## ABSTRACT

Compact massive relic galaxies are a class of galaxies that exhibit characteristics suggesting they have remained largely unchanged since their initial formation, making them "relics" of the early universe. These galaxies represent a distinct class characterized by strongly peaked high-velocity dispersion profiles with large rotational velocities. This study investigates the formation of such galaxies within the framework of Milgromian Dynamics (MOND), offering a unique perspective on their origin without invoking the presence of cold or warm dark matter. Our analysis focuses on the collapse dynamics of isolated non-rotating post-Big-Bang gas clouds, revealing kinematic and density profiles comparable to observed compact massive relic galaxies like NGC 1277, Mrk 1216, and PGC 032873. The findings underscore the natural emergence of compact massive relic galaxies within a MOND-based Universe, providing valuable insights into the interplay between gravitational dynamics and galaxy formation.

**Key words:** galaxies: evolution – galaxies: formation – galaxies: kinematics and dynamics – software: simulations.

## 1 INTRODUCTION

The most accepted form of cosmological model, known as the dark-energy cold-dark-matter ( $\Lambda$ CDM) model, posits that galaxies form within the cosmic web, influenced by gravitational forces and quantum fluctuations during the early universe (Planck Collaboration et al. 2020; Mukhanov 2005). This model is understood to explain observed features of the universe's large-scale structure. The  $\Lambda$ CDM model suggests that early-type galaxies (ETGs) observed in the present day formed through the size growth of the initially compact quiescent galaxies found at higher redshifts (Daddi et al. 2005; Faber et al. 2007; Bezanson et al. 2009; van Dokkum et al. 2010; van der Wel et al. 2014).

The two-phase galaxy formation paradigm further details this evolution. In the "cosmic dawn," gravitational instabilities lead to the emergence of protogalactic systems (Peebles 1980; Mo et al. 2010). Computational simulations, like those by Abel et al. (2002), support the role of these instabilities. The subsequent "cosmic noon" witnesses heightened star formation and galaxy maturation through mergers and accretion (Somerville & Davé 2015; Hopkins et al. 2006; but see Haslbauer et al. 2023). Observational studies, including those from the Hubble Space Telescope and surveys like the Sloan Digital Sky Survey, contribute essential insights, allowing a nuanced understanding of galaxy evolution across cosmic epochs (Conselice et al. 2016; Bluck et al. 2014). This two-phase model integrates observations and simulations to illuminate the complex interplay between cosmic dynamics and astrophysical mechanisms, offering a comprehensive view of galaxies' diverse properties from their formation to the present universe.

Naab et al. (2009), using a high-resolution  $\Lambda$ CDM hydrodynamical cosmological simulation, illustrates the potential existence of

compact and massive elliptical galaxies at high redshifts. Ongoing investigations, including recent observations from the James-Webb-Space-Telescope (JWST), have contributed to the exploration of this phenomenon (Carnall et al. 2023). The simulation by Naab et al. (2009) reveals that the accretion of stripped stellar material and the dynamical friction of surviving stellar cores contribute to the increase in galaxy size and the reduction of central concentration over time. The overall study suggests that minor mergers, involving the accretion of weakly bound material, play a crucial role in the late-stage evolution of early-type galaxies, allowing compact high-redshift spheroids to transform into present-day systems resembling observed local ellipticals. Oser et al. (2010), in their study of ETGs, show that the early phase (redshift  $z > 2$ ) of the two-phase process involves in-situ star formation within the galaxy from infalling cold gas, followed by an extended phase ( $z < 2$ ) dominated by the accretion of ex-situ stars using  $\Lambda$ CDM cosmological simulations. Their study concludes that the majority of in-situ stars are formed at  $z > 2$  from cold gas flows, and the observational result of "archaeological downsizing" is recovered, where the oldest stars are found in the centers of most massive galaxies.

In  $\Lambda$ CDM, the progenitors of ETGs undergo wet mergers accompanied by intense star formation, resulting in the rapid growth of stellar mass while maintaining compact sizes, yielding the observed compact massive galaxies. These resulting galaxies undergo dry mergers, explaining the increase in stellar size and other structural and chemical evolution aspects of massive ETGs (Daddi et al. 2005). Galaxies resembling high-redshift compact quiescent galaxies, when discovered in the nearby Universe, are referred to as relic galaxies (Trujillo et al. 2009; Damjanov et al. 2009). These compact massive relic galaxies are objects that formed in the early phase of the Universe and are thought to be unaltered since their formation (Ferré-Mateu et al. 2017; Spiniello et al. 2024). Trujillo et al. (2014) suggest that these compact massive relic galaxies formed their stars rapidly indicating they have short star-formation timescales (SFTs) like early-type

† E-mail: pkroupa@uni-bonn.de

galaxies (ETGs, [Thomas et al. 2005](#); [Nelán et al. 2005](#); [McDermid et al. 2015](#); [Yan et al. 2021](#)). Their star formation history (SFH) would peak at the beginning of the Universe and would not have any significant star formation later on.

