(Dated: November 15, 2021)

The PHENIX collaboration presents first measurements of low-momentum ( $0.4 < p_T < 3$  GeV/ $c$ ) direct-photon yields from Au+Au collisions at  $\sqrt{s_{NN}}=39$  and 62.4 GeV. For both beam energies the direct-photon yields are substantially enhanced with respect to expectations from prompt processes, similar to the yields observed in Au+Au collisions at  $\sqrt{s_{NN}}=200$ . Analyzing the photon yield as a function of the experimental observable  $dN_{ch}/d\eta$  reveals that the low-momentum ( $>1$  GeV/ $c$ ) direct-photon yield  $dN_{\gamma}^{dir}/d\eta$  is a smooth function of  $dN_{ch}/d\eta$  and can be well described as proportional to  $(dN_{ch}/d\eta)^{\alpha}$  with  $\alpha \sim 1.25$ . This new scaling behavior holds for a wide range of beam energies at the Relativistic Heavy Ion Collider and Large Hadron Collider, for centrality selected samples, as well as for different,  $A+A$  collision systems. At a given beam energy the scaling also holds for high  $p_T$  ( $> 5$  GeV/ $c$ ) but when results from different collision energies are compared, an additional  $\sqrt{s_{NN}}$ -dependent multiplicative factor is needed to describe the integrated-direct-photon yield.

The measurement of direct photons is a unique tool to study the strongly coupled quark-gluon plasma (QGP) produced in heavy ion collisions and its “fireball” evolution to hadron resonance matter. Direct photons leave the interaction region unmodified, and provide information from different stages of the collision integrated over space and time [1–3]. Of particular interest are low momentum direct photons, which are thought to be radiated mostly by the QGP and the hot hadron gas.

In experiments direct photons are detected simultaneously with a large number of photons from final state hadron decays, mostly from  $\pi^0$  and  $\eta$  mesons. The main experimental challenge is to subtract these decay contributions from the measurement to obtain the photons directly emitted from the collision. In addition to photons from the hot fireball, direct photons are also emitted from initial hard scattering processes, such as quark-gluon Compton scattering among the incoming partons. Disentangling this prompt component from the photons emitted from the fireball is the second experimental challenge.

Although a very promising observable, only recently PHENIX discovered first evidence of low  $p_T$  direct photons in central  $A+A$  collisions at  $\sqrt{s_{NN}} = 200$  GeV [4]. Since then PHENIX has published centrality dependent yields in Au+Au [5] as well as azimuthal asymmetries of direct photon emission [6, 7]. Results on yields are also available from STAR [8] for the same collision system and from ALICE [9, 10] for Pb+Pb collisions at  $\sqrt{s_{NN}} = 2760$  GeV.

A consistent picture emerges based on those data: a

large number of low  $p_T$  direct photons are radiated from the fireball, the yield has a strong centrality dependence and a significant azimuthal anisotropy expressed by the coefficients  $v_2$  and  $v_3$  of a Fourier expansion of the direct photon yield with respect to the reaction plane.

A large body of theoretical work on direct photon emission exists in the literature. Many model calculations are qualitatively consistent with the data, but a quantitative description remains difficult, primarily due to the simultaneous presence of large yields and azimuthal anisotropies [11–34].

In this publication we present low- $p_T$  direct photon data from Au+Au collisions at  $\sqrt{s_{NN}} = 39$  GeV and 62.4 GeV taken with the PHENIX experiment in 2010. We compare the spectra and the integrated yields to those from  $p+p$  and Au+Au collisions at various centralities at  $\sqrt{s_{NN}} = 200$  GeV [4, 5], and to those from Pb+Pb collisions at  $\sqrt{s_{NN}} = 2760$  GeV [9]. This covers a factor of 70 in  $\sqrt{s_{NN}}$  for colliding systems of comparable size.

