Abstract

We critically reexamine two possible Dark Matter candidates within the Standard Model. First, we consider the $uuddss$ hexa-quark. Its QCD binding energy could be large enough to make it (quasi) stable. We show that the cosmological Dark Matter abundance is reproduced thermally if its mass is 1.2 GeV. However, we also find that such mass is excluded by stability of Oxygen nuclei. Second, we consider the possibility that the instability in the Higgs potential leads to the formation of primordial black holes while avoiding vacuum decay during inflation. We show that the non-minimal Higgs coupling to gravity must be as small as allowed by quantum corrections, $|\xi_H| < 0.01$. Even so, one must assume that the Universe survived in e^{120} independent regions to fluctuations that lead to vacuum decay with probability 1/2 each.

1 Introduction

In this work we critically re-examine two different intriguing possibilities that challenge the belief that the existence of Dark Matter (DM) implies new physics beyond the Standard Model (SM).

DM as the $uudds$ hexa-quark

The binding energy of the hexa-quark di-baryon $uudds$ is expected to be large, given that the presence of the strange quark s allows it to be a scalar, isospin singlet [1], called H or \mathcal{S} , and sometimes named *sexa-quark*. A large binding energy might make \mathcal{S} light enough that it is stable or long lived. All possible decay modes of a free \mathcal{S} are kinematically forbidden if \mathcal{S} is lighter than about 1.87 GeV. Then \mathcal{S} could be a Dark Matter candidate within the Standard Model [2–4].

In section 2.1 we use the recent theoretical and experimental progress about tetra- and penta-quarks to infer the mass of the \mathcal{S} hexa-quark. In section 2.2 we present the first cosmological computation of the relic \mathcal{S} abundance, finding that the desired value is reproduced for $M_{\mathcal{S}} \approx 1.2$ GeV. In section 2.3 we revisit the bound from nuclear stability ($NN \rightarrow \mathcal{S}X$ production within nuclei) at the light of recent numerical computations of one key ingredient: the nuclear wave-function [5], finding that \mathcal{S} seems excluded.

DM as primordial black holes

Primordial Black Holes (PBH) are hypothetical relics which can originate from gravitational collapse of sufficiently large density fluctuations. The formation of PBHs is not predicted by standard inflationary cosmology: the primordial inhomogeneities observed on large cosmological scales are too small. PBH can arise in models with large inhomogeneities on small scales, $k \gg \text{Mpc}^{-1}$. PBH as DM candidates are subject to various constraints. BH lighter than $6 \cdot 10^{-17} M_\odot$ are excluded because of Hawking radiation. BH heavier than $10^5 M_\odot$ are safely excluded. In the intermediate region, a variety of bounds make the possibility that $\Omega_{\text{PBH}} = \Omega_{\text{DM}}$ problematic but maybe not excluded — the issue is presently subject to an intense debate. According to [6] DM as PHB with mass $M \sim 10^{-15} M_\odot$ are not excluded, as previously believed. And the HSC/Subaru microlensing constraint on PBH [7] is partially in the wave optics region. This can invalidate its bound below $\sim 10^{-11} M_\odot$.

Many ad hoc models that can produce PBH as DM have been proposed. Recently [8] claimed that a mechanism of this type is present within the Standard Model given that, for present best-fit values of the measured SM parameters, the SM Higgs potential is unstable at $h > h_{\text{max}} \sim 10^{10} \text{ GeV}$ [9]. We here critically re-examine the viability of the proposed mechanism, which assumes that the Higgs, at some point during inflation, has a homogeneous vev mildly above the top of the barrier and starts rolling down. When inflation ends, reheating adds a large thermal mass to the effective Higgs potential, which, under certain conditions, brings the Higgs back to the origin, $h = 0$ [10]. If falling stops very close to the disaster, this process generates inhomogeneities which lead to the formation of primordial black holes. In section 3 we extend the computations of [8] adding a non-vanishing non-minimal coupling ξ_H of the Higgs to gravity, which is unavoidably generated by quantum effects [11]. We find that ξ_H must be as small as allowed by quantum effects. Under the assumptions made [8] we reproduce their results; however in section 3.6 we also find that such assumptions imply an extreme fine-tuning.

The first mechanism is affected by the observed baryon asymmetry, but does not depend on the unknown physics that generates the baryon asymmetry. The second possibility depends on inflation, but the mechanism only depends on the (unknown) value of the Hubble constant during inflation. In both cases the DM candidate is part of the SM. Conclusions are given in section 4.

2 DM as the $uuddss$ hexa-quark

The hexa-quark $\mathcal{S} = uuddss$ is stable if all its possible decay modes are kinematically closed:

$$\mathcal{S} \rightarrow \begin{cases} d\bar{e}\bar{\nu}_e & M_{\mathcal{S}} < M_d + M_e = 1.8761 \text{ GeV} \\ p\bar{p}e\bar{e}\bar{\nu}_e\bar{\nu}_e & M_{\mathcal{S}} < 2(M_p + M_e) = 1.8775 \text{ GeV} \\ p\bar{e}\bar{\nu}_e n & M_{\mathcal{S}} < M_p + M_e + M_n = 1.8783 \text{ GeV} \\ nn & M_{\mathcal{S}} < 2M_n = 1.8791 \text{ GeV} \end{cases} \quad (1)$$

A stable \mathcal{S} is a possible DM candidate. A too light \mathcal{S} can make nuclei unstable. Scanning over all stable nuclei, we find that none of them gets destabilised by single \mathcal{S} emission if $M_{\mathcal{S}} > 1.874 \text{ GeV}$, with ${}^6\text{Li}$ giving the potentially highest sensitivity to $M_{\mathcal{S}}$.

2.1 Mass of the hexa-quark from a di-quark model

We estimate the mass of the hexa-quark \mathcal{S} viewing it as a neutral scalar di-baryon constituted by three spin zero di-quarks

$$\mathcal{S} = \epsilon^{\alpha\beta\gamma} [ud]_{\alpha,s=0} [us]_{\beta,s=0} [ds]_{\gamma,s=0} \quad (2)$$

where α, β, γ are color indices. This is possible thanks to the strange s quark, while spin zero di-quarks of the kind $[uu], [dd], [ss]$ are forbidden by Fermi statistics because of antisymmetry in color and spin. We assume the effective Hamiltonian for the hexa-quark [12]

$$H = \sum_{i \neq j = \{u,d,s\}} (m_{ij} + 2\kappa_{ij} \mathbf{S}_i \cdot \mathbf{S}_j) \quad (3)$$

where the κ_{ij} are effective couplings determined by the strong interactions at low energies, color factors, quark masses and wave-functions at the origin. The m_{ij} are the masses of the di-quarks in \mathcal{S} made of i and j constituent quarks [13]. \mathbf{S}_i is the spin of i -th quark. Another important assumption, which is well motivated by studies on tetra-quarks [12], is that spin-spin interactions are essentially within di-quarks and zero outside, as if they were sufficiently separated in space.

Considering di-quark masses to be additive in the constituent quark masses, and taking q and s constituent quark masses from the baryons one finds

$$m_{[qq]} \simeq 0.72 \text{ GeV}, \quad m_{[qs]} \sim 0.90 \text{ GeV} \quad q = \{u, d\}. \quad (4)$$

The chromomagnetic couplings κ_{ij} could as well be derived in the constituent quark model using data on baryons

$$\kappa_{qq} \simeq 0.10 \text{ GeV}, \quad \kappa_{qs} \simeq 0.06 \text{ GeV}. \quad (5)$$

However it is known that to reproduce the masses of light scalar mesons, interpreted as tetraquarks, $\sigma(500), f_0(980), a_0(980), \kappa$ [14], we need

$$\kappa_{qq} \simeq 0.33 \text{ GeV}, \quad \kappa_{qs} \simeq 0.27 \text{ GeV}. \quad (6)$$

Spin-spin couplings in tetra-quarks are found to be about a factor of four larger compared to the spin-spin couplings among the same pairs of quarks in the baryons, which make also di-quarks. It is difficult to assess if this would change within an hexa-quark. At any rate we can attempt a simple mass formula for \mathcal{S}

$$M_{\mathcal{S}} = (m_{[qq]} - 3/2\kappa_{qq}) + 2(m_{[qs]} - 3/2\kappa_{qs}) \quad (7)$$

which in terms of light tetra-quark masses means $M_{\mathcal{S}} = M_{\sigma}/2 + M_{f_0}$. Using the determination of chromo-magnetic couplings from baryons we would obtain

$$M_{\mathcal{S}} \approx 2.17 \text{ GeV} \quad (8)$$

whereas keeping the chromo-magnetic couplings needed to fit light tetra-quarks gives

$$M_{\mathcal{S}} \approx 1.2 \text{ GeV} \quad (9)$$

if the same values for the chromo-magnetic couplings to fit light tetra-quark masses are taken (or 1.4 GeV using (6)). There is quite a lot of experimental information on tetra-quarks [12], whereas hexa-quarks, for the moment, are purely hypothetical objects. On purely qualitative grounds we might expect that the mass of \mathcal{S} could be closer to the heavier value being a di-baryon and not a di-meson (tetra-quark) like light scalar mesons.

In the absence of any other experimental information it is impossible to provide an estimate of the theoretical uncertainty on $M_{\mathcal{S}}$.

Lattice computations performed at unphysical values of quark masses find small values for the \mathcal{S} binding energy, about 13, 75, 20 MeV [15–17]. Extrapolations to physical quark masses suggest that \mathcal{S} does not have a sizeable binding energy, see e.g. [18]. Furthermore, the binding energy of the deuteron is small, indirectly disfavouring a very large binding energy for the (somehow similar) \mathcal{S} , which might too be a molecule-like state.¹ Despite of this, we over-optimistically treat $M_{\mathcal{S}}$ as a free parameter in the following.

We also notice that the \mathcal{S} particle could be much larger than what envisaged in [2–4] and that its coupling to photons, in the case of 2 – 3 fm size (see the considerations on diquark-diquark repulsion at small distances in [19]), could be relevant for momentum transfers k as small as $k \sim 60$ MeV, compared to $k \approx 0.5$ GeV considered by Farrar.

2.2 Cosmological relic density of the hexa-quark

We here compute the relic density of \mathcal{S} Dark Matter, studying if it can match the measured value $\Omega_{\text{DM}} h^2 = 0.1186$, i.e. $\Omega_{\text{DM}} \approx 5.3 \Omega_b$ [20]. A key ingredient of the computation is the baryon asymmetry. Its value measured in CMB and BBN is $Y_B = n_B/s = 0.8 \cdot 10^{-10}$. The DM abundance is reproduced (using $M_{\mathcal{S}} = 1.2$ GeV for definiteness) for

$$\frac{Y_{\mathcal{S}}}{Y_B} = \frac{\Omega_{\text{DM}} M_p}{\Omega_B M_{\mathcal{S}}} \approx 4.2. \quad (10)$$

Thereby the baryon asymmetry before \mathcal{S} decoupling must be

$$Y_{BS} = Y_B + 2Y_{\mathcal{S}} \approx 9.3Y_B. \quad (11)$$

One needs to evolve a network of Boltzmann equations for the main hadrons: p , n , Λ , Σ^0 , Σ^+ , Σ^- , Ξ^0 , Ξ^- and \mathcal{S} . Strange baryons undergo weak decays with lifetimes $\tau \sim 10^{-10}$ s, a few

¹We thank M. Karliner, A. Francis, J. Green for discussions.

orders of magnitude faster than the Hubble time. This means that such baryons stay in thermal equilibrium. We thereby first compute the thermal equilibrium values taking into account the baryon asymmetry. Thermal equilibrium implies that the chemical potentials $\mu(T)$ satisfy

$$\mu_b = \mu_S/2, \quad b = \{p, n, \Lambda, \dots\}. \quad (12)$$

Their overall values are determined imposing that the total baryon asymmetry equals

$$\sum_b \frac{n_b^{\text{eq}} - n_{\bar{b}}^{\text{eq}}}{s} + 2 \frac{n_S^{\text{eq}} - n_{\bar{S}}^{\text{eq}}}{s} = Y_{BS}. \quad (13)$$

The equilibrium values can be analytically computed in Boltzmann approximation (which becomes exact in the non-relativistic limit)

$$n_i^{\text{eq}} = g_i \frac{M_i^2 T}{2\pi^2} K_2\left(\frac{M_i}{T}\right) e^{\pm\mu_i/T} \quad (14)$$

where the + (−) holds for (anti)particles. We then obtain the abundances in thermal equilibrium plotted in fig. 1, assuming $M_S = 1.2 \text{ GeV}$. We see that the desired \mathcal{S} abundance is reproduced if the interactions that form/destroy \mathcal{S} decouple at $T_{\text{dec}} \approx 25 \text{ MeV}$. This temperature is so low that baryon anti-particles have negligible abundances, and computations can more simply be done neglecting anti-particles.² Then, the desired decoupling temperature is simply estimated imposing $n_S^{\text{eq}}/n_p^{\text{eq}} \sim Y_{BS} e^{(2M_p - M_S)/T} \sim 1$, and decreases if M_S is heavier:

$$T_{\text{dec}}|_{\text{desired}} \approx \frac{2M_p - M_S}{|\ln Y_{BS}|} \approx 89 \text{ MeV} - 0.048 M_S. \quad (17)$$

To compute the decoupling temperature, we consider the three different kind of processes that can lead to formation of \mathcal{S} :

1. Strong interactions of two heavier QCD hadrons that contain the needed two s quarks. One example is $\Lambda\Lambda \leftrightarrow \mathcal{S}X$, where X denotes pions. These are doubly Boltzmann suppressed by $e^{-2m_s/T}$ at temperatures $T < m_s$.

