, or other substance which takes, when heated, a sharp impression. While the impression—say, in gutta-percha—is still soft, we insert a wire into the side of it. As gutta-percha is not a conductor of electricity, it is necessary to make the side on which the impression is taken conducting; this is done by brushing it over with plumbago by a camel-hair brush. The wire is next attached to the zinc pole of a weakly charged Daniell's cell, and a copper plate is attached by a wire to the copper pole of the cell; or, as is now usual, the current required is supplied by Dynamo-electric Machines (q.v.). When the impression and the copper plate are dipped into a strong solution of the sulphate of copper, they act as the – and + electrodes. The copper of the solution begins to deposit itself on the impression, first at the black-leaded surface in the vicinity of the connecting wire, then it gradually creeps over the whole conducting surface. After a day or two on the old method—after a few hours when the magneto-electric is used—the impression is taken out; and the copper deposited on it, which has now formed a tolerably strong plate, can be easily removed by inserting the point of a knife between the impression and the edge of the plate. On the side of this plate, next the matrix, we have a perfect copy of the original seal. If a medal or coin is to be taken, we may proceed in the same way, or we may take the medal itself, and lay the copper on it. In the latter case, the first cast, so to speak, that we take of each face is negative, showing depressions where the medal shows relief; but this is taken as the matrix for a second copy, which exactly resembles the original. The adhesion between the two is slight, and they can be easily separated. The cell of a battery is not needed to excite the current. A galvanic pair can be made out of the object to be coated and a piece of zinc. The figure shows how this may be done. B is a glass vessel containing sulphate of copper; A is another, supported on B by a wire frame, and containing a weak solution of sulphuric acid. The glass vessel A is without a bottom, but is closed below by a bladder. A piece of zinc, Z, is put in the sulphuric acid, and a wire, D, coated with insulating varnish, establishes a connection between it and the impression, C, which is laid below the bladder. Electrotype is of the greatest importance in the arts; by means of it duplicates in copper of pages of type are obtained, as is done with this Encyclopædia; engraved copper plates may be multiplied indefinitely, so that proof-impressions need be no rarity; woodcuts can be converted into copper; bronzes can be copied; and similar like applications are made of it too numerous to mention. By connecting a copper plate ready for corrosion with the + pole, and making it a + electrode, it can be etched with more certainty than with the simple acid, and without the acid fumes.



Electroplating.—This is the art of coating the baser metals with silver by the galvanic current. It is one theoretically of great simplicity, but requires in the successful application of it very considerable experience and skill. Articles that are electroplated are generally made of brass, bronze, copper, or nickel silver. The best electroplated goods are of nickel silver. When Britannia metal, iron, zinc, or lead are electroplated, they must be first electro-coppered, as silver does not adhere to the bare surface of these metals. Great care is taken in cleaning the articles previous to electroplating, for any surface impurity would spoil the success of the operation. They are first boiled in caustic potash to remove any adhering grease; they are then immersed in dilute nitric acid to dissolve any rust or oxide that may be formed on the surface; and they are lastly scoured with fine sand. Before being put into the silvering bath, they are washed with nitrate of mercury, which leaves a thin film of mercury on them, and this acts as a cement between the article and the silver. The bath where the electroplating takes place is a large trough of earthenware or other non-conducting substance. It contains a weak solution of cyanide of silver in cyanide of potassium (water, 100 parts; cyanide of potassium, 10 parts; cyanide of silver, 1 part). A plate of silver forms the + electrode; and the articles to be plated, hung by pieces of wire to a metal rod lying across the trough, constitute the – electrode.

When the plate is connected with the copper or + pole of a one or more celled galvanic battery, according to the strength required, or subjected to the magneto-electric current, and the rod is joined with the zinc or – pole, chemical decomposition immediately ensues in the bath, the silver of the cyanide begins to deposit itself on the suspended objects, and the cyanogen, liberated at the plate, dissolves it, re-forming the cyanide of silver. According, then, as the solution is weakened by the loss of the metal going to form the electro-coating, it is strengthened by the cyanide of silver formed at the plate. The thickness of the plate depends on the time of its immersion. The electric current thus acts as the carrier of the metal of the plate to the objects immersed. In this way, silver becomes perfectly plastic in our hands. We can by this means, without mechanical exertion or the craft of the workman, convert a piece of silver of any shape, however irregular, into a uniform plate, which covers, but in no way defaces, objects of the most complicated and delicate forms. When the plated objects are taken from the bath, they appear dull and white; the dullness is first removed by a small circular brush of brass wire driven by a lathe, and the final polish is given by burnishing. The process of electro-gilding is almost identical with that of electroplating. Success in either is attained by proper attention to the strength of the battery, the strength of the solution, the temperature, and the size of the + electrode.

