Table of Contents

Introduction	1
Prerequisites for using Amazon Redshift	1
Amazon Redshift architecture	2
Data warehouse architecture	2
Performance	5
Columnar storage	8
Workload management	10
Using Amazon Redshift with other services	12
Sample database	13
Best practices	21
Conduct a proof of concept	21
Step 1: Scope your POC	22
Step 2: Launch Amazon Redshift	23
Step 3: Load your data	24
Step 4: Analyze your data	26
Step 5: Optimize	28
Best practices for designing tables	29
Choose the best sort key	29
Choose the best distribution style	30
Use automatic compression	31
Define constraints	32
Use the smallest possible column size	32
Use date/time data types for date columns	32
Best practices for loading data	33
Learn how to load data	33
Use a COPY command to load data	33
Use a single COPY command	34
Loading data files	34
Compressing your data files	35
Verify data files before and after a load	35
Use a multi-row insert	35
Use a bulk insert	36
Load data in sort key order	36
Load data in sequential blocks	37

Use time-series tables	37
Schedule around maintenance windows	38
Best practices for designing queries	38
Follow Advisor recommendations	40
Amazon Redshift Regions where Advisor is supported	41
Viewing Advisor recommendations	42
Advisor recommendations	43
Tutorials	58
Automatic table optimization	59
Enabling, disabling, and monitoring automatic table optimization	60
Enabling automatic table optimization	60
Removing automatic table optimization from a table	60
Monitoring automatic table optimization	61
Column compression	61
Compression encodings	63
Testing compression encodings	73
Data distribution	80
Data distribution concepts	80
Distribution styles	82
Viewing distribution styles	83
Evaluating query patterns	85
Designating distribution styles	85
Evaluating the query plan	86
Query plan example	89
Distribution examples	93
Sort keys	96
Multidimensional data layout sorting (preview)	97
Compound sort key	98
Interleaved sort key	99
Table constraints	100
Loading data	102
Loading tables with COPY	105
Credentials and access permissions	107
Preparing your input data	109
Loading data from Amazon S3	110
Loading data from Amazon EMR	122

Loading data from remote hosts	128
Loading from Amazon DynamoDB	137
Verifying that the data loaded correctly	140
Validating input data	141
Loading tables with automatic compression	141
Optimizing for narrow tables	144
Loading default column values	144
Troubleshooting data loads	145
Loading tables with continuous file ingestion (preview)	152
Loading tables with DML	154
Updating and inserting	155
Performing a deep copy	163
Analyzing tables	167
Automatic analyze	167
Analysis of new table data	168
ANALYZE command history	173
Vacuuming tables	174
Automatic table sort	175
Automatic vacuum delete	176
VACUUM frequency	176
Sort stage and merge stage	176
Vacuum threshold	177
Vacuum types	177
Minimizing vacuum times	177
Managing concurrent write operations	186
Serializable isolation	187
Write and read/write operations	192
Concurrent write examples	193
Tutorial: Loading data from Amazon S3	195
Prerequisites	195
Overview	196
Step 1: Create a cluster	196
Step 2: Download the data files	197
Step 3: Upload the files to an Amazon S3 bucket	198
Step 4: Create the sample tables	200
Step 5: Run the COPY commands	203

Step 6: Vacuum and analyze the database	221
Step 7: Clean up your resources	222
Summary	222
Unloading data	224
Unloading data to Amazon S3	224
Unloading encrypted data files	228
Unloading data in delimited or fixed-width format	229
Reloading unloaded data	231
User-defined functions	232
UDF security and permissions	232
Preventing UDF naming conflicts	233
Overloading function names	233
Avoiding conflict with built-in Amazon Redshift functions	234
Scalar SQL UDFs	234
Example	235
Scalar Python UDFs	235
Example	236
Python UDF data types	237
Python language support	238
Constraints	243
Logging errors and warnings	243
Scalar Lambda UDFs	245
Managing Lambda UDF security and permissions	246
Configuring the authorization parameter for Lambda UDFs	247
Using the JSON interface between Amazon Redshift and Lambda	248
Use case examples for UDFs	251
Creating stored procedures	253
Stored procedure overview	253
Naming stored procedures	257
Security and privileges	258
Returning a result set	259
Managing transactions	261
Trapping errors	274
Logging stored procedures	283
Limitations	283
PL/pgSQL language reference	284

PL/pgSQL reference conventions	285
Structure of PL/pgSQL	285
Supported PL/pgSQL statements	291
Materialized views	308
Materialized view queries	311
Automatic query rewriting to use materialized views	312
Usage notes	312
Limitations	313
Refreshing a materialized view	314
Autorefreshing a materialized view	317
Automated materialized views	318
SQL scope and considerations for automated materialized views	319
Automated materialized views limitations	320
Billing for automated materialized views	320
Additional resources	321
Using a user-defined function (UDF) in a materialized view	321
Referencing a UDF in a materialized view	321
Streaming ingestion to a materialized view	323
How data flows from a streaming service to Redshift	323
Data parsing best practices for improving performance	324
Streaming ingestion behavior and data types	325
Getting started with streaming ingestion from Amazon Kinesis Data Streams	329
Getting started with streaming ingestion from Amazon Managed Streaming for Apache Kafka (Amazon MSK)	334
Electric vehicle station-data streaming ingestion tutorial, using Kinesis	345
Data Catalog views	350
Prerequisites	350
End-to-end example	352
Secure logging	353
Considerations	358
Querying spatial data	359
Tutorial: Using spatial SQL functions	362
Prerequisites	363
Step 1: Create tables and load test data	363
Step 2: Query spatial data	366
Step 3: Clean up your resources	370

Loading a shapefile	370
Terminology	372
Bounding box	372
Geometric validity	373
Geometric simplicity	375
H3	377
Considerations	377
Querying data with federated queries	379
Getting started with using federated queries to PostgreSQL	380
Getting started using federated queries to PostgreSQL with CloudFormation	381
Launching a CloudFormation stack for Redshift federated queries	382
Querying data from the external schema	383
Getting started with using federated queries to MySQL	384
Creating a secret and an IAM role	385
Prerequisites	385
Examples of using a federated query	388
Example of using a federated query with PostgreSQL	388
Example of using a mixed-case name	390
Example of using a federated query with MySQL	392
Data type differences	393
Considerations	397
Supported versions of federated databases	399
Amazon Redshift Spectrum	400
Amazon Redshift Spectrum overview	400
Amazon Redshift Spectrum Regions	402
Amazon Redshift Spectrum limitations	402
Getting started with Amazon Redshift Spectrum	403
Prerequisites	403
CloudFormation	404
Getting started with Redshift Spectrum step by step	404
Step 1. Create an IAM role	404
Step 2: Associate the IAM role with your cluster	408
Step 3: Create an external schema and an external table	409
Step 4: Query your data in Amazon S3	410
Launch your CloudFormation stack and then query your data	414
IAM policies for Amazon Redshift Spectrum	417

Amazon S3 permissions	418
Cross-account Amazon S3 permissions	419
Grant or restrict access using Redshift Spectrum	420
Minimum permissions	420
Chaining IAM roles	422
Accessing AWS Glue data	423
Redshift Spectrum and Lake Formation	431
Using data filters for row-level and cell-level security	433
Data files for queries in Amazon Redshift Spectrum	433
Data formats for Redshift Spectrum	434
Compression types for Redshift Spectrum	435
Encryption for Redshift Spectrum	436
External schemas	436
Working with external catalogs	439
External tables	443
Pseudocolumns	445
Partitioning Redshift Spectrum external tables	446
Mapping to ORC columns	452
Creating external tables for Hudi-managed data	455
Creating external tables for Delta Lake data	456
Using Apache Iceberg tables	458
Considerations when using Apache Iceberg tables	459
Supported data types	461
Amazon Redshift Spectrum query performance	463
Data handling options	466
Performing correlated subqueries	467
Metrics	468
Query troubleshooting	468
Retries exceeded	469
Access throttled	469
Resource limit exceeded	471
No rows returned for a partitioned table	471
Not authorized error	471
Incompatible data formats	472
Syntax error when using Hive DDL in Amazon Redshift	472
Permission to create temporary tables	473

Invalid range	473
Invalid Parquet version number	473
Tutorial: Querying nested data with Amazon Redshift Spectrum	473
Overview	474
Step 1: Create an external table that contains nested data	475
Step 2: Query your nested data in Amazon S3 with SQL extensions	476
Nested data use cases	480
Nested data limitations (preview)	482
Serializing complex nested JSON	484
HyperLogLog sketches	488
Considerations	489
Limitations	490
Examples	490
Example: Return cardinality in a subquery	490
Example: Return an HLLSKETCH type from combined sketches in a subquery	491
Example: Return a HyperLogLog sketch from combining multiple sketches	492
Example: Generate HyperLogLog sketches over S3 data using external tables	493
Cross-database queries	496
Considerations	498
Limitations	498
Examples	499
Using cross-database queries with the query editor	504
Data sharing	506
Data sharing overview	507
Data sharing use cases	507
Data sharing at different levels	508
Data sharing consistency management	508
Considerations when using data sharing in Amazon Redshift	509
Cluster encryption management	509
Limitations	510
Regions where data sharing is available	510
Datashares	514
Standard datashares	514
AWS Data Exchange datashares	516
AWS Lake Formation-managed datashares	519
Datashare producers and consumers	521

Datashare details	522
Querying datashares	531
Monitoring and auditing data sharing	532
Integrating Amazon Redshift data sharing with AWS CloudTrail	534
Managing data sharing tasks	534
Managing data sharing using the SQL interface	534
Managing data sharing using the console	579
Managing data sharing with CloudFormation	594
Managing data sharing with writes using the console (preview)	599
Semistructured data in Amazon Redshift	614
Use cases for the SUPER data type	614
Concepts for SUPER data type use	615
Considerations for SUPER data	617
SUPER sample dataset	618
Loading semistructured data into Amazon Redshift	620
Parsing JSON documents to SUPER columns	620
Using COPY to load JSON data in Amazon Redshift	621
Unloading semistructured data	626
Querying semistructured data	627
Navigation	628
Unnesting queries	629
Object unpivoting	631
Dynamic typing	632
Lax semantics	635
Types of introspection	636
Order by	637
Operators and functions	638
Arithmetic operators	638
Arithmetic functions	639
Array functions	640
SUPER configurations	641
Lax and strict modes for SUPER	642
Accessing JSON fields with uppercase and mixedcase letters	642
Parsing options	644
Limitations	644
SUPER data type and materialized views	647

Accelerating PartiQL queries	648
Limitations for using the SUPER data type with materialized views	652
Machine learning	653
Machine learning overview	654
How machine learning can solve a problem	655
Terms and concepts for Amazon Redshift ML	656
Machine learning for novices and experts	658
Costs for using Amazon Redshift ML	660
Getting started with Amazon Redshift ML	662
Administrative setup	662
Using model explainability with Amazon Redshift ML	668
Amazon Redshift ML probability metrics	668
Tutorials for Amazon Redshift ML	671
Tutorial: Build customer churn models	673
Tutorial: Building remote inference models	682
Tutorial: Building K-means clustering models	687
Tutorial: Building multi-class classification models	696
Tutorial: Building XGBoost models	706
Tutorial: Building regression models	712
Tutorial: Building regression models with linear learner	725
Tutorial: Building multi-class classification models with linear learner	733
Query performance tuning	756
Query processing	756
Query planning and execution workflow	757
Creating and interpreting a query plan	759
Reviewing query plan steps	767
Factors affecting query performance	769
Query analysis and improvement	771
Query analysis workflow	771
Reviewing query alerts	772
Analyzing the query plan	774
Analyzing the query summary	775
Query improvement	782
Diagnostic queries for query tuning	786
Query troubleshooting	790
Connection fails	791

Query hangs	792
Query takes too long	793
Load fails	794
Load takes too long	795
Load data is incorrect	795
Setting the JDBC fetch size parameter	796
Workload management	797
Switching WLM mode	799
Modifying the WLM configuration	799
Migrating from manual WLM to automatic WLM	799
Automatic WLM	801
Priority	802
Concurrency scaling mode	802
User groups	802
Query groups	802
Wildcards	803
Query monitoring rules	803
Checking for automatic WLM	803
Query priority	804
Manual WLM	809
Concurrency scaling mode	810
Concurrency level	811
User groups	813
Query groups	813
Wildcards	813
WLM memory percent to use	813
WLM timeout	814
Query monitoring rules	815
WLM query queue hopping	815
Tutorial: Configuring manual WLM queues	818
Concurrency scaling	836
Concurrency scaling capabilities	837
Limitations for concurrency scaling	838
Regions for concurrency scaling	839
Concurrency scaling candidates	840
Configuring concurrency scaling queues	805

Monitoring concurrency scaling	841
Concurrency scaling system views	842
Short query acceleration	843
Maximum SQA runtime	844
Monitoring SQA	844
WLM queue assignment rules	845
Queue assignments example	847
Assigning queries to queues	849
Assigning queries to queues based on user roles	849
Assigning queries to queues based on user groups	850
Assigning a query to a query group	850
Assigning queries to the superuser queue	851
Dynamic and static properties	851
WLM dynamic memory allocation	853
Dynamic WLM example	854
Query monitoring rules	856
Defining a query monitor rule	857
Query monitoring metrics for Amazon Redshift provisioned	859
Query monitoring metrics for Amazon Redshift Serverless	862
Query monitoring rules templates	864
System tables and views for query monitoring rules	865
WLM system tables and views	866
WLM service class IDs	868
Database security	869
Amazon Redshift security overview	870
Default database user permissions	871
Superusers	872
Users	872
Creating, altering, and deleting users	873
Groups	874
Creating, altering, and deleting groups	874
Example for controlling user and group access	874
Schemas	876
Search path	877
Creating, altering, and deleting schemas	877
Permissions	878

Role-based access control	878
Role hierarchy	879
Role assignment	879
Amazon Redshift system-defined roles	880
System permissions	882
Database object permissions	888
ALTER DEFAULT PRIVILEGES for RBAC	888
Considerations for role usage	888
Managing roles	889
Tutorial: Creating roles and querying with RBAC	889
Row-level security	908
Using RLS policies in SQL statements	909
Combining multiple policies per user	909
RLS policy ownership and management	911
Policy-dependent objects and principles	912
Considerations and limitations	914
Best practices	918
End-to-end example	919
Metadata security	924
Dynamic data masking	925
Overview	925
SQL commands for DDM policies	926
DDM policy hierarchy	927
Using DDM with SUPER type paths	929
Conditional dynamic data masking	934
DDM system views	935
Considerations	937
End-to-end example	941
Scoped permissions	945
Considerations	945
SQL reference	947
Amazon Redshift SQL	947
SQL functions supported on the leader node	947
Amazon Redshift and PostgreSQL	950
Using SQL	958
SQL reference conventions	958

Basic elements	959
Expressions	1014
Conditions	1019
SQL commands	1047
ABORT	1051
ALTER DATABASE	1052
ALTER DATASHARE	1056
ALTER DEFAULT PRIVILEGES	1060

Introduction

Welcome to the *Amazon Redshift Database Developer Guide*. This guide focuses on helping you understand how to use Amazon Redshift to create and manage a data warehouse. If you work with databases as a designer, software developer, or administrator, this guide gives you the information you need to design, build, query, and maintain your data warehouse.

Amazon Redshift is a fully managed, petabyte-scale data warehouse service in the cloud. Amazon Redshift Serverless lets you access and analyze data without the usual configurations of a provisioned data warehouse. Resources are automatically provisioned and data warehouse capacity is intelligently scaled to deliver fast performance for even the most demanding and unpredictable workloads. You don't incur charges when the data warehouse is idle, so you only pay for what you use. Regardless of the size of the dataset, you can load data and start querying right away in the Amazon Redshift query editor v2 or in your favorite business intelligence (BI) tool. Enjoy the best price performance and familiar SQL features in an easy-to-use, zero administration environment.

Topics

- [Prerequisites for using Amazon Redshift](#)
- [Amazon Redshift architecture](#)
- [Sample database](#)

Prerequisites for using Amazon Redshift

This topic describes prerequisites you need to use Amazon Redshift.

Before you use this guide, you should read [Get started with Redshift Serverless data warehouses](#), which goes over how to complete the following tasks.

- Create a data warehouse with Amazon Redshift Serverless.
- Loading in sample data with Amazon Redshift query editor v2
- Loading in data from Amazon S3.

You should also know how to use your SQL client and should have a fundamental understanding of the SQL language.

Amazon Redshift architecture

This topic helps you understand the components that make up Amazon Redshift.

An Amazon Redshift data warehouse is an enterprise-class relational database query and management system.

Amazon Redshift supports client connections with many types of applications, including business intelligence (BI), reporting, data, and analytics tools.

When you run analytic queries, you are retrieving, comparing, and evaluating large amounts of data in multiple-stage operations to produce a final result.

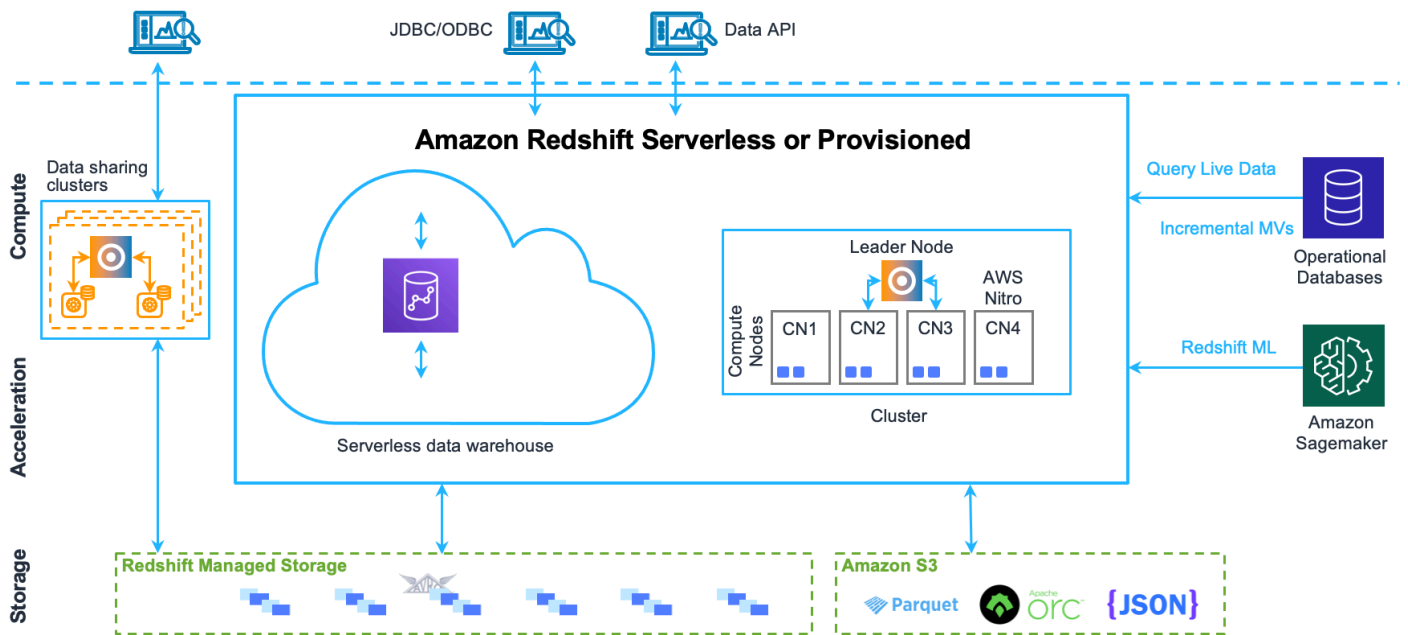

Amazon Redshift achieves efficient storage and optimum query performance through a combination of massively parallel processing, columnar data storage, and very efficient, targeted data compression encoding schemes. This section presents an introduction to the Amazon Redshift system architecture.

Topics

- [Workload management](#)
- [Using Amazon Redshift with other services](#)

Data warehouse system architecture

This section explains the components that make up the Amazon Redshift data warehouse architecture, as shown in the following figure.

Client applications

Amazon Redshift integrates with various data loading and ETL (extract, transform, and load) tools and business intelligence (BI) reporting, data mining, and analytics tools. Amazon Redshift is based on open standard PostgreSQL, so most existing SQL client applications will work with only minimal changes. For information about important differences between Amazon Redshift SQL and PostgreSQL, see [Amazon Redshift and PostgreSQL](#).

Clusters

The core infrastructure component of an Amazon Redshift data warehouse is a *cluster*.

A cluster is composed of one or more *compute nodes*. If a cluster is provisioned with two or more compute nodes, an additional *leader node* coordinates the compute nodes and handles external communication. Your client application interacts directly only with the leader node. The compute nodes are transparent to external applications.

Leader node

The leader node manages communications with client programs and all communication with compute nodes. It parses and develops execution plans to carry out database operations, in particular, the series of steps necessary to obtain results for complex queries. Based on the execution plan, the leader node compiles code, distributes the compiled code to the compute nodes, and assigns a portion of the data to each compute node.

The leader node distributes SQL statements to the compute nodes only when a query references tables that are stored on the compute nodes. All other queries run exclusively on the leader node. Amazon Redshift is designed to implement certain SQL functions only on the leader node. A query that uses any of these functions will return an error if it references tables that reside on the compute nodes. For more information, see [SQL functions supported on the leader node](#).

Compute nodes

The leader node compiles code for individual elements of the execution plan and assigns the code to individual compute nodes. The compute nodes run the compiled code and send intermediate results back to the leader node for final aggregation.

Each compute node has its own dedicated CPU and memory, which are determined by the node type. As your workload grows, you can increase the compute capacity of a cluster by increasing the number of nodes, upgrading the node type, or both.

Amazon Redshift provides several node types for your compute needs. For details of each node type, see [Amazon Redshift clusters](#) in the *Amazon Redshift Management Guide*.

Redshift Managed Storage

Data warehouse data is stored in a separate storage tier Redshift Managed Storage (RMS). RMS provides the ability to scale your storage to petabytes using Amazon S3 storage. RMS lets you scale and pay for computing and storage independently, so that you can size your cluster based only on your computing needs. It automatically uses high-performance SSD-based local storage as tier-1 cache. It also takes advantage of optimizations, such as data block temperature, data block age, and workload patterns to deliver high performance while scaling storage automatically to Amazon S3 when needed without requiring any action.

Node slices

A compute node is partitioned into slices. Each slice is allocated a portion of the node's memory and disk space, where it processes a portion of the workload assigned to the node. The leader node manages distributing data to the slices and apportions the workload for any queries or other database operations to the slices. The slices then work in parallel to complete the operation.

The number of slices per node is determined by the node size of the cluster. For more information about the number of slices for each node size, go to [About clusters and nodes](#) in the *Amazon Redshift Management Guide*.

When you create a table, you can optionally specify one column as the distribution key. When the table is loaded with data, the rows are distributed to the node slices according to the distribution key that is defined for a table. Choosing a good distribution key enables Amazon Redshift to use parallel processing to load data and run queries efficiently. For information about choosing a distribution key, see [Choose the best distribution style](#).

Internal network

Amazon Redshift takes advantage of high-bandwidth connections, close proximity, and custom communication protocols to provide private, very high-speed network communication between the leader node and compute nodes. The compute nodes run on a separate, isolated network that client applications never access directly.

Databases

A cluster contains one or more databases. User data is stored on the compute nodes. Your SQL client communicates with the leader node, which in turn coordinates query run with the compute nodes.

Amazon Redshift is a relational database management system (RDBMS), so it is compatible with other RDBMS applications. Although it provides the same functionality as a typical RDBMS, including online transaction processing (OLTP) functions such as inserting and deleting data, Amazon Redshift is optimized for high-performance analysis and reporting of very large datasets.

Amazon Redshift is based on PostgreSQL. Amazon Redshift and PostgreSQL have a number of very important differences that you need to take into account as you design and develop your data warehouse applications. For information about how Amazon Redshift SQL differs from PostgreSQL, see [Amazon Redshift and PostgreSQL](#).

Amazon Redshift Performance

This topic describes the Amazon Redshift components that drive performance. Understanding these components will help you tune performance and troubleshoot poor performance with Amazon Redshift.

Amazon Redshift achieves extremely fast query run by employing these performance features.

Topics

- [Massively parallel processing](#)

- [Columnar data storage](#)
- [Data compression](#)
- [Query optimizer](#)
- [Result caching](#)
- [Compiled code](#)

Massively parallel processing

Massively parallel processing (MPP) enables fast run of the most complex queries operating on large amounts of data. Multiple compute nodes handle all query processing leading up to final result aggregation, with each core of each node running the same compiled query segments on portions of the entire data.

Amazon Redshift distributes the rows of a table to the compute nodes so that the data can be processed in parallel. By selecting an appropriate distribution key for each table, you can optimize the distribution of data to balance the workload and minimize movement of data from node to node. For more information, see [Choose the best distribution style](#).

Loading data from flat files takes advantage of parallel processing by spreading the workload across multiple nodes while simultaneously reading from multiple files. For more information about how to load data into tables, see [Amazon Redshift best practices for loading data](#).

Columnar data storage

Columnar storage for database tables drastically reduces the overall disk I/O requirements and is an important factor in optimizing analytic query performance. For more information, see [Columnar storage](#).

When columns are sorted appropriately, the query processor is able to rapidly filter out a large subset of data blocks. For more information, see [Choose the best sort key](#).

Data compression

Data compression reduces storage requirements, thereby reducing disk I/O, which improves query performance. When you run a query, the compressed data is read into memory, then uncompressed during query run. Loading less data into memory enables Amazon Redshift to allocate more memory to analyzing the data. Because columnar storage stores similar data sequentially, Amazon

Redshift is able to apply adaptive compression encodings specifically tied to columnar data types. The best way to enable data compression on table columns is by allowing Amazon Redshift to apply optimal compression encodings when you load the table with data. To learn more about using automatic data compression, see [Loading tables with automatic compression](#).

Query optimizer

The Amazon Redshift query run engine incorporates a query optimizer that is MPP-aware and also takes advantage of the columnar-oriented data storage. The Amazon Redshift query optimizer implements significant enhancements and extensions for processing complex analytic queries that often include multi-table joins, subqueries, and aggregation. To learn more about optimizing queries, see [Query performance tuning](#).

Result caching

To reduce query runtime and improve system performance, Amazon Redshift caches the results of certain types of queries in memory on the leader node. When a user submits a query, Amazon Redshift checks the results cache for a valid, cached copy of the query results. If a match is found in the result cache, Amazon Redshift uses the cached results and doesn't run the query. Result caching is transparent to the user.

Result caching is turned on by default. To turn off result caching for the current session, set the [enable_result_cache_for_session](#) parameter to off.

Amazon Redshift uses cached results for a new query when all of the following are true:

- The user submitting the query has access permission to the objects used in the query.
- The table or views in the query haven't been modified.
- The query doesn't use a function that must be evaluated each time it's run, such as GETDATE.
- The query doesn't reference Amazon Redshift Spectrum external tables.
- Configuration parameters that might affect query results are unchanged.
- The query syntactically matches the cached query.

To maximize cache effectiveness and efficient use of resources, Amazon Redshift doesn't cache some large query result sets. Amazon Redshift determines whether to cache query results based on a number of factors. These factors include the number of entries in the cache and the instance type of your Amazon Redshift cluster.

To determine whether a query used the result cache, query the [SVL_QLOG](#) system view. If a query used the result cache, the `source_query` column returns the query ID of the source query. If result caching wasn't used, the `source_query` column value is NULL.

The following example shows that queries submitted by `userid 104` and `userid 102` use the result cache from queries run by `userid 100`.

```
select userid, query, elapsed, source_query from svl_qlog
where userid > 1
order by query desc;
```

userid	query	elapsed	source_query
104	629035	27	628919
104	629034	60	628900
104	629033	23	628891
102	629017	1229393	
102	628942	28	628919
102	628941	57	628900
102	628940	26	628891
100	628919	84295686	
100	628900	87015637	
100	628891	58808694	

Compiled code

The leader node distributes fully optimized compiled code across all of the nodes of a cluster. Compiling the query decreases the overhead associated with an interpreter and therefore increases the runtime speed, especially for complex queries. The compiled code is cached and shared across sessions on the same cluster. As a result, future runs of the same query will be faster, often even with different parameters.

The query run engine compiles different code for the JDBC and ODBC connection protocols, so two clients using different protocols each incur the first-time cost of compiling the code. Clients that use the same protocol, however, benefit from sharing the cached code.

Columnar storage

This section describes columnar storage, which is the method Amazon Redshift uses to store tabular data efficiently.

Columnar storage for database tables is an important factor in optimizing analytic query performance, because it drastically reduces the overall disk I/O requirements. It reduces the amount of data you need to load from disk.

The following series of illustrations describe how columnar data storage implements efficiencies, and how that translates into efficiencies when retrieving data into memory.

This first illustration shows how records from database tables are typically stored into disk blocks by row.

SSN	Name	Age	Addr	City	St
101259797	SMITH	88	899 FIRST ST	JUNO	AL
892375862	CHIN	37	16137 MAIN ST	POMONA	CA
318370701	HANDU	12	42 JUNE ST	CHICAGO	IL

In a typical relational database table, each row contains field values for a single record. In row-wise database storage, data blocks store values sequentially for each consecutive column making up the entire row. If block size is smaller than the size of a record, storage for an entire record may take more than one block. If block size is larger than the size of a record, storage for an entire record may take less than one block, resulting in an inefficient use of disk space. In online transaction processing (OLTP) applications, most transactions involve frequently reading and writing all of the values for entire records, typically one record or a small number of records at a time. As a result, row-wise storage is optimal for OLTP databases.

The next illustration shows how with columnar storage, the values for each column are stored sequentially into disk blocks.

SSN	Name	Age	Addr	City	St
101259797	SMITH	88	899 FIRST ST	JUNO	AL
892375862	CHIN	37	16137 MAIN ST	POMONA	CA
318370701	HANDU	12	42 JUNE ST	CHICAGO	IL

Using columnar storage, each data block stores values of a single column for multiple rows. As records enter the system, Amazon Redshift transparently converts the data to columnar storage for each of the columns.

In this simplified example, using columnar storage, each data block holds column field values for as many as three times as many records as row-based storage. This means that reading the same number of column field values for the same number of records requires a third of the I/O operations compared to row-wise storage. In practice, using tables with very large numbers of columns and very large row counts, storage efficiency is even greater.

An added advantage is that, since each block holds the same type of data, block data can use a compression scheme selected specifically for the column data type, further reducing disk space and I/O. For more information about compression encodings based on data types, see [Compression encodings](#).

The savings in space for storing data on disk also carries over to retrieving and then storing that data in memory. Since many database operations only need to access or operate on one or a small number of columns at a time, you can save memory space by only retrieving blocks for columns you actually need for a query. Where OLTP transactions typically involve most or all of the columns in a row for a small number of records, data warehouse queries commonly read only a few columns for a very large number of rows. This means that reading the same number of column field values for the same number of rows requires a fraction of the I/O operations. It uses a fraction of the memory that would be required for processing row-wise blocks. In practice, using tables with very large numbers of columns and very large row counts, the efficiency gains are proportionally greater. For example, suppose a table contains 100 columns. A query that uses five columns will only need to read about five percent of the data contained in the table. This savings is repeated for possibly billions or even trillions of records for large databases. In contrast, a row-wise database would read the blocks that contain the 95 unneeded columns as well.