²Let us consider, for example, the process $\Lambda + \Lambda \leftrightarrow \mathcal{S} + X$ where X denotes other SM particles that do not carry the baryon asymmetry, such as pions. Thermal equilibrium of the above process implies

$$\frac{n_S}{n_\Lambda^2} = \frac{n_S^{\text{eq}}}{n_\Lambda^{\text{eq}2}} = \frac{g_S}{g_\Lambda^2} \left(\frac{2\pi M_S}{M_\Lambda^2 T}\right)^{3/2} e^{(2M_\Lambda - M_S)/T}. \quad (15)$$

Inserting $n_\Lambda \sim n_p e^{(M_p - M_\Lambda)/T}$ with $n_p \approx Y_{BS} s$ gives

$$\frac{n_S}{n_p} \sim \frac{n_\Lambda^2}{n_p} e^{(2M_\Lambda - M_S)/T} \sim Y_{BS}^2 e^{(2M_p - M_S)/T} \quad (16)$$

Namely, $n_S \ll n_p$ at large T ; $n_S \gg n_p$ at low T . A DM abundance comparable to the baryon abundance is only obtained if reactions that form \mathcal{S} decouple at the T in eq. (17).

Figure 1: **Left:** thermal equilibrium values of hadron abundances assuming $Y_{BS} = 7.6 \cdot 10^{-10}$ and $M_S = 1.2$ GeV: the desired abundances are obtained if decoupling of \mathcal{S} interactions occurs at $T \sim 25$ MeV. We see that in this phase anti-particles are negligible. **Right:** thermal equilibrium values of Γ_S/H .

2. Strong interactions of one heavier strange hadron and weak $\Delta S = 1$ interactions that form the other s (as $d\bar{u} \rightarrow s\bar{u}$) from lighter hadrons. One example is $p\Lambda \leftrightarrow \mathcal{S}X$. These are singly Boltzmann suppressed by $e^{-m_s/T}$ and by $G_F^2 \Lambda_{\text{QCD}}^4 \sim 10^{-10}$.
3. Double-weak interactions that form two s quarks starting from lighter hadrons. One example is $pp \rightarrow \mathcal{S}X$. These are doubly suppressed by $(G_F^2 \Lambda_{\text{QCD}}^4)^2$.

At $T \sim 25$ MeV the abundance of strange hadrons is still large enough that QCD processes dominate over EW processes: interactions that form and destroy \mathcal{S} proceed dominantly through QCD collisions of strange hadrons:

$$\Lambda\Lambda, n\Xi^0, p\Xi^-, \Sigma^+\Sigma^- \leftrightarrow \mathcal{S}X \quad (18)$$

where X can be a π^0 or a γ , as preferred by approximate isospin conservation. The Λ can be substituted by the Σ^0 .

Defining $z = M_S/T$ and $Y_p = n_p/s$, the Boltzmann equation for the \mathcal{S} abundance is

$$sHz \frac{dY_S}{dz} = \gamma_S^{\text{eqb}} \left[\frac{Y_B^2}{Y_B^{\text{eqb}2}} - \frac{Y_S}{Y_S^{\text{eqb}}} \right] \quad (19)$$

where the superscript ‘eqb’ denotes thermal equilibrium at fixed baryon asymmetry and Y_B is summed over all baryons, but the dibaryon \mathcal{S} . A second equation for Y_B is not needed, given

Figure 2: *Thermal hexa-quark abundance within the SM with the baryon asymmetry in eq. (11).*

that baryon number is conserved: $(Y_B - Y_{\bar{B}}) + 2(Y_S - Y_{\bar{S}}) = Y_{B\mathcal{S}}$. Furthermore, $Y_{\bar{S}}$ is negligible, and $Y_{\bar{B}}$ is negligible around decoupling. The \mathcal{S} production rate is obtained after summing over all $bb' \leftrightarrow \mathcal{S}X$ processes of eq. (18). In the non-relativistic limit the interaction rate gets approximated as

$$2\gamma_S^{\text{eqb}} \stackrel{T \ll M_S}{\simeq} \sum_{b,b'} n_b^{\text{eqb}} n_{b'}^{\text{eqb}} \langle \sigma_{bb'} v_{\text{rel}} \rangle^{\text{eqb}}. \quad (20)$$

The opposite process is more conveniently written in terms of the \mathcal{S} breaking width defined by $\gamma_S^{\text{eqb}}(T) = n_S^{\text{eqb}} \Gamma_S^{\text{eqb}}$ and given by

$$\Gamma_S^{\text{eqb}} = \sum_{b,b'} \frac{n_b^{\text{eqb}} n_{b'}^{\text{eqb}}}{2n_S^{\text{eq}}} \langle \sigma_{bb'} v_{\text{rel}} \rangle_{\text{eqb}} \quad (21)$$

This gets Boltzmann suppressed at $T \lesssim M_\Lambda - M_p \sim m_s$, when hyperons disappear from the thermal plasma. Assuming $Y_S \lesssim Y_B$, the Boltzmann equation is approximatively solved by $Y_S \sim Y_S^{\text{eqb}}$ evaluated at the decoupling epoch where $\Gamma_S^{\text{eqb}} \sim H$, which corresponds to $T_{\text{dec}} \sim m_s / \ln Y_B$. This leads to the estimated final abundance

$$\frac{Y_S}{Y_B} \sim Y_B (M_{\text{Pl}} T_{\text{dec}} \sigma_S)^{\frac{2M_p - M_S}{2M_\Lambda - M_S}}. \quad (22)$$

The fact that \mathcal{S} is in thermal equilibrium down to a few tens of MeV means that whatever happens at higher temperatures gets washed out. Notice the unusual dependence on the cross section for \mathcal{S} formation: increasing it delays the decoupling, increasing the \mathcal{S} abundance.

Figure 3: *Sample diagram that dominates nucleon decay into \mathcal{S} inside nuclei. The initial state can also be nn or pp .*

Fig. 2 shows the numerical result for the relic \mathcal{S} abundance, computed inserting in the Boltzmann equation a s -wave $\sigma_{bb'}v_{\text{rel}} = \sigma_0$, varied around $1/\text{GeV}^2$. The cosmological DM abundance is reproduced for $M_{\mathcal{S}} \approx 1.2 \text{ GeV}$, while a large $M_{\mathcal{S}}$ gives a smaller relic abundance. Bound-state effects at BBN negligibly affect the result, and in particular do not allow to reproduce the DM abundance with a heavier $M_{\mathcal{S}} \approx 1.8 \text{ GeV}$.

We conclude this section with some sparse comments. Possible troubles with bounds from direct detection have been pointed out in [4, 21, 22]: a DM velocity somehow smaller than the expected one can avoid such bounds reducing the kinetic energy available for direct detection. Using a target made of anti-matter (possibly in the upper atmosphere) would give a sharp annihilation signal, although with small rates. The magnetic dipole interaction of \mathcal{S} does not allow to explain the recent 21 cm anomaly along the lines of [23] (an electric dipole would be needed). The interactions of DM with the baryon/photon fluid may alter the evolution of cosmological perturbations leaving an imprint on the matter power spectrum and the CMB. However, they are not strong enough to produce significant effects. The \mathcal{S} particle is electrically neutral and has spin zero, such that its coupling to photons is therefore suppressed by powers of the QCD scale [3]. So elastic scattering of \mathcal{S} with photons is not cosmologically relevant.

A light \mathcal{S} would affect neutron stars, as they are expected to contain Λ particles, made stable by the large Fermi surface energy of neutrons. Then, $\Lambda\Lambda \rightarrow \mathcal{S}$ would give a loss of pressure, possibly incompatible with the observed existence of neutron stars with mass $2.0M_{\text{sun}}$ [1]. However, we cannot exclude \mathcal{S} on this basis, because production of Λ hyperons poses a similar puzzle. \mathcal{S} as DM could interact with cosmic ray p giving and photon and other signals [24] and would be geometrically captured in the sun, possibly affecting helioseismology.³

In the next section we discuss the main problem which seems to exclude \mathcal{S} as DM.

³We thank M. Pospelov for suggesting these ideas.

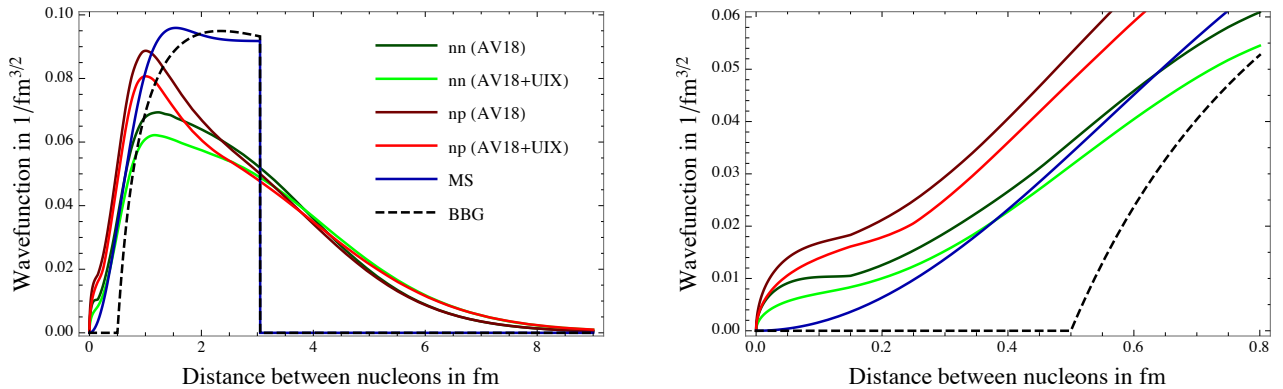

Figure 4: Wave functions $\psi_{\text{nuc}}(a)$ as function of the relative distance a between two nucleons in $^{16}\text{O}_8$. The darker (lighter) green curve shows ψ_{nuc}^{nn} , obtained from [5], using the AV18 (AV18+UIX) potential, the darker (lighter) red curve shows ψ_{nuc}^{np} using the AV18 (AV18+UIX) potential, the blue curve is the MS wave function used in [2], the dashed black curve is the BBG wave function with hard core radius $r_{\text{core}} = 0.5$ fm. **Left:** Wave functions over the entire range. **Right:** Zoom-in to the region relevant for our calculation.

