(Dated: May 17, 2022)

In ferromagnetic metals, the interconversion of spin and charge currents via the spin Hall effect and its inverse can depend on the angle between the ferromagnet's magnetization and the spin current polarization direction. Here, such a spin-dependent (inverse) spin Hall effect is found in the ferromagnetic alloy $\text{Co}_{60}\text{Fe}_{20}\text{B}_{20}$. In a non-local magnon transport experiment, $\text{Co}_{60}\text{Fe}_{20}\text{B}_{20}$ is used to both excite and detect magnonic spin currents flowing in the ferrimagnetic insulator $\text{Y}_3\text{Fe}_5\text{O}_{12}$. We find that the signal amplitude is significantly modulated by tuning the direction of the $\text{Co}_{60}\text{Fe}_{20}\text{B}_{20}$ magnetization. We design a sample structure that completely prevents direct magnonic coupling between the ferromagnets. Thus, we can identify unambiguously an intrinsic electronic origin of the observed effect.

^{a)}Electronic mail: Klaeui@uni-mainz.de

Pure spin currents that exclusively carry angular momentum have become a key feature of various spintronics concepts as they allow one to transport^{1,2} or manipulate³ information in magnetic systems in the absence of net charge motion. In general, pure spin currents can be carried by an equal number of electrons with opposite spin momenta moving in opposite directions or magnons, the quanta of spin waves.⁴ Feasible methods to generate or detect pure spin currents are provided by the spin Hall effect (SHE) and its inverse (ISHE).⁵ In conductors with strong spin orbit interaction, charge currents are converted into transverse electronic spin currents by means of the SHE, while the ISHE describes the reversed process. When in contact with a magnetic insulator, this can be used, for instance, to either generate^{6,7} or detect⁸ magnonic spin flow in the insulating magnetic layer.

So far, research mainly focused on spin Hall studies in non-magnetic materials such as $4d/5d$ transition metals and their alloys.^{5,9} Recently, metallic ferromagnets (FM) have also been shown to exhibit the (I)SHE.¹⁰ However, in ferromagnets there is with the magnetization direction an additional degree of freedom, which could impact the conversion efficiency. In the literature, contradicting claims have been put forward with no effect of the magnetization direction reported in Ref. 11, while for a fixed spin current polarization direction the detection efficiency was shown in Ref. 12 and 13 to depend on the FM's magnetization orientation. This has been used, for instance, in recent devices to implement a spin valve like effect.¹² However, in both these previous experiments the FM detectors directly interface the magnetic system mediating the magnonic spin currents such that the latter couple to the FM ISHE detector. Assuming a two spin current model,¹⁴ the transferred angular momentum thus may be transported by both magnonic¹⁵ and electronic spin currents in the FM detector, potentially resulting in different effects. Therefore, to unambiguously identify the effect of charge based spin currents for the detection efficiency of the ISHE in a metallic ferromagnet, one needs to design a system where the magnonic contribution can be fully suppressed.

In this letter, the magnetization orientation-dependent interconversion of spin and charge information (i.e. SHE and ISHE) is probed in the metallic ferromagnet $\text{Co}_{60}\text{Fe}_{20}\text{B}_{20}$ (CoFeB). Performing a non-local magnon transport experiment,^{6,7,16} the signal amplitudes induced by spin currents that are either triggered or detected in the CoFeB are measured as a function of the external field amplitude that sets the angle between the detector magnetization and the spin current polarization direction. To exclude magnonic effects, we add a non-magnetic

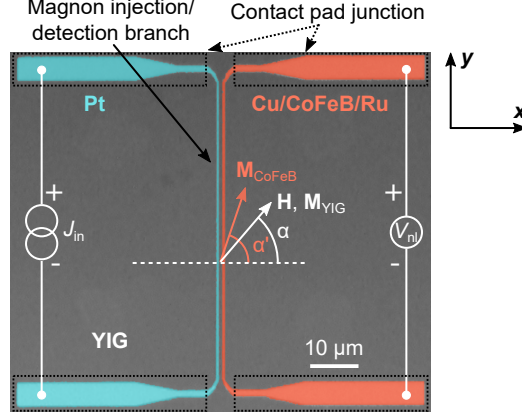

Figure 1. Colored optical micrograph of the implemented non-local device structure comprising two parallel, electrically insulated Pt (blue) and Cu/CoFeB/Ru (orange) wires. The electrical wiring as well as the magnetic field direction definition are indicated. The micrograph was taken before the deposition of contact pads.