The 39 and 62.4 GeV spectra are obtained from two data samples of minimum bias Au+Au collisions that have a total of  $7.79 \times 10^7$  and  $2.12 \times 10^8$  events, respectively. The minimum bias trigger and centrality selection is derived from data taken with the PHENIX beam-beam counters [35]. The data analysis uses the same techniques deployed for the analysis of the  $\sqrt{s_{NN}} = 200$  GeV Au+Au data [5], which were taken in the same year under nearly identical conditions. Here we give a brief overview of the setup and data analysis, and refer to our previous publication for more details [5].

Photons are reconstructed through their conversion to

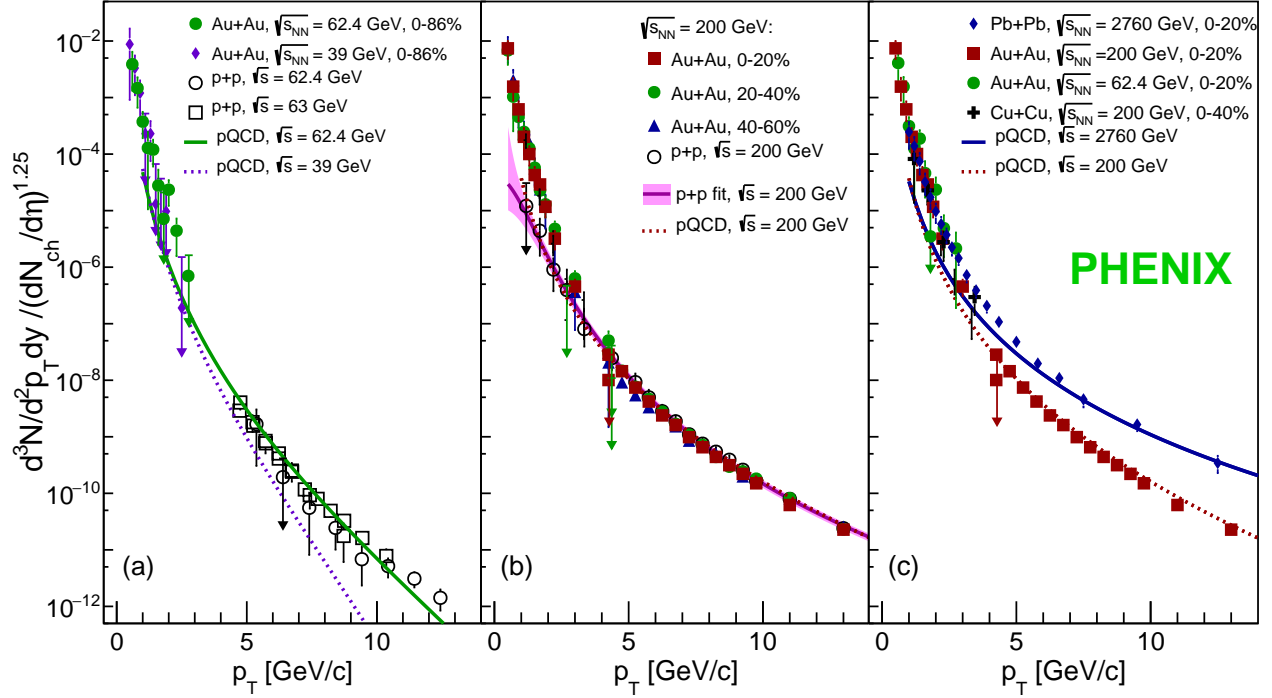

FIG. 1. Direct photon spectra normalized by  $(dN_{ch}/d\eta)^{1.25}$  for Au+Au at 39 and 64.2 GeV (a) and (b) at 200 GeV [6]; panel (c) compares for different  $A+A$  systems at different  $\sqrt{s_{NN}}$  [9, 36]. Panels (a) and (b) also show  $p+p$  data [5, 37–39]. All panels show pQCD calculations for the corresponding  $\sqrt{s}$  [16, 40]. All error bars are quadratic sum systematic and statistical uncertainties. Uncertainties on the  $dN_{ch}/d\eta$  are not included.