2.3 Super-Kamiokande bound on nuclear stability

Two nucleons $N = \{n, p\}$ inside a nucleus \mathcal{N} can make a double weak decay into \mathcal{S} , emitting π , γ or e [2]. This is best probed by Super-Kamiokande (SK), which contains $\sim 8 \times 10^{32}$ Oxygen nuclei. No dedicated search for $^{16}\text{O}_8 \rightarrow \mathcal{N}' \mathcal{S} X$ (where X can be one or two π, γ, e and \mathcal{N}' can be $^{14}\text{O}_8, ^{14}\text{N}_7, ^{14}\text{C}_6$, depending on the charge of X) has been performed,⁴ but a very conservative limit

$$\tau(^{16}\text{O}_8 \rightarrow \mathcal{N}' \mathcal{S} X) \gtrsim 10^{26} \text{ yr} \quad (23)$$

is obtained by requiring the rate of such transitions to be smaller than the rate of triggered background events in SK, which is about 10 Hz [27]. A more careful analysis would likely improve this bound by three orders of magnitude [2].

The amplitude for the formation of \mathcal{S} is reasonably dominated by the sample diagram in fig. 3: doubly-weak production of two virtual strange Λ^* baryons (e.g. through $p \rightarrow \pi^+ \Lambda^*$ and $n \rightarrow \pi^0 \Lambda^*$; at quark level $u \rightarrow s \bar{d} u$ and $d \rightarrow s \bar{u} u$), followed by the strong process $\Lambda^* \Lambda^* \rightarrow \mathcal{S}$:

$$\mathcal{M}_{NN \rightarrow \mathcal{S} X} \approx \mathcal{M}_{NN \rightarrow \Lambda^* \Lambda^* X} \times \mathcal{M}_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}}. \quad (24)$$

⁴SK searched for di-nucleon decays into pions [25] and leptons [26] and obtained bounds on the lifetime around $\sim 10^{32}$ years. However these bounds are not directly applicable to $^{16}\text{O}_8 \rightarrow \mathcal{N}' \mathcal{S} X$ where the invisible \mathcal{S} takes away most of the energy reducing the energy of the visible pions and charged leptons, in contrast to what is assumed in [25, 26].

The predicted life-time is then obtained as [2]⁵

$$\tau(\mathcal{N} \rightarrow \mathcal{N}' \mathcal{S} X) \simeq \frac{\text{yr}}{|\mathcal{M}|_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}}^2} \times \begin{cases} 3 & \text{if } M_{\mathcal{S}} \lesssim 1.74 \text{ GeV} \\ 10^5 & \text{if } 1.74 \text{ GeV} \lesssim M_{\mathcal{S}} \lesssim 1.85 \text{ GeV} \end{cases} \quad (25)$$

where the smaller value holds if \mathcal{S} is so light that the decay can proceed through real π or $\pi\pi$ emission, while the longer life-time is obtained if instead only lighter $e^+\nu$ or γ can be emitted.

The key factor is the dimension-less matrix element $\mathcal{M}_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}}$ for the transition $\Lambda^* \Lambda^* \rightarrow \mathcal{S}$ inside a nucleus, that we now discuss. Following [2], we assume that the initial state wave function can be factorized into wave functions of the two Λ^* baryons and a relative wave function $\psi_{\text{nuc}}(\vec{a})$ for the separation \vec{a} between the center of mass of the Λ^* 's. The matrix element is given by the wave-function overlap

$$\mathcal{M}_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}} = \int \psi_{\mathcal{S}}^*(\vec{\rho}^a, \vec{\lambda}^a, \vec{\rho}^b, \vec{\lambda}^b, \vec{a}) \psi_{\Lambda^*}(\vec{\rho}^a, \vec{\lambda}^a) \psi_{\Lambda^*}(\vec{\rho}^b, \vec{\lambda}^b) \psi_{\text{nuc}}(\vec{a}) d^3a d^3\rho^a d^3\rho^b d^3\lambda^a d^3\lambda^b. \quad (26)$$

Here, $\vec{\rho}^{a,b}, \vec{\lambda}^{a,b}$ are center-of-mass coordinates which parametrise the relative positions of the quarks within each Λ^* . Using the Isgur-Karl (IK) model [28] the wave functions for the quarks inside the Λ^* and inside the \mathcal{S} are approximated by

$$\psi_{\Lambda^*}(\vec{\rho}, \vec{\lambda}) = \left(\frac{1}{r_N \sqrt{\pi}} \right)^3 \exp \left[-\frac{\vec{\rho}^2 + \vec{\lambda}^2}{2r_N^2} \right], \quad (27)$$

$$\psi_{\mathcal{S}}(\vec{\rho}^a, \vec{\lambda}^a, \vec{\rho}^b, \vec{\lambda}^b, \vec{a}) = \left(\frac{3}{2} \right)^{3/4} \left(\frac{1}{r_S \sqrt{\pi}} \right)^{15/2} \exp \left[-\frac{\vec{\rho}^{a2} + \vec{\lambda}^{a2} + \vec{\rho}^{b2} + \vec{\lambda}^{b2} + \frac{3}{2}\vec{a}^2}{2r_S^2} \right], \quad (28)$$

where r_N and r_S are the radii of the nucleons respectively of \mathcal{S} .⁶ Performing all integrals except the final integral over $a \equiv |\vec{a}|$ gives

$$|\mathcal{M}|_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}} = \frac{1}{2} \left(\frac{3}{2} \right)^{3/4} \left(\frac{2r_N r_S}{r_N^2 + r_S^2} \right)^6 \left(\frac{1}{r_S \sqrt{\pi}} \right)^{3/2} \int da 4\pi a^2 e^{-3a^2/4r_S^2} \psi_{\text{nuc}}(a). \quad (29)$$

As shown in fig. 5 below (and as discussed in [2]), if r_S is not much smaller than r_N , the overlap integral is not very much suppressed and $\tau(^{16}\text{O}_8 \rightarrow \mathcal{N}' \mathcal{S} X)$ is tens of orders of magnitude below the experimental limit, and is clearly excluded. This conclusion is independent of the form of ψ_{nuc} .

However if r_S were a few times smaller than r_N — a possibility which seems unlikely due to diquark repulsions (see e.g. [19]) but cannot firmly be excluded — then $\tau(^{16}\text{O}_8 \rightarrow \mathcal{N}' \mathcal{S} X)$ is

⁵A numerical factor of 1440 due to spin and flavor effects has already been factored out from $|\mathcal{M}|_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}}^2$ here and in the following. Note also that the threshold $2M_N - M_\pi = 1.74 \text{ GeV}$ neglects the small difference in binding energy between \mathcal{N} and \mathcal{N}' .

⁶One should be aware that the IK model has serious shortcomings. One issue is that it is a non-relativistic model — an assumption which is problematic in particular for small \mathcal{S} . Another problem is that the value of r_N that gives a good fit to the lowest lying $\frac{1}{2}^+$ and $\frac{3}{2}^+$ baryons — $r_N = 0.49 \text{ fm}$ — is smaller than the charge radius of the proton: $r_N = 0.87 \text{ fm}$. Therefore we consider both $r_N = 0.49 \text{ fm}$ and $r_N = 0.87 \text{ fm}$, as done in [2].

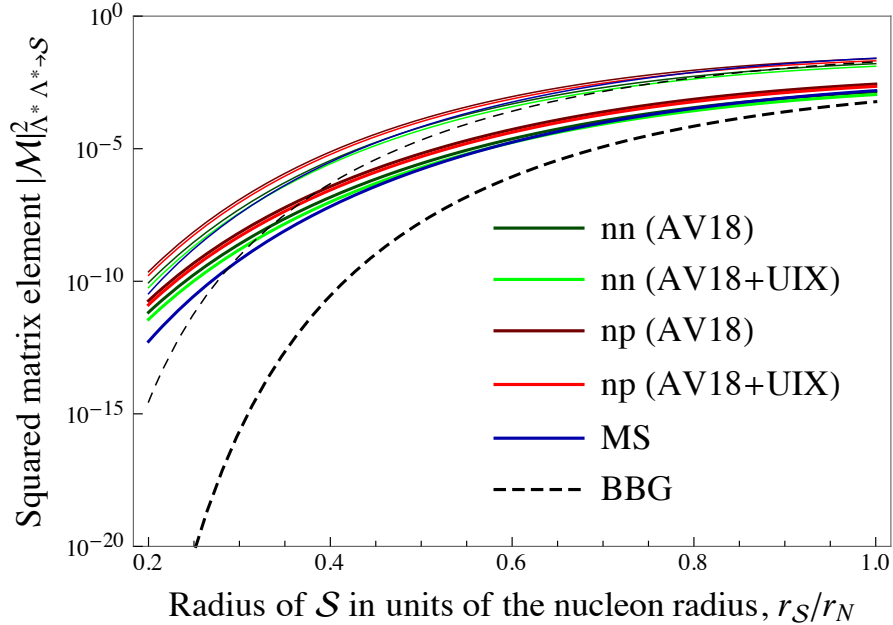

Figure 5: The dimension-less squared matrix element for nuclear decay into \mathcal{S} , $|\mathcal{M}|_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}}^2$, as a function of the \mathcal{S} radius $r_{\mathcal{S}}$ in units of the nucleon radius r_N , using different nuclear wave functions. The color coding, defined in fig. 4, refers to the nuclear wave functions used. The thinner (thicker) curves assume $r_N = 0.87$ fm ($r_N = 0.49$ fm). The Super Kamiokande bound would be evaded for $|\mathcal{M}|_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}}^2 \lesssim 10^{-20}$ (10^{-25}) for $M_{\mathcal{S}} > 1.74$ GeV (for $M_{\mathcal{S}} < 1.74$ GeV).

extremely sensitive to the probability of the overlap of two nucleons inside the oxygen core at very small distances (less than, say, 0.5 fm). The wave function of nucleon pairs ψ_{nuc} at such small distances has not been probed experimentally. In fact, at such small distances nucleons are not the appropriate degrees of freedom.⁷ Thus, for a very small \mathcal{S} one can only make an educated guess of $\tau(^{16}\text{O}_8 \rightarrow \mathcal{N}' \mathcal{S} X)$, since the form of ψ_{nuc} is uncertain. Nevertheless, we will show in the following that for a reasonable form of ψ_{nuc} a stable \mathcal{S} is excluded even if it were very small.

Numerical computations of the ground-state wave-functions of nuclei, including $^{16}\text{O}_8$ have been performed e.g. in [5]. The quantity that determines ψ_{nuc} is the two-nucleon point density ρ_{NN} , defined in eq. (58) of [5]. We obtain $\rho_{NN}(a)$ by interpolating the data given in [5] and adding the constraint $\rho_{NN}(0) = 0$, which is a conservative assumption for our purposes since $\rho_{NN}(0) \neq 0$ would lead to a larger matrix element. There are 28 neutron-neutron pairs and 64 proton-neutron pairs in $^{16}\text{O}_8$ so one has $\int da 4\pi a^2 \rho_{nn}(a) = 28$ and $\int da 4\pi a^2 \rho_{pn}(a) = 64$. We

⁷Data indicate that about 20% of the nucleons form pn pairs so close (about 1 fm) that the local density reaches the nucleon density (about 2.5 times larger than the nuclear density) and thus that the quark structure of nucleons starts becoming relevant already at $a \sim 1$ fm [29].

