Abstract. The CERN Neutrino to Gran Sasso (CNGS) project aims to produce a high energy, wide band beam at CERN and send it toward the INFN Gran Sasso National Laboratory (LNGS), 732 km away. Its main goal is the observation of the appearance, through neutrino avour oscillation. The beam started its operation in August 2006 for about 12 days: a total amount of $7.6 \cdot 10^{17}$ protons were delivered to the target. The LVD detector, installed in hall A of the LNGS and mainly dedicated to the study of supernova neutrinos, was fully operating during the whole CNGS running time. A total number of 569 events were detected in coincidence with the beam spill time. This is in good agreement with the expected number of events from Montecarlo simulations.

## 1 Introduction

The CERN Neutrinos to Gran Sasso (CNGS) project aims to produce a high energy, wide band beam at CERN and send it toward the INFN Gran Sasso National Laboratory (LNGS). Its main goal is the observation of the appearance, through neutrino avour oscillation, by the Opera experiment.

The LVD detector, installed in the Hall A of the LNGS, is mainly dedicated to the observation of supernova neutrinos. As proven in [1], due to its large area and active mass, LVD can act as a very useful beam monitor, detecting the interaction of neutrinos inside the detector and the muons generated by the interaction in the rock upstream the detector.

The CNGS beam started its operation in August 2006, after three commissioning weeks. LVD was fully operative during the whole rst run of the CNGS beam.

In this work we present the results of the events detected in coincidence with the beam spill time and show some comparisons with the Montecarlo simulation.

## 2 The CNGS beam

The informations about the CNGS beam characteristics are taken by the LHCLOG_CNGS_OPERA database (hereafter DB) [2]. Two main quantities are relevant for each proton extraction:

– the UTC time of the spill (in ns),
– the number of extracted protons on target (p.o.t.) [1].

The CNGS beam started its rst run of operation on 18th August, 2006 ( rst spill at 11:31:54.072 UTC) and nished on 30th August (last spill at 03:30:04.872 UTC). In the following we will refer to this rst run as Run1. The total number of protons delivered against the graphite target is $7.59 \cdot 10^{17}$. The beam intensity per each spill is shown in gure 1. It started with an average intensity of $1.38 \cdot 10^{13}$ p.o.t. per spill until 23rd August; then there was a prede ned stop called "Machine Development" (MD).

[1] Due to some known problems (see [3]) it happened that for some extraction there was only the UTC time or only the number of p.o.t.. In the following we will consider only those extraction where both the informations were present.

On 25th August the run restarted with a slightly higher intensity of $1.64 \times 10^{13}$ p.o.t. per spill, on average.

The time structure of the CNGS beam is characterized by two extractions, $10.5\ \mu s$ long, separated by 50 ms; this pattern is repeated each CNGS cycle, whose duration can change: during Run1 there were two main repetition cycles: 16.8 s and 22.8 s.

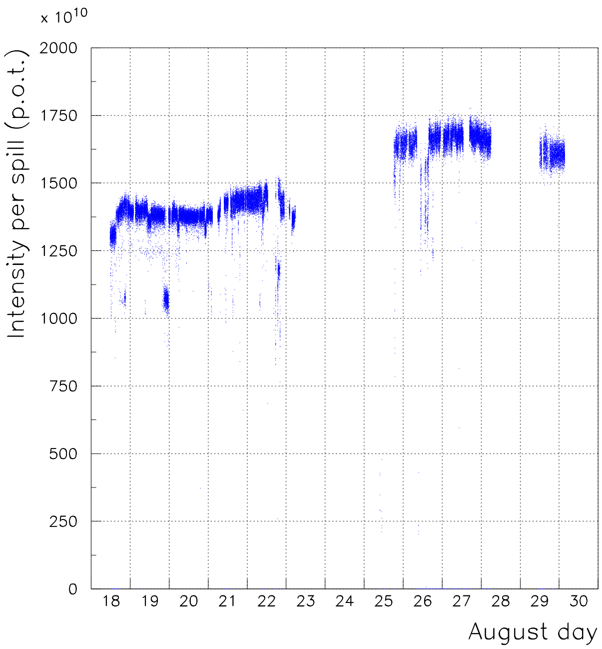

Fig. 1. Beam intensity (in protons on target) per each spill of Run1.