metal spacer layer, which exchange decouples the magnetic system that laterally transports the spin current ($\text{Y}_3\text{Fe}_5\text{O}_{12}$) and the CoFeB injector/detector. The resulting signal amplitudes are compared to magnetoresistance data, revealing a direct correlation between the spin signal amplitude and the direction of the CoFeB magnetization, demonstrating a spin orientation-dependent (I)SHE.

Figure 1 shows an optical micrograph of the implemented device structure, which includes two parallel, electrically insulated Pt and Cu/CoFeB/Ru wires deposited on the insulating ferrimagnet $\text{Y}_3\text{Fe}_5\text{O}_{12}$ (YIG). The latter has a thickness of $d_{\text{YIG}} = 630$ nm and is grown on a (111)-oriented $\text{Gd}_3\text{Ga}_5\text{O}_{12}$ substrate via liquid phase epitaxy. The nanowires were produced by a multi-step lift-off procedure based on electron beam lithography. First, nanowires with a width $w = 250$ nm were patterned, followed by the sputter deposition of 7.5 nm of Pt. For the second type of nanowire ($w = 350$ nm, center-to-center distance to the first wire $d = 1250$ nm), a Cu/CoFeB/Ru multilayer stack with individual layer thicknesses of $d_{\text{Cu}} = 2$ nm, $d_{\text{CoFeB}} = 7$ nm and $d_{\text{Ru}} = 2$ nm was deposited after an additional lithography step. While the Cu layer exchange decouples YIG and CoFeB, Ru acts as a capping layer. For simplicity, the Cu/CoFeB/Ru multilayer is referred to as CoFeB in the following.

In the experiment, both the Pt and CoFeB wire are used for magnon injection and detection in order to study the charge-to-spin (SHE) as well as spin-to-charge (ISHE) conversion in CoFeB, respectively. Applying a charge current to the injector results in both the thermal

and electrical excitation of magnonic spin currents in YIG via, respectively, the spin Seebeck effect¹⁷ (SSE) and the SHE induced spin current in the injector.⁶ The magnons propagate in the magnetic insulator and, when absorbed by the detector, induce an electrical voltage response by means of the ISHE. Implementing a DC measurement scheme, the injector charge current $J_{\text{in}} = \pm 300 \mu\text{A}$ ($j_{\text{in}}^{\text{Pt}} \approx 1.6 \times 10^{11} \text{ A m}^{-2}$, $j_{\text{in}}^{\text{CoFeB}} \approx 7.8 \times 10^{10} \text{ A m}^{-2}$) was supplied by a Keithley 2400 source meter, simultaneously recording the injector resistance. As demonstrated later, magnetoresistance effects reveal relevant information on the magnetic configuration of the system. At the detector, the non-local spin signal was picked up by a Keithley 2182A nanovoltmeter. To separate electrically and thermally generated spin signals, the polarity of the charge current applied to the injector was reversed and the difference (electrically induced signal) or sum (thermally induced signal) of the corresponding non-local voltages was considered:^{16,18}

$$V_{\Delta}^{\text{nl}} = [V_{\text{nl}}(+J_{\text{in}}) - V_{\text{nl}}(-J_{\text{in}})]/2., \quad (1)$$

$$V_{\Sigma}^{\text{nl}} = [V_{\text{nl}}(+J_{\text{in}}) + V_{\text{nl}}(-J_{\text{in}})]/2. \quad (2)$$

For the spin transport measurements, an in-plane magnetic field \mathbf{H} was applied and both angular-dependent (sample rotation in a fixed field, max. $\mu_0 H = 85 \text{ mT}$) and field sweep measurements at different angles (max. $\mu_0 H = 175 \text{ mT}$) were performed. The field configuration is illustrated in Fig. 1, with the angle $\alpha = 0^\circ$ signifying an alignment of \mathbf{H} in the positive \mathbf{x} -direction. All measurements were conducted at room temperature.

