There are many theories where a dark matter particle is part of a multiplet with an electrically charged state. If WIMP dark matter (χ^0) is accompanied by a charged excited state (χ^-) separated by a small mass difference, it can form a stable bound state with a nucleus. In supersymmetric models, the χ^0 and the χ^- could be the neutralino and a charged slepton, such as the neutralino-stau degenerate model. The formation binding process is expected to result in an energy deposition of O(1--10~MeV), making it suitable for detection in large liquid scintillator detectors. We describe new constraints on the bound state formation with a xenon nucleus using the KamLAND-Zen 400 Phase-II dataset. In order to enlarge the searchable parameter space, all xenon isotopes in the detector were used. For a benchmark parameter set of $m_{\chi^0}=100~\text{GeV}$ and $\Delta m=10~\text{MeV}$, this study sets the most stringent upper limits on the recombination cross section $\langle \sigma v \rangle$ and the decay-width of χ^- of $2.0\times10^{-31}~\text{cm}^3/\text{s}$ and $1.1\times10^{-18}~\text{GeV}$, respectively (90% confidence level).

(Dated: January 18, 2021)

A. Introduction

Dark matter is one of the most pressing problems in nature. It is expected to consist of one or more new, beyond the Standard Model particles. A well-motivated class of dark matter particles is weakly interacting massive particles (WIMPs). The neutralino in supersymmetric (SUSY) theory is a good example of a WIMP [1]. It has neutral charge and is stable relative to the age of the Universe. Direct dark matter search experiments have searched for WIMPs interacting with nuclei with a strength weaker than the weak interaction [2, 3]. Despite achieving great sensitivity to the WIMP-nucleus cross section, no signal has been observed so far. Here, we report on an alternative search, where the WIMP is accompanied by a charged excited state. Ref. [4] proposed to observe the bound state formation between the charged excited state and ordinary nuclei as a method to search for this kind of dark matter particle. The KamLAND-Zen detector has the capability to search for O(1-10) MeV energy depositions via this reaction. In this paper, we describe new constraints on this search.

B. The KamLAND-Zen 400 detector

The main goal of KamLAND-Zen is to search for neutrino-less double-beta decays $(0\nu\beta\beta)$ in ¹³⁶Xe nuclei [5]. KamLAND-Zen 400 was the first phase of the project and ran from Sep. 2011 to Oct. 2015. The KamLAND detector, located 2,700 m.w.e underground in the Kamioka mine, was originally designed to measure anti-neutrinos, such as reactor- and geo-neutrinos [6–8]. The detector is layered with an outer and an inner detector. The outer detector (OD) is a cylindrical water Cherenkov detector to veto events primarily from cosmic muons. The inner detector consists of a spherical stainless steel tank with 1879 Photo Multiplier Tubes (PMT) facing the inside volume, filled with organic liquid scintillator (LS) and non-scintillating mineral oil (MO). A 6.5-m-radius spherical balloon made of nylon and EVOH inside the tank contains 1 kton of the LS (KamLS). The remainder of the volume between the balloon and the stainless steel tank is filled with MO. A second, 1.54-m-radius teardrop shaped balloon (inner balloon, IB) with 13 tons of xenon-loaded LS (Xe-LS) was located at the center of the KamLAND detector. The vertex and energy are reconstructed using charge and hit timing information extracted from waveforms acquired with the PMTs.

The IB was constructed from 25 μ m-thick nylon film and surrounded by the KamLS. The Xe-LS was composed of 80.7% decane and 19.3% psedocumene (1,2,4-trimethylbenzene) by volume, 2.29 g/liter of the fluor PPO (2,5-diphenyloxazole) and (2.91 \pm 0.04)% of xenon gas by weight. The xenon gas was isotopically enriched and measured to be (90.77 \pm 0.08)% ¹³⁶Xe and (8.96 \pm 0.02)% ¹³⁴Xe. Other xenon isotopes had negligible presence. The energy response of the Xe-LS and the KamLS were different. The relative light yield of the KamLS to the Xe-LS is estimated to be 1.07 [9]. The difference is taken into account in this study. The KamLAND-Zen 400 data acquisition period is divided into two phases, before and after a Xe-LS purification to handle different background rates in the Xe-LS. Phase-I includes a background from ^{110m}Ag (β -decay, $\tau = 360$ day, Q = 3.01 MeV) creating a peak near 2.7 MeV visible energy. The peak-shape background disappeared after xenon distillation and LS replacement. This analysis only uses the Phase-II dataset taken between Dec. 11th 2013 and Oct. 27th 2015 to avoid the peak-shaped ^{110m}Ag background [10]. The livetime is 534.5 days. The total xenon mass (all isotopes) in KamLAND-Zen 400 Phase-II was 380.7 \pm 3.2 kg.