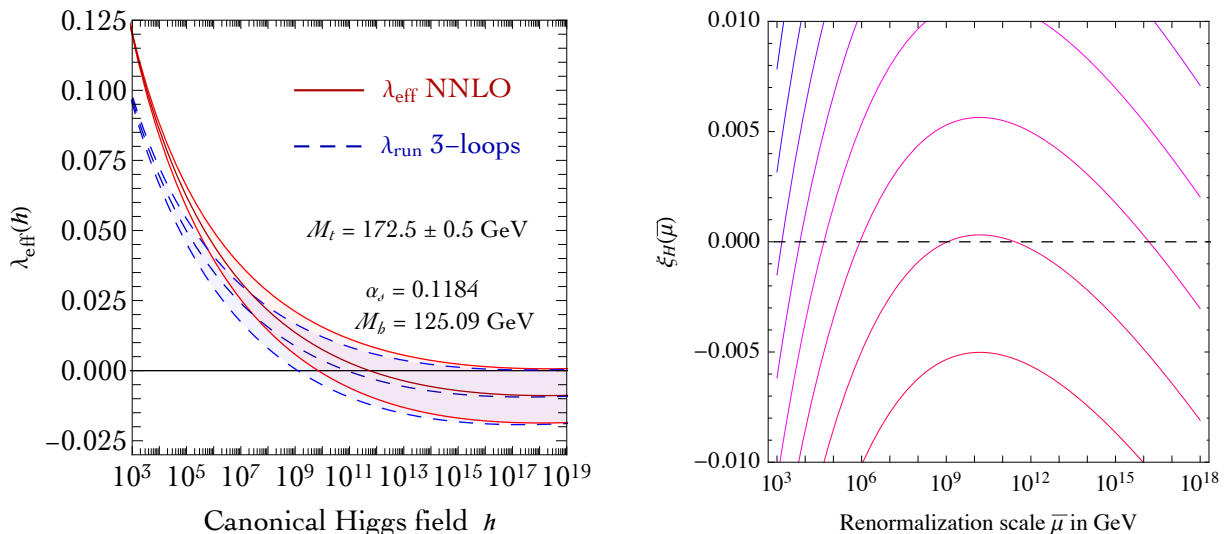

Figure 6: **Left:** RGE running of λ_{eff} (solid red lines) obtained by changing the top mass in its 3σ interval defined by $M_t = 172.5 \pm 0.5$ GeV. For comparison, we show the running of λ at 3-loops (dashed blue lines) without including the Coleman-Weinberg corrections. **Right:** RGE running of a small ξ_H .

therefore define the wavefunctions

$$\psi_{\text{nuc}}^{nn}(a) = \sqrt{\rho_{nn}(a)/28}, \quad \psi_{\text{nuc}}^{pn}(a) = \sqrt{\rho_{pn}(a)/64}. \quad (30)$$

These wave functions are plotted in fig. 4, together with the Miller-Spencer (MS) and the Brueckner-Bethe-Goldstone (BBG) wave function used in [2]. The BBG wave functions assume a hard repulsive core between nucleons such that ψ_{nuc} vanishes at $a < r_{\text{core}}$. We take $r_{\text{core}} = 0.5$ fm for illustration. This is not realistic but allows to see what kind of nuclear wave function would sufficiently suppress the rate of \mathcal{S} -formation in nuclei, if \mathcal{S} is small enough. The resulting $|\mathcal{M}|_{\Lambda^* \Lambda^* \rightarrow \mathcal{S}}^2$ is plotted in fig. 5, again compared to that obtained using the Miller-Spencer and BBG wave functions.

The resulting matrix elements from the MS wave function qualitatively agree to what is obtained using the wave functions extracted from [5]. By contrast, the matrix element using the BBG wave function with hard core radius $r_{\text{core}} = 0.5$ fm is very much suppressed, especially if \mathcal{S} is small. The reason is that, according to the assumption of a hard core repulsive potential, the nucleons can't get close enough to form the small state \mathcal{S} . Since we do not consider a $\psi_{\text{nuc}}(a)$ which vanishes for $a \lesssim 0.5$ fm realistic, we conclude that a stable \mathcal{S} is excluded.

Weaker bounds on \mathcal{S} production are obtained considering baryons containing Λ 's.

3 DM as black holes triggered by Higgs fluctuations

We here present the technical computations relative to the mechanism anticipated in the Introduction. The SM potential is summarized in section 3.1. In section 3.2 we outline the mechanism that generates black holes. Section 3.3 studies the generation of Higgs inhomogeneities. Post-inflationary dynamics is studied in section 3.4. Formation of black holes is considered in section 3.5. The viability of a critical assumption is discussed in section 3.6.

3.1 The Higgs effective potential

The effective potential of the canonically normalised Higgs field during inflation with Hubble constant H_0 is

$$V_{\text{eff}}(h) \approx \frac{\lambda_{\text{eff}}(h)}{4} h^4 - 6\xi_H H_0^2 h^2 + V_0, \quad (31)$$

at $h \gg 174 \text{ GeV}$. Here λ_{eff} is the effective quartic coupling computed including quantum corrections. The second mass term in $V_{\text{eff}}(h)$ can be generated by various different sources [8]. We consider the minimal source: a Higgs coupling to gravity, $\mathcal{L}_\xi = -\xi_H R h^2/2$, with Ricci scalar $R = -12H_0^2$ during inflation. Finally, during inflation the effective potential in eq. (31) is augmented by the vacuum energy associated to the inflaton sector, $V_0 = 3\bar{M}_{\text{Pl}}^2 H_0^2$, where $\bar{M}_{\text{Pl}} \simeq 2.435 \times 10^{18} \text{ GeV}$ is the reduced Planck mass.

We implement the RG-improvement of the effective potential at NNLO precision: running the SM parameters at 3-loops and including 2-loop quantum corrections to the effective potential. We consider fixed values of $\alpha_3(M_Z) = 0.1184$ and $M_h = 125.09 \text{ GeV}$, and we vary the main uncertain parameter, the top mass, in the interval $M_t = 172.5 \pm 0.5 \text{ GeV}$ [32]. In fig. 6a we show the resulting $\lambda_{\text{eff}}(h)$ as function of h .

The non-minimal coupling to gravity ξ_H receives SM quantum corrections encoded in its RGE, which induce $\xi_H \neq 0$ even starting from $\xi_H = 0$ at some energy scale. The RGE running of small values of $\xi_H(\bar{\mu})$ is shown in fig. 6b. As mentioned before, a non-zero ξ_H can be considered as a proxy for an effective mass term during inflation. The latter, for instance, can be generated by a quartic interaction $\lambda_{h\phi}|H|^2\phi^2$ between the Higgs and the inflaton field or by the inflaton decay into SM particles during inflation. For this reasons, it makes sense to include ξ_H as a free parameter in the analysis of the Higgs dynamics during inflation, at most with the theoretical bias that its size could be loop-suppressed.

Analytic approximation

We will show precise numerical results for the SM case. However the discussion is clarified by introducing a simple approximation that encodes the main features of the SM effective potential in eq. (31):

$$V_{\text{eff}}(h) \approx -b \log\left(\frac{h^2}{h_{\text{cr}}^2 \sqrt{e}}\right) \frac{h^4}{4} - 6\xi_H H_0^2 h^2, \quad (32)$$

where h_{cr} is the position of the maximum of the potential with no extra mass term, $\xi_H = 0$. The parameters b and h_{cr} depend on the low-energy SM parameters such as the top mass: they can be computed by matching the numerical value of the Higgs effective potential at the gauge-invariant position of the maximum, $V_{\text{eff}}(h_{\text{cr}}) = bh_{\text{cr}}^4/8$. The result is shown in the right panel of fig. 7.

Results will be better understood when presented in terms of the dimensionless parameters b , ξ_H , h_{cr}/H_0 and T/H_0 , where T is the temperature, as they directly control the dynamics that we are going to study. The parameter b controls the flatness of the potential beyond the potential barrier at h_{cr} , with smaller b corresponding to a flatter potential. The non-minimal coupling ξ_H controls the effective Higgs mass during inflation. Finally \bar{M}_{Pl}/H_0 will set the reheating temperature in eq. (35) and thus the position and size of the thermal barrier.

The position of the potential barrier — defined by the field value where the effective potential has its maximum — strongly depends on the value of the top mass, on the non-minimal coupling to gravity, and, after inflation, on the temperature of the thermal bath which provides an extra mass term. For $\xi_H \neq 0$, the maximum of the Higgs potential gets shifted from h_{cr} to

$$h_{\text{max}} = H_0 \left[-\frac{b}{12\xi_H} \mathcal{W} \left(\frac{-12\xi_H H_0^2}{bh_{\text{cr}}^2} \right) \right]^{-1/2}, \quad (33)$$

where $\mathcal{W}(z)$ is the product-log function defined by $z = \mathcal{W}e^{\mathcal{W}}$. The condition

$$-12\xi_H H_0^2 > -\frac{bh_{\text{cr}}^2}{e}, \quad (34)$$

must be satisfied otherwise the effective mass is too negative and it erases the potential barrier, thus leading to a classical instability.

The thermal potential

After the end of inflation, the Higgs effective potential receives large thermal corrections from the SM bath at generic temperature T . The initial temperature of the thermal bath is fixed by the dynamics of reheating after inflation. We assume instantaneous reheating, as this is most efficient for rescuing the falling Higgs field. The reheating temperature is then given by

$$T_{\text{RH}} = \left(\frac{45}{4\pi^3 g_*} \right)^{1/4} M_{\text{Pl}}^{1/2} H_0^{1/2}, \quad (35)$$

where $g_* = 106.75$ is the number of SM degrees of freedom. After reheating the Universe becomes radiation-dominated, the Ricci scalar vanishes, and so the contribution to the effective potential from the non-minimal Higgs coupling to gravity.

The effective Higgs potential at finite temperature is obtained adding an extra thermal contribution V_{T} which can be approximated as an effective thermal mass for the Higgs field, $M_{\text{T}}^2 \simeq 0.12 T^2$ (see e.g. [10])

$$V_{\text{eff}}^{\text{T}}(h) \approx -b \log \left(\frac{h^2}{h_{\text{cr}}^2 \sqrt{e}} \right) \frac{h^4}{4} + V_{\text{T}}(h), \quad V_{\text{T}}(h) \approx \frac{1}{2} M_{\text{T}}^2 h^2 e^{-h/2\pi T}. \quad (36)$$

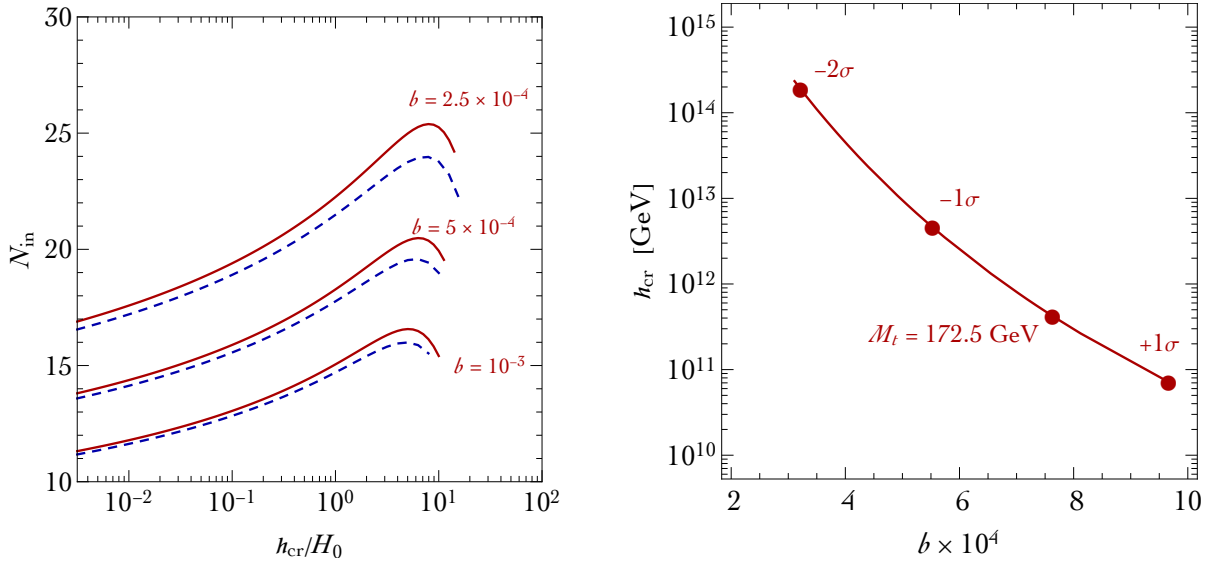

Figure 7: **Left:** Number of e -folds N_{in} at the beginning of the Higgs fall that gives the maximal h_{end} rescued by the reheating temperature. This is computed as function of the Hubble constant during inflation, for 3 different values of the uncertain parameter b that approximates the Higgs potential. Continuous (dashed) curves correspond to $\xi_H = 0$ (-10^{-3}). **Right:** SM values of b and of the position h_{cr} of the top of the SM potential as function of the top mass.

