ABSTRACT: The Lund-jet plane has recently been proposed as a powerful jet substructure tool with a broad range of applications. In this paper, we provide an all-order single logarithmic calculation of the primary Lund-plane density in Quantum Chromodynamics, including contributions from the running of the coupling, collinear effects for the leading parton, and soft logarithms that account for large-angle and clustering effects. We also identify a new source of clustering logarithms close to the boundary of the jet, deferring their resummation to future work. We then match our all-order results to exact next-to-leading order predictions. For phenomenological applications, we supplement our perturbative calculation with a Monte Carlo estimate of non-perturbative corrections. The precision of our final predictions for the Lund-plane density is 5–7% at high transverse momenta, worsening to about 20% at the lower edge of the perturbative region, corresponding to transverse momenta of about 5 GeV. We compare our results to a recent measurement by the ATLAS collaboration at the Large-Hadron Collider, revealing good agreement across the perturbative domain, i.e. down to about 5 GeV.

1 Introduction

In the exploration of the fundamental interactions and particles at high-energy colliders, jets are among the most abundantly produced and widely used probes. Over the past decade, it has become apparent that considerable valuable information is carried by the internal structure of the jets, especially at high transverse momenta (see e.g. [1–3] for recent reviews). That information is increasingly being used for distinguishing hadronic decays of boosted electroweak particles from quark or gluon-induced jets (e.g. [4–9]), for

distinguishing quark and gluon-induced jets from each other (e.g. [10–13]), and for studying the modification of jets that propagate through the medium produced in heavy-ion collisions (e.g. [14–23]).

A huge variety of observables has been explored (e.g. [24–33]) for studying jet substructure, supplemented in recent years by a range of machine-learning approaches (e.g. [32, 34–45]). With such a diverse range of observables, it has become challenging to obtain a detailed understanding of the specific jet features probed by each one. At the same time approaches have emerged in which one designs an infinite set of observables which, taken as a whole, can encode complete information about a jet. Specific examples are energy-flow polynomials [32] and the proposal [33] (see also [14]) to determine a full Lund diagram [46] for each jet. As well as encoding complete information about the radiation in a jet, both of these approaches provide observables that can be directly measured and that also perform well as inputs to machine-learning. Here we concentrate on Lund diagrams.

Lund diagrams [46] are two-dimensional representations of the phase-space for radiation in jets, which have long been used to help understand Monte-Carlo event generators and all-order logarithmic resummations in QCD. The phase-space for a single emission involves three degrees of freedom, and Lund diagrams highlight the logarithmic distribution of two of those degrees of freedom, typically chosen to be the emission’s transverse momentum (k_t) and angle (Δ). In leading-order QCD, the logarithms of both variables are uniformly distributed.

A core idea introduced in Refs. [33] and [14] and briefly reviewed in section 2, is to use a Cambridge/Aachen declustering sequence to represent a jet’s internal structure as a series of points in the two-dimensional Lund plane, with the option of concentrating on “primary” emissions, those that can be viewed as emitted by the jet’s main hard prong. The location of a given point immediately indicates whether it is in a perturbative or non-perturbative region, whether it is mainly final-state radiation or a mix with initial-state radiation, underlying event, etc. The set of points obtained for a single jet can be used as an input to multi-variate tagging methods [33], or can be used to construct other specialised observables [47]. Given an ensemble of many jets, one can also determine the average density of points in each region of the (primary) Lund plane, $\rho(\Delta, k_t)$. This average density is of interest in fundamental measurements of QCD radiation [48–50], both in perturbative and non-perturbative regions, and in studies of modifications of jet structure in heavy-ion collisions [14].

The purpose of this article is to carry out a baseline calculation of the all-order perturbative structure of the primary Lund-plane density, identifying the key physical aspects that are relevant for understanding the density, and providing a prediction that accounts for all single-logarithmic corrections $\alpha_s^n \ln^m \Delta \ln^{n-m} k_t$ multiplying the leading-order, $\mathcal{O}(\alpha_s)$, result for the density. The relevant contributions are discussed in section 3 and include running-coupling effects, collinear flavour-changing effects and various effects of soft radiation at commensurate angles (which we compute only in the large- N_c approximation).¹

¹We only consider jets initiated by massless partons, though a similar calculation for jets initiated by a massive parton would also be of interest given the sensitivity to dead-cone effects [49] and an associated recent measurement [50].

In section 4 we match the all-order results to a next-to-leading order (NLO) calculation using the NLOJet++ program [51], in section 5 we address the question of non-perturbative corrections and in section 6 we combine the different results into a set of final predictions that we compare to recent experimental measurements from the ATLAS collaboration [48].

2 The primary Lund plane density and basic setups

Let us assume we have a jet with transverse momentum p_{\perp} , obtained from a given jet algorithm such as the anti- k_t algorithm [52]. We first re-cluster the constituents of the jet using the Cambridge/Aachen (C/A) algorithm [53, 54] as often used in jet substructure techniques. We then iteratively repeat the following steps, starting with j defined as the full (re-clustered) jet:

1. Undo the last step of clustering: $j \rightarrow j_1 + j_2$, taking j_1 to be the *harder branch*, i.e. $p_{\perp 1} > p_{\perp 2}$.
2. Record the properties of the branching $\mathcal{T} \equiv \{k_t, \Delta, z, \dots\}$ defined as

$$\Delta \equiv \Delta_{12} = \sqrt{(y_1 - y_2)^2 + (\phi_1 - \phi_2)^2}, \quad (2.1a)$$

$$k_t \equiv p_{\perp 2} \Delta_{12}, \quad z \equiv \frac{p_{\perp 2}}{p_{\perp 1} + p_{\perp 2}}. \quad (2.1b)$$

where y and ϕ denote the rapidity and azimuthal angle of a particle, specifically $y = \frac{1}{2} \ln \frac{E+p_z}{E-p_z}$.

3. Redefine $j \leftarrow j_1$ and iterate (i.e. iterate following the harder branch)

The iteration stops when j can no longer be de-clustered, giving an ordered list of tuples:

$$\mathcal{L}_{\text{primary}} = [\mathcal{T}^{(1)}, \dots, \mathcal{T}^{(i)}, \dots, \mathcal{T}^{(n)}]. \quad (2.2)$$

Additional variables can be added to each tuple, for example an azimuthal angle. One can also choose to follow softer branchings at each step, which would lead to exploration of secondary, tertiary, etc. Lund planes. Neither of these aspects is relevant for the discussion presented here.

The primary Lund plane density is then defined as the density of emissions in the (logarithmic) Δ, k_t plane:²

$$\rho(\Delta, k_t) = \frac{1}{N_{\text{jets}}} \frac{dn_{\text{emissions}}}{d \ln 1/\Delta d \ln k_t}. \quad (2.3)$$

Alternatively, one can introduce a primary Lund plane density in the Δ, z plane:

$$\tilde{\rho}(\Delta, z) = \frac{1}{N_{\text{jets}}} \frac{dn_{\text{emissions}}}{d \ln 1/\Delta d \ln 1/z}, \quad (2.4)$$

as measured by the ATLAS collaboration.

²Throughout this paper, we use a subscript “ \perp ” to denote transverse momenta with respect to the beam, and a subscript “ t ” to denote the transverse momenta of emissions relative to their emitter.

Note that integrating the primary Lund plane density over $\ln 1/\Delta$ and $\ln k_t$ (or $\ln 1/z$) gives the average number of primary emissions per jet. If the integration is performed with an additional Soft-Drop [28, 29] condition, one obtains the Iterated Soft-Drop multiplicity [11] (see also chapter III of [55]).

In practice, we will focus on two kinematic configurations:

- **High- p_\perp setup.** This is close to the original proposal from [33]. We cluster jets with the anti- k_t algorithm with $R = 1$, keep all jets with $p_\perp \geq 2$ TeV. The primary Lund-plane density $\rho(\Delta, k_t)$ is then reconstructed according to the procedure described above.
- **ATLAS setup.** This is similar to the ATLAS measurement presented in [48]. Jets are reconstructed with the anti- k_t algorithm with a radius $R = 0.4$. The two largest- p_\perp jets with $|\eta| < 2.1$ are kept (with η the pseudo-rapidity, defined as $\eta = -\ln \tan \frac{\theta}{2}$). One then imposes that the leading jet has a p_\perp of at least 675 GeV and that the p_\perp of the second jet is at least $\frac{2}{3}$ of the p_\perp of the leading jet. For each of the two jets, we construct the Lund plane $\tilde{\rho}(\Delta, z)$ as follows: we take all the particles within a radius $R = 0.4$ of the jet axis, recluster them with the C/A algorithm with $R = 0.4$ and apply the de-clustering procedure highlighted above.

In practice the ATLAS measurement only includes charged tracks with p_\perp above 500 MeV within a distance $\sqrt{(\eta - \eta_{\text{jet}})^2 + (\phi - \phi_{\text{jet}})^2} = 0.4$ of the jet axis³ in their reconstruction of the Lund plane. We will treat this as a non-perturbative correction (going from a full-particle measurement to a measurement based on tracks above 500 MeV). We note that the use of charged tracks makes this measurement collinear unsafe since, for example, arbitrarily collinear branchings can affect the relative fractions of charged and neutral particles in each branch, and consequently the definition of the harder branch in the de-clustering procedure. Numerically, this effect is small, as we shall verify later.

In all cases, the initial jet clustering is done using FastJet [58, 59] and the Lund plane is constructed using the code available with `fastjet-contrib` [60].

3 All-order calculation

The average Lund plane density measures an effective intensity of radiation per unit logarithm of k_t and of angle. As such at LO, in the simultaneously soft and collinear limit, i.e.

³This distance uses pseudo-rapidity η instead of rapidity y . The two variables are identical for massless objects. For individual experimental objects, it is the pseudorapidity that is measured. However for any object that is massive, rapidity is to be strongly favoured [56, 57] because rapidity differences are invariant under longitudinal boosts, while pseudorapidity differences are not. Every stage of jet clustering creates massive objects, even starting from massless ones. The pseudorapidity of a jet displays various pathologies: for example, a jet consisting of two massless particles with identical pseudorapidities $\eta_1 = \eta_2$ has a rapidity $y_{\text{jet}} = \eta_1 = \eta_2$, while the jet's pseudorapidity is different $\eta_{\text{jet}} \neq \eta_1$, by an amount that depends non-trivially on the kinematics of the jet. Therefore even if the inputs to the initial jet clustering are selected based on their pseudo-rapidity, we recommend using rapidity for all subsequent operations.

away from the large-angle and the collinear edges of the plane, it is given by

$$\rho_{\text{LO},i}^{\text{soft-coll.}}(\Delta, k_t) = \frac{2\alpha_s C_i}{\pi}, \quad (3.1)$$

where C_i is the Casimir of the hard parton of flavour i initiating the jet, $C_i = C_A$ for a gluon-initiated jet and C_F for a quark-initiated jet.

Beyond leading order, each additional factor of α_s can be associated with up to one logarithm of either Δ or of p_\perp/k_t . As a result, at any given order, say α_s^{n+1} , the logarithmically dominant terms have the structure $\alpha_s^{n+1} \ln^m \Delta \ln^{n-m} \frac{p_\perp}{k_t}$ with $0 \leq m \leq n$. Our goal is to calculate this complete set of single-logarithmic contributions to $\rho(\Delta, k_t)$, i.e. for all n and m , including the full (non-logarithmic) Δ dependence for terms with $m = 0$ and the full k_t dependence for terms with $m = n$. In the case of $\tilde{\rho}(\Delta, z)$, we will equivalently aim to account for all terms $\alpha_s^{n+1} \ln^m \Delta \ln^{n-m} z$.

The logarithms have several physical origins. These are (i) running coupling corrections, enhanced by logarithms of the transverse momentum k_t ; (ii) hard-collinear logarithms of the emission angle Δ which can induce flavour-changing effects and affect the behaviour of ρ close to the $z = 1$ line; (iii) soft emissions at large angles enhanced by the logarithm of either k_t or the emission energy fraction z ; and (iv) Cambridge/Aachen clustering effects for emissions with commensurate angles, enhanced by logarithms of k_t or z . Each of these effects is discussed separately in the following sections.

3.1 Running coupling corrections

This is by far the simplest correction: the scale of the running coupling is simply set by the transverse momentum of the emission. We therefore have

$$\rho_{\text{rc},i}(\Delta, k_t) = \frac{2\alpha_s(k_t)C_i}{\pi}. \quad (3.2)$$

We use the 2-loop running coupling in the CMW scheme [61]:

$$\alpha_s(k_t) = \frac{\alpha_s}{1 - 2\alpha_s\beta_0 \ln(p_\perp R/k_t)} - \frac{\beta_1\alpha_s^2 \ln(1 - 2\alpha_s\beta_0 \ln(p_\perp R/k_t))}{\beta_0 [1 - 2\alpha_s\beta_0 \ln(p_\perp R/k_t)]^2} + \frac{K}{2\pi} \frac{\alpha_s^2}{[1 - 2\alpha_s\beta_0 \ln(p_\perp R/k_t)]^2}, \quad (3.3)$$

with

$$\beta_0 = \frac{11C_A - 2n_f}{12\pi}, \quad \beta_1 = \frac{17C_A^2 - 5C_A n_f - 3C_F}{24\pi^2}, \quad K = \left(\frac{67}{18} - \frac{\pi^2}{6}\right) C_A - \frac{5}{9} n_f. \quad (3.4)$$

The reference $\alpha_s \equiv \alpha_s(p_\perp R)$ is taken at the scale $p_\perp R$ with p_\perp the transverse momentum of the jet and R the jet radius. We use $n_f = 5$ flavours for $k_t \geq m_b = 4.78$ GeV, $n_f = 4$ for $m_b > k_t \geq m_c = 1.67$ GeV and $n_f = 3$ below. Furthermore, we freeze the coupling at $k_t = 1$ GeV.

At our accuracy, it would have been sufficient to use the 1-loop running coupling (without the CMW scheme term, i.e. K). We have instead used the 2-loop running for two main reasons. Firstly, several of our result depend on the structure of the hard events

under consideration (dijet events in our case). These events will be obtained using the NLOJet++ program [51] with underlying PDF sets that use at least a 2-loop running. It is therefore more coherent to use a 2-loop running also in the computation of ρ . Secondly, the running coupling is numerically the largest of the logarithmically-enhanced contributions. Including the 2-loop corrections therefore makes sense from a purely phenomenological perspective.

3.2 Hard-collinear effects

Eq. (3.2) assumes that the primary branch followed by the declustering procedure keeps the flavour of the initial parton. In this case, all the emissions for a quark-initiated jet (gluon-initiated jet) come with a C_F (C_A) colour factor.

In practice, however, hard and collinear branchings have two effects at single-logarithmic accuracy: (i) they can change the flavour of the harder branch via either a $q \rightarrow qg$ splitting where the daughter gluon carries more than half the parent quark’s momentum, or from a $g \rightarrow q\bar{q}$ splitting; and (ii) successive collinear branchings can reduce the transverse momentum of the leading parton thereby creating a difference between the $z = 1$ and the $k_t = p_\perp \Delta$ lines in the Lund plane. These effects are of the form $\alpha_s^{n+1} \ln^n 1/\Delta$, associated with a series of emissions strongly ordered in angle and without soft enhancement.