Typical database block sizes range from 2 KB to 32 KB. Amazon Redshift uses a block size of 1 MB, which is more efficient and further reduces the number of I/O requests needed to perform any database loading or other operations that are part of query run.

Workload management

This section describes workload management (WLM), which helps you understand how Amazon Redshift prepares and runs queries.

Amazon Redshift workload management (WLM) enables flexible management priorities within workloads so that short, fast-running queries don't get stuck in queues behind long-running queries. Amazon Redshift creates query queues at runtime according to *service classes*, which define the configuration parameters for various types of queues, including internal system queues and user-accessible queues. From a user perspective, a user-accessible service class and a queue are functionally equivalent. For consistency, this documentation uses the term *queue* to mean a user-accessible service class as well as a runtime queue.

Redshift offers automatic workload management, called **automatic WLM**, which is tuned to handle varying workloads and is the recommended default. With automatic WLM, Redshift determines resource utilization as queries arrive and dynamically determines whether to run them on the main cluster, on a concurrency-scaling cluster, or to send each to a queue. (When queries are queued, automatic WLM prioritizes shorter-duration queries.) Automatic WLM maximizes total throughput and enables you to maintain efficient data-warehouse resources. You run workloads without having to be concerned with their size or how they're scheduled. Automatic WLM is the default for provisioned clusters. For more information, see [Implementing automatic WLM](#).

 **Note**

Amazon Redshift Serverless workgroups always use automatic WLM.

In times where a lot of queries or resource-intensive queries are running, workload management can scale to additional compute resources when workloads queue on local resources. Concurrency scaling with automatic WLM supports consistent performance for virtually unlimited concurrent users and queries.

Redshift provisioned clusters offer **manual WLM** if you need fine-grained manual optimization. Here, the customer manages resource allocation, query concurrency and queuing. When a query runs, WLM assigns the query to a queue according to the user's user group or by matching a query group that is listed in the queue configuration. This is configured with a query-group label that the user sets. For more information, see [Implementing manual WLM](#).

Though Manual WLM can be fine tuned over time to match your workload patterns, in most cases we discourage its use because its static nature can make it more difficult for you to adapt to changing workloads through the course of a day or over an extended period. It requires more monitoring and ongoing tuning. In addition, Manual WLM in many cases doesn't use compute

resources as efficiently as automatic WLM, such as for example if queues are set manually to limit memory allocated to them.

An important metric to measure the success of workload management configuration is system throughput, which in other words is how many queries are completed successfully. System throughput is measured in queries per second. For more information about system metrics, see [Monitoring Amazon Redshift cluster performance](#).

The easiest way to manage your WLM configuration is by using the Amazon Redshift Management console. You can also use the [Amazon Redshift command line interface](#) (CLI) or the [Amazon Redshift API](#). For more information about implementing and using workload management, see [Implementing workload management](#).

Using Amazon Redshift with other services

This section describes how you can use other services as sources and destinations for Amazon Redshift data.

Amazon Redshift integrates with other AWS services to enable you to move, transform, and load your data quickly and reliably, using data security features.

S3

Amazon Simple Storage Service (Amazon S3) is a web service that stores data in the cloud. Amazon Redshift leverages parallel processing to read and load data from multiple data files stored in Amazon S3 buckets. For more information, see [Loading data from Amazon S3](#).

You can also use parallel processing to export data from your Amazon Redshift data warehouse to multiple data files on Amazon S3. For more information, see [Unloading data in Amazon Redshift](#).

DynamoDB

Amazon DynamoDB is a fully managed NoSQL database service. You can use the COPY command to load an Amazon Redshift table with data from a single Amazon DynamoDB table. For more information, see [Loading data from an Amazon DynamoDB table](#).

SSH

You can use the COPY command in Amazon Redshift to load data from one or more remote hosts, such as Amazon EMR clusters, Amazon EC2 instances, or other computers. COPY connects

to the remote hosts using SSH and runs commands on the remote hosts to generate data. Amazon Redshift supports multiple simultaneous connections. The COPY command reads and loads the output from multiple host sources in parallel. For more information, see [Loading data from remote hosts](#).

AWS Data Pipeline

You can use AWS Data Pipeline to automate data movement and transformation into and out of Amazon Redshift. By using the built-in scheduling capabilities of AWS Data Pipeline, you can schedule and run recurring jobs without having to write your own complex data transfer or transformation logic. For example, you can set up a recurring job to automatically copy data from Amazon DynamoDB into Amazon Redshift. For a tutorial that walks you through the process of creating a pipeline that periodically moves data from Amazon S3 to Amazon Redshift, see [Copy data to Amazon Redshift using AWS Data Pipeline](#) in the AWS Data Pipeline Developer Guide.

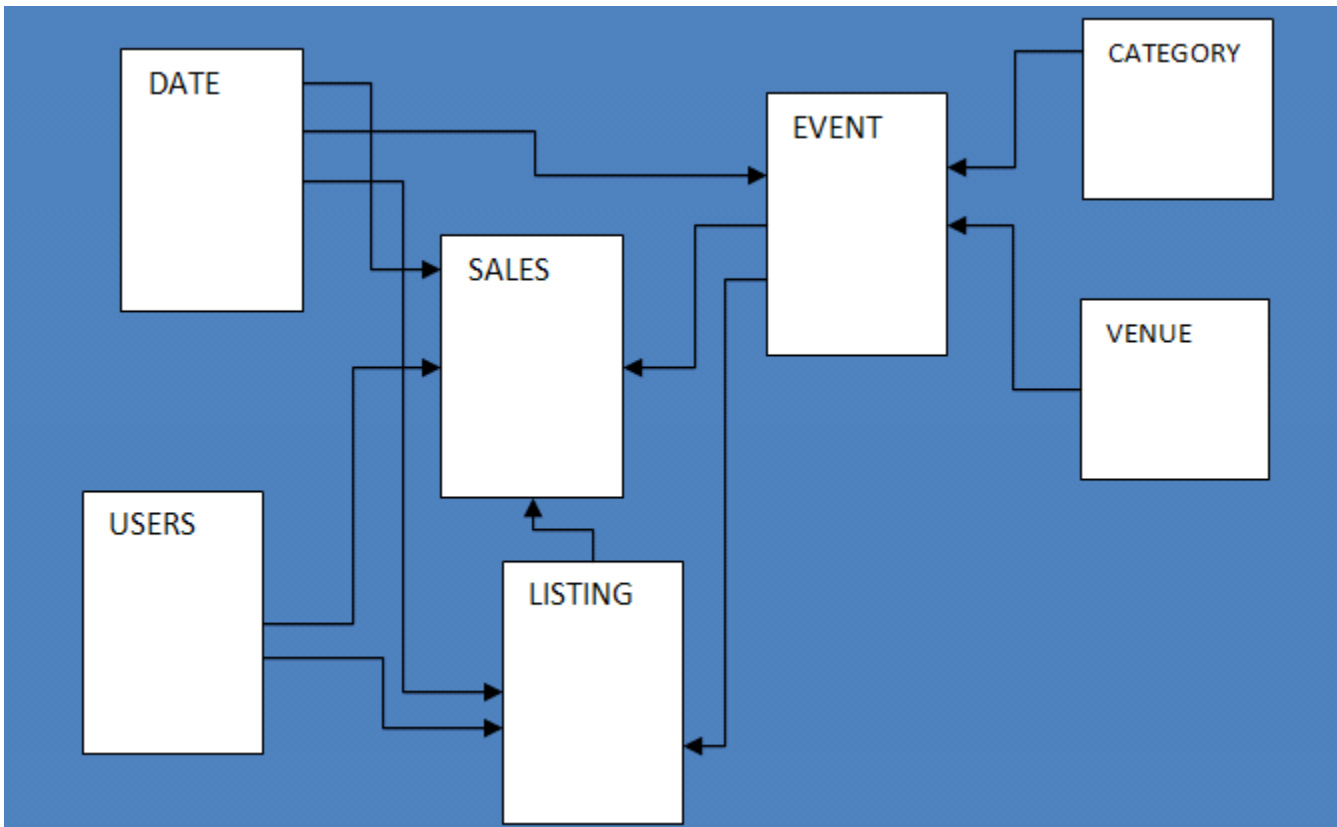

AWS DMS

You can migrate data to Amazon Redshift using AWS Database Migration Service. AWS DMS can migrate your data to and from most widely used commercial and open-source databases such as Oracle, PostgreSQL, Microsoft SQL Server, Amazon Redshift, Aurora DB cluster, DynamoDB, Amazon S3, MariaDB, and MySQL. For more information, see [Using an Amazon Redshift database as a target for AWS Database Migration Service](#).

Sample database

This section describes TICKIT, a sample database that Amazon Redshift documentation examples use.

This small database consists of seven tables: two fact tables and five dimensions. You can load the TICKIT dataset by following the steps in [Step 4: Load data from Amazon S3 to Amazon Redshift](#) in the Amazon Redshift Getting Started Guide.

This sample database application helps analysts track sales activity for the fictional TICKIT web site, where users buy and sell tickets online for sporting events, shows, and concerts. In particular, analysts can identify ticket movement over time, success rates for sellers, and the best-selling events, venues, and seasons. Analysts can use this information to provide incentives to buyers and sellers who frequent the site, to attract new users, and to drive advertising and promotions.

For example, the following query finds the top five sellers in San Diego, based on the number of tickets sold in 2008:

```
select sellerid, username, (firstname || ' ' || lastname) as name,
city, sum(qtysold)
from sales, date, users
where sales.sellerid = users.userid
and sales.dateid = date.dateid
and year = 2008
and city = 'San Diego'
group by sellerid, username, name, city
order by 5 desc
limit 5;
```

```
sellerid | username | name | city | sum
```

```

-----+-----+-----+-----+-----
49977 | JJK84WTE | Julie Hanson      | San Diego | 22
19750 | AAS23BDR | Charity Zimmerman | San Diego | 21
29069 | SVL81MEQ | Axel Grant        | San Diego | 17
43632 | VAG08HKW | Griffin Dodson    | San Diego | 16
36712 | RXT40MKU | Hiram Turner      | San Diego | 14
(5 rows)

```

The database used for the examples in this guide contains a small data set; the two fact tables each contain less than 200,000 rows, and the dimensions range from 11 rows in the CATEGORY table up to about 50,000 rows in the USERS table.

In particular, the database examples in this guide demonstrate the key features of Amazon Redshift table design:

- Data distribution
- Data sort
- Columnar compression

For information about the schemas of the tables in the TICKIT database, choose the following tabs:

CATEGORY table

Column name	Data type	Description
CATID	SMALLINT	Primary key, a unique ID value for each row. Each row represents a specific type of event for which tickets are bought and sold.
CATGROUP	VARCHAR(10)	Descriptive name for a group of events, such as Shows and Sports .
CATNAME	VARCHAR(10)	Short descriptive name for a type of event within a group, such as Opera and Musicals .
CATDESC	VARCHAR(50)	Longer descriptive name for the type of event, such as Musical theatre .

DATE table

Column name	Data type	Description
DATEID	SMALLINT	Primary key, a unique ID value for each row. Each row represents a day in the calendar year.
CALDATE	DATE	Calendar date, such as 2008-06-24 .
DAY	CHAR(3)	Day of week (short form), such as SA .
WEEK	SMALLINT	Week number, such as 26 .
MONTH	CHAR(5)	Month name (short form), such as JUN .
QTR	CHAR(5)	Quarter number (1 through 4).
YEAR	SMALLINT	Four-digit year (2008).
HOLIDAY	BOOLEAN	Flag that denotes whether the day is a public holiday (U.S.).

EVENT table

Column name	Data type	Description
EVENTID	INTEGER	Primary key, a unique ID value for each row. Each row represents a separate event that takes place at a specific venue at a specific time.
VENUEID	SMALLINT	Foreign-key reference to the VENUE table.
CATID	SMALLINT	Foreign-key reference to the CATEGORY table.
DATEID	SMALLINT	Foreign-key reference to the DATE table.
EVENTNAME	VARCHAR(200)	Name of the event, such as Hamlet or La Traviata .

Column name	Data type	Description
STARTTIME	TIMESTAMP	Full date and start time for the event, such as 2008-10-10 19:30:00 .

VENUE table

Column name	Data type	Description
VENUEID	SMALLINT	Primary key, a unique ID value for each row. Each row represents a specific venue where events take place.
VENUENAME	VARCHAR(100)	Exact name of the venue, such as Cleveland Browns Stadium .
VENUECITY	VARCHAR(30)	City name, such as Cleveland .
VENUESTATE	CHAR(2)	Two-letter state or province abbreviation (United States and Canada), such as OH .
VENUESEATS	INTEGER	Maximum number of seats available at the venue, if known, such as 73200 . For demonstration purposes, this column contains some null values and zeroes.

USERS table

Column name	Data type	Description
USERID	INTEGER	Primary key, a unique ID value for each row. Each row represents a registered user (a buyer or seller or both) who has listed or bought tickets for at least one event.

Column name	Data type	Description
USERNAME	CHAR(8)	An 8-character alphanumeric username, such as PGL08LJI .
FIRSTNAME	VARCHAR(30)	The user's first name, such as Victor .
LASTNAME	VARCHAR(30)	The user's last name, such as Hernandez .
CITY	VARCHAR(30)	The user's home city, such as Naperville .
STATE	CHAR(2)	The user's home state, such as GA .
EMAIL	VARCHAR(100)	The user's email address; this column contains random Latin values, such as turpis@cumsanlaoreet.org .
PHONE	CHAR(14)	The user's 14-character phone number, such as (818) 765-4255 .
LIKESPORTS, ...	BOOLEAN	A series of 10 different columns that identify the user's likes and dislikes with true and false values.

LISTING table

Column name	Data type	Description
LISTID	INTEGER	Primary key, a unique ID value for each row. Each row represents a listing of a batch of tickets for a specific event.
SELLERID	INTEGER	Foreign-key reference to the USERS table, identifying the user who is selling the tickets.
EVENTID	INTEGER	Foreign-key reference to the EVENT table.
DATEID	SMALLINT	Foreign-key reference to the DATE table.

Column name	Data type	Description
NUMTICKETS	SMALLINT	The number of tickets available for sale, such as 2 or 20 .
PRICEPERTICKET	DECIMAL(8,2)	The fixed price of an individual ticket, such as 27.00 or 206.00 .
TOTALPRICE	DECIMAL(8,2)	The total price for this listing (NUMTICKETS*PRICEPERTICKET).
LISTTIME	TIMESTAMP	The full date and time when the listing was posted, such as 2008-03-18 07:19:35 .

SALES table

Column name	Data type	Description
SALESID	INTEGER	Primary key, a unique ID value for each row. Each row represents a sale of one or more tickets for a specific event, as offered in a specific listing.
LISTID	INTEGER	Foreign-key reference to the LISTING table.
SELLERID	INTEGER	Foreign-key reference to the USERS table (the user who sold the tickets).
BUYERID	INTEGER	Foreign-key reference to the USERS table (the user who bought the tickets).
EVENTID	INTEGER	Foreign-key reference to the EVENT table.
DATEID	SMALLINT	Foreign-key reference to the DATE table.
QTY SOLD	SMALLINT	The number of tickets that were sold, from 1 to 8 . (A maximum of 8 tickets can be sold in a single transaction.)

Column name	Data type	Description
PRICEPAID	DECIMAL(8,2)	The total price paid for the tickets, such as 75.00 or 488.00 . The individual price of a ticket is PRICEPAID/QTYSOLD.
COMMISSION	DECIMAL(8,2)	The 15% commission that the business collects from the sale, such as 11.25 or 73.20 . The seller receives 85% of the PRICEPAID value.
SALETIME	TIMESTAMP	The full date and time when the sale was completed, such as 2008-05-24 06:21:47 .

Amazon Redshift best practices

Following, you can find best practices for planning a proof of concept, designing tables, loading data into tables, and writing queries for Amazon Redshift, and also a discussion of working with Amazon Redshift Advisor.

Amazon Redshift is not the same as other SQL database systems. To fully realize the benefits of the Amazon Redshift architecture, you must specifically design, build, and load your tables to use massively parallel processing, columnar data storage, and columnar data compression. If your data loading and query execution times are longer than you expect, or longer than you want, you might be overlooking key information.

If you are an experienced SQL database developer, we strongly recommend that you review this topic before you begin developing your Amazon Redshift data warehouse.

If you are new to developing SQL databases, this topic is not the best place to start. We recommend that you begin by reading [Run commands to define and use a database in your data warehouse](#) in the *Amazon Redshift Getting Started Guide*, and trying the examples yourself.

In this topic, you can find an overview of the most important development principles, along with specific tips, examples, and best practices for implementing those principles. No single practice can apply to every application. Evaluate all of your options before finishing a database design. For more information, see [Automatic table optimization](#), [Loading data in Amazon Redshift](#), [Query performance tuning](#), and the reference chapters.

Topics

- [Conduct a proof of concept \(POC\) for Amazon Redshift](#)
- [Amazon Redshift best practices for designing tables](#)
- [Amazon Redshift best practices for loading data](#)
- [Amazon Redshift best practices for designing queries](#)
- [Follow recommendations from Amazon Redshift Advisor](#)

Conduct a proof of concept (POC) for Amazon Redshift

Amazon Redshift is a popular cloud data warehouse, which offers a fully managed cloud-based service that integrates with an organization's Amazon Simple Storage Service data lake, real-time

streams, machine learning (ML) workflows, transactional workflows, and much more. The following sections guide you through the process of doing a proof of concept (POC) on Amazon Redshift. The information here helps you set goals for your POC, and takes advantage of tools that can automate the provisioning and configuration of services for your POC.

Note

For a copy of this information as a PDF, choose the link **Run your own Redshift POC** on the [Amazon Redshift resources](#) page.

When doing a POC of Amazon Redshift, you test, prove out, and adopt features ranging from best-in-class security capabilities, elastic scaling, easy integration and ingestion, and flexible decentralized data architecture options.

Follow these steps to conduct a successful POC.

Step 1: Scope your POC

When conducting a POC, you can either choose to use your own data, or you can choose to use benchmarking datasets. When you choose your own data you run your own queries against the data. With benchmarking data, sample queries are provided with the benchmark. See [Use sample datasets](#) for more details if you are not ready to conduct a POC with your own data just yet.

In general, we recommend using two weeks of data for an Amazon Redshift POC.

Start by doing the following:

1. **Identify your business and functional requirements**, then work backwards. Common examples are: faster performance, lower costs, test a new workload or feature, or comparison between Amazon Redshift and another data warehouse.
2. **Set specific targets** which become the success criteria for the POC. For example, from *faster performance*, come up with a list of the top five processes you wish to accelerate, and include the current run times along with your required run time. These can be reports, queries, ETL processes, data ingestion, or whatever your current pain points are.
3. **Identify the specific scope and artifacts** needed to run the tests. What datasets do you need to migrate or continuously ingest into Amazon Redshift, and what queries and processes are needed to run the tests to measure against the success criteria? There are two ways to do this:

Bring your own data

- To test your own data, come up with the minimum viable list of data artifacts which is required to test for your success criteria. For example, if your current data warehouse has 200 tables, but the reports you want to test only need 20, your POC can be run faster by using only the smaller subset of tables.

Use sample datasets

- If you don't have your own datasets ready, you can still get started doing a POC on Amazon Redshift by using the industry-standard benchmark datasets such as [TPC-DS](#) or [TPC-H](#) and run sample benchmarking queries to harness the power of Amazon Redshift. These datasets can be accessed from within your Amazon Redshift data warehouse after it is created. For detailed instructions on how to access these datasets and sample queries, see [Step 2: Launch Amazon Redshift](#).

Step 2: Launch Amazon Redshift

Amazon Redshift accelerates your time to insights with fast, easy, and secure cloud data warehousing at scale. You can start quickly by launching your warehouse on the [Redshift Serverless console](#) and get from data to insights in seconds. With Redshift Serverless, you can focus on delivering on your business outcomes without worrying about managing your data warehouse.

Set up Amazon Redshift Serverless

The first time you use Redshift Serverless, the console leads you through the steps required to launch your warehouse. You might also be eligible for a credit towards your Redshift Serverless usage in your account. For more information about choosing a free trial, see [Amazon Redshift free trial](#). Follow the steps in the [Creating a data warehouse with Redshift Serverless](#) in the *Amazon Redshift Getting Started Guide* to create a data warehouse with Redshift Serverless. If you do not have a dataset that you would like to load, the guide also contains steps on how to load a sample data set.

If you have previously launched Redshift Serverless in your account, follow the steps in [Creating a workgroup with a namespace](#) in the *Amazon Redshift Management Guide*. After your warehouse is available, you can opt to load the sample data available in Amazon Redshift. For information about using Amazon Redshift query editor v2 to load data, see [Loading sample data](#) in the *Amazon Redshift Management Guide*.

If you are bringing your own data instead of loading the sample data set, see [Step 3: Load your data](#).

Step 3: Load your data

After launching Redshift Serverless, the next step is to load your data for the POC. Whether you are uploading a simple CSV file, ingesting semi-structured data from S3, or streaming data directly, Amazon Redshift provides the flexibility to quickly and easily move the data into Amazon Redshift tables from the source.

Choose one of the following methods to load your data.

Upload a local file

For quick ingestion and analysis, you can use [Amazon Redshift query editor v2](#) to easily load data files from your local desktop. It has the capability to process files in various formats such as CSV, JSON, AVRO, PARQUET, ORC, and more. To enable your users, as an administrator, to load data from a local desktop using query editor v2 you have to specify a common Amazon S3 bucket, and the user account must be [configured with the proper permissions](#). You can follow [Data load made easy and secure in Amazon Redshift using Query Editor V2](#) for step-by-step guidance.

Load an Amazon S3 file

To load data from an Amazon S3 bucket into Amazon Redshift, begin by using the [COPY command](#), specifying the source Amazon S3 location and target Amazon Redshift table. Ensure that the IAM roles and permissions are properly configured to allow Amazon Redshift access to the designated Amazon S3 bucket. Follow [Tutorial: Loading data from Amazon S3](#) for step-by-step guidance. You can also choose the **Load data** option in query editor v2 to directly load data from your S3 bucket.

Continuous data ingestion

[Autocopy \(in preview\)](#) is an extension of the [COPY command](#) and automates continuous data loading from Amazon S3 buckets. When you create a copy job, Amazon Redshift detects when new Amazon S3 files are created in a specified path, and then loads them automatically without your intervention. Amazon Redshift keeps track of the loaded files to verify that they are loaded only one time. For instructions on how to create copy jobs, see [COPY JOB \(preview\)](#)

Note

Autocopy is currently in preview and supported only in provisioned clusters in specific AWS Regions. To create a preview cluster for autocopy, see [Loading tables with continuous file ingestion from Amazon S3 \(preview\)](#).

Load your streaming data

Streaming ingestion provides low-latency, high-speed ingestion of stream data from [Amazon Kinesis Data Streams](#) and [Amazon Managed Streaming for Apache Kafka](#) into Amazon Redshift. Amazon Redshift streaming ingestion uses a materialized view, which is updated directly from the stream utilizing [auto refresh](#). The materialized view maps to the stream data source. You can

perform filtering and aggregations on the stream data as part of the materialized view definition. For step-by-step guidance to load data from a stream, see [Getting started with Amazon Kinesis Data Streams](#) or an [Getting started with Amazon Managed Streaming for Apache Kafka](#).

Step 4: Analyze your data

After creating your Redshift Serverless workgroup and namespace, and loading your data, you can immediately run queries by opening the **Query editor v2** from the navigation panel of the [Redshift Serverless console](#). You can use query editor v2 to test query functionality or query performance against your own datasets.

Query using Amazon Redshift query editor v2

You can access query editor v2 from the Amazon Redshift console. See [Simplify your data analysis with Amazon Redshift query editor v2](#) for a complete guide on how to configure, connect, and run queries with query editor v2.

Alternatively, if you want to run a load test as part of your POC, you can do this by the following steps to install and run Apache JMeter.

Run a load test using Apache JMeter

To perform a load test to simulate “N” users submitting queries concurrently to Amazon Redshift, you can use [Apache JMeter](#), an open-source Java based tool.

To install and configure Apache JMeter to run against your Redshift Serverless workgroup, follow the instructions in [Automate Amazon Redshift load testing with the AWS Analytics Automation Toolkit](#). It uses the [AWS Analytics Automation toolkit \(AAA\)](#), an open source utility for dynamically deploying Redshift solutions, to automatically launch these resources. If you have loaded your own data into Amazon Redshift, be sure to perform the Step #5 – Customize SQL option, to make sure you supply the appropriate SQL statements you would like to test against your tables. Test each of these SQL statements one time using query editor v2 to make sure they run without errors.

After you complete customizing your SQL statements and finalizing your test plan, save and run your test plan against your Redshift Serverless workgroup. To monitor the progress of your test, open the [Redshift Serverless console](#), navigate to **Query and database monitoring**, choose the **Query history** tab and view information about your queries.

For performance metrics, choose the **Database performance** tab on the Redshift Serverless console, to monitor metrics such as **Database Connections** and **CPU utilization**. Here you can view a graph to monitor the RPU capacity used and observe how Redshift Serverless automatically scales to meet concurrent workload demands while the load test is running on your workgroup.

RPU capacity used

Overall capacity in Redshift processing units (RPUs).

Average capacity used

Database connections is another useful metric to monitor while running the load test to see how your workgroup is handling numerous concurrent connections at a given time to meet the increasing workload demands.

Database connections

The number of active database connections.

See [Find the best Amazon Redshift configuration for your workload using Redshift Test Drive](#) for information about using Test Drive to evaluate different Amazon Redshift configurations.

Amazon Redshift best practices for designing tables

As you plan your database, certain key table design decisions heavily influence overall query performance. These design choices also have a significant effect on storage requirements, which in turn affects query performance by reducing the number of I/O operations and minimizing the memory required to process queries.

In this section, you can find a summary of the most important design decisions and best practices for optimizing query performance. [Automatic table optimization](#) provides more detailed explanations and examples of table design options.

Topics

- [Choose the best sort key](#)
- [Choose the best distribution style](#)
- [Let COPY choose compression encodings](#)
- [Define primary key and foreign key constraints](#)
- [Use the smallest possible column size](#)
- [Use date/time data types for date columns](#)

Choose the best sort key

Amazon Redshift stores your data on disk in sorted order according to the sort key. The Amazon Redshift query optimizer uses sort order when it determines optimal query plans.

Note

When you use automatic table optimization, you don't need to choose the sort key of your table. For more information, see [Automatic table optimization](#).

Some suggestions for the best approach follow:

- To have Amazon Redshift choose the appropriate sort order, specify `AUTO` for the sort key.

- If recent data is queried most frequently, specify the timestamp column as the leading column for the sort key.

Queries are more efficient because they can skip entire blocks that fall outside the time range.

- If you do frequent range filtering or equality filtering on one column, specify that column as the sort key.

Amazon Redshift can skip reading entire blocks of data for that column. It can do so because it tracks the minimum and maximum column values stored on each block and can skip blocks that don't apply to the predicate range.

- If you frequently join a table, specify the join column as both the sort key and the distribution key.

Doing this enables the query optimizer to choose a sort merge join instead of a slower hash join. Because the data is already sorted on the join key, the query optimizer can bypass the sort phase of the sort merge join.

Choose the best distribution style

When you run a query, the query optimizer redistributes the rows to the compute nodes as needed to perform any joins and aggregations. The goal in selecting a table distribution style is to minimize the impact of the redistribution step by locating the data where it needs to be before the query is run.

Note

When you use automatic table optimization, you don't need to choose the distribution style of your table. For more information, see [Automatic table optimization](#).

Some suggestions for the best approach follow:

1. Distribute the fact table and one dimension table on their common columns.

Your fact table can have only one distribution key. Any tables that join on another key aren't collocated with the fact table. Choose one dimension to collocate based on how frequently it is joined and the size of the joining rows. Designate both the dimension table's primary key and the fact table's corresponding foreign key as the DISTKEY.

2. Choose the largest dimension based on the size of the filtered dataset.

Only the rows that are used in the join must be distributed, so consider the size of the dataset after filtering, not the size of the table.

3. Choose a column with high cardinality in the filtered result set.

If you distribute a sales table on a date column, for example, you should probably get fairly even data distribution, unless most of your sales are seasonal. However, if you commonly use a range-restricted predicate to filter for a narrow date period, most of the filtered rows occur on a limited set of slices and the query workload is skewed.

4. Change some dimension tables to use ALL distribution.

If a dimension table cannot be colocated with the fact table or other important joining tables, you can improve query performance significantly by distributing the entire table to all of the nodes. Using ALL distribution multiplies storage space requirements and increases load times and maintenance operations, so you should weigh all factors before choosing ALL distribution.

To have Amazon Redshift choose the appropriate distribution style, specify AUTO for the distribution style.

For more information about choosing distribution styles, see [Data distribution for query optimization](#).

Let COPY choose compression encodings

You can specify compression encodings when you create a table, but in most cases, automatic compression produces the best results.

ENCODE AUTO is the default for tables. When a table is set to ENCODE AUTO, Amazon Redshift automatically manages compression encoding for all columns in the table. For more information, see [CREATE TABLE](#) and [ALTER TABLE](#).

The COPY command analyzes your data and applies compression encodings to an empty table automatically as part of the load operation.

Automatic compression balances overall performance when choosing compression encodings. Range-restricted scans might perform poorly if sort key columns are compressed much more highly than other columns in the same query. As a result, automatic compression chooses a less efficient compression encoding to keep the sort key columns balanced with other columns.

Suppose that your table's sort key is a date or timestamp and the table uses many large varchar columns. In this case, you might get better performance by not compressing the sort key column at all. Run the [ANALYZE COMPRESSION](#) command on the table, then use the encodings to create a new table, but leave out the compression encoding for the sort key.

There is a performance cost for automatic compression encoding, but only if the table is empty and does not already have compression encoding. For short-lived tables and tables that you create frequently, such as staging tables, load the table once with automatic compression or run the ANALYZE COMPRESSION command. Then use those encodings to create new tables. You can add the encodings to the CREATE TABLE statement, or use CREATE TABLE LIKE to create a new table with the same encoding.

For more information, see [Loading tables with automatic compression](#).

Define primary key and foreign key constraints

Define primary key and foreign key constraints between tables wherever appropriate. Even though they are informational only, the query optimizer uses those constraints to generate more efficient query plans.

Do not define primary key and foreign key constraints unless your application enforces the constraints. Amazon Redshift does not enforce unique, primary-key, and foreign-key constraints.

See [Table constraints](#) for additional information about how Amazon Redshift uses constraints.

Use the smallest possible column size

Don't make it a practice to use the maximum column size for convenience.

Instead, consider the largest values you are likely to store in your columns and size them accordingly. For instance, a CHAR column for storing U.S. state and territory abbreviations used by the post office only needs to be CHAR(2).