Electroph'orus, an instrument for obtaining electricity by means of induction. It generally consists of a tin mould, A, which in practice is kept in connection with the ground, filled with shell-lac or resin, B, and a movable metal cover, C, with a glass handle, D, as shown in the fig. The shell-lac is poured in when melted, and is mixed with some other substance to make it less brittle. When the apparatus is used, the surface of the resin or the shell-lac is smartly beaten with cats' fur. This electrifies the resin negatively. When the cover is brought near the lower part of the apparatus, it is charged positively on its under surface, negatively on its upper. If then it is touched, the negative escapes, and the cover is charged with + electricity; and if removed and applied to any conductor, it will give a positive charge to it. The process may be repeated for a great number of times with only a small diminution of B's charge, except by connection or dampness. It is usual to have the earth connection made by a metallic pin passing through B to A, or by a piece of tinfoil, *e*, pasted extending slightly over B, and connected with A.



Electrophorus.

Electroplating, Electrotype. See ELECTRO-METALLURGY.

Electrum (amber; Gr. *ēlektron*) is a term also applied to native gold as it is associated with silver.

Electuary, a form of medicinal preparation in which the remedy is enveloped or suspended in honey or syrup, so as to make a thick, semi-fluid mixture.

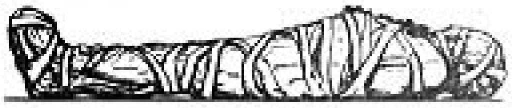
Elements, CHEMICAL, the simplest known constituents of all compound substances. Chemists regard as elementary substances or elements only those substances which have not been proved to be compound. It is not inconceivable that some of the substances at present designated elements (for list of known elements, see ATOMIC THEORY) may hereafter be proved to consist of more than one simple kind of matter, but in the meantime they are correctly called elements, as that term is applied above. The elements are somewhat arbitrarily divided into non-metals and metals, the latter forming by far the larger class. There is no sharp line of demarcation between the two classes, several elements occupying positions on the border line. The elements commonly classed as non-metals are thirteen in number, and are as follows: Hydrogen, chlorine, bromine, iodine, fluorine, oxygen, sulphur, selenium, boron, nitrogen, phosphorus, carbon, silicon. Hydrogen, however, in its chemical relations behaves like a metal. Speculation at present is on the whole rather favourable to the view that all the elements are composed of one fundamental elementary substance (see also CHEMISTRY, and METALS). The time-honoured 'Four Elements' of the Greeks—air, fire, water, earth—are discussed at EMPEDOCLES. The 'Shoo-king,' a Chinese work older than Solomon, has five elements—water, fire, wood, metal, earth. The Indian Institutes of Manu have also five—subtle ether, air, fire, water, and earth.

Elixir (Arab. *el iksir*, 'the philosopher's stone;' see ALCHEMY), a term in pharmacy which has come down from the days of Alchemy (q.v.). By the alchemists the term was applied to various solutions employed in the attempt to transmute metals. But the most notable elixir, sought after by many, was the *elixir vitæ*, 'the elixir of life,' that sublime, potent, perfect, invaluable preparation which, if discovered, would confer immortality or at least extreme length of life on him who drank it. The name has recently been appropriated to a class of American pharmaceutical preparations. These are very different from the old-fashioned elixirs, which corresponded in the main to our modern tinctures; for in the American elixirs the first object sought is to present the medicine under an agreeable form, even if frequently with a loss of potency. These newer elixirs are often highly alcoholic, and are sweetened and flavoured with great skill. In British pharmacy, *Elixir of Vitriol* is almost the only representative of the old class, and is prepared by mixing together sulphuric acid, alcohol, tincture of ginger, and spirit of cinnamon. This preparation, also known as aromatic sulphuric acid, is useful for quenching thirst, sharpening the appetite, checking profuse perspiration, and often reducing the action of the pulse. The dose may range from ten to forty drops, administered in syrup or water.

Elmo's-Fire, ST, is the popular name of an electric appearance sometimes seen, especially in southern climates during thunder-storms, of a brush or star of light at the tops of masts, spires, or other pointed objects. It is also observed at the tops of trees, on the manes of horses, and occasionally about human heads. It is similar in kind to the luminous glow seen at the point when a lightning-rod is working imperfectly, or when there is any very rapid production of electricity (see ELECTRICITY). In the four years 1884–87 eleven cases of St Elmo's fire were recorded at the Ben Nevis observatory. The phenomenon, as seen at sea, was woven by the Greeks into the myth of Castor and Pollux, and was regarded as of friendly omen. The name of *Elmo* is by many thought to be a corruption of that of Helena, the sister of Castor and Pollux. Others take it to be a corruption of St Erasmus, a Syrian bishop and martyr of the 3d century (Italianised, *Ermo, Elmo*). The phenomenon has also been called the fire of St Elias, of St Clara, of St Nicolas, and of Helena, as well as *composite*, *composant* or *corposant* (i.e. *corpus sanctum*).

Elutriation is the term applied to the process of separating, by means of water, the finer particles of earths and pigments from the heavier portions. The apparatus generally used is a large vat, in which grinding wheels revolve; and the substance to be reduced to powder being placed in the vat along with water, the wheels in revolving not only pulverise the material, but from their motion being communicated to the water the latter is enabled to retain in mechanical suspension the finer particles of the clay, &c. By allowing a stream of water to flow in and out of the vat, the finer particles can be constantly floated away, and the liquid being run into settling vats, the fine powder settles to the bottom, when the water can be run off from the surface. This process is much employed in the manufacture of the materials used in pottery, and in the preparation of pigments.

