In this work, we propose and explore for the first time a new collider signature of heavy neutral scalars typically found in many distinct classes of multi-Higgs models. This signature, particularly relevant in the context of the Large Hadron Collider (LHC) measurements, is based on a topology with two charged leptons and four jets arising from first and second generation quarks. As an important benchmark scenario of the multi-Higgs models, we focus on a recently proposed Branco-Grimus-Lavoura (BGL) type model enhanced with an Abelian U(1) flavor symmetry and featuring an additional sector of right-handed neutrinos. We discuss how kinematics of the scalar fields in this model can be used to efficiently separate the signal from the dominant backgrounds and explore the discovery potential of the new heavy scalars in the forthcoming LHC runs. The proposed method can be applied for analysis of the statistical significance of heavy scalars' production at the LHC and future colliders in any multi-Higgs model.

I. INTRODUCTION

The current basis for our understanding of particle physics is leaning on the theoretical framework of the Standard Model (SM), which was ultimately confirmed by the discovery of the Higgs boson [1,2], whose properties closely match the SM expectations. Despite this, an explanation for neutrino masses, for the observed hierarchies in the fermionic sector and for the existence of dark matter cannot be accommodated in the SM. Possible solutions to the aforementioned questions require a new physics (NP) framework that typically incorporates new

scalar fields, including both electrically charged and neutral Higgs states with distinct CP properties.

The presence of multiple beyond the SM (BSM) particles can lead to interesting phenomenology at collider experiments, with a multitude of possible different final states. Indeed, over the years, various searches have been conducted by the experimental community, including decays that involve vector bosons [3–5], multijets [6,7], and charged leptons [8–10]. However, the presence of new scalars that interact and/or mix with one another lead to additional topologies, which have not been covered by experiments. In particular, decay chains featuring various BSM fields in internal propagators offer a solid physics case to test generic multi-Higgs models at the LHC. In this regard, while there have been a number of recent searches [11,12], they have been limited in scope, especially when compared to topologies where a BSM field decays immediately into a pair of SM particles. Therefore, the proposal in this article aims at filling such a gap and enlarging the explored parameter space in view of the LHC run-III, which is already collecting data, and of the upcoming High-Luminosity (HL) upgrade.

In this regard, we consider a particular example of a multi-Higgs model featuring the Branco-Grimus-Lavoura (BGL) flavor structure [13] as a benchmark for our

phenomenological analysis. Besides the two Higgs doublets and a complex singlet scalar charged under a global flavor U(1) symmetry, the model also incorporates an additional sector with three generations of right-handed neutrinos and a type-I seesaw mechanism for the generation of light neutrino masses, which was recently explored by some of the authors in [14]. In this work, a comprehensive phenomenological analysis of this model has been performed, where electroweak (EW) precision, Higgs, flavor, and the existing collider observables were scrutinized. A selection of the phenomenologically validated points are then used as benchmark scenarios for exploring the discovery potential of the heavy neutral BSM scalars in the considered NP framework.

This article is organized as follows. In Sec. II, we briefly discuss a particular benchmark NP model that is chosen for our numerical analysis. In Sec. III, we give a general overview of the current experimental status regarding the search for heavy BSM scalar states at collider experiments. In Sec. IV, we discuss a number of processes involving such states that have been so far a subject of little or no attention in the literature. Here, we propose a new promising signature featuring a final state with four jets and a pair of charged leptons and with multiple neutral BSM scalars in internal propagators. In Sec. V, we present the details of the newly developed methodology, while in Sec. VI, we calculate the statistical significance for the discovery/exclusion of new Higgs states. Finally, in Sec. VII, we conclude and summarize our results.

II. BENCHMARK MODEL

The recently proposed BGL-like next-to-minimal two Higgs doublet model (BGL-NTHDM) has been thoroughly discussed both from the theoretical and phenomenological points of view in [14]. Here, for completeness of information, we briefly present its key features. The BGL structure results from a global flavor U(1) symmetry, broken once the Higgs doublets and the scalar singlet develop vacuum expectation values (VEVs) [13]. The allowed Yukawa interactions read as

$$\begin{aligned}
 -\mathcal{L}_{\text{Yukawa}} = & \overline{q_L^0} \Gamma_a \Phi^a d_R^0 + \overline{q_L^0} \Delta_a \tilde{\Phi}^a u_R^0 + \overline{\ell_L^0} \Pi_a \Phi^a e_R^0 \\
 & + \overline{\ell_L^0} \Sigma_a \tilde{\Phi}^a \nu_R + \frac{1}{2} \overline{\nu_R^c} (A + BS + CS^*) \nu_R + \text{H.c.},
 \end{aligned} \tag{2.1}$$

where the index $a = 1, 2$ runs over the two doublets Φ^a and all the matrices are written in the flavor basis, with Γ_a, Δ_a being the Yukawa matrices for down-quarks, up-quarks, and Π_a, Σ_a are the charged lepton and neutrino Yukawa matrices, respectively. Besides, here B and C are the Majorana-like Yukawa couplings with a complex SU(2) singlet scalar field S , whereas A is a Majorana mass term

for the right-handed neutrinos. We adopt the notation where $\tilde{\Phi} \equiv i\sigma_2 \Phi^*$ and the superscript 0 indicates that the fields are written in the gauge basis. The textures of the quark-sector Yukawa matrices are given as

$$\begin{aligned}
 \Gamma_1: & \begin{pmatrix} \times & \times & \times \\ \times & \times & \times \\ 0 & 0 & 0 \end{pmatrix}, & \Gamma_2: & \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ \times & \times & \times \end{pmatrix}, \\
 \Delta_1: & \begin{pmatrix} \times & \times & 0 \\ \times & \times & 0 \\ 0 & 0 & 0 \end{pmatrix}, & \Delta_2: & \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \times \end{pmatrix},
 \end{aligned} \tag{2.2}$$

while those of the charged and neutral leptons read as

$$\begin{aligned}
 \Pi_1, \Sigma_1, B = & \begin{pmatrix} \times & \times & 0 \\ \times & \times & 0 \\ 0 & 0 & 0 \end{pmatrix}, \\
 \Pi_2, \Sigma_2 = & \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & \times \end{pmatrix} \quad A = \mathbb{0}, \\
 C = & \begin{pmatrix} 0 & 0 & \times \\ 0 & 0 & \times \\ \times & \times & 0 \end{pmatrix}.
 \end{aligned} \tag{2.3}$$

In the gauge basis, the fermion mass matrices can be cast as

$$\begin{aligned}
 M_u^0 & \equiv \frac{1}{\sqrt{2}} (v_1 \Delta_1 + v_2 \Delta_2), \\
 M_d^0 & \equiv \frac{1}{\sqrt{2}} (v_1 \Gamma_1 + v_2 \Gamma_2), \\
 M_e^0 & \equiv \frac{1}{\sqrt{2}} (v_1 \Pi_1 + v_2 \Pi_2),
 \end{aligned} \tag{2.4}$$

where u, d, e denote up, down quarks, and charged leptons, while v_1 and v_2 are the VEVs arising from the first and second Higgs doublets, respectively. Such mass matrices can be rotated to the physical basis via bi-unitary transformations.

Generically, each fermion $f = u, d, e$ can be diagonalized as follows:

$$N_f = U_{fL}^\dagger M_f^0 U_{fR}, \tag{2.5}$$

where U are the unitary matrices, with the subscripts L(R) denoting left (right) chirality, and N_f are the diagonal fermion mass matrices. It follows from the textures in Eqs. (2.2) and (2.3) that both the charged lepton and up-quark Yukawa matrices can be simultaneously

diagonalized, and therefore, there are no tree-level FCNCs for both sectors. For down-quarks, Γ_1 and Γ_2 can not be simultaneously diagonalized, and therefore, FCNCs will be present readily at tree level, mediated by new BSM scalars. As in the standard BGL construction [13], the effect of the global flavor symmetry results in a suppression of FCNCs by the off diagonal elements of the Cabibbo-Kobayashi-Maskawa (CKM) matrix.