$e^+e^-$  pairs in the detector material, specifically the readout boards of the Hadron Blind Detector (HBD) [41] that are located at a radius of 60 cm from the collision point. The trajectories and momenta of the  $e^+$  and  $e^-$  are determined by the central arm tracking detectors [42]. Each of the two central arms covers  $90^\circ$  in azimuth and a rapidity range of  $|\eta| < 0.35$ . A transverse momentum cut,  $p_T > 200$  MeV/c, is applied to each trajectory. To identify trajectories as  $e^+$  or  $e^-$  candidates, we require a minimum of three associated signals in the ring-imaging Čerenkov detector [43] and that the energy measured in the Electromagnetic Calorimeter (EMCal) [44] matches the measured momentum ( $E/p > 0.5$ ).

All  $e^+$  and  $e^-$  reconstructed in the same arm are matched to pairs. In the 2010 setup there is no tracking near the collision point, so the origin of the tracks is assumed. For each  $e^+e^-$  pair the mass is calculated twice: first assuming the pair originated at the event vertex ( $m_{vtx}$ ), then assuming the  $e^+e^-$  is a conversion pair from the HBD readout boards ( $m_{HBD}$ ). In the latter case,  $m_{HBD}$  will be consistent with zero, within a mass resolution of a few MeV/ $c^2$ , while  $m_{vtx}$  will be about 12 MeV/ $c^2$ . With a cut on both masses a sample of photon conversion is selected with a purity of about 99%. The combinatorial background is negligible, because the

conversion material, in radiation length  $X/X_0 \sim 3\%$ , is about 10 times thicker than materials closer to the vertex; and it is at a relatively large distance from the event vertex. The 1% contamination is mostly from  $\pi^0$  Dalitz decays,  $\pi^0 \rightarrow \gamma e^+e^-$ , and from conversions in front of the HBD readout boards.

The direct photon content in the inclusive photon sample is determined by the ratio  $R_\gamma$ , which is the ratio of all emitted photons ( $\gamma^{incl}$ ) to those from hadron decays ( $\gamma^{hadron}$ ).  $R_\gamma$  is determined using a double ratio method:

$$R_\gamma = \frac{\gamma^{incl}}{\gamma^{hadron}} = \frac{\langle \varepsilon_\gamma f \rangle \left( N_\gamma^{incl} / N_\gamma^{\pi^0, tag} \right)_{Data}}{\left( \gamma^{hadron} / \gamma^{\pi^0} \right)_{Sim}}. \quad (1)$$

All quantities in this equation are functions of the conversion photon  $p_T^{ee}$ . The measured quantities are the number of detected conversion photons  $N_\gamma^{incl}$  and the subset of those that are tagged as  $\pi^0$  decay photon  $N_\gamma^{\pi^0, tag}$ . The tagged photons  $N_\gamma^{\pi^0, tag}$  are determined statistically in bins of the  $p_T^{ee}$ . Each conversion photon is paired with all showers with  $E > 400$  MeV measured in the EMCal of the same arm. The invariant  $e^+e^- \gamma$  mass is calculated and the counts above the combinatorial background in the  $\pi^0$  mass peak give  $N_\gamma^{\pi^0, tag}$ . To convert

the ratio  $N_{\gamma}^{incl}/N_{\gamma}^{\pi^0,tag}$  to  $\gamma^{incl}/\gamma^{\pi^0}$  only  $N_{\gamma}^{\pi^0,tag}$  needs to be corrected for the momentum averaged conditional acceptance-efficiency  $\langle \varepsilon_{\gamma,f} \rangle$  for the second decay photon to be reconstructed in the EMCAL. All other corrections to the numerator and denominator cancel [5]. Because rather loose cuts are applied to the EMCAL showers,  $\langle \varepsilon_{\gamma,f} \rangle$  is mostly determined by the  $\pi^0$  decay kinematics and the detector geometry. Thus,  $\langle \varepsilon_{\gamma,f} \rangle$  can be calculated to a few percent accuracy using a Monte-Carlo simulation of  $\pi^0$  decays in the acceptance. Photons from pions are determined from the measured  $\pi^0$  spectra [45] and the decay kinematics. The spectrum of decay photons ( $\gamma^{hadron}$ ) is derived from  $\gamma^{\pi^0}$  and the  $\eta/\pi^0$  ratio [46], which is independent of collision system and energy, with additional contribution from heavier mesons of about 4%.