Embalming (so named from the balm or balsam often employed), the art of preserving the body after death, invented by the Egyptians, whose prepared bodies are known by the name of mummies, and are called in the hieroglyphs *sahu*, and by St Augustine *gabbaroe*. This art seems to have derived its origin from the idea that the preservation of the body was necessary for the return of the soul to the human form after it had completed its cycle of existence of three or ten thousand years. Sanitary reasons may also have influenced the ancient Egyptians; and the legend of Osiris, whose body, destroyed by Typhon, was found by Isis, and embalmed by his son Anubis, gave a religious sanction to the rite. The art appears as old as 4000 B.C. at least, for the bodies of Cheops, Mycerinus, and others of the age of the 4th dynasty, were embalmed. One of the earliest embalmments recorded in literature is that of the patriarch Jacob; and the body of Joseph was thus prepared, and transported out of Egypt. The process has been described by Herodotus and Diodorus; but their accounts are only partially confirmed by an examination of the mummies. A scribe marked with a reed-pen a line on the left side beneath the ribs, down which line the *paraschistes*, or ripper of the district (an officer of low class), made a deep incision with a rude knife of stone; he was then pelted with stones, and pursued with curses. The *tarichcutes*, or salter, next proceeded to remove the entrails and lungs, with the exception of the heart and kidneys, while a colleague extracted the brain through the nose. The body was ready for the salts and spices necessary for its preservation, the quality of which depended upon the sum to be expended. When Herodotus visited Egypt, three methods prevailed: the first, accessible only to the wealthy, consisted in passing peculiar drugs through the nostrils into the cavities of the skull, rinsing the belly in palm-wine, and filling it with myrrh, cassia, and other substances, and stitching up the incision in the left flank. The mummy was then pickled in natron for seventy days, and then washed and elaborately bandaged up in rolls of linen, cemented by gums, and set upright in a wooden coffin against the walls of the house or tomb. This process cost a silver talent, perhaps equal to £725 of our money. A cheaper process, by means of an injection of cedar-oil, cost a *mina*, relatively worth about £243. The poorer classes washed the corpse in myrrh, and salted it for seventy days. When thus prepared, and covered with a pictorial representation of the deceased, attired as a labourer in the world to come, and duly labelled as a 'justified Osiris,' the mummy was placed in a costly coffin (see SARCOPHAGUS) ready for sepulture, but was frequently kept some time before being buried—often at home—and even produced at festive entertainments, to recall to the guests the transient lot of humanity. All classes were embalmed, even malefactors; but various methods were employed besides those mentioned by Herodotus. Some mummies are found merely dried in the sand; others salted by natron, or soaked in bitumen (Jew's pitch) with or without the flank incision, having the brains removed through the eyes or base of the cranium, with the viscera returned into the body, placed upon it, or deposited in jars in shapes of the genii of the dead, the skin partially gilded, the flank incision covered with a tin plate, the fingers cased in silver, the eyes removed and replaced. So effectual were some of these processes that after 2000 or 3000 years the soles of the feet are still elastic and soft to the touch. The sacred animals were also mummied.



Egyptian Mummy.

Mummy Case of Queen Ahmes Nofretari: Height 9 feet. (From Maspero's *L'Archéologie Egyptienne.*)

but by simpler processes than men. It has been computed that since the practice began in 4000 B.C., down to 700 A.D., when it practically ceased, probably as many as 730,000,000 bodies were embalmed in Egypt; of which many millions are yet concealed. Important finds are made from time to time, as in 1881, when upwards of thirty mummies of potentates, including that of Rameses II., were discovered together at Deir-el-Bahari. Mummies, it may be observed in passing, were used in the 15th and 16th centuries of the Christian era for drugs and other medical purposes, and as nostrums against diseases, and a peculiar brown colour, used as the background of pictures, was obtained from the bitumen.

Other less successful means of embalming were used by nations of antiquity. The Persians employed wax; the Assyrians, honey; the Jews, aloes and spices; Alexander the Great was preserved in wax and honey, and some Roman bodies have been found thus embalmed. The Guanches, or ancient inhabitants of the Canary Isles, used an elaborate process like the Egyptian; and desiccated bodies, preserved by atmospheric or other circumstances for centuries, have been found in France, Sicily, England, and America, especially in Central America and Peru. In Burma the bodies of priests are stuffed with spices and honey and coated with wax and gold-leaf. The art of embalming was probably never wholly lost in Europe; De Bils, Swammerdam, Clauderus, Gooch, Bell, and others attained great success in the art; and a mode of embalming by incisions all over the body is detailed by Penicher. Ruysch, and after him William Hunter, injected essential oils through the principal arteries into the body. Boudet embalmed the bodies with camphor, balsam of Peru, Jew's pitch, tan, and salt. The discovery of Chaussier of the preservative power of corrosive sublimate, by which animal matter becomes rigid, hard, and grayish, introduced a new means of embalming by Beclard and Larrey; but owing to the desiccation, the features do not retain their shape. The discovery of the preservative power of a mixture of equal parts of acetate and chloride of alumina, or of sulphate of alumina, by Gannal in 1834, and of that of arsenic by Tranchini, and of pyroxilic spirits by Babington and Rees in 1839, and of the antiseptic nature of chloride of zinc, have led to the application of these salts to the embalming or preparation of bodies required to be preserved for a limited time. The latest method, by injection of a fluid into the arteries, is described by Dr B. W. Richardson, who has himself embalmed fifty bodies. The process is very common in the United States.

