Evidence of spin-orbital angular momentum interactions in relativistic heavy-ion collisions

ALICE Collaboration*

Abstract

The first evidence of spin alignment of vector mesons (K^{*0} and ϕ) in heavy-ion collisions at the Large Hadron Collider (LHC) is reported. The spin density matrix element ρ_{00} is measured at midrapidity ($|y| < 0.5$) in Pb–Pb collisions at a center-of-mass energy ($\sqrt{s_{NN}}$) of 2.76 TeV with the ALICE detector. ρ_{00} values are found to be less than 1/3 (1/3 implies no spin alignment) at low transverse momentum ($p_T < 2$ GeV/c) for K^{*0} and ϕ at a level of 3σ and 2σ , respectively. No significant spin alignment is observed for the K_S^0 meson (spin = 0) in Pb–Pb collisions and for the vector mesons in pp collisions. The measured spin alignment is unexpectedly large but qualitatively consistent with the expectation from models which attribute it to a polarization of quarks in the presence of angular momentum in heavy-ion collisions and a subsequent hadronization by the process of recombination.

Ultra-relativistic heavy-ion collisions create a system of deconfined quarks and gluons, called the Quark–Gluon Plasma (QGP) [1–3] and provide the opportunity to study its properties. In collisions with non-zero impact parameter, a large angular momentum of $O(10^7) \hbar$ [4] and magnetic field of $O(10^{14})$ T [5] are also expected. While the magnetic field is short lived (a few fm/c), the angular momentum is conserved and could affect the system throughout its evolution. Experimental observables like correlations in azimuthal angle [6, 7] could be used to study the influence of these initial conditions on the properties and the dynamical evolution of the QGP and its subsequent hadronization.

Spin-orbit interactions have wide observable consequences in several branches of physics [8–10]. In the presence of a large angular momentum, the spin-orbit coupling of quantum chromodynamics (QCD) could lead to a polarization of quarks followed by a net-polarization of vector mesons (K^{*0} and ϕ) [11–15] along the direction of the angular momentum.

The spin state of a vector meson is described by a 3×3 Hermitian spin-density matrix [15]. Its trace is 1 and ρ_{11} and ρ_{-1-1} cannot be measured separately in two-body decays to pseudoscalar mesons. Consequently, there is only one independent diagonal element, ρ_{00} . The elements of the spin-density matrix can be studied by measuring the angular distributions of the decay products of vector mesons with respect to a quantization axis. Here two different quantization axes are used: i) a vector perpendicular to the production plane (PP) of the vector meson and ii) the normal to the reaction plane (RP) of the system. The PP is defined by the flight direction of the vector meson and the beam direction.

The spin-density matrix element ρ_{00} is determined from the distribution of the angle θ^* between the kaon decay daughter and the quantization axis in the decay rest frame [16],[B],

$$\frac{dN}{d\cos\theta^*} \propto [1 - \rho_{00} + \cos^2\theta^*(3\rho_{00} - 1)]. \quad (1)$$

ρ_{00} is 1/3 in the absence of spin alignment and the angular distribution in Eq. 1 is uniform. The experimental signature of spin alignment is a non-uniform angular distribution ($\rho_{00} \neq 1/3$).

The direction of the angular momentum in non-central heavy-ion collisions is perpendicular to the reaction plane (subtended by the beam axis and impact parameter) [12]. The spin-orbit interaction is expected to lead to spin alignment with respect to the reaction plane (RP). The reaction plane orientation cannot be measured directly, but is estimated from the final state distributions of particles. This experimentally measured plane is called the event plane (EP) [17]. The deviation of the EP with respect to the RP is corrected using the EP resolution (R) and observed ρ_{00}^{obs} [18],

$$\rho_{00} = \frac{1}{3} + \left(\rho_{00}^{obs} - \frac{1}{3} \right) \frac{4}{1 + 3R}. \quad (2)$$

