Local multiplicity fluctuations in hadronic Z decay

The L3 Collaboration

Abstract

 \mathbf{u} we turn in hadronic Z decays are studied using the l3 decays are studied using the l $t_{\rm max}$ at lep. Bunching parameters are used for the used for the addition to the $t_{\rm max}$ normalised factorial moment method. The bunching parameters directly demonstrate that the fluctuations in rapidity are multifractal. Monte Carlo models show agreement with the data, reproducing the trend, although not always the magnitude, of the factorial moments and bunching parameters.

Submitted to Phys. Lett. ^B

1 Introduction

Hadronic nal states of e⁺ e collisions provide a favourable environment for QCD studies. Initially, the hadronic system is simply a quark-antiquark pair. The energy of this pair is dissipated during a complex, non-linear QCD parton shower and non-perturbative hadronisation process. Monte Carlo (MC) programs incorporating the QCD parton shower and phenomenological models of hadronisation and resonance decay have been successful in describing global features.

In this paper we use high statistics data from the L3 experiment at LEP to study fluctuations in the charged particle multiplicity distribution in small regions of phase space, as a function of the size of the region. If particles were independently produced, the local multiplicity distribution would be a Poissonian. A deviation of this distribution from a Poissonian measures dynamical local multiplicity fluctuations, which are a consequence of short-range correlations between final-state particles. Parton showers, fragmentation, resonance decays and Bose-Einstein interference can all contribute to these correlations.

Fluctuations are often studied using the normalised factorial moments (NFMs) of the local multiplicity distribution, $P_n(\delta)$, which is the probability to find n particles inside a phase space bin of size δ [1]. The NFM of order q, $F_q(\delta)$, is defined by

$$
F_q(\delta) = \frac{\langle n^{[q]} \rangle}{\langle n \rangle^q}, \tag{1}
$$

$$
\langle n^{[q]} \rangle = \sum_{n=q}^{\infty} n^{[q]} P_n(\delta), \qquad n^{[q]} = n(n-1) \dots (n-q+1).
$$
 (2)

If $P_n(\delta)$ is a Poisson distribution, $F_q(\delta)=1$ for all q. If there are fluctuations, $F_q(\delta)$ deviates from unity. Further, if the fluctuations are self-similar, *i.e.*, $F_q(\lambda \delta) = \lambda^{-\phi_q} F_q(\delta)$, then a powerlike increase emerges with decreasing $o, \; r_q(o) \propto o^{-\gamma q},$ where the intermittancy indices $\varphi_q =$ $(q-1)d_q$, and d_q are the anomalous fractal dimensions. Local fluctuations are classified as monofractal (d_q is independent of q) or multifractal (d_q is a function of q). (See recent reviews [2]).

Local uctuations in e⁺ e processes have been studied in several experiments [3{11]. The data do indeed exhibit an approximate power-like rise of the NFMs with decreasing δ , especially when evaluated in two-dimensional phase space variables. All four lep experiments \mathbf{r} have found that current MC models can, in general, describe the NFMs, even without additional tuning. Exceptions have, however, been found in rapidity defined with respect to the sphericity axis by delivery by delay by delphibition charges charged charge-multiplicity and \mathbf{r}_1 regions).

Recently, it has been realized that the factorial moment method poorly reflects the information on local fluctuations, since the NFM of order q contains a contamination from lower-order correlation functions $[2]$. As a result, the nature of the fluctuations is difficult to determine from the behaviour of the NFMs. Factorial moments also suffer from a statistical bias due to the finite size of the event sample. This is because measurements of the NFMs are dominated by the first few terms of expression (2) . In most cases this leads to a significant underestimate of the measured NFMs with respect to their true values [12].

An alternative to the NFMs is provided by bunching parameters (BPs), $\eta_q(\delta)$, [13,14] which are defined by

$$
\eta_q(\delta) = \frac{q}{q-1} \frac{P_q(\delta) P_{q-2}(\delta)}{P_{q-1}^2(\delta)}, \qquad q = 2, 3, \tag{3}
$$

They are more sensitive than the NFMs to the variation in the shape of $P_n(\delta)$ with decreasing 0. In the case of self-similar nuctuations, one expects $\eta_2(\sigma) \propto \sigma^{-2}$. For multifractal local fluctuations, the $\eta_q(\delta)$ are δ -dependent functions for all $q \geq 3$, while for monofractal behaviour $\eta_q(\delta)$ is independent of δ for $q \geq 3$ [13]. For independent particle production, the BPs are δ -independent constants (for a Poisson distribution, $\eta_q(\delta) = 1$), for all q.