Embryology is that department of biology which reads the development of the individual organism. It is a succession of studies in anatomy and physiology which, when read into unity, give the history of the organism from its earliest individual appearance on to that vague point when it may be said to exhibit all the main features of adult life. The investigation necessarily takes two forms: a description of the structure of successive stages (*morphological*), and an analysis of the vital processes associated with each step (*physiological*). Nor is any embryological investigation complete which does not link the everyday development of individuals with the historical evolution of the race.

History.—Although the development of the chick, so much studied in embryological laboratories to-day, was watched 2000 years ago in Greece, it was only in the scientific renaissance of the 17th century that observation began to grow strong enough to wrestle with conjecture. Harvey, who towered as a strong genius above his contemporaries, and saw much farther, sought in 1651 to establish two main propositions: (1) that every animal was produced from an ovum—*ovum esse primordium commune omnibus animalibus;* and (2) that the organs arose by new formation (*epigenesis*), not from the mere expansion of some invisible preformation. These valuable generalisations were not, however, accepted, and even observations like those of Malpighi seemed for the time to tell against Harvey's prevision. The time was past for absolutely fanciful theories, and yet the dominant doctrine which persisted even into the 19th century was mystical enough. The germ, whether egg or seed, was believed to be a miniature model of the adult. 'Preformed' in all transparency, the organism lay *in esse* in the germ, only requiring to be 'unfolded.' Just like a bud which hides within its hull the floral organs of the future, so was every germ. 'There is no becoming,' Haller said; 'no part of the body is made from another; all are created at once.' But the germ was more than a marvellous bud-like miniature of the adult; it included all future generations. That germ lay within germ, in ever smaller miniature, after the fashion of an infinite juggler's box, was the logical corollary of the theory of preformation and unfolding. One of the controversies of the time was whether ovum or sperm was the more important. The ovists asserted the claims of the ovum, which only required to be awakened by the spermatozoon to begin its unfolding. The animalculists, on the other hand, maintained that the male element contained the preformed germ, and that the ovum was merely for its preliminary nutriment.

All this was virtually shattered by Wolff (1759), who reasserted Harvey's epigenesis, and showed that the germ consisted of almost structureless material, and that the process of development was a gradual organisation. Yet Wolff's work had not the effect of entirely demolishing preformationist conceptions. They lingered on, and had this much truth in them that the germs are indeed potential, though not miniature, organisms. To some extent Wolff reacted too far against the mystics in his emphasis on the simplicity of the germ, so that a correction was necessary when the cellular character of the reproductive elements was realised about a hundred years later. The observation of structural progress was slow in gaining self-confidence, for it was not till 1817 that Pander took up Wolff's work virtually where he left it. He was immediately reinforced and soon left behind by Von Baer, whose results laid a firm foundation for modern embryology. Since the establishment of the Cell-theory (see CELL) in 1838-39, and the associated researches which showed that the organism starts from a fusion of two sex-cells, and that development consists in the division of the fertilised ovum and differentiation of the results, progress has been both sure and rapid. The more modern demonstration of the fact of evolution has afforded a fresh impulse by its interpretation of the present as the literal child of the past.

The egg-cell or ovum is in all organisms the starting-point of the embryo, but development can rarely begin till this female element is supplemented by the male cell or spermatozoon. These sex-cells are liberated units of the parent-organism, but in most cases they stand in marked contrast to the great congeries of cells which form the 'body.' All the component units of the organism are indeed lineal descendants of a fertilised ovum, but the 'body'-cells become greatly changed into muscle, nerve, skeleton, and the like, while the reproductive cells retain with more or less intactness the characters of the original parent germ. It is this fact which makes the reproduction of like by like possible.

The unicellular animals or Protozoa, having obviously no 'body,' are directly comparable to the sex-cells of higher animals. The 'body' is the addition which makes the difference. In a few Protozoa, however, the results of the division of a unit remain associated together, and a loose colony of cells arises. Such a Protozoon behaves like an ovum or like a primitive male-cell in any of the higher animals. The loose colony may be very unstable, and may soon resolve itself into its component units, exactly as the primitive male-cell, which has divided into a clump of spermatozoa, breaks up and sets these active units free. But the colony may be more stable and retain its continuity (like a segmented ovum), thus bridging the gulf between unicellular and multicellular organisms. In such cases certain cells are set apart as reproductive, and eventually set adrift to start a fresh colony. This is the beginning of the differentiation of special reproductive cells. At first these were probably all alike and able to develop of themselves, but in a manner which does not concern us here (see SEX) they became differentiated as male and female elements, mutually dependent and complementary.