While not particularly relevant for the current study, the model also features an additional sector of massive right-handed neutrinos, which, for completeness, is briefly outlined below (for more details, see [14]). Defining the neutrino fields as

$$n_L^0 \equiv \begin{pmatrix} \nu_L^0 \\ \nu_R^c \end{pmatrix}, \quad (2.6)$$

the mass matrix can be cast in the standard seesaw format as

$$\mathcal{M} \equiv \begin{pmatrix} \mathbb{0} & m_D \\ m_D^T & M_R \end{pmatrix}, \quad (2.7)$$

where one defines

$$m_D \equiv \frac{1}{\sqrt{2}}(v_1 \Sigma_1 + v_2 \Sigma_2),$$

$$M_R \equiv A + \frac{v_S}{\sqrt{2}}(B + C), \quad (2.8)$$

and v_S is the VEV in the real component of the complex scalar singlet. As it was noted in our previous work [14], the model possesses enough freedom to simultaneously fit the Pontecorvo-Maki-Nakagawa-Sakata (PMNS) neutrino mixing matrix and the active neutrino mass differences.

The scalar potential is defined as $V = V_0 + V_1$, with

$$V_0 = \mu_a^2 |\Phi^a|^2 + \lambda_a |\Phi^a|^4 + \lambda_3 |\Phi_1|^2 |\Phi_2|^2 + \lambda_4 |\Phi_1^\dagger \Phi_2|^2$$

$$+ \mu_S^2 |S|^2 + \lambda'_1 |S|^4 + \lambda'_2 |\Phi_1|^2 |S|^2 + \lambda'_3 |\Phi_2|^2 |S|^2,$$

$$V_1 = \mu_3^2 \Phi_2^\dagger \Phi_1 + \frac{1}{2} \mu_b^2 S^2 + a_1 \Phi_1^\dagger \Phi_2 S + a_2 \Phi_1^\dagger \Phi_2 S^\dagger$$

$$+ a_3 \Phi_1^\dagger \Phi_2 S^2 + \text{H.c.} \quad (2.9)$$

While V_0 contains the quartic couplings $(\lambda_{1,2,3,4}, \lambda'_{1,2,3})$ and the quadratic mass terms $(\mu_{1,2,S}^2)$, V_1 contains the soft U(1)-breaking interactions $(\mu_3, \mu_b, a_{1,2})$, as well as the quartic coupling between the singlet and the two Higgs doublets (a_3) invariant under the U(1) flavor symmetry. Once the scalars develop VEVs, six physical states emerge, including three CP -even neutral scalars $H_1, H_2,$ and $H_3,$

with H_1 corresponding to the SM-like Higgs boson, two CP -odd neutral scalars A_2 and $A_3,$ and a charged scalar $H^\pm.$

III. HEAVY HIGGS PARTNERS AT THE LHC

Multi-Higgs models provide a plethora of new scalar states that can be either charged or neutral and possess CP -even or CP -odd properties, leading to characteristic signatures in collider measurements. A summary of the most recent searches, performed in years of 2020 and 2021 at both the CMS and ATLAS experiments, is shown in Table I. Various combinations of final states have been searched for, particularly, for the neutral fields commonly referred to as Higgs partners, H and $A,$ including final states with light jets, b jets and charged leptons. It is also interesting to note that searches involving decays into other BSM fields are also included, such as $A \rightarrow HZ^0$ in [12] and $H \rightarrow AA$ in [10]. These channels are of particular relevance for the Higgs partners' search since interactions between different BSM scalars are common to most (if not all) multi-Higgs extensions of the SM. We do note that in [10], the search focused in the low-mass regime for the CP -odd scalar, complementing the high-mass regime in ATLAS for the processes $A \rightarrow \tau^+ \tau^-$ and $A \rightarrow \tau^+ \tau^- b \bar{b}$ [8] and $A \rightarrow \gamma \gamma$ [3], has been performed. Note, the CP -odd (A) and CP -even (H) scalars often share the same final states as highlighted in Table I.

Regarding the charged Higgs bosons, some searches have also been reported recently, with a focus on the tbH^+ vertex, either through decay into tb [17,18] or considering a charged Higgs state produced via a top/antibottom pair [7]. An additional search focusing on the vector-boson fusion (VBF) mechanism was also performed by CMS [19]. The top/antibottom channel appears to be the preferred channel in the search for charged Higgs bosons, corroborated by previous searches in [20–26]. Indeed, these studies indicate that for a charged Higgs state with a mass below that of the top quark, it will be predominantly produced via top quark decays, whereas heavy charged scalars would be typically produced in association with a top quark [27,28]. For masses below the kinematic threshold for the production of a top quark, the decay modes $H^\pm \rightarrow \tau^\pm \nu_\tau$ become dominant [27,28].

Besides the searches in [3,10] (see also Table I), the preference in the literature has been given to the BSM scenarios where new scalars purely decay into SM states. However, multi-Higgs models enable interactions among different BSM scalars such that a richer set of final states involving multiple scalars is possible and must be considered as discussed below.

IV. LHC PHENOMENOLOGY OF BSM SCALARS

The model considered in this article was previously validated in [14], where several points consistent with EW, Higgs, collider, and flavor physics observables were

TABLE I. A summary of the most recent searches conducted between the years of 2020 and 2021 by the ATLAS and CMS experiments at the LHC. Here, H_1 is the SM-like Higgs boson, A represents a neutral pseudoscalar, H is a CP -even neutral scalar, and H^\pm is a charged scalar. Here, “BR” stands for the corresponding branching ratio. As for the production mechanisms of the Higgs states, “ggF” indicates the gluon-gluon fusion, while “VBF” corresponds to the vector boson fusion.

| Scalar field | Decay channel | Mass limits (GeV) | Comments | References |
|-------------------------|--------------------------------------|-------------------|--|------------|
| A | $A \rightarrow \tau^+\tau^-$ | [200, 2500] | Limits given in terms of $\sigma \times \text{BR}$ | [8] |
| | $A \rightarrow \tau^+\tau^-b\bar{b}$ | [200, 2500] | Limits given in terms of $\sigma \times \text{BR}$ | [8] |
| | $H_1 \rightarrow AZ^0$ | [0.5, 4.0] | Hadronic decays with $\text{BR}(A \rightarrow gg) = 1$ or $\text{BR}(A \rightarrow s\bar{s}) = 1$ | [11] |

| | $H^\pm \rightarrow W^\pm Z^0$ | [200, 1500] | Considers VBF production Limits as $\sigma \times \text{BR}$ | [19] |
| | $H^\pm \rightarrow cs$ | [80, 160] | Assumes $\text{BR}(H^\pm \rightarrow cs) = 1$ Limits as $\text{BR}(t \rightarrow H^+b)$ vs m_{H^+} | [7] |

found.¹ In particular, it was shown that scenarios with light scalars, i.e., being not too far above the Higgs boson mass, are still allowed and can be potentially probed at the LHC run-III or its high-luminosity (HL) phase. Testing these possibilities is, therefore, of phenomenological interest. Our focus here is on either single or double-production channels for the new physics states present in the model, in particular, charged-, (H^\pm), neutral- (H_2 and H_3), and pseudoscalars (A_2 and A_3). While a multitude of topologies for collider searches of these states can be proposed, our current analysis

is dedicated to a single production process featuring the final states of four jets and two charged leptons and leaving other possible topologies for a future work.