Once  $R_{\gamma}$  is established the direct photon spectrum can be calculated as:

$$\gamma^{\text{direct}} = (R_{\gamma} - 1) \gamma^{\text{hadron}}. \quad (2)$$

The uncertainty on  $\gamma^{\text{hadron}}$ , approximately 10% [5], cancels in  $R_{\gamma}$  (with that of  $\gamma^{\pi^0}$  in (1)) but has to be applied to  $\gamma^{\text{direct}}$ . The systematic uncertainties of the new data at 39 and 62.4 GeV are similar in magnitude to those for 200 GeV presented in [5]. For the integrated yield we treat every systematic uncertainty as  $p_T$ -correlated in the interest of consistency throughout the different data sets.

Figure 1 shows the invariant yield of direct photons normalized to  $(dN_{ch}/d\eta)^{1.25}$ , this normalization is discussed below. Panel (a) shows Au+Au minimum bias data at  $\sqrt{s_{NN}} = 62.4$  and 39 GeV, panel (b) gives Au+Au data in three centrality classes at 200 GeV, and panel (c) compares data from different beam energies and systems. Below 3 GeV/c the 62.4 and 39 GeV data show a substantial direct photon yield, which are comparable in magnitude and spectral shape, albeit within large uncertainties. For 62.4 GeV we can also extract a direct photon signal for 0%–20% and 20%–40% centrality selection and find that the direct photon yield increases with centrality. All observations are similar to those already published for Au+Au collisions at  $\sqrt{s_{NN}} = 200$  GeV [5].

For the 200 GeV data, the centrality dependence of direct photons was analyzed in terms of the number of nucleon participants  $N_{\text{part}}$ . It was found that the integrated photon yield increases as  $(N_{\text{part}})^{\alpha}$ . This approach is not useful for comparing results across  $\sqrt{s_{NN}}$ , because  $N_{\text{part}}$  saturates at the same value for similar size systems at different beam energies. Instead we choose  $dN_{ch}/d\eta$ , which is a measured observable, for the comparison.

Direct photon production at high  $p_T$  is dominated by hard scattering and scales with the number of binary collisions  $N_{\text{coll}}$ . To study the interplay of bulk and hard particle production, we plot  $N_{\text{coll}}$  versus  $dN_{ch}/d\eta$  at midrapidity for several beam energies in Fig. 2. The PHENIX data are taken from [47] and the  $\sqrt{s_{NN}} = 2760$  GeV data are from ALICE [48]. The data exhibit a remarkable scaling between  $N_{\text{coll}}$  and  $dN_{ch}/d\eta$ , which takes the form:

$$N_{\text{coll}} = \frac{1}{SY(\sqrt{s_{NN}})} \times \left( \frac{dN_{ch}}{d\eta} \right)^{\alpha} \quad (3)$$

FIG. 2. Number of binary collisions,  $N_{\text{coll}}$ , vs.  $dN_{ch}/d\eta|_{\eta=0}$ , for four beam energies. All data are simultaneously fitted by a power-law with  $\alpha = 1.25$ . The error bars show the uncertainty from of  $N_{\text{coll}}$  from the Glauber MC.

Here we introduce the specific yield  $SY$ , which increases logarithmically with  $\sqrt{s_{NN}}$  as  $SY(\sqrt{s_{NN}}) = 0.98 \log(\sqrt{s_{NN}}) - 1.83$ . In contrast, the power  $\alpha$  is independent of  $\sqrt{s_{NN}}$ . We fit all data simultaneously and find  $\alpha = 1.25 \pm 0.02$ . This finding combined with the results of [49] imply that  $N_{\text{coll}} \sim (dN_{ch}/d\eta)^{1.25} \sim N_{qp}^{1.25}$ , where  $N_{qp}$  is the number of quark participants.