There are specific qualitative predictions for the spin alignment effect [13]: (a) $\rho_{00} > 1/3$ if the hadronization of a polarized parton proceeds via fragmentation and less than 1/3 for hadronization via recombination, (b) ρ_{00} is expected to have a smaller deviation from 1/3 for both central (impact parameter $\lesssim 3$ fm) and peripheral (impact parameter $\gtrsim 11$ fm) heavy-ion collisions, and a maximum deviation for mid-central collisions, where the angular momentum is also maximal, (c) the ρ_{00} value is expected to have maximum deviation from 1/3 at low p_T and reach the value of 1/3 at high p_T in the recombination scenario, and (d) the effect is expected to be larger for K^{*0} compared to ϕ due to their constituent quark composition. The initial large magnetic field might also affect the ρ_{00} values [15]. This leads to $\rho_{00} > 1/3$ for neutral and $\rho_{00} < 1/3$ for charged vector mesons. Hence magnetic field and angular momentum could have opposite effects on electrically neutral K^{*0} , ϕ . All of these features are probed for K^{*0} and ϕ mesons in Pb–Pb collisions presented in this letter. As a cross check, a control measurement is carried out using pp collisions, which do not possess large initial angular momentum, and the same analysis is done in Pb–Pb collisions for K_S^0 meson, which has zero spin. In addition, the measurements are carried out by randomizing the directions of the event (RndEP) and production planes (RndPP).

The analyses are carried out using 43 million minimum bias pp collisions at $\sqrt{s} = 13$ TeV, taken in 2015 and 14 million minimum bias Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV, collected in 2010. The minimum bias event selection in Pb–Pb collisions require at least one hit in any of V0A, V0C, and Silicon Pixel Detectors while in pp collisions at least one hit in both V0A and V0C is required. The events are further required to have a primary vertex position within ± 10 cm of the detector center along the beam axis. The events were classified by collision centrality classes based on the amplitude measured in the V0 counters [19]. The measurements are performed at midrapidity ($|y| < 0.5$) as a function of p_T and are reported for pp collisions as well as for different centrality classes in Pb–Pb collisions. The K_S^0 analysis is performed only for Pb–Pb collisions in the 20–40% centrality class which corresponds to the top 20–40% of V0 amplitude distribution. The details of the ALICE detector, trigger conditions, centrality selection, and second order event plane estimation using the V0 detectors at forward rapidity, can be found in [19–22]. The K^{*0} and ϕ candidates are reconstructed via their decays into charged $K\pi$ and KK pairs, respectively, while the K_S^0 is reconstructed via its decay into two charged pions. The Time Projection Chamber (TPC) [23] and Time-of-Flight (TOF) detector [24] are used to identify the decay products of these mesons via specific ionization energy loss and time-of-flight measurements, respectively. The K^{*0} and ϕ yields are determined via the invariant mass technique [25–27]. The background coming from combinatorial pairs and misidentified particles is removed by constructing the invariant mass distribution from so-called mixed events for the K^{*0} and ϕ [25, 26]. The combinatorial background for the K_S^0 candidates is significantly reduced by selecting the distinctive V-shaped decay topology [27].

The invariant mass distributions are fitted with a Breit-Wigner and Voigtian (convolution of Breit-Wigner and Gaussian distributions) function for the K^{*0} and ϕ signals, respectively, along with a 2nd order polynomial that describes the residual background [25, 26]. Extracted yields are then corrected for the reconstruction efficiency and acceptance in each $\cos\theta^*$ and p_T bin [25, 26]. The reconstruction efficiency is determined from Monte Carlo simulations of the ALICE detector response based on GEANT3 simulation [25, 26]. The signal extraction procedures for the vector mesons and K_S^0 are identical to those used in earlier publications reporting the p_T distribution of the mesons [25–27]. The mass peak positions and widths of the resonances across all the $\cos\theta^*$ bins for various p_T intervals in pp collisions and in different centrality classes of Pb–Pb collisions are consistent with those obtained from earlier analyses [25–27] and no significant dependence on $\cos\theta^*$ is seen. The resulting efficiency and acceptance corrected $dN/d\cos\theta^*$ distributions for selected p_T intervals in minimum bias pp collisions and in 10–50% central Pb–Pb collisions are shown in Fig. 1. These distributions are fitted with the functional form given in Eq. 1 to determine ρ_{00} for each p_T bin in pp and Pb–Pb collisions. For the EP results, the resolution values R are 0.71, 0.53, 0.72, 0.66, and 0.40 for 10–50%, 0–10%, 10–30%, 30–50%, and 50–80% collision centralities, respectively [28].