Use date/time data types for date columns

Amazon Redshift stores DATE and TIMESTAMP data more efficiently than CHAR or VARCHAR, which results in better query performance. Use the DATE or TIMESTAMP data type, depending on the resolution you need, rather than a character type when storing date/time information. For more information, see [Datetime types](#).

Amazon Redshift best practices for loading data

Loading very large datasets can take a long time and consume a lot of computing resources. How your data is loaded can also affect query performance. This section presents best practices for loading data efficiently using COPY commands, bulk inserts, and staging tables.

Topics

- [Learn how to load data with a tutorial](#)

Learn how to load data with a tutorial

[Tutorial: Loading data from Amazon S3](#) walks you beginning to end through the steps to upload data to an Amazon S3 bucket and then use the COPY command to load the data into your tables. The tutorial includes help with troubleshooting load errors and compares the performance difference between loading from a single file and loading from multiple files.

Use a COPY command to load data

The COPY command loads data in parallel from Amazon S3, Amazon EMR, Amazon DynamoDB, or multiple data sources on remote hosts. COPY loads large amounts of data much more efficiently than using INSERT statements, and stores the data more effectively as well.

For more information about using the COPY command, see [Loading data from Amazon S3](#) and [Loading data from an Amazon DynamoDB table](#).

Use a single COPY command to load from multiple files

Amazon Redshift can automatically load in parallel from multiple compressed data files. You can specify the files to be loaded by using an Amazon S3 object prefix or by using a manifest file.

However, if you use multiple concurrent COPY commands to load one table from multiple files, Amazon Redshift is forced to perform a serialized load. This type of load is much slower and requires a VACUUM process at the end if the table has a sort column defined. For more information about using COPY to load data in parallel, see [Loading data from Amazon S3](#).

Loading data files

Source-data files come in different formats and use varying compression algorithms. When loading data with the COPY command, Amazon Redshift loads all of the files referenced by the Amazon S3 bucket prefix. (The prefix is a string of characters at the beginning of the object key name.) If the prefix refers to multiple files or files that can be split, Amazon Redshift loads the data in parallel, taking advantage of Amazon Redshift's MPP architecture. This divides the workload among the nodes in the cluster. In contrast, when you load data from a file that can't be split, Amazon Redshift is forced to perform a serialized load, which is much slower. The following sections describe the recommended way to load different file types into Amazon Redshift, depending on their format and compression.

Loading data from files that can be split

The following files can be automatically split when their data is loaded:

- an uncompressed CSV file
- a CSV file compressed with BZIP
- a columnar file (Parquet/ORC)

Amazon Redshift automatically splits files 128MB or larger into chunks. Columnar files, specifically Parquet and ORC, aren't split if they're less than 128MB. Redshift makes use of slices working in parallel to load the data. This provides fast load performance.

Loading data from files that can't be split

File types such as JSON, or CSV, when compressed with other compression algorithms, such as GZIP, aren't automatically split. For these we recommend manually splitting the data into multiple

smaller files that are close in size, from 1 MB to 1 GB after compression. Additionally, make the number of files a multiple of the number of slices in your cluster. For more information about how to split your data into multiple files and examples of loading data using COPY, see [Loading data from Amazon S3](#).

Compressing your data files

When you want to compress large load files, we recommend that you use gzip, lzop, bzip2, or Zstandard to compress them and split the data into multiple smaller files.

Specify the GZIP, LZOP, BZIP2, or ZSTD option with the COPY command. This example loads the TIME table from a pipe-delimited lzop file.

```
copy time
from 's3://amzn-s3-demo-bucket/data/timerows.lzo'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
lzop
delimiter '|';
```

There are instances when you don't have to split uncompressed data files. For more information about splitting your data and examples of using COPY to load data, see [Loading data from Amazon S3](#).

Verify data files before and after a load

Before you load data from Amazon S3, first verify that your Amazon S3 bucket contains all the correct files, and only those files. For more information, see [Verifying that the correct files are present in your bucket](#).

After the load operation is complete, query the [STL_LOAD_COMMITS](#) system table to verify that the expected files were loaded. For more information, see [Verifying that the data loaded correctly](#).

Use a multi-row insert

If a COPY command is not an option and you require SQL inserts, use a multi-row insert whenever possible. Data compression is inefficient when you add data only one row or a few rows at a time.

Multi-row inserts improve performance by batching up a series of inserts. The following example inserts three rows into a four-column table using a single INSERT statement. This is still a small insert, shown simply to illustrate the syntax of a multi-row insert.

```
insert into category_stage values
(default, default, default, default),
(20, default, 'Country', default),
(21, 'Concerts', 'Rock', default);
```

For more details and examples, see [INSERT](#).

Use a bulk insert

Use a bulk insert operation with a `SELECT` clause for high-performance data insertion.

Use the [INSERT](#) and [CREATE TABLE AS](#) commands when you need to move data or a subset of data from one table into another.

For example, the following `INSERT` statement selects all of the rows from the `CATEGORY` table and inserts them into the `CATEGORY_STAGE` table.

```
insert into category_stage
(select * from category);
```

The following example creates `CATEGORY_STAGE` as a copy of `CATEGORY` and inserts all of the rows in `CATEGORY` into `CATEGORY_STAGE`.

```
create table category_stage as
select * from category;
```

Load data in sort key order

Load your data in sort key order to avoid needing to vacuum.

If each batch of new data follows the existing rows in your table, your data is properly stored in sort order, and you don't need to run a vacuum. You don't need to presort the rows in each load because `COPY` sorts each batch of incoming data as it loads.

For example, suppose that you load data every day based on the current day's activity. If your sort key is a timestamp column, your data is stored in sort order. This order occurs because the current day's data is always appended at the end of the previous day's data. For more information, see [Load your data in sort key order](#). For more information about vacuum operations, see [Vacuuming tables](#).

Load data in sequential blocks

If you need to add a large quantity of data, load the data in sequential blocks according to sort order to eliminate the need to vacuum.

For example, suppose that you need to load a table with events from January 2017 to December 2017. Assuming each month is in a single file, load the rows for January, then February, and so on. Your table is completely sorted when your load completes, and you don't need to run a vacuum. For more information, see [Use time-series tables](#).

When loading very large datasets, the space required to sort might exceed the total available space. By loading data in smaller blocks, you use much less intermediate sort space during each load. In addition, loading smaller blocks make it easier to restart if the COPY fails and is rolled back.

Use time-series tables

If your data has a fixed retention period, you can organize your data as a sequence of time-series tables. In such a sequence, each table is identical but contains data for different time ranges.

You can easily remove old data simply by running a DROP TABLE command on the corresponding tables. This approach is much faster than running a large-scale DELETE process and saves you from having to run a subsequent VACUUM process to reclaim space. To hide the fact that the data is stored in different tables, you can create a UNION ALL view. When you delete old data, refine your UNION ALL view to remove the dropped tables. Similarly, as you load new time periods into new tables, add the new tables to the view. To signal the optimizer to skip the scan on tables that don't match the query filter, your view definition filters for the date range that corresponds to each table.

Avoid having too many tables in the UNION ALL view. Each additional table adds a small processing time to the query. Tables don't need to use the same time frame. For example, you might have tables for differing time periods, such as daily, monthly, and yearly.

If you use time-series tables with a timestamp column for the sort key, you effectively load your data in sort key order. Doing this eliminates the need to vacuum to re-sort the data. For more information, see [Load your data in sort key order](#).

Schedule around maintenance windows

If a scheduled maintenance occurs while a query is running, the query is terminated and rolled back and you need to restart it. Schedule long-running operations, such as large data loads or VACUUM operation, to avoid maintenance windows. You can also minimize the risk, and make restarts easier when they are needed, by performing data loads in smaller increments and managing the size of your VACUUM operations. For more information, see [Load data in sequential blocks](#) and [Vacuuming tables](#).

Amazon Redshift best practices for designing queries

To maximize query performance, follow these recommendations when creating queries:

- Design tables according to best practices to provide a solid foundation for query performance. For more information, see [Amazon Redshift best practices for designing tables](#).
- Avoid using `select *`. Include only the columns you specifically need.
- Use a [CASE conditional expression](#) to perform complex aggregations instead of selecting from the same table multiple times.
- Don't use cross-joins unless absolutely necessary. These joins without a join condition result in the Cartesian product of two tables. Cross-joins are typically run as nested-loop joins, which are the slowest of the possible join types.
- Use subqueries in cases where one table in the query is used only for predicate conditions and the subquery returns a small number of rows (less than about 200). The following example uses a subquery to avoid joining the LISTING table.

```
select sum(sales.qtysold)
from sales
where salesid in (select listid from listing where listtime > '2008-12-26');
```

- Use predicates to restrict the dataset as much as possible.
- In the predicate, use the least expensive operators that you can. [Comparison condition](#) operators are preferable to [LIKE](#) operators. LIKE operators are still preferable to [SIMILAR TO](#) or [POSIX operators](#).
- Avoid using functions in query predicates. Using them can drive up the cost of the query by requiring large numbers of rows to resolve the intermediate steps of the query.

- If possible, use a WHERE clause to restrict the dataset. The query planner can then use row order to help determine which records match the criteria, so it can skip scanning large numbers of disk blocks. Without this, the query execution engine must scan participating columns entirely.
- Add predicates to filter tables that participate in joins, even if the predicates apply the same filters. The query returns the same result set, but Amazon Redshift is able to filter the join tables before the scan step and can then efficiently skip scanning blocks from those tables. Redundant filters aren't needed if you filter on a column that's used in the join condition.

For example, suppose that you want to join SALES and LISTING to find ticket sales for tickets listed after December, grouped by seller. Both tables are sorted by date. The following query joins the tables on their common key and filters for `listing.listtime` values greater than December 1.

```
select listing.sellerid, sum(sales.qtysold)
from sales, listing
where sales.salesid = listing.listid
and listing.listtime > '2008-12-01'
group by 1 order by 1;
```

The WHERE clause doesn't include a predicate for `sales.saletime`, so the execution engine is forced to scan the entire SALES table. If you know the filter would result in fewer rows participating in the join, then add that filter as well. The following example cuts execution time significantly.

```
select listing.sellerid, sum(sales.qtysold)
from sales, listing
where sales.salesid = listing.listid
and listing.listtime > '2008-12-01'
and sales.saletime > '2008-12-01'
group by 1 order by 1;
```

- Use sort keys in the GROUP BY clause so the query planner can use more efficient aggregation. A query might qualify for one-phase aggregation when its GROUP BY list contains only sort key columns, one of which is also the distribution key. The sort key columns in the GROUP BY list must include the first sort key, then other sort keys that you want to use in sort key order. For example, it is valid to use the first sort key, the first and second sort keys, the first, second, and third sort keys, and so on. It is not valid to use the first and third sort keys.

You can confirm the use of one-phase aggregation by running the [EXPLAIN](#) command and looking for XN GroupAggregate in the aggregation step of the query.

- If you use both GROUP BY and ORDER BY clauses, make sure that you put the columns in the same order in both. That is, use the approach just following.

```
group by a, b, c
order by a, b, c
```

Don't use the following approach.

```
group by b, c, a
order by a, b, c
```

Follow recommendations from Amazon Redshift Advisor

To help you improve the performance and decrease the operating costs for your Amazon Redshift cluster, Amazon Redshift Advisor offers you specific recommendations about changes to make. Advisor develops its customized recommendations by analyzing performance and usage metrics for your cluster. These tailored recommendations relate to operations and cluster settings. To help you prioritize your optimizations, Advisor ranks recommendations by order of impact.

Advisor bases its recommendations on observations regarding performance statistics or operations data. Advisor develops observations by running tests on your clusters to determine if a test value is within a specified range. If the test result is outside of that range, Advisor generates an observation for your cluster. At the same time, Advisor creates a recommendation about how to bring the observed value back into the best-practice range. Advisor only displays recommendations that should have a significant impact on performance and operations. When Advisor determines that a recommendation has been addressed, it removes it from your recommendation list.

For example, suppose that your data warehouse contains a large number of uncompressed table columns. In this case, you can save on cluster storage costs by rebuilding tables using the ENCODE parameter to specify column compression. In another example, suppose that Advisor observes that your cluster contains a significant amount of data in uncompressed table data. In this case, it provides you with the SQL code block to find the table columns that are candidates for compression and resources that describe how to compress those columns.

Amazon Redshift Regions where Advisor is supported

The Amazon Redshift Advisor feature is available only in the following AWS Regions:

- US East (N. Virginia) Region (us-east-1)
- US East (Ohio) Region (us-east-2)
- US West (N. California) Region (us-west-1)
- US West (Oregon) Region (us-west-2)
- Africa (Cape Town) Region (af-south-1)
- Asia Pacific (Hong Kong) Region (ap-east-1)
- Asia Pacific (Hyderabad) Region (ap-south-2)
- Asia Pacific (Jakarta) Region (ap-southeast-3)
- Asia Pacific (Melbourne) Region (ap-southeast-4)
- Asia Pacific (Mumbai) Region (ap-south-1)
- Asia Pacific (Osaka) Region (ap-northeast-3)
- Asia Pacific (Seoul) Region (ap-northeast-2)
- Asia Pacific (Singapore) Region (ap-southeast-1)
- Asia Pacific (Sydney) Region (ap-southeast-2)
- Asia Pacific (Tokyo) Region (ap-northeast-1)
- Canada (Central) Region (ca-central-1)
- Canada West (Calgary) Region (ca-west-1)
- China (Beijing) Region (cn-north-1)
- China (Ningxia) Region (cn-northwest-1)
- Europe (Frankfurt) Region (eu-central-1)
- Europe (Ireland) Region (eu-west-1)
- Europe (London) Region (eu-west-2)
- Europe (Milan) Region (eu-south-1)
- Europe (Paris) Region (eu-west-3)
- Europe (Spain) Region (eu-south-2)
- Europe (Stockholm) Region (eu-north-1)

- Europe (Zurich) Region (eu-central-2)
- Israel (Tel Aviv) Region (il-central-1)
- Middle East (Bahrain) Region (me-south-1)
- Middle East (UAE) Region (me-central-1)
- South America (São Paulo) Region (sa-east-1)

- [Amazon Redshift Advisor recommendations](#)

Viewing Amazon Redshift Advisor recommendations

You can access Amazon Redshift Advisor recommendations using the Amazon Redshift console, Amazon Redshift API, or AWS CLI. To access recommendations you must have permission `redshift:ListRecommendations` attached to your IAM role or identity.

Viewing Amazon Redshift Advisor recommendations on the Amazon Redshift provisioned console

You can view Amazon Redshift Advisor recommendations on the AWS Management Console.

To view Amazon Redshift Advisor recommendations for Amazon Redshift clusters on the console

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Advisor**.
3. Expand each recommendation to see more details. On this page, you can sort and group recommendations.

Viewing Amazon Redshift Advisor recommendations using Amazon Redshift API operations

You can list Amazon Redshift Advisor recommendations for Amazon Redshift clusters using the Amazon Redshift API. Typically, you develop an application in your programming language of

your choice to call the `redshift:ListRecommendations` API using an AWS SDK. For more information, see [ListRecommendations](#) in the *Amazon Redshift API Reference*.

Viewing Amazon Redshift Advisor recommendations using AWS Command Line Interface operations

You can list Amazon Redshift Advisor recommendations for Amazon Redshift clusters using the AWS Command Line Interface. For more information, see [list-recommendations](#) in the *AWS CLI Command Reference*.

Amazon Redshift Advisor recommendations

Amazon Redshift Advisor offers recommendations about how to optimize your Amazon Redshift cluster to increase performance and save on operating costs. You can find explanations for each recommendation in the console, as described preceding. You can find further details on these recommendations in the following sections.

Topics

- [Compress Amazon S3 file objects loaded by COPY](#)
- [Isolate multiple active databases](#)
- [Reallocate workload management \(WLM\) memory](#)
- [Skip compression analysis during COPY](#)
- [Split Amazon S3 objects loaded by COPY](#)
- [Update table statistics](#)
- [Enable short query acceleration](#)
- [Alter distribution keys on tables](#)
- [Alter sort keys on tables](#)
- [Alter compression encodings on columns](#)
- [Data type recommendations](#)

Compress Amazon S3 file objects loaded by COPY

The `COPY` command takes advantage of the massively parallel processing (MPP) architecture in Amazon Redshift to read and load data in parallel. It can read files from Amazon S3, DynamoDB tables, and text output from one or more remote hosts.

When loading large amounts of data, we strongly recommend using the COPY command to load compressed data files from S3. Compressing large datasets saves time uploading the files to Amazon S3. COPY can also speed up the load process by uncompressing the files as they are read.

Analysis

Long-running COPY commands that load large uncompressed datasets often have an opportunity for considerable performance improvement. The Advisor analysis identifies COPY commands that load large uncompressed datasets. In such a case, Advisor generates a recommendation to implement compression on the source files in Amazon S3.

Recommendation

Ensure that each COPY that loads a significant amount of data, or runs for a significant duration, ingests compressed data objects from Amazon S3. You can identify the COPY commands that load large uncompressed datasets from Amazon S3 by running the following SQL command as a superuser.

```
SELECT
    wq.userid, query, exec_start_time AS starttime, COUNT(*) num_files,
    ROUND(MAX(wq.total_exec_time/1000000.0),2) execution_secs,
    ROUND(SUM(transfer_size)/(1024.0*1024.0),2) total_mb,
    SUBSTRING(querytxt,1,60) copy_sql
FROM stl_s3client s
JOIN stl_query q USING (query)
JOIN stl_wlm_query wq USING (query)
WHERE s.userid>1 AND http_method = 'GET'
      AND POSITION('COPY ANALYZE' IN querytxt) = 0
      AND aborted = 0 AND final_state='Completed'
GROUP BY 1, 2, 3, 7
HAVING SUM(transfer_size) = SUM(data_size)
AND SUM(transfer_size)/(1024*1024) >= 5
ORDER BY 6 DESC, 5 DESC;
```

If the staged data remains in Amazon S3 after you load it, which is common in data lake architectures, storing this data in a compressed form can reduce your storage costs.

Implementation tips

- The ideal object size is 1–128 MB after compression.

- You can compress files with gzip, lzop, or bzip2 format.

Isolate multiple active databases

As a best practice, we recommend isolating databases in Amazon Redshift from one another. Queries run in a specific database and can't access data from any other database on the cluster. However, the queries that you run in all databases of a cluster share the same underlying cluster storage space and compute resources. When a single cluster contains multiple active databases, their workloads are usually unrelated.

Analysis

The Advisor analysis reviews all databases on the cluster for active workloads running at the same time. If there are active workloads running at the same time, Advisor generates a recommendation to consider migrating databases to separate Amazon Redshift clusters.

Recommendation

Consider moving each actively queried database to a separate dedicated cluster. Using a separate cluster can reduce resource contention and improve query performance. It can do so because it allows you to set the size for each cluster for the storage, cost, and performance needs of each workload. Also, unrelated workloads often benefit from different workload management configurations.

To identify which databases are actively used, you can run this SQL command as a superuser.

```
SELECT database,
       COUNT(*) as num_queries,
       AVG(DATEDIFF(sec,starttime,endtime)) avg_duration,
       MIN(starttime) as oldest_ts,
       MAX(endtime) as latest_ts
FROM stl_query
WHERE userid > 1
GROUP BY database;
```

Implementation tips

- Because a user must connect to each database specifically, and queries can only access a single database, moving databases to separate clusters has minimal impact for users.

- One option to move a database is to take the following steps:
 1. Temporarily restore a snapshot of the current cluster to a cluster of the same size.
 2. Delete all databases from the new cluster except the target database to be moved.
 3. Resize the cluster to an appropriate node type and count for the database's workload.

Reallocate workload management (WLM) memory

Amazon Redshift routes user queries to [Implementing manual WLM](#) for processing. Workload management (WLM) defines how those queries are routed to the queues. Amazon Redshift allocates each queue a portion of the cluster's available memory. A queue's memory is divided among the queue's query slots.

When a queue is configured with more slots than the workload requires, the memory allocated to these unused slots goes underutilized. Reducing the configured slots to match the peak workload requirements redistributes the underutilized memory to active slots, and can result in improved query performance.

Analysis

The Advisor analysis reviews workload concurrency requirements to identify query queues with unused slots. Advisor generates a recommendation to reduce the number of slots in a queue when it finds the following:

- A queue with slots that are completely inactive throughout the analysis.
- A queue with more than four slots that had at least two inactive slots throughout the analysis.

Recommendation

Reducing the configured slots to match peak workload requirements redistributes underutilized memory to active slots. Consider reducing the configured slot count for queues where the slots have never been fully used. To identify these queues, you can compare the peak hourly slot requirements for each queue by running the following SQL command as a superuser.

```
WITH
generate_dt_series AS (select sysdate - (n * interval '5 second') as dt from (select
row_number() over () as n from stl_scan limit 17280)),
apex AS (
```

```

SELECT iq.dt, iq.service_class, iq.num_query_tasks, count(iq.slot_count) as
service_class_queries, sum(iq.slot_count) as service_class_slots
FROM
    (select gds.dt, wq.service_class, wsc.num_query_tasks, wq.slot_count
    FROM stl_wlm_query wq
    JOIN stv_wlm_service_class_config wsc ON (wsc.service_class =
wq.service_class AND wsc.service_class > 5)
    JOIN generate_dt_series gds ON (wq.service_class_start_time <= gds.dt AND
wq.service_class_end_time > gds.dt)
    WHERE wq.userid > 1 AND wq.service_class > 5) iq
GROUP BY iq.dt, iq.service_class, iq.num_query_tasks),
maxes as (SELECT apex.service_class, trunc(apex.dt) as d, date_part(h,apex.dt) as
dt_h, max(service_class_slots) max_service_class_slots
          from apex group by apex.service_class, apex.dt,
date_part(h,apex.dt))
SELECT apex.service_class - 5 AS queue, apex.service_class, apex.num_query_tasks AS
max_wlm_concurrency, maxes.d AS day, maxes.dt_h || ':00 - ' || maxes.dt_h || ':59' as
hour, MAX(apex.service_class_slots) as max_service_class_slots
FROM apex
JOIN maxes ON (apex.service_class = maxes.service_class AND apex.service_class_slots =
maxes.max_service_class_slots)
GROUP BY apex.service_class, apex.num_query_tasks, maxes.d, maxes.dt_h
ORDER BY apex.service_class, maxes.d, maxes.dt_h;

```

The `max_service_class_slots` column represents the maximum number of WLM query slots in the query queue for that hour. If underutilized queues exist, implement the slot reduction optimization by [modifying a parameter group](#), as described in the *Amazon Redshift Management Guide*.

Implementation tips

- If your workload is highly variable in volume, make sure that the analysis captured a peak utilization period. If it didn't, run the preceding SQL repeatedly to monitor peak concurrency requirements.
- For more details on interpreting the query results from the preceding SQL code, see the [wlm_apex_hourly.sql script](#) on GitHub.

Skip compression analysis during COPY

When you load data into an empty table with compression encoding declared with the COPY command, Amazon Redshift applies storage compression. This optimization ensures that data in your cluster is stored efficiently even when loaded by end users. The analysis required to apply compression can require significant time.

Analysis

The Advisor analysis checks for COPY operations that were delayed by automatic compression analysis. The analysis determines the compression encodings by sampling the data while it's being loaded. This sampling is similar to that performed by the [ANALYZE COMPRESSION](#) command.

When you load data as part of a structured process, such as in an overnight extract, transform, load (ETL) batch, you can define the compression beforehand. You can also optimize your table definitions to skip this phase permanently without any negative impacts.

Recommendation

To improve COPY responsiveness by skipping the compression analysis phase, implement either of the following two options:

- Use the column ENCODE parameter when creating any tables that you load using the COPY command.
- Turn off compression altogether by supplying the COMPUPDATE OFF parameter in the COPY command.

The best solution is generally to use column encoding during table creation, because this approach also maintains the benefit of storing compressed data on disk. You can use the ANALYZE COMPRESSION command to suggest compression encodings, but you must recreate the table to apply these encodings. To automate this process, you can use the [AWS ColumnEncodingUtility](#), found on GitHub.

To identify recent COPY operations that triggered automatic compression analysis, run the following SQL command.

```
WITH xids AS (  
  SELECT xid FROM stl_query WHERE userid>1 AND aborted=0  
  AND querytxt = 'analyze compression phase 1' GROUP BY xid
```

```

INTERSECT SELECT xid FROM stl_commit_stats WHERE node=-1)
SELECT a.userid, a.query, a.xid, a.starttime, b.complyze_sec,
       a.copy_sec, a.copy_sql
FROM (SELECT q.userid, q.query, q.xid, date_trunc('s',q.starttime)
      starttime, substring(querytxt,1,100) as copy_sql,
      ROUND(datediff(ms,starttime,endtime)::numeric / 1000.0, 2) copy_sec
      FROM stl_query q JOIN xids USING (xid)
      WHERE (querytxt ilike 'copy %from%' OR querytxt ilike '% copy %from%')
      AND querytxt not like 'COPY ANALYZE %') a
LEFT JOIN (SELECT xid,
                 ROUND(sum(datediff(ms,starttime,endtime))::numeric / 1000.0,2) complyze_sec
            FROM stl_query q JOIN xids USING (xid)
            WHERE (querytxt like 'COPY ANALYZE %'
                  OR querytxt like 'analyze compression phase %')
            GROUP BY xid ) b ON a.xid = b.xid
WHERE b.complyze_sec IS NOT NULL ORDER BY a.copy_sql, a.starttime;

```

Implementation tips

- Ensure that all tables of significant size created during your ETL processes (for example, staging tables and temporary tables) declare a compression encoding for all columns except the first sort key.
- Estimate the expected lifetime size of the table being loaded for each of the COPY commands identified by the SQL command preceding. If you are confident that the table will remain extremely small, turn off compression altogether with the `COMPUPDATE OFF` parameter. Otherwise, create the table with explicit compression before loading it with the COPY command.

Split Amazon S3 objects loaded by COPY

The COPY command takes advantage of the massively parallel processing (MPP) architecture in Amazon Redshift to read and load data from files on Amazon S3. The COPY command loads the data in parallel from multiple files, dividing the workload among the nodes in your cluster. To achieve optimal throughput, we strongly recommend that you divide your data into multiple files to take advantage of parallel processing.

Analysis

The Advisor analysis identifies COPY commands that load large datasets contained in a small number of files staged in Amazon S3. Long-running COPY commands that load large datasets

from a few files often have an opportunity for considerable performance improvement. When Advisor identifies that these COPY commands are taking a significant amount of time, it creates a recommendation to increase parallelism by splitting the data into additional files in Amazon S3.

Recommendation

In this case, we recommend the following actions, listed in priority order:

1. Optimize COPY commands that load fewer files than the number of cluster nodes.
2. Optimize COPY commands that load fewer files than the number of cluster slices.
3. Optimize COPY commands where the number of files is not a multiple of the number of cluster slices.

Certain COPY commands load a significant amount of data or run for a significant duration. For these commands, we recommend that you load a number of data objects from Amazon S3 that is equivalent to a multiple of the number of slices in the cluster. To identify how many S3 objects each COPY command has loaded, run the following SQL code as a superuser.

```
SELECT
  query, COUNT(*) num_files,
  ROUND(MAX(wq.total_exec_time/1000000.0),2) execution_secs,
  ROUND(SUM(transfer_size)/(1024.0*1024.0),2) total_mb,
  SUBSTRING(querytxt,1,60) copy_sql
FROM stl_s3client s
JOIN stl_query q USING (query)
JOIN stl_wlm_query wq USING (query)
WHERE s.userid>1 AND http_method = 'GET'
      AND POSITION('COPY ANALYZE' IN querytxt) = 0
      AND aborted = 0 AND final_state='Completed'
GROUP BY query, querytxt
HAVING (SUM(transfer_size)/(1024*1024))/COUNT(*) >= 2
ORDER BY CASE
  WHEN COUNT(*) < (SELECT max(node)+1 FROM stv_slices) THEN 1
  WHEN COUNT(*) < (SELECT COUNT(*) FROM stv_slices WHERE node=0) THEN 2
  ELSE 2+((COUNT(*) % (SELECT COUNT(*) FROM stv_slices))/(SELECT COUNT(*)::DECIMAL FROM
    stv_slices))
END, (SUM(transfer_size)/(1024.0*1024.0))/COUNT(*) DESC;
```

Implementation tips

- The number of slices in a node depends on the node size of the cluster. For more information about the number of slices in the various node types, see [Clusters and Nodes in Amazon Redshift](#) in the *Amazon Redshift Management Guide*.
- You can load multiple files by specifying a common prefix, or prefix key, for the set, or by explicitly listing the files in a manifest file. For more information about loading files, see [Loading data from compressed and uncompressed files](#).
- Amazon Redshift doesn't take file size into account when dividing the workload. Split your load data files so that the files are about equal size, between 1 MB and 1 GB after compression.

Update table statistics

Amazon Redshift uses a cost-based query optimizer to choose the optimum execution plan for queries. The cost estimates are based on table statistics gathered using the ANALYZE command. When statistics are out of date or missing, the database might choose a less efficient plan for query execution, especially for complex queries. Maintaining current statistics helps complex queries run in the shortest possible time.

Analysis

The Advisor analysis tracks tables whose statistics are out-of-date or missing. It reviews table access metadata associated with complex queries. If tables that are frequently accessed with complex patterns are missing statistics, Advisor creates a **critical** recommendation to run ANALYZE. If tables that are frequently accessed with complex patterns have out-of-date statistics, Advisor creates a **suggested** recommendation to run ANALYZE.

Recommendation

Whenever table content changes significantly, update statistics with ANALYZE. We recommend running ANALYZE whenever a significant number of new data rows are loaded into an existing table with COPY or INSERT commands. We also recommend running ANALYZE whenever a significant number of rows are modified using UPDATE or DELETE commands. To identify tables with missing or out-of-date statistics, run the following SQL command as a superuser. The results are ordered from largest to smallest table.

To identify tables with missing or out-of-date statistics, run the following SQL command as a superuser. The results are ordered from largest to smallest table.

```

SELECT
  ti.schema||'.'||ti."table" tablename,
  ti.size table_size_mb,
  ti.stats_off statistics_accuracy
FROM svv_table_info ti
WHERE ti.stats_off > 5.00
ORDER BY ti.size DESC;

```

Implementation tips

The default ANALYZE threshold is 10 percent. This default means that the ANALYZE command skips a given table if fewer than 10 percent of the table's rows have changed since the last ANALYZE. As a result, you might choose to issue ANALYZE commands at the end of each ETL process. Taking this approach means that ANALYZE is often skipped but also ensures that ANALYZE runs when needed.