## 3 The LVD detector

LVD is a large volume liquid scintillator detector dedicated to the study of core collapse supernova neutrinos. The active scintillator mass is about 1000 t, while the iron and stainless steel support structure is $\sim 900$ t. It has a modular structure, made of 840 identical scintillation counters. Each counter is viewed on the top by three photomultiplier tubes. The counters are grouped in three big modules, called "towers", with independent data acquisition. The energy calibration of the scintillation counters is done each month through the (known) energy released by cosmic muons. The highest detectable energy in each counter is between 200 and 400 MeV.

The front area of the whole detector (orthogonal to the CNGS beam) is $\sim 12 \times 10\ m^2$, see figure 2. A detailed description of the detector and its performances is in [7].

During Run1 LVD was fully operative with 100% of uptime (defined as the fraction of time where LVD is able to detect an event) and an average active mass of 950 t.

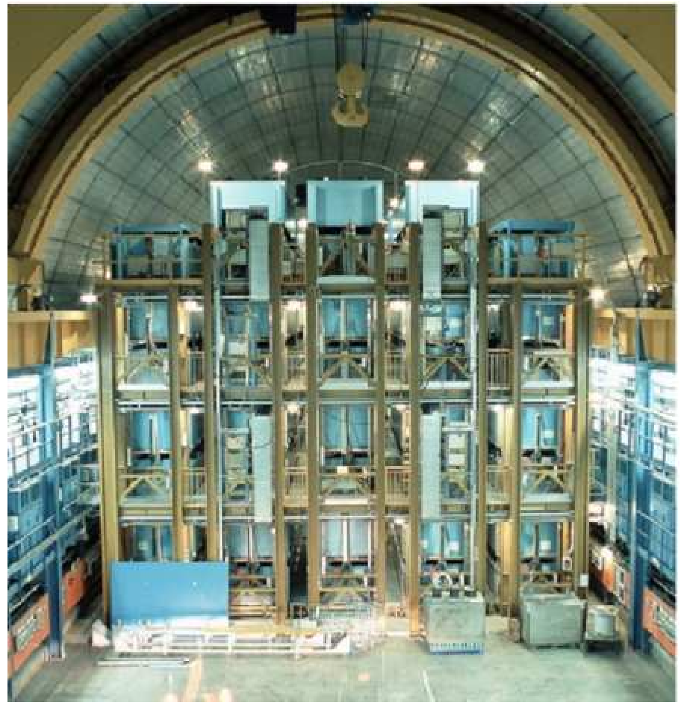

Fig. 2. Front view of the LVD detector.

## 4 MC simulation of the expected events

The CNGS events in LVD can be subdivided into two main categories:

- charged current (CC) interactions in the rock upstream the LNGS; they produce a muon that can reach LVD and be detected,
- CC and neutral current (NC) interactions in the material (liquid scintillator and iron of the support structure) of LVD.

We developed a full Montecarlo simulation that includes the generation of the neutrino interaction products, the propagation of the muon in the Gran Sasso rock and the response of the LVD detector. The details of the simulation were described in [1]; however, with respect to that paper, some modifications were done with up-to-date informations. In particular we now use the CNGS flux calculated in 2005 by the Fluka group [4] and the neutrino cross section NUX-FLUKA [5]. There are also some modifications in the detector: there are actually 7 active levels of scintillation counters instead of the 8 previously considered, and the energy threshold for the definition of a CNGS event is now 100 MeV instead of 200 MeV.