For an initial parton of flavour i , we use

$$p(x, j|i, t_{\text{coll}}(\Delta; \Delta_0, \mu)), \quad (3.5)$$

to denote the probability of having a leading parton of flavour j , carrying a longitudinal fraction x , when the primary Lund declustering procedure has reached an angular scale Δ . The dependence on Δ is encoded through a “collinear evolution time”

$$t_{\text{coll}}(\Delta; \Delta_0, \mu) = I_\alpha(\Delta p_\perp, \Delta_0 p_\perp; \mu), \quad (3.6)$$

where I_α is the integration of the coupling between two transverse momentum scales:

$$\begin{aligned} I_\alpha(k_t, k_{t0}; \mu) &= \int_{k_t}^{k_{t0}} \frac{dq_t}{q_t} \frac{\alpha_s(q_t)}{\pi}, \\ &= \frac{1}{2\pi\beta_0} \left[\ln \frac{\lambda_0}{\lambda} - \frac{\beta_1 \alpha_s}{\beta_0} \left(\frac{1 + \ln \lambda}{\lambda} - \frac{1 + \ln \lambda_0}{\lambda_0} \right) + \frac{K \alpha_s}{2\pi} \left(\frac{1}{\lambda} - \frac{1}{\lambda_0} \right) \right], \end{aligned} \quad (3.7)$$

with $\alpha_s \equiv \alpha_s(\mu)$, $\lambda = 1 + 2\alpha_s \beta_0 \ln(k_t/\mu)$ and $\lambda_0 = 1 + 2\alpha_s \beta_0 \ln(k_{t0}/\mu)$. The expression on the second line corresponds to a fixed number of flavours. The parameter Δ_0 in (3.6) is the large-angle scale at which the collinear evolution starts and can be varied to get an estimate of the uncertainties associated with the resummation of the collinear logarithms.

The evolution of the probability densities $p(x, j|i, t)$ is given by

$$\frac{dp(x, j|i, t)}{dt} = \int_0^1 dz \sum_{k=q,g} \left[\frac{\mathcal{P}_{jk}^{(R)}(z)}{z} p_k \left(\frac{x}{z}, k|i, t \right) - \mathcal{P}_{jk}^{(V)}(z) p_j(x, k|i, t) \right]. \quad (3.8)$$

The kernels $\mathcal{P}_{jk}^{(R)}(z)$ and $\mathcal{P}_{jk}^{(V)}(z)$ correspond to real and virtual emissions respectively and are straightforwardly obtained from the DGLAP splitting functions, imposing that the leading parton is defined following the larger- p_\perp branch:

$$\mathcal{P}_{qq}^{(R)}(z) = P_{qq}(z)\Theta(z > 1/2), \quad \mathcal{P}_{qq}^{(V)}(z) = P_{qq}(z), \quad (3.9a)$$

$$\mathcal{P}_{gq}^{(R)}(z) = P_{gq}(z)\Theta(z > 1/2), \quad \mathcal{P}_{gq}^{(V)}(z) = 0, \quad (3.9b)$$

$$\mathcal{P}_{gg}^{(R)}(z) = [P_{gg}(z) + P_{gg}(1-z)]\Theta(z > 1/2), \quad \mathcal{P}_{gg}^{(V)}(z) = P_{gg}(z) + P_{gg}(z), \quad (3.9c)$$

$$\mathcal{P}_{qg}^{(R)}(z) = [P_{qg}(z) + P_{qg}(1-z)]\Theta(z > 1/2), \quad \mathcal{P}_{qg}^{(V)}(z) = 0. \quad (3.9d)$$

where the $P_{ij}(z)$ are the normal full (real) DGLAP splitting functions,

$$P_{qq}(z) = C_F \frac{1+z^2}{1-z}, \quad P_{gq}(z) = P_{qg}(1-z), \quad (3.10a)$$

$$P_{gg}(z) = C_A \left[\frac{z}{1-z} + \frac{1-z}{z} + z(1-z) \right], \quad P_{qg}(z) = n_f T_R [z^2 + (1-z)^2], \quad (3.10b)$$

including appropriate symmetry factors. If the leading parton carries a longitudinal momentum xp_\perp at an angle Δ , the splitting variables (cf. (2.1)) are related through $z = \frac{k_t}{xp_\perp \Delta}$. Therefore, for a jet initiated by a hard parton of flavour i , the primary Lund-plane density including collinear effects takes the form

$$\rho_{\text{coll},i}(\Delta, k_t) = \sum_j \int_0^1 dx p(x, j|i, t_{\text{coll}}(\Delta; \Delta_0, \mu)) \left[\frac{xp_\perp \Delta}{2C_j k_t} \mathcal{P}_j \left(\frac{k_t}{xp_\perp \Delta} \right) \right] \rho_{\text{rc},j}(\Delta, k_t), \quad (3.11)$$

This expression includes the effects of the flavour changes and the distribution of the longitudinal momentum fraction of the leading parton. The factor $\frac{z}{2C_j} \mathcal{P}_j(z)$, with $\mathcal{P}_j(z) = \sum_k \mathcal{P}_{kj}^{(R)}(1-z)$, accounts for the fact that close to the $z = 1$ boundary, one should use the full splitting function instead of its soft limit.

In practice, an exact analytic calculation of $p(x, j|i, t_{\text{coll}})$ is not possible. It is however straightforward to obtain it numerically using the approach of Ref. [62].⁴ A sample of the resulting distributions is shown in Fig. 1 for both quark-initiated and gluon-initiated jets. The distributions progressively shift towards smaller values of x as expected.

From Eq. (3.8) one can also deduce a few analytic properties of $p(x, j|i, t_{\text{coll}})$. In particular, if one takes the 0th and 1st moments of (3.8) one obtains respectively an evolution equation for the average fraction of quarks and gluons and the average longitudinal momentum of the leading parton. We therefore define

$$f(j|i, t_{\text{coll}}) = \int_0^1 dx p(x, j|i, t_{\text{coll}}) \quad \text{and} \quad \bar{x}(j|i, t_{\text{coll}}) = \frac{1}{f_j(i, t_{\text{coll}})} \int_0^1 dx x p(x, j|i, t_{\text{coll}}). \quad (3.12)$$

For both f and $f\bar{x}$ one can write a closed equation which admits a solution under the form of a (matrix) exponential. The solutions to these equations are given in Appendix A.

⁴We actually use a simplified version where, after a given splitting, only the harder of the two branches is further split.

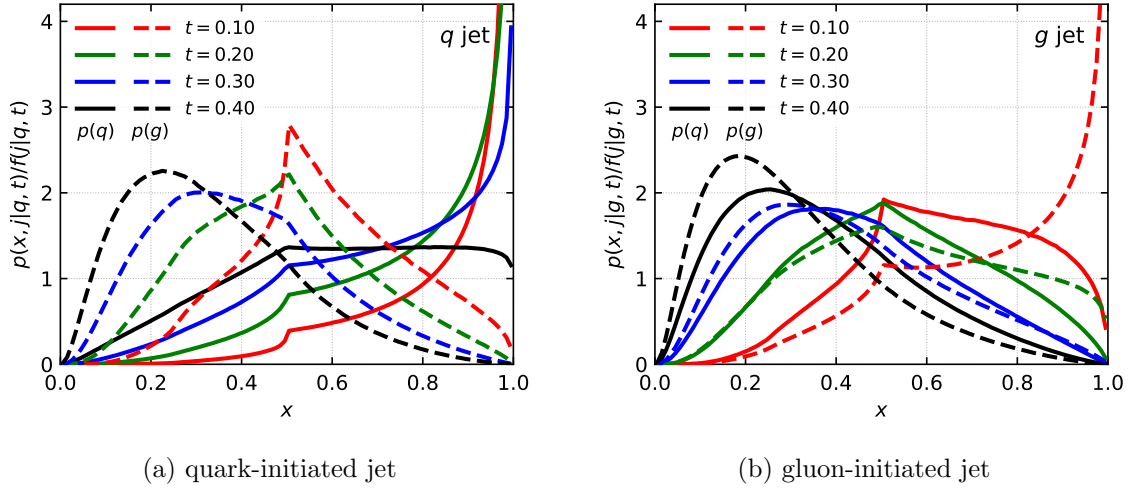

Figure 1: Distributions $p(x, j|i, t_{\text{coll}})/f(j|i, t_{\text{coll}})$, with $f(j|i, t_{\text{coll}})$ the average fraction of partons of flavour j after a time t_{coll} starting from a flavour i (cf. Eq. (3.12)), for different values of t_{coll} as a function of x . The left (right) plot correspond to quark (gluon)-initiated jets. On both plots, the solid (dashed) lines correspond to a quark (gluon) leading parton.

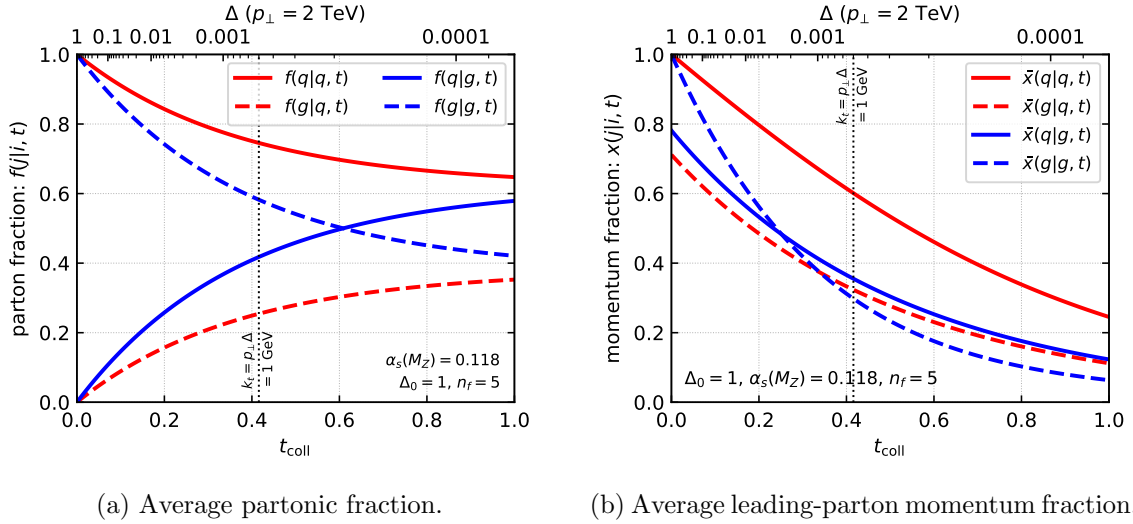

Figure 2: Average parton fraction (left) and longitudinal momentum (right) as a function of the evolution time variable t_{coll} . The red (blue) curves correspond to a quark (gluon) initial parton. The solid (dashed) curves correspond to a quark (gluon) leading parton at time t_{coll} . The top axis shows the angle corresponding to t_{coll} for a 2-TeV jet. The t_{coll} axis extends significantly beyond the typical perturbative region so as to help illustrate the asymptotic trends.

Plots of $f(j|i, t)$ and $\bar{x}(j|i, t)$ are shown in Fig. 2 from which we can make several observations. First, as $t_{\text{coll}} \rightarrow \infty$, i.e. $\Delta \rightarrow 0$ (modulo Landau-pole complications), the quark and gluon fractions tend to constants that are independent of the initial flavour of

the jet. From (A.1) one finds

$$f(q|\text{any}, t_{\text{coll}} \rightarrow \infty) = \frac{s_g}{s_q + s_g}, \quad f(g|\text{any}, t_{\text{coll}} \rightarrow \infty) = \frac{s_q}{s_q + s_g}, \quad (3.13)$$

with $s_q = C_F(2 \ln 2 - \frac{5}{8})$ and $s_g = \frac{1}{3}n_f$. This means about 62.1% quarks and 37.9% gluons for $n_f = 5$, in agreement with Fig. 2a. Furthermore, for $t_{\text{coll}} \rightarrow 0$, we find

$$\lim_{t_{\text{coll}} \rightarrow 0} \frac{\bar{x}(g|q, t_{\text{coll}})}{t_{\text{coll}}} = \frac{w_{gq}}{s_q} \simeq 0.712, \quad \lim_{t_{\text{coll}} \rightarrow 0} \frac{\bar{x}(q|g, t_{\text{coll}})}{t_{\text{coll}}} = \frac{w_{qg}}{s_g} \simeq 0.78125, \quad (3.14)$$

where the w_{gq} and w_{qg} coefficients are given analytically in Appendix A. The results in Eq. (3.14) correspond to the average harder-parton momentum fractions after a single $q \rightarrow qg$ splitting (with the gluon the harder particle) or a single $g \rightarrow q\bar{q}$ splitting. The numerical values are in agreement with Fig. 2b.

3.3 Soft emissions at large or commensurate angles

The average primary Lund density is subject to several classes of effect associated with the non-trivial characteristics of soft radiation. At $\mathcal{O}(\alpha_s)$, when one goes beyond the collinear limit of Eq. (3.1) and considers radiation at angles $\Delta \sim 1$, soft gluon radiation is a coherent sum from all hard coloured partons in the event rather than just a single parton. At higher orders, two further effects arise: the presence of a first soft gluon contributes to the radiation of a subsequent second soft gluon at commensurate angles, and so forth for higher numbers of gluons, contributing effects similar to non-global logarithms; and in the presence of two or more gluons at commensurate angles, one must account for the way in which jet clustering determines whether a given gluon is classified as a primary or a secondary Lund emission. These two effects are present both for large and (perhaps more surprisingly) small Δ .

In this section we will consider all of these effects, using the large- N_C limit so as to retain simple colour algebra. After considering how we decompose events into separate colour flows, we shall in section 3.3.1 examine the impact of different colour flows on the large-angle part of the Lund plane at $\mathcal{O}(\alpha_s)$. Then in section 3.3.2 we shall consider the case of double (energy-ordered) soft gluon emission and derive the structure of the non-global and clustering logarithms in the small-angle limit at order α_s^2 . Finally in section 3.3.3 we will discuss how we generalise these results to resum all sources of single soft logarithms to all orders.