A. CP -even neutral scalars

The model considered in this work features two CP -even scalars $H_{2,3}$ with different couplings, masses (satisfying $m_{H_3} > m_{H_2}$) and branching ratios (BRs) for separate decay modes. In what follows, both $H_{2,3}$ are assumed to be heavier than the Higgs boson (denoted as H_1). Here, we are only interested in channels with sizeable BRs by requiring them to be greater than 20%. As it was previously shown in [14], the decay channels with small BRs typically result in small cross sections, even below the allowed sensitivity of the HL phase of the LHC. With this in mind, we have

¹Some of the data and the UFO model (both Python2 and Python3 versions) are publicly available in one of the author’s GitHub page (see <https://github.com/Mrazi09/BGL-ML-project>). The numerical values for the various couplings/masses is also shown in Appendix B.

selected six preferred scenarios among the valid parameter-space points of [14], for which the characteristics of the next-to-lightest Higgs state H_2 —the mass and the dominant BR—read as

| | |
|---------------------------------------|--|
| Benchmark H1: $M_{H_2} = 599.09$ GeV, | $\text{BR}(H_2 \rightarrow A_2 Z^0) = 90.7\%$, |
| Benchmark H2: $M_{H_2} = 286.92$ GeV, | $\text{BR}(H_2 \rightarrow H_1 H_1) = 66.7\%$, |
| Benchmark H3: $M_{H_2} = 527.55$ GeV, | $\text{BR}(H_2 \rightarrow A_2 Z^0) = 52.1\%$, |
| Benchmark H4: $M_{H_2} = 397.45$ GeV, | $\text{BR}(H_2 \rightarrow A_2 Z^0) = 41.7\%$, |
| Benchmark H5: $M_{H_2} = 215.56$ GeV, | $\text{BR}(H_2 \rightarrow c\bar{c}) = 56.0\%$, |
| Benchmark H6: $M_{H_2} = 402.81$ GeV, | $\text{BR}(H_2 \rightarrow A_2 Z^0) = 89.6\%$, |

that are worth of a dedicated phenomenological analysis. Note, however, that single H_2 production processes with the dominant decay channels corresponding to those of the benchmarks H1, H2, H3, H4, and H6 have already been studied at the LHC. In particular, the most recent H_2 searches in the H1, H3, H4, and H6 channels are already indicated in Table I. Besides, final states with at least two b jets were considered for the benchmark H2 [29–34]. Notice that the benchmark H5, whose BR into a pair of charm quarks is 56%, represents a rather attractive physics case motivating the searches involving light jets in the final state. Of course, a fully hadronic signal is not optimal in the context of the LHC since the SM multijet background is expected to dominate over the signal. While fully hadronic final states have been searched for at the ATLAS

experiment (see, e.g., [6,35–37]), such a signature can become a lot cleaner, e.g., at future lepton colliders.

With this in mind, one may consider two possible cases—double and single H_2 production—separately. For the latter case, the focus is typically on associated production with a Z^0 boson (see Fig. 1) subsequently decaying into a pair of leptons, thus minimizing the relevant QCD backgrounds. For the former case, all leading-order (LO) diagrams are shown in Fig. 2, where both s and t channels contribute to the matrix element. Additionally, the gluon-gluon fusion mode is relevant and needs also to be included in the calculation. The major ingredients of the background are represented by diboson, $V + \text{jets}$ and $t\bar{t}$ production modes that will be carefully considered in what follows.

FIG. 1. The LO Feynman diagrams for production of the single H_2 CP -even scalar in the s channel (top two diagrams) and the t channel (bottom diagram) processes. Here, q denotes the SM quarks, g corresponds to a gluon, and $A_{i=2,3}$ —to CP -odd scalars, while j stands for a jet originating from the physical quarks of first and second generations u, s, d, c , and their antiparticles.

FIG. 2. The LO Feynman diagrams for pair-production of the H_2 CP -even scalars in the s channel (top two diagrams) and the t channel (bottom diagram) processes. Here, q denotes the SM quarks, g corresponds to a gluon, and $H_{i=1,2,3}$ —to CP -even scalars, while j stands for a jet originating from the physical quarks of first and second generations u, s, d, c , and their antiparticles.

We can now focus our attention on the heaviest scalar state, H_3 . Again, we are interested in points with BRs higher than 20%. Considering the same benchmark scenarios as above,

| | |
|---------------------------------------|---|
| Benchmark H1: $M_{H_3} = 907.61$ GeV, | $BR(H_3 \rightarrow A_2A_2) = 79.0\%$, |
| Benchmark H2: $M_{H_3} = 741.53$ GeV, | $BR(H_3 \rightarrow H^+W^-) = 22.3\%$, |
| Benchmark H3: $M_{H_3} = 724.46$ GeV, | $BR(H_3 \rightarrow A_2A_2) = 35.6\%$, |
| Benchmark H4: $M_{H_3} = 705.62$ GeV, | $BR(H_3 \rightarrow A_2Z^0) = 33.9\%$, |
| Benchmark H5: $M_{H_3} = 626.92$ GeV, | $BR(H_3 \rightarrow H^+H^-) = 50.3\%$, |
| Benchmark H6: $M_{H_3} = 439.59$ GeV, | $BR(H_3 \rightarrow A_2Z^0) = 66.9\%$, |

one can deduce topologies that are distinct from those of the H_2 scalar. While a number of interesting channels can be derived from here, one may disregard the benchmarks H1 and H3 as the corresponding decay channel $H_3 \rightarrow A_2A_2$ has already been studied in dedicated experimental analyses [9,10,16]. Additionally, we note that for the benchmarks H4 and H6, there have already been searches performed by ATLAS [12] focusing on the inverse channel, $A \rightarrow HZ^0$. Our current work represents a novel analysis of H_3 production in the benchmark scenarios H2 and H5 whose final-state topologies, to the best of our knowledge, have not yet been investigated by LHC experiments. Indeed, the corresponding decays are of great interest as they allow us to simultaneously probe the masses and/or couplings of both the neutral and charged scalars, with the

latter decaying before reaching the detector. For this purpose, one should consider the largest corresponding BRs which, for the benchmark H2, read as

$$BR(H^+ \rightarrow A_2W^+) = 72.6\%, \quad BR(A_2 \rightarrow c\bar{c}) = 97.3\%.$$

Combining this information, the proposed topology is shown in Fig. 3. As one can notice, this results in a rich final state featuring four jets originating from quarks, one muon and a neutrino that acts as missing transverse energy (MET) in the detector. Besides, note that three of the new scalars contribute in the internal propagators as virtual states within the same topology, thus, opening up a new possibility to constrain the charged, the CP -even and the CP -odd sectors with a single process.

FIG. 3. The LO Feynman diagrams for production of the single H_3 CP -even scalar. Here, q denotes the SM quarks and j stands for a jet originating from the physical quarks of first and second generations u, s, d, c , and their antiparticles. While not explicitly shown here, the gluon-gluon fusion contribution may play an important role in the cross section and hence has been included in the numerical analysis.

In order to ensure that H_3 and H^\pm are produced on shell, one requires the following mass hierarchy:

$$M_{H_3} > M_{H^\pm} + M_W, \quad M_{H^\pm} > M_{A_2} + M_W. \quad (4.1)$$

| | |
|---------------------------------------|--|
| Benchmark H1: $M_{A_2} = 314.99$ GeV, | $\text{BR}(A_2 \rightarrow c\bar{c}) = 86.5\%$, |
| Benchmark H2: $M_{A_2} = 159.20$ GeV, | $\text{BR}(A_2 \rightarrow c\bar{c}) = 97.3\%$, |
| Benchmark H3: $M_{A_2} = 205.41$ GeV, | $\text{BR}(A_2 \rightarrow c\bar{c}) = 97.3\%$, |
| Benchmark H4: $M_{A_2} = 188.01$ GeV, | $\text{BR}(A_2 \rightarrow c\bar{c}) = 97.3\%$, |
| Benchmark H5: $M_{A_2} = 177.49$ GeV, | $\text{BR}(A_2 \rightarrow c\bar{c}) = 96.9\%$, |
| Benchmark H6: $M_{A_2} = 217.36$ GeV, | $\text{BR}(A_2 \rightarrow c\bar{c}) = 96.7\%$. |

We notice that for these scenarios that we have picked, A_2 almost always decays into $c\bar{c}$ pair. So far, most searches at the LHC have focused on the lepton channel (see Table I and references therein) and mostly on the low-mass domain [9,16], $m_A < 62$ GeV, i.e., well below the A_2 masses in the above benchmarks. Please do note that the pattern of high BRs to a pair of c quarks should not be interpreted as a feature of the model. Indeed, there are valid parameter points where such decays are not dominant.