Discussing these compact relics has not been easy as originally there were no well-defined criteria to identify them (i.e. concerning the limits of compactness and masses). A fully detailed study of the structural and stellar population properties for a sample of such galaxies by [Trujillo et al. \(2009\)](#) rejected all candidates after a detailed analysis of their morphologies, structural profiles, kinematics and stellar populations. Examining the kinematics, morphology, and stellar properties of nearby compact massive galaxies revealed that these nearby objects exhibit elongated morphologies, fast rotation, young luminosity-weighted ages, and recent significant star formation bursts, with some being compatible with having very old stellar populations, distinguishing them as unique entities that deviate from the typical patterns observed in present-day massive ellipticals, spirals, or dwarfs ([Ferré-Mateu et al. 2012](#); [Trujillo et al. 2012](#)). NGC 1277 was claimed to be the first fully confirmed massive relic ([Trujillo et al. 2014](#)). Subsequently, a dozen new massive relic candidates with similar properties to NGC 1277 and hosting extreme super-massive black holes were reported ([van den Bosch et al. 2012](#)). Compact relic galaxies are a peculiar type of object when compared to their massive elliptical galaxy counterparts as the former are observed to have large velocity dispersions and large rotational velocities whereas elliptical galaxies are observed to be more 'pressure-supported' systems (i.e. with lower rotational velocities, [Trujillo et al. 2014](#); [Ferré-Mateu et al. 2017](#)).

Over the last decade, a cluster of putative relic galaxies has been identified in close proximity ( $z \approx 0.05$ ) and subsequently validated for their relic classification through meticulous examinations of diverse attributes, including galaxy-wide initial mass functions (IMF), globular cluster populations, and dynamical properties ([Trujillo et al. 2014](#); [Ferré-Mateu et al. 2015, 2017](#); [Yıldırım et al. 2015, 2017](#); [Spiniello et al. 2021](#); [Martín-Navarro et al. 2019](#); [Kang & Lee 2021](#)). The ongoing INSPIRE survey endeavors to corroborate additional relic candidates at redshifts extending up to  $z = 0.5$  ([Spiniello et al. 2021](#)). The criteria delineating relic galaxy candidates mirror attributes reminiscent of high-redshift red nuggets, necessitating substantial mass ( $\approx 10^{12} M_{\odot}$ ), compactness ( $r_{\text{eff}} \leq 1.5$  kpc), quiescence, and notable age (age  $> 10$  Gyr). While observational investigations into relic galaxies in the nearby Universe furnish valuable insights into broader processes of galaxy formation and evolution, the direct observation of their individual formative processes remains an elusive pursuit.

Recent  $\Lambda$ CDM cosmological simulations explore the evolution of individual compact galaxies over time, without the constraints and biases inherent in real observations ([Wellons et al. 2015](#); [Stringer et al. 2015](#); [Rodríguez-Gomez et al. 2016](#); [Furlong et al. 2017](#)). However, these simulations also possess limitations, emphasizing the importance of analog searches within simulations as a means to assess and refine numerical models ([Schaye et al. 2015](#); [Dubois et al. 2016](#); [Genel et al. 2018](#); [Naiman et al. 2018](#); [Pillepich et al. 2018](#); [Davé et al. 2019](#); [Vogelsberger et al. 2020](#)).

Although the  $\Lambda$ CDM cosmological simulations are able to reproduce the compact massive relic galaxies and achieve "archaeological downsizing" (but have not yet been able to address how and why massive galaxies form quicker in the early Universe compared to the less massive galaxies) it is in tension with the observed fraction of elliptical galaxies in the Universe. [Delgado-Serrano et al. \(2010\)](#) finds that there has not been a significant change in the fraction of elliptical galaxies compared to what it was 6 Gyr ago (see also

[Tamburri et al. 2014](#)). [Martín-Navarro et al. \(2018\)](#) find that most stars in elliptical galaxies formed over 10 Gyr ago. [Salvador-Rusiñol et al. \(2020\)](#) analyse nearly 29000 galaxies from the Baryon Oscillation Spectroscopic Survey finding that the residual star formation contributed less than one percent mass fraction in massive ETGs over the past 2Gyr, with a decreasing trend in young star fraction with increasing galaxy mass. [Salvador-Rusiñol et al. \(2022\)](#) in their study suggest an intrinsic, in situ process triggering star formation at later epochs in NGC 1277, emphasizing a general constraint on the presence of young stars in the cores of massive early-type galaxies, with potential contributions from evolved stars. [Vazdekis et al. \(2016\)](#) show that spheroids predominantly consist of old stars, and [de La Rosa et al. \(2011\)](#) and [McDermid et al. \(2015\)](#) demonstrate faster and earlier star formation in massive ETGs, resulting in compact, metal-rich, and  $\alpha$ -enhanced systems. [Haslbauer et al. \(2022a\)](#) highlights the tension between the observed proportion of galaxy morphological types and the predictions of the  $\Lambda$ CDM framework, indicating the need for further investigation and potential refinements to the current understanding of galaxy formation and dynamics.