ANALYZE statistics have the most impact for columns that are used in joins (for example, JOIN tbl_a ON col_b) or as predicates (for example, WHERE col_b = 'xyz'). By default, ANALYZE collects statistics for all columns in the table specified. If needed, you can reduce the time required to run ANALYZE by running ANALYZE only for the columns where it has the most impact. You can run the following SQL command to identify columns used as predicates. You can also let Amazon Redshift choose which columns to analyze by specifying ANALYZE PREDICATE COLUMNS.

```

WITH predicate_column_info as (
SELECT ns.nspname AS schema_name, c.relname AS table_name, a.attnum as col_num,
  a.attname as col_name,
  CASE
    WHEN 10002 = s.stakind1 THEN array_to_string(stavalues1, '|||')
    WHEN 10002 = s.stakind2 THEN array_to_string(stavalues2, '|||')
    WHEN 10002 = s.stakind3 THEN array_to_string(stavalues3, '|||')
    WHEN 10002 = s.stakind4 THEN array_to_string(stavalues4, '|||')
    ELSE NULL::varchar
  END AS pred_ts
FROM pg_statistic s
JOIN pg_class c ON c.oid = s.starelid
JOIN pg_namespace ns ON c.relnamespace = ns.oid
JOIN pg_attribute a ON c.oid = a.attrelid AND a.attnum = s.staattnum)
SELECT schema_name, table_name, col_num, col_name,
  pred_ts NOT LIKE '2000-01-01%' AS is_predicate,

```

```
CASE WHEN pred_ts NOT LIKE '2000-01-01%' THEN (split_part(pred_ts,
' || ',1))::timestamp ELSE NULL::timestamp END as first_predicate_use,
CASE WHEN pred_ts NOT LIKE '% || 2000-01-01%' THEN (split_part(pred_ts,
' || ',2))::timestamp ELSE NULL::timestamp END as last_analyze
FROM predicate_column_info;
```

For more information, see [Analyzing tables](#).

Enable short query acceleration

Short query acceleration (SQA) prioritizes selected short-running queries ahead of longer-running queries. SQA runs short-running queries in a dedicated space, so that SQA queries aren't forced to wait in queues behind longer queries. SQA only prioritizes queries that are short-running and are in a user-defined queue. With SQA, short-running queries begin running more quickly and users see results sooner.

If you turn on SQA, you can reduce or eliminate workload management (WLM) queues that are dedicated to running short queries. In addition, long-running queries don't need to contend with short queries for slots in a queue, so you can configure your WLM queues to use fewer query slots. When you use lower concurrency, query throughput is increased and overall system performance is improved for most workloads. For more information, see [Short query acceleration](#).

Analysis

Advisor checks for workload patterns and reports the number of recent queries where SQA would reduce latency and the daily queue time for SQA-eligible queries.

Recommendation

Modify the WLM configuration to turn on SQA. Amazon Redshift uses a machine learning algorithm to analyze each eligible query. Predictions improve as SQA learns from your query patterns. For more information, see [Configuring Workload Management](#).

When you turn on SQA, WLM sets the maximum runtime for short queries to dynamic by default. We recommend keeping the dynamic setting for SQA maximum runtime.

Implementation tips

To check whether SQA is turned on, run the following query. If the query returns a row, then SQA is turned on.

```
select * from stv_wlm_service_class_config
```

```
where service_class = 14;
```

For more information, see [Monitoring SQA](#).

Alter distribution keys on tables

Amazon Redshift distributes table rows throughout the cluster according to the table distribution style. Tables with KEY distribution require a column as the distribution key (DISTKEY). A table row is assigned to a node slice of a cluster based on its DISTKEY column value.

An appropriate DISTKEY places a similar number of rows on each node slice and is frequently referenced in join conditions. An optimized join occurs when tables are joined on their DISTKEY columns, accelerating query performance.

Analysis

Advisor analyzes your cluster's workload to identify the most appropriate distribution key for the tables that can significantly benefit from a KEY distribution style.

Recommendation

Advisor provides [ALTER TABLE](#) statements that alter the DISTSTYLE and DISTKEY of a table based on its analysis. To realize a significant performance benefit, make sure to implement all SQL statements within a recommendation group.

Redistributing a large table with ALTER TABLE consumes cluster resources and requires temporary table locks at various times. Implement each recommendation group when other cluster workload is light. For more details on optimizing table distribution properties, see the [Amazon Redshift Engineering's Advanced Table Design Playbook: Distribution Styles and Distribution Keys](#).

For more information about ALTER DISTSTYLE and DISTKEY, see [ALTER TABLE](#).

Note

If you don't see a recommendation that doesn't necessarily mean that the current distribution styles are the most appropriate. Advisor doesn't provide recommendations when there isn't enough data or the expected benefit of redistribution is small.

Advisor recommendations apply to a particular table and don't necessarily apply to a table that contains a column with the same name. Tables that share a column name can have different characteristics for those columns unless data inside the tables is the same.

If you see recommendations for staging tables that are created or dropped by ETL jobs, modify your ETL processes to use the Advisor recommended distribution keys.

Alter sort keys on tables

Amazon Redshift sorts table rows according to the table [sort key](#). The sorting of table rows is based on the sort key column values.

Sorting a table on an appropriate sort key can accelerate performance of queries, especially those with range-restricted predicates, by requiring fewer table blocks to be read from disk.

Analysis

Advisor analyzes your cluster's workload over several days to identify a beneficial sort key for your tables.

Recommendation

Advisor provides two groups of ALTER TABLE statements that alter the sort key of a table based on its analysis:

- Statements that alter a table that currently doesn't have a sort key to add a COMPOUND sort key.
- Statements that alter a sort key from INTERLEAVED to COMPOUND or no sort key.

Using compound sort keys significantly reduces maintenance overhead. Tables with compound sort keys don't need the expensive VACUUM REINDEX operations that are necessary for interleaved sorts. In practice, compound sort keys are more effective than interleaved sort keys for the vast majority of Amazon Redshift workloads. However, if a table is small, it's more efficient not to have a sort key to avoid sort key storage overhead.

When sorting a large table with the ALTER TABLE, cluster resources are consumed and table locks are required at various times. Implement each recommendation when a cluster's workload is moderate. More details on optimizing table sort key configurations can be found in the [Amazon Redshift Engineering's Advanced Table Design Playbook: Compound and Interleaved Sort Keys](#).

For more information about ALTER SORTKEY, see [ALTER TABLE](#).

Note

If you don't see a recommendation for a table, that doesn't necessarily mean that the current configuration is the best. Advisor doesn't provide recommendations when there isn't enough data or the expected benefit of sorting is small.

Advisor recommendations apply to a particular table and don't necessarily apply to a table that contains a column with the same name and data type. Tables that share column names can have different recommendations based on the data in the tables and the workload.

Alter compression encodings on columns

Compression is a column-level operation that reduces the size of data when it's stored. Compression is used in Amazon Redshift to conserve storage space and improve query performance by reducing the amount of disk I/O. We recommend an optimal compression encoding for each column based on its data type and on query patterns. With optimal compression, queries can run more efficiently and the database can take up minimal storage space.

Analysis

Advisor performs analysis of your cluster's workload and database schema continually to identify the optimal compression encoding for each table column.

Recommendation

Advisor provides ALTER TABLE statements that change the compression encoding of particular columns, based on its analysis.

Changing column compression encodings with [ALTER TABLE](#) consumes cluster resources and requires table locks at various times. It's best to implement recommendations when the cluster workload is light.

For reference, [ALTER TABLE examples](#) shows several statements that change the encoding for a column.

Note

Advisor doesn't provide recommendations when there isn't enough data or the expected benefit of changing the encoding is small.

Data type recommendations

Amazon Redshift has a library of SQL data types for various use cases. These include integer types like INT and types to store characters, like VARCHAR. Redshift stores types in an optimized way to provide fast access and good query performance. Also, Redshift provides functions for specific types, which you can use to format or perform calculations on query results.

Analysis

Advisor performs analysis of your cluster's workload and database schema continually to identify columns that can benefit significantly from a data type change.

Recommendation

Advisor provides an ALTER TABLE statement that adds a new column with the suggested data type. An accompanying UPDATE statement copies data from the existing column to the new column. After you create the new column and load the data, change your queries and ingestion scripts to access the new column. Then leverage features and functions specialized to the new data type, found in [SQL functions reference](#).

Copying existing data to the new column can take time. We recommend that you implement each advisor recommendation when the cluster's workload is light. Reference the list of available data types at [Data types](#).

Note that Advisor doesn't provide recommendations when there isn't enough data or the expected benefit of changing the data type is small.

Tutorials for Amazon Redshift

Follow the steps in these tutorials to learn about Amazon Redshift features:

[Tutorial: Loading data from Amazon S3](#)

In this tutorial, you walk through the process of loading data into your Amazon Redshift database tables from data files in an S3 bucket from beginning to end.

[Tutorial: Querying nested data with Amazon Redshift Spectrum](#)

In this tutorial, you use Redshift Spectrum to query nested data. Redshift Spectrum lets you query data in Parquet, ORC, JSON, or Ion file formats.

[Tutorial: Configuring manual workload management \(WLM\) queues](#)

In this tutorial, you configure Amazon Redshift to use manual workload management (WLM) queues. Amazon Redshift uses WLM queues to manage how resources are divided to run concurrent queries. You must configure Amazon Redshift to use manual WLM if you need to use multiple WLM WLM queues.

[Tutorial: Using spatial SQL functions with Amazon Redshift](#)

In this tutorial, you query data using spatial functions. You use spatial functions to query geometry and geography data.

[Tutorials for Amazon Redshift ML](#)

In these tutorials, you create and use machine learning models.

[Tutorial: Creating roles and querying with RBAC](#)

In this tutorial, you use role-based access control (RBAC) to create and use permissions in a database you create. With RBAC, you can create roles with specific permissions, such as read-only or read-write permissions. You can then assign these roles to users to grant them the specified permissions.

Automatic table optimization

Automatic table optimization is a self-tuning capability that automatically optimizes the design of tables by applying sort and distribution keys without the need for administrator intervention. By using automation to tune the design of tables, you can get started and get the fastest performance without investing time to manually tune and implement table optimizations.

Automatic table optimization continuously observes how queries interact with tables. It uses advanced artificial intelligence methods to choose sort and distribution keys to optimize performance for the cluster's workload. If Amazon Redshift determines that applying a key improves cluster performance, tables are automatically altered within hours from the time the cluster was created, with minimal impact to queries.

To take advantage of this automation, an Amazon Redshift administrator creates a new table, or alters an existing table to enable it to use automatic optimization. Existing tables with a distribution style or sort key of AUTO are already enabled for automation. When you run queries against those tables, Amazon Redshift determines if a sort key or distribution key will improve performance. If so, then Amazon Redshift automatically modifies the table without requiring administrator intervention. If a minimum number of queries are run, optimizations are applied within hours of the cluster being launched.

If Amazon Redshift determines that a distribution key improves the performance of queries, tables where distribution style is AUTO can have their distribution style changed to KEY.

Topics

- [Enabling, disabling, and monitoring automatic table optimization](#)
- [Column compression to reduce the size of stored data](#)
- [Data distribution for query optimization](#)
- [Sort keys](#)
- [Table constraints](#)

Enabling, disabling, and monitoring automatic table optimization

By default, tables created without explicitly defining sort keys or distributions keys are set to AUTO. At the time of table creation, you can also explicitly set a sort or a distribution key manually. If you set the sort or distribution key, then the table is not automatically managed.

Enabling automatic table optimization

To enable an existing table to be automatically optimized, use the ALTER statement options to change the table to AUTO. You might choose to define automation for sort keys, but not for distribution keys (and vice versa). If you run an ALTER statement to convert a table to be an automated table, existing sort keys and distribution styles are preserved.

```
ALTER TABLE table_name ALTER SORTKEY AUTO;
```

```
ALTER TABLE table_name ALTER DISTSTYLE AUTO;
```

For more information, see [ALTER TABLE](#).

Initially, a table has no distribution key or sort key. The distribution style is set to either EVEN or ALL depending on table size. As the table grows in size, Amazon Redshift applies the optimal distribution keys and sort keys. Optimizations are applied within hours after a minimum number of queries are run. When determining sort key optimizations, Amazon Redshift attempts to optimize the data blocks read from disk during a table scan. When determining distribution style optimizations, Amazon Redshift tries to optimize the number of bytes transferred between cluster nodes.

Removing automatic table optimization from a table

You can remove a table from automatic optimization. Removing a table from automation involves selecting a sort key or distribution style. To change distribution style, specify a specific distribution style.

```
ALTER TABLE table_name ALTER DISTSTYLE EVEN;
```

```
ALTER TABLE table_name ALTER DISTSTYLE ALL;
```

```
ALTER TABLE table_name ALTER DISTSTYLE KEY DISTKEY c1;
```

To change a sort key, you can define a sort key or choose none.

```
ALTER TABLE table_name ALTER SORTKEY(c1, c2);
```

```
ALTER TABLE table_name ALTER SORTKEY NONE;
```

Monitoring automatic table optimization

The system view `SVV_ALTER_TABLE_RECOMMENDATIONS` records the current Amazon Redshift Advisor recommendations for tables. This view shows recommendations for all tables, those that are defined for automatic optimization and those that aren't.

To view if a table is defined for automatic optimization, query the system view `SVV_TABLE_INFO`. Entries appear only for tables visible in the current session's database. Recommendations are inserted into the view twice per day starting within hours from the time the cluster was created. After a recommendation is available, it's started within an hour. After a recommendation has been applied (either by Amazon Redshift or by you), it no longer appears in the view.

The system view `SVL_AUTO_WORKER_ACTION` shows an audit log of all actions taken by Amazon Redshift, and the previous state of the table.

The system view `SVV_TABLE_INFO` lists all of the tables in the system, along with a column to indicate whether the sort key and distribution style of the table is set to `AUTO`.

For more information about these system views, see [System monitoring \(provisioned only\)](#).

Column compression to reduce the size of stored data

Compression is a column-level operation that reduces the size of data when it is stored.

Compression conserves storage space and reduces the size of data that is read from storage, which reduces the amount of disk I/O and therefore improves query performance.

`ENCODE AUTO` is the default for tables. When a table is set to `ENCODE AUTO`, Amazon Redshift automatically manages compression encoding for all columns in the table. For more information, see [CREATE TABLE](#) and [ALTER TABLE](#).

However, if you specify compression encoding for any column in the table, the table is no longer set to ENCODE AUTO. Amazon Redshift no longer automatically manages compression encoding for all columns in the table.

You can apply a compression type, or *encoding*, to the columns in a table manually when you create the table. Or you can use the COPY command to analyze and apply compression automatically. For more information, see [Let COPY choose compression encodings](#). For details about applying automatic compression, see [Loading tables with automatic compression](#).

 **Note**

We strongly recommend using the COPY command to apply automatic compression.

You might choose to apply compression encodings manually if the new table shares the same data characteristics as another table. Or you might do so if you discover in testing that the compression encodings applied during automatic compression are not the best fit for your data. If you choose to apply compression encodings manually, you can run the [ANALYZE COMPRESSION](#) command against an already populated table and use the results to choose compression encodings.

To apply compression manually, you specify compression encodings for individual columns as part of the CREATE TABLE statement. The syntax is as follows.

```
CREATE TABLE table_name (column_name  
data_type ENCODE encoding-type)[, ...]
```

Here, *encoding-type* is taken from the keyword table in the following section.

For example, the following statement creates a two-column table, PRODUCT. When data is loaded into the table, the PRODUCT_ID column is not compressed, but the PRODUCT_NAME column is compressed, using the byte dictionary encoding (BYTEDICT).

```
create table product(  
product_id int encode raw,  
product_name char(20) encode bytedict);
```

You can specify the encoding for a column when it is added to a table using the ALTER TABLE command.

```
ALTER TABLE table-name ADD [ COLUMN ] column_name column_type ENCODE encoding-type
```

Topics

- [Compression encodings](#)
- [Testing compression encodings](#)

Compression encodings

A *compression encoding* specifies the type of compression that is applied to a column of data values as rows are added to a table.

ENCODE AUTO is the default for tables. When a table is set to ENCODE AUTO, Amazon Redshift automatically manages compression encoding for all columns in the table. For more information, see [CREATE TABLE](#) and [ALTER TABLE](#).

However, if you specify compression encoding for any column in the table, the table is no longer set to ENCODE AUTO. Amazon Redshift no longer automatically manages compression encoding for all columns in the table.

When you use CREATE TABLE, ENCODE AUTO is disabled when you specify compression encoding for any column in the table. If ENCODE AUTO is disabled, Amazon Redshift automatically assigns compression encoding to columns for which you don't specify an ENCODE type as follows:

- Columns that are defined as sort keys are assigned RAW compression.
- Columns that are defined as BOOLEAN, REAL, or DOUBLE PRECISION data types are assigned RAW compression.
- Columns that are defined as SMALLINT, INTEGER, BIGINT, DECIMAL, DATE, TIMESTAMP, or TIMESTAMPTZ data types are assigned AZ64 compression.
- Columns that are defined as CHAR or VARCHAR data types are assigned LZ0 compression.

You can change a table's encoding after creating it by using ALTER TABLE. If you disable ENCODE AUTO using ALTER TABLE, Amazon Redshift no longer automatically manages compression encodings for your columns. All columns will keep the compression encoding types that they had when you disabled ENCODE AUTO until you change them or you enable ENCODE AUTO again.

Amazon Redshift supports the following compression encodings:

Raw

Raw encoding is the default encoding for columns that are designated as sort keys and columns that are defined as `BOOLEAN`, `REAL`, or `DOUBLE PRECISION` data types. With raw encoding, data is stored in raw, uncompressed form.

AZ64

AZ64 is a proprietary compression encoding algorithm designed by Amazon to achieve a high compression ratio and improved query processing. At its core, the AZ64 algorithm compresses smaller groups of data values and uses single instruction, multiple data (SIMD) instructions for parallel processing. Use AZ64 to achieve significant storage savings and high performance for numeric, date, and time data types.

You can use AZ64 as the compression encoding when defining columns using `CREATE TABLE` and `ALTER TABLE` statements with the following data types:

- `SMALLINT`
- `INTEGER`
- `BIGINT`
- `DECIMAL`
- `DATE`
- `TIMESTAMP`
- `TIMESTAMPTZ`

Byte-dictionary

In byte dictionary encoding, a separate dictionary of unique values is created for each block of column values on disk. (An Amazon Redshift disk block occupies 1 MB.) The dictionary contains up to 256 one-byte values that are stored as indexes to the original data values. If more than 256 values are stored in a single block, the extra values are written into the block in raw, uncompressed form. The process repeats for each disk block.

This encoding is very effective on low cardinality string columns. This encoding is optimal when the data domain of a column is fewer than 256 unique values.

For columns with the string data type (`CHAR` and `VARCHAR`) encoded with `BYTEDICT`, Amazon Redshift performs vectorized scans and predicate evaluations that operate over compressed

data directly. These scans use hardware-specific single instruction and multiple data (SIMD) instructions for parallel processing. This significantly speeds up the scanning of string columns. Byte-dictionary encoding is especially space-efficient if a CHAR/VARCHAR column holds long character strings.

Suppose that a table has a COUNTRY column with a CHAR(30) data type. As data is loaded, Amazon Redshift creates the dictionary and populates the COUNTRY column with the index value. The dictionary contains the indexed unique values, and the table itself contains only the one-byte subscripts of the corresponding values.

Note

Trailing blanks are stored for fixed-length character columns. Therefore, in a CHAR(30) column, every compressed value saves 29 bytes of storage when you use the byte-dictionary encoding.

The following table represents the dictionary for the COUNTRY column.

Unique data value	Dictionary index	Size (fixed length, 30 bytes per value)
England	0	30
United States of America	1	30
Venezuela	2	30
Sri Lanka	3	30
Argentina	4	30
Japan	5	30
Total		180

The following table represents the values in the COUNTRY column.

Original data value	Original size (fixed length, 30 bytes per value)	Compressed value (index)	New size (bytes)
England	30	0	1
England	30	0	1
United States of America	30	1	1
United States of America	30	1	1
Venezuela	30	2	1
Sri Lanka	30	3	1
Argentina	30	4	1
Japan	30	5	1
Sri Lanka	30	3	1
Argentina	30	4	1
Total	300		10

The total compressed size in this example is calculated as follows: 6 different entries are stored in the dictionary ($6 * 30 = 180$), and the table contains 10 1-byte compressed values, for a total of 190 bytes.

Delta

Delta encodings are very useful for date time columns.

Delta encoding compresses data by recording the difference between values that follow each other in the column. This difference is recorded in a separate dictionary for each block of column values on disk. (An Amazon Redshift disk block occupies 1 MB.) For example, suppose that the column contains 10 integers in sequence from 1 to 10. The first are stored as a 4-byte

integer (plus a 1-byte flag). The next nine are each stored as a byte with the value 1, indicating that it is one greater than the previous value.

Delta encoding comes in two variations:

- DELTA records the differences as 1-byte values (8-bit integers)
- DELTA32K records differences as 2-byte values (16-bit integers)

If most of the values in the column could be compressed by using a single byte, the 1-byte variation is very effective. However, if the deltas are larger, this encoding, in the worst case, is somewhat less effective than storing the uncompressed data. Similar logic applies to the 16-bit version.

If the difference between two values exceeds the 1-byte range (DELTA) or 2-byte range (DELTA32K), the full original value is stored, with a leading 1-byte flag. The 1-byte range is from -127 to 127, and the 2-byte range is from -32K to 32K.

The following table shows how a delta encoding works for a numeric column.

Original data value	Original size (bytes)	Difference (delta)	Compressed value	Compressed size (bytes)
1	4		1	1+4 (flag + actual value)
5	4	4	4	1
50	4	45	45	1
200	4	150	150	1+4 (flag + actual value)
185	4	-15	-15	1
220	4	35	35	1
221	4	1	1	1
Totals	28			15

LZO

LZO encoding provides a very high compression ratio with good performance. LZO encoding works especially well for CHAR and VARCHAR columns that store very long character strings. They are especially good for free-form text, such as product descriptions, user comments, or JSON strings.

Mostly

Mostly encodings are useful when the data type for a column is larger than most of the stored values require. By specifying a mostly encoding for this type of column, you can compress the majority of the values in the column to a smaller standard storage size. The remaining values that cannot be compressed are stored in their raw form. For example, you can compress a 16-bit column, such as an INT2 column, to 8-bit storage.

In general, the mostly encodings work with the following data types:

- SMALLINT/INT2 (16-bit)
- INTEGER/INT (32-bit)
- BIGINT/INT8 (64-bit)
- DECIMAL/NUMERIC (64-bit)

Choose the appropriate variation of the mostly encoding to suit the size of the data type for the column. For example, apply MOSTLY8 to a column that is defined as a 16-bit integer column. Applying MOSTLY16 to a column with a 16-bit data type or MOSTLY32 to a column with a 32-bit data type is disallowed.

Mostly encodings might be less effective than no compression when a relatively high number of the values in the column can't be compressed. Before applying one of these encodings to a column, perform a check. *Most* of the values that you are going to load now (and are likely to load in the future) should fit into the ranges shown in the following table.

Encoding	Compressed storage size	Range of values that can be compressed (values outside the range are stored raw)
MOSTLY8	1 byte (8 bits)	-128 to 127
MOSTLY16	2 bytes (16 bits)	-32768 to 32767

Encoding	Compressed storage size	Range of values that can be compressed (values outside the range are stored raw)
MOSTLY32	4 bytes (32 bits)	-2147483648 to +2147483647

Note

For decimal values, ignore the decimal point to determine whether the value fits into the range. For example, 1,234.56 is treated as 123,456 and can be compressed in a MOSTLY32 column.

For example, the VENUEID column in the VENUE table is defined as a raw integer column, which means that its values consume 4 bytes of storage. However, the current range of values in the column is 0 to 309. Therefore, recreating and reloading this table with MOSTLY16 encoding for VENUEID would reduce the storage of every value in that column to 2 bytes.

If the VENUEID values referenced in another table were mostly in the range of 0 to 127, it might make sense to encode that foreign-key column as MOSTLY8. Before making the choice, run several queries against the referencing table data to find out whether the values mostly fall into the 8-bit, 16-bit, or 32-bit range.

The following table shows compressed sizes for specific numeric values when the MOSTLY8, MOSTLY16, and MOSTLY32 encodings are used:

Original value	Original INT or BIGINT size (bytes)	MOSTLY8 compressed size (bytes)	MOSTLY16 compressed size (bytes)	MOSTLY32 compressed size (bytes)
1	4	1	2	4
10	4	1	2	4
100	4	1	2	4
1000	4	Same as raw data size	2	4

Original value	Original INT or BIGINT size (bytes)	MOSTLY8 compressed size (bytes)	MOSTLY16 compressed size (bytes)	MOSTLY32 compressed size (bytes)
10000	4		2	4
20000	4		2	4
40000	8		Same as raw data size	4
100000	8			4
2000000000	8			4

Run length

Run length encoding replaces a value that is repeated consecutively with a token that consists of the value and a count of the number of consecutive occurrences (the length of the run). A separate dictionary of unique values is created for each block of column values on disk. (An Amazon Redshift disk block occupies 1 MB.) This encoding is best suited to a table in which data values are often repeated consecutively, for example, when the table is sorted by those values.

For example, suppose that a column in a large dimension table has a predictably small domain, such as a COLOR column with fewer than 10 possible values. These values are likely to fall in long sequences throughout the table, even if the data is not sorted.

We don't recommend applying run length encoding on any column that is designated as a sort key. Range-restricted scans perform better when blocks contain similar numbers of rows. If sort key columns are compressed much more highly than other columns in the same query, range-restricted scans might perform poorly.

The following table uses the COLOR column example to show how the run length encoding works.

Original data value	Original size (bytes)	Compressed value (token)	Compressed size (bytes)
Blue	4	{2,Blue}	5

Original data value	Original size (bytes)	Compressed value (token)	Compressed size (bytes)
Blue	4		0
Green	5	{3,Green}	6
Green	5		0
Green	5		0
Blue	4	{1,Blue}	5
Yellow	6	{4,Yellow}	7
Yellow	6		0
Yellow	6		0
Yellow	6		0
Total	51		23

Text255 and Text32k

Text255 and text32k encodings are useful for compressing VARCHAR columns in which the same words recur often. A separate dictionary of unique words is created for each block of column values on disk. (An Amazon Redshift disk block occupies 1 MB.) The dictionary contains the first 245 unique words in the column. Those words are replaced on disk by a one-byte index value representing one of the 245 values, and any words that are not represented in the dictionary are stored uncompressed. The process repeats for each 1-MB disk block. If the indexed words occur frequently in the column, the column yields a high compression ratio.

For the text32k encoding, the principle is the same, but the dictionary for each block does not capture a specific number of words. Instead, the dictionary indexes each unique word it finds until the combined entries reach a length of 32K, minus some overhead. The index values are stored in two bytes.

For example, consider the VENUENAME column in the VENUE table. Words such as **Arena**, **Center**, and **Theatre** recur in this column and are likely to be among the first 245 words

encountered in each block if text255 compression is applied. If so, this column benefits from compression. This is because every time those words appear, they occupy only 1 byte of storage (instead of 5, 6, or 7 bytes, respectively).

ZSTD

Zstandard (ZSTD) encoding provides a high compression ratio with very good performance across diverse datasets. ZSTD works especially well with CHAR and VARCHAR columns that store a wide range of long and short strings, such as product descriptions, user comments, logs, and JSON strings. Where some algorithms, such as Delta encoding or Mostly encoding, can potentially use more storage space than no compression, ZSTD is unlikely to increase disk usage.

ZSTD supports SMALLINT, INTEGER, BIGINT, DECIMAL, REAL, DOUBLE PRECISION, BOOLEAN, CHAR, VARCHAR, DATE, TIMESTAMP, and TIMESTAMPTZ data types.

The following table identifies the supported compression encodings and the data types that support the encoding.

Encoding type	Keyword in CREATE TABLE and ALTER TABLE	Data types
Raw (no compression)	RAW	All
AZ64	AZ64	SMALLINT, INTEGER, BIGINT, DECIMAL, DATE, TIMESTAMP, TIMESTAMPTZ
Byte dictionary	BYTEDICT	SMALLINT, INTEGER, BIGINT, DECIMAL, REAL, DOUBLE PRECISION, CHAR, VARCHAR, DATE, TIMESTAMP, TIMESTAMPTZ
Delta	DELTA DELTA32K	SMALLINT, INT, BIGINT, DATE, TIMESTAMP, DECIMAL INT, BIGINT, DATE, TIMESTAMP, DECIMAL

Encoding type	Keyword in CREATE TABLE and ALTER TABLE	Data types
LZO	LZO	SMALLINT, INTEGER, BIGINT, DECIMAL, CHAR, VARCHAR, DATE, TIMESTAMP, TIMESTAMPTZ, SUPER
Mostlyn	MOSTLY8	SMALLINT, INT, BIGINT, DECIMAL
	MOSTLY16	INT, BIGINT, DECIMAL
	MOSTLY32	BIGINT, DECIMAL
Run-length	RUNLENGTH	SMALLINT, INTEGER, BIGINT, DECIMAL, REAL, DOUBLE PRECISION, BOOLEAN, CHAR, VARCHAR, DATE, TIMESTAMP, TIMESTAMPTZ
Text	TEXT255	VARCHAR only
	TEXT32K	VARCHAR only
Zstandard	ZSTD	SMALLINT, INTEGER, BIGINT, DECIMAL, REAL, DOUBLE PRECISION, BOOLEAN, CHAR, VARCHAR, DATE, TIMESTAMP, TIMESTAMPTZ, SUPER

Testing compression encodings

If you decide to manually specify column encodings, you might want to test different encodings with your data.

Note

We recommend that you use the `COPY` command to load data whenever possible, and allow the `COPY` command to choose the optimal encodings based on your data. Or you can use the [ANALYZE COMPRESSION](#) command to view the suggested encodings for existing

data. For details about applying automatic compression, see [Loading tables with automatic compression](#).

To perform a meaningful test of data compression, you must have a large number of rows. For this example, we create a table and insert rows by using a statement that selects from two tables; VENUE and LISTING. We leave out the WHERE clause that would normally join the two tables. The result is that *each* row in the VENUE table is joined to *all* of the rows in the LISTING table, for a total of over 32 million rows. This is known as a Cartesian join and normally is not recommended. However, for this purpose, it's a convenient method of creating many rows. If you have an existing table with data that you want to test, you can skip this step.

After we have a table with sample data, we create a table with seven columns. Each has a different compression encoding: raw, bytedict, lzo, run length, text255, text32k, and zstd. We populate each column with exactly the same data by running an INSERT command that selects the data from the first table.

