We study the possibility of realizing the neutrino seesaw mechanism in the $E_8 \times E_8$ heterotic string. In particular, we consider its \mathbb{Z}_6 orbifold compactifications leading to the supersymmetric standard model gauge group and matter content. We find that these models possess all the necessary ingredients for the seesaw mechanism, including the required Dirac Yukawa couplings and large Majorana mass terms. We argue that this situation is quite common in heterotic orbifolds. In contrast to the conventional seesaw of grand unified theories (GUTs), no large GUT representations are needed to generate the Majorana mass terms. The total number of right-handed neutrinos can be very large, up to $\mathcal{O}(100)$.

The seesaw mechanism [1, 2, 3] is perhaps the most attractive way to explain the smallness of the neutrino masses. Its essential ingredients are heavy Majorana neutrinos and their Yukawa couplings to the left-handed neutrinos. The supersymmetric seesaw mechanism is described by the superpotential

$$W = Y_\nu^{ij} \phi^u \ell_i N_j + \frac{1}{2} M_{jk} N_j N_k, \quad (1)$$

where ϕ^u and ℓ_i ($i = 1, 2, 3$) are the Higgs and lepton doublets, and N_j ($1 \leq j \leq n$) are some heavy standard model singlets. At low energies, this leads to 3 light neutrinos with masses of order $(Y_\nu \langle \phi^u \rangle)^2 / M$, where Y_ν and M represent typical values of Y_ν^{ij} and M_{jk} , respectively. For $Y_\nu \sim 1$ and $M \sim 10^{16}$ GeV, one has $m_\nu \sim 10^{-3}$ eV. The scales of the atmospheric and solar neutrino oscillations, $\sqrt{\Delta m_{\text{atm}}^2} \simeq 0.04$ eV and $\sqrt{\Delta m_{\text{sol}}^2} \simeq 0.008$ eV [4], are suspiciously close to this scale. This hints at GUT structures behind the seesaw.

In conventional GUTs, N_j are members of GUT matter multiplets, e.g. a **16**-plet of $SO(10)$, and M_{jk} are related to a vacuum expectation value (VEV) of a large GUT representation, e.g. a $\overline{\mathbf{126}}$ -plet of $SO(10)$. In this case the Majorana mass terms originate from the coupling **16 16 $\overline{\mathbf{126}}$** (cf. [5]).

Difficulties arise when one attempts to embed this attractive mechanism in string theory [6], which is the best candidate for the ultraviolet completion of the standard model. One of the problems is that string GUTs usually do not allow for large GUT representations such as $\overline{\mathbf{126}}$. Other obstacles are posed by string selection rules for the superpotential couplings which forbid some of the necessary couplings in certain models [7]. For some string models one can obtain Dirac neutrino masses [8, 9]. Re-

cently, large Majorana masses have been obtained from instanton effects [10, 11, 12] and small Majorana masses from large volume compactifications [13]. However, it turned out to be very difficult to obtain the standard seesaw mechanism in consistent string models which lead to the gauge group and the matter content of the minimal supersymmetric standard model (MSSM).

The purpose of this letter is to show that these problems can be circumvented in the $E_8 \times E_8$ heterotic string [14, 15]. We base our study on orbifold compactifications of the heterotic string [16, 17, 18, 19, 20]. Recent work on an orbifold GUT interpretation of heterotic models [21, 22, 23] has triggered renewed interest in these constructions. It has led to the idea of stringy local grand unification [24, 25, 26, 27], which allows for an intuitive explanation of the multiplet structure of the standard model as well as gauge coupling unification.