First, the behavior of the non-local device was verified by angular-dependent measurements capturing both the electrically and thermally excited signal. In Fig. 2a,b, V_{Δ}^{nl} (circles) and V_{Σ}^{nl} (squares) are shown as a function of α for the two distinct configurations of either using CoFeB as injector and Pt as detector (CoFeB \rightarrow Pt, Fig. 2a) or vice versa (Pt \rightarrow CoFeB, Fig. 2b). Note that the applied field of $\mu_0 H = 85 \text{ mT}$ is larger than the saturation field of both YIG and CoFeB (see Supporting Information) such that their respective magnetizations are always completely aligned along the field direction. Considering first the electrically induced signal, V_{Δ}^{nl} reveals for both configurations a $\cos^2(\alpha)$ angular dependence, which is given by the combination of the individual symmetries of the magnon injection and detection processes via SHE and ISHE, respectively.⁶ The signals have a negative sign and, within the error, equal amplitude with $V_{\Delta}^{\text{nl}}(\text{CoFeB} \rightarrow \text{Pt}) = (-203 \pm 4) \text{ nV}$ and $V_{\Delta}^{\text{nl}}(\text{Pt} \rightarrow \text{CoFeB}) = (-202 \pm 3) \text{ nV}$. The negative sign of V_{Δ}^{nl} signifies that the ISHE

Figure 2. (a),(b) Angular-dependent non-local voltages induced by electrically (V_{Δ}^{nl}) and thermally (V_{Σ}^{nl}) excited spin currents for a field larger than the saturation field. In (a) CoFeB is used as injector and Pt as detector, while results obtained for the reversed configuration are shown in (b).

charge current in the detector and J_{in} applied to the injector flow in the same direction, meaning that the spin Hall angle of CoFeB and Pt have the same sign.¹⁶

Regarding the thermal response, V_{Σ}^{nl} detected by the Pt detector (Fig. 2a) exhibits a $\cos(\alpha)$ symmetry, which is, in the case of YIG/Pt, characteristic for an SSE induced signal.¹⁹ In the Pt \rightarrow CoFeB configuration, the angular dependence of the voltage measured by the CoFeB detector notably differs (Fig. 2b), approximately matching a $\sin(2\alpha)$ variation. Apart from a SSE current flowing in the YIG,¹⁹ the signal can be given by further magneto-thermal effects like the anomalous²⁰ or planar²¹ Nernst effect that may arise in the CoFeB. The observed $\sin(2\alpha)$ symmetry possibly suggests a dominating planar Nernst effect, which is a result of an in-plane temperature gradient and the spin-thermoelectric equivalent of the anisotropic magnetoresistance (AMR²²).²¹ Altogether, this result demonstrates that V_{Σ}^{nl} , which mainly relates to thermal effects, is not suitable to quantify the spin-charge interconversion in CoFeB. This measurement scheme will therefore not be considered in light of this aspect hereafter. Instead, this work will focus on V_{Δ}^{nl} originating from electrically induced magnon transport.

The necessary information on the magnetic configuration of the system is provided by magnetoresistance (MR) effects. While for YIG/Pt only the spin Hall magnetoresistance (SMR) is expected to appear,²³ both SMR and AMR can be observed in YIG/CoFeB. The SMR amplitude depends on the angle between the polarization of the SHE induced spin current in the Pt or CoFeB wire and the YIG magnetization,²³ while the AMR is determined