C. The model and the expected signal

As mentioned in Section A, there are scenarios where a WIMP is part of a multiplet with an electrically charged excited state [4, 11]. If such a WIMP does not have a large enough annihilation cross-section, co-annihilation only can determine the dark matter's abundance. If the mass difference Δm between the WIMP and the excited state is sufficiently small, the charged excitation of the WIMP can form a stable bound state with a nucleus [4]. In this process, the Coulomb binding energy, whose value depends on the target nucleus, is released and the observable energy is of the order O(1--10 MeV). Detectors studying neutrinos and $0\nu\beta\beta$ are well-suited to detect events in this energy range. The bound state formation process and the effective Yukawa-type Lagrangian, which governs the bound state formation are given by [4](case A in the reference):

$$N_Z + \chi^0 \to (N_Z \chi^-) + e^+, \tag{1}$$

$$\mathcal{L} = \bar{\chi^0} (g_{eL} \mathbf{P}_L + g_{eR} \mathbf{P}_R) e \chi^{-\dagger} + \text{H.c.}, \tag{2}$$

^{*} Corresponding author. hosokawa@awa.tohoku.ac.jp

FIG. 1. The expected energy spectra via the bound state formation for several Δm in the KamLAND-Zen 400 detector.

where N_Z is the target nucleus with atomic number Z, $g_{eL,R}$ are the general complex couplings of the chirality projections $\mathbf{P}_{L,R}$, and χ^0 (χ^-) is the WIMP ground (excited) state, respectively. In SUSY models, the latter two could be the neutralino and a charged slepton, such as the neutralino-stau degenerate model [12, 13]. If the bound state ($N_Z\chi^-$) is not in its ground state, it will de-excite by emitting γ -rays. In addition to the de-excitation γ -rays and a positron, annihilation γ -rays could be observed in this process. Therefore, the observable energy is given by [4]:

$$E_{\text{tot}} = E_{e^+} + E_{\gamma} + 2m_e,$$
 (3)

where

$$E_{e^{+}} = E_b^{(n,l)} - \Delta m - m_e, \tag{4}$$

$$E_{\gamma} = E_b^{(0)} - E_b^{(n,l)},\tag{5}$$

so that

$$E_{\text{tot}} = E_b^{(0)} - \Delta m + m_e, \tag{6}$$

where E_{e^+} and E_{γ} are the kinetic energy of the positron and the de-excitation γ -rays. The Coulomb binding energy E_b of $(N_Z\chi^-)$ allows to bridge the mass difference $\Delta m \equiv m_{\chi^-} - m_{\chi^0}$, the value depends on the target nucleus. Assuming a step-like nuclear charge distribution, $E_b^{(0)}$, the binding energy corresponding to the ground state of $(N_Z\chi^-)$, is calculated to be 18.4 MeV for a xenon target [11]. By increasing Z, $E_b^{(0)}$ also increases and the searchable Δm region is larger, so that xenon nuclei offer a good target. $E_b^{(n,l)}$ is the excited-state energy with the usual principal and orbital quantum numbers of the capture level (n,l); The energy distributions of the positrons and the γ -rays change with $E_b^{(n,l)}$. However, $E_{\rm tot}$ is monochromatic, regardless of the capture level. The signal shape is basically determined only by the energy response of the detector. Figure 1 shows the expected energy spectra for several Δm values, where $E_{\rm vis}$ is the visible energy in KamLAND-Zen and differs from the intrinsic energy deposition due to energy non-linearity and the light yield difference between the Xe-LS and the KamLS. The energy non-linearity, the light yield difference and the energy resolution ($\sigma_E = 7.3\%/\sqrt{E({\rm MeV})}$) are taken into account [5]. The higher and lower visible energy ranges correspond to lower and higher Δm , respectively. Here a single nuclear de-excitation γ -ray with total energy E_{γ} is considered; multiple γ -rays emissions give a negligible difference from the single gamma-ray analysis.

The expected number of signals in an energy bin $\Delta E = E_{\text{max}} - E_{\text{min}}$ is given by [4]:

$$N_{\text{expected}} = \frac{MT N_T \rho_{\text{DM}} \langle \sigma v \rangle}{2m_{\chi^0}} \left[\text{Erf} \left(\frac{E_{\text{max}} - E_{\text{tot}}}{\sqrt{2}\sigma_E} \right) - \text{Erf} \left(\frac{E_{\text{min}} - E_{\text{tot}}}{\sqrt{2}\sigma_E} \right) \right], \tag{7}$$

where MT, N_T , $\rho_{\rm DM}$ and $\langle \sigma v \rangle$ are detector exposure, number of target nuclei, the local density of dark matter and the WIMP-nucleus recombination cross section with incoming dark matter velocity v, respectively. In general, the signal is expected to have a Gaussian peak. However, the simulated signal shapes in the KamLAND-Zen 400 detector