The key point of local grand unification is that fields localized in the compact space at points with a GUT symmetry appear as complete representations of that GUT in the low-energy spectrum. This applies, in particular, to **16**-plets of local $SO(10)$ GUTs. On the other hand, the low-energy gauge group is an intersection of various local GUTs in $E_8 \times E_8$ and can be just the standard model gauge group. It has been shown that, in the context of the \mathbb{Z}_6 -II orbifold, the concept of local grand unification facilitates construction of phenomenologically promising models which admit vacua with the exact matter content of the MSSM [24, 27, 28]. These models inherit certain features of the underlying GUTs such as the GUT structure of matter multiplets and the standard GUT hypercharge. There are also significant differences from the usual 4D GUTs. Most importantly, the bulk and higher twisted sector states appear in split

multiplets, thus allowing for natural doublet–triplet splitting. Furthermore, mixing of the localized generations with vector–like bulk states breaks the unwanted GUT relations for the fermion masses [27, 29].

The Yukawa couplings do not necessarily preserve the symmetry of local GUTs. The symmetry of the non–local coupling in 10D is an intersection of the local gauge groups at the vertices (Fig. 1). This implies, for example, that the Majorana mass terms for the neutrino components of the **16**–plets can originate from the coupling

$$\nu_{\mathbf{16}} \times \nu_{\mathbf{16}} \times (\text{SM singlets}), \quad (2)$$

where the singlets belong neither to $\mathbf{16}^{(-)}$ nor to $\mathbf{126}^{(-)}$ of $\text{SO}(10)$. Furthermore, any SM singlet can play the role

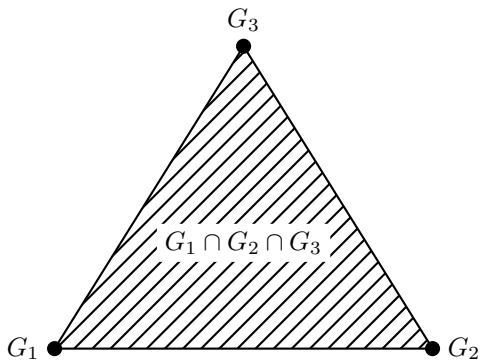

FIG. 1: Couplings involving fields localized at different fixed points in 10D preserve the symmetry corresponding to the intersection of the local gauge groups G_i .

of the right–handed neutrino as long as it has a Yukawa coupling to the lepton doublets and a large Majorana mass. These are abundant in orbifold models and typical models contain $\mathcal{O}(100)$ such singlets.

Heterotic orbifold models are defined by the orbifold twist v , torus lattice and the gauge backgrounds which include the gauge shift V and the Wilson lines W . With an appropriate choice of these quantities, one can obtain models with (i) the standard model gauge group G_{SM} times extra group factors, and (ii) 3 matter generations, 2 Higgs doublets plus extra vector–like states [24, 28]. Such models contain an ‘anomalous’ $\text{U}(1)$ which induces the Fayet–Iliopoulos (FI) D -term,

$$D_{\text{anom}} = \frac{g M_{\text{Pl}}^2}{192\pi^2} \text{Tr } \mathbf{t}_{\text{anom}} + \sum_i q_i |\phi_i|^2, \quad (3)$$

where \mathbf{t}_{anom} is the anomalous $\text{U}(1)$ generator, q_i are the anomalous charges of fields ϕ_i and g is the gauge coupling. This triggers spontaneous gauge symmetry breaking while preserving supersymmetry [30]. Some of the fields charged under the anomalous $\text{U}(1)$ (and, in addition, under other gauge groups) develop non–zero VEVs thereby reducing gauge symmetry. The scale of these VEVs is set by the FI term which is somewhat below the string scale. This eventually determines the seesaw scale.

In general, any SM singlets can get large VEVs as long as it is consistent with supersymmetry, and one can obtain the standard model gauge symmetry times that of the hidden sector,

$$G \longrightarrow \text{SU}(3)_c \times \text{SU}(2)_L \times \text{U}(1)_Y \times G_{\text{hidden}}. \quad (4)$$

The singlet VEVs are not necessarily associated with flat directions in the field space and generally correspond to isolated solutions to supersymmetry equations [27]. The hidden matter gauge group G_{hidden} can be responsible for spontaneous supersymmetry breaking. In fact, within the class of models with the MSSM spectrum, gaugino condensation in the hidden sector favours TeV–scale soft masses for the observable fields [31].