From an experimental point of view, the BPs have several advantages [14]: (1) They are less severely affected by statistical bias than the NFMs, since the BP of order q depends only on the behaviour of the multiplicity distribution near multiplicity $n = q - 1$; (2) for the calculation of the BP of order q, one only needs to be able to resolve q particles in a bin, rather than all particles as for the NFMs; and (3) many systematic errors cancel in the ratio of probabilities.

When defined in this way, the NFMs and BPs both require dividing phase space into a number of bins. This has the disadvantage of losing information on local fluctuations in particle density ("spikes") that are divided by bin boundaries. To remedy this problem with the NFS , and in addition to increase the effective statistics, normalized density strip integrals have been proposed [15]. Analogously, a new type of bunching parameter has been suggested [14], which can be used to study the fluctuation of the number of spikes (defined in section 2) per event. Generalized integral bunching parameters (GBPs) are defined by

$$
\chi_q(\epsilon) = \frac{q}{q-1} \frac{\Pi_q(\epsilon) \Pi_{q-2}(\epsilon)}{\Pi_{q-1}^2(\epsilon)},\tag{4}
$$

where $\Pi_{\alpha}(\epsilon)$ is the probability of an event to have q spikes of size less than ϵ , irrespective of how many particles are inside each spike. For purely independent particle production, with the multiplicity distribution characterised by a Poissonian, $\chi_q(\epsilon) = 1$ for all q.

In this paper we study fluctuations in rapidity, defined with respect to the thrust axis, using factorial moments and, for the first time, bunching parameters. We also study fluctuations in the four-momentum difference using generalized bunching parameters.

2 Methods

In order to improve the accuracy we use the bin-averaged "horizontal" NFMs [1] and BPs [13, 14]: The NFM of order q is calculated using the standard definition:

$$
F_q(M) = \frac{1}{M} \sum_{m=1}^{M} \frac{\langle n_m^{[q]} \rangle}{\langle \bar{n} \rangle^q}, \qquad n_m^{[q]} = n_m(n_m - 1) \dots (n_m - q + 1), \tag{5}
$$

where n_m is the number of particles in bin m , $\langle n \rangle = N/M$, is the average multiplicity for full phase space, $M = \Delta/\delta$ is the total number of bins, and Δ represents the full phase space volume. The "horizontal" BP of order q is calculated using

$$
\eta_q(M) = \frac{q}{q-1} \frac{\bar{N}_q(M) \bar{N}_{q-2}(M)}{\bar{N}_{q-1}^2(M)}, \qquad \bar{N}_q(M) = \frac{1}{M} \sum_{m=1}^M N_q(m, \delta), \qquad (6)
$$

where $N_q(m, \delta)$ is the number of events having q particles in bin m and M has the same meaning as for the NFMs.

Note that bin-averaging, as used in the above definitions, is only justified for a flat singleparticle density distribution. To be able to study non-flat distributions, we transform the original phase space variable to one in which the underlying density is uniform [16].

For the generalized bunching parameters we need to define the number of spikes of size less than ϵ . To do so we need both a measure of the size of a spike and a method of assigning particles to spikes. For the spike size, σ , we use the so-called Grassberger-Hentschel-Procaccia counting topology [17] for which is the maximum of all pairwise distances between particles in the spike. As distance between particles i and j we use the squared four-momentum difference $Q_{ij}^{\tau} =$ $-(p_i - p_j)$. Spikes are then defined in the following way: Consider all possible combinations of two or more particles. For each combination σ is determined. If σ is larger than some maximum, ϵ , the combination is discarded. Of the remaining combinations, those completely contained in another (larger) combination are also discarded. Combinations left after this procedure are called spikes (of size less than ϵ). Note that while the assignment of particles to spikes is not unique (the same particle can be in more than one spike), the number of spikes is unambiguously defined.