The ovum has all the essential characters of an ordinary animal cell. The cell-substance consists of Protoplasm (q.v.) and of material ascending to or descending from that climax. As in other cases, the cell-substance may be traversed by a network,—one of the intricacies which modern microscopic technique has revealed. Like other cells, the ovum includes a central differentiation or nucleus, technically called the germinal vesicle. This exhibits the essential nuclear elements in the form of rods, bands, or network, and other minute features described in the article CELL. The nucleus plays a most important part in the history of the ovum, and is believed to be the bearer of the hereditary characteristics.

As to the precise origin of the ova, it is enough here to state that in sponges they are simply well-fed cells in the general substance (middle stratum) of the sponge; that in Cœlenterates they may originate from outer or from inner layer; while in other animals they are almost always associated with the middle layer of the body, and as we ascend are more and more restricted to a distinct region or to a definite organ—the *ovary*.

The very young ovum is often at least like an Amœba (q.v.), and in Hydra (q.v.) this character persists. The first chapter in its history is one of nutrition and growth. This often occurs at the expense of neighbour cells, and the ovum may be the successful survivor of a clump. In other cases the nutriment, for immediate or future use, may be derived from the vascular fluid of the animal, or from special glands, which are sometimes simply degenerate portions of an originally larger ovary. The capital of nutriment thus derived is distinguished as the yolk. It varies greatly in quantity and disposition, and has great influence in determining the precise form which the future division of the ovum will take. It may be small in quantity and uniformly diffused through the cell, as in mammalian ova; there may be a larger quantity, which sinks to the lower part, as in frog spawn; there may be a very large amount, which quite dwarfs the genuine living matter, as in birds' eggs; or there may be a central accumulation, as in crustaceans and insects. The egg is very generally surrounded with some membrane, sheath, or shell, made by itself, or contributed by surrounding cells, or the product of special glands. In such envelopes there is often a special aperture (micropyle) through which alone the spermatozoon can enter. Hard shells like those of birds' eggs must obviously be formed after fertilisation has taken place.

The Male-cell or Spermatozoon.—In the unicellular organisms, among which we find the key to all beginnings, two cells, unable apparently to live independently, unite, and thus make a fresh start. In such cases the two units are usually similar in appearance, though doubtless different in chemical state. Sometimes, however, a small active cell unites with a larger and more passive neighbour, and here we find the first hint of the profound difference between the sexes—a difference of which the contrast between spermatozoon and ovum is literally a concentrated expression.

The spermatozoon is a true cell, though the nuclear portion often predominates over the cell-substance. It is one of the smallest animal cells, as the ovum is one of the largest; it is highly active, while the ovum is peculiarly passive; it rarely bears any nutritive material, while the ovum is very generally weighted with yolk. In its minute size, active locomotor energy, and persistent vitality, the sperm-cell resembles a flagellate Monad among Protozoa, while the ovum is strictly comparable to an Amœba or to one of the yet more passive or encysted forms. In most animals the spermatozoon exhibits three distinct parts: (*a*) the 'head,' or essential portion, consisting

Fig. 1.—Organisms:
a, ovum showing egg membrane, granules, and germinal vesicle; b, spermatozoon; c, hermaphrodite gland of snail, with ova and sperms; d, amœboid ovum; e, coalescence of sperm-cell and egg-cell.

almost wholly of nucleus; (*b*) the mobile 'tail' of contractile protoplasm which drives the 'head' along; and (*c*) a small middle portion connecting the head and tail.

In its origin the male-cell resembles the ovum, and the two cells are of course the physiological complements of one another. In history, however, the ovum is strictly comparable not to the sperm, but to the cell which divided to give rise to the sperms. The primitive-male-cell, or mother-sperm-cell, is the homologue of the ovum. Just as the latter divides in segmentation, so the mother-sperm-cell divides, and the divisions exhibited in what is technically called spermatogenesis are closely parallel to the various modes of segmentation exhibited by ova. The mother-sperm-cell segments, but the results have no coherence; they go asunder as spermatozoa. Thus, though all cells may be said to rank as equals, the sperm-cell has a longer history behind it than the ovum. The differences both in form and history express the great differences in chemical constitution which are summed up in the words male and female.

Maturation of the Ovum.—The egg-cell having attained its definite size or limit of growth, usually exhibits a somewhat enigmatical phenomenon known as the extrusion of polar globules. In the great majority of cases it buds off two tiny cells, by a true process of cell-division, in which the nucleus plays its usual orderly part. This extrusion is probably universal, but has not yet been observed in bird or reptile eggs. The polar cells come to nothing, though they may linger for a while in the precincts of the ovum. Their expulsion usually takes place before fertilisation has even begun, but sometimes is subsequent to the entrance of the spermatozoon into the ovum. The result of the twofold budding is that the *mass* of the nuclear elements is reduced by three-fourths, though their number appears to remain constant. In many parthenogenetic ova, which develop without fertilisation, Weismann has recently shown that only one polar globule is formed, and this he believes to be constant, and essentially associated with parthenogenesis.