The resulting number of expected events, at the nominal intensity $4.5 \times 10^{19}$ p.o.t./y is 32160/y, equivalent to $7.147 \times 10^{-16}$ events per p.o.t. (considering 200 effective days per year, it corresponds to $\sim 160$ CNGS events per day): 78% are muons from the rock, 17% are CC interactions in the detector and 5% are NC.

During Run1 the total number of p.o.t. was $7.59 \times 10^{17}$, thus 542 events are expected in LVD.

## 5 CNGS detected events

The LVD events are filtered using a very loose selection cut: we require to have at least one scintillation counter with an energy release larger that 100 MeV. The resulting rate is quite stable, with an average value of 0.37 Hz, see figure 3.

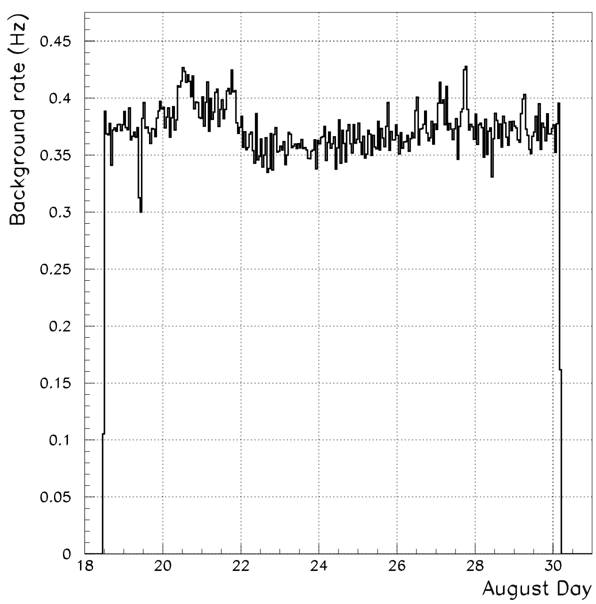

Fig. 3. Background rate of events during Run1. These events present at least one scintillation counter with an energy release larger than 100 MeV.

Among this sample the first selection criteria is based on the coincidence of the LVD event time with the beam spill time written in the DB. Two main corrections have been done: the neutrino time of flight from Cern to the LNGS (2.440 ms) and the propagation of the GPS time signal from the outside laboratories to slave clocks in the underground hall (42116, 42064 and 42041 ns respectively for tower 1, 2 and 3), measured in July, 2006 together with the other experiments at LNGS [6].

During Run1 there were some additional time shifts between the LNGS time and the UTC time written in the DB: from the beginning until $18^{th}$ 16:00 it was +100 μs, then +10 μs until $22^{nd}$ 9:00 and −2 ms until $23^{rd}$ 5:30. After the MD there was no additional bias.

After applying all these corrections, we search for the CNGS events in the interval [−15; +25] μs around the start time of the beam spill. In this way 569 events are selected; their distribution in the time window is shown in figure 4.

The four events with time difference between −13 and −8 μs occured on $19^{th}$ August when there was a failure in the LNGS master clock. The second master was switched on and a time shift of about 10 μs was present. Thus those events are considered in the analysis.

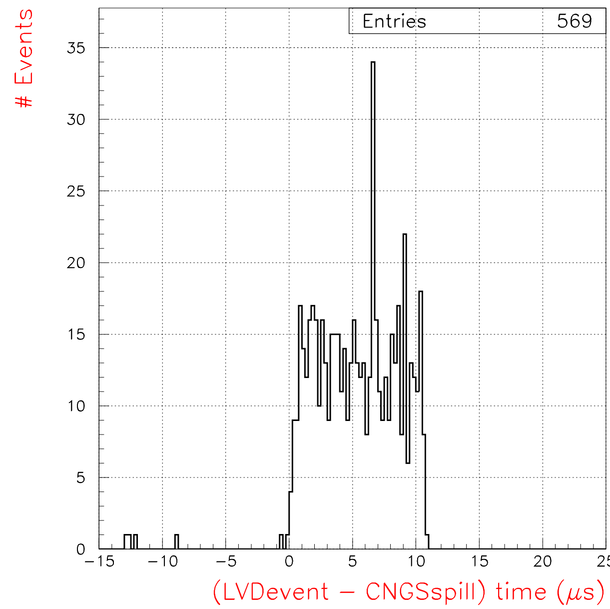

Fig. 4. Distribution of the detection time of the 569 CNGS events, with respect to the initial time of the beam spill.