For the benchmark scenario H2, the condition (4.1) is satisfied, with $M_{H^\pm} = 448.52$ GeV and $M_{A_2} = 188.01$ GeV. Based on the ATLAS analysis [38], for this type of topology, the main backgrounds include $t\bar{t}$ + jets, V + jets (with $V = W, Z^0$), and single top production. An additional sizeable contribution from fakes (events with either jet or photon that are mistagged as a lepton) and nonprompt leptons (leptons that originate from decays from the hadronized quarks in the jets) is also relevant. For the benchmark H5, the neutral scalar would decay into a pair of charged Higgs bosons. However, based on the available branching ratios, the dominant decays would proceed into a $c\bar{c}$ pair, with $\text{BR}(H^\pm \rightarrow c\bar{c}) = 92.8\%$, resulting in an undesirable fully hadronic final state.

B. CP -odd neutral scalars

In addition to the CP -even states discussed above, our framework features two heavy CP -odd fields, A_2 and A_3 (with the mass hierarchy of $m_{A_2} < m_{A_3}$) whose signal and background topologies will also be analyzed in this work. Again, here we focus on specific topologies suggested by $A_{2,3}$ decay modes with the largest BRs. Starting with the lightest one, A_2 , the corresponding masses and the dominant BRs for the benchmark scenarios from H1 to H6 read

In what follows, we would like to consider the topologies involving A_2 decays into light jets. In particular, we consider very similar topologies to those already shown in Figs. 1 and 2, with the replacement $H_2 \rightarrow A_2$. Various LO diagrams that contribute to such a signal are shown in Figs. 4 and 5. Since the final states are identical to those of H_2 , the main irreducible backgrounds remain the same as for the H_2 topologies considered above.

For the heavier CP -odd state, A_3 , the dominant BRs read as

FIG. 4. The LO Feynman diagrams for production of the single A_2 CP-odd scalar in the s channel (top two diagrams) and the t channel (bottom diagram) processes. Here, q denotes the SM quarks, g corresponds to a gluon, and $H_{i=1,2,3}$ —to CP-even scalars, while j stands for a jet originating from the physical quarks of first and second generations u, s, d, c (and their antiparticles) and $\ell = e, \mu$ denotes the first and second generation charged leptons (and their antiparticles).

FIG. 5. The LO Feynman diagrams for pair production of the A_2 CP-even scalars in the s channel (top two diagrams) and the t channel (bottom diagram) processes. Here, q denotes the SM quarks, g corresponds to a gluon, and $H_{i=1,2,3}$ —to CP-even scalars, while j stands for a jet originating from the physical quarks of first and second generations u, s, d, c and their antiparticles.

| | |
|---------------------------------------|--|
| Benchmark H1: $M_{A_3} = 955.09$ GeV, | $\text{BR}(A_3 \rightarrow A_2 H_2) = 24.5\%$, |
| Benchmark H2: $M_{A_3} = 566.75$ GeV, | $\text{BR}(A_3 \rightarrow H_2 Z^0) = 44.4\%$, |
| Benchmark H3: $M_{A_3} = 707.60$ GeV, | $\text{BR}(A_3 \rightarrow H^+ W^-) = 36.1\%$, |
| Benchmark H4: $M_{A_3} = 611.07$ GeV, | $\text{BR}(A_3 \rightarrow H_2 Z^0) = 38.78\%$, |
| Benchmark H5: $M_{A_3} = 683.60$ GeV, | $\text{BR}(A_3 \rightarrow H^+ W^-) = 27.1\%$, |
| Benchmark H6: $M_{A_3} = 772.32$ GeV, | $\text{BR}(A_3 \rightarrow A_2 H_2) = 59.6\%$. |

Combining this information with that of Table I, we note that the preferred channels in the search for A_3 would rely on $A_3 \rightarrow A_2 H_2$ (in the benchmark scenarios H1 and H6) or $A_3 \rightarrow H^+ W^-$ (in the benchmark scenarios H3 and H5) decays. The remaining benchmarks H2 and H4 result in topologies that have been probed already by ATLAS Collaboration in [12]. Both dominant A_3 decay modes in H1/H6 and H3/H5 are interesting since the vast majority of analyses performed at the LHC so far typically do not consider decay channels that involve multiple BSM particles in the internal propagators (the existing examples are listed in Table I), which results in considerably weaker constraints on these decay modes.

In our analysis, we first focus on the decay $A_3 \rightarrow A_2 H_2$ which is dominant in the benchmark scenarios H1 and H6. Then, combining with the information on the BRs for H_2 and A_2 shown above, we deduce that the optimal final state in this case would be $4j + 2\ell$, where we assume a Z^0 boson decaying into a pair of leptons. The LO Feynman diagram for such a topology is shown in Fig. 6, with the background being dominated by $Z^0 + \text{jets}$, $t\bar{t}$ and diboson production processes.

C. Charged scalars

For each of the six considered benchmark points, the masses and the largest BRs for the charged scalar H^\pm read as

| | |
|---|--|
| Benchmark H1: $M_{H^\pm} = 566.40$ GeV, | $\text{BR}(H^+ \rightarrow A_2 W^+) = 93.6\%$, |
| Benchmark H2: $M_{H^\pm} = 411.94$ GeV, | $\text{BR}(H^+ \rightarrow A_2 W^+) = 72.6\%$, |
| Benchmark H3: $M_{H^\pm} = 524.70$ GeV, | $\text{BR}(H^+ \rightarrow A_2 W^+) = 91.0\%$, |
| Benchmark H4: $M_{H^\pm} = 448.52$ GeV, | $\text{BR}(H^+ \rightarrow A_2 W^+) = 88.8\%$, |
| Benchmark H5: $M_{H^\pm} = 156.89$ GeV, | $\text{BR}(H^+ \rightarrow c\bar{s}) = 92.8\%$, |
| Benchmark H6: $M_{H^\pm} = 330.88$ GeV, | $\text{BR}(H^+ \rightarrow A_2 W^+) = 63.8\%$. |

Here, one notices that there are two interesting distinct scenarios that can be probed at the LHC. In particular, the benchmarks scenarios H1 to H4 and H6 result in the following process: $pp \rightarrow H^+ \rightarrow A_2 W^+ \rightarrow jj\ell^+\nu_\ell$. Note that the majority of the experimental studies focusing on the charged Higgs boson search assume its production via the tbH^+ coupling. The more interesting and novel channels that can be considered are those where H^+ is produced via lighter quarks as shown by a LO diagram in Fig. 7. Additionally, for the benchmark H5, the H^+ coupling to light quarks, $c\bar{s}$, is dominant. Indeed, as noted throughout this work, a substantial part of the preferred decay channels of the new scalars tend to be those involving decays to light quarks, which are not well constrained by collider measurements so far. The main irreducible background is expected to be dominated by $W + \text{jets}$, diboson, and $t\bar{t}$ production processes.

D. Production cross sections

For the topologies introduced above, we have computed the corresponding production cross sections for proton-proton collisions at the centre-of-mass energy of $\sqrt{s} = 14$ TeV using MadGraph. These results are listed in Table II. One can readily observe that every single topology for the selected benchmarks shown in Table II can potentially be probed both at the LHC Run-III and at the HL-LHC. Note that all considered signal processes are within the reach of the current data for the run-II luminosity of $\mathcal{L} = 139 \text{ fb}^{-1}$. It is then possible to look for these signals without having to wait for new batches of data.

In fact, we can deduce from such a simple calculation that the single A_3 production process is the most challenging for future searches, with the smallest amount of expected events, *i.e.*, $N = 17$ at the LHC run-III and $N = 178$ at the HL-LHC. On the other hand, production

FIG. 6. The LO Feynman diagrams for production of the single A_3 CP -odd scalar. Here, q denotes the SM quarks, j stands for a jet originating from the physical quarks of first and second generations u, s, d, c (and their antiparticles) and $\ell = e, \mu$ denotes the first and second generation charged leptons (and their antiparticles). While not explicitly shown here, the gluon-gluon fusion contribution may play an important role in the cross section and hence has been included in the numerical analysis.