Panel (b) of Fig. 1 shows that at high- $p_T$  the direct photon yield normalized by  $(dN_{ch}/d\eta)^{1.25}$  is the same for all Au+Au centrality selections and for  $p+p$  at  $\sqrt{s_{NN}} = 200$  GeV. This is expected, because at high  $p_T$  photons are predominantly produced in hard scattering and there is no nuclear modification to the spectra. Above 3–4 GeV the data agree well with a perturbative quantum chromodynamics (pQCD) calculation for a normalization and factorization scale of  $\mu = 0.5p_T$  [40, 50], also shown in the figure. The pQCD calculation was normalized to the experimental  $dN_{ch}/d\eta$  for  $\sqrt{s} = 200$  GeV from [51]. The  $p+p$  data were fitted with a modified power law function  $a(1 + p_T^2/b)^c$  [36]. Below 2 GeV/c the Au+Au yield is significantly enhanced compared to that from  $p+p$ . Surprisingly, the yield from Au+Au continues to follow the  $N_{\text{coll}}$  scaling behavior independent of centrality. We find a universal momentum spectrum of direct photons after they are normalized to  $N_{\text{coll}} = (dN_{ch}/d\eta)^{1.25}$ .

FIG. 3. Integrated direct photon yield ( $p_T > 1.0$  GeV/c) vs.  $dN_{ch}/d\eta$ , for data sets shown in Fig. 1. The dashed line is a power law fit with a fixed  $\alpha = 1.25$  slope. Also shown is the integrated yield of the fit to  $p+p$  data and from the pQCD calculations, both scaled by  $N_{coll}$  [16, 40].

FIG. 4. Integrated direct photon yield ( $p_T > 5.0$  GeV/c) vs.  $dN_{ch}/d\eta$ , for different data sets. The dashed lines show power law fits to the data with fixed slope of  $\alpha = 1.25$ . Integrated yields from pQCD calculations scaled by  $N_{coll}$  are also shown.

In panels (a) and (c) of Fig. 1 we see that for  $p_T < 2$  GeV/c the same scaling occurs not only for different centrality selections, but also for different  $\sqrt{s_{NN}}$  and collision systems. At higher  $p_T$  the expected difference with  $\sqrt{s_{NN}}$  is observed. Like for  $\sqrt{s_{NN}} = 200$  GeV, at high  $p_T$  the 2760 GeV data are well described by the pQCD calculation, though only above 5–6 GeV rather than 3–4 GeV. Note that the extrapolated pQCD calculations for  $p+p$  at different  $\sqrt{s}$  seem to converge to the same normalized yield at low  $p_T$  as well, but at a tenth of the A+A yield.

We quantify direct photon emission by integrating the invariant yield above  $p_T = 1.0$  GeV/c and  $p_T = 5.0$  GeV/c. The integrals with the lower threshold will be dominated by excess low  $p_T$  photons unique to A+A

collisions, while the higher threshold characterizes the production in the pQCD region. The results are shown in Figs. 3 and 4 as a function of  $dN_{ch}/d\eta$ . Also plotted are power-law functions  $A(dN_{ch}/d\eta)^\alpha$  with fixed  $\alpha = 1.25$  and normalization fitted to the data.

For the lower  $p_T$  threshold the integrated yields from A+A (Fig. 3) show the scaling behavior with  $(dN_{ch}/d\eta)^{1.25}$  observed in Fig. 1. The A+A points are compared to the integrated yield for  $\sqrt{s} = 200$  GeV  $p+p$  compared to the integrated yield for  $\sqrt{s} = 200$  GeV  $p+p$  obtained from the fit to the data, which is scale with  $N_{coll}$  to the corresponding  $dN_{ch}/d\eta$  for each  $\sqrt{s_{NN}} = 200$  GeV A+A point. The width of the band is given by the combined uncertainties of the fit function and  $N_{coll}$ . It is parallel to the A+A trend but lower by about an order of magnitude. Also shown are the scaled integrated yields from pQCD calculations for  $\sqrt{s} = 62.4, 200,$  and  $2760$  GeV. They are consistent with the shaded band independent of beam energy.