We start by recalling that in the large- N_C limit, a given Born-level process can be expressed as a sum over several partonic channels where each of them is a weighted sum of different colour flows:

$$\rho_{\text{soft}}(\Delta, k_t) = \sum_{c \in \text{channel}} \sum_{f \in \text{flows}} w_{c,f} \rho_{\text{soft}}^{(c,f)}(\Delta, k_t). \quad (3.15)$$

In this context, for each colour flow, one can view the Born-level process as a superposition of colour dipoles. Let us consider a dijet process with two incoming partons, $p_{1,2}$, and two outgoing partons, a jet parton p_j and a recoiling parton p_r . The relative weights of

the different partonic channels can be obtained from the $2 \rightarrow 2$ squared matrix elements, e.g. using `NLOJet++`. Then, a $q_{\text{in}}q'_{\text{in}} \rightarrow q_{\text{out}}q'_{\text{out}}$ channel would have, in the large- N_c limit, a single colour flow with weight $w = 1$ corresponding to dipoles $[(q_{\text{in}}q'_{\text{out}}) + (q'_{\text{in}}q_{\text{out}})]$. Similarly, a $g_{\text{in}}q_{\text{in}} \rightarrow g_{\text{out}}q_{\text{out}}$ channel would have two colour flows:

$$[(g_{\text{in}}g_{\text{out}}) + (q_{\text{in}}g_{\text{out}}) + (g_{\text{in}}q_{\text{out}})] \quad \text{with weight} \quad \frac{s^2}{s^2 + u^2}, \quad (3.16a)$$

$$[(g_{\text{in}}g_{\text{out}}) + (g_{\text{out}}q_{\text{out}}) + (g_{\text{in}}q_{\text{in}})] \quad \text{with weight} \quad \frac{u^2}{s^2 + u^2}, \quad (3.16b)$$

with s, t, u the usual Mandelstam variables. The complete set of colour flows, dipole superpositions and weights can, for example, be deduced from Ref. [63].

In the next sections, it will be helpful to separate ρ_{soft} in different contributions according to the Born-level flavour of the jet:

$$\rho_{\text{soft}}(\Delta, k_t) = \sum_{i \in \text{jet flavours}} f_i \rho_{\text{soft},i}(\Delta, k_t), \quad (3.17)$$

where f_i denotes the relative fraction of quark and gluon jets. This separation in jet flavours can be straightforwardly obtained from (3.15).

We can expand $\rho_{\text{soft},i}$ as a series in α_s :

$$\rho_{\text{soft},i}(\Delta, k_t) = \sum_{n=1}^{\infty} \alpha_s^n \rho_{\text{soft},i}^{(n)}(\Delta, k_t). \quad (3.18)$$

In the first subsection below, we will show that $\rho_{\text{soft},i}^{(1)}$ deviates from (3.1) by corrections that are power-suppressed in Δ . At our single-logarithmic accuracy, we have

$$\alpha_s^n \rho_{\text{soft},i}^{(n)}(\Delta, k_t) \propto \alpha_s^n \ln^{n-1} \left(\frac{p_{\perp} \Delta}{k_t} \right). \quad (3.19)$$

These soft logarithms are either due to non-global configurations or to clustering logarithms associated with the Cambridge/Aachen reclustering used to construct the primary Lund-plane density. It is interesting to note that these clustering logarithms are present at arbitrarily small angles, which is somehow uncommon (though addressed also in [64]). We show how they appear at order α_s^2 in section 3.3.2 and provide an all-order resummation in section 3.3.3.

3.3.1 Soft emissions at large angles: fixed-order study

For definiteness, let us consider the case of two incoming partons, $\ell_{1,2}$, and two outgoing partons, $\ell_{j,r}$, with the following kinematics:⁵

$$\ell_1^\mu \equiv \frac{Q}{2}(0, 0, 1, 1), \quad (3.20a)$$

$$\ell_2^\mu \equiv \frac{Q}{2}(0, 0, -1, 1), \quad (3.20b)$$

$$\ell_j^\mu \equiv p_{\perp}(1, 0, \sinh y_{\text{jet}}, \cosh y_{\text{jet}}), \quad (3.20c)$$

$$\ell_r^\mu \equiv p_{\perp}(-1, 0, -\sinh y_{\text{jet}}, \cosh y_{\text{jet}}), \quad (3.20d)$$

⁵4-momenta are written as (p_x, p_y, p_z, E) .

where $Q = p_\perp \cosh y_{\text{jet}}$ (with the jet transverse momentum $p_\perp \equiv \ell_\perp$, while its rapidity is equal to y_{jet}). We consider the jet of radius R around ℓ_j , while ℓ_r corresponds to the recoiling hard jet.

In the large- N_c approximation we have to consider soft gluon emission from any of 6 possible colour dipoles: one incoming-incoming, two jet-incoming, two recoil-incoming and one jet-recoil. For a given dipole with legs ℓ_a and ℓ_b , the contribution from a soft emission of momentum $k^\mu \equiv k_\perp(\cos \phi, \sin \phi, \sinh y, \cosh y)$ takes the form

$$\alpha_s \rho_{\text{soft},ab}^{(1)}(\Delta, k_t) = \int_0^{p_\perp} k_\perp dk_\perp \int dy \int_0^{2\pi} \frac{d\phi}{2\pi} \frac{\alpha_s N_c}{2\pi} \frac{\ell_a \cdot \ell_b}{(\ell_a \cdot k)(k \cdot \ell_b)} \Delta \delta(\Delta - \Delta R) k_t \delta(k_t - k_\perp \Delta R), \quad (3.21)$$

with $\Delta R = \sqrt{(y - y_{\text{jet}})^2 + \phi^2}$. For each dipole configuration, we can set $y = y_{\text{jet}} + \Delta R \cos \psi$ and $\phi = \Delta R \sin \psi$. The k_\perp and ΔR integrations can then be evaluated trivially, leaving the integration over ψ . This integration usually cannot be computed exactly so we instead perform a series expansion in Δ^2 :

$$\alpha_s \rho_{\text{soft},12}^{(1)} = \frac{\alpha_s N_c}{\pi} \Delta^2, \quad (3.22a)$$

$$\alpha_s \rho_{\text{soft},1j}^{(1)} = \frac{\alpha_s N_c}{\pi} \left[1 + \frac{\Delta^2}{4} + \frac{\Delta^4}{144} + \mathcal{O}(\Delta^8) \right], \quad (3.22b)$$

$$\alpha_s \rho_{\text{soft},jr}^{(1)} = \frac{\alpha_s N_c}{\pi} \left[1 + \frac{\tanh^2 y_{\text{jet}}}{4} \Delta^2 + \frac{(\cosh^2 y_{\text{jet}} - 3)^2}{144 \cosh^4 y_{\text{jet}}} \Delta^4 + \frac{\tanh^2 y_{\text{jet}}}{64 \cosh^4 y_{\text{jet}}} \Delta^6 + \mathcal{O}(\Delta^8) \right], \quad (3.22c)$$

$$\alpha_s \rho_{\text{soft},1r}^{(1)} = \frac{\alpha_s N_c}{\pi} \left[\frac{e^{2y_{\text{jet}}}}{4 \cosh^2 y_{\text{jet}}} \Delta^2 + \frac{1}{16 \cosh^4 y_{\text{jet}}} \Delta^4 + \frac{\tanh^2 y_{\text{jet}}}{64 \cosh^4 y_{\text{jet}}} \Delta^6 + \mathcal{O}(\Delta^8) \right], \quad (3.22d)$$

where additionally $\rho_{\text{soft},2j}^{(1)} = \rho_{\text{soft},1j}^{(1)}$ and $\rho_{\text{soft},2r}^{(1)}$ is obtained from $\rho_{\text{soft},1r}^{(1)}$ via the replacement $y_{\text{jet}} \rightarrow -y_{\text{jet}}$.

In the collinear limit, $\Delta \ll 1$, $\rho_{\text{soft},2j}^{(1)}$, $\rho_{\text{soft},1j}^{(1)}$ and $\rho_{\text{soft},jr}^{(1)}$ all tend to a constant, with corrections taking the form of power corrections in Δ^2 , as expected. The other dipoles are suppressed by a factor Δ^2 .

While running-coupling and collinear flavour-changing effects only depend on the flavour of the jet, the corrections due to soft emissions at large angles involve the structure of the whole event. The relative weight of each dipole depends on the channel and colour flow under consideration, cf. (3.15).

3.3.2 Soft emissions and Cambridge/Aachen clustering: fixed-order study

Say we want to extend the calculation from section 3.3.1 to order α_s^2 . The same calculation as above would have to be repeated with two soft emissions, k_1 and k_2 , strongly ordered in energy ($k_{\perp 1} \gg k_{\perp 2}$). Measuring the emission k_2 and integrating out k_1 yields a contribution to the primary Lund plane density of the form

$$\alpha_s^2 \rho_{\text{soft}}^{(2)} \propto \alpha_s^2 \ln \frac{k_t}{p_\perp \Delta}. \quad (3.23)$$

In the limit $\Delta \rightarrow 0$ the prefactor is simple, and we calculate it here.

For concreteness, we illustrate the case of a quark-induced jet. We denote by θ_i the angle between k_i and the quark and by θ_{12} the angle between k_1 and k_2 and work in a limit where all angles are small. In contrast to section 3.3.1, we now use a frame where the jet is perpendicular to the beam. In conjunction with the small-angle limit, this ensures that angles and rapidity-azimuth distances are equivalent, as are energies and transverse momenta (with respect to the beam).

Let us first consider three simple nested-collinear limits. When $\theta_1 \gg \theta_2$, gluon k_2 is emitted with colour factor C_F and declustered as a primary emission, i.e. the LO $2\alpha_s C_R/\pi$ emission intensity for gluon k_2 is unaffected by the presence of gluon k_1 . The situation is similar when $\theta_1 \ll \theta_2$. When $\theta_{12} \ll \theta_1$, gluon k_2 is emitted with colour factor C_A and declustered as a secondary emission, i.e. on gluon k_1 's Lund leaf. The only non-trivial situation is when the angles θ_1 , θ_2 and θ_{12} are commensurate, $\theta_1 \sim \theta_2 \sim \theta_{12} \ll 1$. In this region, one needs to account for the non-trivial matrix element for the emission of two gluons at commensurate angles and for the effects of the Cambridge/Aachen clustering used to construct the Lund plane. Together, these induce an $\mathcal{O}(\alpha_s^2 \ln k_t/(p_\perp \Delta))$ correction to the $2\alpha_s C_R/\pi$ behaviour, where the logarithm is associated with the integral over the transverse momentum of gluon k_1 .

This contribution to the primary Lund density for a quark-induced jet can be written

$$\alpha_s^2 \rho_{\text{soft}}^{(2)} = \left(\frac{\alpha_s}{\pi^2}\right)^2 \int_0^{p_\perp} \frac{dk_{\perp 1}}{k_{\perp 1}} \int_0^{k_{\perp 1}} \frac{dk_{\perp 2}}{k_{\perp 2}} \int d^2\theta_1 \frac{C_F}{\theta_1^2} \int d^2\theta_2 \Delta \delta(\Delta - \theta_2) k_t \delta(k_t - k_{\perp 2} \Delta) \left[\left[\left(C_F - \frac{C_A}{2} \right) \frac{1}{\theta_2^2} + \frac{C_A}{2} \frac{1}{\theta_{12}^2} + \frac{C_A}{2} \frac{\theta_1^2}{\theta_2^2 \theta_{12}^2} \right] [1 - \Theta(\theta_{12} < \theta_1) \Theta(\theta_{12} < \theta_2)] - \frac{C_F}{\theta_2^2} \right], \quad (3.24)$$

where $k_{\perp i}$ is the transverse momentum of k_i relative to the beam. In this expression the first (second) term of the curly bracket corresponds to a real (virtual) emission k_1 . For the real emission, we have two factors: the first square bracket corresponds to the matrix element for the emission of the soft gluon k_2 and the second square bracket imposes that the gluon k_2 is reconstructed as a primary emission, i.e. is not clustered with the emission k_1 .

Eq. (3.24) genuinely encodes clustering effects. If we first consider the C_F^2 contribution, naively associated with two emissions from the hard quark, the virtual term partially cancels the real contribution, leaving a negative contribution with a factor $\Theta(\theta_{12} < \theta_1) \Theta(\theta_{12} < \theta_2)$, i.e. where emission k_2 clusters with emission k_1 . Obviously, this contribution disappears in the collinear limit $\theta_2 \ll \theta_1, \theta_{12}$ as expected. Focusing now on the $C_F C_A$ term, naively associated with secondary k_2 emission, the only contribution comes from the situation where the emission is not clustered with its emitter, k_1 , which vanishes in the collinear limit $\theta_{21} \ll \theta_1$.

The $k_{\perp 1}$ integration in Eq. (3.24) has a logarithmic enhancement from strong energy ordering $k_{\perp 2} \ll k_{\perp 1} \ll p_\perp$, leading to a contribution proportional to $\alpha_s^2 \ln \frac{k_t}{p_\perp \Delta}$, as anticipated in Eq. (3.23), and no collinear divergence. The integrand is suppressed in the limits $\theta_1 \rightarrow 0$ and $\theta_1 \rightarrow \infty$ and only receives a contribution from $\theta_1 \sim \theta_2$.⁶

⁶A consequence of this is that, at our logarithmic accuracy, we can safely set the upper bound on the

The integration over $k_{\perp 1}$, $k_{\perp 2}$, θ_2 and one of the azimuthal angles (φ_1 or φ_2) can be trivially performed, leaving an integration over θ_1 and an azimuthal angle φ . One finds⁷

$$\alpha_s^2 \rho_{\text{soft}}^{(2)} = 0.323066 \left(\frac{2\alpha_s}{\pi} \right)^2 C_F (C_F - C_A) \ln \frac{k_t}{p_{\perp} \Delta} \quad [\text{quark}]. \quad (3.25)$$

The calculation for a gluon jet can be obtained by replacing $C_F \rightarrow C_A$ in Eq. (3.24). That replacement carries through directly to Eq. (3.25), giving

$$\alpha_s^2 \rho_{\text{soft}}^{(2)} = 0 \quad [\text{gluon}]. \quad (3.26)$$

Thus for a purely gluonic theory, the energy-ordered double-soft emission pattern and the C/A clustering combine in such a way that there is no $\alpha_s^2 \ln k_t / (p_{\perp} \Delta)$ correction to the Lund density when Δ is small.

The above results are valid at small angles. Two additional classes of effect arise at large angles. Firstly, the clustering effects become sensitive to the coherent structure of the radiation from the complete hard event. This relates to the discussion in section 3.3.1. Secondly, if one identifies the jet with the anti- k_t algorithm and reclusters its constituents with the C/A algorithm, there is an interplay between the two clusterings. This leads to another source of logarithmic enhancement

$$\alpha_s^n \ln^m \left(\frac{p_{\perp} R}{k_t} \right) \ln^p \left(\frac{R}{R - \Delta} \right), \quad \text{with } m \leq n - 1, p \leq n - 1. \quad (3.27)$$

The $\ln(\frac{R}{R-\Delta})$ structure appears when a first emission, close to but outside the anti- k_t jet boundary, splits collinearly such that one of its offspring is inside the boundary.⁸ The all-order resummation of these *boundary logarithms* is beyond the scope of this paper. They are however briefly discussed in Appendix B. Note that if the original jet is identified with the C/A algorithm, these boundary logarithms are absent.

3.3.3 Soft emissions: all-order treatment

The treatment of soft single logarithms to all orders requires us to consider configurations with arbitrarily many energy-ordered gluons at commensurate angles [66], for which analytic approaches exist only in specific limits [67]. The technique we adopt is similar to that originally proposed for the resummation of non-global logarithms in [66] and the related clustering logarithms [68, 69]. We rely on a large- N_C approximation (with sub-leading colour corrections up to order α_s^2 in the collinear limit). Techniques that exist to resum non-global logarithms at full N_C are so far applicable only for a limited set of observables [70, 71].