At $h \lesssim T$ we can neglect the exponential suppression in the thermal mass, and the maximum of the effective potential in eq. (36) is given by

$$h_{\text{max}}^{\text{T}} = M_{\text{T}} \left[b \mathcal{W} \left(\frac{M_{\text{T}}^2}{b h_{\text{cr}}^2} \right) \right]^{-1/2}. \quad (37)$$

3.2 Outline of the mechanism

During inflation, the Higgs field is subject to quantum fluctuations. Depending on the value of H_0 , these quantum fluctuations could lead the Higgs beyond the barrier, and make it roll towards Planckian values. If T_{RH} is high enough and h is not too far, thermal corrections can “rescue” the Higgs, bringing it back to the origin [10]. The mechanism relies on a tuning such that the following situation occurs [8]:

- i)* At $N_{\text{in}} \sim 20$ e -folds before the end of inflation, the Higgs background value h is brought by quantum fluctuation to some $h_{\text{in}} \neq 0$. This configuration must be spatially homogeneous on an inflating local patch large enough to encompass our observable Universe today. We

consider the de Sitter metric in flat slicing coordinates, $ds^2 = -dt^2 + a^2(t)d\vec{x}^2$. We will discuss later how precisely this assumption must be satisfied, and its plausibility.

- ii)* When the classical evolution prevails over the quantum corrections, the Higgs field, starting from the initial position h_{in} , begins to slow roll down the negative potential. This condition reads

$$\underbrace{\left| \frac{V'_{\text{eff}}(h_{\text{in}})}{3H_0^2} \right|}_{\text{classical}} > \underbrace{\frac{cH_0}{2\pi}}_{\text{quantum}} . \quad (38)$$

where c is a constant of order 1, fixed to $c = 1$ in [8]. We will explore what happens choosing $c = 0.9$ or $c = 1.1$. From this starting point t_{in} on, the classical evolution of the background Higgs value is described by

$$\ddot{h}_{\text{cl}} + 3H_0\dot{h}_{\text{cl}} + V'_{\text{eff}}(h_{\text{cl}}) = 0 \quad (39)$$

where the subscript $_{\text{cl}}$ indicates that this is a classical motion. Dots indicate derivatives with respect to time t .

- iii)* At the end of inflation, $N_{\text{end}} = 0$, the Higgs is rescued by thermal effects. This happens if the value of the Higgs field h_{end} at the end of inflation is smaller than the position of the thermal potential barrier at reheating, $h_{\text{max}}^{\text{TRH}}$. A significant amount of PBH arises only if this condition is barely satisfied in all Universe. This is why the homogeneity assumption in *i)* is needed.

To compute condition *iii)* we fix the initial value of the classical motion h_{in} such that eq. (38) is satisfied with $c = 1$; next, we maximise the h_{end} obtained solving eq. (39) by tuning the amount of inflation where the fall happens, as parameterized by N_{in} . The left panel of fig. 7 shows the initial value N_{in} obtained following this procedure as a function of h_{cr} in units of H_0 . Smaller values of b (i.e. smaller values of M_t) imply a flattening of the potential, and the classical dynamics during inflation is slower. The right side of the curves is limited by the classicality condition in eq. (38). A $\xi_H < 0$ shifts the position of the potential barrier towards the limiting value $h_{\text{max}}^{\text{T}}$ in eq. (37) — which does not depend on ξ_H — above which the rescue mechanism due to thermal effects is no-longer effective: its net effect is to reduce the number of e -folds during which classical motion can happen (for fixed b).

We anticipate here the feature of PBH formation which implies the restriction on the parameter space mentioned at point *i)*: Higgs fall must start at least $N_{\text{in}} \sim 20$ e -folds before the end of inflation. The collapse of the mass inside the horizon N e -folds before inflation end forms a PBH with mass (see also section 3.5)

$$M_{\text{PBH}} \approx \frac{\bar{M}_{\text{Pl}}^2}{H_0} e^{2N} . \quad (40)$$

PBH must be heavy enough to avoid Hawking evaporation. The lifetime of a PBH with mass M_{PBH} due to Hawking radiation at Bekenstein-Hawking temperature $T_{\text{BH}} = 1/(8\pi G_N M_{\text{PBH}})$ is

$$\Gamma_{\text{PBH}}^{-1} \approx 4 \times 10^{11} \left[\frac{\mathcal{F}(M_{\text{PBH}})}{15.35} \right]^{-1} \left(\frac{M_{\text{PBH}}}{10^{13} \text{ g}} \right)^3 \text{ s} , \quad (41)$$

where $\mathcal{F} \rightarrow 1$ at $M_{\text{PBH}} > 10^{17} \text{ g}$. BH heavier than $M_{\text{PBH}} > 10^{15} \text{ g}$ are cosmologically stable, and BH heavier than $M_{\text{PBH}} > 10^{16.5} \text{ g}$ are allowed by bounds on Hawking radiation as a (significant fraction of) DM. Since $N < N_{\text{in}}$, imposing $M_{\text{PBH}} > 10^{16.5} \text{ g}$ implies a conservative lower limit on N_{in} :

$$N_{\text{in}} > \frac{1}{2} \ln \left[7.2 \times 10^{21} \frac{H_0}{\bar{M}_{\text{Pl}}} \right] = 18.3 \quad \text{for } H_0 = 10^{-6} \bar{M}_{\text{Pl}}. \quad (42)$$

3.3 Higgs fluctuations during inflation

We now consider the evolution of Higgs perturbations during inflation. Expanding h in Fourier space with comoving wavenumber k ,⁸ the equation for the mode δh_k takes the form

$$\delta \ddot{h}_k + 3H_0 \delta \dot{h}_k + \frac{k^2}{a^2} \delta h_k + V_{\text{eff}}''(h_{\text{cl}}) \delta h = 0 , \quad (43)$$

where we neglected metric fluctuations. In terms of the number of e -folds N and of the Mukhanov-Sasaki variable $u_k \equiv a \delta h_k$ it becomes

$$\frac{d^2 u_k}{dN^2} + \frac{du_k}{dN} + \left(\frac{k^2}{a^2 H_0^2} - 2 \right) u_k + \frac{V_{\text{eff}}''(h_{\text{cl}})}{H_0^2} u_k = 0 . \quad (44)$$

It is convenient to consider the evolution of the perturbation making reference to a specific moment before the end of inflation: at the initial value N_{in} defined in section 3.2. We recall that in our convention $N_{\text{end}} = 0$ at the end of inflation. Eq. (44) becomes

$$\frac{d^2 u_k}{dN^2} - \frac{du_k}{dN} + \left[\left(\frac{k}{a_{\text{in}} H_0} \right)^2 e^{2(N-N_{\text{in}})} - 2 \right] u_k + \frac{V_{\text{eff}}''(h_{\text{cl}})}{H_0^2} u_k = 0 . \quad (45)$$

In this form, the Mukhanov-Sasaki equation is particularly illustrative. Consider the evolution of the perturbation for a mode of interest k that we fix compared to the reference value $a_{\text{in}} H_0$ at $t = t_{\text{in}}$. In particular, we consider the case of a mode k that is sub-horizon at the beginning of the classical evolution, that is $k \gg a_{\text{in}} H_0$. From eq. (45), we see that in the subsequent evolution with $N < N_{\text{in}}$ the exponential suppression will turn the mode from sub-horizon to super-horizon.

We are now in the position to solve eq. (45). To this end, we need boundary conditions for u_k and its time derivative. We use the Bunch-Davies conditions at $N = N_{\text{in}}$ for modes that are

⁸The comoving wavenumber $k = |\vec{k}|$ is time independent, and it is related to the physical momentum via $k_{\text{phys}} = k/a(t)$, which decreases as the space expands.

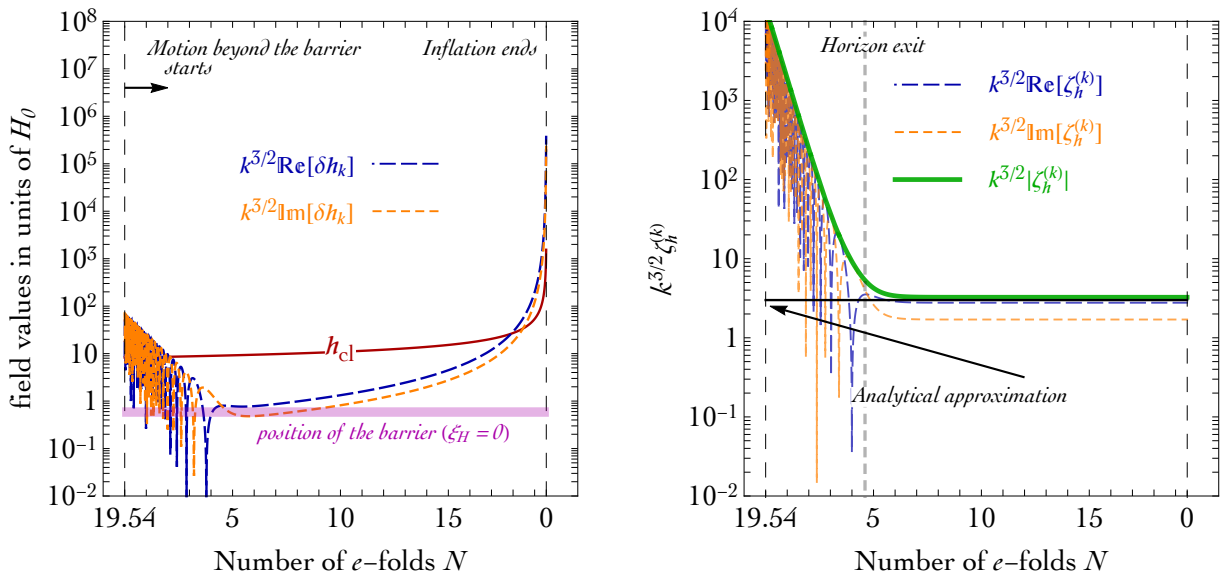

Figure 8: **Left:** Sample evolution of the classical Higgs background (h_{cl} , red solid line) and of a perturbation with $k/a_{\text{in}}H_0 = 10^2$ (dashed lines). **Right:** Higgs curvature perturbation $\zeta_h^{(k)}$ during inflation. We compare the full numerical result with the analytical approximation (last term in eq. (52), solid horizontal black line). The vertical dashed gray line marks the instant of horizon exit. We use the analytical approximation in eq. (32) with $h_{\text{cr}} = 4 \cdot 10^{12}$ GeV, $b = 0.09/(4\pi)^2$ (which corresponds to $M_t = 172$ GeV) and $H_0 = 10^{12}$ GeV.

sub-horizon at the beginning of the classical evolution, $k/a_{\text{in}}H_0 \geq 1$, and we treat the real and imaginary part of u_k separately since they behave like two independent harmonic oscillators for each comoving wavenumber k . At generic e -fold time N , the perturbation δh_k is related to the Mukhanov-Sasaki variable u_k by

$$k^{3/2} \frac{\delta h_k}{H_0} \Big|_N = \left(\frac{k}{a_{\text{in}}H_0} \right) e^{N-N_{\text{in}}} (\sqrt{k} u_k) \Big|_N. \quad (46)$$