To test compression encodings, do the following:

1. (Optional) First, use a Cartesian join to create a table with a large number of rows. Skip this step if you want to test an existing table.

```
create table cartesian_venue(  
venueid smallint not null distkey sortkey,  
venueid varchar(100),  
venuecity varchar(30),  
venuestate char(2),  
venuestate integer);  
  
insert into cartesian_venue  
select venueid, venueid, venuecity, venuestate, venuestate  
from venue, listing;
```

2. Next, create a table with the encodings that you want to compare.

```
create table encodingvenue (  
venueid varchar(100) encode raw,  
venuebytedict varchar(100) encode bytedict,  
venueid varchar(100) encode lzo,  
venueid varchar(100) encode runlength,  
venueid varchar(100) encode text255,
```

```
venuetext32k varchar(100) encode text32k,
venuezstd varchar(100) encode zstd);
```

3. Insert the same data into all of the columns using an INSERT statement with a SELECT clause.

```
insert into encodingvenue
select venuename as venueraw, venuename as venuebytedict, venuename as venuelzo,
venuename as venuerunlength, venuename as venuetext32k, venuename as venuetext255,
venuename as venuezstd
from cartesian_venue;
```

4. Verify the number of rows in the new table.

```
select count(*) from encodingvenue

count
-----
38884394
(1 row)
```

5. Query the [STV_BLOCKLIST](#) system table to compare the number of 1 MB disk blocks used by each column.

The MAX aggregate function returns the highest block number for each column. The STV_BLOCKLIST table includes details for three system-generated columns. This example uses `col < 6` in the WHERE clause to exclude the system-generated columns.

```
select col, max(blocknum)
from stv_blocklist b, stv_tbl_perm p
where (b.tbl=p.id) and name = 'encodingvenue'
and col < 7
group by name, col
order by col;
```

The query returns the following results. The columns are numbered beginning with zero. Depending on how your cluster is configured, your result might have different numbers, but the relative sizes should be similar. You can see that BYTEDICT encoding on the second column produced the best results for this dataset. This approach has a compression ratio of better than 20:1. LZO and ZSTD encoding also produced excellent results. Different datasets produce different results, of course. When a column contains longer text strings, LZO often produces the best compression results.

```

col | max
-----+-----
 0 | 203
 1 |  10
 2 |  22
 3 | 204
 4 |  56
 5 |  72
 6 |  20
(7 rows)

```

If you have data in an existing table, you can use the [ANALYZE COMPRESSION](#) command to view the suggested encodings for the table. For example, the following example shows the recommended encoding for a copy of the VENUE table, CARTESIAN_VENUE, that contains 38 million rows. Notice that ANALYZE COMPRESSION recommends LZO encoding for the VENUENAME column. ANALYZE COMPRESSION chooses optimal compression based on multiple factors, which include percent of reduction. In this specific case, BYTEDICT provides better compression, but LZO also produces greater than 90 percent compression.

```
analyze compression cartesian_venue;
```

Table	Column	Encoding	Est_reduction_pct
reallybigvenue	venueid	lzo	97.54
reallybigvenue	venuename	lzo	91.71
reallybigvenue	venuecity	lzo	96.01
reallybigvenue	venuestate	lzo	97.68
reallybigvenue	venueseats	lzo	98.21

Example

The following example creates a CUSTOMER table that has columns with various data types. This CREATE TABLE statement shows one of many possible combinations of compression encodings for these columns.

```

create table customer(
  custkey int encode delta,
  custname varchar(30) encode raw,
  gender varchar(7) encode text255,

```

```
address varchar(200) encode text255,
city varchar(30) encode text255,
state char(2) encode raw,
zipcode char(5) encode bytedict,
start_date date encode delta32k);
```

The following table shows the column encodings that were chosen for the CUSTOMER table and gives an explanation for the choices:

Column	Data type	Encoding	Explanation
CUSTKEY	int	delta	CUSTKEY consists of unique, consecutive integer values. Because the differences are one byte, DELTA is a good choice.
CUSTNAME	varchar(30)	raw	CUSTNAME has a large domain with few repeated values. Any compression encoding would probably be ineffective.
GENDER	varchar(7)	text255	GENDER is very small domain with many repeated values. Text255 works well with VARCHAR columns in which the same words recur.
ADDRESS	varchar(200)	text255	ADDRESS is a large domain, but contains many repeated

Column	Data type	Encoding	Explanation
			words, such as Street, Avenue, North, South, and so on. Text 255 and text 32k are useful for compressing VARCHAR columns in which the same words recur. The column length is short, so text255 is a good choice.
CITY	varchar(30)	text255	CITY is a large domain, with some repeated values. Certain city names are used much more commonly than others. Text255 is a good choice for the same reasons as ADDRESS.

Column	Data type	Encoding	Explanation
STATE	char(2)	raw	In the United States, STATE is a precise domain of 50 two-character values. Bytedict encoding would yield some compression, but because the column size is only two characters, compression might not be worth the overhead of uncompressing the data.
ZIPCODE	char(5)	bytedict	ZIPCODE is a known domain of fewer than 50,000 unique values. Certain zip codes occur much more commonly than others. Bytedict encoding is very effective when a column contains a limited number of unique values.
START_DATE	date	delta32k	Delta encodings are very useful for date time columns, especially if the rows are loaded in date order.

Data distribution for query optimization

When you load data into a table, Amazon Redshift distributes the rows of the table to each of the compute nodes according to the table's distribution style. When you run a query, the query optimizer redistributes the rows to the compute nodes as needed to perform any joins and aggregations. The goal in choosing a table distribution style is to minimize the impact of the redistribution step by locating the data where it must be before the query is run.

Note

This section will introduce you to the principles of data distribution in an Amazon Redshift database. We recommend that you create your tables with `DISTSTYLE AUTO`. If you do so, then Amazon Redshift uses automatic table optimization to choose the data distribution style. For more information, see [Automatic table optimization](#). The rest of this section provides details about distribution styles.

Data distribution concepts

Some data distribution concepts for Amazon Redshift follow.

Nodes and slices

An Amazon Redshift cluster is a set of nodes. Each node in the cluster has its own operating system, dedicated memory, and dedicated disk storage. One node is the *leader node*, which

manages the distribution of data and query processing tasks to the compute nodes. The *compute nodes* provide resources to do those tasks.

The disk storage for a compute node is divided into a number of *slices*. The number of slices per node depends on the node size of the cluster. The nodes all participate in running parallel queries, working on data that is distributed as evenly as possible across the slices. For more information about the number of slices that each node size has, see [About clusters and nodes](#) in the *Amazon Redshift Management Guide*.

Data redistribution

When you load data into a table, Amazon Redshift distributes the rows of the table to each of the node slices according to the table's distribution style. As part of a query plan, the optimizer determines where blocks of data must be located to best run the query. The data is then physically moved, or redistributed, while the query runs. Redistribution might involve either sending specific rows to nodes for joining or broadcasting an entire table to all of the nodes.

Data redistribution can account for a substantial portion of the cost of a query plan, and the network traffic it generates can affect other database operations and slow overall system performance. To the extent that you anticipate where best to locate data initially, you can minimize the impact of data redistribution.

Data distribution goals

When you load data into a table, Amazon Redshift distributes the table's rows to the compute nodes and slices according to the distribution style that you chose when you created the table. Data distribution has two primary goals:

- To distribute the workload uniformly among the nodes in the cluster. Uneven distribution, or data distribution skew, forces some nodes to do more work than others, which impairs query performance.
- To minimize data movement as a query runs. If the rows that participate in joins or aggregates are already collocated on the nodes with their joining rows in other tables, the optimizer doesn't need to redistribute as much data when queries run.

The distribution strategy that you choose for your database has important consequences for query performance, storage requirements, data loading, and maintenance. By choosing the best distribution style for each table, you can balance your data distribution and significantly improve overall system performance.

Distribution styles

When you create a table, you can designate one of the following distribution styles: AUTO, EVEN, KEY, or ALL.

If you don't specify a distribution style, Amazon Redshift uses AUTO distribution.

AUTO distribution

With AUTO distribution, Amazon Redshift assigns an optimal distribution style based on the size of the table data. For example, if AUTO distribution style is specified, Amazon Redshift initially assigns the ALL distribution style to a small table. When the table grows larger, Amazon Redshift might change the distribution style to KEY, choosing the primary key (or a column of the composite primary key) as the distribution key. If the table grows larger and none of the columns are suitable to be the distribution key, Amazon Redshift changes the distribution style to EVEN. The change in distribution style occurs in the background with minimal impact to user queries.

To view actions that Amazon Redshift automatically performed to alter a table distribution key, see [SVL_AUTO_WORKER_ACTION](#). To view current recommendations regarding altering a table distribution key, see [SVV_ALTER_TABLE_RECOMMENDATIONS](#).

To view the distribution style applied to a table, query the PG_CLASS_INFO system catalog view. For more information, see [Viewing distribution styles](#). If you don't specify a distribution style with the CREATE TABLE statement, Amazon Redshift applies AUTO distribution.

EVEN distribution

The leader node distributes the rows across the slices in a round-robin fashion, regardless of the values in any particular column. EVEN distribution is appropriate when a table doesn't participate in joins. It's also appropriate when there isn't a clear choice between KEY distribution and ALL distribution.

KEY distribution

The rows are distributed according to the values in one column. The leader node places matching values on the same node slice. If you distribute a pair of tables on the joining keys, the leader node collocates the rows on the slices according to the values in the joining columns. This way, matching values from the common columns are physically stored together.

ALL distribution

A copy of the entire table is distributed to every node. Where EVEN distribution or KEY distribution place only a portion of a table's rows on each node, ALL distribution ensures that every row is collocated for every join that the table participates in.

ALL distribution multiplies the storage required by the number of nodes in the cluster, and so it takes much longer to load, update, or insert data into multiple tables. ALL distribution is appropriate only for relatively slow moving tables; that is, tables that are not updated frequently or extensively. Because the cost of redistributing small tables during a query is low, there isn't a significant benefit to define small dimension tables as `DISTSTYLE ALL`.

Note

After you have specified a distribution style for a column, Amazon Redshift handles data distribution at the cluster level. Amazon Redshift does not require or support the concept of partitioning data within database objects. You don't need to create table spaces or define partitioning schemes for tables.

In certain scenarios, you can change the distribution style of a table after it is created. For more information, see [ALTER TABLE](#). For scenarios when you can't change the distribution style of a table after it's created, you can recreate the table and populate the new table with a deep copy. For more information, see [Performing a deep copy](#)

Viewing distribution styles

To view the distribution style of a table, query the `PG_CLASS_INFO` view or the `SVV_TABLE_INFO` view.

The `RELEFFECTIVEDISTSTYLE` column in `PG_CLASS_INFO` indicates the current distribution style for the table. If the table uses automatic distribution, `RELEFFECTIVEDISTSTYLE` is 10, 11, or 12, which indicates whether the effective distribution style is AUTO (ALL), AUTO (EVEN), or AUTO (KEY). If the table uses automatic distribution, the distribution style might initially show AUTO (ALL), then change to AUTO (EVEN) or AUTO (KEY) when the table grows.

The following table gives the distribution style for each value in `RELEFFECTIVEDISTSTYLE` column:

<code>RELEFFECTIVEDISTSTYLE</code>	Current distribution style
0	EVEN

RELEFFECTIVEDISTSTYLE	Current distribution style
1	KEY
8	ALL
10	AUTO (ALL)
11	AUTO (EVEN)
12	AUTO (KEY)

The DISTSTYLE column in SVV_TABLE_INFO indicates the current distribution style for the table. If the table uses automatic distribution, DISTSTYLE is AUTO (ALL), AUTO (EVEN), or AUTO (KEY).

The following example creates four tables using the three distribution styles and automatic distribution, then queries SVV_TABLE_INFO to view the distribution styles.

```
create table public.dist_key (col1 int)
diststyle key distkey (col1);

insert into public.dist_key values (1);

create table public.dist_even (col1 int)
diststyle even;

insert into public.dist_even values (1);

create table public.dist_all (col1 int)
diststyle all;

insert into public.dist_all values (1);

create table public.dist_auto (col1 int);

insert into public.dist_auto values (1);

select "schema", "table", diststyle from SVV_TABLE_INFO
where "table" like 'dist%';
```

```
schema | table | diststyle
```

```
-----+-----+-----  
public   | dist_key      | KEY(col1)  
public   | dist_even     | EVEN  
public   | dist_all      | ALL  
public   | dist_auto     | AUTO(ALL)
```

Evaluating query patterns

Choosing distribution styles is only one aspect of database design. Consider distribution styles within the context of the entire system, balancing distribution with other important factors such as cluster size, compression encoding methods, sort keys, and table constraints.

Test your system with data that is as close to real data as possible.

To make good choices for distribution styles, you must understand the query patterns for your Amazon Redshift application. Identify the most costly queries in your system and base your initial database design on the demands of those queries. Factors that determine the total cost of a query include how long the query takes to run and how much computing resources it consumes. Other factors that determine query cost are how often it is run, and how disruptive it is to other queries and database operations.

Identify the tables that are used by the most costly queries, and evaluate their role in query runtime. Consider how the tables are joined and aggregated.

Use the guidelines in this section to choose a distribution style for each table. When you have done so, create the tables and load them with data that is as close as possible to real data. Then test the tables for the types of queries that you expect to use. You can evaluate the query explain plans to identify tuning opportunities. Compare load times, storage space, and query runtimes to balance your system's overall requirements.

Designating distribution styles

The considerations and recommendations for designating distribution styles in this section use a star schema as an example. Your database design might be based on a star schema, some variant of a star schema, or an entirely different schema. Amazon Redshift is designed to work effectively with whatever schema design you choose. The principles in this section can be applied to any design schema.

1. Specify the primary key and foreign keys for all your tables.

Amazon Redshift does not enforce primary key and foreign key constraints, but the query optimizer uses them when it generates query plans. If you set primary keys and foreign keys, your application must maintain the validity of the keys.

2. Distribute the fact table and its largest dimension table on their common columns.

Choose the largest dimension based on the size of dataset that participates in the most common join, not only the size of the table. If a table is commonly filtered, using a WHERE clause, only a portion of its rows participate in the join. Such a table has less impact on redistribution than a smaller table that contributes more data. Designate both the dimension table's primary key and the fact table's corresponding foreign key as DISTKEY. If multiple tables use the same distribution key, they are also collocated with the fact table. Your fact table can have only one distribution key. Any tables that join on another key isn't collocated with the fact table.

3. Designate distribution keys for the other dimension tables.

Distribute the tables on their primary keys or their foreign keys, depending on how they most commonly join with other tables.

4. Evaluate whether to change some of the dimension tables to use ALL distribution.

If a dimension table cannot be collocated with the fact table or other important joining tables, you can improve query performance significantly by distributing the entire table to all of the nodes. Using ALL distribution multiplies storage space requirements and increases load times and maintenance operations, so you should weigh all factors before choosing ALL distribution. The following section explains how to identify candidates for ALL distribution by evaluating the EXPLAIN plan.

5. Use AUTO distribution for the remaining tables.

If a table is largely denormalized and does not participate in joins, or if you don't have a clear choice for another distribution style, use AUTO distribution.

To let Amazon Redshift choose the appropriate distribution style, don't explicitly specify a distribution style.

Evaluating the query plan

You can use query plans to identify candidates for optimizing the distribution style.

After making your initial design decisions, create your tables, load them with data, and test them. Use a test dataset that is as close as possible to the real data. Measure load times to use as a baseline for comparisons.

Evaluate queries that are representative of the most costly queries you expect to run, specifically queries that use joins and aggregations. Compare runtimes for various design options. When you compare runtimes, don't count the first time the query is run, because the first runtime includes the compilation time.

DS_DIST_NONE

No redistribution is required, because corresponding slices are collocated on the compute nodes. You typically have only one DS_DIST_NONE step, the join between the fact table and one dimension table.

DS_DIST_ALL_NONE

No redistribution is required, because the inner join table used DISTSTYLE ALL. The entire table is located on every node.

DS_DIST_INNER

The inner table is redistributed.

DS_DIST_OUTER

The outer table is redistributed.

DS_BCAST_INNER

A copy of the entire inner table is broadcast to all the compute nodes.

DS_DIST_ALL_INNER

The entire inner table is redistributed to a single slice because the outer table uses DISTSTYLE ALL.

DS_DIST_BOTH

Both tables are redistributed.

DS_DIST_NONE and DS_DIST_ALL_NONE are good. They indicate that no distribution was required for that step because all of the joins are collocated.

DS_DIST_INNER means that the step probably has a relatively high cost because the inner table is being redistributed to the nodes. DS_DIST_INNER indicates that the outer table is already properly distributed on the join key. Set the inner table's distribution key to the join key to convert this to DS_DIST_NONE. In some cases, distributing the inner table on the join key isn't possible because the outer table isn't distributed on the join key. If this is the case, evaluate whether to use ALL distribution for the inner table. If the table isn't updated frequently or extensively, and it's large enough to carry a high redistribution cost, change the distribution style to ALL and test again. ALL distribution causes increased load times, so when you retest, include the load time in your evaluation factors.

DS_DIST_ALL_INNER is not good. It means that the entire inner table is redistributed to a single slice because the outer table uses DISTSTYLE ALL, so that a copy of the entire outer table is located on each node. This results in inefficient serial runtime of the join on a single node, instead taking advantage of parallel runtime using all of the nodes. DISTSTYLE ALL is meant to be used only for the inner join table. Instead, specify a distribution key or use even distribution for the outer table.

DS_BCAST_INNER and DS_DIST_BOTH are not good. Usually these redistributions occur because the tables are not joined on their distribution keys. If the fact table does not already have a distribution key, specify the joining column as the distribution key for both tables. If the fact table already has a distribution key on another column, evaluate whether changing the distribution key to collocate this join improve overall performance. If changing the distribution key of the outer table isn't an optimal choice, you can achieve collocation by specifying DISTSTYLE ALL for the inner table.

The following example shows a portion of a query plan with DS_BCAST_INNER and DS_DIST_NONE labels.

```
-> XN Hash Join DS_BCAST_INNER (cost=112.50..3272334142.59 rows=170771 width=84)
    Hash Cond: ("outer".venueid = "inner".venueid)
    -> XN Hash Join DS_BCAST_INNER (cost=109.98..3167290276.71 rows=172456
width=47)
        Hash Cond: ("outer".eventid = "inner".eventid)
        -> XN Merge Join DS_DIST_NONE (cost=0.00..6286.47 rows=172456 width=30)
            Merge Cond: ("outer".listid = "inner".listid)
            -> XN Seq Scan on listing (cost=0.00..1924.97 rows=192497
width=14)
            -> XN Seq Scan on sales (cost=0.00..1724.56 rows=172456 width=24)
```

After changing the dimension tables to use DISTSTYLE ALL, the query plan for the same query shows DS_DIST_ALL_NONE in place of DS_BCAST_INNER. Also, there is a dramatic change in the

relative cost for the join steps. The total cost is 14142.59 compared to 3272334142.59 in the previous query.

```
-> XN Hash Join DS_DIST_ALL_NONE (cost=112.50..14142.59 rows=170771 width=84)
    Hash Cond: ("outer".venueid = "inner".venueid)
    -> XN Hash Join DS_DIST_ALL_NONE (cost=109.98..10276.71 rows=172456 width=47)
        Hash Cond: ("outer".eventid = "inner".eventid)
        -> XN Merge Join DS_DIST_NONE (cost=0.00..6286.47 rows=172456 width=30)
            Merge Cond: ("outer".listid = "inner".listid)
            -> XN Seq Scan on listing (cost=0.00..1924.97 rows=192497
width=14)
                -> XN Seq Scan on sales (cost=0.00..1724.56 rows=172456 width=24)
```

Query plan example

This example shows how to evaluate a query plan to find opportunities to optimize the distribution.

Run the following query with an EXPLAIN command to produce a query plan.

```
explain
select lastname, catname, venueid, venuecity, venuestate, eventname,
month, sum(pricepaid) as buyercost, max(totalprice) as maxtotalprice
from category join event on category.catid = event.catid
join venue on venue.venueid = event.venueid
join sales on sales.eventid = event.eventid
join listing on sales.listid = listing.listid
join date on sales.dateid = date.dateid
join users on users.userid = sales.buyerid
group by lastname, catname, venueid, venuecity, venuestate, eventname, month
having sum(pricepaid)>9999
order by catname, buyercost desc;
```

In the TICKIT database, SALES is a fact table and LISTING is its largest dimension. In order to collocate the tables, SALES is distributed on the LISTID, which is the foreign key for LISTING, and LISTING is distributed on its primary key, LISTID. The following example shows the CREATE TABLE commands for SALES and LISTING.

```
create table sales(
  salesid integer not null,
  listid integer not null distkey,
```

```

sellerid integer not null,
buyerid integer not null,
eventid integer not null encode mostly16,
dateid smallint not null,
qtysold smallint not null encode mostly8,
pricepaid decimal(8,2) encode delta32k,
commission decimal(8,2) encode delta32k,
saletime timestamp,
primary key(salesid),
foreign key(listid) references listing(listid),
foreign key(sellerid) references users(userid),
foreign key(buyerid) references users(userid),
foreign key(dateid) references date(dateid))
    sortkey(listid,sellerid);

```

```

create table listing(
listid integer not null distkey sortkey,
sellerid integer not null,
eventid integer not null encode mostly16,
dateid smallint not null,
numtickets smallint not null encode mostly8,
priceperticket decimal(8,2) encode bytedict,
totalprice decimal(8,2) encode mostly32,
listtime timestamp,
primary key(listid),
foreign key(sellerid) references users(userid),
foreign key(eventid) references event(eventid),
foreign key(dateid) references date(dateid));

```

In the following query plan, the Merge Join step for the join on SALES and LISTING shows DS_DIST_NONE, which indicates that no redistribution is required for the step. However, moving up the query plan, the other inner joins show DS_BCAST_INNER, which indicates that the inner table is broadcast as part of the query execution. Because only one pair of tables can be collocated using key distribution, five tables must be rebroadcast.

QUERY PLAN

```

XN Merge (cost=1015345167117.54..1015345167544.46 rows=1000 width=103)
  Merge Key: category.catname, sum(sales.pricepaid)
  -> XN Network (cost=1015345167117.54..1015345167544.46 rows=170771 width=103)
    Send to leader
    -> XN Sort (cost=1015345167117.54..1015345167544.46 rows=170771 width=103)
      Sort Key: category.catname, sum(sales.pricepaid)

```

```

-> XN HashAggregate (cost=15345150568.37..15345152276.08 rows=170771
width=103)
  Filter: (sum(pricepaid) > 9999.00)
    -> XN Hash Join DS_BCAST_INNER (cost=742.08..15345146299.10
rows=170771 width=103)
      Hash Cond: ("outer".catid = "inner".catid)
        -> XN Hash Join DS_BCAST_INNER
(cost=741.94..15342942456.61 rows=170771 width=97)
          Hash Cond: ("outer".dateid = "inner".dateid)
            -> XN Hash Join DS_BCAST_INNER
(cost=737.38..15269938609.81 rows=170766 width=90)
              Hash Cond: ("outer".buyerid = "inner".userid)
                -> XN Hash Join DS_BCAST_INNER
(cost=112.50..3272334142.59 rows=170771 width=84)
                  Hash Cond: ("outer".venueid =
"inner".venueid)
                    -> XN Hash Join DS_BCAST_INNER
(cost=109.98..3167290276.71 rows=172456 width=47)
                      Hash Cond: ("outer".eventid =
"inner".eventid)
                        -> XN Merge Join DS_DIST_NONE
(cost=0.00..6286.47 rows=172456 width=30)
                          Merge Cond: ("outer".listid =
"inner".listid)
                            -> XN Seq Scan on listing
(cost=0.00..1924.97 rows=192497 width=14)
                              -> XN Seq Scan on sales
(cost=0.00..1724.56 rows=172456 width=24)
                                  -> XN Hash (cost=87.98..87.98
rows=8798 width=25)
                                      -> XN Seq Scan on event
(cost=0.00..87.98 rows=8798 width=25)
                                          -> XN Hash (cost=2.02..2.02 rows=202
width=41)
                                              -> XN Seq Scan on venue
(cost=0.00..2.02 rows=202 width=41)
                                                  -> XN Hash (cost=499.90..499.90 rows=49990
width=14)
                                                      -> XN Seq Scan on users
(cost=0.00..499.90 rows=49990 width=14)
                                                          -> XN Hash (cost=3.65..3.65 rows=365 width=11)
                                                              -> XN Seq Scan on date (cost=0.00..3.65
rows=365 width=11)
                                                                  -> XN Hash (cost=0.11..0.11 rows=11 width=10)

```

```
-> XN Seq Scan on category (cost=0.00..0.11 rows=11
width=10)
```

One solution is to alter the tables to have DISTSTYLE ALL.

```
ALTER TABLE users ALTER DISTSTYLE ALL;
ALTER TABLE venue ALTER DISTSTYLE ALL;
ALTER TABLE category ALTER DISTSTYLE ALL;
ALTER TABLE date ALTER DISTSTYLE ALL;
ALTER TABLE event ALTER DISTSTYLE ALL;
```

Run the same query with EXPLAIN again, and examine the new query plan. The joins now show DS_DIST_ALL_NONE, indicating that no redistribution is required because the data was distributed to every node using DISTSTYLE ALL.

```
QUERY PLAN
XN Merge (cost=1000000047117.54..1000000047544.46 rows=1000 width=103)
  Merge Key: category.catname, sum(sales.pricepaid)
  -> XN Network (cost=1000000047117.54..1000000047544.46 rows=170771 width=103)

```

Distribution examples

The following examples show how data is distributed according to the options that you define in the CREATE TABLE statement.

DISTKEY examples

Look at the schema of the USERS table in the TICKIT database. USERID is defined as the SORTKEY column and the DISTKEY column:

```

select "column", type, encoding, distkey, sortkey
from pg_table_def where tablename = 'users';

```

column	type	encoding	distkey	sortkey
userid	integer	none	t	1
username	character(8)	none	f	0
firstname	character varying(30)	text32k	f	0

...

USERID is a good choice for the distribution column on this table. If you query the SVV_DISKUSAGE system view, you can see that the table is very evenly distributed. Column numbers are zero-based, so USERID is column 0.

```
select slice, col, num_values as rows, minvalue, maxvalue
from svv_diskusage
where name='users' and col=0 and rows>0
order by slice, col;
```

slice	col	rows	minvalue	maxvalue
0	0	12496	4	49987
1	0	12498	1	49988
2	0	12497	2	49989
3	0	12499	3	49990

(4 rows)

The table contains 49,990 rows. The rows (num_values) column shows that each slice contains about the same number of rows. The minvalue and maxvalue columns show the range of values on each slice. Each slice includes nearly the entire range of values, so there's a good chance that every slice participates in running a query that filters for a range of user IDs.

This example demonstrates distribution on a small test system. The total number of slices is typically much higher.

If you commonly join or group using the STATE column, you might choose to distribute on the STATE column. The following example shows a case where you create a new table with the same data as the USERS table but set the DISTKEY to the STATE column. In this case, the distribution isn't as even. Slice 0 (13,587 rows) holds approximately 30 percent more rows than slice 3 (10,150 rows). In a much larger table, this amount of distribution skew can have an adverse impact on query processing.

```
create table userskey distkey(state) as select * from users;

select slice, col, num_values as rows, minvalue, maxvalue from svv_diskusage
where name = 'userskey' and col=0 and rows>0
order by slice, col;

slice | col | rows | minvalue | maxvalue
```

```

-----+-----+-----+-----+-----
  0 |  0 | 13587 |      5 |    49989
  1 |  0 | 11245 |      2 |    49990
  2 |  0 | 15008 |      1 |    49976
  3 |  0 | 10150 |      4 |    49986
(4 rows)

```

DISTSTYLE EVEN example

If you create a new table with the same data as the USERS table but set the DISTSTYLE to EVEN, rows are always evenly distributed across slices.

```

create table userseven diststyle even as
select * from users;

select slice, col, num_values as rows, minvalue, maxvalue from svv_diskusage
where name = 'userseven' and col=0 and rows>0
order by slice, col;

```

```

slice | col | rows | minvalue | maxvalue
-----+-----+-----+-----+-----
  0 |  0 | 12497 |      4 |    49990
  1 |  0 | 12498 |      8 |    49984
  2 |  0 | 12498 |      2 |    49988
  3 |  0 | 12497 |      1 |    49989
(4 rows)

```

However, because distribution is not based on a specific column, query processing can be degraded, especially if the table is joined to other tables. The lack of distribution on a joining column often influences the type of join operation that can be performed efficiently. Joins, aggregations, and grouping operations are optimized when both tables are distributed and sorted on their respective joining columns.

DISTSTYLE ALL example

If you create a new table with the same data as the USERS table but set the DISTSTYLE to ALL, all the rows are distributed to the first slice of each node.

```

select slice, col, num_values as rows, minvalue, maxvalue from svv_diskusage
where name = 'usersall' and col=0 and rows > 0
order by slice, col;

```

```

slice | col | rows | minvalue | maxvalue
-----+-----+-----+-----+-----
    0 |   0 | 49990 |         4 |    49990
    2 |   0 | 49990 |         2 |    49990

```

(4 rows)

Sort keys

Note

We recommend that you create your tables with `SORTKEY AUTO`. If you do so, then Amazon Redshift uses automatic table optimization to choose the sort key. For more information, see [Automatic table optimization](#). The rest of this section provides details about the sort order.

When you create a table, you can alternatively define one or more of its columns as *sort keys*. When data is initially loaded into the empty table, the rows are stored on disk in sorted order. Information about sort key columns is passed to the query planner, and the planner uses this information to construct plans that exploit the way that the data is sorted. For more information, see [CREATE TABLE](#). For information on best practices when creating a sort key, see [Choose the best sort key](#).

Sorting enables efficient handling of range-restricted predicates. Amazon Redshift stores columnar data in 1 MB disk blocks. The min and max values for each block are stored as part of the metadata. If a query uses a range-restricted predicate, the query processor can use the min and max values to rapidly skip over large numbers of blocks during table scans. For example, suppose that a table stores five years of data sorted by date and a query specifies a date range of one month. In this case, you can remove up to 98 percent of the disk blocks from the scan. If the data is not sorted, more of the disk blocks (possibly all of them) have to be scanned.

You can specify either a compound or interleaved sort key. A compound sort key is more efficient when query predicates use a *prefix*, which is a subset of the sort key columns in order. An interleaved sort key gives equal weight to each column in the sort key, so query predicates can use any subset of the columns that make up the sort key, in any order.

To understand the impact of the chosen sort key on query performance, use the [EXPLAIN](#) command. For more information, see [Query planning and execution workflow](#).

To define a sort type, use either the `INTERLEAVED` or `COMPOUND` keyword with your `CREATE TABLE` or `CREATE TABLE AS` statement. The default is `COMPOUND`. `COMPOUND` is recommended when you update your tables regularly with `INSERT`, `UPDATE`, or `DELETE` operations. An `INTERLEAVED` sort key can use a maximum of eight columns. Depending on your data and cluster size, `VACUUM REINDEX` takes significantly longer than `VACUUM FULL` because it makes an additional pass to analyze the interleaved sort keys. The sort and merge operation can take longer for interleaved tables because the interleaved sort might have to rearrange more rows than a compound sort.

To view the sort keys for a table, query the [SVV_TABLE_INFO](#) system view.

- [Interleaved sort key](#)

Multidimensional data layout sorting (preview)

The following is prerelease documentation for the multidimensional data layout sorting of tables, which is in preview release. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

Note

This feature is only available using a preview cluster or preview workgroup. To create a preview cluster, see [Creating a preview cluster](#) in the *Amazon Redshift Management Guide*. To create a preview workgroup, see [Creating a preview workgroup](#) in the *Amazon Redshift Management Guide*.

A multidimensional data layout sort key is a type of `AUTO` sort key that is based on repetitive predicates found in a workload. If your workload has repetitive predicates, then Amazon Redshift can improve table scan performance by colocating data rows that satisfy the repetitive predicates.