The GBPs are then given by

$$
\chi_q(Q^2) = \frac{q}{q-1} \frac{S_q(Q^2) S_{q-2}(Q^2)}{S_{q-1}^2(Q^2)},\tag{7}
$$

where $S_g(Q^2)$ is the number of events having q spikes of size less than Q^2 .

3 Data Samples and Analysis Procedures

We use data, corresponding to an integrated fuminosity of 52 pp $^{-}$, collected at a centre of mass energy of $\sqrt{s} \simeq 91.2$ GeV during the 1994 LEP running period. Hadronic events are selected using (1) energy deposits in the electromagnetic and hadronic calorimeters, and (2) momenta measured in the Time Expansion Chamber (TEC) and the Silicon Microvertex Detector (SMD). The L3 detector is described in detail in ref. [18].

First, a loose calorimeter-based selection is performed in order to reject non-hadronic background. Using clusters with energy larger than 100 MeV, we require

$$
0.6 < \frac{E^{\text{C}}}{\sqrt{s}} < 1.4, \qquad \frac{E_{\perp}}{E^{\text{C}}} < 0.4, \qquad \frac{E_{\parallel}}{E^{\text{C}}} < 0.4, \qquad 13 < N_{\text{cl}} < 75,
$$

where E^+ is the total energy observed in the calorimeters, E_{\perp} (E_{\parallel}) is the energy imbalance in the plane perpendicular (parallel) to the beam direction, and Ncl is the number of calorimeter clusters. To ensure that the event is contained in the barrel region of the calorimeters we require j cos through the polar angle of the polar angle of the polar angle of the polar angle of the event through a Ω

To obtain a sample with well-measured charged tracks, a further selection is performed using only tracks which have passed certain quality cuts. The distance of closest approach (projected onto the transverse plane) of a track to the nominal interaction vertex is required to be less than 5 mm and its transverse momentum must be larger than 100 MeV. To ensure that \mathbf{r} with the full acceptance of the tec and small acceptance of the tec and small axis, the thrust axis, the thrus as determined tracks, must satisfy α in the charged tracks, is cost in 0.011 , and the selected tracks are the selected to the selected tracks, which is a selected to the selected tracks of the selected tracks of the using criteria similar to the above calorimeter-based selection, but using tracks:

$$
\frac{\sum_{i} p_i}{\sqrt{s}} > 0.15, \qquad \frac{\left|\sum_{i} p_{\parallel i}\right|}{\sum_{i} p_i} < 0.75, \qquad \frac{\left|\sum_{i} \vec{p}_{\perp i}\right|}{\sum_{i} p_i} < 0.75, \qquad N_{\text{ch}} > 4,
$$

and the contract of the contra

and the contract of the contra

and the contract of the contra

and the contract of the contra

where p_i is the momentum of particle i and the sum runs over all tracks of an event, and where Nch is the number of charged tracks. The resulting sample contains about 1 million events.

The experimental distributions are corrected for selection and acceptance losses using two samples, generator level" and "detector level" of e+e $\;\rightarrow$ hadrons MC events generated with jetset 7.4 ps [19] including initial-state photon radiation. At the generator level particles with lifetime $c\tau > 1$ cm are assumed stable. The detector level sample has passed a full detector simulation [20] including time-dependent variations of the detector response based on continuous detector monitoring and calibration. It has been reconstructed with the same program as the data and passed through the same selection procedure.

In this paper we study fluctuations in the rapidity with respect to the thrust axis, y , and the square of the pairwise four-momentum difference, φ . Both for the calculation of φ and for the grouping of tracks into small bins of rapidity, the resolution of the angle between pairs of tracks is of crucial importance. For this reason we impose additional stringent quality cuts on track reconstruction, which results in rejection of 39% of the tracks. With this selection we achieve very good agreement between data and simulation for the distributions of the difference in angle between pairs of tracks for both the azimuthal angle about, and the polar angle with respect to, the beam, as is shown in Figs. 1a and 1b, respectively.

The uncorrected distributions of y, and Q^2 , are compared to the detector level MC distributions in Figs. 1c and 1d, respectively. There is reasonable agreement, which indicates the \mathbf{r} detector simulation and the jetset prediction and the jetset predictions. It should be noted that \mathbf{r} these distributions have not been used in the tuning of JETSET's parameters.