The non–zero singlet VEVs lead to the mass terms for the vector–like states,

$$W = x_i \bar{x}_j \langle s_a s_b \dots \rangle, \quad (5)$$

where x_i, \bar{x}_j are the vector–like exotics and $\langle s_k \rangle$ are the SM singlet VEVs in string units. Such a coupling must be consistent with the string selection rules [32, 33]. It has been shown that many \mathbb{Z}_6 -II models satisfy this requirement and all of the vector–like exotics can be decoupled [28]. This results in the MSSM spectrum at low energies.

Similarly, the singlet VEVs induce ‘Majorana’ mass terms for the SM singlets as well as the neutrino Yukawa couplings of Eq. (1),

$$M_{ij} \sim \langle s_a s_b \dots \rangle, \quad Y_\nu^{ij} \sim \langle s_\alpha s_\beta \dots \rangle, \quad (6)$$

as long as it is consistent with string selection rules.

Identification of right–handed neutrinos is intimately related to the issue of baryon/lepton number violation. In generic vacua, any SM singlet can play the role of the right–handed neutrino. However, such vacua also suffer from excessive R–parity violating interactions. The simplest way to suppress these interactions is to identify a $B-L$ gauge symmetry and enforce either its approximate conservation or conservation of its discrete (‘matter parity’) subgroup. In local GUTs, the $B-L$ generator resembles the standard GUT $B-L$, but also requires extra $\text{U}(1)$ components beyond $\text{SO}(10)$. It is non–anomalous and produces the standard $B-L$ charges for the SM matter. If $B-L$ is broken by VEVs of fields carrying even charges under $B-L$, the matter parity $(-1)^{3(B-L)}$ is conserved. This forbids dangerous R–parity violating interactions and requires the right–handed neutrino to carry the charge $q_{B-L} = \pm 1$. Another possibility is that $\text{U}(1)_{B-L}$ is broken at an intermediate scale M_{B-L} such that all R–parity violating couplings are suppressed by M_{B-L}/M_{Pl} . In this case, Majorana mass terms for the right–handed neutrinos are allowed only upon $B-L$ breaking, which lowers the seesaw scale to intermediate energies. In what follows, we consider these possibilities in specific heterotic orbifold models.

Model 1 [28]. It is a \mathbb{Z}_6 -II orbifold based on a Lie torus lattice $G_2 \times \text{SU}(3) \times \text{SO}(4)$ with a twist vector $v_6 =$

$(\frac{1}{6}, \frac{1}{3}, -\frac{1}{2})$ (see [27] for details). The gauge shift in an orthonormal $E_8 \times E_8$ basis is given by

$$V = \left(\frac{1}{3}, -\frac{1}{2}, -\frac{1}{2}, 0^5\right) \left(\frac{1}{2}, -\frac{1}{6}, (-\frac{1}{2})^5, \frac{1}{2}\right),$$

while the Wilson lines are chosen as

$$\begin{aligned} W_2 &= \left(\frac{1}{4}, (-\frac{1}{4})^4, (\frac{1}{4})^3\right) \left(1, -1, -\frac{5}{2}, -\frac{3}{2}, -\frac{1}{2}, -\frac{5}{2}, -\frac{3}{2}, \frac{3}{2}\right), \\ W_3 &= \left(-\frac{1}{2}, -\frac{1}{2}, (\frac{1}{6})^6\right) \left(\frac{10}{3}, 0, -6, -\frac{7}{3}, -\frac{4}{3}, -5, -3, 3\right). \end{aligned}$$

Here the superscripts denote repeated entries. The gauge group after compactification is $G_{\text{SM}} \times \text{SO}(8) \times \text{SU}(2) \times \text{U}(1)^7$, while the matter content is that of the MSSM plus vector-like exotics. The $B-L$ generator is identified with

$$\mathbf{t}_{B-L} = \left(1, 1, 0, 0, 0, -\frac{2}{3}, -\frac{2}{3}, -\frac{2}{3}\right) \left(\frac{1}{2}, \frac{1}{2}, 0, \frac{1}{2}, \frac{1}{2}, 0, 0, 0\right).$$