In figure 5 (left) we show the comparison between the expected and detected event rate per each day of data acquisition; in figure 5 (right) the comparison of the integral number of events, hour by hour, is shown. Given the presently limited statistics, the agreement is rather good.

Two examples of typical CNGS events in LVD are shown in figure 6 (muon from the rock) and 7 (neutrino interaction inside the detector).

### 5.1 Comparison with the MC simulation

In the following we show the comparison between the CNGS detected events and the results of our MC simulation, normalized to the same number of events. In figure 8 we show the distribution of the number of scintillation counters hit per each event, with an energy threshold of 10 MeV, normalized to the total sample of 569 detected events; given the available statistics the agreement is good.

In order to select the events generated in the rock, producing a penetrating muon inside the detector, we perform the muon track reconstruction with a linear fit to the centers of the hit scintillation counters. Requiring at least 3 hit counters and a good $\chi^2$ (probability larger than 1% in both the TOP and SIDE projections) we select 319 events. From the MC simulation we estimate that, using this selection cut, the efficiency to detect "muons from the rock" is about 80% and the contamination of "internal events" is low (less than 5%).

In figure 9 the total amount of energy detected by the scintillation counters in "muonic" events is displayed.

For this selected sample of events we can reconstruct the muon direction and compare it with the expectation