The distributions of NFMs and BPs are corrected bin-by-bin for detector effects. The corrected value in a bin is found by multiplying the value calculated directly from the data by a correction factor given by the ratio $C_q = M_q^{s \to}/M_q^{s \to}$, where $M_q^{s \to}$ and $M_q^{s \to}$ are the corresponding NFM or BP calculated from the generator- and detector-level MC samples, respectively. These corrections, which tend to be larger for smaller bin size, are in no case larger than about 5%.

To reduce possible systematic bias, the minimum bin size is chosen comparable to the experimental resolution, which was estimated [21, 22] by MC simulation. In the case of Q^2 , the smallest bin size is large enough that the measurements are not strongly affected by Dalitz decays ($\pi^* \to e^+e^- \gamma$) or by photon conversions.

The error bars on the results include contributions from both statistical and systematic errors on the raw quantities and on the correction factors. The statistical errors on the $F_q(M)$ and $\eta_{q}(M)$ are derived from the covariance matrix of the NFMs and BPs. The statistical errors for the GBPs are derived according to the expression obtained in ref. [14]. Systematic errors on the raw quantities have been estimated by varying the event- and track-selection criteria. As systematic error on C_q , we take half of the difference between the correction factors determined using jetset and those using her will be using hermig. In th

The predictions of the jetset $\mathbf{1}$ and here $\mathbf{1}$ and here $\mathbf{1}$ and here $\mathbf{1}$ and $\mathbf{2}$ models, $\mathbf{1}$ and $\mathbf{2}$ and $\mathbf{3}$ and $\mathbf{4}$ and $\mathbf{5}$ and $\mathbf{4}$ and $\mathbf{5}$ and $\mathbf{4}$ and \math all of which have been tuned to reproduce global event-shape and single-particle inclusive distributions $[10,25]$, are compared to the data. The Bose-Einstein effect is a potential source of particle correlations. JETSET and ARIADNE include the same modelling of this effect. 7 HERWIG does not incorporate a Bose-Einstein model. We also compare the data with predictions of JETSET without Bose-Einstein interference.^{†)} The errors on the JETSET predictions include both statistical and systematic errors. These systematic errors were estimated by varying, by one standard deviation, the following following parameters tuned in ref. $[-1, -1]$: the Lund

 \pm 1 ne Dose-Einstein model used is the luboei model of jetset.

 \vee i ne parameters of jettset were retuned with Bose-Einstein interference disabled. This resulted in changes of parj(21), parj(42), and parj(81) from 0.411, 0.886, and 0.311 to 0.343, 1.1, and 0.312, respectively.

fragmentation function parameter b, the width of the Gaussian p_x and p_y hadronic transverse momentum distribution, and the value of the value of stribution, showers, in parton showers. Systematic errors \mathbf{r} are similarly determined. The errors on the arian similar si are comparable to those on JETSET, while those of HERWIG are about 50% larger. The errors on the MC results are dominated by the systematic errors.

4 Results

4.1 Fluctuations in rapidity, y

To study fluctuations inside jets, we first determine the thrust axis and analyse the NFMs and BPs in the full rapidity range $|y| \leq 5$. Since the single-particle rapidity distribution is non-uniform, we first transform y to a uniformly distributed variable [16].

The horizontally normalised NFMs are shown in Fig. 2 as a function of the number of bins, M, in the transformed rapidity. They rise with increasing M and then saturate. All of the MCs are in reasonable agreement with the data. It is also seen that the Bose-Einstein effect in

Fig. 3 shows the results for the results for the horizontally normalised BPs. All higher-order (q \sim 2) BPs. All highershow an approximate power-law increase with increasing M . The MCs also show a power-law behaviour, although some differences in slope are apparent. That these BPs vary with M is a direct indication that the nuctuations in y are multifractal" [13], as is expected in QCD [20-28].

The second-order BP decreases with increasing M up to $M \approx 20$, which is found to correspond to the value of M at which the maximum of the multiplicity distribution $P_n(\delta)$ first occurs at $n = 0$. The large errors on the data for $M \lesssim 30$ arise mainly from the systematic error α dierence between correction factors determined using α The data are shown using the JETSET correction factors.