FIG. 7. The LO Feynman diagrams for production of the single H^+ charged Higgs scalar. Here, q denotes the SM quarks and j stands for a jet originating from the physical quarks of first and second generations u, s, d, c and their antiparticles.

of such a scalar leads to a very interesting final state, with four jets and two charged leptons. In this case, the jets originate from A_2 , whose mass in the selected benchmark

scenarios varies between 150 and 400 GeV. As noted in [38], the most relevant background processes for this type of processes are due to $Z^0 + \text{jets}$ and $t\bar{t}$ final states, while the other contributions are subleading. Besides requiring that the invariant mass of the lepton pair is close to the mass of the Z^0 boson, one also requires that the invariant mass of two jet pairs is in a vicinity of the A_2 mass (see Fig. 6), thus enabling one to reduce the dominant $Z^0 + \text{jets}$ background. In addition, the fact that the signal features a high-multiplicity of jets may also help in reducing the dominant background. In this work, we perform a detailed analysis of the single A_3 production process shown in Fig. 6. A similar treatment of other topologies is left for a future work.

V. SINGLE A_3 PRODUCTION: FEATURE SELECTION AND CUTS

The events are generated for proton-proton collisions and at the maximal LHC center-of-mass energy of $\sqrt{s} = 14$ TeV for both the signal processes illustrated in Fig. 6 and the background processes discussed in [38]. In practical calculations, we adopt the QCD collinear parton distribution functions in the proton, the strong coupling constant and their evolution from the NNPDF2.3 analysis [39].

Our study starts with the model implementation in SARAH [40], where the Lagrangian in the gauge basis has been implemented. From SARAH, we compute all interaction vertices in the mass basis and export them to MadGraph (MG5) [41], which is used to compute the matrix elements for signal, $Z^0 + \text{jets}$ and diboson background topologies at the LO level. The cross sections for $t\bar{t}$ and single- t background processes have been adopted from the literature instead. In particular, the $t\bar{t}$ production cross section is normalized to the theoretical calculation at next-to-next-to leading order (NNLO) in perturbative QCD. The mass dependence of the $t\bar{t}$ cross section can be parametrized by [42]

$$\sigma(m_t) = \sigma(m_{\text{ref}}) \left(\frac{m_{\text{ref}}}{m_t} \right)^4 \left[1 + a_1 \left(\frac{m_t - m_{\text{ref}}}{m_{\text{ref}}} \right) + a_2 \left(\frac{m_t - m_{\text{ref}}}{m_{\text{ref}}} \right)^2 \right], \quad (5.1)$$

TABLE II. The predicted total cross sections σ (in fb) for each of the topologies introduced in the previous section. The calculation is made at the LO level. Additionally, we present the expected numbers of events found as $N = \sigma \mathcal{L}$ at both the LHC run-III (at luminosity of $\mathcal{L} = 300 \text{ fb}^{-1}$) and the HL-LHC (at luminosity of $\mathcal{L} = 3000 \text{ fb}^{-1}$) phases.

| | Cross section | Events at run-III | Events at HL-LHC | Benchmarks |
|-------------------------------------|----------------------|-------------------|------------------|------------|
| Figure 1 (H_2 single production) | $\sigma = 0.172$ fb | 51 | 515 | H5 |
| Figure 2 (H_2 double production) | $\sigma = 0.350$ fb | 105 | 1050 | H5 |
| Figure 3 (H_3 single production) | $\sigma = 0.194$ fb | 58 | 582 | H2 |

| Figure 5 (A_2 single production) | $\sigma = 7.71$ fb | 2313 | 23130 | H4 |
| Figure 6 (A_3 single production) | $\sigma = 0.0594$ fb | 17 | 178 | H1 |
| Figure 7 (H^+ single production) | $\sigma = 34.5$ fb | 10350 | 103500 | H1 |

where m_t is the top-quark mass chosen in the Monte Carlo generator, m_{ref} is a reference mass scale, $\sigma(m_{\text{ref}})$ is the cross section at that scale, and $a_{1,2}$ are the fitting parameters. In MadGraph, we set the top mass at 173 GeV. For the values of the fitting parameters known from [43], the total $t\bar{t}$ cross section is $\sigma(m_t) = 985.543$ pb. Similarly, the next-to-leading order (NLO) corrections to the single-top production cross section are also included, providing us with: $\sigma(t - \text{channel}) = 248.05$ pb, $\sigma(s - \text{channel}) = 11.39$ pb, and $\sigma(Wt - \text{channel}) = 83.56$ pb (see [44] for further details).

For the signal topology, we separately generate samples of 600k events for each of the six benchmark scenarios described above, corresponding to different values of scalar bosons' masses and BRs. For this purpose, a total of 3M events for $Z^0 + \text{jets}$, 1M events for $t\bar{t}$, and 300k events for other processes (with diboson, single top, and $t\bar{t}$ plus vector boson final states) are generated. For the SM background one has used the default UFO codes and parameter cards available in MadGraph. Our samples contain up to four jets, emerging from both light and heavy quarks. For matching and merging of the jets to the original quarks, we rely on the automatic procedures available in MadGraph, which by default considers the kT-MLM matching scheme [45]. For jet tagging, we employ the following strategy: for each event, we pick all existing jets (which in practical terms involves getting all entries inside the `Jet` class on Delphes) and impose a b tagging method, such that then we can divide into a list of jets tagged as originating from b quarks and another list of jets not tagged as such, which we identify as a list of light jets. Since in the signal topology, we do not consider the case where the A_2 fields decay into b quarks, the list of b jets is discarded. We also do not apply any tau tagging algorithm in the selection of jets.

Since the LHC is a hadron collider, production of scalars via gluon-gluon fusion is also of relevance. While couplings between scalars and gluons are not present at tree-level, they appear at one-loop level via triangle quark loops.

This contribution is determined by considering the effective $gg\Phi$ coupling, where Φ is a scalar and g is the gluon. The computation of this effective coupling is done via SPheno [46] and has subsequently been used as an input in the MadGraph parameter card. Hadronization and showering of the final-state particles have been performed with PYTHIA8 [47]. Then, the fast simulation of the ATLAS detector is conducted with Delphes [48], from where we extract the relevant kinematic information about the final-state particles using ROOT [49].

The input data are composed of normalized multidimensional distributions based on kinematical and angular observables reconstructed from final state particles. The relevant kinematical variables are summarized in Table III. Note that, for our signal, the final state is comprised of four light jets meaning that, in general, one can not distinguish between the jets originating from the first A_2 state and those from the second one. However, through the use of kinematic properties, one can correctly match the jets with a particular A_2 they originate from. For instance, if all the jets are correctly matched to their original A_2 parent, the reconstructed invariant mass difference between A_2 states must be small, within a given threshold ε , i.e., $\Delta M \equiv M(j_1, j_2) - M(j_3, j_4) < \varepsilon$ GeV.

As such, in order to perform the correct matching, we take all the jets in each event and compute ΔM for every single combination. From those combinations that lead to a ΔM below the threshold, we select the smallest mass difference. In fact, such a restriction heavily impacts the backgrounds. Indeed, the mass difference between the two pairs of jets will unlikely be small, and as such the backgrounds are expected to lead to arbitrary values of ΔM , heavily reducing the backgrounds, in particular, the $Z^0 + \text{jets}$ one.

Once the jets have been correctly matched to the corresponding parent A_2 states, we need to also match one of the jet pairs and the lepton pair to the H_2 state.

TABLE III. Angular and kinematic observables selected for our study of the signal topology shown in Fig. 6. All variables are computed in the laboratory frame. To simplify the presentation, we define (j_a, j_b) to indicate different combinations of jets. Reconstructed variables involve various final states, which are shown in parentheses. Variables that involve A_3 are reconstructed using all final states ($A_3 = \sum_{i=1}^4 j_i^\mu + \ell^{\mu,+} + \ell^{\mu,-}$).

| | Dimensionful | Dimensionless | |

FIG. 8. The mass distributions for both A_2 and H_2 scalars for the benchmark H1. We adopt the notation such that $A_{2,1}$ is the A_2 that originates from the H_2 parent, whereas $A_{2,2}$ originates from A_3 . In the y axis, we show the normalized events, and we consider 30 bins for both signal and background components. The mass observables are displayed in units of GeV.