(Fig.1) have non-Gaussian distributions due to the light yield difference between the Xe-LS and the KamLS. The ΔE has therefore to be defined considering the non-Gaussian signal shape. Once the WIMP mass m_{χ^0} and Δm are chosen, the induced detector signal can be translated into a constraint on $\langle \sigma v \rangle$ or the χ^{-} 's decay width $\Gamma_{\chi^{-}}$, following Eq.(7) [4]:

$$\langle \sigma v \rangle \simeq (|g_{eL}|^2 + |g_{eR}|^2)/(8\pi m_{\chi^0}) \times \sum_{n,l} B_{n,l},$$

$$B_{n,l} \simeq (E_b^{(n,l)} - \Delta m - m_e) \sqrt{(E_b^{(n,l)} - \Delta m)^2 - m_e^2} \times \int d^3 r_1 d^3 r_2 \phi_{n,l}^*(\vec{r}_1) \phi_{n,l}(\vec{r}_2) e^{i\mu \vec{v} \cdot (\vec{r}_1 - \vec{r}_2)},$$
(9)

$$B_{n,l} \simeq (E_b^{(n,l)} - \Delta m - m_e) \sqrt{(E_b^{(n,l)} - \Delta m)^2 - m_e^2} \times \int d^3 r_1 d^3 r_2 \phi_{n,l}^*(\vec{r}_1) \phi_{n,l}(\vec{r}_2) e^{i\mu \vec{v} \cdot (\vec{r}_1 - \vec{r}_2)}, \tag{9}$$

$$\Gamma_{\chi^{-}} = \tau_{\chi^{-}}^{-1} \tag{10}$$

$$\simeq \frac{\sqrt{\Delta m^2 - m_e^2}}{4\pi m_{v^0}} (\Delta m + m_e) (|g_{eL}|^2 + |g_{eR}|^2), \tag{11}$$

where $B_{n,l}$, $\phi_{n,l}$ and τ_{χ^-} are the contributions from the capture into the state (n,l), the wave function of the relative motion of $(N\chi^-)$ with reduced mass μ and the lifetime of χ^- , respectively. A translation into a constraint on Γ_{χ^-} allows us to combine our results with the limits on the stau's decay width $\Gamma_{\tilde{\tau}}$ obtained in collider experiments, such as CMS [14].

Analysis

As a preliminary step to the analysis, we apply the same event selection to the dataset as for the $0\nu\beta\beta$ analysis [5]:

- 1. Events with energies over ~ 30 MeV and OD-triggered events are vetoed as muon events. Events within 2 ms after a muon crossing are also vetoed to reject PMT afterpulses and instability of signal baseline;
- 2. Sequential decays of ²¹⁴Bi-Po and ²¹²Bi-Po are tagged by delayed-coincidence and pileup-detection methods and rejected;
- 3. Events from shorter-lived spallation products i.e. ⁶He, ⁸Li, ¹⁰C and ¹²B, are suppressed by a triple-coincidence tag of a muon, a neutron identified by capture γ rays and the product's decay;
- 4. Anti-neutrino events which produce a positron and a neutron from inverse β -decay are identified with the delayed-coincidence tagging method and vetoed;
- 5. Badly reconstructed events are identified by time-charge-hit discriminator and rejected.

The total detection efficiency for the bound state formation is over 99.9%, where the deadtime due to the spallation cut and post-muon events are taken into account in the livetime calculation.

Figure 2 shows the observed energy spectrum, which includes the high-energy range (above 4.8 MeV) not used in the $0\nu\beta\beta$ analysis for two different fiducial volumes. The two-neutrino double-beta decay $(2\nu\beta\beta)$ events dominate the energy region. The Q-value of 136 Xe $2\nu\beta\beta$ is 2.458 MeV and the spectrum has a continuous distribution. The IB is not as clean as the Xe-LS and contains radioactive sources from the 232 Th and 238 U decay series. Therefore, the background rate with a 2-m-radius fiducial volume is much higher than with a 1-m-radius. The peak at 4 MeV in the 2-m-radius analysis is dominated by $\beta + \gamma$ -rays (Q-value ~ 5 MeV) from ²⁰⁸Tl decay contained in the IB. The high energy region above 5 MeV is dominated by short-lived spallation events from cosmic muons such as ¹²B, ⁸Li and ⁸B. The high energy detector response is understood within 1% uncertainty in the KamLS by using spallation events just after muon events [9, 15].