Here, we report the formation of compact massive relic galaxies to be naturally arising in a monolithic post Big-Bang non-rotating cloud collapse in a Milgromian Dynamics (MOND) simulation. We caution that we are not performing any direct comparison with compact relic galaxies formed in  $\Lambda$ CDM as our work is solely based on galaxies formed in the MOND framework. Also, a direct comparison to results from  $\Lambda$ CDM simulations may be considered of limited interpretative value as our work is not based on cosmological simulations. Interested readers can see [Wellons et al. \(2015, 2016\)](#), [Barber et al. \(2016\)](#), [van Son et al. \(2019\)](#) for more details on the formation of compact galaxies in  $\Lambda$ CDM. In previous work, we have shown ([Eappen et al. 2022](#)) that the SFTs observed for ETGs are a natural occurrence in MOND, but found some discrepancies in structure and morphology, possibly related to the neglect of early mergers. It, therefore, appeared that our simulated galaxies should rather resemble compact massive relic galaxies, which we demonstrate hereafter.

Regular ETGs, in particular ellipticals, could be the product of a monolithic collapse and the subsequent merger of similar-mass galaxies. That is, a proto-massive group or cluster forms from a collapsing massive post-Big-Bang gas cloud with the inner cMpc (co-moving Mpc) region forming two or more early-type galaxies (each forming as in [Eappen et al. 2022](#)) that then merge to become the present-day ETGs. Here, we revisit one non-merger model from the suit of simulations of [Eappen et al. \(2022\)](#) which is in agreement with the downsizing and also aligns with recent findings from JWST observations on rapid early galaxy formation ([Carnall et al. 2023](#); [Labbe et al. 2022](#)) to show in more depth that such models agree extremely well with the observed relic galaxies which are assumed to have remained largely unevolved since their formation ([Trujillo et al. 2009, 2014](#); [Ferré-Mateu et al. 2017](#); [Spiniello et al. 2024](#)).

Section 2 discusses the kinematical and density properties of the observed and simulated compact massive relic galaxies and Section 3 contains the concluding remarks.

## 2 ARE COMPACT RELICS NATURALLY ARISING IN MOND?

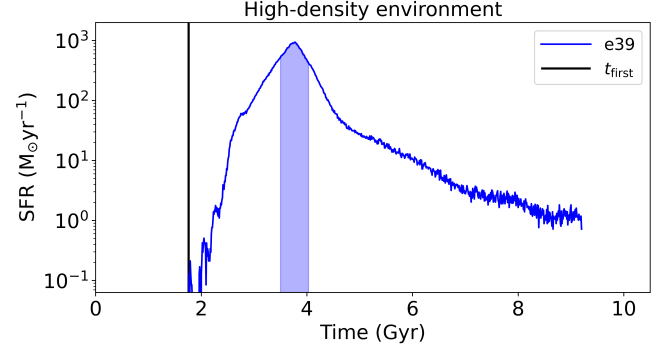

A correction to the Newtonian theory of gravity, MOND, was proposed by [Milgrom \(1983\)](#) to account for the ubiquitous mass discrepancies in the Universe, without invoking the exotic dark matter that is required if one adheres to standard dynamics. MOND introduces a new constant,  $a_0$ , into physics which has the dimensions of

acceleration and the principle of MOND is that the standard form of dynamics shifts to space-time scale invariance of the equation of motion under the transformation  $(t, r) \rightarrow (\lambda t, \lambda r)$ , where  $\lambda$  is an arbitrary number, when the acceleration is much smaller than  $a_0$  (Milgrom 2009). This new dynamics can be formulated as a non-relativistic gravitational theory by generalising the classical action for gravity: the extremum of the action then yields a generalised Poisson equation (see Bekenstein & Milgrom 1984; Milgrom 2008, 2010, 2014; Famaey & McGaugh 2012; Banik & Zhao 2022 for detailed reviews on the theory). This theory is found to accommodate the observed laws of galactic dynamics such as asymptotically flat rotation curves and also predicted galaxy scaling relations obeyed by galaxies such as the Baryonic Tully Fisher Relation (McGaugh et al. 2000; McGaugh 2005, 2012) and the Radial Acceleration Relation (Sanders 1990; McGaugh 2004; Lelli et al. 2017).

Structure formation in a MOND cosmology was pioneered by Sanders (1998). He proposed that the thermal and dynamical history of the early MOND Universe is exactly that of the standard Big-Bang model and all predictions relevant to the nucleosynthesis of the light elements carry over to MOND cosmology and after non-relativistic matter dominates the mass density of the Universe. Due to the non-linearity of gravitation, structure formation in MOND cosmology diverges from that of standard cosmology. This is also implied by Nusser (2002) who notes the rapid growth of small fluctuations with MOND. The Malekjani et al. (2009) study provides insights into the dynamics of structure formation and evolution within a MOND framework, highlighting the accelerated formation of structures without the need for dark matter. This picture from the spherical collapse model in MOND provides a bottom-top scenario for the structure formation in which the smaller structures formed before the larger ones. The cosmological structure formation simulations in the  $\nu$ HDM MOND model (Wittenburg et al. 2023) simulations demonstrate that the formation of a cosmic web of filaments and voids is not unique to standard Einstein/Newton-based cosmology, indicating that MOND-based cosmological frameworks can also reproduce this characteristic feature of the large-scale structure in the universe. This however does not mean that a MOND cosmological model automatically solves all problems, as for example, the  $\nu$ HDM model appears to form galaxies too late and also too massive structures overall (Kroupa et al. 2023).