There are three main sources of systematic uncertainties in the measurements of the angular distribution of vector meson decays. (a) Meson yield extraction: this contribution is estimated by varying the fit ranges for the yield extraction, the normalization range for the signal+background and background invariant mass distributions, the procedure to integrate the signal function to get the yields, and by leaving the width of the resonance peak free or keeping it fixed to the PDG value as discussed in Ref. [25, 26]. The uncertainties for ρ_{00} is at a level of 12(8)% at the lowest p_T and decrease with p_T to 4(3)% at the highest p_T studied for the $K^{*0}(\phi)$. (b) Track selection: this contribution includes variations of the selection on the distance of closest approach to the collision vertex, the number of crossed pad rows in the TPC [23], the ratio of found clusters to the expected clusters, and the quality of the track fit. The systematic uncertainties for ρ_{00} are 14(6)% at the lowest p_T and about 11(5)% at the highest p_T for $K^{*0}(\phi)$. (c) Particle identification: this is evaluated by varying the particle identification criteria related to the TPC and TOF detectors. The corresponding uncertainty is 5(3)% at the lowest p_T and about 4(4.5)% at the highest p_T studied for $K^{*0}(\phi)$. Systematic uncertainties due to different variations are considered as uncorrelated and the total systematic uncertainty on ρ_{00} is obtained by adding all the contributions in quadrature. Several consistency checks are carried out and details can be found in the Supplemental

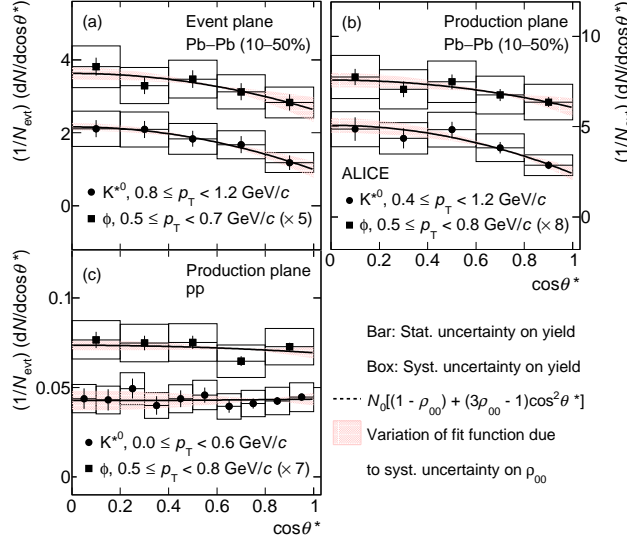

Figure 1: (Color online) Angular distribution of the decay daughter in the rest frame of the meson with respect to the quantization axis at $|y| < 0.5$ for pp collisions at $\sqrt{s} = 13$ TeV and Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV. Panels (a) and (b) show results for K^{*0} and ϕ with respect to EP and PP. Panel (c) is the results for vector mesons in pp collisions with respect to PP.

Material B. The final measurement is reported for the average yield of particles (K^{*0}) and anti-particles (\bar{K}^{*0}) as results for K^{*0} and \bar{K}^{*0} were consistent.