In particular, there must exist a given combination that approaches the decay threshold, $M_{H_2} = M_{A_2} + M_{Z^0}$. To determine this, we consider the jet combinations that most closely match the mass of H_2 to be the one associated with the upper A_2 blue whereas the other pair corresponds to the lower A_2 red as depicted in Fig. 6.

With this technique, we can successfully reconstruct all particles in the chain. Considering $\Delta M < 25$ GeV, this can be observed in Fig. 8, where the mass distributions of both A_2 and H_2 are presented. One notices a very well-defined Breit-Wigner shape, indicating a successful reconstruction. However, such a Breit-Wigner distribution is not perfect with an accumulation of events right below the mass peak (in particular, for the A_2 mass plots). This result indicates that the method achieves the full reconstruction leaving only some jet pairs that were incorrectly matched. However, since the peak is well defined, we are confident that the vast majority of combinations are correct. Naturally, using the Monte Carlo history, one can identify all the jets. However, that method can not be extended to real data, whereas using the detailed kinematical information of the jets can be more easily realized in experimental setups.

Besides the constraint on the mass difference, we also impose additional cuts which help to further separate signal and background events. In particular, we consider the following cuts:

$$\begin{aligned} p_T(\ell^\pm) &> 20 \text{ GeV}, \\ |\eta(\ell^\pm)| &\leq 2.47, \\ p_T(\text{jet}) &> 20 \text{ GeV} \\ |\eta(\text{jet})| &\leq 2.5 \quad \text{and} \\ M(\text{jet}) &> 15 \text{ GeV}. \end{aligned}$$

Since we have a large number of different kinematic/angular variables, it is expected that some of these do not offer any significant discriminating power. In particular, ϕ distributions are typically flat over the entire range of angles and tend to be poor discriminators between the signal and the background. As such, we tested multiple combinations of variables and selected the one giving the

best result, in a preanalysis phase with the Toolkit for Multivariate Data Analysis (TMVA) [50] library. From here, we have determined the set of best ten observables that offer a greater discrimination power of the signal over the background.

As a suitable example, let us focus on the sample H1, with masses of the BSM fields fixed as² $M_{H_2} = 600$ GeV, $M_{H_3} = 900$ GeV, $M_{A_2} = 300$ GeV and $M_{A_3} = 1$ TeV. In this analysis, we consider nine different classification tests included in the toolkit, namely the Fisher, Likelihood, BDT, BDTD, BDTG, BDTB, SVM, DNN, and MLP methods. We select the top ten observables which correspond to the method that offered the best accuracy in separating the signal from the backgrounds. In our case, we have found that the BDTD method performed the best. The observables that the BDTD method found to offer the best results are presented in Fig. 9. Our initial estimates indicate that the best observables are $\Delta\Theta(\ell_1, \ell_2)$, $\Delta\Theta(j_1, j_2)$, $\Delta\Phi(\ell_1, \ell_2)$, $\Delta R(\ell_1, \ell_2)$, $\cos(\theta_{\ell_1, \ell_2})$, $p_T(Z^0)$, $p_T(\ell_1)$, $p_T(j_1)$, $p_T(j_2)$, and $\Delta R(A_{2,1}, A_{2,2})$ including both kinematic and angular variables. Notably, the mass distributions are not advantageous for the signal-background separation, typically underperforming in the classification. While the mass distributions of the backgrounds such as $Z^0 + \text{jets}$ do not peak in the considered regions, the distributions from single-top and $t\bar{t}$ populate those domains of the phase space due to the top quark contribution running in internal propagators. In our analysis we have found that, indeed, angular distributions tend to offer a better separation than the kinematic ones. Additional information is shown in Fig. 10, where we plot the receiver operating characteristic (ROC) curves for the nine different methods of classification tests, and in Fig. 11, where we show the discriminant distributions for the three best performing methods—BDTD, BDT, and BDTG. Note that one can achieve a very good separation between the signal and the backgrounds using only the distributions shown in Fig. 9. We also notice that, despite some small fluctuations, the test

²For their exact values, see Sec. IV.

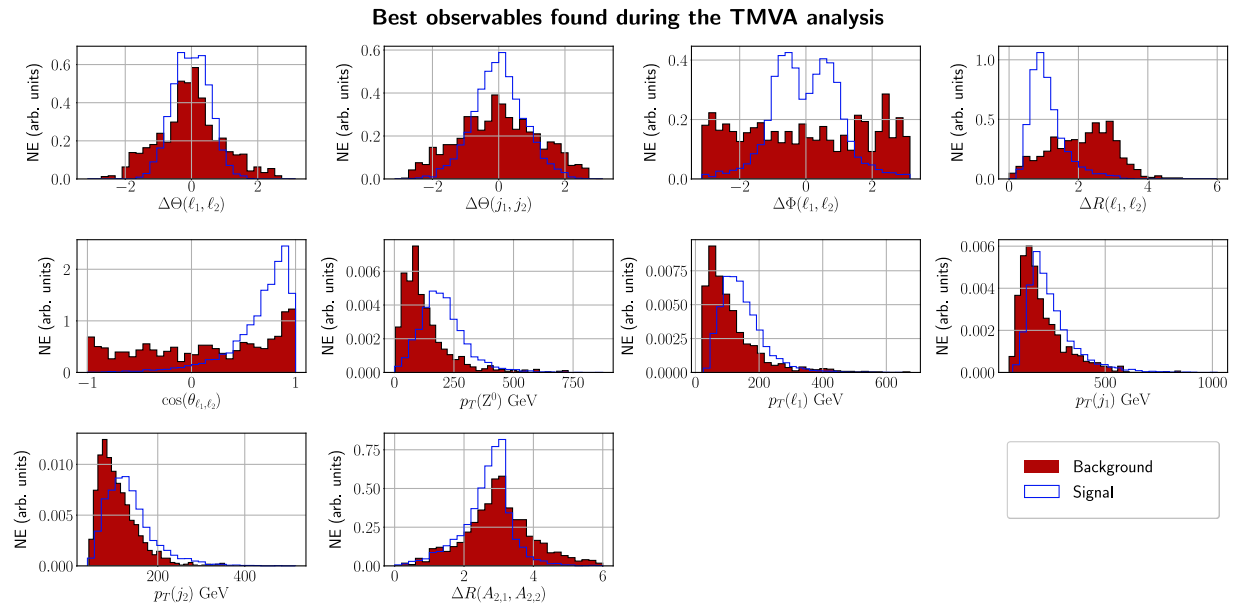

FIG. 9. The kinematic and angular observables which were given more importance in the classification by the TMVA toolkit, for the signal sample H1. Reading from left to right and top to bottom, we have $\Delta\Theta(\ell_1, \ell_2)$, $\Delta\Theta(j_1, j_2)$, $\Delta\Phi(\ell_1, \ell_2)$, $\Delta R(\ell_1, \ell_2)$, $\cos(\theta_{\ell_1, \ell_2})$, $p_T(Z^0)$, $p_T(\ell_1)$, $p_T(j_1)$, $p_T(j_2)$, and $\Delta R(A_{2,1}, A_{2,2})$. In y axis, we show normalized events and we consider 30 bins for both the signal and the backgrounds. Dimensionful observables are displayed in units of GeV. The signal histograms are shown in blue and the background ones—in red.

data, indicated with dots in Fig. 11, closely follow the results from the training dataset indicating low overfitting.

This analysis strongly suggests that we can achieve a very good signal-from-background separation. Of course, in order to be able to establish exclusion limits on the BSM particles, one needs to make sure that the cuts involved in

the analysis keep a substantial amount of the signal, while significantly reducing the corresponding backgrounds.

In Tables IV and V, we present the results for the predicted cross sections before and after imposing the selection criteria, as well indicating the number of expected events at both run-III and the HL phase of the LHC.

FIG. 10. ROC curves for each of the nine methods of classification tests in the TMVA analysis for the H1 benchmark.