Compared to the typical treatment of non-global and clustering logarithms we have one extra difficulty and one simplification. The difficulty has the following origin. Since

θ_1 integration to infinity.

⁷The numerical pre-factor is analytically found to be $\frac{-i\pi}{36} - \frac{i}{\pi} [\text{Li}_2(\frac{1+i\sqrt{3}}{2}) + \frac{1}{2}\text{Li}_2(\frac{1-i\sqrt{3}}{2}) + \frac{5}{2}\text{Li}_2(\frac{-1+i\sqrt{3}}{2}) + \text{Li}_2(\frac{-i}{\sqrt{3}}) - \text{Li}_2(\frac{i}{\sqrt{3}}) + \text{Li}_2(\frac{3+i\sqrt{3}}{6}) - \text{Li}_2(\frac{3-i\sqrt{3}}{6})]$.

⁸ It is related to the $\Delta\eta \ln \Delta\eta$ term observed in Eq. (3.13) of [65].

non-global logarithms stem from emissions at commensurate angles one can usually impose an angular cut-off at an angle θ_{\min} that is small compared to the physical angle one probes ($\pi/2$, a jet radius, the rapidity width of a slice, ...). This helps limit the particle multiplicity and associated computational cost of the calculations. In the case of the primary Lund plane, we instead have to probe a large range of angles, meaning that potential angular cut-offs have to be taken small/large enough to cover this extended phase-space, resulting in increased computational demands.⁹ The simplification relative to normal non-global logarithm calculations relates to the fact that the Lund plane density doesn't involve any Sudakov suppression (unlike say a hemisphere mass). That Sudakov suppression, specifically the part associated with primary emissions, can lead to low computational efficiency unless dedicated subtraction techniques are applied. In the case of the Lund plane density one can simply generate all the emissions without separating primary emissions from the other ones.

The basic approach to simulating soft emissions is to directly order them in energy, as done in [66]. In this case we just need to generate the full angular structure of the emissions and only retain their energy ordering. If gluon k_j is emitted after k_i , then it has a much smaller energy. In this case clustering with the anti- k_t algorithm is equivalent to keeping the particles in a radius R around the hard parton. For C/A clustering, all the necessary distances are available from the angular structure of the event and the recombination of two particles is equivalent to replacing them with the harder one.

For our ultimate primary Lund plane predictions, we want to focus on the phase-space above a certain k_t cut, below which the non-perturbative effects dominate. For a given minimum relative transverse momentum $k_{t,\min}$ the minimum accessible angle is $\Delta_{\min} = k_{t,\min}/p_{\perp}$. We therefore have to take an angular cut-off for the event simulations that is sufficiently smaller than Δ_{\min} . If we generate emissions down to an energy E_{\min} , many of these emissions will have a k_t much smaller than $k_{t,\min}$. For example for $\Delta = \Delta_{\min}$, emissions would be generated down to $k_t = E_{\min}\Delta_{\min} \ll k_{t,\min}$. This is not a problem per se, except for the fact that this approach generates many more emissions than absolutely necessary, which ends up being computationally challenging.

For this reason, we have adopted a different approach, more traditional in parton-shower event generators, namely we generate the emissions ordered in k_t . Say we work with a fixed coupling. The event is described as a collection of dipoles, each with a hard scale corresponding to their invariant mass Q . For the initial condition, we decompose the Born-level event as a sum over all possible dipole configurations. At any given stage of the event generation, corresponding to a given scale $k_t = k_{ti}$, we should be able to generate the next emission at a scale $k_{t,i+1} < k_{ti}$. If a dipole (p_1, p_2) of invariant mass Q_{12} splits, this is done by first generating $k_{t,i+1}$ according to the following Sudakov factor (which includes

⁹Similar non-global and clustering logarithms have been studied down to small angles in Ref. [64] for the study of the SoftDrop grooming radius at NLL accuracy. There, the authors relied on the fact that the behaviour of the clustering logarithms becomes independent of Δ at small-enough Δ . In this paper, we decided not to rely on this behaviour so as to also reach a good level of numerical precision for the approach to this asymptotic regime within our single-logarithmic accuracy, and to do so over the relatively large energy range needed to cover the full Lund plane.

collinear radiation at each end of the dipole):

$$\exp \left[- \int_{\ln k_{t,i+1}}^{\ln k_{ti}} d \ln q_t \int_{\ln \ell_t / Q_{12}}^{\ln Q_{12} / \ell_t} d \eta \frac{2 \alpha_s N_c}{\pi} \right] = \exp \left[- \frac{\alpha_s N_c}{\pi} \ln \frac{k_{ti}}{k_{t,i+1}} \ln \frac{Q_{12}^2}{k_{ti} k_{t,i+1}} \right]. \quad (3.28)$$

One then decides the rapidity η of the emission, uniformly distributed between $\ln k_{t,i+1}/Q_{12}$ and $\ln Q_{12}/k_{t,i+1}$ as well as an azimuthal angle ϕ . The 4-momentum of the new emission is thus reconstructed as

$$k_{i+1}^\mu = \xi_1 p_1^\mu + \xi_2 p_2^\mu + k_{t,i+1}^\mu \quad (3.29)$$

with

$$\xi_1 = \frac{k_{t,i+1}}{Q_{12}} e^\eta, \quad \xi_2 = \frac{k_{t,i+1}}{Q_{12}} e^{-\eta}, \quad k_{t,i+1}^\mu = k_{t,i+1} (\cos \phi n_1^\mu + \sin \phi n_2^\mu) \quad (3.30)$$

and $n_{1,2}$ two unit vectors orthogonal to p_1 and p_2 .

Note that when a dipole (p_1, p_2) splits into two new dipoles (p_1, k_{i+1}) , (k_{i+1}, p_2) , the energy scales of the two new dipoles can be straightforwardly obtained using

$$Q_{1k}^2 = (p_1 + k_{i+1})^2 = \xi_2 Q_{12}^2 = Q_{12} k_{t,i+1} e^{-\eta}, \quad (3.31)$$

$$Q_{k2}^2 = (p_2 + k_{i+1})^2 = \xi_1 Q_{12}^2 = Q_{12} k_{t,i+1} e^{+\eta} \quad (3.32)$$

In order to reduce the inclusion of uncontrolled corrections beyond our intended resummation of single logarithms, we can perform another simplification. Recall that we are aiming to resum the energy logarithms due to clustering effects. Instead of computing the energy of each particle explicitly from its 4-momentum, we can directly project this momentum along the direction of the initial dipole. Let us denote by (p, \bar{p}) the hard-scattering momenta of a given initial colour dipole. For each emission, we want to find the contributions z and \bar{z} of its momentum fractions along the p and \bar{p} directions respectively. For the emission of a new particle k from a (p_1, p_2) dipole, we have

$$p_1^\mu = z_1 p^\mu + \bar{z}_1 \bar{p}^\mu + p_{t,1}^\mu \quad (3.33)$$

$$p_2^\mu = z_2 p^\mu + \bar{z}_2 \bar{p}^\mu + p_{t,2}^\mu \quad (3.34)$$

The new emission k therefore has a projection z_k, \bar{z}_k along the p, \bar{p} directions given by

$$z_k = \xi_1 z_1 + \xi_2 z_2 \approx \frac{k_t}{Q_{12}} \max(z_1 e^\eta, z_2 e^{-\eta}), \quad (3.35)$$

$$\bar{z}_k = \xi_1 \bar{z}_1 + \xi_2 \bar{z}_2 \approx \frac{k_t}{Q_{12}} \max(\bar{z}_1 e^\eta, \bar{z}_2 e^{-\eta}), \quad (3.36)$$

where we have used Eq. (3.30) and replaced the sum over the two contributions by its maximum at our accuracy.

Iterating the above procedure for emissions ordered in k_t produces an event where each particle has a 4-momentum as well as longitudinal fractions z and \bar{z} along their initial (p, \bar{p}) dipole. To reconstruct the primary Lund plane density we then proceed as follows: the anti- k_t jet of radius R is made of all the emissions within a radius R of an initial hard

parton. These particles can then be clustered using the C/A jet algorithm. This clustering uses the exact 4-momenta of the jets and a winner-takes-all-like [72] recombination scheme where the recombined particle is taken as the one of the two recombining particles with the largest \bar{z} momentum along the jet direction.¹⁰ When we reconstruct the primary Lund plane density, the Δ coordinate is again taken from the exact angular kinematics, the z variable from the event \bar{z} and hence k_t is obtained as $p_{t,\text{hard}}z\Delta$ with $p_{t,\text{hard}}$ the jet transverse momentum (w.r.t. the colliding beams) of the initial hard parton.

The above discussion is strictly speaking valid only in a fixed-coupling approximation. To account for running-coupling effects, we use the following procedure. For given Born-level kinematics (see e.g. (3.20)) and a given colour flow corresponding to a given initial set of dipoles, we generate a Monte Carlo event using a fixed α_s .¹¹ Following the procedure outlined in the previous paragraph we obtain the coordinates Δ and z of the primary Lund declusterings. From the z coordinate, we then determine an emission “time” $t_{\text{soft,fc}}$ defined as $t_{\text{soft,fc}} = \alpha_s \ln 1/z$. This procedure yields a resummed density $\rho_{\text{soft}}(\Delta, t_{\text{soft,fc}})$. To include running-coupling corrections at a given k_t and Δ , we simply use $\rho_{\text{soft}}(\Delta, t_{\text{soft}})$ with a t_{soft} defined to include running-coupling effects:

$$\rho_{\text{soft}}(\Delta, t_{\text{soft}}(k_t, p_{\perp}\Delta; \mu)), \quad (3.37)$$

with (cf. Eq. (3.6))

$$t_{\text{soft}}(k_t, p_{\perp}\Delta; \mu) = \int_{k_t}^{p_{\perp}\Delta} \frac{dq_{t1}}{q_{t1}} \frac{\alpha_s(q_{t1})}{\pi} \equiv I_{\alpha}(k_t, p_{\perp}\Delta; \mu). \quad (3.38)$$

Additionally, this approach can be straightforwardly extended to generate results at fixed-order. This will be useful to compare to the results derived in section 3.3.1 and 3.3.2 as well as for matching with exact fixed-order results in section 4.

As a validation of our numerical approach, we first compare the output of the numerical approach to the analytic results for soft gluon radiation at fixed order. The predictions for soft radiation at large angle at $\mathcal{O}(\alpha_s)$, obtained in section 3.3.1, are compared to our numerical results in Fig. 3a. The comparison is done assuming the large- N_c limit and is independent of $\ln k_t$ (modulo the soft approximation of the kinematic constraint, $k_t/(p_{\perp}\Delta) \leq 1$). The figure shows excellent agreement with the analytic results from Eq. (3.22).

With Fig. 3b, we study the numerical results for C/A clustering effects at $\mathcal{O}(\alpha_s^2)$, Eqs. (3.25) and (3.26). For a gluon jet, we need to consider two dipoles. Since our calculation is done in the collinear limit, we have considered a range of small values of Δ . The linear rise with $\ln z$, with the expected analytic coefficient, is clearly visible for quark jets, together with no effects at this order for gluon jets.

All-order results are shown in Fig. 4 for two different regions in angle. We see that apart from the region of very small z (large t_{soft}), the resummation has a relatively small

¹⁰The usage of the \bar{z} momentum fractions guarantees that in the collinear limit only the logarithmically-enhanced contributions are kept. At large angles, and, in particular, for initial dipoles which do not involve the jet momentum, one could generate subleading corrections as well. In practice however, our fixed-order tests indicate that these subleading corrections are very small, if present at all.

¹¹In practice, we take the coupling at the scale $p_{\perp}R$.

(a) Effects of soft gluon radiation at large angles for different dipole configurations (including or not the jet).

(b) Effects of Cambridge/Aachen clustering at order α_s^2 in the collinear limit. Results are shown for two dipole configurations corresponding to a quark and gluon jet respectively.

Figure 3: Comparisons at fixed order between our numerical results for soft gluon radiation (solid lines) and analytic predictions from sections 3.3.1 and 3.3.2 (dashed lines).

(a) Large angle, $0.449 < \Delta < 0.670$

(b) Small angle, $0.061 < \Delta < 0.091$

Figure 4: All-order resummation of logarithms from soft-gluon emissions. For both plots, we give the results for a quark configuration (solid lines) and a gluon configuration (dashed lines). LO ($\mathcal{O}(\alpha_s)$) and NLO ($\mathcal{O}(\alpha_s^2)$) results are shown for comparison. For the quark configuration we have used a (1j) dipole connecting the incoming particle ℓ_1 and the outgoing “jet” ℓ_j , while for the gluon configuration, we have considered the superposition of 2 dipoles (1j, 2j), i.e. one dipole connecting the incoming ℓ_1 with ℓ_j and a second dipole connecting the other incoming parton ℓ_2 with ℓ_j (cf. (3.20)).

effect compared to the NLO result. A feature that is particularly intriguing is that in the collinear region, $\Delta \ll 1$, Fig. 4b, the result appears to be independent of t_{soft} . Recall

that for gluon jets, at order α_s^2 the soft logarithmic term was identically zero for small Δ , Eq. (3.26). Fig. 4b leads us to wonder whether the soft single logarithmic terms remain zero for gluon jets at all orders, or whether they are non-zero but simply too small to observe in our calculation. Note however that at large angles, Fig. 4a, there is a clear t_{soft} dependence both at α_s^2 and beyond, i.e. the soft single logarithmic coefficients are non-zero.

3.4 Full resummed result

Our final resummed predictions include all the effects discussed in this section: the running of the strong coupling, collinear effects — flavour changes, splitting functions and the momentum of the leading parton — as well as soft-gluon emissions to all orders including large-angle contributions and clustering effects for emissions at commensurate angles:

$$\rho_{\text{resum}}(\Delta, k_t|p_\perp) = \sum_{i,j=q,g} f_i(\mu_F) \int_0^1 dx p(x, j|i, t_{\text{coll}}(\Delta_0, \Delta; \mu_R)) \frac{\alpha_s(\xi_K k_t)}{\pi} \left(\frac{\mathcal{P}_j(z \equiv k_t/(xp_\perp \Delta))}{2C_j/z} \right) \rho_{\text{soft},j}(\Delta, t_{\text{soft}}(xp_\perp \Delta, \xi_Z k_t; \mu_R)) \quad (3.39)$$

In this expression, the factor α_s/π includes the 2-loop running coupling discussed in section 3.1. The scales $\mu_R = \xi_R p_\perp R$, $\mu_F = \xi_F p_\perp R$ and the factors ξ_K and ξ_Z probe the scale uncertainties and are discussed below. The factor $p(x, j|i, t_{\text{coll}})$ — computed numerically by solving Eq. (3.8) with an approach similar to Ref. [62] — encodes the probability for the leading parton to have a momentum fraction x and a flavour j , starting from a jet of flavour i (with initial fraction f_i) computed in the collinear limit as in section 3.2. Similarly, the factor $z\mathcal{P}_j/(2C_j)$ accounts for the collinear structure associated with an observed Lund-plane emission at finite z (cf. e.g. Eq. (3.11)). Finally, the factor ρ_{soft} resums the soft logarithms at large angles as well as C/A clustering logarithms, as described in section 3.3.3. In practice, ρ_{soft} depends on the full colour structure of an event. We have computed it by interfacing Born-level events obtained with the NLOJet++ program to the numerical code from section 3.3.3. Each Born-level event is separated (at large- N_c) into different (weighted) dipole configurations. The result is binned as a function of t_{soft} , Δ , and the jet p_\perp and flavour. The different dipole configurations contributing to a given jet flavour are summed, as only the sum is needed to combine ρ_{soft} with the collinear effects in writing (3.39).