Instead of storing data of a table in strict column order, a multidimensional data layout sort key stores data by analyzing repetitive predicates that appear in a workload. More than one repetitive predicate can be found in a workload. Depending on your workload, this kind of sort key can improve performance of many predicates. Amazon Redshift automatically determines if this sort key method should be used for tables that are defined with an AUTO sort key.

For example, suppose you have a table that has data sorted in column order. Many data blocks might need to be examined to determine if they satisfy the predicates in your workload. But, if the data is stored on disk in a predicate order, then fewer blocks need to be scanned to satisfy the query. Using a multidimensional data layout sort key is beneficial in this case.

To view whether a query is using a multidimensional data layout key, see the `step_attribute` column of the [SYS_QUERY_DETAIL](#) view. When the value is `multi-dimensional` then multidimensional data layout was used for the query. To view whether a table defined with the AUTO sort key is using a multidimensional data layout, see the `sortkey1` column of the [SVV_TABLE_INFO](#) view. When the value is `padb_internal_mddl_key_col` then multidimensional data layout was used for the table sort key.

To prevent Amazon Redshift from using a multidimensional data layout sort key, choose a different table sort key option other than `SORTKEY AUTO`. For more information on `SORTKEY` options, see [CREATE TABLE](#).

Compound sort key

A compound key is made up of all of the columns listed in the sort key definition, in the order they are listed. A compound sort key is most useful when a query's filter applies conditions, such as filters and joins, that use a prefix of the sort keys. The performance benefits of compound sorting decrease when queries depend only on secondary sort columns, without referencing the primary columns. `COMPOUND` is the default sort type.

Compound sort keys might speed up joins, `GROUP BY` and `ORDER BY` operations, and window functions that use `PARTITION BY` and `ORDER BY`. For example, a merge join, which is often faster than a hash join, is feasible when the data is distributed and presorted on the joining columns. Compound sort keys also help improve compression.

As you add rows to a sorted table that already contains data, the unsorted region grows, which has a significant effect on performance. The effect is greater when the table uses interleaved sorting, especially when the sort columns include data that increases monotonically, such as date

or timestamp columns. Run a `VACUUM` operation regularly, especially after large data loads, to re-sort and re-analyze the data. For more information, see [Reduce the size of the unsorted region](#). After vacuuming to resort the data, it's a good practice to run an `ANALYZE` command to update the statistical metadata for the query planner. For more information, see [Analyzing tables](#).

Interleaved sort key

An interleaved sort gives equal weight to each column, or subset of columns, in the sort key. If multiple queries use different columns for filters, then you can often improve performance for those queries by using an interleaved sort style. When a query uses restrictive predicates on secondary sort columns, interleaved sorting significantly improves query performance as compared to compound sorting.

Important

Don't use an interleaved sort key on columns with monotonically increasing attributes, such as identity columns, dates, or timestamps.

The performance improvements you gain by implementing an interleaved sort key should be weighed against increased load and vacuum times.

Interleaved sorts are most effective with highly selective queries that filter on one or more of the sort key columns in the `WHERE` clause, for example `select c_name from customer where c_region = 'ASIA'`. The benefits of interleaved sorting increase with the number of sorted columns that are restricted.

An interleaved sort is more effective with large tables. Sorting is applied on each slice. Thus, an interleaved sort is most effective when a table is large enough to require multiple 1 MB blocks per slice. Here, the query processor can skip a significant proportion of the blocks using restrictive predicates. To view the number of blocks a table uses, query the [STV_BLOCKLIST](#) system view.

When sorting on a single column, an interleaved sort might give better performance than a compound sort if the column values have a long common prefix. For example, URLs commonly begin with `"http://www"`. Compound sort keys use a limited number of characters from the prefix, which results in a lot of duplication of keys. Interleaved sorts use an internal compression scheme for zone map values that enables them to better discriminate among column values that have a long common prefix.

When migrating Amazon Redshift provisioned clusters to Amazon Redshift Serverless, Redshift converts tables with interleaved sort keys and `DISTSTYLE KEY` to compound sort keys. The `DISTSTYLE` doesn't change. For more information on distribution styles, see [Working with data distribution styles](#).

VACUUM REINDEX

As you add rows to a sorted table that already contains data, performance might deteriorate over time. This deterioration occurs for both compound and interleaved sorts, but it has a greater effect on interleaved tables. A `VACUUM` restores the sort order, but the operation can take longer for interleaved tables because merging new interleaved data might involve modifying every data block.

When tables are initially loaded, Amazon Redshift analyzes the distribution of the values in the sort key columns and uses that information for optimal interleaving of the sort key columns. As a table grows, the distribution of the values in the sort key columns can change, or skew, especially with date or timestamp columns. If the skew becomes too large, performance might be affected. To re-analyze the sort keys and restore performance, run the `VACUUM` command with the `REINDEX` key word. Because it must take an extra analysis pass over the data, `VACUUM REINDEX` can take longer than a standard `VACUUM` for interleaved tables. To view information about key distribution skew and last reindex time, query the [SVV_INTERLEAVED_COLUMNS](#) system view.

For more information about how to determine how often to run `VACUUM` and when to run a `VACUUM REINDEX`, see [Decide whether to reindex](#).

Table constraints

Uniqueness, primary key, and foreign key constraints are informational only; *they are not enforced by Amazon Redshift* when you populate a table. For example, if you insert data into a table with dependencies, the insert can succeed even if it violates the constraint. Nonetheless, primary keys and foreign keys are used as planning hints and they should be declared if your ETL process or some other process in your application enforces their integrity.

For example, the query planner uses primary and foreign keys in certain statistical computations. It does this to infer uniqueness and referential relationships that affect subquery decorrelation techniques. By doing this, it can order large numbers of joins and remove redundant joins.

The planner leverages these key relationships, but it assumes that all keys in Amazon Redshift tables are valid as loaded. If your application allows invalid foreign keys or primary keys, some

queries could return incorrect results. For example, a `SELECT DISTINCT` query might return duplicate rows if the primary key is not unique. Do not define key constraints for your tables if you doubt their validity. However, always declare primary and foreign keys and uniqueness constraints when you know that they are valid.

Amazon Redshift *does* enforce NOT NULL column constraints.

For more information about table constraints, see [CREATE TABLE](#). For information about how to drop a table with dependencies, see [DROP TABLE](#).

Loading data in Amazon Redshift

There are several ways to load data into an Amazon Redshift database. One popular source of data to load are Amazon S3 files. The following table summarizes some of the methods to use with starting from an Amazon S3 source.

Method to use	Description	When method needed
COPY command	Runs a batch file ingestion to load data from your Amazon S3 files. This method leverages parallel processing capabilities of Amazon Redshift. For more information, see Loading tables with the COPY command .	Should be used when basic data loading requirements to initiate batch file ingestion manually is needed. This method is used mostly with custom and third-party file ingestion pipelines or one-time, or ad hoc, file ingestion workloads.
COPY... CREATE JOB command (auto-copy)	Runs your COPY commands automatically when a new file is created on tracked Amazon S3 paths. For more information, see Loading tables with continuous file ingestion from Amazon S3 (preview) .	Should be used when a file ingestion pipeline needs to automatically ingest data when a new file is created on Amazon S3. Amazon Redshift keeps track of ingested files to prevent data duplication. This method requires configuration by Amazon S3 bucket owners.
Load from data lake queries	Create external tables to run data lake queries on your Amazon S3 files and then run INSERT INTO command to load results from your data lake queries into local tables. For more information, see	Should be used in any of the following scenarios: <ul style="list-style-type: none"> • Loading from AWS Glue and open table formats (such as Apache Iceberg, Apache Hudi, or Delta Lake).

Method to use	Description	When method needed
	External tables for Redshift Spectrum .	<ul style="list-style-type: none"> • Source files need to be ingested partially (for example, needed for running a WHERE clause to ingest particular rows). • More flexibility needed to ingest particular columns (like running a SELECT command) or doing basic data transformation on the go (such as applying basic operations or calling UDFs on the values from the source file).

Other methods that you can consider

Streaming ingestion	Streaming ingestion provides low-latency, high-speed ingestion of stream data from Amazon Kinesis Data Streams and Amazon Managed Streaming for Apache Kafka into an Amazon Redshift provisioned or Redshift Serverless materialized view. For more information, see Getting started with streaming ingestion from Amazon Kinesis Data Streams and Getting started with streaming ingestion from Amazon Managed Streaming for Apache Kafka (Amazon MSK) .	Should be considered for use cases when data is first streamed into files on Amazon S3 and then loaded from Amazon S3. If keeping data on Amazon S3 is not needed, you can often consider streaming your data directly into Amazon Redshift.
---------------------	---	--

Method to use	Description	When method needed
Running data lake queries	Running queries directly from a data lake table instead of ingesting contents of the table into a local table. For more information, see Amazon Redshift Spectrum .	Should be used when the use case doesn't require the performance of local table queries in Amazon Redshift.
Batch loading using Amazon Redshift query editor v2	You can prepare and run your batch file ingestion workloads visually on Amazon Redshift query editor v2. For more information, see Loading data from S3 in the <i>Amazon Redshift Management Guide</i> .	Should be used when you want the query editor v2 to prepare COPY statements and you want a visual tool to simplify the COPY statement preparation process.
Load data from a local file using Amazon Redshift query editor v2	You can directly upload files from your desktop into Amazon Redshift tables without the need for manually uploading your files into Amazon S3. For more information, see Loading data from a local file setup and workflow in the <i>Amazon Redshift Management Guide</i> .	Should be used when you need to quickly load files from your local computer for one-time querying purposes. With this method, Amazon Redshift query editor v2 temporarily stores the file on a customer-owned Amazon S3 bucket and runs a copy command using this Amazon S3 path.

A COPY command is the most efficient way to load a table. You can also add data to your tables using INSERT commands, though it is much less efficient than using COPY. The COPY command is able to read from multiple data files or multiple data streams simultaneously. Amazon Redshift allocates the workload to the Amazon Redshift nodes and performs the load operations in parallel, including sorting the rows and distributing data across node slices.

Note

Amazon Redshift Spectrum external tables are read-only. You can't COPY or INSERT to an external table.

To access data on other AWS resources, Amazon Redshift must have permission to access those resources and to perform the necessary actions to access the data. You can use AWS Identity and Access Management (IAM) to limit the access users have to Amazon Redshift resources and data.

After your initial data load, if you add, modify, or delete a significant amount of data, you should follow up by running a VACUUM command to reorganize your data and reclaim space after deletes. You should also run an ANALYZE command to update table statistics.

Loading tables with the COPY command

The COPY command leverages the Amazon Redshift massively parallel processing (MPP) architecture to read and load data in parallel from files on Amazon S3, from a DynamoDB table, or from text output from one or more remote hosts.

Before learning all the options of the COPY command, we recommend learning the basic options to load Amazon S3 data. The *Amazon Redshift Getting Started Guide* demonstrates a simple use of the COPY command to load Amazon S3 data using a default IAM role. See [Step 4: Load data from Amazon S3 to Amazon Redshift](#) for details.

Note

We strongly recommend using the COPY command to load large amounts of data. Using individual INSERT statements to populate a table might be prohibitively slow. Alternatively, if your data already exists in other Amazon Redshift database tables, use INSERT INTO ... SELECT or CREATE TABLE AS to improve performance. For information, see [INSERT](#) or [CREATE TABLE AS](#).

To load data from another AWS resource, Amazon Redshift must have permission to access the resource and perform the necessary actions.

To grant or revoke privilege to load data into a table using a COPY command, grant or revoke the INSERT privilege.

Your data needs to be in the proper format for loading into your Amazon Redshift table. This section presents guidelines for preparing and verifying your data before the load and for validating a COPY statement before you run it.

To protect the information in your files, you can encrypt the data files before you upload them to your Amazon S3 bucket; COPY will decrypt the data as it performs the load. You can also limit access to your load data by providing temporary security credentials to users. Temporary security credentials provide enhanced security because they have short life spans and cannot be reused after they expire.

Amazon Redshift has features built in to COPY to load uncompressed, delimited data quickly. But you can compress your files using gzip, lzop, or bzip2 to save time uploading the files.

If the following keywords are in the COPY query, automatic splitting of uncompressed data is not supported: ESCAPE, REMOVEQUOTES, and FIXEDWIDTH. But the CSV keyword is supported.

To help keep your data secure in transit within the AWS Cloud, Amazon Redshift uses hardware accelerated SSL to communicate with Amazon S3 or Amazon DynamoDB for COPY, UNLOAD, backup, and restore operations.

When you load your table directly from an Amazon DynamoDB table, you have the option to control the amount of Amazon DynamoDB provisioned throughput you consume.

You can optionally let COPY analyze your input data and automatically apply optimal compression encodings to your table as part of the load process.

Credentials and access permissions

To load or unload data using another AWS resource, such as Amazon S3, Amazon DynamoDB, Amazon EMR, or Amazon EC2, Amazon Redshift must have permission to access the resource and perform the necessary actions to access the data. For example, to load data from Amazon S3, COPY must have LIST access to the bucket and GET access for the bucket objects.

To obtain authorization to access a resource, Amazon Redshift must be authenticated. You can choose either role-based access control or key-based access control. This section presents an overview of the two methods. For complete details and examples, see [Permissions to access other AWS Resources](#).

Role-based access control

With role-based access control, Amazon Redshift temporarily assumes an AWS Identity and Access Management (IAM) role on your behalf. Then, based on the authorizations granted to the role, Amazon Redshift can access the required AWS resources.

We recommend using role-based access control because it provides more secure, fine-grained control of access to AWS resources and sensitive user data, in addition to safeguarding your AWS credentials.

To use role-based access control, you must first create an IAM role using the Amazon Redshift service role type, and then attach the role to your data warehouse. The role must have, at a minimum, the permissions listed in [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#). For steps to create an IAM role and attach it to your cluster, see [Creating an IAM Role to Allow Your Amazon Redshift Cluster to Access AWS Services](#) in the *Amazon Redshift Management Guide*.

You can add a role to a cluster or view the roles associated with a cluster by using the Amazon Redshift Management Console, CLI, or API. For more information, see [Authorizing COPY and UNLOAD Operations Using IAM Roles](#) in the *Amazon Redshift Management Guide*.

When you create an IAM role, IAM returns an Amazon Resource Name (ARN) for the role. To run a COPY command using an IAM role, provide the role ARN using the IAM_ROLE parameter or the CREDENTIALS parameter.

The following COPY command example uses IAM_ROLE parameter with the role MyRedshiftRole for authentication.

```
COPY customer FROM 's3://amzn-s3-demo-bucket/mydata'  
IAM_ROLE 'arn:aws:iam::12345678901:role/MyRedshiftRole';
```

The AWS user must have, at a minimum, the permissions listed in [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#).

Key-based access control

With key-based access control, you provide the access key ID and secret access key for a user that is authorized to access the AWS resources that contain the data.

Note

We strongly recommend using an IAM role for authentication instead of supplying a plain-text access key ID and secret access key. If you choose key-based access control, never use your AWS account (root) credentials. Always create an IAM user and provide that user's access key ID and secret access key. For steps to create an IAM user, see [Creating an IAM User in Your AWS Account](#).

Preparing your input data

If your input data is not compatible with the table columns that will receive it, the COPY command will fail.

Use the following guidelines to help ensure that your input data is valid:

- Your data can only contain UTF-8 characters up to four bytes long.
- Verify that CHAR and VARCHAR strings are no longer than the lengths of the corresponding columns. VARCHAR strings are measured in bytes, not characters, so, for example, a four-character string of Chinese characters that occupy four bytes each requires a VARCHAR(16) column.
- Multibyte characters can only be used with VARCHAR columns. Verify that multibyte characters are no more than four bytes long.
- Verify that data for CHAR columns only contains single-byte characters.
- Do not include any special characters or syntax to indicate the last field in a record. This field can be a delimiter.
- If your data includes null terminators, also referred to as NUL (UTF-8 0000) or binary zero (0x00), you can load these characters as NULLS into CHAR or VARCHAR columns by using the NULL AS option in the COPY command: `null as '\0'` or `null as '\000'`. If you do not use NULL AS, null terminators will cause your COPY to fail.
- If your strings contain special characters, such as delimiters and embedded newlines, use the ESCAPE option with the [COPY](#) command.
- Verify that all single and double quotation marks are appropriately matched.
- Verify that floating-point strings are in either standard floating-point format, such as 12.123, or an exponential format, such as 1.0E4.
- Verify that all timestamp and date strings follow the specifications for [DATEFORMAT and TIMEFORMAT strings](#). The default timestamp format is YYYY-MM-DD hh:mm:ss, and the default date format is YYYY-MM-DD.
- For more information about boundaries and limitations on individual data types, see [Data types](#). For information about multibyte character errors, see [Multibyte character load errors](#)

Loading data from Amazon S3

The COPY command leverages the Amazon Redshift massively parallel processing (MPP) architecture to read and load data in parallel from a file or multiple files in an Amazon S3 bucket. You can take maximum advantage of parallel processing by splitting your data into multiple files, in cases where the files are compressed. (There are exceptions to this rule. These are detailed in [Loading data files](#).) You can also take maximum advantage of parallel processing by setting distribution keys on your tables. For more information about distribution keys, see [Data distribution for query optimization](#).

Data is loaded into the target table, one line per row. The fields in the data file are matched to table columns in order, left to right. Fields in the data files can be fixed-width or character delimited; the default delimiter is a pipe (|). By default, all the table columns are loaded, but you can optionally define a comma-separated list of columns. If a table column is not included in the column list specified in the COPY command, it is loaded with a default value. For more information, see [Loading default column values](#).

Topics

- [Loading data from compressed and uncompressed files](#)
- [Uploading files to Amazon S3 to use with COPY](#)
- [Using the COPY command to load from Amazon S3](#)

Loading data from compressed and uncompressed files

When you load compressed data, we recommend that you split the data for each table into multiple files. When you load uncompressed, delimited data, the COPY command uses massively parallel processing (MPP) and scan ranges to load data from large files in an Amazon S3 bucket.

Loading data from multiple compressed files

In cases where you have compressed data, we recommend that you split the data for each table into multiple files. The COPY command can load data from multiple files in parallel. You can load multiple files by specifying a common prefix, or *prefix key*, for the set, or by explicitly listing the files in a manifest file.

Split your data into files so that the number of files is a multiple of the number of slices in your cluster. That way, Amazon Redshift can divide the data evenly among the slices. The number of slices per node depends on the node size of the cluster. For example, each dc2.large compute node

has two slices, and each dc2.8xlarge compute node has 16 slices. For more information about the number of slices that each node size has, see [About clusters and nodes](#) in the *Amazon Redshift Management Guide*.

The nodes all participate in running parallel queries, working on data that is distributed as evenly as possible across the slices. If you have a cluster with two dc2.large nodes, you might split your data into four files or some multiple of four. Amazon Redshift doesn't take file size into account when dividing the workload. Thus, you need to ensure that the files are roughly the same size, from 1 MB to 1 GB after compression.

To use object prefixes to identify the load files, name each file with a common prefix. For example, you might split the `venue.txt` file into four files, as follows.

```
venue.txt.1
venue.txt.2
venue.txt.3
venue.txt.4
```

If you put multiple files in a folder in your bucket and specify the folder name as the prefix, `COPY` loads all of the files in the folder. If you explicitly list the files to be loaded by using a manifest file, the files can reside in different buckets or folders.

For more information about manifest files, see [Example: COPY from Amazon S3 using a manifest](#).

Loading data from uncompressed, delimited files

When you load uncompressed, delimited data, the `COPY` command uses the massively parallel processing (MPP) architecture in Amazon Redshift. Amazon Redshift automatically uses slices working in parallel to load ranges of data from a large file in an Amazon S3 bucket. The file must be delimited for parallel loading to occur. For example, pipe delimited. Automatic, parallel data loading with the `COPY` command is also available for CSV files. You can also take advantage of parallel processing by setting distribution keys on your tables. For more information about distribution keys, see [Data distribution for query optimization](#).

Automatic, parallel data loading isn't supported when the `COPY` query includes any of the following keywords: `ESCAPE`, `REMOVEQUOTES`, and `FIXEDWIDTH`.

Data from the file or files is loaded into the target table, one line per row. The fields in the data file are matched to table columns in order, left to right. Fields in the data files can be fixed-width

or character delimited; the default delimiter is a pipe (|). By default, all the table columns are loaded, but you can optionally define a comma-separated list of columns. If a table column isn't included in the column list specified in the COPY command, it's loaded with a default value. For more information, see [Loading default column values](#).

Follow this general process to load data from Amazon S3, when your data is uncompressed and delimited:

1. Upload your files to Amazon S3.
2. Run a COPY command to load the table.
3. Verify that the data was loaded correctly.

For examples of COPY commands, see [COPY examples](#). For information about data loaded into Amazon Redshift, check the [STL_LOAD_COMMITS](#) and [STL_LOAD_ERRORS](#) system tables.

For more information about nodes and the slices contained in each, see [About clusters and nodes](#) in the *Amazon Redshift Management Guide*.

Uploading files to Amazon S3 to use with COPY

There are a couple approaches to take when uploading text files to Amazon S3:

- If you have compressed files, we recommend that you split large files to take advantage of parallel processing in Amazon Redshift.
- On the other hand, COPY automatically splits large, uncompressed, text-delimited file data to facilitate parallelism and effectively distribute the data from large files.

Create an Amazon S3 bucket to hold your data files, and then upload the data files to the bucket. For information about creating buckets and uploading files, see [Working with Amazon S3 Buckets](#) in the *Amazon Simple Storage Service User Guide*.

Important

The Amazon S3 bucket that holds the data files must be created in the same AWS Region as your cluster unless you use the [REGION](#) option to specify the Region in which the Amazon S3 bucket is located.

Ensure that the S3 IP ranges are added to your allowlist. To learn more about the required S3 IP ranges, see [Network isolation](#).

You can create an Amazon S3 bucket in a specific Region either by selecting the Region when you create the bucket by using the Amazon S3 console, or by specifying an endpoint when you create the bucket using the Amazon S3 API or CLI.

Following the data load, verify that the correct files are present on Amazon S3.

Topics

- [Managing data consistency](#)
- [Uploading encrypted data to Amazon S3](#)
- [Verifying that the correct files are present in your bucket](#)

Managing data consistency

Amazon S3 provides strong read-after-write consistency for COPY, UNLOAD, INSERT (external table), CREATE EXTERNAL TABLE AS, and Amazon Redshift Spectrum operations on Amazon S3 buckets in all AWS Regions. In addition, read operations on Amazon S3 Select, Amazon S3 Access Control Lists, Amazon S3 Object Tags, and object metadata (for example, HEAD object) are strongly consistent. For more information about data consistency, see [Amazon S3 Data Consistency Model](#) in the *Amazon Simple Storage Service User Guide*.

Uploading encrypted data to Amazon S3

Amazon S3 supports both server-side encryption and client-side encryption. This topic discusses the differences between the server-side and client-side encryption and describes the steps to use client-side encryption with Amazon Redshift. Server-side encryption is transparent to Amazon Redshift.

Server-side encryption

Server-side encryption is data encryption at rest—that is, Amazon S3 encrypts your data as it uploads it and decrypts it for you when you access it. When you load tables using a COPY command, there is no difference in the way you load from server-side encrypted or unencrypted objects on Amazon S3. For more information about server-side encryption, see [Using Server-Side Encryption](#) in the *Amazon Simple Storage Service User Guide*.

Client-side encryption

In client-side encryption, your client application manages encryption of your data, the encryption keys, and related tools. You can upload data to an Amazon S3 bucket using client-side encryption, and then load the data using the COPY command with the ENCRYPTED option and a private encryption key to provide greater security.

You encrypt your data using envelope encryption. With *envelope encryption*, your application handles all encryption exclusively. Your private encryption keys and your unencrypted data are never sent to AWS, so it's very important that you safely manage your encryption keys. If you lose your encryption keys, you won't be able to unencrypt your data, and you can't recover your encryption keys from AWS. Envelope encryption combines the performance of fast symmetric encryption while maintaining the greater security that key management with asymmetric keys provides. A one-time-use symmetric key (the envelope symmetric key) is generated by your Amazon S3 encryption client to encrypt your data, then that key is encrypted by your root key and stored alongside your data in Amazon S3. When Amazon Redshift accesses your data during a load, the encrypted symmetric key is retrieved and decrypted with your real key, then the data is decrypted.

To work with Amazon S3 client-side encrypted data in Amazon Redshift, follow the steps outlined in [Protecting Data Using Client-Side Encryption](#) in the *Amazon Simple Storage Service User Guide*, with the additional requirements that you use:

- **Symmetric encryption** – The AWS SDK for Java AmazonS3EncryptionClient class uses envelope encryption, described preceding, which is based on symmetric key encryption. Use this class to create an Amazon S3 client to upload client-side encrypted data.
- **A 256-bit AES root symmetric key** – A root key encrypts the envelope key. You pass the root key to your instance of the AmazonS3EncryptionClient class. Save this key, because you will need it to copy data into Amazon Redshift.
- **Object metadata to store encrypted envelope key** – By default, Amazon S3 stores the envelope key as object metadata for the AmazonS3EncryptionClient class. The encrypted envelope key that is stored as object metadata is used during the decryption process.

Note

If you get a cipher encryption error message when you use the encryption API for the first time, your version of the JDK may have a Java Cryptography Extension (JCE)

jurisdiction policy file that limits the maximum key length for encryption and decryption transformations to 128 bits. For information about addressing this issue, go to [Specifying Client-Side Encryption Using the AWS SDK for Java](#) in the *Amazon Simple Storage Service User Guide*.

For information about loading client-side encrypted files into your Amazon Redshift tables using the COPY command, see [Loading encrypted data files from Amazon S3](#).

Example: Uploading client-side encrypted data

For an example of how to use the AWS SDK for Java to upload client-side encrypted data, go to [Protecting data using client-side encryption](#) in the *Amazon Simple Storage Service User Guide*.

The second option shows the choices you must make during client-side encryption so that the data can be loaded in Amazon Redshift. Specifically, the example shows using object metadata to store the encrypted envelope key and the use of a 256-bit AES root symmetric key.

This example provides example code using the AWS SDK for Java to create a 256-bit AES symmetric root key and save it to a file. Then the example upload an object to Amazon S3 using an S3 encryption client that first encrypts sample data on the client-side. The example also downloads the object and verifies that the data is the same.

Verifying that the correct files are present in your bucket

After you upload your files to your Amazon S3 bucket, we recommend listing the contents of the bucket to verify that all of the correct files are present and that no unwanted files are present. For example, if the bucket `amzn-s3-demo-bucket` holds a file named `venue.txt.back`, that file will be loaded, perhaps unintentionally, by the following command:

```
COPY venue FROM 's3://amzn-s3-demo-bucket/venue' ... ;
```

If you want to control specifically which files are loaded, you can use a manifest file to explicitly list the data files. For more information about using a manifest file, see the [copy_from_s3_manifest_file](#) option for the COPY command and [Example: COPY from Amazon S3 using a manifest](#) in the COPY examples.

For more information about listing the contents of the bucket, see [Listing Object Keys](#) in the *Amazon S3 Developer Guide*.

Using the COPY command to load from Amazon S3

Use the [COPY](#) command to load a table in parallel from data files on Amazon S3. You can specify the files to be loaded by using an Amazon S3 object prefix or by using a manifest file.

The syntax to specify the files to be loaded by using a prefix is as follows:

```
COPY <table_name> FROM 's3://<bucket_name>/<object_prefix>'
  authorization;
```

The manifest file is a JSON-formatted file that lists the data files to be loaded. The syntax to specify the files to be loaded by using a manifest file is as follows:

```
COPY <table_name> FROM 's3://<bucket_name>/<manifest_file>'
  authorization
  MANIFEST;
```

The table to be loaded must already exist in the database. For information about creating a table, see [CREATE TABLE](#) in the SQL Reference.

The values for *authorization* provide the AWS authorization Amazon Redshift needs to access the Amazon S3 objects. For information about required permissions, see [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#). The preferred method for authentication is to specify the IAM_ROLE parameter and provide the Amazon Resource Name (ARN) for an IAM role with the necessary permissions. For more information, see [Role-based access control](#).

To authenticate using the IAM_ROLE parameter, replace *<aws-account-id>* and *<role-name>* as shown in the following syntax.

```
IAM_ROLE 'arn:aws:iam::<aws-account-id>:role/<role-name>'
```

The following example shows authentication using an IAM role.

```
COPY customer
FROM 's3://amzn-s3-demo-bucket/mydata'
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

For more information about other authorization options, see [Authorization parameters](#)

If you want to validate your data without actually loading the table, use the NOLOAD option with the [COPY](#) command.

The following example shows the first few rows of a pipe-delimited data in a file named `venue.txt`.

```
1|Toyota Park|Bridgeview|IL|0
2|Columbus Crew Stadium|Columbus|OH|0
3|RFK Stadium|Washington|DC|0
```

Before uploading the file to Amazon S3, split the file into multiple files so that the COPY command can load it using parallel processing. The number of files should be a multiple of the number of slices in your cluster. Split your load data files so that the files are about equal size, between 1 MB and 1 GB after compression. For more information, see [Loading data from compressed and uncompressed files](#).

For example, the `venue.txt` file might be split into four files, as follows:

```
venue.txt.1
venue.txt.2
venue.txt.3
venue.txt.4
```

The following COPY command loads the VENUE table using the pipe-delimited data in the data files with the prefix 'venue' in the Amazon S3 bucket `amzn-s3-demo-bucket`.

Note

The Amazon S3 bucket `amzn-s3-demo-bucket` in the following examples does not exist. For sample COPY commands that use real data in an existing Amazon S3 bucket, see [Load sample data](#).

```
COPY venue FROM 's3://amzn-s3-demo-bucket/venue'
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
DELIMITER '|';
```

If no Amazon S3 objects with the key prefix 'venue' exist, the load fails.

Topics

- [Using a manifest to specify data files](#)
- [Loading compressed data files from Amazon S3](#)

- [Loading fixed-width data from Amazon S3](#)
- [Loading multibyte data from Amazon S3](#)
- [Loading encrypted data files from Amazon S3](#)

Using a manifest to specify data files

You can use a manifest to make sure that the COPY command loads all of the required files, and only the required files, for a data load. You can use a manifest to load files from different buckets or files that do not share the same prefix. Instead of supplying an object path for the COPY command, you supply the name of a JSON-formatted text file that explicitly lists the files to be loaded. The URL in the manifest must specify the bucket name and full object path for the file, not just a prefix.

For more information about manifest files, see the COPY example [Using a manifest to specify data files](#).

The following example shows the JSON to load files from different buckets and with file names that begin with date stamps.

```
{
  "entries": [
    {"url": "s3://amzn-s3-demo-bucket1/2013-10-04-custdata", "mandatory": true},
    {"url": "s3://amzn-s3-demo-bucket1/2013-10-05-custdata", "mandatory": true},
    {"url": "s3://amzn-s3-demo-bucket2/2013-10-04-custdata", "mandatory": true},
    {"url": "s3://amzn-s3-demo-bucket2/2013-10-05-custdata", "mandatory": true}
  ]
}
```

The optional `mandatory` flag specifies whether COPY should return an error if the file is not found. The default of `mandatory` is `false`. Regardless of any `mandatory` settings, COPY will terminate if no files are found.

The following example runs the COPY command with the manifest in the previous example, which is named `cust.manifest`.