For the  $p_T$  threshold of 5 GeV/c the integrated yields from Au+Au and  $p+p$  at 200 GeV follow the same trend (Fig. 4), and are consistent with the pQCD calculation. The 2760 GeV data follow the same trend, but the yields are significantly higher. The pQCD calculation is slightly below the data.

While convenient and related to  $N_{coll}$ , the functional form  $A(dN_{ch}/d\eta)^\alpha$  does not lend itself to an obvious interpretation. It is also not unique; for instance the data can be equally well fitted by  $A(dN_{ch}/d\eta) + B(dN_{ch}/d\eta)^{4/3}$ . The important point is that A+A data from different centralities and a wide range of collision energies can be empirically described in terms of  $dN_{ch}/d\eta$  with just two parameters, suggesting some fundamental commonality in the underlying physics.

There are two main conclusions from the A+A data and the analyses presented in this paper. (i) At a given beam energy the direct photon yield scales with  $dN_{ch}/d\eta^{1.25}$  or  $N_{coll}$  for all observed  $p_T$ , independent of centrality. There seems to be no qualitative change in the photon sources and/or their relative contributions. (ii) From  $\sqrt{s_{NN}} = 39$  to 2760 GeV the same scaling is observed for  $p_T < 2$  GeV/c. This suggests that the main sources contributing to this  $p_T$  range are very similar also across beam energies.

If thermal radiation is the source of low  $p_T$  direct photons, the similarity at the same  $dN_{ch}/d\eta$  across beam energies and centralities for  $p_T < 2$  GeV/c, suggests that the bulk of the matter that emits the radiation is similar in terms of temperature and space time evolution. This would be natural, if most of the photons are emitted near the transition from QGP to hadronic gas.

While at high  $p_T$  the scaled yields in  $p+p$  and A+A are identical, they differ by a factor of 10 at low  $p_T$ . This implies that there must be a transition from the small  $p+p$  yield to the enhanced A+A-like low  $p_T$  yields in the  $dN_{ch}/d\eta$  range of  $\approx 2$  to 20, which will be accessible with the data taken by PHENIX with small systems  $p+Au$ ,

$d+Au$ , and  $^3\text{He}+Au$ .

We thank the staff of the Collider-Accelerator and Physics Departments at Brookhaven National Laboratory and the staff of the other PHENIX participating institutions for their vital contributions. We acknowledge support from the Office of Nuclear Physics in the Office of Science of the Department of Energy, the National Science Foundation, Abilene Christian University Research Council, Research Foundation of SUNY, and Dean of the College of Arts and Sciences, Vanderbilt University (U.S.A), Ministry of Education, Culture, Sports, Science, and Technology and the Japan Society for the Promotion of Science (Japan), Conselho Nacional de Desenvolvimento Científico e Tecnológico and Fundação de Amparo à Pesquisa do Estado de São Paulo (Brazil), Natural Science Foundation of China (People's Republic of China), Croatian Science Foundation and Ministry of Science and Education (Croatia), Ministry of Education, Youth and Sports (Czech Republic), Centre National de la Recherche Scientifique, Commissariat à l'Énergie Atomique, and Institut National de Physique Nucléaire et de Physique des Particules (France), Bundesministerium für Bildung und Forschung, Deutscher Akademischer Austausch Dienst, and Alexander von Humboldt Stiftung (Germany), J. Bolyai Research Scholarship, EFOP, the New National Excellence Program (ÚNKP), NKFIH, and OTKA (Hungary), Department of Atomic Energy and Department of Science and Technology (India), Israel Science Foundation (Israel), Basic Science Research Program through NRF of the Ministry of Education (Korea), Physics Department, Lahore University of Management Sciences (Pakistan), Ministry of Education and Science, Russian Academy of Sciences, Federal Agency of Atomic Energy (Russia), VR and Wallenberg Foundation (Sweden), the U.S. Civilian Research and Development Foundation for the Independent States of the Former Soviet Union, the Hungarian American Enterprise Scholarship Fund, the US-Hungarian Fulbright Foundation, and the US-Israel Binational Science Foundation.