The structure of Eq. (3.39) is illustrated in Fig. 5, which shows that to obtain the density at a point (Δ, k_t) in the Lund plane (the black dot), one first resums collinear effects down to the angle Δ (the solid blue line) then resums the soft emissions at commensurate angles between $xp_\perp \Delta$ and k_t (the solid red line). In particular, one sees that at large angles, where the details of the dipole configuration matter, collinear effects can be neglected in (3.39) and the sum over dipole configurations can be performed trivially. At small angles, the clustering logarithms resummed in ρ_{soft} depend only on the jet flavour.

Our results for the resummation of the soft gluons are strictly-speaking obtained in the large- N_c limit. It is however possible to restore the full- N_c behaviour up to and including $\mathcal{O}(\alpha_s^2)$ in the collinear limit, i.e. in the limits that have been discussed in sections 3.3.1

Figure 5: Schematic representation of Eq. (3.39) where the density at a point (Δ, k_t) in the Lund plane is obtained by first resumming collinear effects at angles larger than Δ and then soft gluons (at commensurate angles) down to a scale k_t .

and 3.3.2. First, we multiply the soft density for quark jets, $\rho_{\text{soft},q}$ by a factor $2C_F/C_A$ to guarantee the proper result from Section 3.3.1 at order α_s . Then, we multiply t_{soft} by $2(C_A - C_F)/C_A$ for quark jets, to guarantee the proper expansion, Eq. (3.25), at order α_s^2 in the collinear limit. At large angles the structure of subleading- N_C corrections is more complicated, and we will rely on matching with fixed-order calculations to address these terms up to order α_s^2 .

To obtain our final predictions integrated over p_\perp , we have again used NLOJet++ to obtain the jet cross-section, the quark and gluon fractions $f_{q,g}$, the average jet p_\perp and the average $\alpha_s(\mu_R)$ (as well as ρ_{soft}) in a series of bins in p_\perp . The contribution of each bin is evaluated using (3.39) at the average p_\perp in the bin and summed with weight proportional to the bin cross-section.

Compared to section 3.3.3, the definition of t_{soft} from Eq. (3.38) has to be adjusted to ensure $t_{\text{soft}} \rightarrow 0$ when $k_t \rightarrow \frac{1}{2}x p_\perp \Delta$ (i.e. $z \rightarrow \frac{1}{2}$). This is simply done by writing

$$t_{\text{soft}}(\xi_Z k_t, p_\perp \Delta; \mu) \equiv I_\alpha \left(\frac{\xi_Z x k_t}{x - (2 - \xi_Z) \frac{k_t}{p_\perp \Delta}}, x p_\perp \Delta; \mu \right), \quad (3.40)$$

where we have introduced a parameter ξ_Z that allows us, by a standard variation of ξ_Z between 1/2 and 2, to probe the uncertainties associated with the resummation of soft gluons. Similarly, we estimate the renormalisation ($\mu_R = \xi_R p_\perp R$) and factorisation ($\mu_F = \xi_F p_\perp R$) scale uncertainties using the 7-point rule [73] around $\mu_R = \mu_F = p_\perp R$ ($\xi_R = \xi_F = 1$). The factorisation scale only influences the Born-level spectrum and the quark/gluon fractions $f_{q,g}$. The choice of μ_R should also be reflected in the factor α_s/π in (3.39) as well as in the definition of t_{coll} and t_{soft} , via the reference scale $\mu_R = \xi_R p_\perp R$ for α_s in (3.3). Additionally, the uncertainty of the choice of scale for the argument of α_s in (3.2) is taken into account by setting the scale to $\xi_K k_t$ and varying ξ_K between 1/2 and 2. This is the dominant source of uncertainty in our calculation. The uncertainty on the collinear resummation could be estimated by varying Δ_0 in (3.39). However, since the effect of the collinear resummation is small (see e.g. Figs. 6 and 7), we have neglected this and set

(a) large angles: $0.549 < \Delta < 0.670$

(b) small angles: $0.074 < \Delta < 0.091$

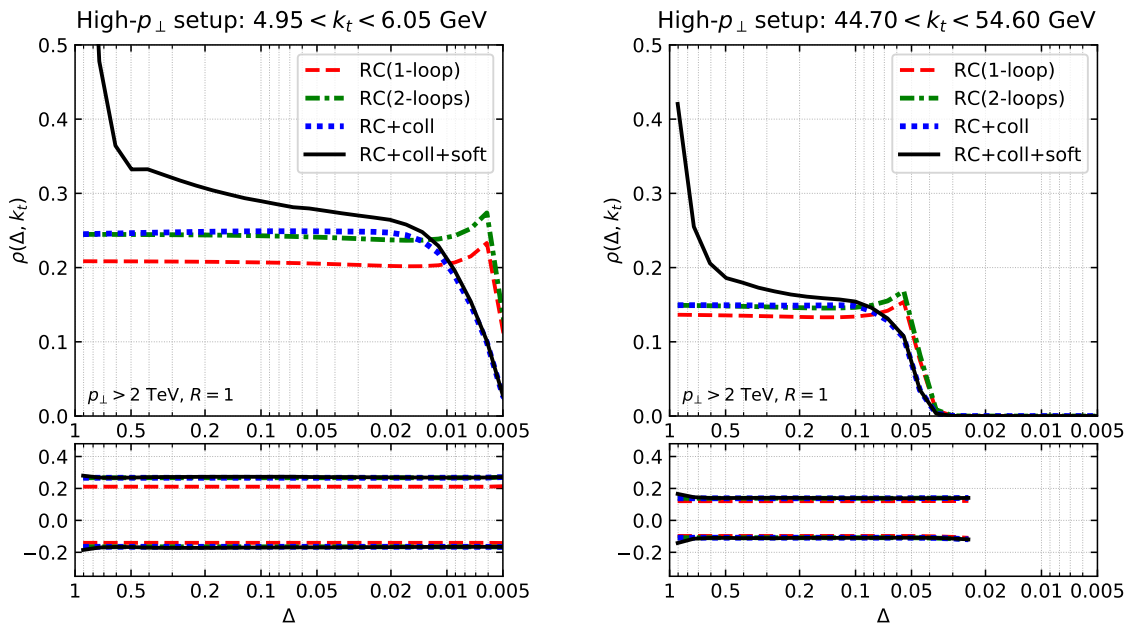

Figure 6: Slices of the resummed primary Lund-plane density $\rho_{\text{resum}}(\Delta, k_t)$ at constant Δ . The upper panels correspond to the density $\rho_{\text{resum}}(\Delta, k_t)$ itself while the lower panels show the relative scale uncertainties $\frac{\delta\rho}{\rho}(\Delta, k_t)$. We show results including different contributions: the dashed (red) line includes only 1-loop running, the (dash-dotted) green line includes 2-loop running-coupling corrections, the (dotted) blue lines adds the resummation of collinear effects (flavour changes and leading-parton momentum), and the solid black line is our full resummed result, including soft-gluon resummations as well.

$\Delta_0 = R$.¹² To be conservative, the final perturbative uncertainty is obtained by summing in quadrature the three individual sources of uncertainties: the 7-point variation of μ_R (or ξ_R) and μ_F (or ξ_F), the variation of ξ_K and the variation of ξ_Z .¹³

We present some representative results obtained with Eq. (3.39) in Figs. 6 (for slices of the Lund plane in a narrow bin of Δ) and 7 (for slices in a narrow bin of k_t). In each plot, we

¹²Varying Δ_0 would come with the additional complication that, for $\Delta_0 > R$, collinear radiation at angles larger than the jet radius would cause the Born-level p_\perp and the jet p_\perp to differ. Since, in our case, $\ln(R)$ is not large, we can neglect this effect.

¹³Recall that t_{coll} , Eq. (3.6) and t_{soft} , Eq. (3.40) are written terms of I_α , Eq. (3.7) and that they all have a structure $\alpha_s^n L^n$, where each factor of L can be one of $\ln \Delta$ or $\ln p_t R/k_t$. To probe uncertainties, we should examine variations that generate terms $\alpha_s^n L^{n-1}$. The variation of μ in Eq. (3.7) does not generate such terms, but only terms $\alpha_s^n L^{n-2}$. One approach to generating terms $\alpha_s^n L^{n-1}$ is to change the argument of α_s within the integral in Eq. (3.7), i.e. replacing $\alpha_s(q_t)$ with $\alpha_s(\xi q_t)$, where ξ is the scale variation factor. This is equivalent to replacing $I_\alpha(k_t, k_{t0}; \mu) \rightarrow I_\alpha(\xi k_t, \xi k_{t0}; \mu)$, i.e. changing both integration boundaries. A second approach is to change just one boundary by a factor ξ , which can be thought of as a replacement $L \rightarrow L \pm \ln \xi$. The prescription that we have adopted for t_{soft} corresponds to the second approach, specifically varying the lower boundary (which has a larger numerical impact than varying the upper boundary). Ultimately, the choice we make here is not especially critical, because the overall perturbative uncertainty is dominated by the ξ_K variations.

(a) small k_t , $4.95 < k_t < 6.05$ GeV

(b) large k_t , $44.7 < k_t < 54.6$ GeV

Figure 7: Same as Fig. 6, now for slices of constant k_t .

show results obtained using Eq. (3.2), i.e. just running-coupling effects, with 1-loop (red) and 2-loop (green) running. The blue curves then add collinear effects (i.e. Eq. (3.11)) and the black curves add soft-gluon emissions corresponding to our full resummed results from Eq. (3.39). The bottom panels of each plot show the corresponding scale uncertainties. These plots show that 2-loop running-coupling corrections are numerically similar in size to the resummation of the soft logarithms. Those soft-gluon effects are most significant at small k_t and at large angle. It is worth noting though that their effect is also visible at large k_t in Fig. 6a. This is due to the power corrections in Δ^2 starting at order α_s , as discussed in section 3.3.1.

Collinear effects are small except close to the $k_t = \frac{1}{2}p_\perp\Delta$ endpoint where the use of the full splitting function and the probability distribution for the momentum fraction of the leading parton have a clearly visible effect (see Fig. 7 in particular). Flavour-changing collinear effects are small but are still visible in Fig. 7a, reflected in the difference between the green and blue lines for $\Delta \gtrsim 0.02$. In particular, as one goes to smaller values of Δ , there is an increase in the fraction of jets whose leading parton is a gluon. This flavour-changing effect is modest in size, in part because the initial Born-level spectrum has a quark fraction of about 77.5%, relatively close to the asymptotic fraction of 62% that is visible in Fig. 2a (cf. Eq. (3.13)).

The perturbative scale uncertainties are about 10% at large k_t , slowly growing to $\sim 15\%$ at $k_t \sim 20$ GeV and to $\sim 30\%$ at $k_t = 2$ GeV (averaging the upper and lower uncertainties). They are dominated by the scale variation, ξ_K , in the argument of α_s with

an additional small contribution from the variation of ξ_Z at small k_t .¹⁴

While all the above expressions are given for the primary Lund-plane density $\rho(\Delta, k_t)$, they can almost straightforwardly be adapted to $\tilde{\rho}(\Delta, z)$, as measured e.g. by the ATLAS collaboration. Specifically, Eq. (3.39) becomes

$$\tilde{\rho}_{\text{resum}}(\Delta, z|p_\perp) = \sum_{i,j=q,g} f_i \int_0^1 dx p(x, j|i, t_{\text{coll}}(\Delta_0, \Delta; p_\perp R)) \frac{\alpha_s(xz p_\perp \Delta)}{\pi} \left(\frac{\mathcal{P}_j(z)}{2C_j/z} \right) \rho_{\text{soft},j}(\Delta, t_{\text{soft}}(xp_\perp \Delta, xz p_\perp \Delta; p_\perp R)). \quad (3.41)$$

We just note that, while keeping k_t large enough in Eq. (3.39) guarantees that we stay in the perturbative region, the integration over x in (3.41) potentially extends to arbitrarily small $xz p_\perp \Delta$ momentum scales. This is regulated by our freezing of the running coupling at 1 GeV. In practice, this only affects the small values of z in a region where the non-perturbative corrections dominate anyway.

In anticipation of the matching of our resummed predictions to exact fixed-order results for $\rho(\Delta, k_t)$, we note that our all-order equations (3.39) and (3.41) can be expanded to fixed-order. For Eq. (3.39), at NLO we have

$$\alpha_s(k_t) = \alpha_s + 2\alpha_s^2 \beta_0 \ln \frac{p_\perp R}{k_t}, \quad (3.42a)$$

$$p(x, j|i, t_{\text{coll}}) = \delta_{ij} \delta(1-x) + \frac{\alpha_s}{\pi} \ln \frac{\Delta_0}{\Delta} \int dz \left[\mathcal{P}_{ji}^{(R)}(z) \delta(z-x) - \mathcal{P}_{ji}^{(V)}(z) \delta(1-x) \right], \quad (3.42b)$$

$$\rho_{\text{soft},j}(\Delta, t_{\text{soft}}) = \alpha_s \rho_{\text{soft},j}^{(1)}(\Delta, k_t) + \alpha_s^2 \rho_{\text{soft},j}^{(2)}(\Delta, k_t) = \alpha_s \rho_{\text{soft},j}^{(1)}(\Delta) + \frac{\alpha_s^2}{\pi} \ln \frac{p_\perp \Delta}{k_t} \rho_{\text{soft},j}^{(2-\text{em})}(\Delta). \quad (3.42c)$$

with $\alpha_s \equiv \alpha_s(p_\perp R)$. We have explicitly written $\alpha_s^2 \rho_{\text{soft}}^{(2)}(\Delta, k_t) = \frac{\alpha_s^2}{\pi} \ln \frac{p_\perp \Delta}{k_t} \rho_{\text{soft}}^{(2-\text{em})}(\Delta)$, i.e. as a logarithm times a factor depending only on Δ . The coefficients of the ρ_{soft} expansion can be obtained, as for ρ_{soft} itself, using the numerical approach from section 3.3.3 with a Born-level spectrum from NLOJet++. Inserting the elements of Eq. (3.42) into (3.39), we get a trivial LO contribution involving $\rho_{\text{soft},j}^{(1)}(\Delta)$. The NLO, i.e. $\mathcal{O}(\alpha_s^2)$, result receives 3 contributions, one from each of the lines of Eq. (3.42). A similar fixed-order expansion can be obtained for $\tilde{\rho}(\Delta, z)$.

4 Matching with fixed-order

In order to get a full coverage of the primary Lund-plane density, including regions which are not dominated by large logarithms, it is useful to supplement our resummation with as many orders of the α_s series expansion of $\rho(\Delta, k_t)$ as are known exactly.