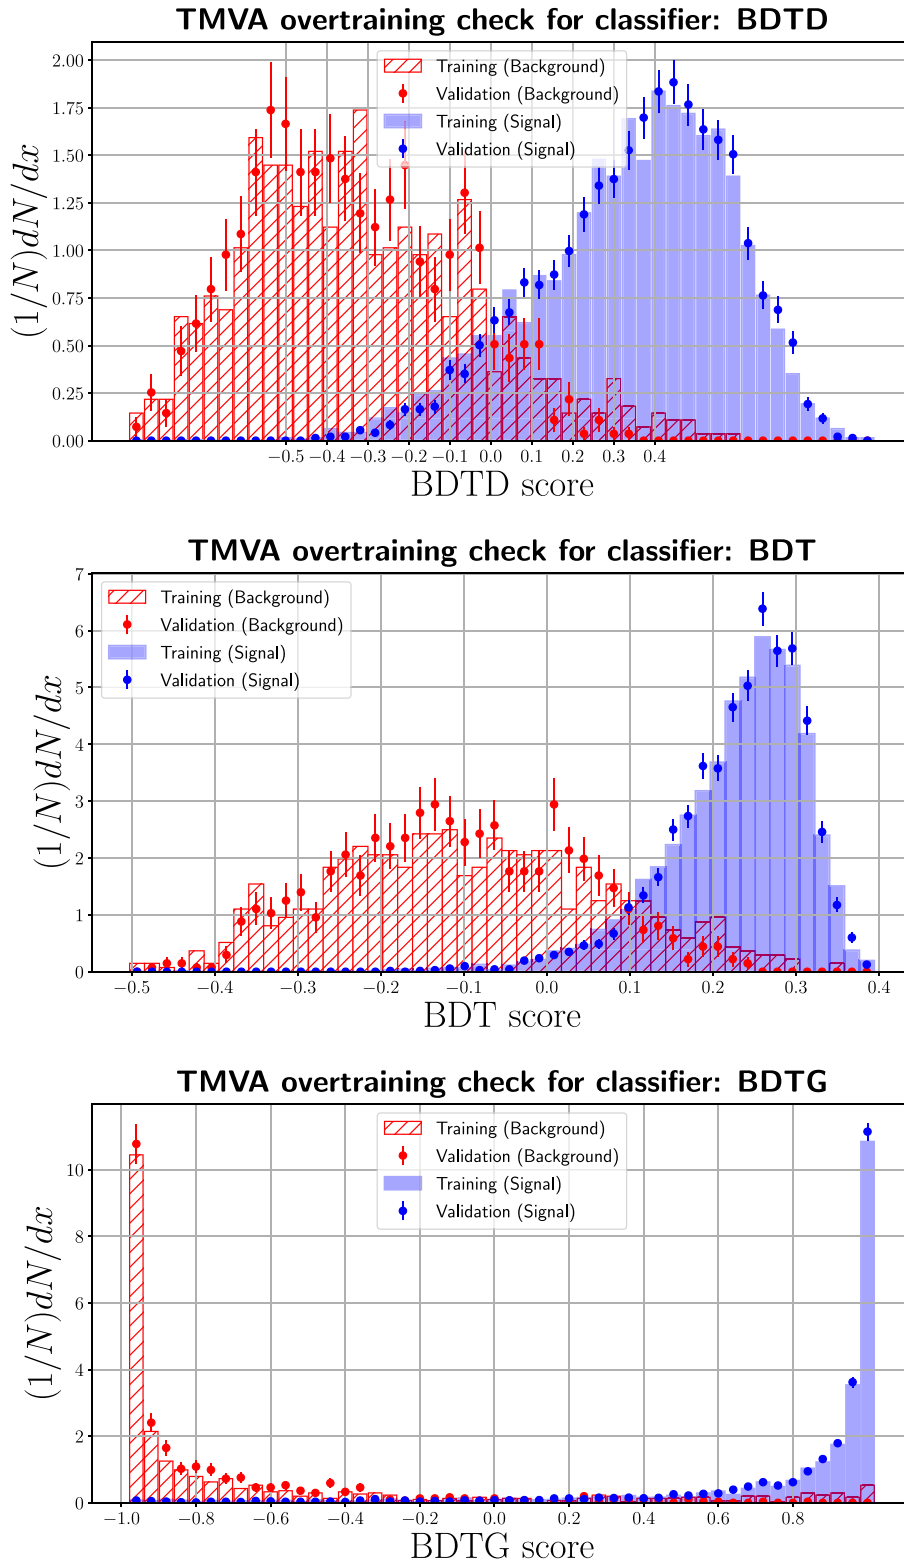

FIG. 11. Distributions of the BDTD (top), BDT (middle), and BDTG (bottom) discriminants for the signal (in blue) and the background (in red) corresponding to the H1 benchmark. The results from the training (histograms) and validation (points with error bars) datasets are superimposed.

TABLE IV. The predicted total cross section (in fb) for both the signal and each respective background, before and after the selection cut. In the last three columns, we indicate the number of expected events following the imposition of the selection criteria, calculated as $N = \sigma\mathcal{L}$ for run-III and the HL phase of the LHC, whereas for the last column, we showcase the total number of events for signal and backgrounds based on the NN cut that provided the maximal significance. For the benchmarks H2 to H5, no events survive after the imposition of the selection criteria, with $M(j) > 15$ GeV and $\Delta M < 25$ GeV.

| $t\bar{t} + V$ | 33.41 | 0.25 | 75 | 750 | |
| Diboson | 7.79×10^4 | 13.39 | 4017 | 40170 | |

In Table IV, in particular, the jet mass cuts are set at $M(j) > 15$ GeV and $\Delta M < 25$ GeV, whereas in Table V, the cuts are set to $M(j) > 10$ GeV and $\Delta M < 35$ GeV. First, we notice a massive reduction of the backgrounds. As an example, consider the most dominant one before the cuts, namely, $Z^0 + \text{jets}$. After the selection criteria are imposed, the background is reduced by almost 5–6 orders of magnitude, from 4.12×10^6 fb to 9.64 fb in Table IV and to 92.25 fb in Table V. The same conclusion holds for the remaining background processes. Indeed, unlike the analysis of [38], the $t\bar{t}$ and single top backgrounds now become more important than those from $Z^0 + \text{jets}$. Similar to [38], the diboson and $t\bar{t} + V$ backgrounds remain negligible.

Regarding the signal, we note that the more constraining cuts lead to a greater reduction of the cross section, as expected. For example, for the benchmark H1, we see from Table IV that the signal is reduced by 1 order of magnitude, from 0.0594 fb to 0.0064 fb, while from Table V, we have a reduction of the signal by a factor of 2. For the benchmark H2, the reduction is much sharper, from 0.16 fb to 0.000699 fb in Table IV and to 0.0048 fb in

Table V. Additionally, we have found that for the benchmarks H2, H3, H4, and H5, the imposed selection criteria are too restrictive and no signal events survive.

A sharp observed reduction of the signal for the benchmark H6 is related with the masses of the scalar fields in the decay chain. As noted in Sec. IV, the masses of scalars in benchmark H1 are larger in comparison to those in benchmark H6. Therefore, the outgoing jets originating from A_2 in benchmark H1 are expected to have higher p_T 's and masses in comparison to those originating from the H_2 scalar. Indeed, greater efficiencies are expected for the larger mass regions. Additionally, this reduction also implies a low number of events at the LHC. For the mass cuts of $M(j) > 15$ GeV and $\Delta M < 25$ GeV, we expect only two events at run-III and 19 events at HL-LHC, for the benchmark H1, whereas for the benchmark H6, we predict only two events surviving the considered cuts at the HL phase. Indeed, for these scenarios, probing such a signal topology may be difficult at run-III, as a low number of events associated with the stringent cuts on the mass of the jets may be overshadowed by systematic/statistical uncertainties present in a real experimental setup. In fact, by

FIG. 12. Statistical significance with the mass cuts $M(j) > 15$ GeV and $\Delta M < 25$ GeV. Results are shown for an integrated luminosity of 3000 fb^{-1} and for the NN architecture indicated in Table VIII of Appendix A.