Figure 2 shows the measured ρ_{00} as a function of p_T for K^{*0} and ϕ mesons in pp collisions and Pb–Pb collisions, along with the measurements for K_S^0 in Pb–Pb collisions. In mid-central (10–50%) Pb–Pb collisions, ρ_{00} is below $1/3$ at the lowest measured p_T and increases to $1/3$ within uncertainties for $p_T > 2$ GeV/c. At low p_T , the central value of ρ_{00} is smaller for K^{*0} than for ϕ , although the results are compatible within uncertainties. In pp collisions, ρ_{00} is independent of p_T and equal to $1/3$ within uncertainties. For the spin zero hadron K_S^0 , ρ_{00} is consistent with $1/3$ within uncertainties in Pb–Pb collisions. The results with random event plane directions are also compatible with no spin alignment for the studied p_T range, except for the smallest p_T bin, where ρ_{00} less than $1/3$ but still larger than for EP and PP measurements. The results for the random production plane (the momentum vector direction of each vector meson is randomized) are similar to RndEP measurements. These results indicate that a spin alignment is present at lower p_T , which is a qualitatively consistent with predictions [13].

Figure 3 shows ρ_{00} for K^{*0} and ϕ mesons as a function of average number of participating nucleons ($\langle N_{part} \rangle$) [19, 21] for Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV. Large $\langle N_{part} \rangle$ correspond to central collisions and small $\langle N_{part} \rangle$ correspond to peripheral collisions (See Table B.1 of Supplemental Material B). In the lowest p_T range, ρ_{00} shows maximum deviation from $1/3$ for intermediate centrality and approaches $1/3$ for both central and peripheral collisions. This centrality dependence is qualitatively consistent with the dependence of the initial angular momentum on impact parameter in heavy-ion collisions [4]. At higher p_T , ρ_{00} is consistent with $1/3$ for all centrality classes. For the low- p_T measurements in 10–30% (20–40% for ϕ meson w.r.t. PP) mid-central Pb–Pb collisions, the maximum deviations of ρ_{00} from $1/3$ with respect to the PP (EP) are 3.2 (2.6) σ and 2.1 (1.9) σ for K^{*0} and ϕ mesons, respectively. The errors (σ) are calculated by adding statistical and systematic uncertainties in quadrature.

The relation between the ρ_{00} values with respect to different quantization axes can be expressed using Eq. 2 and calculating the corresponding factor R . This gives $\Delta\rho_{00}(\text{RndEP}) = \Delta\rho_{00}(\text{EP}) \times \frac{1}{4}$ ($R = 0$ for random plane) and $\Delta\rho_{00}(\text{PP}) = \Delta\rho_{00}(\text{EP}) \times \frac{1+3v_2}{4}$ ($R = v_2$ for production plane, where v_2 is the second Fourier coefficient of the azimuthal distribution of produced particles relative to the event plane angle). Here $\Delta\rho_{00} = \rho_{00} - 1/3$. This is further confirmed using a toy model simulation with the PYTHIA 8.2

Figure 2: (Color online) Transverse momentum dependence of ρ_{00} for K^{*0} , ϕ , and K_S^0 mesons at $|y| < 0.5$ in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV and minimum bias pp collisions at $\sqrt{s} = 13$ TeV. Results are shown for spin alignment with respect to the event plane (panels a,b), production plane (c,d) and random event plane (e,f) for K^{*0} (left column) and ϕ (right column). The statistical and systematic uncertainties are shown as bars and boxes, respectively.

Figure 3: (Color online) Measurements of ρ_{00} as a function of $\langle N_{\text{part}} \rangle$ for K^{*0} and ϕ mesons at low and high p_T in Pb–Pb collisions. The statistical and systematic uncertainties are shown as bars and boxes, respectively. Some data points are shifted horizontally for better visibility.

event generator [29] by incorporating v_2 and spin alignment (See Supplemental Material B for further details).