¹⁴The kink in the upper uncertainty bands between 1 and 2 GeV comes from our freezing of the running coupling at 1 GeV.

In this paper we focus on dijet events, for which we can obtain the primary Lund-plane density using the `NLOJet++` program,

$$\rho_{\text{fixed-order}}(\Delta, k_t) = \alpha_s(p_\perp R) \rho^{(1)}(\Delta, k_t) + \alpha_s^2(p_\perp R) \rho^{(2)}(\Delta, k_t) + \mathcal{O}(\alpha_s^3). \quad (4.1)$$

The first (LO) and second (NLO) contributions are accessible using respectively LO and NLO 3-jet calculations [51].

Compared to the all-order calculation discussed in section 3, the LO contribution includes the first-order soft gluon radiation at large angles. The NLO contribution includes the first non-trivial running-coupling, flavour-changing and clustering corrections.¹⁵ We have checked numerically that there was an agreement between `NLOJet++` and our analytic calculations for the soft-and-collinear behaviour at $\mathcal{O}(\alpha_s)$ and for the logarithmic dependence at $\mathcal{O}(\alpha_s^2)$, although small deviations expected from our large- N_c approximation — used to calculate dipole decompositions and soft logarithms beyond the collinear limit — are observed at large angles. We show some explicit examples in Appendix C.

Knowing both the all-order resummation and the exact fixed-order results, we obtain a matched prediction using

$$\rho(\Delta, k_t) = \frac{\rho_{\text{resum}}(\Delta, k_t) \rho_{\text{NLO}}(\Delta, k_t)}{\rho_{\text{resum,NLO}}(\Delta, k_t)}, \quad (4.2)$$

where $\rho_{\text{resum,NLO}}$ is the expansion to $\mathcal{O}(\alpha_s^2)$ of the resummed result (3.39). This expression is such that it reproduces the resummed calculation in the region where large logarithms are present, and the exact NLO result when expanded to second order in α_s .

Explicit examples of matched predictions, including different levels of approximations for the resummation, are presented in Fig. 8 for the k_t dependence at fixed Δ . First, we see that the exact NLO results (red) are close to what is obtained using the expansion of our resummed calculation (green). Next, the resummed result (blue) shows a strong enhancement at small k_t , primarily due to the running coupling, and to soft-gluon clustering effects. Finally, the matched result (black) smoothly interpolates between the fixed-order result at large angle and large k_t and the resummed result at smaller angle or k_t .

The bands in the upper panel of Fig. 8 as well as the curves in the lower panel show our theoretical uncertainties. One of the striking features is that the matching with NLO reduces the uncertainties compared to the resummed result. This is valid across the whole kinematic range and especially visible at larger k_t . Final uncertainties after matching are $\sim 6\%$ at $k_t = 200$ GeV, increasing to $\sim 12\%$ at 20 GeV and $\sim 30\%$ at 2 GeV.

5 Non-perturbative effects

Before making our final predictions it is interesting to estimate non-perturbative corrections to the calculation we have provided so far. We do so using a Monte-Carlo approach. We have studied the primary Lund-plane density using 5 different Monte-Carlo generators/tunes: Pythia8 (v8.230) [74] with the Monash 2013 tune [75], tune 4C [76] and the

¹⁵In these fixed-order calculations the central renormalisation and factorisation scales have been set to $p_\perp R$ with p_\perp the jet transverse momentum.

(a) large angles: $0.549 < \Delta < 0.670$

(b) small angles: $0.074 < \Delta < 0.091$

Figure 8: Slices of the primary Lund-plane density $\rho(\Delta, k_t)$ at constant Δ . The upper panels correspond to the density $\rho(\Delta, k_t)$ itself, while the lower panels show the relative scale uncertainties $\frac{\delta\rho}{\rho}(\Delta, k_t)$. We show results for the exact NLO calculation (red), the NLO expansion of the resummed results (green), the full resummed result (blue) and the NLO+resummation matched result (black).

ATLAS 2014 tune [77] (the variant with NNPDF 2.3 PDFs [78]), Herwig7.2.0 [79–81] and Sherpa 2.2.8 [82]. For each generator/tune we first study the primary Lund-plane density at parton level. We can then switch to hadron level to study the effect of hadronisation, include multi-parton interactions (MPI) to study the effects of the Underlying Event, and examine the impact of using only charged tracks as done in the ATLAS measurement [83].

For the central value of the non-perturbative corrections, we take the average of the Monte-Carlo generators, excluding Herwig7. The reason behind this exclusion is that our perturbative results are in the same ballpark as parton-level results from Pythia8 and Sherpa but differ significantly from parton-level Herwig7 results (see Appendix D). We obtain the (upper and lower) uncertainties on the non-perturbative corrections from the envelope of the Lund-plane density ratios for the 5 Monte-Carlo generators/tunes. To remain conservative, we keep the Herwig7 results in our non-perturbative uncertainty estimates.

Our results are presented in Fig. 9, for our high- p_\perp setup separately for hadronisation and Underlying Event corrections. It is clearly visible that hadronisation corrections become sizeable at low k_t , with a negative effect above ~ 3 GeV and a positive effect below. Their effect is almost invisible for $k_t \gtrsim 10$ –20 GeV. Underlying-Event corrections are instead important (and positive) at low-to-moderate k_t and large angles. The

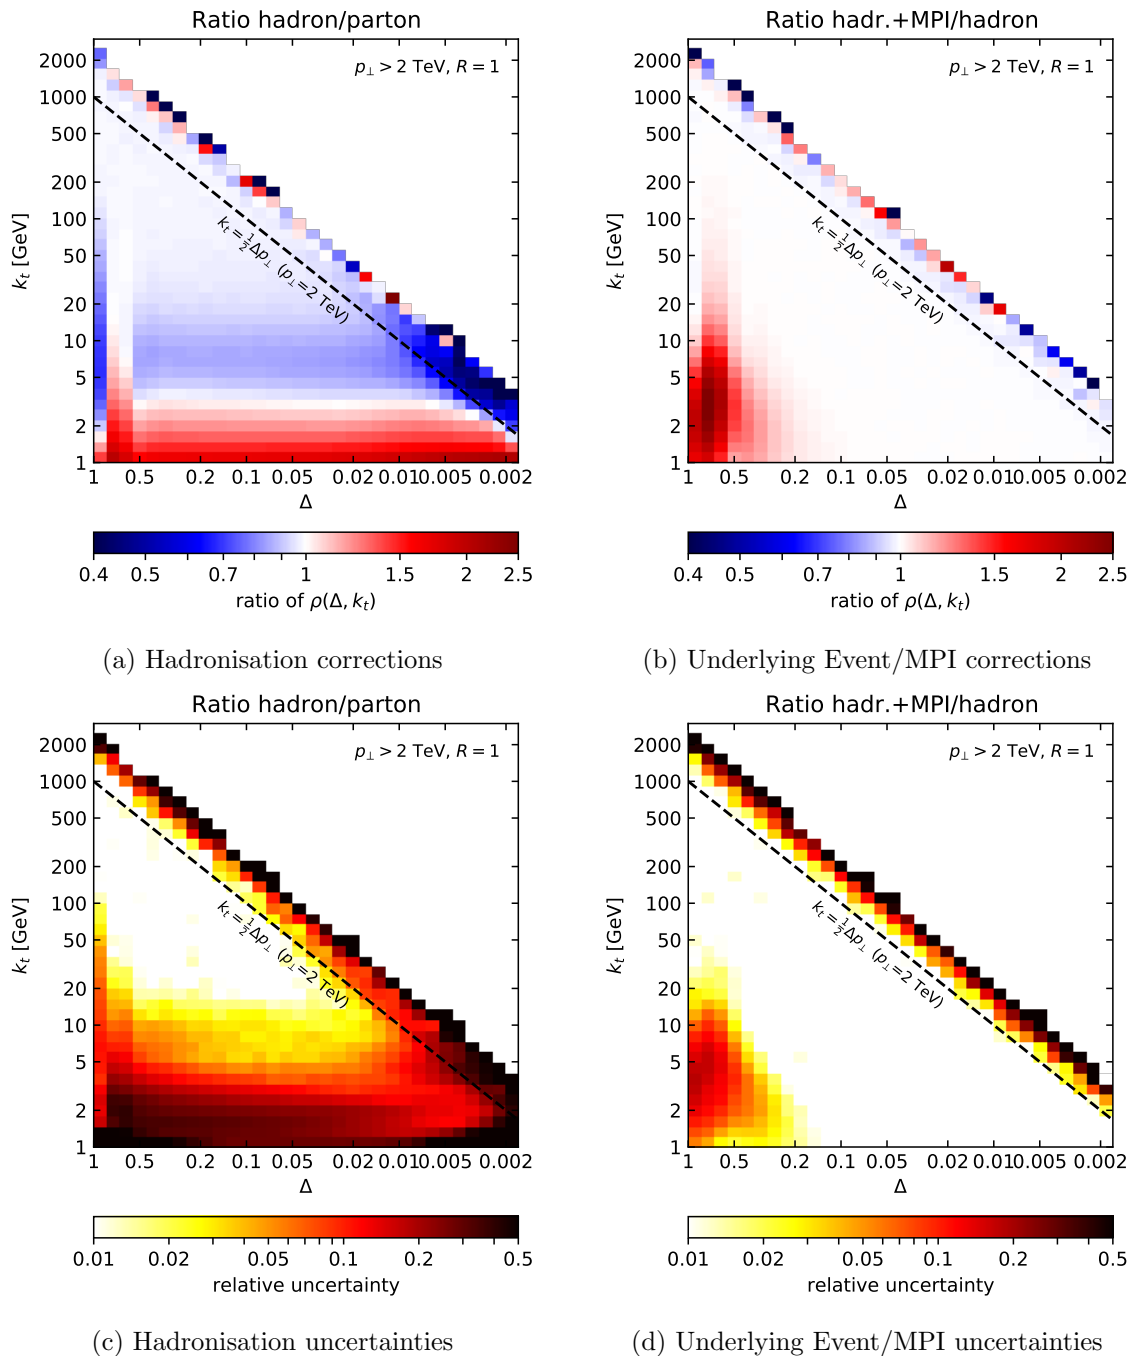

Figure 9: Non-perturbative corrections (top) and uncertainties (bottom). The diagonal dashed line corresponds to the kinematic limit, $k_t = \frac{1}{2} p_\perp \Delta$, for jets with $p_\perp = 2$ TeV.

non-perturbative uncertainties — shown in Fig. 9c and 9d for hadronisation and the Underlying Event, respectively — are small, $\mathcal{O}(1-2)\%$, whenever the overall corrections are themselves small. At large Δ , the non-perturbative corrections appear to have additional structure and enhanced uncertainties. This structure can be attributed to the interplay

(a) Lund-plane density $\rho(\Delta, k_t)$ (b) Perturbative uncertainty (c) Full uncertainty

Figure 10: Predictions for the primary Lund plane density for the high- p_\perp setup (a) and associated perturbative (b) and full (c) uncertainties. Full uncertainties sum the perturbative and non-perturbative contributions in quadrature.

between the initial anti- k_t clustering and the C/A re-clustering as already discussed in [33] and related boundary logarithms discussed in section 3.3.2 and Appendix B.

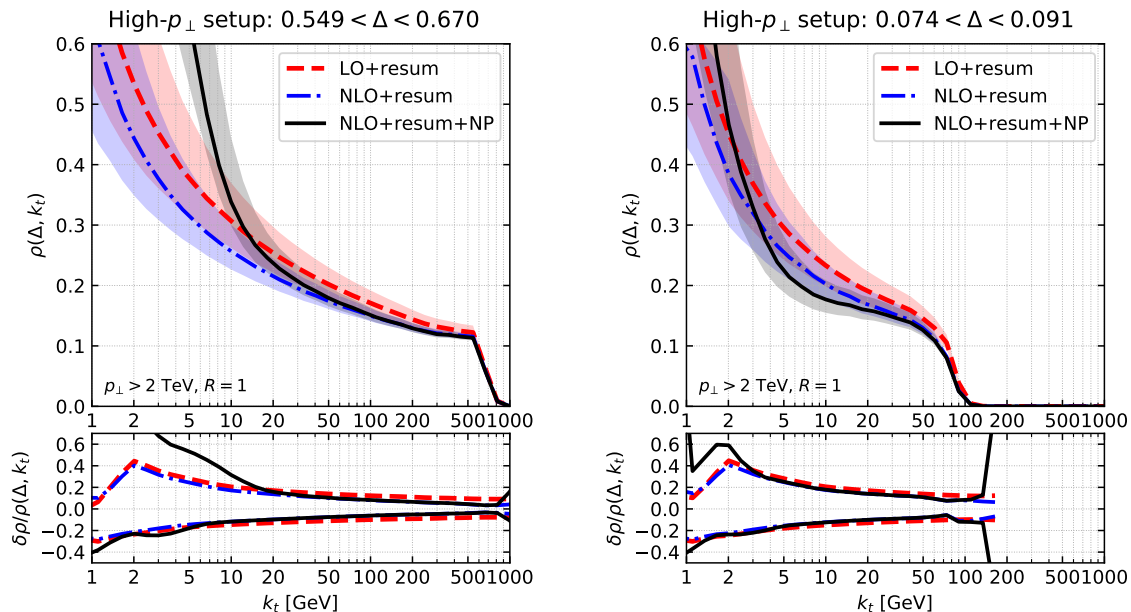

The diagonal dashed line in Fig. 9 corresponds to $k_t = \frac{1}{2}p_\perp \Delta$ for $p_\perp = 2$ TeV. This is the kinematic limit for the lowest-energy selected jets. The Lund plane density quickly decreases above that line. The large fluctuations and uncertainties observed in Fig. 9 around the dotted line are a trace of the statistical fluctuations in our Monte Carlo samples.

6 Final predictions

Our final predictions include both the matched perturbative predictions, discussed in section 4, multiplied by the non-perturbative corrections obtained in section 5.

We show in Fig. 10a the resulting two-dimensional average primary Lund-plane density $\rho(\Delta, k_t)$, and in Figs. 10b and 10c the associated relative uncertainty at perturbative level and at the non-perturbative level respectively. Fig. 11 shows slices at fixed angle Δ , which help to better visualise certain features. The density plot, Fig. 10a, shows all the expected features: the gradual increase towards small k_t due to the running of α_s ; the extra enhancement due to soft-gluon emissions, both at large angles and at small k_t/Δ (or equivalently z); the reduction close to the kinematic limit associated with the “energy loss” of the leading branch; and the increase at low k_t and in the bottom-left corner of the Lund plane due to non-perturbative effects.