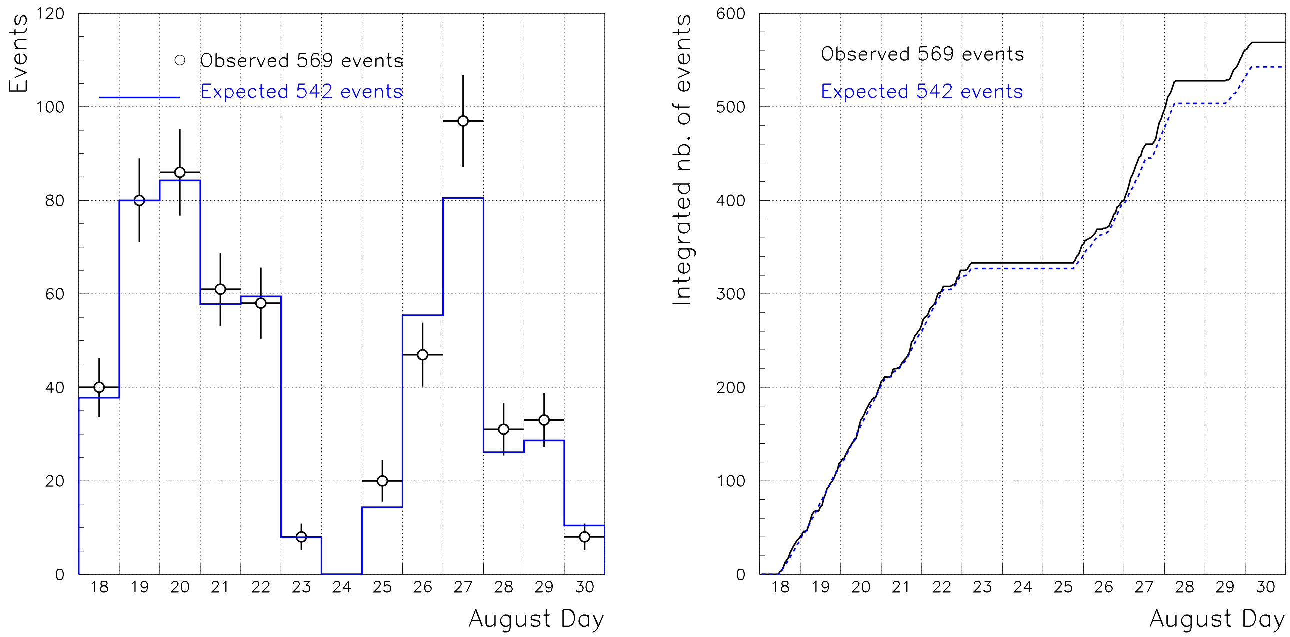

Fig. 5. Comparison between the expected and detected number of events during Run1. In the left panel there is the number of events per day: observed (black circles) and expected (blue line). In the right one the integrated number of events: observed (black solid line) and expected (blue dashed line).

from the reconstruction of MC events. The results are shown for the angle between the muon and the main axis of the hall A: its projections in the SIDE and TOP view of the detector are in figure10 and 11 respectively.

The events are almost horizontal and the main part of them are reconstructed exactly at 0° because of the discreteness of the scintillation counters (cross section $1 \times 1$ m$^2$). In the TOP view the beam is parallel to the hall A axis, while in the SIDE view the beam "comes out" from the floor with an angle of 3.2°, as seen in figure10. The agreement of the data and the MC simulation is very good in both the projections.

### 5.2 Background

The background is estimated considering the rate of events shown in figure3 among which the CNGS events are searched for, with an average value of 0.37 Hz. We remind that the time window where we search for the events around the beam spill time is 40 μs wide, and the number of useful spills in the DB is 51581. Thus the number of events due to the background, during Run1, is

$$N_{bkg} = 0.37\,\mathrm{Hz} \times 40\,\mu\mathrm{s} \times 51581 = 0.764$$

practically negligible.

## 6 Conclusions

We presented the results of the first events detected by the LVD detector in coincidence with the CNGS beam. The first run of the CNGS beam was started in August 2006, with an overall number of $7.6 \times 10^{17}$ protons delivered to the target. The LVD detector was fully operative during the whole run, with an average active mass of 950 t.

LVD can detect the CNGS neutrinos through the observation of penetrating muons originated by $\nu_\mu$ CC interactions in the rock upstream the LNGS and through internal CC and NC neutrino interactions.

The expected number of events, as predicted by our Montecarlo simulation, is 542. We searched for the CNGS events by looking at the time coincidence with the beam spill time; the number of detected events is 569.

There is a good agreement, between the detected events and the MC simulation, in the distribution of the number of hit counters, the total energy released in the apparatus and the direction of the reconstructed muons.

We estimate that the number of events due to the background is lower than one in the whole Run1 time.

Thus, this first run of the CNGS beam confirmed that, as it was proposed in [1], LVD can act as a very useful CNGS beam monitor.

Also the Opera collaboration reported about their measurements [8]: they detect 319 events against a prediction of 300, obtaining results very similar to ours. A detailed discussion about the comparison of expected and detect events in LVD is postponed to the next CNGS runs (scheduled in fall 2007), when a large number of events will be available and the beam characteristics will be better under control.

Fig. 6. Display of a CNGS events: typical charged current interaction in the rock upstream LVD, producing a muon that goes through the detector. The colours represent the amount of energy released in the scintillation counters, summed along each projected view; the legenda is expressed in GeV. The black straight line is the result of a linear fit to the hit counters.

## 7 Acknowledgements

We thank G. Battistoni, A. Ferrari and P. Sala for providing us the tables of the neutrino cross-sections and A. Guglielmi for the details of the CNGS MC simulation. We also would like to thank D. Autiero for his help in accessing the information in the CERN database and for many discussions about the details of the beam characteristics and status during Run1.