The actual formation of galaxies with simulations of dissipationless collapse in MOND was investigated for the first time by Nipoti et al. (2007) and Sanders (2008). This work shows less-massive galaxies would collapse before the more massive ones (fig. 3 in Sanders 1998, fig. 4 in Sanders 2008) suggesting inconsistency with the observed downsizing. The work presented in Eappen et al. (2022) re-addresses the formation of elliptical galaxies using hydrodynamical MOND simulations with star formation. Given that the background MOND cosmological model is not yet clearly defined (e.g. Katz et al. 2013 and Skordis & Złošnik 2021), the work presented here follows the collapse of post-Big-Bang gas clouds with no rotation. Eappen et al. (2022) extract the required conditions for the formed ETGs to confer with downsizing, finding that the gas clouds need to start with a radius near 500 kpc independently of mass.

A numerical simulation technique is needed to solve the equations of motion of particles and the hydro-dynamical equations with star-formation and baryonic feedback algorithms that describe the mathematical MOND models to allow to study galaxy formation. The Phantom of Ramses code developed in Bonn (POR, Lüghausen et al. 2015; Nagesh et al. 2021 a customized version of RAMSES, Teyssier 2002) uses a multi-grid code to solve the generalised MOND

**Figure 1.** SFH of the model galaxy formed in MOND (Table 1). The solid black line is the time when the first stellar particle is formed and the shaded blue region is the star-forming timescale (SFT),  $\Delta\tau_m$ .  $t = 0$  corresponds to the Big-Bang.

**Table 1.** Initial conditions and properties of the model galaxy from Eappen et al. (2022).

Model Name	$M_{\text{initial}}$ ( $10^{11} M_{\odot}$ )	$R_{\text{initial}}$ (kpc)	$\Delta\tau_m$ (Gyr)	$r_{\text{eff}}$ (kpc)	$SFR_{\text{peak}}$ ( $M_{\odot}\text{yr}^{-1}$ )
e39	0.7	500	0.54	1.04	9.39E+02

Note: Column 1: Model name, Column 2 ( $M_{\text{initial}}$ ): initial mass of the post-Big-Bang gas cloud, Column 3 ( $R_{\text{initial}}$ ): initial radius of the post-Big-Bang gas cloud. Column 4 ( $\Delta\tau_m$ ): SFT. Column 5 ( $r_{\text{eff}}$ ): projected effective-radius and Column 6 ( $SFR_{\text{peak}}$ ): SFR at the peak of the SFH. SFT is defined as the full - width at half maximum of the distribution of the ages of stellar particles (see Fig. 1).

Poisson equation<sup>1</sup>. Eappen et al. (2022) use POR to constrain the initial conditions of the post-Big-Bang gas clouds required to form ETGs and we use one of the model galaxies described in that work for the study here. We note that the properties of observed disc galaxies arise from the collapse of rotating gas clouds (Wittenburg et al. 2020). The employed star-formation and feedback sub-grid physics adequately reproduce observed disc galaxies (Nagesh et al. 2022).

That ETGs may have acquired significant amount of mass through later mergers of star-forming galaxies (as expected in  $\Lambda$ CDM theory) is disfavoured by the NUV and optical survey of Salvador-Rusiñol et al. (2021) and by the comparison of the CO absorption features in NGC 1277 with a large representative sample of ETGs (Eftekhari et al. 2022). The observed ETGs thus appear to have formed the vast majority of their stellar mass rapidly on a time scale comparable to the downsizing time-scale of Thomas et al. (2005), McDermid et al. (2015) (see also Yan et al. 2021). Eappen et al. (2022) show that the SFTs observed (as deduced by Thomas et al. 2005) for ETGs are a natural occurrence in the MOND paradigm if ETGs form from monolithically collapsing non-rotating post-Big-Bang gas clouds. This quick and early mass assembly is very similar to the compact massive relics as described in Trujillo et al. (2014), Ferré-Mateu et al. (2017) and Spiniello et al. (2024).

Here we use the model galaxy ‘e39’ from Eappen et al. (2022) (Table 1) to compare its kinematics and density profile with real compact massive relics in the Universe (Table 2). The model galaxy

<sup>1</sup> Candlish et al. (2015) developed a similar code independently called RAYMOND.