The import of the process is much disputed. Cells do indeed usually divide at the limit of growth (see CELL), but the division here is peculiarly unequal so far as cell-substance is concerned. The marked inequality suggests the theory proposed by Minot, Balfour, and Van Beneden, that the polar globules are male extrusions from the predominantly female egg-cell. The retention of one in parthenogenetic ova is supposed to be what makes independent development possible. The retained polar globule replaces the otherwise necessary sperm. Bütschli looks at the matter rather historically than physiologically, and interprets this premature division of the ovum as the survival of an ancient habit which the mother-sperm-cell still retains. The polar cells are thus rudimentary or abortive female germs. This, however, hardly explains why they should so constantly occur. Weismann supposes the two polar globules to be very different from one another: the first extrudes a nuclear substance which was only useful while the egg was a-making; the second gets rid of half of the essential germ-plasma, the bearer of hereditary characteristics, all in order to make room for the addition of a corresponding quantity by the spermatozoon. Parthenogenetic ova only give off the first, and retain all their germ-plasma. Thus they are as able to start in development as fertilised ova which exhibit the circuitous process of first giving half of their germ-plasma away and then getting a similar quantity back from another source. There is no proof that the two extrusions are different in character, and Weismann's theory seems to invest ova with a prevision of the benefits of fertilisation. The simplest view is that the ovum divides at the limit of growth, that the inequality of division expresses an opposition between what is extruded and what is retained, and that this means the getting rid of some waste or male elements. In the differentiation of the male elements both among plants and animals, a parallel but reverse antithesis is often demonstrable.

Fig. 2.—Development of Sperms; maturation and fertilisation of Ova (diagrammatic):

1-4, Division of a mother-sperm-cell or primitive-male-cell into a ball of spermatozoa which breaks up; *a-f*, maturation and fertilisation of ovum; *a*, amœboid young ovum; *b*, later stage; *c*, budding off of a first polar cell; *d*, budding off of a second; *e*, spermatozoa round ovum, one entering; *f*, male and female nuclei about to fuse on completion of fertilisation.

Fertilisation.—The 'ovists' thought that the ovum was all-important, and only required the sperm's wakening touch to unfold its preformed model. The 'animalculists' were equally certain that the spermatozoon was all-important, and only required to be fed by the ovum. Even after the mutual dependence of the sex-elements had been recognised, the opinion prevailed that contact of the two was unessential, and that by an *aura seminalis* fertilisation was possible. In 1677 Hamm and Leeuwenhoek first distinctly saw spermatozoa; in 1780 Spallanzani showed by artificial fertilisation that the eggs must come into contact with the seminal fluid; in 1843 Martin Barry observed the spermatozoon in union with the ovum of the rabbit; in 1846 Kölliker proved the cellular origin and nucleated character of the male elements; and in 1872–75 Bütschli and Auerbach observed two nuclei in fertilised eggs. The dates of these representative discoveries show how gradually the result has been reached that the essence of fertilisation is the intimate union of a male and female cell.

It is needless to cite the numerous investigators who have made the following statements possible: (1) Only one male element really unites with the egg-cell. By a sudden change after the entrance of one sperm the ovum usually ceases to be receptive. The entrance of more than one occasionally occurs, but the result is pathological. (2) The union is very intimate; the nuclei are at least as important as the protoplasm, and according to most authorities much more so. (3) The two nuclei are attracted or drawn to one another, and fuse intimately to form a single nucleus of double origin. (4) Intimate as the union is, its orderliness is not less conspicuous; half of the result is still traceable to the male and half to the female.

While these are the demonstrable structural facts, what the union means is another matter. Some compare the action of the sperm to a ferment, others to stimulating waste products, while Weismann virtually denies sex differences altogether, and maintains that the union is a mere quantitative addition of the amount of germ-plasma lost in extruding the second polar globule. That the spermatozoon furnishes half of the architectural nuclear substance and thereby half of the hereditary characteristics is certain, that it also affords a chemical stimulus to division it is difficult to doubt. In single-celled animals fertilisation is essential to the continued vitality of the species; in all cases the intimate mingling of sex-elements, different in constitution and past experience, secures both an average constancy and minor variations.

Segmentation.—Soon after the essential act of fertilisation has been accomplished in the intimate union of the nuclei, the egg begins to divide. What physical and chemical attractions and repulsions operate in this process we do not know. It is certain that the nuclear elements, which play a very important part throughout, have what we cannot but call a strong individuality of behaviour. It is certain too that the cell-substance plays an important part, and that it is not merely passive material with which the nucleus operates. Recent observers, led by Van Beneden, have elucidated something of the marvellous interaction between nuclei and cell-substance. It would seem that there is an intracellular muscular system, that from certain centres in the protoplasm strands radiate which moor themselves to the nuclear elements and move them about. It has been further established that the double nucleus of the fertilised ovum is accurately composed half of female and half of male elements. When the egg divides into two, the nucleus of each daughter-cell is again half male and half female, and it is probable that this exact dualism persists yet further.