We show in the left panel of fig. 8 our results for the time evolution of the classical background h_{cl} and the perturbation δh_k (both real and imaginary part) during the last 20 e -folds of inflation. As a benchmark value, we consider an initial sub-horizon mode with $k/a_{\text{in}}H_0 = 100$. After few e -folds of inflation such mode exits the horizon: oscillations stop, and from this point on, further evolution is driven by the time derivative of the classical background. This is a trivial consequence of the equations of motion on super-horizon scales. Differentiating eq. (39) with respect to the cosmic time shows that \dot{h}_{cl} and δh_k satisfy the same equation on super-horizon scales, and, therefore, they must be proportional, $\delta h_k = C(k)\dot{h}_{\text{cl}}$ for $k \ll aH_0$ [8]. The proportionality function $C(k)$ can be obtained by a matching procedure. Deep inside

the horizon, in the limit $k \gg aH_0$, the Mukhanov-Sasaki variable $u_k \equiv a \delta h_k$ reproduces the preferred vacuum of an harmonic oscillator in flat Minkowski space, and we have, after introducing the conformal time τ as $dt = a d\tau$, $u_k = e^{-ik\tau}/\sqrt{2k}$. Roughly matching the absolute value of the solutions at horizon crossing we determine the absolute value of $C(k)$ as

$$|\delta h_k| = \frac{H_0}{\sqrt{2k^3} \dot{h}_{\text{cl}}(t_k)} \dot{h}_{\text{cl}}(t) , \quad (47)$$

where we indicate with t_k the time of horizon exit for the mode k — the time at which $k = a(t_k)H_0 \equiv a_k H_0$ (equivalently, $-k\tau_k = 1$). The number of e -fold at horizon exit is given by

$$\frac{k}{a_{\text{in}} H_0} = e^{N_{\text{in}} - N_k} . \quad (48)$$

Primordial curvature perturbations

The primordial curvature perturbation $\zeta(\vec{x}, t)$ on uniform energy density slices ρ is defined (at the linear order) by the perturbed line element [33, 34]

$$ds^2 = a^2(t)[1 + 2\zeta(\vec{x}, t)]\delta_{ij}dx^i dx^j , \quad (49)$$

and it is related to the (total) energy density perturbation $\delta\rho$ and to the curvature perturbation on a generic slicing Ψ by the gauge invariant formula

$$\zeta = \Psi + \mathcal{H} \frac{\delta\rho}{\rho'} = \Psi + H \frac{\delta\rho}{\dot{\rho}} , \quad (50)$$

where we introduced the conformal time by means of $dt = a d\tau$ and $\mathcal{H} = aH$ where $\mathcal{H} = a'/a$, and prime $'$ indicates derivative with respect to τ . The virtue of this definition is that, on super-horizon scales, ζ is practically identical to the comoving curvature perturbation \mathcal{R} defined on hypersurfaces of constant comoving time. Furthermore, on super-horizon scales ζ is conserved provided that the pressure perturbation is adiabatic. In conventional single-field inflation models, purely adiabatic perturbations are generated due to quantum fluctuations of the single field driving inflation. The considered setup differs from a conventional scenario because of the presence, in addition to the inflaton, of the Higgs field [8]. During inflation, the curvature perturbation on uniform energy density slices is given, in spatially-flat gauge, by

$$\zeta = H_0 \frac{\delta\rho}{\dot{\rho}} = \frac{\dot{\rho}_\phi}{\dot{\rho}} \zeta_\phi + \frac{\dot{\rho}_h}{\dot{\rho}} \zeta_h , \quad (51)$$

where we separated the inflaton component ζ_ϕ and the Higgs component $\zeta_h \equiv H_0 \delta\rho_h / \dot{\rho}_h$ [8]. We assume that there is no energy transfer between the Higgs and the inflaton sector, and that the latter generates, on large scales, the perturbations responsible for the CMB anisotropies and large scale structures. Given these assumptions, ζ_ϕ and ζ_h are separately conserved on

super-horizon scales [35]. As customary, we can decompose ζ_h in Fourier modes. For a given comoving wavenumber k we have, in spatially-flat gauge

$$\zeta_h^{(k)} = H_0 \frac{\delta\rho_h^{(k)}}{\dot{\rho}_h} = - \frac{[\dot{h}_{\text{cl}}\delta h_k + V'_{\text{eff}}(h_{\text{cl}})\delta h_k]}{3\dot{h}_{\text{cl}}^2} \simeq \frac{H_0^2}{\sqrt{2k^3}\dot{h}_{\text{cl}}(t_k)} \Big|_{k \ll aH_0}, \quad (52)$$

where the last analytical approximation is valid for the absolute value of $\zeta_h^{(k)}$ in the super-horizon limit, and where we used $\rho_h = \dot{h}_{\text{cl}}^2/2 + V_{\text{eff}}(h_{\text{cl}})$ in the first equality.

The right panel of fig. 8 compares the numerical result for $\zeta_h^{(k)}$ — that is the first equality in eq. (52) — with its analytical approximation. The plot, moreover, shows that on super-horizon scales $\zeta_h^{(k)}$ stays constant, as it should be since we are working under the underlying assumption that there are no interactions between the Higgs and the inflationary sector.

3.4 Higgs dynamics after inflation

Assuming instantaneous reheating, the energy density of the inflaton is instantaneously converted into radiation at the end of inflation. The inflaton energy density ρ_{R} is related to the temperature of the thermal bath by

$$\rho_{\text{R}} = \frac{\pi^2 g_*}{30} T^4. \quad (53)$$

The dynamics after reheating is described by the following system of coupled Higgs-radiation equations

$$\ddot{h}_{\text{cl}} + (3H + \Gamma)\dot{h}_{\text{cl}} + V'_T(h_{\text{cl}}) = 0, \quad (54a)$$

$$\dot{\rho}_{\text{R}} + 4H\rho_{\text{R}} = \Gamma\rho_h, \quad (54b)$$

where the energy density of the Higgs field is given by

$$\rho_h = \frac{\dot{h}_{\text{cl}}^2}{2} + V_{\text{eff}}^T(h_{\text{cl}}), \quad (55)$$

and the Hubble parameter is related to the total energy density by

$$H^2 = \frac{\rho_{\text{R}} + \rho_h}{3\bar{M}_{\text{Pl}}^2}. \quad (56)$$

The damping factor Γ takes into account the Higgs decays at temperature T , and represents the energy transportation from the Higgs field to radiation. We use the expression quoted in [8], $\Gamma \simeq 10^{-3}T$. In the following, we shall adopt the assumption of sudden decay approximation. In this approximation — corresponding to $\Gamma = 0$ in eq.s (54) — Higgs and radiation evolve separately, and Higgs decay occurs instantaneously at $H = \Gamma$. The system in eq.s (54) can be solved using the following boundary conditions. As far as the classical Higgs field is concerned,

we use the field values at the end of inflation computed in section 3.3. The evolution of ρ_{R} , on the contrary, starts from the temperature in eq. (35).⁹ Using the solution for ρ_{R} , eq. (53) gives the time-evolution of the temperature.

After instantaneous reheating, the Higgs potential suddenly changes from the expression in eq. (32) to the one in eq. (36), and interactions with the SM bath generate a large thermal mass. If $h_{\text{end}} < h_{\text{max}}^{\text{T}}$, the fall of the Higgs field is rescued by thermal corrections, and its background value starts oscillating around the minimum at zero until the decay becomes efficient at $H = \Gamma$. At this stage, the Higgs component ζ_h of the curvature perturbation is not conserved compared to the value computed in eq. (52) during inflation. This is because the interactions with the SM plasma that are responsible for the appearance of the thermal mass introduce a non-adiabatic component in the pressure perturbation.

We compute — in spatially flat gauge, and for a given comoving wavenumber k — the total curvature perturbation after reheating according to

$$\zeta^{(k)} = H \frac{\delta\rho}{\dot{\rho}} = \frac{\dot{h}_{\text{cl}}\delta h_k + V_{\text{eff}}^{\text{T}\prime}(h_{\text{cl}})\delta h_k}{-4\rho_{\text{R}} - 3\dot{h}_{\text{cl}}^2}, \quad (58)$$

where radiation perturbations are set to zero. We compute $\zeta^{(k)}$ numerically at the time of Higgs decay, $H = \Gamma$. After Higgs decay, radiation remains as the only component of the Universe and $\zeta^{(k)}$ is, therefore, conserved.

3.5 The power spectrum and the PBHs abundance

The curvature power spectrum is given by

$$\mathcal{P}_{\zeta} = \frac{k^3}{2\pi^2} |\zeta^{(k)}|^2. \quad (59)$$

A numerical example is shown in fig. 9. Its left panel shows that a small $\xi_H = -10^{-3}$ only has a minor effect. The cut in the power spectrum at small k arises because of assumption *i*): before that classical rolling starts, the Higgs field is away from its minimum and exactly homogeneous. Relaxing this assumption would increase the power spectrum at small k .

The right panel shows the significant effect of a small change in the arbitrary order one parameter c that defines the classicality condition in eq. (38). Reducing c anticipates the initial moment t_{in} (or equivalently N_{in}) where the Higgs starts to roll down the potential. As a consequence earlier quantum fluctuations get taken into account by our computation of section 3.3.

⁹More precisely conservation of total energy determines the reheating temperature as

$$3\bar{M}_{\text{Pl}}^2 H_0^2 + \frac{\dot{h}_{\text{cl}}^2}{2} + V_{\text{eff}}(h_{\text{cl}}) \Big|_{h_{\text{cl}}=h_{\text{end}}} = \frac{\pi^2 g_*}{30} T^4 + \frac{\dot{h}_{\text{cl}}^2}{2} + V_{\text{eff}}^{\text{T}}(h_{\text{cl}}) \Big|_{h_{\text{cl}}=h_{\text{end}}}. \quad (57)$$

The approximation in eq. (35) is valid because the inflaton energy density dominates over the Higgs contribution.

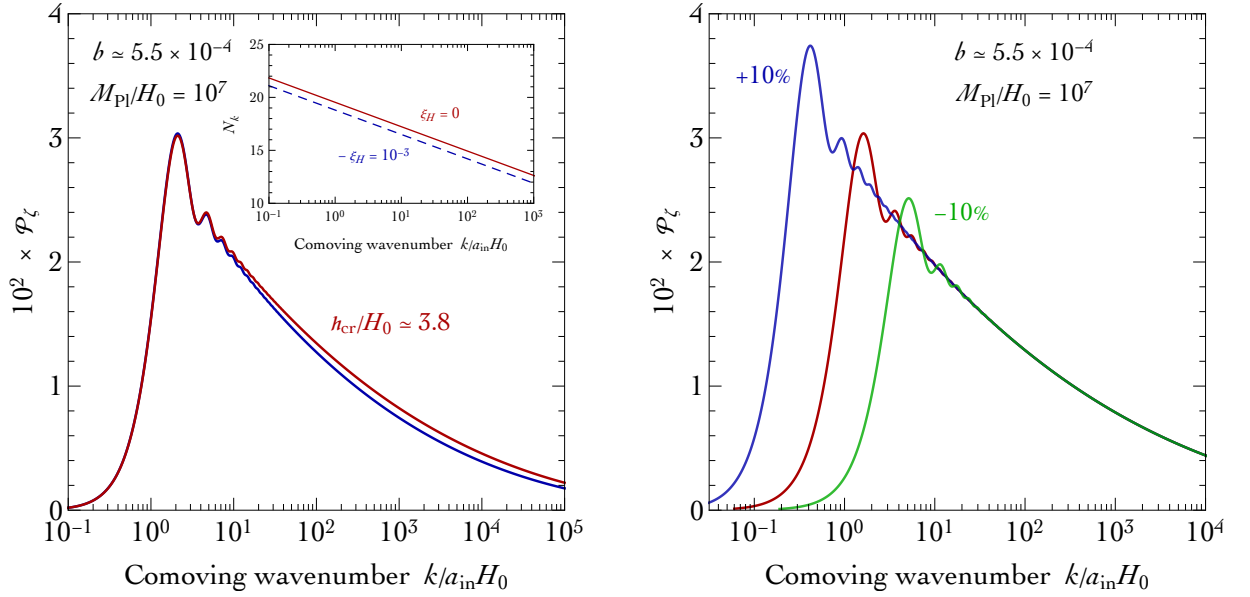

Figure 9: **Left:** power spectrum of Higgs fluctuations produced by rescued Higgs fall for $\xi_H = 0$ (red curve) and $\xi_H = -10^{-3}$ (blue), which has a minor impact. In the inset we show the number of e -folds at horizon exit for each mode. **Right:** how the power spectrum changes when the classicality condition in eq. (38) is changed by $\pm 10\%$.

Finally, we can now compute the mass and amount of PBH generated by Higgs fluctuations. The radius of hubble horizon or the wavelength of the modes determines the typical mass of the PBHs [36]:

$$M_{\text{PBH}} \approx \frac{\gamma}{2} \frac{M_{\text{Pl}}^2}{H_0} e^{2N}, \quad (60)$$

where N is the number of e -folds when the k -mode leave the horizon; $\gamma \approx 0.2$ is a correction factor [37]. For example $H_0 = 10^{12}$ GeV and $N = 20$ gives $M_{\text{PBH}} \approx 10^{-15} M_{\odot}$.