The second-order BP is related to the width of the multiplicity distribution [13, 14]. Hence, HERWIG's overestimation of η_2 means that HERWIG's local multiplicity distributions are too broad. This agrees with ALEPH's conclusion from a direct measurement of the dispersion for various (large) intervals of rapidity [29], but emphasizes the contribution of the low values of n in this discrepancy.

To study the second-order BP in more detail, we split 2 into two components:

$$
\eta_2(M) = \eta_2^{(\pm \pm)}(M) + \eta_2^{(+-)}(M). \tag{8}
$$

The definition of $\eta_2^{--\prime}(M)$ $\chi_2^{(2\pi)}(M)$ is as in equation (6), but with $N_2(m,\delta)$ replaced by $N_2^{(2\pi)}(m,\delta),$ the number of events having two like-charged particles inside bin m of size δ . Analogously, $\eta_2^{\scriptscriptstyle \vee}$ $\hspace{0.1cm}^{\scriptscriptstyle \vee}$ $\hspace{0.1cm}$ \hspace 2 (M) is constructed from the number of events having two oppositely charged particles $\mathbf r$ the bin. Note that for combinatorial reasons, $\eta_2^{(n-r)}(M)$ $\chi_2^{(2+\gamma)}(M) < \eta_2^{(1-\gamma)}(M)$. However, both would be independent of ^M in the case of independent production.

Fig. 4 shows that $\eta_2^{--\prime}(M)$ $\chi_2^{(2)}(M)$ and $\eta_2^{(1)}$ '(M) $\hat{q}^2 \gamma(M)$ behave differently. While $\eta_2^{(2-\gamma)}(M)$ $2 \left(\begin{array}{c} 2 \end{array} \right)$ shows the shows the set of $\frac{1}{2}$ expected rise (and saturation of the data at large M), η_2^s '(M) 2 (M) shows a decrease at low M. M.

The anti-bunching tendency (decrease of 2 with increasing α with increasing α particles for $M \lesssim 20$ is also seen in all MCs. Resonance decays are a likely explanation of this

 $^\tau$ I his conclusion is possible without measuring the intermittency indices φ_a . In contrast, to reveal multifractanty with IVF MS one must hist in the IVF MS by a power law. Decause of the saturation of the $F_q(M)$ observed in Figure 2, this procedure is fraught with ambiguity.

effect. Their decay particles tend to be of opposite charge and are typically separated in rapidity by $\delta y \sim 0.5{\text -}1.0$. As a result, a rapidity separation of this order of magnitude is more frequent between unlike-charged particles than between like-charged and η_2^{γ} ' (M) $2 \left(M \right)$ is much larger than $\eta_2^{\lambda - \mu} (M)$ 2 (M) at small M (large y). However, this direction of this direction \mathcal{L} with direction \mathcal{L} until about $M = 20$, which corresponds to $\delta y = 0.5$.

For like-signed combinations the MCs all show good agreement with the data. However, for unlike-charged combinations HERWIG overestimates the data, while the other MCs agree herwig over the data, while the other MCs agreement of the o reasonably well-been able the errors on the errors jetset predictions are dominantly systematic. They are mainly due to the uncertainty on the parameter responsible for the width of the Gaussian hadronic transverse momentum distribution in the Lund model. This shows the importance of tragmentation for the bunching parameters. For η_2 \rightarrow as 2 , as for $\frac{1}{2}$, the error at small M comes at $\frac{1}{2}$ mainly from differences in the correction factors; other errors are comparable to the errors on the corresponding points for η_2^{--} . If \mathcal{L} . The extension interference interference interference interference in jetset is to to be extended in the extension of \mathcal{L} increase the value of η_2^{--} and $\frac{\lambda_2}{2}$ and to decrease that of η_2 λ .

4.2 Fluctuations in four-momentum difference, Q^2

The behaviour of the GBPs for the invariant two-particle squared four-momentum difference, $\chi_{a} (Q^{2})$, is shown in Fig. 5 as a function of $-\ln Q^{2}$. All GBPs, for both data and Monte Carlo, rise similarly with increasing $-\ln Q^2$ (decreasing Q^2). This corresponds to a bunching effect for all orders, similar to the behaviour of fluctuations in y . The MC models show a similar trend with $-\ln Q^2$ but tend to underestimate the values of $\chi_q(Q^2)$; herwig agrees best with the data.