In the past, spin alignment measurements in e^+e^- [30–32], hadron–proton [33] and nucleon–nucleus collisions [34] were carried out to understand the role of spin in the dynamics of particle production, finding $\rho_{00} > 1/3$ and off-diagonal elements close to zero with respect to the PP. For pp collisions at $\sqrt{s} = 13$ TeV, we find $\rho_{00} \sim 1/3$ within the studied p_T range (see Fig. 2). New preliminary results from RHIC have found deviations of ρ_{00} from $1/3$ indicating spin alignment for vector mesons at lower $\sqrt{s_{NN}}$ [35, 36]. The ρ_{00} for ϕ mesons in mid-central Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV is less than $1/3$ while the preliminary finding for mid-central Au–Au collisions at $\sqrt{s_{NN}} = 200$ GeV is ρ_{00} greater than $1/3$. The $\rho_{00} > 1/3$ for ϕ mesons has been interpreted as evidence for a coherent ϕ meson field [37]. Similar conclusions cannot be easily applied to K^{*0} as it consists of valence quarks of unequal mass (s and \bar{d}), which makes it impossible to separate the effects of vorticity and due to electromagnetic and mesonic fields. Significant polarization of Λ baryons (spin = $1/2$) was reported at low RHIC energies. The polarization is found to decrease with increasing $\sqrt{s_{NN}}$ [38, 39]. At the LHC, the global polarization for Λ baryon is compatible with zero within uncertainties (P_Λ (%) = $0.01 \pm 0.06 \pm 0.03$) [40]. The spin alignment for vector mesons in heavy ion collisions could have contributions from angular momentum [12, 13], electromagnetic fields [15] and mesonic fields [37]. While no quantitative theoretical calculation for vector meson polarization at LHC energies exists, the expected order of magnitude can be estimated and the measurements for vector mesons and hyperons can be related in a model dependent way. Considering only the angular momentum contribution and recombination as the process of hadronization [13], the ρ_{00} of vector mesons are related to quark polarization as $\rho_{00} = \frac{1-P_q P_{\bar{q}}}{3+P_q P_{\bar{q}}}$ where P_q and $P_{\bar{q}}$ are quark and anti-quark polarization, respectively. Assuming $P_u = P_{\bar{u}} = P_d = P_{\bar{d}}$ and $P_s = P_{\bar{s}}$, the measured p_T integrated ρ_{00} values for K^{*0} and ϕ mesons in 10–50% Pb–Pb collisions could translate to light quark polarization of ~ 0.8 and strange quark polarization of ~ 0.2 . Using a thermal and non-relativistic approach as discussed in [41], vorticity (ω) and temperature (T) are related to ρ_{00} and vector meson polarization (P_V) as $\rho_{00} \simeq \frac{1}{3} \left(1 - \frac{(\omega/T)^2}{3} \right)$ and $P_V \simeq (2\omega/3T)$, respectively. Also in this approach, the measured ρ_{00} for K^{*0} would correspond to K^{*0} polarization of ~ 0.6 and the ρ_{00} for ϕ mesons would give ϕ meson polarization of ~ 0.3 .

In the recombination model, Λ polarization depends linearly on quark polarization whereas vector meson polarization depends quadratically on it. One would therefore expect the polarization for K^{*0} to be of the same order or smaller than the one measured for the Λ at LHC [40], i.e. vanishing small ($O(0.01\%)$) rather than order 1. The large effect observed for the ρ_{00} in mid-central Pb–Pb collisions at low p_T is therefore puzzling. This result should stimulate further theoretical work in order to study which effects could make such a huge difference between Λ and K^{*0} polarization. Possible reasons may include the transfer of the quark polarization to the hadrons (baryon vs. meson), details of the hadronization mechanism (recombination vs. fragmentation), re-scattering, regeneration, and possibly the lifetime and mass of the relevant hadron. Moreover, the vector mesons are predominantly directly produced whereas the hyperons have large contributions from resonance decays.

In conclusion, for the first time, evidence has been found for a significant spin alignment of vector mesons in heavy-ion collisions. The effect is strongest at low p_T with respect to a vector perpendicular to the reaction plane and for mid-central (10–50%) collisions. These observations are qualitatively consistent with expectations from the effect of large initial angular momentum in non-central heavy-ion collisions, which leads to quark polarization via spin-orbit coupling, subsequently transferred to hadronic degrees of freedom by hadronization via recombination. However, the measured spin alignment is surprisingly large compared to the polarization measured for Λ hyperons where, in addition, a strong decrease in polarization with $\sqrt{s_{NN}}$ is observed. In future measurements, the difference in the polarization of $K^{*\pm}$ and K^{*0} , due to their difference in magnetic moment, would be directly sensitive to the effect of the large initial magnetic field produced in heavy-ion collisions.