To compute the fraction of the Hubble volume collapsing to PBHs, we need the variance of the smoothed density perturbation over a radius R , $\sigma^2(R) = \langle \delta^2(\mathbf{x}, R) \rangle$, where $\delta(\mathbf{x}, R) = \int d^3x' \delta(\mathbf{x}') W(\mathbf{x} - \mathbf{x}', R)$ is the density fluctuation smoothed by a window function $W(\mathbf{x}, R)$, assumed to be Gaussian

$$W(\mathbf{x}, R) = \frac{1}{(2\pi)^{3/2} R^3} \exp\left(-\frac{|\mathbf{x}|^2}{2R^2}\right). \quad (61)$$

The variance can be computed in terms of density power spectrum $P_{\delta}(k)$, which is related to the curvature perturbation ζ power spectrum $P_{\zeta}(k)$ as [38]

$$\sigma^2(R) = \int d \ln k P_{\delta}(k) \widetilde{W}^2(kR), = \int d \ln k \frac{16}{81} (kR)^4 P_{\zeta}(k) \widetilde{W}^2(kR), \quad (62)$$

where $\widetilde{W}(k) = \exp(-k^2/2)$ is the Fourier transform of the window function. Assuming that PHBs are formed when the density perturbation exceeds $\delta_{\text{th}} \approx 0.5$ [39], the fraction of the

Universe ending up in PHBs is given by the tail of the assumed Gaussian distribution:

$$\beta(M_{\text{PBH}}) = \gamma \int_{\delta_{\text{th}}}^{\infty} d\delta \frac{1}{\sqrt{2\pi}\sigma(M_{\text{PBH}})} \exp\left(-\frac{\delta^2}{2\sigma^2(M_{\text{PBH}})}\right) \stackrel{\sigma \ll \delta_{\text{th}}}{\simeq} \frac{\gamma\sigma}{\sqrt{2\pi}\delta_{\text{th}}} \exp\left(-\frac{\delta_{\text{th}}^2}{2\sigma^2}\right) \quad (63)$$

The latter approximation is relevant, given that the obtained power spectra P_ζ are of order 10^{-2} . We convert $\sigma(R)$ to a function $\sigma(M_{\text{PBH}})$, taking into account that the size R is related to the mass M_{PBH} as $R \approx 2GM_{\text{PBH}}/\gamma a$. The fraction of PHB relative to the DM abundance at given mass, $f_{\text{PBH}}(M_{\text{PBH}})$, is given by [38]

$$f_{\text{PBH}} \approx 2.7 \times 10^8 \left(\frac{10.75}{g_{*,\text{form}}}\right)^{1/4} \left(\frac{\gamma}{0.2} \frac{M_\odot}{M_{\text{PBH}}}\right)^{1/2} \beta. \quad (64)$$

The distribution of PHBs as function of their mass M_{PBH} is strongly peaked at the value that maximises $\sigma(M)$, in view of the exponential factor in eq. (63). In terms of the power spectrum P_ζ this means that the PBH abundance roughly scales as e^{-1/P_ζ} and is dominated by the top of the peak of $P_\zeta(k)$. The PBH mass distribution is peaked at the value corresponding to the k that maximises $P_\zeta(k)$. The desired abundance is reproduced for $\max P_\zeta \sim 10^{-2}$, and slightly larger (smaller) values produce way too many (too few) PBH.

This means that, due to the fine-tuned nature of the mechanism (as in all models that can generate PBH) the amount and mass of PBH depends in an extremely sensitive way on the uncertain SM and cosmological parameters, mainly the top mass and the Hubble constant H_0 . Furthermore, uncertainties in the computation of black hole formation (such as the value of δ_{th}) imply uncertainties of many order of magnitude in the PBH density.

For example, a 10% variation in the order one arbitrary constant c that parameterizes the classicality condition has a order one impact on the power spectrum (fig. 9), and consequently a huge impact on the PBH abundance.

In addition to SM parameters and to H_0 , the PBH abundance also depends on two extra parameters that characterise the assumed initial condition: constant $h(x) = h_{\text{in}}$ at N_{in} e -folds before the end of inflation, when the approximated classicality condition is satisfied. The next section reconsiders if this assumption is justified.

3.6 Is a homogeneous Higgs background a sensible assumption?

The computation was based on assumption *i*): at $N_{\text{in}} \approx 20$ e -folds before the end of inflation, the Higgs field must be away from its minimum and constant within the presently observable horizon.

Approximate Higgs homogeneity?

We here show that approximate homogeneity is a natural product of inflation, provided that the SM Higgs potential satisfies certain conditions. Quantum corrections in inflationary (de Sitter) space-time have been studied in [40], that showed that long wavelength fluctuations can

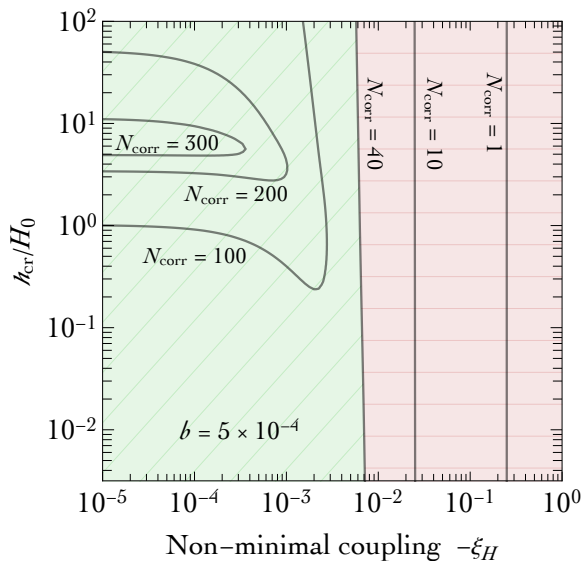

Figure 10: *Contour plot of the correlation length N_{corr} of Higgs inflationary fluctuations as function of the main parameters, ξ_H and h_{cr}/H_0 . The needed homogeneous patch, $N_{\text{corr}} > 40$, can be obtained in the green region, which corresponds to a small negative ξ_H .*

be described by a Fokker-Planck equation for $\rho(h, N)$, the probability of finding the Higgs field at the value h at N e -folds of inflation:

$$-\frac{\partial \rho}{\partial N} = \frac{H_0^2}{8\pi^2} \frac{\partial^2 \rho}{\partial h^2} + \frac{\partial}{\partial h} \left(\frac{V'_{\text{eff}} \rho}{3H_0^2} \right). \quad (65)$$

The first term on the right-hand side is a diffusion term due to quantum fluctuations while the second term is a drift (or transport) term due to the potential. After some e -folds, the distribution converges to its equilibrium value $\rho_{\text{eq}}(h) \propto \exp(-8\pi^2 V_{\text{eff}}(h)/3H^4)$ [40].

We are interested in the probability of having a roughly constant Higgs away from its minimum $h = 0$ within the presently observable horizon. This configuration is a natural outcome of inflationary dynamics provided that the correlation length of Higgs fluctuations is larger than the present horizon. Following [40], the computation of the correlation length is simplified observing that correlation functions depend on space and time separations respecting the $O(4,1)$ invariance of de Sitter. Thereby we can compute the evolution of Higgs fluctuations at a fixed point in space, and study the correlation as function of time t , or equivalently as function of the number of e -folds N . At large time separation the correlation is well approximated by its dominant exponential, and parameterized in terms of a correlation time τ_{corr} or equivalently in terms of number of e -folds $N_{\text{corr}} = H_0 \tau_{\text{corr}}$ as [40]

$$\langle h(t_1, \vec{x}) h(t_2, \vec{x}) \rangle \simeq \langle h^2 \rangle e^{-|t_1 - t_2|/\tau_{\text{corr}}} = \langle h^2 \rangle e^{-|N_1 - N_2|/N_{\text{corr}}}. \quad (66)$$

O(4,1) invariance implies that the spatial correlation length is exponentially large $e^{HN_{\text{corr}}}$, namely space is exponentially inflated. We demand that N_{corr} is larger than about 40 in order to produce a smooth region as large as our Universe at $N_{\text{in}} \approx 20$ e -folds before the end of inflation. Before computing numerically N_{corr} for the SM potential, it is useful to consider some simple limits:

- 0) A massless free scalar h is a simple but special case, because it does not ‘thermalise’ to the equilibrium distribution. Rather, it undergoes random walk diffusion. Starting from $h = 0$, after N e -folds one has $\langle h^2 \rangle^{1/2} = \sqrt{N}H_0/2\pi$ and the correlation length in a region with given $\langle h \rangle$ is $N_{\text{corr}} = 2\pi\langle h \rangle/H$. Imposing $N_{\text{corr}} > 40$ implies $H_0 < 0.16\langle h \rangle$.
- m) A free scalar with squared mass $m^2 > 0$ fluctuates as $\langle h^2 \rangle^{1/2} = \sqrt{3/2}H^2/2\pi m$ with correlation length $N_{\text{corr}} = 3H^2/m^2$ [40]. For $m^2 = -12\xi_H H^2$ one gets $N_{\text{corr}} = -1/4\xi_H > 40$ for $-0.006 < \xi_H < 0$. Roughly, this will be our final result.
- λ) A massless scalar with an interaction $\lambda h^4/4$ and $\lambda > 0$ fluctuates as $\langle h^2 \rangle^{1/2} = 0.36H/\lambda^{1/4}$ with $N_{\text{corr}} = 7.62/\sqrt{\lambda}$. So $N_{\text{corr}} > 40$ for $\lambda < 0.036$. This is satisfied in the SM at large energy.

The above two results agree, up to order one factors, approximating a generic $V(h)$ as a massive field with $m^2 = V''$. The precise value of the correlation length can be obtained as proposed in [40]: the dominant exponential that solves eq. (65) can be computed as the eigenvalue of a Schroedinger-like equation. In the SM $\lambda_{\text{eff}}(h)$ runs to negative values, making the curvature V'' negative at large field values; the patch with a large correlation length is created while h is climbing the potential in its region with positive curvature. The result is shown in fig. 10a, and basically agrees with the result anticipated at point m): ξ_H must be negative and small. Such a small ξ_H is roughly compatible with the size of quantum corrections to ξ_H . The running Higgs quartic coupling is small enough that it does not spoil the mechanism, as qualitatively understood at point λ).

In conclusion, a roughly homogeneous Higgs field (up to fluctuation of order H_0) encompassing our whole horizon is a natural outcome of inflation, provided that ξ_H is small enough. In a multiverse context, its fine-tuned value that leads to DM as PBH can be justified on anthropic basis.

Exact Higgs homogeneity?

Fig. 11a shows that the initial homogeneous Higgs fields $h(x) = h_{\text{in}}$ at $N = N_{\text{in}}$ e -folds before the end of inflation must be tuned to a part in about 10^{-3} in order to produce a final h_{end} close to the maximal value that can be rescued by reheating, as needed to produce a substantial amount of primordial black holes. An interesting PBH abundance is obtained within the narrow strip in fig. 11a. Its boundaries have been computed as follows:

- A slightly smaller h_{in} leads to a negligible PBH amount. In fig. 11a we show the peak value of the power spectrum, and shade in gray regions where it is below 10^{-2} .