```
COPY customer
FROM 's3://amzn-s3-demo-bucket/cust.manifest'
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
MANIFEST;
```

Using a manifest created by UNLOAD

A manifest created by an [UNLOAD](#) operation using the MANIFEST parameter might have keys that are not required for the COPY operation. For example, the following UNLOAD manifest includes a meta key that is required for an Amazon Redshift Spectrum external table and for loading data files in an ORC or Parquet file format. The meta key contains a content_length key with a value that is the actual size of the file in bytes. The COPY operation requires only the url key and an optional mandatory key.

```
{
  "entries": [
    {"url": "s3://amzn-s3-demo-bucket/unload/manifest_0000_part_00", "meta":
    { "content_length": 5956875 }},
    {"url": "s3://amzn-s3-demo-bucket/unload/unload/manifest_0001_part_00", "meta":
    { "content_length": 5997091 }}
  ]
}
```

For more information about manifest files, see [Example: COPY from Amazon S3 using a manifest](#).

Loading compressed data files from Amazon S3

To load data files that are compressed using gzip, lzop, or bzip2, include the corresponding option: GZIP, LZOP, or BZIP2.

For example, the following command loads from files that were compressing using lzop.

```
COPY customer FROM 's3://amzn-s3-demo-bucket/customer.lzo'
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
DELIMITER '|' LZOP;
```

Note

If you compress a data file with lzop compression and use the `--filter` option, the COPY command doesn't support it.

Loading fixed-width data from Amazon S3

Fixed-width data files have uniform lengths for each column of data. Each field in a fixed-width data file has exactly the same length and position. For character data (CHAR and VARCHAR) in a

fixed-width data file, you must include leading or trailing spaces as placeholders in order to keep the width uniform. For integers, you must use leading zeros as placeholders. A fixed-width data file has no delimiter to separate columns.

To load a fixed-width data file into an existing table, USE the FIXEDWIDTH parameter in the COPY command. Your table specifications must match the value of fixedwidth_spec in order for the data to load correctly.

To load fixed-width data from a file to a table, issue the following command:

```
COPY table_name FROM 's3://amzn-s3-demo-bucket/prefix'  
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
FIXEDWIDTH 'fixedwidth_spec';
```

The *fixedwidth_spec* parameter is a string that contains an identifier for each column and the width of each column, separated by a colon. The **column:width** pairs are delimited by commas. The identifier can be anything that you choose: numbers, letters, or a combination of the two. The identifier has no relation to the table itself, so the specification must contain the columns in the same order as the table.

The following two examples show the same specification, with the first using numeric identifiers and the second using string identifiers:

```
'0:3,1:25,2:12,3:2,4:6'
```

```
'venueid:3,venueid:25,venueid:12,venueid:2,venueid:6'
```

The following example shows fixed-width sample data that could be loaded into the VENUE table using the preceding specifications:

```
1 Toyota Park           Bridgeview  IL0  
2 Columbus Crew Stadium Columbus    OH0  
3 RFK Stadium           Washington  DC0  
4 CommunityAmerica Ballpark Kansas City KS0  
5 Gillette Stadium      Foxborough MA68756
```

The following COPY command loads this data set into the VENUE table:

```
COPY venue
```

```
FROM 's3://amzn-s3-demo-bucket/data/venue_fw.txt'  
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
FIXEDWIDTH 'venueid:3,venueid:25,venueid:12,venueid:2,venueid:6';
```

Loading multibyte data from Amazon S3

If your data includes non-ASCII multibyte characters (such as Chinese or Cyrillic characters), you must load the data to VARCHAR columns. The VARCHAR data type supports four-byte UTF-8 characters, but the CHAR data type only accepts single-byte ASCII characters. You cannot load five-byte or longer characters into Amazon Redshift tables. For more information about CHAR and VARCHAR, see [Data types](#).

To check which encoding an input file uses, use the Linux *file* command:

```
$ file ordersdata.txt  
ordersdata.txt: ASCII English text  
$ file uni_ordersdata.dat  
uni_ordersdata.dat: UTF-8 Unicode text
```

Loading encrypted data files from Amazon S3

You can use the COPY command to load data files that were uploaded to Amazon S3 using server-side encryption, client-side encryption, or both.

The COPY command supports the following types of Amazon S3 encryption:

- Server-side encryption with Amazon S3-managed keys (SSE-S3)
- Server-side encryption with AWS KMS keys (SSE-KMS)
- Client-side encryption using a client-side symmetric root key

The COPY command doesn't support the following types of Amazon S3 encryption:

- Server-side encryption with customer-provided keys (SSE-C)
- Client-side encryption using an AWS KMS key
- Client-side encryption using a customer-provided asymmetric root key

For more information about Amazon S3 encryption, see [Protecting Data Using Server-Side Encryption](#) and [Protecting Data Using Client-Side Encryption](#) in the Amazon Simple Storage Service User Guide.

The [UNLOAD](#) command automatically encrypts files using SSE-S3. You can also unload using SSE-KMS or client-side encryption with a customer managed symmetric key. For more information, see [Unloading encrypted data files](#)

The COPY command automatically recognizes and loads files encrypted using SSE-S3 and SSE-KMS. You can load files encrypted using a client-side symmetric root key by specifying the ENCRYPTED option and providing the key value. For more information, see [Uploading encrypted data to Amazon S3](#).

To load client-side encrypted data files, provide the root key value using the MASTER_SYMMETRIC_KEY parameter and include the ENCRYPTED option.

```
COPY customer FROM 's3://amzn-s3-demo-bucket/encrypted/customer'  
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
MASTER_SYMMETRIC_KEY '<root_key>'  
ENCRYPTED  
DELIMITER '|';
```

To load encrypted data files that are gzip, lzop, or bzip2 compressed, include the GZIP, LZOP, or BZIP2 option along with the root key value and the ENCRYPTED option.

```
COPY customer FROM 's3://amzn-s3-demo-bucket/encrypted/customer'  
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
MASTER_SYMMETRIC_KEY '<root_key>'  
ENCRYPTED  
DELIMITER '|'  
GZIP;
```

Loading data from Amazon EMR

You can use the COPY command to load data in parallel from an Amazon EMR cluster configured to write text files to the cluster's Hadoop Distributed File System (HDFS) as fixed-width files, character-delimited files, CSV files, or JSON-formatted files.

Process for loading data from Amazon EMR

This section walks you through the process of loading data from an Amazon EMR cluster. The following sections provide the details that you must accomplish each step.

- [Step 1: Configure IAM permissions](#)

The users that create the Amazon EMR cluster and run the Amazon Redshift COPY command must have the necessary permissions.

- [**Step 2: Create an Amazon EMR cluster**](#)

Configure the cluster to output text files to the Hadoop Distributed File System (HDFS). You will need the Amazon EMR cluster ID and the cluster's main public DNS (the endpoint for the Amazon EC2 instance that hosts the cluster).

- [**Step 3: Retrieve the Amazon Redshift cluster public key and cluster node IP addresses**](#)

The public key enables the Amazon Redshift cluster nodes to establish SSH connections to the hosts. You will use the IP address for each cluster node to configure the host security groups to permit access from your Amazon Redshift cluster using these IP addresses.

- [**Step 4: Add the Amazon Redshift cluster public key to each Amazon EC2 host's authorized keys file**](#)

You add the Amazon Redshift cluster public key to the host's authorized keys file so that the host will recognize the Amazon Redshift cluster and accept the SSH connection.

- [**Step 5: Configure the hosts to accept all of the Amazon Redshift cluster's IP addresses**](#)

Modify the Amazon EMR instance's security groups to add input rules to accept the Amazon Redshift IP addresses.

- [**Step 6: Run the COPY command to load the data**](#)

From an Amazon Redshift database, run the COPY command to load the data into an Amazon Redshift table.

Step 1: Configure IAM permissions

The users that create the Amazon EMR cluster and run the Amazon Redshift COPY command must have the necessary permissions.

To configure IAM permissions

1. Add the following permissions for the user that will create the Amazon EMR cluster.

```
ec2:DescribeSecurityGroups
ec2:RevokeSecurityGroupIngress
ec2:AuthorizeSecurityGroupIngress
```

```
redshift:DescribeClusters
```

2. Add the following permission for the IAM role or user that will run the COPY command.

```
elasticmapreduce:ListInstances
```

3. Add the following permission to the Amazon EMR cluster's IAM role.

```
redshift:DescribeClusters
```

Step 2: Create an Amazon EMR cluster

The COPY command loads data from files on the Amazon EMR Hadoop Distributed File System (HDFS). When you create the Amazon EMR cluster, configure the cluster to output data files to the cluster's HDFS.

To create an Amazon EMR cluster

1. Create an Amazon EMR cluster in the same AWS Region as the Amazon Redshift cluster.

If the Amazon Redshift cluster is in a VPC, the Amazon EMR cluster must be in the same VPC group. If the Amazon Redshift cluster uses EC2-Classic mode (that is, it is not in a VPC), the Amazon EMR cluster must also use EC2-Classic mode. For more information, see [Managing Clusters in Virtual Private Cloud \(VPC\)](#) in the *Amazon Redshift Management Guide*.

2. Configure the cluster to output data files to the cluster's HDFS. The HDFS file names must not include asterisks (*) or question marks (?).

Important

The file names must not include asterisks (*) or question marks (?).

3. Specify **No** for the **Auto-terminate** option in the Amazon EMR cluster configuration so that the cluster remains available while the COPY command runs.

Important

If any of the data files are changed or deleted before the COPY completes, you might have unexpected results, or the COPY operation might fail.

- Note the cluster ID and the main public DNS (the endpoint for the Amazon EC2 instance that hosts the cluster). You will use that information in later steps.

Step 3: Retrieve the Amazon Redshift cluster public key and cluster node IP addresses

To retrieve the Amazon Redshift cluster public key and cluster node IP addresses for your cluster using the console

- Access the Amazon Redshift Management Console.
- Choose the **Clusters** link in the navigation pane.
- Select your cluster from the list.
- Locate the **SSH Ingestion Settings** group.

Note the **Cluster Public Key** and **Node IP addresses**. You will use them in later steps.

SSH Ingestion Settings

Cluster Public Key:

```
ssh-rsa
ExampleKeyDAQABAAABAQCKIVhE2BnJ92xM4ZimOaAeW
ssIDXB3haUmYMpevnnNj/wRRgpcomi7Eo3Fk+Eb7qLk4
qUgQvDMliaxM0Bf2XjRWZBuidQC1DUcuprnRth4XnnIR
lx1pUPq/re/8nQ95pVRS
/sYHWwtOraZ1rbECLqhJ40GQLeB5oFJ0ML1MiVfD31xC
jF66kOgI8GAkW0vdgMMPHSr12jjIbyDA+E3+rs1H8g80
gVhMj7iB4PE+9pnwSi
/aEtwPXzuh6Stbt2t1cuH0ZqZMcyo0tvDLwQit4Qc+06
bBK5CRyu/r6raQbIIS0xddiopvnSSMpihiExample=/
Amazon-Redshift
```

Node IP Addresses:

Node	Public IP	Private IP
Leader	192.0.2.0	198.51.100.0
Compute-0	203.0.113.0	10.24.34.0
Compute-1	198.51.100.0	192.0.2.0

You will use the private IP addresses in Step 3 to configure the Amazon EC2 host to accept the connection from Amazon Redshift.

To retrieve the cluster public key and cluster node IP addresses for your cluster using the Amazon Redshift CLI, run the `describe-clusters` command. For example:

```
aws redshift describe-clusters --cluster-identifier <cluster-identifier>
```

The response will include a `ClusterPublicKey` value and the list of private and public IP addresses, similar to the following:

```
{
  "Clusters": [
    {
      "VpcSecurityGroups": [],
      "ClusterStatus": "available",
      "ClusterNodes": [
        {
          "PrivateIPAddress": "10.nnn.nnn.nnn",
          "NodeRole": "LEADER",
          "PublicIPAddress": "10.nnn.nnn.nnn"
        },
        {
          "PrivateIPAddress": "10.nnn.nnn.nnn",
          "NodeRole": "COMPUTE-0",
          "PublicIPAddress": "10.nnn.nnn.nnn"
        },
        {
          "PrivateIPAddress": "10.nnn.nnn.nnn",
          "NodeRole": "COMPUTE-1",
          "PublicIPAddress": "10.nnn.nnn.nnn"
        }
      ],
      "AutomatedSnapshotRetentionPeriod": 1,
      "PreferredMaintenanceWindow": "wed:05:30-wed:06:00",
      "AvailabilityZone": "us-east-1a",
      "NodeType": "dc2.large",
      "ClusterPublicKey": "ssh-rsa AAAABexamplepublickey...Y3TA1 Amazon-
Redshift",
      ...
    }
  ]
}
```

To retrieve the cluster public key and cluster node IP addresses for your cluster using the Amazon Redshift API, use the `DescribeClusters` action. For more information, see [describe-clusters](#) in the *Amazon Redshift CLI Guide* or [DescribeClusters](#) in the Amazon Redshift API Guide.

Step 4: Add the Amazon Redshift cluster public key to each Amazon EC2 host's authorized keys file

You add the cluster public key to each host's authorized keys file for all of the Amazon EMR cluster nodes so that the hosts will recognize Amazon Redshift and accept the SSH connection.

To add the Amazon Redshift cluster public key to the host's authorized keys file

1. Access the host using an SSH connection.

For information about connecting to an instance using SSH, see [Connect to Your Instance](#) in the *Amazon EC2 User Guide*.

2. Copy the Amazon Redshift public key from the console or from the CLI response text.
3. Copy and paste the contents of the public key into the `/home/<ssh_username>/.ssh/authorized_keys` file on the host. Include the complete string, including the prefix "ssh-rsa " and suffix "Amazon-Redshift". For example:

```
ssh-rsa AAAACTP3isxgGzVWoIWpbVvRC0zYdVifMih... uA70BnMHCaMiRdmvsD0edZD0edZ Amazon-Redshift
```

Step 5: Configure the hosts to accept all of the Amazon Redshift cluster's IP addresses

To allow inbound traffic to the host instances, edit the security group and add one Inbound rule for each Amazon Redshift cluster node. For **Type**, select SSH with TCP protocol on Port 22. For **Source**, enter the Amazon Redshift cluster node private IP addresses you retrieved in [Step 3: Retrieve the Amazon Redshift cluster public key and cluster node IP addresses](#). For information about adding rules to an Amazon EC2 security group, see [Authorizing Inbound Traffic for Your Instances](#) in the *Amazon EC2 User Guide*.

Step 6: Run the COPY command to load the data

Run a [COPY](#) command to connect to the Amazon EMR cluster and load the data into an Amazon Redshift table. The Amazon EMR cluster must continue running until the COPY command completes. For example, do not configure the cluster to auto-terminate.

Important

If any of the data files are changed or deleted before the COPY completes, you might have unexpected results, or the COPY operation might fail.

In the COPY command, specify the Amazon EMR cluster ID and the HDFS file path and file name.

```
COPY sales
FROM 'emr://myemrclusterid/myoutput/part*' CREDENTIALS
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

You can use the wildcard characters asterisk (*) and question mark (?) as part of the file name argument. For example, `part*` loads the files `part-0000`, `part-0001`, and so on. If you specify only a folder name, COPY attempts to load all files in the folder.

Important

If you use wildcard characters or use only the folder name, verify that no unwanted files will be loaded or the COPY command will fail. For example, some processes might write a log file to the output folder.

Loading data from remote hosts

You can use the COPY command to load data in parallel from one or more remote hosts, such as Amazon EC2 instances or other computers. COPY connects to the remote hosts using SSH and runs commands on the remote hosts to generate text output.

The remote host can be an Amazon EC2 Linux instance or another Unix or Linux computer configured to accept SSH connections. This guide assumes your remote host is an Amazon EC2 instance. Where the procedure is different for another computer, the guide will point out the difference.

Amazon Redshift can connect to multiple hosts, and can open multiple SSH connections to each host. Amazon Redshift sends a unique command through each connection to generate text output to the host's standard output, which Amazon Redshift then reads as it would a text file.

Before you begin

Before you begin, you should have the following in place:

- One or more host machines, such as Amazon EC2 instances, that you can connect to using SSH.
- Data sources on the hosts.

You will provide commands that the Amazon Redshift cluster will run on the hosts to generate the text output. After the cluster connects to a host, the COPY command runs the commands, reads the text from the hosts' standard output, and loads the data in parallel into an Amazon Redshift table. The text output must be in a form that the COPY command can ingest. For more information, see [Preparing your input data](#)

- Access to the hosts from your computer.

For an Amazon EC2 instance, you will use an SSH connection to access the host. You must access the host to add the Amazon Redshift cluster's public key to the host's authorized keys file.

- A running Amazon Redshift cluster.

For information about how to launch a cluster, see [Amazon Redshift Getting Started Guide](#).

Loading data process

This section walks you through the process of loading data from remote hosts. The following sections provide the details that that you must accomplish in each step.

- [Step 1: Retrieve the cluster public key and cluster node IP addresses](#)

The public key enables the Amazon Redshift cluster nodes to establish SSH connections to the remote hosts. You will use the IP address for each cluster node to configure the host security groups or firewall to permit access from your Amazon Redshift cluster using these IP addresses.

- [Step 2: Add the Amazon Redshift cluster public key to the host's authorized keys file](#)

You add the Amazon Redshift cluster public key to the host's authorized keys file so that the host will recognize the Amazon Redshift cluster and accept the SSH connection.

- **Step 3: Configure the host to accept all of the Amazon Redshift cluster's IP addresses**

For Amazon EC2, modify the instance's security groups to add input rules to accept the Amazon Redshift IP addresses. For other hosts, modify the firewall so that your Amazon Redshift nodes are able to establish SSH connections to the remote host.

- **Step 4: Get the public key for the host**

You can optionally specify that Amazon Redshift should use the public key to identify the host. You must locate the public key and copy the text into your manifest file.

- **Step 5: Create a manifest file**

The manifest is a JSON-formatted text file with the details Amazon Redshift needs to connect to the hosts and fetch the data.

- **Step 6: Upload the manifest file to an Amazon S3 bucket**

Amazon Redshift reads the manifest and uses that information to connect to the remote host. If the Amazon S3 bucket does not reside in the same Region as your Amazon Redshift cluster, you must use the [REGION](#) option to specify the Region in which the data is located.

- **Step 7: Run the COPY command to load the data**

From an Amazon Redshift database, run the COPY command to load the data into an Amazon Redshift table.

Step 1: Retrieve the cluster public key and cluster node IP addresses

To retrieve the cluster public key and cluster node IP addresses for your cluster using the console

1. Access the Amazon Redshift Management Console.
2. Choose the **Clusters** link in the navigation pane.
3. Select your cluster from the list.
4. Locate the **SSH Ingestion Settings** group.

Note the **Cluster Public Key** and **Node IP addresses**. You will use them in later steps.

SSH Ingestion Settings

Cluster Public Key:

```
ssh-rsa
ExampleKeyDAQABAAABAQCKIVhE2BnJ92xM4ZimOaAeW
ssIDXB3haUmYMpevnnNj/wRRgpcomi7Eo3Fk+Eb7qLk4
qUgQvDMLiaxM0Bf2XjRWZBUidQC1DUcuprnRth4XnnIR
lx1pUPq/re/8nQ95pVRS
/sYHWwtOraZ1rbECLqhJ40GQLeB5oFJ0ML1MiVfD31xC
jf66kOgI8GakW0vdgMMPHSr12jjIbyDA+E3+rs1H8g8O
gVhMj7iB4PE+9pnwSi
/aEtwPXzuh6Stbt2t1cuH0Zq2Mcyo0tvDLwQit4Qc+06
bBK5CRyu/r6raQbIIS0xddiopvnSSMpihiExample=/
Amazon-Redshift
```

Node IP Addresses:

Node	Public IP	Private IP
Leader	192.0.2.0	198.51.100.0
Compute-0	203.0.113.0	10.24.34.0
Compute-1	198.51.100.0	192.0.2.0

You will use the IP addresses in Step 3 to configure the host to accept the connection from Amazon Redshift. Depending on what type of host you connect to and whether it is in a VPC, you will use either the public IP addresses or the private IP addresses.

To retrieve the cluster public key and cluster node IP addresses for your cluster using the Amazon Redshift CLI, run the `describe-clusters` command.

For example:

```
aws redshift describe-clusters --cluster-identifier <cluster-identifier>
```

The response will include the `ClusterPublicKey` and the list of private and public IP addresses, similar to the following:

```
{
  "Clusters": [
    {
      "VpcSecurityGroups": [],
      "ClusterStatus": "available",
```

```

    "ClusterNodes": [
      {
        "PrivateIPAddress": "10.nnn.nnn.nnn",
        "NodeRole": "LEADER",
        "PublicIPAddress": "10.nnn.nnn.nnn"
      },
      {
        "PrivateIPAddress": "10.nnn.nnn.nnn",
        "NodeRole": "COMPUTE-0",
        "PublicIPAddress": "10.nnn.nnn.nnn"
      },
      {
        "PrivateIPAddress": "10.nnn.nnn.nnn",
        "NodeRole": "COMPUTE-1",
        "PublicIPAddress": "10.nnn.nnn.nnn"
      }
    ],
    "AutomatedSnapshotRetentionPeriod": 1,
    "PreferredMaintenanceWindow": "wed:05:30-wed:06:00",
    "AvailabilityZone": "us-east-1a",
    "NodeType": "dc2.large",
    "ClusterPublicKey": "ssh-rsa AAAABExamplepublickey...Y3TA1 Amazon-
Redshift",
    ...
    ...
  }

```

To retrieve the cluster public key and cluster node IP addresses for your cluster using the Amazon Redshift API, use the DescribeClusters action. For more information, see [describe-clusters](#) in the *Amazon Redshift CLI Guide* or [DescribeClusters](#) in the Amazon Redshift API Guide.

Step 2: Add the Amazon Redshift cluster public key to the host's authorized keys file

You add the cluster public key to each host's authorized keys file so that the host will recognize Amazon Redshift and accept the SSH connection.

To add the Amazon Redshift cluster public key to the host's authorized keys file

1. Access the host using an SSH connection.

For information about connecting to an instance using SSH, see [Connect to Your Instance](#) in the *Amazon EC2 User Guide*.

2. Copy the Amazon Redshift public key from the console or from the CLI response text.
3. Copy and paste the contents of the public key into the `/home/<ssh_username>/.ssh/authorized_keys` file on the remote host. The `<ssh_username>` must match the value for the "username" field in the manifest file. Include the complete string, including the prefix "ssh-rsa " and suffix "Amazon-Redshift". For example:

```
ssh-rsa AAAACTP3isxgGzVWoIWpbVvRC0zYdVifM1h... uA70BnMHCaMiRdmvsD0edZD0edZ Amazon-Redshift
```

Step 3: Configure the host to accept all of the Amazon Redshift cluster's IP addresses

If you are working with an Amazon EC2 instance or an Amazon EMR cluster, add Inbound rules to the host's security group to allow traffic from each Amazon Redshift cluster node. For **Type**, select SSH with TCP protocol on Port 22. For **Source**, enter the Amazon Redshift cluster node IP addresses you retrieved in [Step 1: Retrieve the cluster public key and cluster node IP addresses](#). For information about adding rules to an Amazon EC2 security group, see [Authorizing Inbound Traffic for Your Instances](#) in the *Amazon EC2 User Guide*.

Use the private IP addresses when:

- You have an Amazon Redshift cluster that is not in a Virtual Private Cloud (VPC), and an Amazon EC2 -Classic instance, both of which are in the same AWS Region.
- You have an Amazon Redshift cluster that is in a VPC, and an Amazon EC2 -VPC instance, both of which are in the same AWS Region and in the same VPC.

Otherwise, use the public IP addresses.

For more information about using Amazon Redshift in a VPC, see [Managing Clusters in Virtual Private Cloud \(VPC\)](#) in the *Amazon Redshift Management Guide*.

Step 4: Get the public key for the host

You can optionally provide the host's public key in the manifest file so that Amazon Redshift can identify the host. The COPY command does not require the host public key but, for security reasons, we strongly recommend using a public key to help prevent 'man-in-the-middle' attacks.

You can find the host's public key in the following location, where `<ssh_host_rsa_key_name>` is the unique name for the host's public key:

```
: /etc/ssh/<ssh_host_rsa_key_name>.pub
```

Note

Amazon Redshift only supports RSA keys. We do not support DSA keys.

When you create your manifest file in Step 5, you will paste the text of the public key into the "Public Key" field in the manifest file entry.

Step 5: Create a manifest file

The COPY command can connect to multiple hosts using SSH, and can create multiple SSH connections to each host. COPY runs a command through each host connection, and then loads the output from the commands in parallel into the table. The manifest file is a text file in JSON format that Amazon Redshift uses to connect to the host. The manifest file specifies the SSH host endpoints and the commands that are run on the hosts to return data to Amazon Redshift. Optionally, you can include the host public key, the login user name, and a mandatory flag for each entry.

Create the manifest file on your local computer. In a later step, you upload the file to Amazon S3.

The manifest file is in the following format:

```
{
  "entries": [
    {
      "endpoint": "<ssh_endpoint_or_IP>",
      "command": "<remote_command>",
      "mandatory": true,
      "publickey": "<public_key>",
      "username": "<host_user_name>"
    }
  ]
}
```

```
{
  "endpoint": "<ssh_endpoint_or_IP>",
  "command": "<remote_command>",
  "mandatory": true,
  "publickey": "<public_key>",
  "username": "host_user_name"
}
```

The manifest file contains one "entries" construct for each SSH connection. Each entry represents a single SSH connection. You can have multiple connections to a single host or multiple connections to multiple hosts. The double quotation marks are required as shown, both for the field names and the values. The only value that does not need double quotation marks is the Boolean value **true** or **false** for the mandatory field.

The following describes the fields in the manifest file.

endpoint

The URL address or IP address of the host. For example,

"ec2-111-222-333.compute-1.amazonaws.com" or "22.33.44.56"

command

The command that will be run by the host to generate text or binary (gzip, lzop, or bzip2) output. The command can be any command that the user *"host_user_name"* has permission to run. The command can be as simple as printing a file, or it could query a database or launch a script. The output (text file, gzip binary file, lzop binary file, or bzip2 binary file) must be in a form the Amazon Redshift COPY command can ingest. For more information, see [Preparing your input data](#).

publickey

(Optional) The public key of the host. If provided, Amazon Redshift will use the public key to identify the host. If the public key is not provided, Amazon Redshift will not attempt host identification. For example, if the remote host's public key is: `ssh-rsa AbcCbaxxx...xxxDHKJ root@amazon.com`, enter the following text in the public key field: `AbcCbaxxx...xxxDHKJ`.

mandatory

(Optional) Indicates whether the COPY command should fail if the connection fails. The default is `false`. If Amazon Redshift does not successfully make at least one connection, the COPY command fails.

username

(Optional) The username that will be used to log on to the host system and run the remote command. The user login name must be the same as the login that was used to add the public key to the host's authorized keys file in Step 2. The default username is "redshift".

The following example shows a completed manifest to open four connections to the same host and run a different command through each connection:

```
{
  "entries": [
    {"endpoint": "ec2-184-72-204-112.compute-1.amazonaws.com",
      "command": "cat loaddata1.txt",
      "mandatory": true,
      "publickey": "ec2publickeyportionoftheec2keypair",
      "username": "ec2-user"},
    {"endpoint": "ec2-184-72-204-112.compute-1.amazonaws.com",
      "command": "cat loaddata2.txt",
      "mandatory": true,
      "publickey": "ec2publickeyportionoftheec2keypair",
      "username": "ec2-user"},
    {"endpoint": "ec2-184-72-204-112.compute-1.amazonaws.com",
      "command": "cat loaddata3.txt",
      "mandatory": true,
      "publickey": "ec2publickeyportionoftheec2keypair",
      "username": "ec2-user"},
    {"endpoint": "ec2-184-72-204-112.compute-1.amazonaws.com",
      "command": "cat loaddata4.txt",
      "mandatory": true,
      "publickey": "ec2publickeyportionoftheec2keypair",
      "username": "ec2-user"}
  ]
}
```

Step 6: Upload the manifest file to an Amazon S3 bucket

Upload the manifest file to an Amazon S3 bucket. If the Amazon S3 bucket does not reside in the same AWS Region as your Amazon Redshift cluster, you must use the [REGION](#) option to specify the AWS Region in which the manifest is located. For information about creating an Amazon S3 bucket and uploading a file, see [Amazon Simple Storage Service User Guide](#).

Step 7: Run the COPY command to load the data

Run a [COPY](#) command to connect to the host and load the data into an Amazon Redshift table. In the COPY command, specify the explicit Amazon S3 object path for the manifest file and include the SSH option. For example,

```
COPY sales
FROM 's3://amzn-s3-demo-bucket/ssh_manifest'
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
DELIMITER '|'
SSH;
```

Note

If you use automatic compression, the COPY command performs two data reads, which means it runs the remote command twice. The first read is to provide a sample for compression analysis, then the second read actually loads the data. If running the remote command twice might cause a problem because of potential side effects, you should turn off automatic compression. To turn off automatic compression, run the COPY command with the COMPUPDATE option set to OFF. For more information, see [Loading tables with automatic compression](#).

Loading data from an Amazon DynamoDB table

You can use the COPY command to load a table with data from a single Amazon DynamoDB table.

Important

The Amazon DynamoDB table that provides the data must be created in the same AWS Region as your cluster unless you use the [REGION](#) option to specify the AWS Region in which the Amazon DynamoDB table is located.

The COPY command uses the Amazon Redshift massively parallel processing (MPP) architecture to read and load data in parallel from an Amazon DynamoDB table. You can take maximum advantage of parallel processing by setting distribution styles on your Amazon Redshift tables. For more information, see [Data distribution for query optimization](#).

⚠ Important

When the COPY command reads data from the Amazon DynamoDB table, the resulting data transfer is part of that table's provisioned throughput.

To avoid consuming excessive amounts of provisioned read throughput, we recommend that you not load data from Amazon DynamoDB tables that are in production environments. If you do load data from production tables, we recommend that you set the READRATIO option much lower than the average percentage of unused provisioned throughput. A low READRATIO setting will help minimize throttling issues. To use the entire provisioned throughput of an Amazon DynamoDB table, set READRATIO to 100.

The COPY command matches attribute names in the items retrieved from the DynamoDB table to column names in an existing Amazon Redshift table by using the following rules:

- Amazon Redshift table columns are case-insensitively matched to Amazon DynamoDB item attributes. If an item in the DynamoDB table contains multiple attributes that differ only in case, such as Price and PRICE, the COPY command will fail.
- Amazon Redshift table columns that do not match an attribute in the Amazon DynamoDB table are loaded as either NULL or empty, depending on the value specified with the EMPTYASNULL option in the [COPY](#) command.
- Amazon DynamoDB attributes that do not match a column in the Amazon Redshift table are discarded. Attributes are read before they are matched, and so even discarded attributes consume part of that table's provisioned throughput.
- Only Amazon DynamoDB attributes with scalar STRING and NUMBER data types are supported. The Amazon DynamoDB BINARY and SET data types are not supported. If a COPY command tries to load an attribute with an unsupported data type, the command will fail. If the attribute does not match an Amazon Redshift table column, COPY does not attempt to load it, and it does not raise an error.