In general supersymmetric configurations, many SM singlets get non-zero VEVs. Choosing a subset of such singlets with 0 or ± 2 $B-L$ charges, the unbroken gauge symmetry is

$$G_{\text{SM}} \times G_{\text{hidden}}, \quad (7)$$

where $G_{\text{hidden}} = \text{SO}(8) \times \text{SU}(2)$, while all of the exotic states get large masses and decouple. This vacuum preserves the matter parity $(-1)^{3(B-L)}$.

We find that there are 39 right-handed neutrinos defined by $q_{B-L} = \pm 1$, two of which are members of the localized **16**-plets. They have Yukawa couplings to the lepton doublets and large Majorana mass terms. We have calculated the 3×39 Yukawa matrix Y_ν and 39×39 Majorana mass matrix M of Eq. (1) up to 6th order in the singlet VEVs. The effective mass matrix for the left-handed neutrinos,

$$M_{\text{eff}} = -v^2 Y_\nu M^{-1} Y_\nu^T \quad (8)$$

with $v = 174 \text{ GeV}$, can be represented by the texture

$$M_{\text{eff}} \sim -\frac{v^2}{M_*} \begin{pmatrix} 1 & s & s \\ s & s^2 & s^2 \\ s & s^2 & s^2 \end{pmatrix}. \quad (9)$$

Here $s < 1$ represents a generic singlet VEV in string units and M_* is the effective seesaw scale. Y_ν contains entries with powers of s between 1 and 5, while the dependence of the eigenvalues of M ranges from s to s^8 . This results in a strong s -dependence of the effective seesaw scale M_* . This scale is further suppressed by the large multiplicity of heavy singlets N , $M_* \propto N^{-x}$ with $0 < x < 2$. The value of x depends on the texture. For example, when all the singlets contribute equally, $x = 2$, whereas $x = 0$ if only a fixed number of neutrinos have non-negligible couplings. For the present model, we find

$$M_* \sim 0.1 s^5 M_{\text{str}} \sim 10^{14} \text{ GeV}, \quad (10)$$

for the string scale $M_{\text{str}} = 2 \cdot 10^{17} \text{ GeV}$ and $s \sim 0.3$. The obtained texture (9) is of course model dependent.

The corresponding charged lepton Yukawa matrix is of the form

$$Y_e \sim \begin{pmatrix} 1 & 1 & c \\ c & c & c^2 \\ 0 & 0 & 0 \end{pmatrix}, \quad (11)$$

where “0” denotes absence of the coupling up to 6th order in the singlet VEVs c . Such zeros are expected to be filled in at higher orders. Here we are again using a single expansion parameter although in practice there are many variables.

These crude estimates show that reasonable fermion masses can in principle be obtained. Inserting order one coefficients in the textures, one finds that the eigenvalues scale as

$$m_{\nu_i} \sim (1, s^2, s^2) \frac{v^2}{M_*}, \quad m_{e_i} \sim (1, c, 0) v, \quad (12)$$

where we have assumed that the MSSM Higgs doublets attain comparable VEVs. For $s \sim 0.3$ and $c \sim 0.1$ the textures reproduce roughly the observed lepton mass hierarchy. The above texture favours the normal neutrino mass hierarchy and can accommodate small and large mixing angles. Further details of the model are available at [34].