**Table 2.** Structural properties of the compact relics.

Galaxy Name	$r_{\text{eff}}$ (kpc)	$V_{\sigma}$ (km/s)	$V_{\text{rot}}$ (km/s)	Mass ( $10^{11} M_{\odot}$ )
NGC 1277	$1.2 \pm 0.1$	$385 \pm 6$	292	$1.3 \pm 0.3$
PGC 032873	$1.8 \pm 0.2$	$358 \pm 5$	285	$2.3 \pm 0.9$
Mrk 1216	$2.3 \pm 0.1$	$368 \pm 3$	200	$2.0 \pm 0.8$
e39	1.04	369.5	203	0.7

Note: Column 1: Name, Column 2: effective-radius, Column 3: central velocity dispersion, Column 4: rotational velocity at  $r_{\text{eff}}$  and Column 5: mass of the galaxy. The values are taken from [Ferré-Mateu et al. \(2017\)](#), see their Fig. 2)

**Table 3.** The specific angular momentum properties of the model galaxy.

Model Name	$j_x$ ( $\text{km s}^{-1} \text{kpc}$ )	$j_y$ ( $\text{km s}^{-1} \text{kpc}$ )	$j_z$ ( $\text{km s}^{-1} \text{kpc}$ )	$j_{\star}$ ( $\text{km s}^{-1} \text{kpc}$ )
e39	1.65	-5.39	-284.01	284.06

Note:  $j_x$ ,  $j_y$  and  $j_z$  are the components of the specific angular momentum vector of the model galaxy along the x, y and the z directions respectively and  $j_{\star}$  is the absolute value of the specific angular momentum.

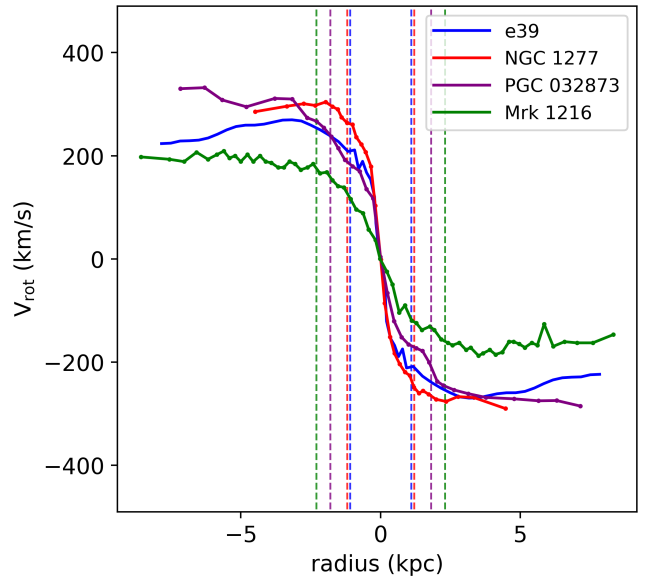

is formed through a monolithic collapse of a non-rotating gas cloud of initial mass  $0.7 \times 10^{11} M_{\odot}$  and initial radius of 500 kpc. The simulations effectively assume the canonical stellar IMF ([Kroupa 2001](#)) for the formation of stellar particles. Only the simple cooling/heating feedback algorithm is used as it is entirely adequate ([Nagesh et al. 2022](#)) and the size of the simulation box is 1000 kpc which achieves a maximum of 0.24 kpc and minimum of 7.81 kpc in spatial resolution (see [Eappen et al. 2022](#) for more details on the initial conditions of the gas cloud and simulation parameters). We use the data published in [Trujillo et al. \(2014\)](#) and [Ferré-Mateu et al. \(2017\)](#) for the galaxies NGC 1277, PGC 032873 and Mrk 1216. [Eappen et al. \(2022\)](#) apply the average stellar age-mass relation for ETGs deduced by [Thomas et al. \(2005\)](#) to place their model galaxies in a time frame relative to the Big-Bang. This is done by shifting the peak of the SFH of a model galaxy to the average age deduced by [Thomas et al. \(2005\)](#) for a galaxy with the same mass. This allows [Eappen et al. \(2022\)](#) to calculate the time when the first stellar particles would have formed in the model galaxies relative to the Big-Bang. The SFH of the model galaxy listed in Table 1 is plotted in Fig. 1 which gives us the time when the first stellar particle formed in the model galaxy,  $t_{\text{first}} = 1.75$  Gyr after Big-Bang in a high-density environment and  $t_{\text{first}} = 3.95$  Gyr after the Big-Bang in a low-density environment (see [Eappen et al. 2022](#) for more details). This is similar to compact massive relics ([Trujillo et al. 2014](#); [Ferré-Mateu et al. 2017](#); [Spiniello et al. 2024](#)) where NGC 1277, PGC 032873 and Mrk 1216 are found to have formed their stars around 10 Gyr ago. Detailed chemical enrichment histories of such collapsing post-Big-Bang gas clouds by applying a self-consistently evolving galaxy-wide IMF are available in [Yan et al. \(2021\)](#). Concerning the age-dating applied in Fig. 1: the peak of the SFH was gauged in [Eappen et al. \(2022\)](#) using the age-dating by [Thomas et al. \(2005\)](#) which has an uncertainty of about 1 Gyr. It is thus likely that some "e39"-type relics would have finished forming by 3 Gyr after the Big-Bang, as suggested by [Spiniello et al. \(2024\)](#).