FIG. 13. Statistical significance with the mass cuts $M(j) > 10$ GeV and $\Delta M < 35$ GeV. Results are shown for an integrated luminosity of 3000 fb^{-1} and for the NN architecture indicated in Table VII of Appendix A.

relaxing such selection criteria from $M(j) > 15$ GeV to $M(j) > 10$ GeV and from $\Delta M < 25$ GeV to $\Delta M < 35$ GeV, we notice from Table V that both benchmark scenarios can now be potentially probed at both run-III and HL-LHC. Although, note that for benchmark H6, only one event is expected at run-III.

Of course, these conclusions are taken from a limited sample of benchmark points, and it is possible that other coupling/mass combinations may lead to different conclusions. At any rate, the results from the considered benchmarks already indicate a nonzero number of expected events, which can enable one to set exclusion limits for the production of these scalars in different regions of the phase space.

VI. STATISTICAL SIGNIFICANCE WITH DEEP LEARNING

The determination of the statistical significance of the considered benchmark points is performed using evolutionary algorithms based on deep learning (DL) methods. The employed methodology is the same as in previous works by some of the authors [51–53], and thus in what follows, we only present the key features.

As detailed in [52], the inputs of the DL evolutionary method consist of normalized kinematic and angular distributions, which in the current analysis are shown in

Fig. 9. Additionally, due to the unbalanced nature of the various classes, i.e., some having more data entries than others, we use a SMOTE algorithm [54] to balance our dataset and use it as input data for the neural networks (NNs). The latter are constructed using TensorFlow [55].

Last but not least, the calculation of the statistical significance is performed using as metric the Asimov significance, defined as

$$\mathcal{Z}_{\mathcal{A}} = \left[2 \left((s+b) \ln \left(\frac{(s+b)(b+\sigma_b^2)}{b^2 + (s+b)\sigma_b^2} \right) - \frac{b^2}{\sigma_b^2} \ln \left(1 + \frac{\sigma_b^2 s}{b(b+\sigma_b)} \right) \right) \right]^{1/2}, \quad (6.1)$$

where s is the number of signal events, b is the number of background events and σ_b is the variance of the background events, with systematic uncertainties of 1%.³

³Based on the European strategy for particle physics (see [56]), both ATLAS and CMS, a guideline of 1%–1.5% systematic was set. Additionally, a recent update [57] improved this estimate to 0.83% based on the collected data from run-II, making a global 1% a realistic benchmark scenario for both run-III and the HL phase. We varied by a factor 2 around 1% systematics and have not found any significant deviations from the calculated values reported in the text.

TABLE VI. The statistical significance for each of the benchmarks/cuts mentioned in the text. Benchmark points that are not shown indicate that the signal cross section is too low for events to be produced at any given luminosity.

| Benchmarks | H1 $M(j) > 15 \text{ GeV}/\Delta M < 25 \text{ GeV}$ | H6 $M(j) > 15 \text{ GeV}/\Delta M < 25 \text{ GeV}$ |
|--------------------------------------|--|--|
| $300 \text{ fb}^{-1} \mathcal{Z}_A$ | 1.96σ | 0.27σ |
| $1000 \text{ fb}^{-1} \mathcal{Z}_A$ | 4.81σ | 0.80σ |
| $3000 \text{ fb}^{-1} \mathcal{Z}_A$ | 10.36σ | 2.02σ |
| Benchmarks | H1 $M(j) > 10 \text{ GeV}/\Delta M < 35 \text{ GeV}$ | H6 $M(j) > 10 \text{ GeV}/\Delta M < 35 \text{ GeV}$ |
| $300 \text{ fb}^{-1} \mathcal{Z}_A$ | 5.48σ | 1.29σ |
| $1000 \text{ fb}^{-1} \mathcal{Z}_A$ | 11.49σ | 2.95σ |
| $3000 \text{ fb}^{-1} \mathcal{Z}_A$ | 19.89σ | 5.12σ |

In what follows, we determine the statistical significance for our benchmark scenarios, considering first the scenario H1 and the HL phase of the LHC. We show the result in terms of the cut on the classifier score in Figs. 12 and 13. The numerical values for the employed cuts are determined by the NN and can be interpreted as a label for identifying whether a set of features can be classified either as signal or as a background event. From here, we also indicate the best Asimov significance obtained for each of the metrics, whose values for both of the employed cuts read as

$$\begin{aligned} \underline{(M(j) > 15/\Delta M < 35 \text{ GeV})}: \mathcal{Z}_A &= 19.89\sigma \\ \underline{(M(j) > 10/\Delta M < 25 \text{ GeV})}: \mathcal{Z}_A &= 10.36\sigma. \end{aligned} \quad (6.2)$$

Notice that, for both cases, we obtain a statistical significance well beyond 5σ , suggesting that the benchmark H1 is a good candidate to be tested at the LHC.

One can also confirm that more lenient constraints lead to a greater significance. Indeed, while more restrictive constraints on the phase space result in further reduced backgrounds, the expected number of events for the signal becomes larger when more lenient cuts are considered. Combining this with the good separation obtained between the background and the signal, see Fig. 11, the overall significance then becomes larger. For the case of the benchmark H6, at the HL phase, the statistical significance reads as

$$\begin{aligned} \underline{(M(j) > 15/\Delta M < 35 \text{ GeV})}: \mathcal{Z}_A &= 5.12\sigma \\ \underline{(M(j) > 10/\Delta M < 25 \text{ GeV})}: \mathcal{Z}_A &= 2.02\sigma, \end{aligned} \quad (6.3)$$

from where we conclude that for the more restrictive cuts, we can only probe this point with a significance of 2.02σ , whereas for more lenient ones, we obtain a statistical significance of 5.12σ . We have also found that this method works more efficiently for larger masses of the scalar fields inside the decay chain, as is the case of H1 in comparison to H6. This results from the fact that, for the lighter scalars'

scenarios, the cut on the invariant masses of the light jets can severely reduce the cross section.

For completeness, we also extended this analysis into luminosities of 300 fb^{-1} and 1000 fb^{-1} presenting the results in Table VI. In particular, we have found that the benchmark H1 can already be tested at run-III, with a significance of up to 5.48σ or 1.96σ , whether we consider the less restrictive or the more lenient selection criteria, respectively. For benchmark H6, on the other hand, it can only be tested at the HL phase of the LHC.

VII. CONCLUSION

In this article, we have conducted a collider phenomenological analysis using as an example model a BGL version of the NTHDM. We have focused on a potential signal topology characterized by two charged leptons and four jets in its final state. Based on Monte Carlo generated datasets, we have demonstrated that one can use the mass-difference information between two pairs of the jets in order to efficiently reconstruct all intermediate particles, while simultaneously damping the main irreducible backgrounds, such as $Z^0 + \text{jets}$. We have used the TMVA framework to identify the ten best observables that offer the greatest discriminating power between signal and background distributions. These were subsequently used as features in a deep-learning evolution algorithm engineered to find the neural network that best optimizes the statistical significance of a hypothetical discovery. We have employed such methods on preselected benchmark points, which are consistent with electroweak and flavor observables' constraints, and whose cross sections are high enough for it to be accessible at future collider experiments. In this regard, we found that one can potentially test the considered model with a statistical significance greater than 5 standard deviations, for both the LHC run-III and its future HL upgrade, depending on the benchmark and employed selection criteria.

More importantly, it is worth mentioning that the main take-away message of this study is that both the methods

and the considered signal topology are model independent and can be applied to any multiscalar scenario featuring, at least, three new physical neutral Higgs bosons allowed to couple in a triple vertex interaction.

APPENDIX B: NUMERICAL BENCHMARKS

Here, we write down the numerical values for the benchmark points that were studied in this work. The values indicated here are not exact, but rounded to 3 significant figures. For exact values, as well as some complementary information, see <https://github.com/Mrazi09/BGL-ML-project>. Quadratic mass terms are in units of GeV^2 ($\mu_1^2, \mu_2^2, \mu_3^2, \mu_b^2$, and μ_s^2) and masses are in units GeV ($M_{H_2}, M_{H_3}, M_{A_2}, M_{A_3}, M_{H^\pm}$). The VEV of the singlet field S is in unit of GeV (v_S),