Model 2 [24]. It is based on the same orbifold with a different choice of the gauge backgrounds. The gauge shift and the Wilson lines are

$$\begin{aligned} V &= \left(\frac{1}{2}, \frac{1}{2}, \frac{1}{3}, 0, 0, 0, 0, 0\right) \left(\frac{1}{3}, 0, 0, 0, 0, 0, 0, 0\right), \\ W_2 &= \left(\frac{1}{2}, 0, \frac{1}{2}, \frac{1}{2}, \frac{1}{2}, 0, 0, 0\right) \left(-\frac{3}{4}, \frac{1}{4}, \frac{1}{4}, -\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}, -\frac{1}{4}\right), \\ W_3 &= \left(\frac{1}{3}, 0, 0, \frac{1}{3}, \frac{1}{3}, \frac{1}{3}, \frac{1}{3}, \frac{1}{3}\right) \left(1, \frac{1}{3}, \frac{1}{3}, \frac{1}{3}, 0, 0, 0, 0\right). \end{aligned}$$

The $B-L$ generator is given by

$$\mathbf{t}_{B-L} = \left(0, 1, 1, 0, 0, -\frac{2}{3}, -\frac{2}{3}, -\frac{2}{3}\right) \left(\frac{1}{2}, \frac{1}{2}, \frac{1}{2}, -\frac{1}{2}, 0, 0, 0, 0\right).$$

This model also produces the exact MSSM gauge group and spectrum (up to the hidden sector) in generic SUSY vacua where many SM singlets get large VEVs. Interestingly, there are 21 SM singlets with $q_{B-L} = +1$ and 18 singlets with $q_{B-L} = -1$. We found that their 21×18 mass matrix M_{ij} has the full rank once singlets with $q_{B-L} = 0$ develop VEVs. Thus, there are exactly three (massless) right-handed neutrinos with $q_{B-L} = +1$ in the limit of $\text{U}(1)_{B-L}$ conservation.

Unlike model 1, model 2 does not have a natural R- or matter parity once the $\text{U}(1)_{B-L}$ symmetry is broken. This is because there are no singlets with even nonzero q_{B-L} . The simplest way to suppress R-parity violation is to break $\text{U}(1)_{B-L}$ at an intermediate scale. This occurs when the SM singlets charged under $B-L$ develop hierarchically small VEVs, $M_{B-L} \ll M_{\text{str}}$. The three right-handed neutrinos with $q_{B-L} = 1$, which remain massless under the conserved $B-L$, now obtain masses of order M_{B-L}^2/M_{str} via VEVs of singlets with $q_{B-L} = 1$. They contribute to the neutrino masses as

$$\Delta m_\nu \sim v^2 \frac{y^2}{M_{B-L}^2/M_{\text{str}}}, \quad (13)$$

where y is the corresponding $B-L$ conserving Yukawa coupling.

Furthermore, states with $q_{B-L} \neq 1$ can also play the role of right-handed neutrinos. The corresponding Yukawa couplings violate $B-L$ and are suppressed by M_{B-L}/M_{str} . Their contribution is

$$\Delta m_\nu \sim v^2 \frac{(M_{B-L}/M_{\text{str}})^2}{\widetilde{M}}, \quad (14)$$

where \widetilde{M} is the corresponding Majorana mass.

Comparing Eqs. (13) and (14), we see that the first contribution induces too large neutrino masses, unless y is suppressed, while the second contribution is very small, unless \widetilde{M} is suppressed. Such suppression can come about when the relevant couplings are only allowed at high orders by string selection rules or if the relevant singlet VEVs are very small. We have calculated Yukawa couplings y for a class of vacua in model 2. Although the necessary ingredients for the seesaw are present, we have not been able to identify a natural suppression mechanism for y when one links suppression of R-parity violation to an approximate $U(1)_{B-L}$. The solution is likely to require going beyond our crude approximation that

many different singlets attain similar VEVs.

Our main conclusion is that heterotic orbifolds allow for many realistic vacua with the massless spectrum of the MSSM [28], which also have the required ingredients for the seesaw. In such vacua, many SM singlets get large VEVs consistent with supersymmetry (not necessarily along flat directions). This generates Majorana masses for abundant SM singlets, which play the role of the right-handed neutrinos. The effective seesaw scale is model-dependent, but typically somewhat below the string scale. In models with local GUTs, this scale is intimately related to $B-L$ breaking. Although the structure of matter multiplets is similar to that of 4D GUTs, no large GUT representations are required to generate Majorana mass terms. As a result, potentially realistic neutrino mass patterns can be obtained.