## 2.1 Kinematical properties

The specific angular momentum is computed (Appendix A) and Table 3 lists the angular momentum properties of the model galaxy. The

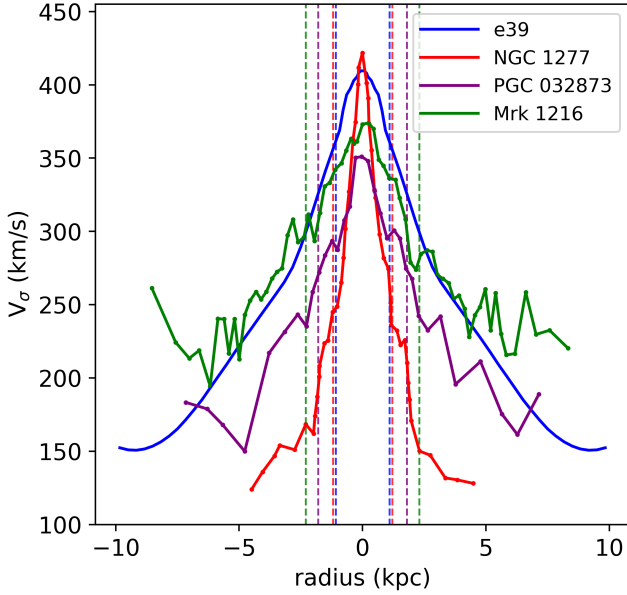

**Figure 2.** Classification diagram of galaxies, using the parameter space of stellar mass and specific angular momentum. The solid blue line shows the scaling relation for pure disc galaxies and the dashed red and solid red line shows, respectively, the scaling relation for fast- and slow-rotating elliptical galaxies ([Romanowsky & Fall 2012](#)). The red filled circles are the observed ETGs classified in terms of their morphology (ranging from S0 to E5, see table 5 of [Romanowsky & Fall 2012](#)). The blue open stars are the model disc galaxies from [Wittenburg et al. \(2020\)](#) and the red open stars are the model ETGs from [Eappen et al. \(2022\)](#). The red filled star is the model galaxy e39.

**Figure 3.** Rotational velocity profile of the ETG formed in MOND (e39) compared with observed compact massive relic galaxies ([Ferré-Mateu et al. 2017](#)) listed in Table 2. The dashed lines show the effective radii of the galaxies.

**Figure 4.** Velocity dispersion profile of the ETG formed in MOND (e39) compared with observed compact massive relic galaxies (Ferré-Mateu et al. 2017) listed in Table 2. The dashed lines show the effective radii of the galaxies.

direction of the rotation for this model is along the  $z$ -axis. The specific angular momentum of the model galaxy is consistent with the specific angular momentum – mass scaling relation deduced by Romanowsky & Fall (2012) for early-type galaxies which puts the model into the category of fast-rotating ETG (Fig. 2). The structural decomposition of fast-rotating ETGs uncovers that there is a hidden disc component that provides the additional angular momentum (Romanowsky & Fall 2012). Fig. 2 shows that the model galaxies formed through the monolithic collapse of rotating gas clouds in MOND fall on the observed angular momentum – mass relation for late-type galaxies (Wittenburg et al. 2020), while the model galaxies formed through monolithic collapse of non-rotating gas clouds in MOND (Eappen et al. 2022) fall on the observed angular momentum – mass relation for ETGs. A detailed study of the morphology and other structural properties of these model galaxies will be discussed in a follow-up paper (Eappen et al. in preparation).

The rotational velocity along the  $z$ -direction (Fig. 3),  $v_{\text{rot}}$ , is calculated as a function of radius,  $r$  of the model galaxy. The velocity dispersion of the model galaxy is calculated by averaging the face-on projection of line-of-sight velocity dispersion of all the stellar particles of the model galaxy (similar to Ferré-Mateu et al. 2017 in their observational study, see Appendix B).

The compact massive relic galaxies are observed to have large rotational velocities and a high central velocity dispersion. They are very fast rotators compared to elliptical galaxies with comparable mass. The model galaxy e39 from Eappen et al. (2022) is comparable to all the three compact massive relics in terms of the effective radius ( $r_{\text{eff}}$ ) and mass.

The velocity dispersion profiles of these galaxies are shown in Fig. 4. It can be seen that the model galaxy has a similar central peak for the velocity dispersion profile to that of the observed compact massive relics but here the decline is not as steep as for NGC 1277. This is likely due to the external field effect since NGC1277 is embedded in a galaxy cluster while model e39 is isolated (the external field effect

is a part of MOND that arises because of its non-linear nature and can be ignored for studies involving isolated models, see Milgrom 1983; Banik & Zhao 2022 for more details). The rotational velocity profile (Fig. 3) for the model galaxy also follows the same trend as the observed compact massive relics but has a lower velocity at  $r_{\text{eff}}$  than NGC 1277. The unique peaked kinematics exhibited by these compact massive relic galaxies may stem from the existence of super-massive black holes, potentially initiating and evolving independently or at varying rates relative to the evolutionary pathways of their host galaxies during earlier cosmic epochs (van den Bosch et al. 2012; Ferré-Mateu et al. 2015; Walsh et al. 2016; Kroupa et al. 2020; Cohn et al. 2023).