The uncertainties are dominated by the perturbative component for $k_t \gtrsim 3\text{--}5$ GeV, except at large angles where non-perturbative effects can have a sizeable impact up to $k_t \sim 10\text{--}20$ GeV. The total uncertainty is found to be about 20% at $k_t \sim 5$ GeV (away from the large-angle region), and decreases to 5–7% for k_t in the 200–500 GeV range. Relative to the LO+resum results, visible in Fig. 11, the inclusion of NLO corrections reduces the uncertainties mainly at high k_t . Even if the non-perturbative corrections have

(a) large angles: $0.549 < \Delta < 0.670$

(b) small angles: $0.074 < \Delta < 0.091$

Figure 11: Slices of the primary Lund-plane density $\rho(\Delta, k_t)$ at constant Δ . The upper panels correspond to the density $\rho(\Delta, k_t)$ itself while the lower panels show the relative scale uncertainties $\frac{\delta\rho}{\rho}(\Delta, k_t)$. We show results for the matched result at LO (red) and NLO (blue), as well as NLO results including non-perturbative corrections (black).

a negligible impact on the uncertainty above $\sim 3\text{--}5$ GeV (10–20 GeV) at small (large) Δ , they result in a (small-but-visible) shift of the central value up to larger values of k_t .

Finally, we discuss our analytic calculations supplemented with non-perturbative corrections for $\tilde{\rho}(\Delta, z)$, corresponding to the ATLAS setup. Besides the differences discussed in section 2, we follow the same strategy as for the high- p_\perp setup: the resummed prediction is obtained using Eq. (3.41), matched to NLOJet++ fixed-order results using Eq. (4.2) and supplemented with non-perturbative corrections — this time correcting so as to correspond to a measurement performed using charged-tracks above 500 MeV — following the procedure outlined in section 5. Details of the non-perturbative corrections are given in Appendix E.

We compare our results to the ATLAS data from Ref. [83] for slices in Δ in Fig. 12 and slices in z in Fig. 13. The vertical dashed lines correspond to the k_t scales estimated using $z = k_t/(p_\perp\Delta)$, i.e. assuming a jet at the lower p_\perp cut of 675 GeV and a leading parton/subject carrying a fraction $x = 1$ of the initial jet transverse momentum. The shaded grey bands indicate regions where the uncertainty on the non-perturbative corrections is larger than 10%. Shaded red bands correspond to the regions sensitive to the boundary logarithms discussed in section 3.3.2. We recall that we have not resummed these terms, so our calculation should be considered incomplete in the red shaded regions. A rough estimate of their potential size is given in Appendix B.

Figure 12: Comparison between our calculations and the ATLAS measurement from Ref. [83], for different bins of Δ . The dashed vertical lines, corresponding to $z = \frac{k_t}{p_\perp \Delta}$ for $p_\perp = 675$ GeV and several k_t values, are meant to indicate the transverse scales one is typically sensitive to. The shaded grey bands indicate bins where the relative uncertainty on the non-perturbative corrections is larger than 10%. The shaded red regions indicate that our calculation is incomplete because of the missing resummation of the boundary logarithms.

For all unshaded bins in Figs. 12 and 13, we see agreement between our predictions and the data to within the experimental and theoretical uncertainties. Generally speaking, the theoretical uncertainties are larger than the experimental ones, though they are comparable at values of z and Δ that correspond to large k_t values. Recall that the theoretical uncertainties are to a large extent dominated by the choice of scale of α_s in the resummation and a higher-order resummation would therefore be beneficial to reduce the uncertainties.

If we consider the grey shaded regions, i.e. those where non-perturbative uncertainties are larger than 10%, the agreement between data and theory remains good to within the total uncertainties in most of the bins, almost all the way down to 2 GeV. In practice this

Figure 13: Same as Fig. 12 this time for slices at constant $\ln(1/z)$.

agreement is facilitated by the non-perturbative blow-up of the uncertainties at low k_t and our predictions' central values are systematically above the data points. Recall, however, that our estimates of non-perturbative corrections rely on the assumption that the parton-level event-generator results are structurally similar to a full perturbative calculation. This assumption is questionable at low k_t : for example, a parton shower may contain a low- k_t cut, with the phase-space below that k_t value being filled up by hadronisation (there is a hint of this occurring in Appendix D, Fig. 16); in contrast our perturbative calculation has no such cut, and so the hadronisation contribution to that region, supplemented with our perturbative contribution, could effectively lead to double counting and so an overestimate relative to the data. In this respect it might be interesting to develop a more analytic understanding of expected hadronisation effects on the Lund plane density.

One region where there is clear disagreement between our predictions and the data is in the (red-shaded) largest angle bin $0.287 < \Delta < 0.400$. This disagreement is only mildly alleviated by our estimate of the potential size of boundary logarithms, cf. Fig. 14 in Appendix B. Several avenues could be of interest for further exploring this region, for example a full resummation of the boundary logarithms, or a measurement with jets whose original clustering was with the C/A algorithm (rather than anti- k_t), so as to remove

these boundary logarithms altogether. Note also that this region is potentially sensitive to underlying-event effects, and if they are incompletely modelled in event generators, this could also contribute to the disagreement.¹⁶

7 Conclusions and outlook

In this paper we have carried out the first calculation of all-order logarithmic contributions to the average primary Lund plane density. We have resummed three classes of single logarithmic terms: (i) running-coupling effects, which are relatively straightforward and the numerically dominant contribution over most of the Lund plane; (ii) soft effects, which involve large-angle contributions and clustering logarithms, both evaluated in the large- N_C limit; and (iii) collinear effects at large momentum fractions, which include contributions that can change both the momentum and the flavour of the leading parton. We have also discovered a new class of logarithmic effects in jets that arise when reclustering an anti- k_t jet’s constituents with the Cambridge/Aachen algorithm. The corresponding terms are relevant close to the large-angle boundary of the Lund plane. We defer their full single logarithmic resummation to future work.

For the purposes of making phenomenological predictions, we have matched our all-order, resummed, calculation to an exact (3-jet) calculation at next-to-leading order with the NLOJet++ program. We then supplemented the perturbative predictions with non-perturbative effects extracted from Monte Carlo simulations with Herwig, Pythia and Sherpa.

The theoretical uncertainty on our perturbative predictions ranges from 5–7% at large k_t to $\sim 20\%$ at $k_t \approx 5$ GeV. Hadronisation and underlying-event corrections are relevant below 20–30 GeV, but in most of the Lund plane dominate the overall uncertainty only below $k_t \sim 3$ –5 GeV (15 GeV at large angles, where the underlying event is a significant contributor), cf. Figs. 10 and 11.

We have made our predictions for two variants of the Lund plane definition, one using angle and absolute transverse momentum (the default for most of this paper), and the other using angle and relative momentum fraction in a given branching. The latter corresponds to the choice made by the ATLAS collaboration in their recent pioneering unfolded measurement of the primary Lund plane density with charged tracks [48].¹⁷ We have compared our results to the ATLAS data, including an additional non-perturbative correction to account for the use of charged tracks, and found good agreement in all regions where we have confidence in our predictions, i.e. the non-shaded regions of Figs. 12 and 13. This includes a broad swathe of the Lund plane, down to scales corresponding to transverse momenta of about 5 GeV.

Our work opens a series of questions that should be kept in mind for future work. First, it would be interesting to extend our calculation beyond single-logarithmic accuracy. We

¹⁶Further contributions can come from subleading- N_c corrections, both from the colour-flow decomposition of the hard matrix elements and from the resummation of soft logarithms. Our expectation is that the former should be modest given the use of $R = 0.4$, and that the latter would not be confined to $\Delta \sim R$.

¹⁷The former has been adopted in preliminary measurements by the ALICE collaboration [50] that probe dead-cone effects.

expect that this would give a considerable reduction in the uncertainty, notably from control over the effective scale to be used in the coupling. Such a calculation, however, remains challenging. Other effects like the subleading-logarithmic and subleading- N_c corrections to the clustering logarithms, or NNLO fixed-order corrections (requiring a NNLO $pp \rightarrow 3$ -jet calculation) would also be expected to bring significant improvements in certain specific regions of the Lund plane.

It would also be of interest to understand the resummation of the boundary logarithms that originate from the interplay between the initial anti- k_t clustering and the C/A reclustering. Practically, however, these logarithms could be avoided by using the C/A algorithm for both the initial clustering and the reclustering. One observation that would also deserve better understanding is the apparent absence of any resummation effect from clustering logarithms in the soft-collinear part of the Lund plane for gluon-induced jets

Keeping the above theoretical limitations in mind (and possible future improvements), one might wish to investigate whether a measurement of the Lund plane density, which intrinsically covers a wide range of transverse-momentum scales, could be helpful to make an extraction of the strong coupling constant, α_s , extending existing work on strong coupling determinations from soft-drop measurements [84, 85]. In a similar spirit, one could perhaps extend the approach of Ref. [86] to develop an analytic approach to non-perturbative corrections at small k_t and potentially even use Lund-plane measurements to determine an effective coupling constant down to small transverse momenta.

Finally, it would be interesting to compare both analytical predictions and measurements of the primary Lund-plane density to recent efforts to develop parton showers with perturbative control beyond leading double logarithmic accuracy (e.g. [47, 87]) and leading colour (e.g. [88, 89]).

Acknowledgements

We are grateful to Paul Caucal and Frédéric Dreyer, as well as to our ATLAS colleagues (Reina Camacho, Matt Leblanc, David Miller, Ben Nachmann and Jennifer Roloff), for many interesting discussions. We also thank Zoltan Nagy for much-appreciated help to improve the coverage of the phase-space for soft-and-collinear emissions with `NLOJet++`. A.L. wished to thank the IPhT for hospitality during his Master’s internship, when the first steps of project were discussed. This work has been supported in part by the French Agence Nationale de la Recherche, under grant ANR-15-CE31-0016 (GS), by a Royal Society Research Professorship (RP\R1\180112) (GPS), and by the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant agreement No. 788223, PanScales) (GPS, GS).

A Analytic results for collinear resummation

In this Appendix we give the explicit analytic solutions for the average quark/gluon fractions $f(j|i, t_{\text{coll}})$ and momentum fraction $\bar{x}(j|i, t_{\text{coll}})$ defined in Eq. (3.12). We find

$$f(q|i, t) = \delta_{iq} - \frac{s_q \delta_{iq} - s_g \delta_{ig}}{s_q + s_g} \left(1 - e^{-(s_q + s_g)t}\right), \quad (\text{A.1a})$$

$$f(g|i, t) = \delta_{ig} + \frac{s_q \delta_{iq} - s_g \delta_{ig}}{s_q + s_g} \left(1 - e^{-(s_q + s_g)t}\right), \quad (\text{A.1b})$$

$$f\bar{x}(q|i, t) = e^{tw_+} \left\{ \left[\cosh(t\tilde{w}_+) + \frac{w_-}{\tilde{w}} \sinh(t\tilde{w}) \right] \delta_{iq} + \frac{w_{qg}}{\tilde{w}} \sinh(t\tilde{w}) \delta_{ig} \right\} \quad (\text{A.1c})$$

$$f\bar{x}(g|i, t) = e^{tt_+} \left\{ \left[\cosh(t\tilde{w}_+) - \frac{w_-}{\tilde{w}} \sinh(t\tilde{w}) \right] \delta_{ig} + \frac{t_{gq}}{\tilde{w}} \sinh(t\tilde{w}) \delta_{iq} \right\}, \quad (\text{A.1d})$$

with

$$w_{\pm} = \frac{w_{qq} \pm w_{gg}}{2}, \quad \tilde{w} = \sqrt{w_-^2 + w_{qg} w_{gq}}. \quad (\text{A.2})$$

and

$$s_q = \int_0^1 dz \left[\mathcal{P}_{qg}^{(R)}(z) - \mathcal{P}_{qg}^{(V)}(z) \right] = C_F \left(2 \ln 2 - \frac{5}{8} \right), \quad (\text{A.3a})$$

$$s_g = \int_0^1 dz \left[\mathcal{P}_{gq}^{(R)}(z) - \mathcal{P}_{gq}^{(V)}(z) \right] = \frac{2n_f T_R}{3}, \quad (\text{A.3b})$$

$$w_{qq} = \int_0^1 dz \left[z \mathcal{P}_{qq}^{(R)}(z) - \mathcal{P}_{qq}^{(V)}(z) \right] = -C_F \left(2 \ln 2 + \frac{1}{6} \right), \quad (\text{A.3c})$$

$$w_{qg} = \int_0^1 dz \left[z \mathcal{P}_{qg}^{(R)}(z) - \mathcal{P}_{qg}^{(V)}(z) \right] = \frac{25}{48} n_f T_R, \quad (\text{A.3d})$$

$$w_{gq} = \int_0^1 dz \left[z \mathcal{P}_{gq}^{(R)}(z) - \mathcal{P}_{gq}^{(V)}(z) \right] = \frac{11}{24} C_F, \quad (\text{A.3e})$$

$$w_{gg} = \int_0^1 dz \left[z \mathcal{P}_{gg}^{(R)}(z) - \mathcal{P}_{gg}^{(V)}(z) \right] = -\frac{2}{3} n_f T_R - C_A \left(2 \ln 2 - \frac{43}{96} \right). \quad (\text{A.3f})$$

Note that the coefficients s_q and s_g are in agreement with the flavour-changing effects calculated in [62].

B Boundary logarithms for $\Delta \sim R$

In this Appendix, we show how new logarithms of $R - \Delta$ arise from secondary emissions at order α_s^2 . We show that these logarithms are a consequence of the interplay between the initial anti- k_t clustering used to obtain the initial jets and the C/A clustering used to construct the primary Lund plane.

Say we start from a dipole (ℓ_i, ℓ_j) and have 2 emissions, k_1 and k_2 , strongly ordered in transverse momentum as discussed in Section 3.3.2. Emission 1 (real or virtual) is integrated over and the softer emission 2 (real) is measured as a contributing to $\rho_{\text{soft}}^{(2)}(k_t, \Delta)$.

We denote by $(k|ij)$ the geometrical pattern associated with the radiation of gluon k from the dipole (ℓ_i, ℓ_j) (i.e. the transverse momenta with respect to the beam are factored

out). We also denote by R_i the distance of i to the jet axis (in rapidity-azimuth) and R_{ij} the distance between i and j . For a parton with Casimir C_R , we have

$$\alpha_s^2 \rho_{\text{soft}}^{(2)} = \left(\frac{\alpha_s}{\pi}\right)^2 \int_0^{p_\perp} \frac{dk_{\perp 1}}{k_{\perp 1}} \int_0^{k_{\perp 1}} \frac{dk_{\perp 2}}{k_{\perp 2}} \int dy_1 dy_2 \int_0^{2\pi} \frac{d\phi_1}{2\pi} \frac{d\phi_2}{2\pi} \Delta \delta(\Delta - R_2) k_t \delta(k_t - k_{\perp 2} \Delta) \\ C_R(1|ij) \left\{ \left[\frac{C_A}{2}(2|i1) + \frac{C_A}{2}(2|1j) + \left(C_R - \frac{C_A}{2}\right)(2|ij) \right] \right. \\ \left. [\Theta(R_1 > R) + \Theta(R_1 < R)\Theta(R_1 < R_{12} \text{ or } R_2 < R_{12})] - C_R(2|ij) \right\}. \quad (\text{B.1})$$

If one combines the C_R contributions, performs the $k_{\perp i}$ integrations and switches to polar coordinates for the y_2, ϕ_2 integration and uses the $\delta(\Delta - R_2)$ constraint to simplify, we get

$$\alpha_s^2 \rho_{\text{soft}}^{(2)} = \left(\frac{\alpha_s}{\pi}\right)^2 \Delta^2 \ln\left(\frac{p_\perp \Delta}{k_t}\right) \int dy_1 \int_0^{2\pi} \frac{d\phi_1}{2\pi} \frac{d\varphi_2}{2\pi} C_R(1|ij) \\ \left\{ \frac{C_A}{2} [(2|i1) + (2|1j) - (2|ij)] [\Theta(R_1 > R) + \Theta(R_1 < R)\Theta(R_1 < R_{12} \text{ or } R_2 < R_{12})] \right. \\ \left. - C_R(2|ij)\Theta(R_1 < R)\Theta(R_{12} < R_1)\Theta(R_{12} < R_2) \right\} \quad (\text{B.2})$$

We can evaluate this numerically, separating the $C_R C_A$ term in an “inside” contribution where k_1 is inside the jet (integrated in polar coordinates around the jet axis) and an “outside” contribution where k_1 is outside the jet (integrated directly in y_1 and ϕ_1). We have done this explicitly as a check of the Monte-Carlo implementation introduced in section 3.3.3 and found perfect agreement (in the large- N_c limit). Note that the combination of dipoles in the first square bracket of Eq. (B.2) vanishes when $y_1 \rightarrow \pm\infty$, showing explicitly that there are no divergences collinear with the beam.