Given the difference in behaviour observed in the previous section between η_2 than and \hat{q}_2 and η_2 , $\overline{}$, we now define second-order GBPs for multiparticle spikes consisting entirely of particles of the same charge, χ_2^{--} , and to $\sum_{\alpha=1}^{\infty}$, and for spikes containing particles of different charge, χ_2^{∞} . These 2 . These GBPs are defined as in eqs. 4 and 7 except that q now refers to the number of sc and dc spikes, respectively. We plot in Fig. 6 the behaviour of χ_2^2 and χ_2^2 . A difference is observed between these two quantities. For sc spikes a strong bunching effect $(\chi_2^{\gamma-\gamma}(Q^2))$ $_2$ (Q²) $>$ 1) is seen at large \sim in Q^2 . This is well reproduced by HERWIG. In the case of dc spikes, the bunching is smaller and tends to saturate at large $-\ln Q^2$.

In contrast to the BPs of the previous section, resonances have little effect on the GBPs. This is because the most copiously produced resonances decay to two particles with a Q^2 so large that the particles are necessarily in different spikes for the spike sizes which we consider $(-\ln Q^2 \gtrsim 2)$. The spike multiplicity distribution is therefore not strongly affected.

It is interesting to observe that JETSET's treatment of BE correlations decreases the values of χ_2 for sc spikes, the opposite of the behaviour for η_2^{--} . The 2 . This comes about because because \sim SET 's modelling of Bose-Einstein interference increases the number of sc spikes. This leads to higher values for η_2^{--} . However, χ_2 is mainly influenced by the shape of the spike-multiplicity distribution rather than by the average spike multiplicity.

5 Conclusions

Local charged particle multiplicity fluctuations in rapidity with respect to the thrust axis have been studied using factorial moments and, for the first time, bunching parameters, which are sensitive to further details. Also, fluctuations of spikes have been studied using generalized

bunching parameters defined in terms of the four-momentum difference, Q². Bunching parameters directly demonstrate a multifractal behaviour of the
uctuations in rapidity, as is expected from QCD.

Monte Carlo models, which have been tuned to reproduce global event-shape distributions and single-particle inclusive distributions provide a reasonable description of uctuations in these variables. They reproduce the trend, although not always the magnitude, of the normalized factorial moments, bunching parameters and generalized integral bunching parameters. It thus appears that the ingredients of these MC models (coherent parton shower, string or cluster fragmentation, and resonance decays) are sufficient to explain the fluctuations observed in the data.

Acknowledgements

We wish to express our gratitude to the cern accelerator divisions for the excellent performance \sim the lep machine. We acknowledge the extra of all engineers and technicians who have \sim participated in the construction and maintenance of this experiment. We thank V. I. Kuvshinov, J.-L. Meunier and R. Peschanski for useful discussions and comments.

Figure 1: Distributions of (a) the difference in polar angle of pairs of tracks, $\delta\theta$, (b) the difference in azimuthal angle of pairs of tracks, $\delta\phi$, (c) the single-particle rapidity with respect to the thrust axis, y , and (d) the inclusive four-momentum difference squared, Q^\star , for uncorrected data (points) compared to the predictions of \mathcal{O} is gramping after detector simulation (histogram).

Figure 2: NFMs as a function of the number of bins, M , in the transformed rapidity defined with respect to the thrust axis. In this and the following figures the shaded areas represent the errors on the jetset predictions. The errors on the ariadne predictions are comparable predictions are compar whereas these on the hermits predictions are about 50% larger.

Figure 3: BPs as a function of the number of bins, M , in the transformed rapidity defined with respect to the thrust axis.

Figure 4: The second-order BP as a function of the number of bins, M , in the transformed rapidity defined with respect to the thrust axis for like-charged and unlike-charged particle combinations.

 ${\rm r}$ leure 5: GBPs as a function of the squared four-momentum difference ω^{-} in GeV $^{-}$ between two charged particles.

Figure 6: The second-order GBP for spikes of same-charged particles (sc) and spikes of dierently charged particles (dc) as a function of the squared four-momentum difference Q^\ast in GeV * between two charged particles.