Although the initial cloud has no angular momentum, the forming galaxy spins up. This is a consequence of the collapse of the cloud not proceeding exactly spherically symmetrically due to not perfect initial spherical symmetry in the numerical model which amplifies due to the enhanced gravitation in MOND and angular momentum conservation. This leads to off-center formation of stellar particles which leads to spherically non-symmetrical gas flows, such that the final compact galaxy always rotates. In the real Universe, gas clouds will never be without angular momentum because of tidal torquing and turbulence, and the models here study the rare collapse of post-Big-Bang clouds that have a negligible specific angular momentum. The more typical outcome of the collapse of rotating clouds leads to disc galaxies with exponential surface density profiles (Wittenburg et al. 2020).

## 2.2 Stellar mass density profile

Trujillo et al. (2014) and Ferré-Mateu et al. (2017) show that the compact massive relics have different stellar mass density profiles compared to present-day disc or elliptical galaxies. When compared to the densest elliptical galaxies, the density profile of NGC 1277 is found to have a denser profile within  $r_{\text{eff}}$  being under-dense beyond  $r_{\text{eff}}$ . Compact massive relic galaxies are found to be equivalent to massive galaxies with a similar stellar mass found in the early Universe (Trujillo et al. 2014). The stellar mass density profile of the model galaxy e39 is similar to the stellar mass density profile of the compact massive relic galaxies as shown in Fig. 5.

## 3 CONCLUSIONS

If the most massive galaxies are formed from one or two major mergers of compact galaxies of comparable masses then this would mean that the intrinsic properties, such as the SFT of a galaxy, would not change significantly over time through mergers and it is the structural properties like  $r_{\text{eff}}$  and morphology that would passively evolve over time. The model galaxies from Eappen et al. (2022) were found to follow the downsizing behaviour as noted in Thomas et al. (2005, 2010); Yan et al. (2021) and formed under monolithic collapse of non-rotating post-Big-Bang gas clouds. Here we study the kinematical properties of one of the models from Eappen et al. (2022) of comparable mass with the observed compact massive relic galaxies NGC 1277, PGC 032873 and Mrk 1216 (Trujillo et al. 2014; Ferré-Mateu et al. 2017) listed in Table 2 and find the model to be very similar to these observed compact massive relic galaxies. These compact massive relics are found to have their average stellar ages similar to ETGs of comparable mass in a high-density environment as found by Thomas et al. (2005), where a galaxy with  $M_* = 10^{11} M_{\odot}$  would have formed 10 Gyr ago. We find that,

**Figure 5.** Surface density profile of the ETG formed in MOND (e39) compared with observed compact massive relic galaxies (Ferré-Mateu et al. 2017). The dashed lines show the effective radii of the galaxies.

- The model galaxy has a short SFT (i.e. it forms early and rapidly, Eappen et al. 2022) similar to compact massive relic galaxies. The model galaxy forms most of its stellar particles around 4 Gyr after the Big-Bang (assuming Thomas et al. 2005 age-dating, see Fig. 1) but falls short to the observed compact massive relics (which forms most of its stellar content within 2 Gyr after the Big-Bang, see Ferré-Mateu et al. 2017). Allowing for the observed dispersion of the ages of ETGs by Thomas et al. (2005), however, avoids this problem.

- The effective-radius ( $r_{\text{eff}} \approx 1$  kpc) of the model galaxy is comparable to NGC 1277 which has a similar mass ( $M_* \approx 10^{11} M_\odot$ ).

- The model galaxy has a high central velocity dispersion similar to the compact massive relics in Ferré-Mateu et al. (2017) (Fig. 4).

- The model galaxy and other ETGs in MOND (Eappen et al. 2022) are found to fall onto the observed angular momentum – mass relation for ETGs which classes them as fast rotators (Fig. 2) with a rotational velocity profile that is comparable to the observed compact massive relics (Fig. 3).

- The stellar mass density profile of the model galaxy is steep, similarly to the compact massive relics (Fig. 5).

Comerón et al. (2023) argue that the relic NGC 1277 cannot be understood within the standard dark-matter based cosmological structure formation models due to its apparent lack of dark matter, while the regular massive ETG NGC 1278 can. For a model of galaxy formation to be valid, it needs to account for all galaxies equally well. While in MOND galaxies "lacking dark matter" can be obtained if the galaxy is immersed in an external field that effectively lowers

its phantom dark matter halo, self-consistent cosmological structure formation simulation are needed to directly address the likelihood of occurrence of such a case.