The different ways in which ova divide depend mainly upon the quantity and disposition of the passive yolk-material. (1) When there is very little nutritive capital, and that uniformly diffused, the whole ovum divides, vertically and horizontally, till a sphere of approximately equal cells is formed. This total segmentation occurs for instance in the ova of sponge, starfish, lancelet, and mammal. (2) In the ova of the frog, where the actual process of division may be most conveniently watched, there is more yolk, which has chiefly sunk to the lower hemisphere of the egg. Division is still total, but after a few segmentations it will be seen that the upper hemisphere cells are dividing more rapidly and are becoming markedly smaller than those in the lower part. The segmentation is total but unequal. (3) In the ova of birds and reptiles and many fishes there is a large quantity of yolk, and the formative substance lies like a drop on the upper surface of the nutrient mass. Division is restricted to the formative protoplasm, and thus the segmentation is conspicuously partial. (4) In the ova of crustaceans, insects, and their allies, the yolk usually accumulates in the centre of the ovum as a more passive, nutritive core, surrounded by the active, formative protoplasm. The latter divides, and forms a sphere or ellipsoid of cells around the less markedly divided yolk. In Peripatus—the survivor of ancestral insects—the whole ovum segments, but the cells are not for a while defined off from one another, so that the result looks like a giant Protozoon with numerous nuclei. Hints of this are seen in other cases.

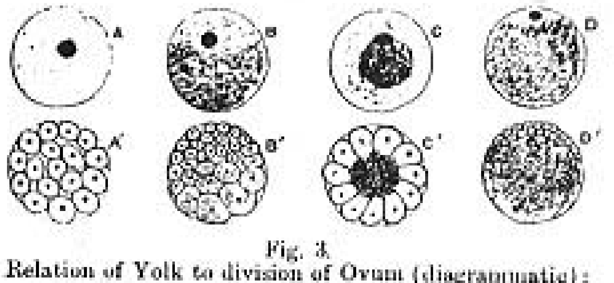


Fig. 3.

Relation of Yolk to division of Ovum (diagrammatic):

A, little and diffuse yolk.	A', total equal division.
B, more yolk at lower pole.	B', total unequal division.
C, central yolk.	C', peripheral division.
D, much yolk.	D', partial division.

Morula and Gastrula.—The result of segmentation is a ball of cells, differing according to the above described modes of division. When a wide cavity has been left, between the cells as they multiplied, a hollow sphere is formed, technically called a *blastosphere*; if no such conspicuous 'segmentation cavity' has been left the result is an almost solid mulberry-like ball of cells—a *morula*. When the division is partial, mainly confined to an area of formative protoplasm lying upon a nutritive mass, the result is a disc of cells which by and by spreads round the yolk. Such a segmented area is generally known as the *blastoderm*. (See D', fig. 3.)

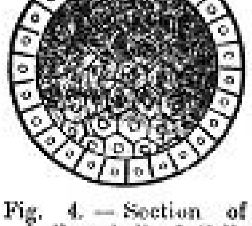

Fig. 4.—Section of hollow ball of Cells or Blastosphere.

The next decisive chapter is one of infolding, or the formation of a *gastrula*. In the simplest cases one hemisphere of a hollow ball of cells is dimpled or invaginated into the other. More accurately, the one hemisphere sinks into and becomes surrounded by the other. The sphere becomes a two-layered sack or gastrula, with an opening technically called the *blastopore*. In many other cases—e.g. fishes, reptiles, and birds—owing to the yolk, complete invagination is not possible. An infolding still occurs, but it is no longer conspicuous, and the gastrula-stage is thus disguised. It must also be noted that the two-layered condition may arise by *arrangement* of the cells, without there being any process that can be called invagination. Thus, in the oval ciliated embryo or *planula* of most Hydrozoa, the two layers have been frequently observed to arise by a process of internal differentiation, known as *delamination*.

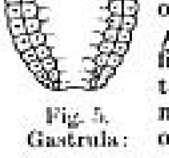

Fig. 5.
Gastrula:
Showing ectoderm, ciliated endoderm, blastopore, and central cavity.

The Germinal Layers.—Even in a simple colony of cells like a Volvox all the units do not remain alike. Inside cells are in different conditions from outside cells, and division of labour with consequent difference of structure is bound to occur. So again, in the ball of cells into which the ovum divides, the one hemisphere with heavier material is usually different from the upper hemisphere, which is specifically lighter and less encumbered with reserve material. Even in the morula or blastosphere differentiation has begun.

But we have just seen that by the folding of one hemisphere into the other, or in other ways, a gastrula often more or less modified arises. The embryo thereby attains definitely differentiated layers—outer and inner. The preformationists spoke of development as an unfolding; we now insist on an infolding. The layered character of the embryo was early recognised by Wolff, and yet more clearly by Pander and Von Baer, but its fundamental import can hardly be said to have been realised till Huxley in 1849 compared the outer and inner cell-layers of Cœlenterates (hydroids, jelly-fish, &c.) to the outer and inner layers which embryologists had begun to demonstrate in development. Soon afterwards Allman gave to the outer and inner layers of Cœlenterates the names *ectoderm* and *endoderm*, which are now universally used for the outer and inner layers of every embryo. The results reached by Huxley and Haeckel, Kovalevsky and Ray Lankester, and many others, have made it certain that the formation of these two germinal layers is constant in animals, that they are exactly comparable throughout the series, and that with few exceptions they give rise to precisely the same adult structures.