The main purpose of this Appendix is to show that the “out” $C_R C_A$ contribution has a collinear divergence when $\Delta \rightarrow R$. To see this, we set $\Delta = R - \epsilon$ with $\epsilon \rightarrow 0$ (or take $\ln(R/\Delta) \rightarrow 0$). The collinear divergence comes from the situation where emission k_1 is close to emission k_2 (with k_1 outside the jet and k_2 inside), where the combination of dipoles can be simplified to $4/\theta_{12}^2$. After a few straightforward manipulations, we reach

$$\alpha_s^2 \rho_{\text{soft}}^{(2)}(\Delta, k_t) = \left(\frac{\alpha_s}{\pi}\right)^2 C_R C_A R^2 \ln\left(\frac{p_\perp \Delta}{k_t}\right) \ln\left(\frac{R}{R - \Delta}\right) \int_0^{2\pi} \frac{d\varphi_2}{2\pi} (2|ij) \quad (\text{B.3})$$

$$= \frac{2\alpha_s C_A}{\pi} \ln\left(\frac{p_\perp \Delta}{k_t}\right) \ln\left(\frac{R}{R - \Delta}\right) [\alpha_s \rho_{\text{soft}}^{(1)}(R, k_t)], \quad (\text{B.4})$$

where $\alpha_s \rho_{\text{soft}}^{(1)}(R, k_t)$ can be taken from Eq. (3.22). This exhibits a logarithmic behaviour when $\Delta \rightarrow R$ (which is integrable if one considers a bin in Δ between some lower bound and R).¹⁸ We have checked that this behaviour is reproduced by the Monte-Carlo described in section 3.3.3.

The physical origin of the collinear enhancement in (B.4) is the interplay between the anti- k_t clustering used to obtain the initial jet and the C/A clustering used to construct

¹⁸A similar enhancement was observed for narrow slices in Ref. [65].

the primary Lund plane. For a jet initially clustered with the C/A algorithm, emissions k_1 and k_2 would be clustered together and emission k_2 would then not be seen as a primary emission.

Equation (B.4) exhibits a double logarithmic behaviour. One should also expect single-logarithmic corrections, proportional to $\ln(R/(R - \Delta))$ without the soft enhancement. In principle, these single-logarithmic terms should be resummed to all orders. We have not, so far, found a simple prescription to achieve this resummation, which involves an interplay between the complex structure of soft emissions at commensurate angles and (potentially hard) collinear splittings at the boundary of the jet.

We however give in this Appendix a simple (incomplete) prescription from which one can gauge the potential impact of this resummation. Coming back to our calculation at $\mathcal{O}(\alpha_s^2)$, we see that the boundary logarithm $\ln(R/(R - \Delta))$ comes from the fact that emissions k_1 and k_2 are collinear to each other and the logarithm $\ln(p_\perp R/\Delta)$ comes from the energy ordering between the two emissions. One would obviously get a single-logarithmic contribution if the two emissions were still collinear but no longer strongly ordered in energy. This contribution, where the first emission is soft and just outside the jet, and the second emission is collinear to the first one and inside the jet, can be straightforwardly computed. A calculation similar to the previous one shows that the energy logarithm is replaced by an integration over the Altarelli-Parisi splitting function $P(z)$ with z the momentum fraction of the collinear branching. One then gets

$$\rho_{\text{soft}+B_g}^{(2)} = \left(\frac{\alpha_s}{\pi}\right)^2 R^2 \left[\ln\left(\frac{p_\perp R}{k_t}\right) + B_g \right] C_R C_A \ln\left(\frac{R}{R - \Delta}\right) \int_0^{2\pi} \frac{d\varphi_2}{2\pi} (2|ij), \quad (\text{B.5})$$

with $B_g = -\frac{11}{12} + \frac{n_f}{6C_A}$ the standard gluon hard-collinear branching contribution obtained from integrating the finite part of the gluon (to anything) splitting function. This is but the first of a tower of terms enhanced by logarithms of $R/(R - \Delta)$. We will examine its magnitude shortly. The full structure of the series involves other potentially complicated effects: (a) an interplay between non-trivial clustering logarithms and these new purely collinear effects; and (b) the way in which the anti- k_t jet clustering affects the jet axis and subsequent identification of the set of particles (or tracks) that gets reclustered with the C/A algorithm, specifically in presence of hard splittings at angles comparable to the jet radius. In addition to these subtleties, one might want to consider a number of combinations of jet clustering: e.g. reclustering a full anti- k_t jet with $R_{C/A} = \infty$, reclustering it with $R_{C/A} = R_{\text{anti-}k_t}$, reclustering only the particles within a distance $R_{\text{anti-}k_t}$ of the anti- k_t jet axis, etc. Given that these effects concern only a single bin in Δ , and that their treatment brings many complications, we postpone their study to future work.

We do nevertheless wish to investigate the size of the one contribution we have outlined in Eq. (B.5). It can be included in the all-order resummation via the following redefinition of t_{soft}

$$t_{\text{soft}} = \int_{k_t}^{p_\perp \Delta} \frac{dq_t}{q_t} \frac{\alpha_s(q_t)}{\pi} \quad \longrightarrow \quad t_{\text{soft}}^{(\text{shifted})} = \int_{k_t e^{-B_g \Delta/R}}^{p_\perp \Delta} \frac{dq_t}{q_t} \frac{\alpha_s(q_t)}{\pi}, \quad (\text{B.6})$$

which would only affect large values of Δ where the boundary logarithms are present. The effect of this (ad-hoc) prescription on the largest bin in Δ is shown in Fig. 14. While the

Figure 14: Estimate of the effect of a hard collinear splitting for the largest- Δ bin of the ATLAS data, using Eqs. (B.5) and (B.6).

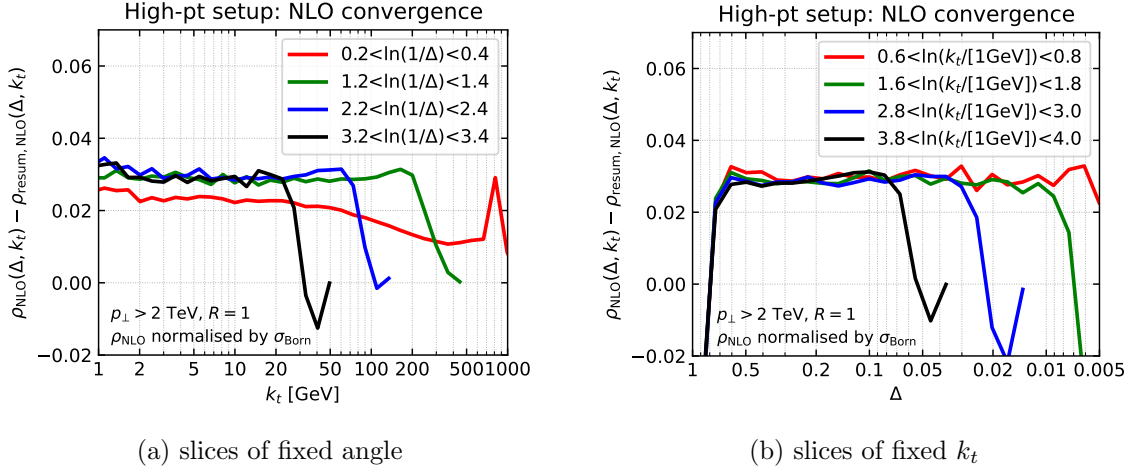

Figure 15: Differences between the exact NLO results and the NLO expansion of our resummation for different slices of the Lund plane. Control of single logarithmic terms in our resummation implies that these differences should tend to a constant both for small k_t and for small Δ , as observed, except as concerns subleading- N_C terms in the small- k_t , large Δ region. The exact NLO results are normalised here to the Born-level jet cross-section.

effect is relatively small (in particular, relative to our uncertainties and to the discrepancy with the data), we see that our results move in the right direction. Pending a full treatment of these boundary logarithms — left for future work — the bin closest to the jet edge should be treated with caution. We signal this limitation by shading the corresponding region in red in our overall comparisons with the ATLAS data, Figs. 12 and 13.

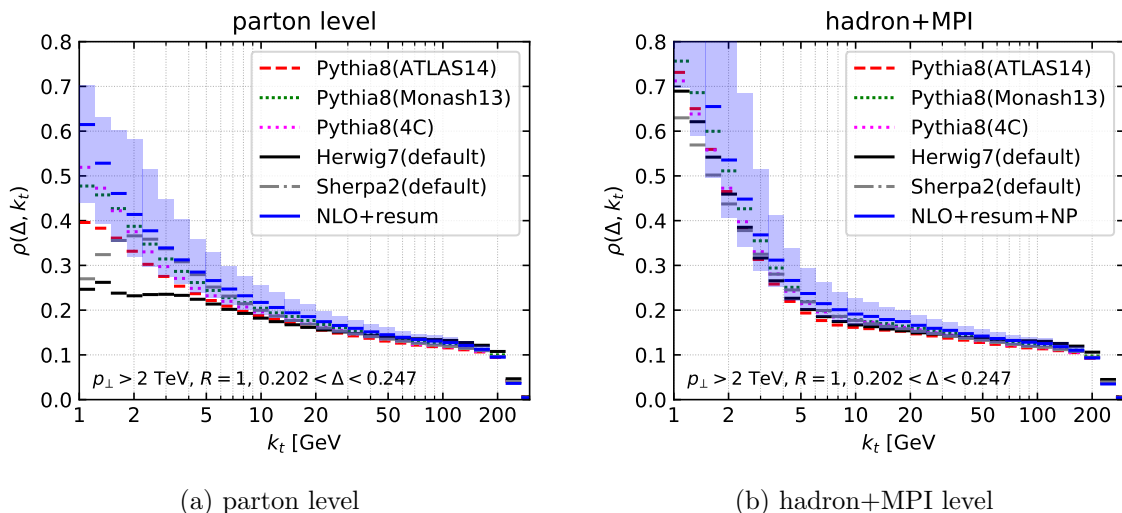

Figure 16: Comparison between our results for ρ and those obtained with the Monte Carlo generators used to estimate non-perturbative uncertainties.

C Validation of the resummation at NLO

As with any resummed calculation, it is important to check that its expansion to fixed order reproduces the behaviour seen in the exact fixed-order calculation, to within the expected accuracy of the resummation. In our case, this means that, at NLO, one should reproduce all contributions of the form $\alpha_s^2 \ln$, where the argument of the logarithm is any variable in the Lund plane. In practice, one therefore expects the difference $\rho_{\text{NLO}} - \rho_{\text{resum,NLO}}$ to tend to a constant when k_t becomes small at a fixed Δ , or when $\Delta \ll 1$ at a fixed k_t . Fig. 15 shows that this is indeed the case for both limits. We note that, while in the main text of the paper, the NLO Lund-plane density has been normalised to the NLO inclusive jet cross-section, for the purpose of Fig. 15 both ρ_{NLO} and $\rho_{\text{resum,NLO}}$ have been normalised using the Born-level jet cross-section.

D Comparison between our calculation and Monte Carlo simulations

We show in Fig. 16 a comparison between our analytic calculations and Monte-Carlo simulations for a slice of the Lund plane at constant angle. In Fig. 16a we compare our perturbative predictions to parton-level simulations and the (blue) uncertainty band corresponds to our perturbative scale uncertainty. In Fig. 16b the comparison is made for the full prediction, including non-perturbative corrections.¹⁹

At hadron+MPI level, we see a globally-decent agreement between our results and those from each Monte Carlo event generator. At parton-level however, the Herwig7 results are systematically much smaller than our analytic results for k_t below ~ 10 GeV. This is

¹⁹Obtained as discussed in section 5, i.e. excluding Herwig7 from the computation of the average non-perturbative corrections to our analytic perturbative results.

(a) Hadronisation and MPI corrections (all particles)

(b) Effects of the charge track selection.

(c) Final set of non-perturbative corrections.

(d) Uncertainties on hadronisation and MPI corrections.

(e) Uncertainties for the charge track selection.

(f) Total uncertainties on non-perturbative corrections.

Figure 17: Non-perturbative effects on $\tilde{\rho}(\Delta, z)$ for the ATLAS setup. The top row shows the average corrections and the lower row shows the associated uncertainties.

the main reason for excluding the Herwig7 Monte Carlo when computing the average non-perturbative correction.

E Non-perturbative corrections for the ATLAS setup

The set of non-perturbative corrections included in our calculation of $\tilde{\rho}(\Delta, z)$ for the “ATLAS setup” (cf. section 2) differs from those included in our default “high- p_{\perp} setup.” The main differences are (i) the use of charged tracks instead of all particles, (ii) a slightly different clustering procedure using a radius of 0.4 for the C/A reclustering, and (iii) the selection of tracks above 500 MeV and within a distance to the jet axis calculated using pseudo-rapidity instead of rapidity.

In Fig. 17, we split the full non-perturbative correction into two separate factors: the corrections due to hadronisation and multi-parton interactions computed on all particles,

Fig. 17a, and the extra corrections associated with the use of charged tracks, the 500 MeV transverse-momentum cut and the track selection based on pseudo-rapidity, Fig. 17b.²⁰ The final set of corrections is shown in Fig. 17c. We clearly see that the use of just charged tracks with momenta greater than 500 MeV induces a strong reduction of $\tilde{\rho}(\Delta, z)$ beyond the perturbative domain ($k_t < 2$ GeV) and a positive correction for $k_t > 2$ GeV. This effect partially cancels the original effect of hadronisation in the region where hadronisation depleted the Lund plane density, i.e. $k_t \gtrsim 5$ GeV. The corresponding uncertainties on the non-perturbative corrections are shown in Fig. 17(d)–(f). While the additional corrections associated with the selection of charged tracks add a little to the uncertainty at large z , the final pattern of uncertainties is largely unmodified compared to that obtained solely from the hadronisation and MPI uncertainties.