B Supplemental material

B.1 Angular distribution of the decay products of the vector meson

The complete angular distribution of the decay products of the vector meson is expressed as,

$$\begin{aligned} \frac{dN}{d\cos\theta^*d\varphi^*} \propto & [\cos^2\theta^*\rho_{00} + \sin^2\theta(\rho_{11} + \rho_{-1-1})/2 \\ & - \sin 2\theta(\cos\phi^*\text{Re}\rho_{10} - \sin\phi^*\text{Im}\rho_{10})/\sqrt{2} \\ & + \sin 2\theta(\cos\phi^*\text{Re}\rho_{-10} + \sin\phi^*\text{Im}\rho_{-10})/\sqrt{2} \\ & - \sin^2\theta(\cos 2\phi^*\text{Re}\rho_{1-1} - \sin 2\phi^*\text{Im}\rho_{1-1})] \end{aligned} \quad (\text{B.1})$$

The angle denoted here as θ^* is that made by one of the decay daughters in the rest frame of the vector meson with respect to the quantization axis and φ^* is the corresponding azimuthal angle. This expression is obtained by applying parity symmetry of QCD, the unit trace condition, and integrating over the azimuthal angle.

B.2 Consistency checks

In order to verify the measurements, several consistency checks are carried out. Specifically, the yields of vector mesons are summed over $\cos\theta^*$ bins for each p_T interval to obtain the p_T distributions; these are found to be consistent within the statistical uncertainties with the published p_T distributions in Pb–Pb collisions [25, 26]. Similarly a closure test (comparison between generated and reconstructed angular distribution) is carried out for the Monte Carlo (MC) data which is used to obtain the reconstruction efficiencies for the mesons. Two different event generators are used to determine the reconstruction efficiency and the results are consistent. The effect of the shape of the p_T distributions in the MC simulations is studied in detail and the impact on the ρ_{00} measurement is found to be small. The dependence of the reconstruction efficiency for a $\cos\theta^*$ range on the azimuthal angle of vector meson (ϕ_V) relative to the event plane angle (Ψ) is also studied. The reconstruction efficiencies obtained in a $\cos\theta^*$ range by integrating over $\phi_V - \Psi$ are similar to the efficiency obtained by averaging over the $\phi_V - \Psi$ bins. Data samples with two different magnetic field polarities in the experiment are separately analyzed and the $\cos\theta^*$ distributions are found to be consistent. In addition, the analysis is performed separately for positive ($0 < y < 0.5$) and negative ($-0.5 < y < 0$) rapidity and also for K^{*0} versus \bar{K}^{*0} ; the different samples are also consistent.

B.3 Analytical relation between EP and PP

The relation between measured ρ_{00} with respect to two different frames of references is

$$\rho_{00}(\text{A}) - \frac{1}{3} = \left(\rho_{00}(\text{B}) - \frac{1}{3} \right) \left(\frac{1}{4} + \frac{3}{4} \cos 2\psi \right), \quad (\text{B.2})$$

where frame A is obtained by rotating frame B by angle ψ . Averaging over angle ψ gives,

$$\rho_{00}(\text{A}) - \frac{1}{3} = \left(\rho_{00}(\text{B}) - \frac{1}{3} \right) \left(\frac{1}{4} + \frac{3}{4} \langle \cos 2\psi \rangle \right). \quad (\text{B.3})$$

The transition from the EP to PP is obtained by taking into account the elliptic flow of the vector meson which leads to

$$\langle \cos 2\psi \rangle = \frac{1}{2\pi} \int_{-\pi}^{\pi} \cos(2\psi) [1 + 2v_2 \cos(2\psi)] d\psi = v_2. \quad (\text{B.4})$$

Using Eq. B.3 and Eq. B.4, analytical relation between EP and PP can be expressed as,

$$\rho_{00}(\text{PP}) - \frac{1}{3} = \left(\rho_{00}(\text{EP}) - \frac{1}{3} \right) \left(\frac{1 + 3v_2}{4} \right). \quad (\text{B.5})$$

B.4 Toy model simulation to understand the relation between EP, PP and RndEP

The spin density matrix element ρ_{00} for vector mesons is measured with respect to EP, PP and RndEP. The measured ρ_{00} values for K^{*0} at $0.8 < p_T < 1.2$ GeV/c with respect to different planes in heavy-ion collisions has the following ordering $\rho_{00}(\text{EP}) < \rho_{00}(\text{PP}) < \rho_{00}(\text{RndEP})$. To understand this ordering a toy model simulation is carried out by using PYTHIA (version 8.2) event generator [29] which has no azimuthal anisotropy and spin alignment.