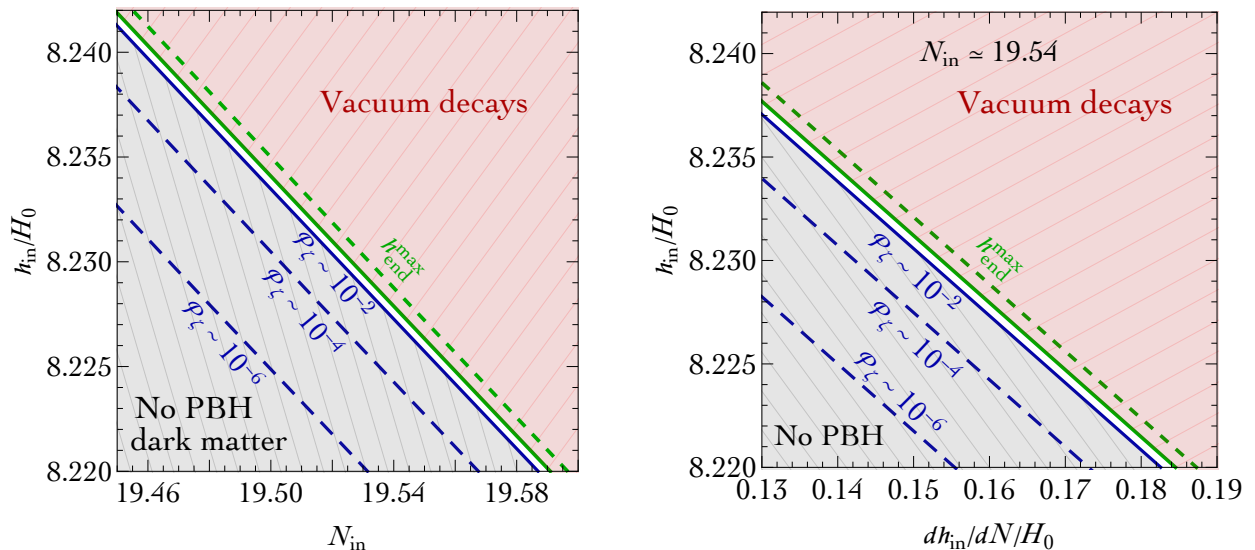

Figure 11: We fix the SM to $M_t = 172 \text{ GeV}$ (which corresponds to $h_{\text{cr}} = 4 \cdot 10^{12} \text{ GeV}$, $b = 0.09/(4\pi)^2$) and $H_0 = 10^{12} \text{ GeV}$ and explore the dependence on the parameters that define the assumed initial condition. **Left:** Final outcome as function of the homogeneous initial value of the Higgs field h_{in} at N_{in} e-folds before the end of inflation and of N_{in} . The desired PBH abundance is produced inside the white band. Inflationary fluctuations in h_{in} are much larger than the needed tuning. **Right:** We fix N_{in} , and introduce dh_{in}/dN as additional parameter.

- A slightly larger h_{in} leads to a too large h_{end} not rescued by reheating. In fig. 11a we shade in red regions where h_{end} is above the maximal value that can be rescued by instantaneous reheating.

In fig. 11b we show that a variation in \dot{h}_{in} has a smaller effect, as it gets red-shifted away.

Within the assumption that h_{in} is homogeneous, its tuned value can be justified on anthropic basis provided that PBH make all DM [41, 8]. However, one single fluctuation $\delta h_{\text{in}} \gtrsim 10^{-3} h_{\text{in}}$ away from the assumed perfect homogeneity can lead to one vacuum decay bubble that, after inflation, expands engulfing the observable Universe.

As discussed previously, inflation can produce an approximate homogeneity within a large patch, but up to fluctuations of order $\delta h_{\text{in}} \sim H_0/2\pi$.¹⁰ Additional fluctuations in \dot{h}_{in} are less significant and we ignore them. The Hubble constant H_0 cannot be significantly reduced, for two reasons. First, $H_0 \gtrsim h_{\text{cr}}$ is needed to keep the Higgs fluctuating around the top of its potential barrier, until it starts to classically roll down. Second, it would suppress the unwanted

¹⁰Technically, such fluctuations appear in our equations when (motivated for example by the arbitrariness in the classicality condition) we start from a different initial time: this shifts the position and the height of the presumed peak of the power spectrum, and thereby the abundance and mass of PBHs.

pre-fall fluctuations δh_{in} at the price of suppressing post-fall fluctuations that generate PBHs, see eq. (52).

Thereby we must take into account the effect of fluctuations in the initial $h(x)$. Pictorially, the status of the Universe should now be represented in fig. 10b not by a point (which can lie in the desired region), but by a dot, much thicker than the desired region.

This is a problem because, at $N_{\text{in}} \approx 20$ e -folds before the end of inflation (which needs at least 60 e -folds), the present Universe is composed by about e^{120} causally disconnected regions. Within each region, the probability that the Higgs fluctuates to the desired tuned h_{in} is about 10^{-2-3} .

Under-fluctuations produce a negligible PBH abundance. On small scales this is not a problem: only the average matters. Accretion of black holes after their formation would increase the average. On large scales of the order of the present horizon (those probed by observations, that find a DM density more homogeneous than what could be justified anthropically), fluctuations of $h(x)$ would produce a PBH density which is not homogeneous.

The effect of over-fluctuations is much worse. Like in a cosmic russian roulette, a too large h_{in} in one of the e^{120} regions can form a vacuum decay bubble that, after the end of inflation, engulfs the whole Universe (a general relativity computation finds that innocuous bubbles that shrink and/or expand behind a black-hole horizon can form, but together with dangerous ones [8]). The probability of avoiding vacuum decay is roughly estimated as $\wp \sim 2^{-e^{120}}$.

As we now discuss, this unlikely possibility cannot be justified on anthropic basis.

To explain why, let us start from an analogous anthropic argument considered by Weinberg [42]: if observers only exist where the cosmological constant Λ is small enough to allow their development (at the price of a tuning with probability $\wp_{\Lambda} \sim 10^{-120}$, which is possible in multiverse with more than 10^{120} different vacua), they should expect to see a cosmological constant around the anthropic bound. Once the desired Universe with small Λ is formed, it is relatively safe. Technically, the time-scale for the variation of the \wp_{Λ} is the Hubble scale, presently 10^{10} yr.

Within the ‘rescued Higgs fall’ mechanism, the probability \wp to form DM but no vacuum decay is much smaller. This might be by itself a problem, unless one relies on eternal inflation and argues that $1/\wp$ is smaller than infinity. The same Weinberg-like argument leads to expectations incompatible with experience. Indeed, the time-scale for the growth of $1/\wp$ is very short. An observer that justifies its lucky survival to vacuum decay as needed for its existence, should expect to be immediately executed by an expanding vacuum decay bubble, given that it arises with statistical certainty in the extra regions which continuously enter in causal contact with the observer due to the Universe expansion.

Needless to say, multiverse probability is a shaky concept, plagued by infinities. Nevertheless, the problem seems worrying enough that one wonders if it can be avoided or alleviated.

One possibility is devising a mechanism that suppresses vacuum decay by rescuing the Higgs more efficiently than the thermal barrier considered in [10, 8]. For example, a non-

thermal distribution¹¹ or an inflation that initially decays to the SM particles more coupled to h , increasing its thermal mass. The green dashed line in fig. 11 shows the extra rescued region imposing what we believe is the most optimistic possibility: $h_{\text{end}} < h_{\text{end}}^{\text{max}}$ with $V_{\text{eff}}(h_{\text{end}}^{\text{max}}) = 0$. Namely, we demand that the negative Higgs potential energy remains smaller than the inflaton potential $V_0 = 3\bar{M}_{\text{Pl}}^2 H_0^2$, otherwise nothing can stop the Higgs fall. Fig. 11 shows that a more efficient rescue mechanism would not qualitatively change the picture. Alternatively, some mechanism beyond the SM could prepare the Higgs in the homogeneous state needed for the ‘rescued Higgs fall’ mechanism. A study of this possibility goes beyond the scope declared in the title of this paper, where we wanted to see if some mechanism can generate dark matter within the Standard Model.

4 Conclusions

We critically re-examined two different Dark Matter candidates which do not require new physics beyond the Standard Model.

The first is a hexa-quark $\mathcal{S} = uudss$ di-baryon, which (being a spin 0 iso-spin singlet) might have a QCD binding energy large enough to make it lighter than $M_{\mathcal{S}} < 1.876 \text{ GeV}$ and thereby stable because all possible decay modes are kinematically closed. In section 2.1 we estimated its mass at the light of recently measured tetra-quarks. We found that \mathcal{S} could be light enough; possibly as light as 1.2 GeV , although we cannot provide a precise mass. In section 2.2 we computed its cosmological relic density, finding that it can reproduce the desired DM density if $M_{\mathcal{S}} \approx 1.2 \text{ GeV}$, while larger masses lead to smaller abundances. The dominant process that keeps \mathcal{S} in thermal equilibrium is scattering of two strange baryons, whose abundance gets Boltzmann suppressed at temperatures smaller than the strange quark mass, leading to \mathcal{S} decoupling at the temperature $T_{\text{dec}} \approx 25 \text{ MeV}$ where \mathcal{S} has the desired abundance. However, in section 2.3 we find, following the strategy of [2], that such a light \mathcal{S} is excluded, because nucleons inside nuclei would bind in \mathcal{S} faster than what is allowed by SuperKamiokande bounds on the stability of Oxygen. We reached this conclusion at the light of recent global fits of nuclear potentials used to compute the nuclear wave-function of Oxygen, which indicate that nucleons are close enough to make \mathcal{S} production too fast. Both \mathcal{S} and nuclei can be stable for $M_{\mathcal{S}} \approx 1.87 \text{ GeV}$; however this mass leads to a relic \mathcal{S} abundance much smaller than the DM abundance. Among sparse comments, we mention that direct detection of \mathcal{S} on an anti-matter target gives an annihilation signal.

In the second part of the paper, we considered the proposal of [8]: given that the SM Higgs potential can be unstable at large field values, during inflation the Higgs might fall from an assumed homogeneous vacuum expectation value h beyond the potential barrier towards the Planck scale. If the fall is tuned such that h almost reaches the maximal value that can be rescued by thermal effects, this process generates small-scale inhomogeneities which form primordial black holes. While DM as PBH seems excluded in the proposed mass range (just

¹¹We thank the authors of [8] for this suggestion.

above the bound on Hawking radiation) the proposal is interesting enough to deserve further scrutiny. We confirmed the computations of [8] and extended them adding a non-minimal coupling ξ_H of the Higgs to gravity. We find that inflationary fluctuations can generate a quasi-homogenous h only if ξ_H is as small as allowed by quantum corrections that unavoidably generate it. Furthermore, we find in section 3.6 that the amount and mass of PBH depend on an extremely sensitive way on the uncertain SM and cosmological parameters, including two extra parameters introduced as assumption: the Higgs starts falling from a homogeneous value at a given moment during inflation. The assumed homogeneity is however not the typical state present during inflation, where the Higgs has fluctuations of order Hubble. This is important for the present mechanism, because it has a Russian roulette feature: the Universe is eaten by a vacuum decay bubble if the Higgs fluctuates to a value too high to be rescued by thermal effects in one of the e^{120} causally disconnected patches in which the present horizon is divided while the Higgs starts falling. The probability of obtaining the observed Universe is so small, about $(1/2)^{e^{120}}$, that trying to justify it through anthropic considerations leads to the issues discussed in section 3.6.

We conclude that tentative searches and interpretations of Dark Matter as a phenomenon beyond the Standard Model remains a justified field.

Note Added

G. Farrar in [arXiv:1805.03723](https://arxiv.org/abs/1805.03723) proposed that a co-stable \mathcal{S} Dark Matter with $1.86 \text{ GeV} < M_{\mathcal{S}} < 1.88 \text{ GeV}$ could be produced with roughly the correct relic abundance at the QCD phase transition at $T \approx 150 \text{ MeV}$. We have not considered this possibility, because this abundance would be washed out by thermal equilibrium through the \mathcal{S} break-up reactions in eq. (18). To avoid this conclusion the \mathcal{S} breaking cross sections should be ~ 10 orders of magnitude smaller than the naive QCD estimate, given by the \mathcal{S} radius squared. We view this as a too extreme possibility given that — while some special suppression could arise at low energy assuming appropriate nucleon potentials — one would need such a strong suppression at $T \approx 150 \text{ MeV}$, where the simpler QCD physics is relevant.

Acknowledgments

We thank G. Ballesteros, I. Bombaci, A. Bonaccorso, A. Francis, A. Gnech, J. Green, M. Karliner, D. Racco, Y. Wang for discussions and M. Redi for participating in an early stage of this project. We especially thank G. Farrar for discussions about \mathcal{S} break-up cross sections and A. Riotto for many useful suggestions at all stages of this work, and in particular for clarifications about non-adiabaticity of ζ_h because of interactions with the plasma. A.U. thanks all participants to the Dark Matter Coffee Break at SISSA for many stimulating discussions about the physics of primordial black holes. This work was supported by the ERC grant NEO-NAT.