In sponges and Cœlenterates only two genuine layers of cells are developed. A middle stratum, seen in faint suggestion in the common Hydra, may indeed appear between outer and inner layers, and may be of the greatest importance in the structure of the animal, but embryologists are not inclined to allow this middle stratum—the so-called *mesoglœa*—to rank as a distinct layer beside the other two.

In higher animals, however, there is a definite middle layer or *mesoderm* between the other two. Its history involves much greater difficulty than that of the ectoderm and endoderm; it seems as if it might arise in some half-dozen different ways. One common mode of origin has been emphasised by the brothers Hertwig in what they call the 'Cœlome-theory.' The inner layer arises by an infolding of the outer, and a primitive gut-cavity (*archenteron*) thus results. Now begins an out-folding. From the gut-cavity two sacks (*cœlome-pockets*) grow out, one on either side, insinuating themselves between the first two layers. The cavities of the sacks form the future body-cavity of the animal; the outer and inner walls form the corresponding two divisions of the mesoderm. However this middle layer arises, it finally exhibits an inner and an outer division, so that the Hertwigs speak of *four* germinal layers. The outer (parietal or somatic) portion of the mesoderm clings to the external body-wall, forming muscles and the like; the inner (visceral or splanchnic) portion cleaves to the internal organs.

Origin of Organs.—With few exceptions, the same organs and structures arise from the same layers—e.g. the nervous system from the ectoderm, the lining of the mid-gut from the endoderm. (*a*) *The ectoderm* or *epiblast* gives origin to outer skin or epidermis, external skeleton, superficial glands, sense-organs, nervous system, the infoldings at both ends of the gut, and probably to the primitive excretory (segmental) duct. (*b*) The *endoderm or hypoblast* forms the lining of the mid-gut, and necessarily, too, of outgrowths from it, such as the lungs and various glands. In vertebrates it also gives rise to that important skeletal axis—the notochord—which always precedes the 'backbone.' (*c*) The *mesoderm* or *mesoblast* gives rise to all the rest. That is to say, the under-skin, the muscles, the connective tissue, the internal skeleton, the lining of the body-cavity, the heart and the blood, and the like are all mesodermic. The reproductive organs, though to some extent structures by themselves, also arise, in the great majority of cases, in connection with the mesoderm. It must be noted, further, that while the main part of a structure is referable to one of the three layers, the entire structure is very often composite. Thus, the eye of vertebrates mainly arises as an outgrowth from the brain, but some of the less essential parts are furnished by the mesoderm. The outgrowths from the mid-gut are in origin endodermic, but they too are always aided by the middle layer.

Physiological Embryology.—The immense progress of embryology within recent years has been almost wholly morphological. Of the physiological conditions of development we know relatively little. The later stages of embryonic life in higher animals have been studied by Preyer and others with much success, but this is but the threshold of investigation. A few luminous results as to the architectural conditions are due to the courage of His and Rauber, who have followed the earlier suggestions of Pander and Lotze. The task, which is involved in stupendous difficulties, has been continued in the experimental investigations of O. Hertwig, Fol, Pflüger, Born, Roux, Schultze, Gerlach, and others. Observations as to the actual dynamics of cell-division, such, for instance, as those of Van Beneden and Boveri, are beginning to appear; while the title of a recent work by Berthold—*Protoplasmic Mechanics*—shows how the biologist persistently seeks the aid of the student of physics in order to explain the architecture of the living organism. 'To think that heredity will build organic beings without mechanical means' is, according to His, 'a piece of unscientific mysticism;' while Pflüger insists on the conception of development as 'an organic crystallisation.' The laws of growth, which express how each fertilised egg-cell must divide, and how the resulting units must arrange themselves first in layers and thereafter into organs, must be expressed in terms of physical and chemical conditions. But this is the task of the future.

Generalisations.—(1) *The Ovum-theory.*—In all cases of ordinary sexual reproduction among plants or animals the offspring develops from a fertilised egg-cell. This is the ovum-theory prophesied by Harvey in 1651, again almost realised by Wolff in 1759, but only demonstrated about a hundred years later when the organism was at length analysed into its component cells (see CELL). The fact that every plant or animal begins at the beginning again, at the level of the Protozoa or single-celled organisms, Agassiz does not hesitate to call one of the greatest discoveries in the natural sciences in modern times.

(2) *The Gastræa-theory.*—The simplest animals are single cells; these occasionally form loose colonies or balls of cells; next come sack-like two-layered organisms, such as the simplest sponges. These are the first three grades among living animals, but they also correspond to the first three chapters in the life-history of each organism. The single cell (the ovum), the ball of cells (the morula or blastosphere), the sack of cells in two layers (the gastrula), we have seen to be the first three stages in development. As this gastrula-stage always occurs, though sometimes disguised by the yolk, in the life-history of animals, Haeckel justly emphasised it as the individual's recapitulation of an ancestral state. The simplest, stable, many-celled animal he believed to be like a gastrula (see fig. 5), and he called this hypothetical ancestor of all higher animals a gastræa. A few living animals are still almost at this level: all animals pass through it in their gastrula-stage. The gastrula is a recapitulation of the ancestral gastræa. Rival conceptions of what the first stable, many-celled animal was like have been since proposed, but the gastræa-theory still holds the field.