It is quite remarkable that a post-Big-Bang non-rotating gas cloud collapse in MOND yields a galaxy that is a fast rotator with very high central velocity dispersion similar to the properties of the observed compact massive relic galaxies. Recent work by Spiniello et al. (2024) shows that most of the stellar content in the compact relic galaxies would have formed before 3 Gyr since the Big-Bang. A direct comparison between the ages of the observed galaxies with our models in this work is not directly possible, as our approach does not rest on cosmological simulations. Instead, we rely on ages from Thomas et al. (2005) to identify an approximate timeframe for the formation of our models in the real Universe. Quasar activity only 0.7 Gyr after the Big Bang as well as the recent discovery of very high redshift galaxies (reaching almost  $10^{10} M_\odot$  only about 0.5 Gyr after the Big Bang, see Carnall et al. 2023; Labbe et al. 2022; Haslbauer et al. 2022b) indicate that galaxies could have formed even faster in the real Universe, which could perhaps be obtained if some post-Big-Bang gas clouds are denser (compared to the model galaxy e39) with a smaller initial radius,  $R_{\text{initial}}$ . Our result shows that the Milgromian law of gravitation naturally yields objects resembling real ones through the monolithic collapse of gas clouds, which did not have to be the case.

While some studies show recent starbursts in compact massive galaxies, these are nevertheless dominated by very old stars (Ferré-Mateu et al. 2012). In fact, Salvador-Rusiñol et al. (2022) find a 0.8 per cent mass fraction of young stars in the centre of NGC 1277, similar to that found in massive ETGs. This suggests that the low levels of young stellar populations in the cores of massive ETGs could be from self-regulated gas returned to the interstellar medium from stellar evolution (Salvador-Rusiñol et al. 2022). The collapse models studied here are thus consistent with the major property of relics in them being compact, fast rotating with high velocity dispersion and of very old age.

The monolithic collapse, incidentally, also naturally explains the rapid emergence of quasars and super-massive black holes and their correlation with host-galaxy-properties (Kroupa et al. 2020). According to these authors, the monolithic collapse first forms an extremely massive star-burst cluster at the centre. This star burst cluster has a top-heavy IMF due to the low metallicity and high density and may appear like a quasar (Jeřábková et al. 2017). The cluster shields itself (Ploeckinger et al. 2019) from further in-falling gas from the forming galaxy through the quasar-like radiation field generated by the ionising stars. After about 50 Myr these die leaving a very large population of stellar-mass black holes. The now in-falling gas from the forming galaxy causes the black hole cluster to shrink to a relativistic condition at which point it implodes catastrophically to a super-massive black hole of near final mass through the radiation of gravitational waves. According to the conservative calculations by Kroupa et al. (2020), this whole process takes less time than the time-scale for the formation of the ETG. The correlation of the so formed super-massive black hole mass with the ETG mass comes naturally through the integrated galaxy-wide IMF (IGIMF, Kroupa & Weidner 2003; Weidner & Kroupa 2006; Jeřábková et al. 2018; Yan et al. 2021) theory that essentially accounts for the mass budget in stars and star clusters in terms of the star-formation rate of the galaxy.

## ACKNOWLEDGEMENTS

The numerical simulations were performed using the Tiger–Cluster of the Astronomical Institute of Charles University, Prague. R.E. is supported by the Grant Agency of Charles University under grant No. 234122. We thank the DAAD Eastern European grant at Bonn University for supporting the research visits. We would also like to thank the referee for their valuable input which helped in improving the manuscript.

## DATA AVAILABILITY

All data used here have been generated as described using the publicly available POR code and the cited literature.

## APPENDIX A: SPECIFIC ANGULAR MOMENTUM

The specific angular momentum vector is obtained from,

$$\mathbf{j} = \frac{\int_r \mathbf{r}_i \times \mathbf{v}_i m_i d^3\mathbf{r}}{\int_r m_i d^3\mathbf{r}}, \quad (\text{A1})$$

where  $\mathbf{r}_i$ ,  $\mathbf{v}_i$  and  $m_i$  are respectively the position- and velocity-vectors and mass of the stellar particle  $i$ . The absolute value of the specific angular momentum is,

$$j_\star = |\mathbf{j}| = (j_x^2 + j_y^2 + j_z^2)^{0.5}, \quad (\text{A2})$$

where  $j_x$ ,  $j_y$  and  $j_z$  are the x, y and z components of  $\mathbf{j}$ .

## APPENDIX B: CALCULATION OF VELOCITY DISPERSION

The mass-weighted square of the line-of-sight velocity dispersion for the model galaxy,  $\sigma^2$ , is the statistical dispersion of speeds about the mean speed  $\bar{v}$  at each radius,

$$\sigma^2 = \left( \frac{\sum_i^n (m_i \cdot v_i - m_{\text{total}} \cdot \bar{v})^2}{m_{\text{total}}} \right)^{0.5} \quad (\text{B1})$$

where  $m_i$  is the mass of the stellar particle  $i$ ,  $v_i$  is the line of sight speed of the stellar particle and  $m_{\text{total}}$  is the total mass of stellar particles within the radius  $r$ .