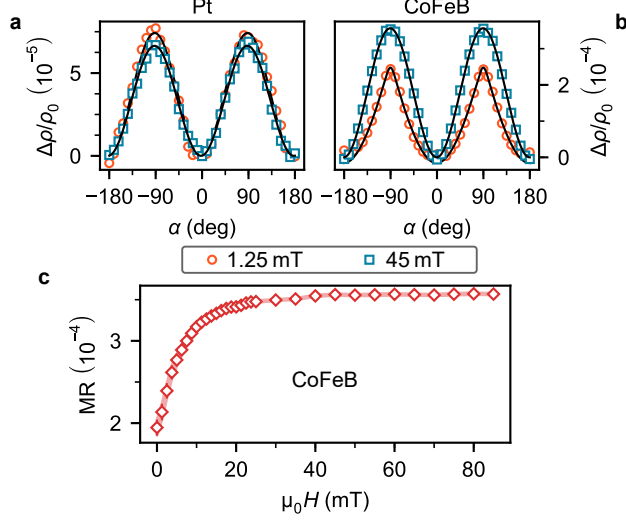

Figure 3. Amplitude $\Delta\rho/\rho_0$ of the angular-dependent magnetoresistance effect in the CoFeB wire (AMR dominated) as a function of magnetic field. Error bars represent the (a), (b) standard error of the mean and (c) propagated errors.

by the angle between J_{in} and the magnetization direction in CoFeB.²² Figure 3a shows angular-dependent SMR data obtained for the Pt injector at two distinct external magnetic fields $\mu_0 H = 1.25$ mT and $\mu_0 H = 45$ mT. For both field values, the resistance change $\Delta\rho/\rho_0$ reveals the expected $\sin^2(\alpha)$ symmetry²³ with comparable SMR amplitudes, signifying that the YIG magnetization follows the external field even at low field strengths. In the case of the CoFeB wire, both shape and amplitude of the angular-dependent magnetoresistance vary significantly for the different field amplitudes applied, see Fig. 3b. At low fields, $\Delta\rho/\rho_0$ exhibits a flat resistance change near $\alpha = 0^\circ, \pm 180^\circ$ and distinct peaks at $\alpha = \pm 90^\circ$, whereas the $\sin^2(\alpha)$ dependence characteristic for both SMR and AMR²² is seen at larger external fields. Considering that the measured resistance is dominated by the magnon injection/detection branch of the wire, see Fig. 1, this behavior can be explained by a dominating AMR and a uniaxial shape anisotropy. The latter forces $\mathbf{M}_{\text{CoFeB}}$ to align along the wire axis at low fields, while at larger fields the Zeeman energy becomes dominating and $\mathbf{M}_{\text{CoFeB}}$ aligns parallel to \mathbf{H} , irrespective of the field direction.

Bearing in mind that the direction of \mathbf{M}_{YIG} is fixed by the external field for basically all field values, the anisotropic MR recorded for CoFeB signifies that \mathbf{M}_{YIG} and $\mathbf{M}_{\text{CoFeB}}$ are indeed, as expected, exchange-decoupled by the Cu interlayer. Furthermore, large external fields are required to achieve parallel alignment of \mathbf{M}_{YIG} and $\mathbf{M}_{\text{CoFeB}}$ for external field di-

rections that are perpendicular to the wire, which confirms that the studied system allows one to investigate the magnetization orientation-dependent generation/detection of spin currents in CoFeB. To derive the angle $\phi = \alpha' - \alpha$ between \mathbf{M}_{YIG} and $\mathbf{M}_{\text{CoFeB}}$, see Fig. 1, one can principally solve the Stoner-Wohlfarth model²⁴ and reconstruct an angular-dependent magnetoresistance, as demonstrated by the solid line in Fig. 2b. However, the additional MR in the nanowire contact pad junctions prevents an unambiguous quantification of ϕ , such that the amplitude of the total MR effect in CoFeB $\Delta\rho/\rho_0 = [\rho(90^\circ) - \rho(0^\circ)]/\rho(0^\circ)$ is used to obtain qualitative information on the CoFeB magnetization orientation at different field strengths. As shown in Fig. 3c, $\Delta\rho/\rho_0$ initially increases with increasing field amplitude until it saturates above a critical value of $\mu_0 H_c \geq 25$ mT. Hence, $\mathbf{M}_{\text{CoFeB}}$ is fully aligned with the external field (\mathbf{M}_{YIG}) in all directions for $H \geq H_c$, whereas a finite angle between \mathbf{M}_{YIG} and $\mathbf{M}_{\text{CoFeB}}$ appears for small fields aligned perpendicular to the wire axis.