For this study we have taken event plane angle as zero, which corresponds impact parameter along x-axis. In order to find the relations between different frames, v_2 (0.15 ± 0.06 , value expected for hadrons with mass similar to K^{*0} in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV [22]) is introduced to K^{*0} by appropriate rotation of its momentum in azimuthal plane. The modified angle in azimuthal plane is calculated by solving the following equation

$$\phi_0 = \phi + v_2 \sin 2\phi, \quad (\text{B.6})$$

where ϕ_0 is azimuthal angle of a K^{*0} in absence of v_2 and for a given value of v_2 , ϕ_0 transforms to ϕ . Then spin alignment ($\rho_{00} = 0.125$, same as measured in data) is introduced with respect to event plane by rotating the momentum of decay daughters in K^{*0} rest frame by solving

$$\cos \theta_0^* = 3/2 \times [(1 - \rho_{00}) \cos \theta^* + 1/3(3\rho_{00} - 1) \cos^3 \theta^*]. \quad (\text{B.7})$$

Here θ_0^* is the angle made by the decay daughter of K^{*0} with the quantization axis in absence of spin alignment. θ_0^* transforms to θ^* to introduce a given input value of ρ_{00} . In this study we assume that the ϕ^* is remain fixed during the rotation. With these modifications, calculations as in the experimental data is carried out. The results are shown in Fig. B.1 for two cases, with and without v_2 . The result corresponding to event plane is correctly retrieved in the model. The model results for $v_2 = 0$, are same for production plane and random event plane. However with $v_2 = 0.15$, the $\rho_{00}(\text{PP})$ value is lower and closer to data for PP. The toy model reproduces the hierarchy observed in the ρ_{00} values for various planes as observed in data. The physical picture is that spin alignment with respect to the event plane is coupled to that in the production plane through the elliptic flow of the system. The $\rho_{00}(\text{RndEP})$ is lower than $1/3$ as the quantization axis is always perpendicular to the beam axis, resulting in a residual effect. If the quantization axis is random in 3 dimension, then the residual effect is not present and the ρ_{00} value is consistent with $1/3$.

Figure B.1: (Color online) ρ_{00} values from data in 10–50% Pb–Pb collisions at $0.8 < p_T < 1.2$ GeV/ c with respect to various planes compared with expectations from model simulations with and without added elliptic flow (v_2). The statistical and systematic uncertainties are shown as bars and boxes, respectively.

B.5 $\langle N_{\text{part}} \rangle$ values and centrality classes

Table B.1 shows collision centrality classes and their corresponding $\langle N_{\text{part}} \rangle$ values, used in Fig. 3

Table B.1: $\langle N_{\text{part}} \rangle$ values for various centrality classes in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV.

Particle	Centrality (%)	$\langle N_{\text{part}} \rangle$
K^{*0} (EP) and ϕ (EP)	0–10%	356.2 ± 3.8
	10–30%	225.5 ± 3.5
	30–50%	108.6 ± 1.8
	50–80%	32.9 ± 1.3
K^{*0} (PP)	2–10%	345.3 ± 4.0
	10–30%	225.5 ± 3.5
	30–50%	108.6 ± 1.8
	50–80%	32.9 ± 1.3
	50–70%	41.0 ± 1.3
	70–90%	11.4 ± 0.3
ϕ (PP)	0–20%	308.1 ± 3.7
	20–40%	157.2 ± 3.1
	40–60%	68.6 ± 2.0
	60–80%	16.9 ± 0.5