In order to optimize the fiducial volume, the radius was selected using a figure of merit (FoM), which is a function of the energy range:

$$FoM(r, \Delta m) \equiv \frac{S}{\sqrt{B}} \equiv \frac{FV(r) \times \epsilon_{det}(r, \Delta m)}{\sqrt{N_{obs}^{90\%}}},$$
(12)

where FV(r) is the volume of the Xe-LS, $N_{\rm obs}^{90\%}$ is the 90% confidence level (C.L.) upper limit on the number of observed events. The reconstructed position of the expected signal is spatially diffused due to the emitted γ -rays. The spatial detection efficiency $\epsilon_{\rm det}(r,\Delta m)$ is estimated from a Monte-Carlo simulation. Similarly to the $0\nu\beta\beta$ analysis, this analysis uses the volume within 2-m-radius from the center of the IB and includes both the internal

FIG. 2. The observed energy spectra in the KamLAND-Zen 400 Phase-II dataset for a 1 m and 2-m-radius fiducial volume.

and external regions of the Xe-LS and the IB. The volume was divided into 20 equal-volume spherical shell bins. The FoM was then calculated for each of the 20 equal-volume bins and the bin with the highest FoM was chosen at 1 MeV Δm intervals.

As shown in Figure 1, the width of the expected spectrum changes with the value of Δm . To improve the S/N ratio, the width of the energy region of interest was defined to be twice the standard deviation of the expected signal. This region includes over 95% of the expected signal.

To improve the sensitivity, the 90% upper limit of the signal rate was calculated from the number of observed and known-background events in the energy range of interest using the Feldman and Cousins method [16]. The best-fit $2\nu\beta\beta$ spectrum and the well-known background spectra fixed in the $0\nu\beta\beta$ analysis were used. The fixed backgrounds are (232 Th series, 210 Bi, 85 Kr) in the Xe-LS, (232 Th series, 210 Bi, 85 Kr, 40 K) in the KamLS and (232 Th series, 210 Bi, 137 Cs, 134 Cs, 40 K) contained on the IB film.

E. Result and conclusion

The results of this study for the WIMP parameter space are shown in Figure 3. No significant excess of events was found. The upper limit for the N_Z - χ^0 recombination cross section $\langle \sigma v \rangle$ is drawn as a function of m_{χ^0} for several Δm values, including a lower limit for the $\tilde{\tau}$ mass obtained by the ATLAS experiment [17]. Figure 4 shows another interpretation of the results. The black curves are the upper limits on the Γ_{χ^-} by KamLAND-Zen 400 Phase-II. The curves corresponds to m_{χ^0} of 100 GeV, 200 GeV, 1 TeV and 10 TeV respectively. Theoretical constraints based on reported spectra of several experiments [4] are also shown. As are lower limits from a search for $\tilde{\tau}$ by the CMS assuming the minimal gauge-mediated super-symmetry breaking (GSMB) model [4, 14].

A search for the bound state formation of a nucleus and an electrically charged WIMP state was performed using data from the $0\nu\beta\beta$ detector KamLAND-Zen 400. The analysis has good sensitivity in the region $\Delta m < 17.8$ MeV and access to higher slepton masses than accessible at the Large Hadron Collider [17] when a SUSY scenario is assumed. The upper limit for the recombination cross section is $\langle \sigma v \rangle < 2.0 \times 10^{-31}$ cm³/s when assuming $\Delta m = 10$ MeV and $m_{\chi^0} = 100$ GeV. The upper limit of the decay width of χ^- assuming $\Delta m = 10$ MeV is $\Gamma_{\chi^-} < 1.1 \times 10^{-18}$ GeV and $\Gamma_{\chi^-} < 1.1 \times 10^{-16}$ GeV for $m_{\chi^0} = 100$ GeV and $m_{\chi^0} = 10$ TeV, respectively.

The KamLAND-Zen 800 experiment, the next phase of KamLAND-Zen 400, has recently started acquiring data with about twice as much xenon and a new IB with ten times lower radioactive contamination [18]. It is expected to improve the sensitivity and decrease the ²⁰⁸Tl background at 4 MeV originating from the IB. However, spallation events from cosmic muons in the high-energy region over 5 MeV will become a challenging background.

FIG. 4. Excluded decay width region of $\tilde{\tau}$ as a function of Δm (bottom axis) and E_{vis} (top axis). The black curves show 90% C.L. upper limits from the KamLAND-Zen 400 Phase-II dataset. Horizontal solid (dashed) lines show the lower limit assuming a $\tilde{\tau}$ mass of 100 (200) GeV by the CMS experiment [4, 14]. Filled regions are theoretical constraints using reported spectra from several experiments [4]. The darker and lighter regions correspond to constraints for 1 TeV and 100 GeV, respectively.