The data shown so far demonstrates that the implemented non-local device indeed enables the electrical generation and detection of spin currents in CoFeB for zero (high field) and finite (low field) angles between the YIG and CoFeB magnetization. As a result, one can probe both a potential spin orientation-dependent SHE and ISHE in the metallic ferromagnet. Figure 4a shows V_{Δ}^{nl} as a function of α and field amplitude in the Pt \rightarrow CoFeB configuration, in which CoFeB acts as the spin current detector. To exploit the whole spectrum of available field amplitudes ($0 \text{ mT} \leq \mu_0 H \leq 175 \text{ mT}$), the angular-dependent data was extracted from uniaxial hysteresis loops measured at different angles α ($\mu_0 H = 0 \text{ mT}$ signifies the remanent state of the system, see Supporting Information). As can be seen in the graphs, the amplitude $\Delta V_{\Delta}^{\text{nl}}$ of the non-local voltage increases with increasing field and fitting yields $\Delta V_{\Delta}^{\text{nl}}(0 \text{ mT}) = (-162 \pm 4) \text{ nV}$, $\Delta V_{\Delta}^{\text{nl}}(10 \text{ mT}) = (-173 \pm 5) \text{ nV}$ and $\Delta V_{\Delta}^{\text{nl}}(150 \text{ mT}) = (-194 \pm 4) \text{ nV}$. The detailed field-dependence is shown in Fig. 4b, revealing an initial increase of the absolute signal amplitude, followed by a saturation. The relative amplitude change between the low and high field level is $[\Delta V_{\Delta}^{\text{nl}}(> 100 \text{ mT}) - \Delta V_{\Delta}^{\text{nl}}(0 \text{ mT})]/\Delta V_{\Delta}^{\text{nl}}(0 \text{ mT}) = (17.2 \pm 3.4) \%$. In the case of the reverse setup, i.e., CoFeB now acts as spin current injector and Pt as detector, a qualitatively similar but weaker effect amplitude of $(5.3 \pm 2.6) \%$ is observed, see Fig. 4c.

To check whether this field-dependent modulation of the electrically induced spin signal correlates with the CoFeB magnetization orientation and, hence, can be explained by a spin-dependent SHE or ISHE, the field dependence of $\Delta V_{\Delta}^{\text{nl}}$ in the Pt \rightarrow CoFeB configuration is

Figure 4. (a) Angular-dependent variation of V_{Δ}^{nl} at different magnetic fields obtained in the Pt \rightarrow CoFeB configuration. The data is extracted from uniaxial hysteresis loops at fixed angles between the external field and the wire axis ($\alpha = 0^\circ$: field perpendicular to the wire), with $\mu_0 H = 0$ mT implying remanence of system. Solid lines correspond to fit functions. (b),(c) Amplitude $\Delta V_{\Delta}^{\text{nl}}$ of the angular-dependent voltage as a function of field for (b) the Pt \rightarrow CoFeB configuration and (c) the CoFeB \rightarrow Pt configuration. Error bars account for (a) the standard error and (b),(c) fit parameter errors.

compared to that of the MR amplitude in CoFeB in Fig. 5. Evidently, $\Delta\rho/\rho_0$ and $|\Delta V_{\Delta}^{\text{nl}}|$ exhibit the same field dependence with an initial amplitude increase and a saturation above $\mu_0 H_c \gtrsim 25$ mT. As mentioned above, the magnetoresistance in CoFeB is AMR dominated and directly depends on the direction of $\mathbf{M}_{\text{CoFeB}}$. The matching field dependences thus

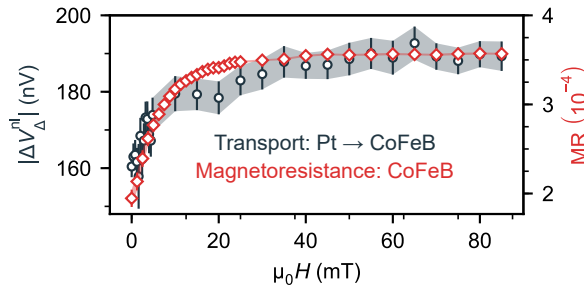

Figure 5. Direct comparison of $\Delta\rho/\rho_0$ (Fig. 3) and the non-local signal amplitude $\delta V_{\Delta}^{\text{nl}}$ (Fig. 4b) in the CoFeB wire as a function of field. Error bars are given by the standard error ($\Delta\rho/\rho_0$) and by extracted fit parameter errors ($\Delta V_{\Delta}^{\text{nl}}$).

demonstrate that the spin-to-charge conversion efficiency in CoFeB exhibits a magnetization orientation dependence, which is termed here spin-dependent inverse spin Hall effect. Bearing in mind Onsager’s reciprocity relations,²⁵ the same conclusion can be drawn for the SHE (see Fig. 4c).

The observation of a spin-dependent SHE and ISHE in CoFeB agrees with the findings reported by Das *et al.* in Ref. 13, who studied the non-local injection and detection of pure spin currents by Ni₈₀Fe₂₀ that was deposited directly on a YIG film, showing a similar effect to the one observed for CoFeB here. However in this previous work, the two magnetic layers are directly exchange coupled, whereas in this work a non-magnetic Cu interlayer is introduced that exchange-decouples the two magnetic layers. It ensures that purely electronic spin currents are probed by the CoFeB such that the field-dependent signal modulation is solely given by electronic effects. In the experiment by Das *et al.*, both magnonic and electronic effects play a role and this may explain the notably larger amplitude change of the spin injection/detection observed for Ni₈₀Fe₂₀ compared to CoFeB in this work. In addition to that, one may have to consider the distinct intrinsic properties of the metallic ferromagnets^{26,27} as well as a possible magnetization orientation dependence of both the spin mixing conductance²⁸ at the YIG/Ni₈₀Fe₂₀ interface and spin memory loss²⁹ at the Cu/CoFeB interface.

We finally turn to the comparison of the spin dependent SHE and ISHE. We find that there is a difference in the amplitude modulation for the spin current detection [(17.2 ± 3.4) %] (Fig. 4b) and generation [(5.3 ± 2.6) %] (Fig. 4c), which may be due to the growth of a Cu/CoFeB/Ru multilayer stack. While in both cases a spin current flows perpendicularly to the Cu/CoFeB interface, a large in-plane charge current flows through the wire when employed as injector. Finite element simulations (see Supporting Information) show that spatially varying current densities in the multilayer, which are due to different resistivities of the single Cu, CoFeB and Ru^{30,31}) layers, lead to Oersted fields that can affect the SHE induced spin current. The simulation data reveals that in the Cu layer notable out-of-plane Oersted field components are created near the wire edges, while the Oersted field in the CoFeB layer is insignificant in comparison. Since the SHE effect creates spin currents with an in-plane spin polarization $\boldsymbol{\mu}_s$ at the Cu/CoFeB interface, this out-of-plane field may alter their amplitude due to a torque $\boldsymbol{\tau} \propto \boldsymbol{\mu}_s \times \mathbf{H}_{Oe}$. However, to verify this mechanism, further studies beyond the scope of this work including varied multilayer configurations are

required.

To summarize, the spin-dependent (inverse) spin Hall effect that exhibits a conversion efficiency that depends on the angle between the magnetization in the ferromagnetic (I)SHE layer and the direction of the spin current polarization has been probed in $\text{Co}_{60}\text{Fe}_{20}\text{B}_{20}$, revealing a significant modulation of the interconversion efficiency in the material. In a non-local transport experiment, magnonic spin currents flowing in the insulating ferrimagnet YIG are generated or detected by exploiting both SHE and ISHE in the CoFeB, respectively. Depending on the relative alignment between the YIG and CoFeB magnetization, the injection or detection efficiency notably changes. Compared to previous work comprising Co ¹² and $\text{Ni}_{80}\text{Fe}_{20}$ ¹³ where both magnonic and electronic effect play a role due to the direct exchange coupling of the spin transport and detector/injector layers, here we decouple these. So in this work the pure electronic origin is investigated and quantified as the introduction of a non-magnetic Cu interlayer ensures purely electronic spin currents emitted or absorbed by the CoFeB. Our results demonstrate the possibility to use CoFeB as an efficient spin current injector or detector for magnonic applications, with its spin orientation-dependent injection/detection efficiency introducing an additional degree of freedom to tune the spin-charge interconversion in flexible novel magnonic devices.