The COPY command uses the following syntax to load data from an Amazon DynamoDB table:

```
COPY <redshift_tablename> FROM 'dynamodb://<dynamodb_table_name>'
authorization
readratio '<integer>';
```

The values for *authorization* are the AWS credentials needed to access the Amazon DynamoDB table. If these credentials correspond to a user, that user must have permission to SCAN and DESCRIBE the Amazon DynamoDB table that is being loaded.

The values for *authorization* provide the AWS authorization your cluster needs to access the Amazon DynamoDB table. The permission must include SCAN and DESCRIBE for the Amazon DynamoDB table that is being loaded. For more information about required permissions, see [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#). The preferred method for authentication is to specify the IAM_ROLE parameter and provide the Amazon Resource Name (ARN) for an IAM role with the necessary permissions. For more information, see [Role-based access control](#).

To authenticate using the IAM_ROLE parameter, *<aws-account-id>* and *<role-name>* as shown in the following syntax.

```
IAM_ROLE 'arn:aws:iam::<aws-account-id>:role/<role-name>'
```

The following example shows authentication using an IAM role.

```
COPY favoritemovies  
FROM 'dynamodb://ProductCatalog'  
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

For more information about other authorization options, see [Authorization parameters](#)

If you want to validate your data without actually loading the table, use the NOLOAD option with the [COPY](#) command.

The following example loads the FAVORITEMOVIES table with data from the DynamoDB table my-favorite-movies-table. The read activity can consume up to 50% of the provisioned throughput.

```
COPY favoritemovies FROM 'dynamodb://my-favorite-movies-table'  
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
READRATIO 50;
```

To maximize throughput, the COPY command loads data from an Amazon DynamoDB table in parallel across the compute nodes in the cluster.

Provisioned throughput with automatic compression

By default, the COPY command applies automatic compression whenever you specify an empty target table with no compression encoding. The automatic compression analysis initially samples a

large number of rows from the Amazon DynamoDB table. The sample size is based on the value of the `COMPROWS` parameter. The default is 100,000 rows per slice.

After sampling, the sample rows are discarded and the entire table is loaded. As a result, many rows are read twice. For more information about how automatic compression works, see [Loading tables with automatic compression](#).

Important

When the `COPY` command reads data from the Amazon DynamoDB table, including the rows used for sampling, the resulting data transfer is part of that table's provisioned throughput.

Loading multibyte data from Amazon DynamoDB

If your data includes non-ASCII multibyte characters (such as Chinese or Cyrillic characters), you must load the data to `VARCHAR` columns. The `VARCHAR` data type supports four-byte UTF-8 characters, but the `CHAR` data type only accepts single-byte ASCII characters. You cannot load five-byte or longer characters into Amazon Redshift tables. For more information about `CHAR` and `VARCHAR`, see [Data types](#).

Verifying that the data loaded correctly

After the load operation is complete, query the [STL_LOAD_COMMITS](#) system table to verify that the expected files were loaded. Run the `COPY` command and load verification within the same transaction so that if there is problem with the load you can roll back the entire transaction.

The following query returns entries for loading the tables in the TICKIT database:

```
SELECT query, trim(filename) AS filename, curtime, status
FROM stl_load_commits
WHERE filename like '%tickit%' order by query;
```

query	filename	curtime	status
22475	tickit/allusers_pipe.txt	2013-02-08 20:58:23.274186	1
22478	tickit/venue_pipe.txt	2013-02-08 20:58:25.070604	1
22480	tickit/category_pipe.txt	2013-02-08 20:58:27.333472	1

```
22482 | tickit/date2008_pipe.txt | 2013-02-08 20:58:28.608305 | 1
22485 | tickit/allevvents_pipe.txt | 2013-02-08 20:58:29.99489 | 1
22487 | tickit/listings_pipe.txt | 2013-02-08 20:58:37.632939 | 1
22489 | tickit/sales_tab.txt | 2013-02-08 20:58:37.632939 | 1
(6 rows)
```

Validating input data

To validate the data in the Amazon S3 input files or Amazon DynamoDB table before you actually load the data, use the NOLOAD option with the [COPY](#) command. Use NOLOAD with the same COPY commands and options you would use to load the data. NOLOAD checks the integrity of all of the data without loading it into the database. The NOLOAD option displays any errors that occur if you attempt to load the data.

For example, if you specified the incorrect Amazon S3 path for the input file, Amazon Redshift would display the following error.

```
ERROR: No such file or directory
DETAIL:
-----
Amazon Redshift error: The specified key does not exist
code:          2
context:       S3 key being read :
location:      step_scan.cpp:1883
process:       xenmaster [pid=22199]
-----
```

To troubleshoot error messages, see the [Load error reference](#).

For an example using the NOLOAD option, see [COPY command with the NOLOAD option](#).

Loading tables with automatic compression

You can apply compression encodings to columns in tables manually, based on your own evaluation of the data. Or you can use the COPY command with COMPUPDATE set to ON to analyze and apply compression automatically based on sample data.

You can use automatic compression when you create and load a brand new table. The COPY command performs a compression analysis. You can also perform a compression analysis without loading data or changing the compression on a table by running the [ANALYZE COMPRESSION](#) command on an already populated table. For example, you can run ANALYZE COMPRESSION when

you want to analyze compression on a table for future use, while preserving the existing data definition language (DDL) statements.

Automatic compression balances overall performance when choosing compression encodings. Range-restricted scans might perform poorly if sort key columns are compressed much more highly than other columns in the same query. As a result, automatic compression skips the data analyzing phase on the sort key columns and keeps the user-defined encoding types.

Automatic compression chooses RAW encoding if you haven't explicitly defined a type of encoding. `ANALYZE COMPRESSION` behaves the same. For optimal query performance, consider using RAW for sort keys.

How automatic compression works

When the `COMPUPDATE` parameter is ON, the `COPY` command applies automatic compression whenever you run the `COPY` command with an empty target table and all of the table columns either have RAW encoding or no encoding.

To apply automatic compression to an empty table, regardless of its current compression encodings, run the `COPY` command with the `COMPUPDATE` option set to ON. To turn off automatic compression, run the `COPY` command with the `COMPUPDATE` option set to OFF.

You cannot apply automatic compression to a table that already contains data.

Note

Automatic compression analysis requires enough rows in the load data (at least 100,000 rows per slice) to generate a meaningful sample.

Automatic compression performs these operations in the background as part of the load transaction:

1. An initial sample of rows is loaded from the input file. Sample size is based on the value of the `COMPROWS` parameter. The default is 100,000.
2. Compression options are chosen for each column.
3. The sample rows are removed from the table.
4. The table is recreated with the chosen compression encodings.
5. The entire input file is loaded and compressed using the new encodings.

After you run the COPY command, the table is fully loaded, compressed, and ready for use. If you load more data later, appended rows are compressed according to the existing encoding.

If you only want to perform a compression analysis, run ANALYZE COMPRESSION, which is more efficient than running a full COPY. Then you can evaluate the results to decide whether to use automatic compression or recreate the table manually.

Automatic compression is supported only for the COPY command. Alternatively, you can manually apply compression encoding when you create the table. For information about manual compression encoding, see [Column compression to reduce the size of stored data](#).

Automatic compression example

In this example, assume that the TICKIT database contains a copy of the LISTING table called BIGLIST, and you want to apply automatic compression to this table when it is loaded with approximately 3 million rows.

To load and automatically compress the table

1. Make sure that the table is empty. You can apply automatic compression only to an empty table:

```
TRUNCATE biglist;
```

2. Load the table with a single COPY command. Although the table is empty, some earlier encoding might have been specified. To facilitate that Amazon Redshift performs a compression analysis, set the COMPUPDATE parameter to ON.

```
COPY biglist FROM 's3://amzn-s3-demo-bucket/biglist.txt'  
IAM_ROLE 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
DELIMITER '|' COMPUPDATE ON;
```

Because no COMPROWS option is specified, the default and recommended sample size of 100,000 rows per slice is used.

3. Look at the new schema for the BIGLIST table in order to review the automatically chosen encoding schemes.

```
SELECT "column", type, encoding  
from pg_table_def where tablename = 'biglist';
```

Column	Type	Encoding
listid	integer	az64
sellerid	integer	az64
eventid	integer	az64
dateid	smallint	none
numtickets	smallint	az64
priceperticket	numeric(8,2)	az64
totalprice	numeric(8,2)	az64
listtime	timestamp without time zone	az64

- Verify that the expected number of rows were loaded:

```
select count(*) from biglist;
```

```
count
-----
3079952
(1 row)
```

When rows are later appended to this table using COPY or INSERT statements, the same compression encodings are applied.

Optimizing storage for narrow tables

If you have a table with very few columns but a very large number of rows, the three hidden metadata identity columns (INSERT_XID, DELETE_XID, ROW_ID) will consume a disproportionate amount of the disk space for the table.

In order to optimize compression of the hidden columns, load the table in a single COPY transaction where possible. If you load the table with multiple separate COPY commands, the INSERT_XID column will not compress well. You must perform a vacuum operation if you use multiple COPY commands, but it will not improve compression of INSERT_XID.

Loading default column values

You can optionally define a column list in your COPY command. If a column in the table is omitted from the column list, COPY will load the column with either the value supplied by the DEFAULT

option that was specified in the CREATE TABLE command, or with NULL if the DEFAULT option was not specified.

If COPY attempts to assign NULL to a column that is defined as NOT NULL, the COPY command fails. For information about assigning the DEFAULT option, see [CREATE TABLE](#).

When loading from data files on Amazon S3, the columns in the column list must be in the same order as the fields in the data file. If a field in the data file does not have a corresponding column in the column list, the COPY command fails.

When loading from Amazon DynamoDB table, order does not matter. Any fields in the Amazon DynamoDB attributes that do not match a column in the Amazon Redshift table are discarded.

The following restrictions apply when using the COPY command to load DEFAULT values into a table:

- If an [IDENTITY](#) column is included in the column list, the EXPLICIT_IDS option must also be specified in the [COPY](#) command, or the COPY command will fail. Similarly, if an IDENTITY column is omitted from the column list, and the EXPLICIT_IDS option is specified, the COPY operation will fail.
- Because the evaluated DEFAULT expression for a given column is the same for all loaded rows, a DEFAULT expression that uses a RANDOM() function will assign to same value to all the rows.
- DEFAULT expressions that contain CURRENT_DATE or SYSDATE are set to the timestamp of the current transaction.

For an example, see "Load data from a file with default values" in [COPY examples](#).

Troubleshooting data loads

When you load data into Amazon Redshift tables you might encounter errors from Amazon S3, invalid input data, and COPY command errors. The following sections provide information about identifying and resolving data load errors.

Topics

- [S3ServiceException errors](#)
- [System tables for troubleshooting data loads](#)
- [Multibyte character load errors](#)

- [Load error reference](#)

S3ServiceException errors

The most common `s3ServiceException` errors are caused by an improperly formatted or incorrect credentials string, having your cluster and your bucket in different AWS Regions, and insufficient Amazon S3 permissions.

The section provides troubleshooting information for each type of error.

Invalid credentials string

If your credentials string was improperly formatted, you will receive the following error message:

```
ERROR: Invalid credentials. Must be of the format: credentials
'aws_access_key_id=<access-key-id>;aws_secret_access_key=<secret-access-key>
[;token=<temporary-session-token>]'
```

Verify that the credentials string does not contain any spaces or line breaks, and is enclosed in single quotation marks.

Invalid access key ID

If your access key ID does not exist, you will receive the following error message:

```
[Amazon](500310) Invalid operation: S3ServiceException:The AWS Access Key Id you
provided does not exist in our records.
```

This is often a copy and paste error. Verify that the access key ID was entered correctly. Also, if you are using temporary session keys, check that the value for token is set.

Invalid secret access key

If your secret access key is incorrect, you will receive the following error message:

```
[Amazon](500310) Invalid operation: S3ServiceException:The request signature we
calculated does not match the signature you provided.
Check your key and signing method.,Status 403,Error SignatureDoesNotMatch
```

This is often a copy and paste error. Verify that the secret access key was entered correctly and that it is the correct key for the access key ID.

Bucket is in a different Region

The Amazon S3 bucket specified in the COPY command must be in the same AWS Region as the cluster. If your Amazon S3 bucket and your cluster are in different Regions, you will receive an error similar to the following:

```
ERROR: S3ServiceException:The bucket you are attempting to access must be addressed using the specified endpoint.
```

You can create an Amazon S3 bucket in a specific Region either by selecting the Region when you create the bucket by using the Amazon S3 Management Console, or by specifying an endpoint when you create the bucket using the Amazon S3 API or CLI. For more information, see [Uploading files to Amazon S3 to use with COPY](#).

For more information about Amazon S3 regions, see [Accessing a Bucket](#) in the *Amazon Simple Storage Service User Guide*.

Alternatively, you can specify the Region using the [REGION](#) option with the COPY command.

Access denied

If the user does not have sufficient permissions, you will receive the following error message:

```
ERROR: S3ServiceException:Access Denied,Status 403,Error AccessDenied
```

One possible cause is the user identified by the credentials does not have LIST and GET access to the Amazon S3 bucket. For other causes, see [Troubleshoot Access Denied \(403 Forbidden\) errors in Amazon S3](#) in the *Amazon Simple Storage Service User Guide*.

For information about managing user access to buckets, see [Identity and access management in Amazon S3](#) in the *Amazon Simple Storage Service User Guide*.

System tables for troubleshooting data loads

The following Amazon Redshift system tables can be helpful in troubleshooting data load issues:

- Query [STL_LOAD_ERRORS](#) to discover the errors that occurred during specific loads.
- Query [STL_FILE_SCAN](#) to view load times for specific files or to see if a specific file was even read.
- Query [STL_S3CLIENT_ERROR](#) to find details for errors encountered while transferring data from Amazon S3.

To find and diagnose load errors

1. Create a view or define a query that returns details about load errors. The following example joins the `STL_LOAD_ERRORS` table to the `STV_TBL_PERM` table to match table IDs with actual table names.

```
create view loadview as
(select distinct tbl, trim(name) as table_name, query, starttime,
trim(filename) as input, line_number, colname, err_code,
trim(err_reason) as reason
from stl_load_errors sl, stv_tbl_perm sp
where sl.tbl = sp.id);
```

2. Set the `MAXERRORS` option in your `COPY` command to a large enough value to enable `COPY` to return useful information about your data. If the `COPY` encounters errors, an error message directs you to consult the `STL_LOAD_ERRORS` table for details.
3. Query the `LOADVIEW` view to see error details. For example:

```
select * from loadview where table_name='venue';
```

tbl	table_name	query	starttime	
100551	venue	20974	2013-01-29 19:05:58.365391	
input	line_number	colname	err_code	reason
venue_pipe.txt	1	0	1214	Delimiter not found

4. Fix the problem in the input file or the load script, based on the information that the view returns. Some typical load errors to watch for include:
 - Mismatch between data types in table and values in input data fields.
 - Mismatch between number of columns in table and number of fields in input data.
 - Mismatched quotation marks. Amazon Redshift supports both single and double quotation marks; however, these quotation marks must be balanced appropriately.
 - Incorrect format for date/time data in input files.
 - Out-of-range values in input files (for numeric columns).
 - Number of distinct values for a column exceeds the limitation for its compression encoding.

Multibyte character load errors

Columns with a CHAR data type only accept single-byte UTF-8 characters, up to byte value 127, or 7F hex, which is also the ASCII character set. VARCHAR columns accept multibyte UTF-8 characters, to a maximum of four bytes. For more information, see [Character types](#).

If a line in your load data contains a character that is not valid for the column data type, COPY returns an error and logs a row in the STL_LOAD_ERRORS system log table with error number 1220. The ERR_REASON field includes the byte sequence, in hex, for the invalid character.

An alternative to fixing not valid characters in your load data is to replace the not valid characters during the load process. To replace not valid UTF-8 characters, specify the ACCEPTINVCHARS option with the COPY command. If the ACCEPTINVCHARS option is set, the character you specify replaces the code point. If the ACCEPTINVCHARS option isn't set, Amazon Redshift accepts the characters as valid UTF-8. For more information, see [ACCEPTINVCHARS](#).

The following list of code points are valid UTF-8, COPY operations don't return an error if the ACCEPTINVCHARS option is not set. However, these code points are not valid characters. You can use the [ACCEPTINVCHARS](#) option to replace a code point with a character that you specify. These code points include the range of values from 0xFDD0 to 0xFDEF and values up to 0x10FFFF, ending with FFFE or FFFF:

- 0xFFFE, 0x1FFFE, 0x2FFFE, ..., 0xFFFFE, 0x10FFFE
- 0xFFFF, 0x1FFFF, 0x2FFFF, ..., 0xFFFFF, 0x10FFFF

The following example shows the error reason when COPY attempts to load UTF-8 character e0 a1 c7a4 into a CHAR column.

```
Multibyte character not supported for CHAR
(Hint: Try using VARCHAR). Invalid char: e0 a1 c7a4
```

If the error is related to a VARCHAR data type, the error reason includes an error code as well as the not valid UTF-8 hex sequence. The following example shows the error reason when COPY attempts to load UTF-8 a4 into a VARCHAR field.

```
String contains invalid or unsupported UTF-8 codepoints.
Bad UTF-8 hex sequence: a4 (error 3)
```

The following table lists the descriptions and suggested workarounds for VARCHAR load errors. If one of these errors occurs, replace the character with a valid UTF-8 code sequence or remove the character.

Error code	Description
1	The UTF-8 byte sequence exceeds the four-byte maximum supported by VARCHAR.
2	The UTF-8 byte sequence is incomplete. COPY did not find the expected number of continuation bytes for a multibyte character before the end of the string.
3	The UTF-8 single-byte character is out of range. The starting byte must not be 254, 255 or any character between 128 and 191 (inclusive).
4	The value of the trailing byte in the byte sequence is out of range. The continuation byte must be between 128 and 191 (inclusive).
5	The UTF-8 character is reserved as a surrogate. Surrogate code points (U+D800 through U+DFFF) are not valid.
8	The byte sequence exceeds the maximum UTF-8 code point.
9	The UTF-8 byte sequence does not have a matching code point.

Load error reference

If any errors occur while loading data from a file, query the [STL_LOAD_ERRORS](#) table to identify the error and determine the possible explanation. The following table lists all error codes that might occur during data loads:

Load error codes

Error code	Description
1200	Unknown parse error. Contact support.
1201	Field delimiter was not found in the input file.

Error code	Description
1202	Input data had more columns than were defined in the DDL.
1203	Input data had fewer columns than were defined in the DDL.
1204	Input data exceeded the acceptable range for the data type.
1205	Date format is not valid. See DATEFORMAT and TIMEFORMAT strings for valid formats.
1206	Timestamp format is not valid. See DATEFORMAT and TIMEFORMAT strings for valid formats.
1207	Data contained a value outside of the expected range of 0-9.
1208	FLOAT data type format error.
1209	DECIMAL data type format error.
1210	BOOLEAN data type format error.
1211	Input line contained no data.
1212	Load file was not found.
1213	A field specified as NOT NULL contained no data.
1214	Delimiter not found.
1215	CHAR field error.
1216	Input line is not valid.
1217	Identity column value is not valid.
1218	When using NULL AS '\0', a field containing a null terminator (NUL, or UTF-8 0000) contained more than one byte.
1219	UTF-8 hexadecimal contains an invalid digit.
1220	String contains invalid or unsupported UTF-8 code points.

Error code	Description
1221	Encoding of the file is not the same as that specified in the COPY command.
1222	Integer value overflow error.
1223	Data type not valid.
1224	Input data not well formed JSON format or super data type.
8001	COPY with MANIFEST parameter requires full path of an Amazon S3 object.
9005	Invalid end key specified.

Loading tables with continuous file ingestion from Amazon S3 (preview)

This is prerelease documentation for autocopy (SQL COPY JOB), which is in preview release. The documentation and the feature are both subject to change. We recommend that you use this feature only in test environments, and not in production environments. Public preview will end on October 31, 2024. Preview clusters will be removed automatically two weeks after the end of the preview. For preview terms and conditions, see [Betas and Previews in AWS Service Terms](#).

Note

You can create an Amazon Redshift cluster in **Preview** to test new features of Amazon Redshift. You can't use those features in production or move your **Preview** cluster to a production cluster or a cluster on another track. For preview terms and conditions, see *Beta and Previews* in [AWS Service Terms](#).

To create a cluster in Preview

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.

2. On the navigation menu, choose **Provisioned clusters dashboard**, and choose **Clusters**. The clusters for your account in the current AWS Region are listed. A subset of properties of each cluster is displayed in columns in the list.
3. A banner displays on the **Clusters** list page that introduces preview. Choose the button **Create preview cluster** to open the create cluster page.
4. Enter properties for your cluster. Choose the **Preview track** that contains the features you want to test. We recommend entering a name for the cluster that indicates that it is on a preview track. Choose options for your cluster, including options labeled as **-preview**, for the features you want to test. For general information about creating clusters, see [Creating a cluster](#) in the *Amazon Redshift Management Guide*.
5. Choose **Create cluster** to create a cluster in preview.
6. When your preview cluster is available, use your SQL client to load and query data.

Your cluster must be created with the preview track named: `preview_2023`. Use a new cluster for testing, restoring a cluster into this track is not supported. The autocopy feature is not available with Amazon Redshift Serverless workgroup.

This preview is available in the following AWS Regions:

- US East (Ohio) Region (`us-east-2`)
- US East (N. Virginia) Region (`us-east-1`)
- US West (Oregon) Region (`us-west-2`)
- Asia Pacific (Tokyo) Region (`ap-northeast-1`)
- Europe (Stockholm) Region (`eu-north-1`)
- Europe (Ireland) Region (`eu-west-1`)

You can use a COPY JOB to load data into your Amazon Redshift tables from files that are stored in Amazon S3. Amazon Redshift detects when new Amazon S3 files are added to the path specified in your COPY command. A COPY command is then automatically run without you having to create an external data ingestion pipeline. Amazon Redshift keeps track of which files have been loaded. Amazon Redshift determines the number of files batched together per COPY command. You can see the resulting COPY commands in system views.

You define a COPY JOB one time. The same parameters are used for future runs.

You manage the load operations using options to CREATE, LIST, SHOW, DROP, ALTER, and RUN jobs. For more information, see [COPY JOB \(preview\)](#).

You can query system views to see the COPY JOB status and progress. Views are provided as follows:

- [SYS_COPY_JOB \(preview\)](#) – contains a row for each currently defined COPY JOB.
- [STL_LOAD_ERRORS](#) – contains errors from COPY commands.
- [STL_LOAD_COMMITS](#) – contains information used to troubleshoot a COPY command data load.
- [SYS_LOAD_HISTORY](#) – contains details of COPY commands.
- [SYS_LOAD_ERROR_DETAIL](#) – contains details of COPY command errors.

To get the list of files loaded by a COPY JOB, run the following example replacing *<job_id>*:

```
SELECT job_id, job_name, data_source, copy_query, filename, status, curtime
FROM sys_copy_job copyjob
JOIN stl_load_commits loadcommit
ON copyjob.job_id = loadcommit.copy_job_id
WHERE job_id = <job_id>;
```

Loading tables with DML commands

Amazon Redshift supports standard data manipulation language (DML) commands (INSERT, UPDATE, and DELETE) that you can use to modify rows in tables. You can also use the TRUNCATE command to do fast bulk deletes.

Note

We strongly encourage you to use the [COPY](#) command to load large amounts of data. Using individual INSERT statements to populate a table might be prohibitively slow. Alternatively, if your data already exists in other Amazon Redshift database tables, use INSERT INTO ... SELECT FROM or CREATE TABLE AS to improve performance. For information, see [INSERT](#) or [CREATE TABLE AS](#).

If you insert, update, or delete a significant number of rows in a table, relative to the number of rows before the changes, run the ANALYZE and VACUUM commands against the table when

you are done. If a number of small changes accumulate over time in your application, you might want to schedule the `ANALYZE` and `VACUUM` commands to run at regular intervals. For more information, see [Analyzing tables](#) and [Vacuuming tables](#).

Topics

- [Updating and inserting new data](#)

Updating and inserting new data

You can efficiently add new data to an existing table by using the `MERGE` command. Perform a merge operation by creating a staging table and then using one of the methods described in this section to update the target table from the staging table. For more information on the `MERGE` command, see [MERGE](#).

The [Merge examples](#) use a sample dataset for Amazon Redshift, called the TICKIT data set. As a prerequisite, you can set up the TICKIT tables and data by following the instructions available in [Getting started with common database tasks](#). More detailed information about the sample data set is found at [Sample database](#).

Merge method 1: Replacing existing rows

If you are overwriting all of the columns in the target table, the fastest method to perform a merge is to replace the existing rows. This scans the target table only once, by using an inner join to delete rows that will be updated. After the rows are deleted, they are replaced with new rows by a single insert operation from the staging table.

Use this method if all of the following are true:

- Your target table and your staging table contain the same columns.
- You intend to replace all of the data in the target table columns with all of the staging table columns.
- You will use all of the rows in the staging table in the merge.

If any of these criteria do not apply, use Merge method 2: Specifying a column list without using `MERGE`, described in the following section.

If you will not use all of the rows in the staging table, filter the `DELETE` and `INSERT` statements by using a `WHERE` clause to leave out rows that are not changing. However, if most of the rows in

the staging table will not participate in the merge, we recommend performing an UPDATE and an INSERT in separate steps, as described later in this section.

Merge method 2: Specifying a column list without using MERGE

Use this method to update specific columns in the target table instead of overwriting entire rows. This method takes longer than the previous method because it requires an extra update step and doesn't use the MERGE command. Use this method if any of the following are true:

- Not all of the columns in the target table are to be updated.
- Most rows in the staging table will not be used in the updates.

Topics

- [Creating a temporary staging table](#)
- [Performing a merge operation by replacing existing rows](#)
- [Performing a merge operation by specifying a column list without using the MERGE command](#)
- [Merge examples](#)

Creating a temporary staging table

The *staging table* is a temporary table that holds all of the data that will be used to make changes to the *target table*, including both updates and inserts.

A merge operation requires a join between the staging table and the target table. To collocate the joining rows, set the staging table's distribution key to the same column as the target table's distribution key. For example, if the target table uses a foreign key column as its distribution key, use the same column for the staging table's distribution key. If you create the staging table by using a [CREATE TABLE LIKE](#) statement, the staging table will inherit the distribution key from the parent table. If you use a CREATE TABLE AS statement, the new table does not inherit the distribution key. For more information, see [Data distribution for query optimization](#)

If the distribution key is not the same as the primary key and the distribution key is not updated as part of the merge operation, add a redundant join predicate on the distribution key columns to enable a collocated join. For example:

```
where target.primarykey = stage.primarykey
```

```
and target.distkey = stage.distkey
```

To verify that the query will use a collocated join, run the query with [EXPLAIN](#) and check for DS_DIST_NONE on all of the joins. For more information, see [Evaluating the query plan](#)

Performing a merge operation by replacing existing rows

When you run the merge operation detailed in the procedure, put all of the steps except for creating and dropping the temporary staging table in a single transaction. The transaction rolls back if any step fails. Using a single transaction also reduces the number of commits, which saves time and resources.

To perform a merge operation by replacing existing rows

1. Create a staging table, and then populate it with data to be merged, as shown in the following pseudocode.

```
CREATE temp table stage (like target);

INSERT INTO stage
SELECT * FROM source
WHERE source.filter = 'filter_expression';
```

2. Use MERGE to perform an inner join with the staging table to update the rows from the target table that match the staging table, then insert all the remaining rows into the target table that don't match the staging table.

We recommend you run the update and insert operations in a single MERGE command.

```
MERGE INTO target
USING stage [optional alias] on (target.primary_key = stage.primary_key)
WHEN MATCHED THEN
UPDATE SET col_name1 = stage.col_name1 , col_name2= stage.col_name2, col_name3 =
  {expr}
WHEN NOT MATCHED THEN
INSERT (col_name1 , col_name2, col_name3) VALUES (stage.col_name1, stage.col_name2,
  {expr});
```

3. Drop the staging table.

```
DROP TABLE stage;
```

Performing a merge operation by specifying a column list without using the MERGE command

When you run the merge operation detailed in the procedure, put all of the steps in a single transaction. The transaction rolls back if any step fails. Using a single transaction also reduces the number of commits, which saves time and resources.

To perform a merge operation by specifying a column list

1. Put the entire operation in a single transaction block.

```
BEGIN transaction;  
...  
END transaction;
```

2. Create a staging table, and then populate it with data to be merged, as shown in the following pseudocode.

```
create temp table stage (like target);  
insert into stage  
select * from source  
where source.filter = 'filter_expression';
```

3. Update the target table by using an inner join with the staging table.
 - In the UPDATE clause, explicitly list the columns to be updated.
 - Perform an inner join with the staging table.
 - If the distribution key is different from the primary key and the distribution key is not being updated, add a redundant join on the distribution key. To verify that the query will use a collocated join, run the query with [EXPLAIN](#) and check for DS_DIST_NONE on all of the joins. For more information, see [Evaluating the query plan](#)
 - If your target table is sorted by timestamp, add a predicate to take advantage of range-restricted scans on the target table. For more information, see [Amazon Redshift best practices for designing queries](#).
 - If you will not use all of the rows in the merge, add a clause to filter the rows that you want to change. For example, add an inequality filter on one or more columns to exclude rows that have not changed.

- Put the update, delete, and insert operations in a single transaction block so that if there is a problem, everything will be rolled back.

For example:

```
begin transaction;

update target
set col1 = stage.col1,
col2 = stage.col2,
col3 = 'expression'
from stage
where target.primarykey = stage.primarykey
and target.distkey = stage.distkey
and target.col3 > 'last_update_time'
and (target.col1 != stage.col1
or target.col2 != stage.col2
or target.col3 = 'filter_expression');
```

4. Delete unneeded rows from the staging table by using an inner join with the target table. Some rows in the target table already match the corresponding rows in the staging table, and others were updated in the previous step. In either case, they are not needed for the insert.

```
delete from stage
using target
where stage.primarykey = target.primarykey;
```

5. Insert the remaining rows from the staging table. Use the same column list in the VALUES clause that you used in the UPDATE statement in step two.

```
insert into target
(select col1, col2, 'expression'
from stage);

end transaction;
```

6. Drop the staging table.

```
drop table stage;
```

Merge examples

The following examples perform a merge to update the SALES table. The first example uses the simpler method of deleting from the target table and then inserting all of the rows from the staging table. The second example requires updating on select columns in the target table, so it includes an extra update step.

The [Merge examples](#) use a sample dataset for Amazon Redshift, called the TICKIT data set. As a prerequisite, you can set up the TICKIT tables and data by following the instructions available in the guide [Getting started with common database tasks](#). More detailed information about the sample data set is found at [Sample database](#).

Sample merge data source

The examples in this section need a sample data source that includes both updates and inserts. For the examples, we will create a sample table named SALES_UPDATE that uses data from the SALES table. We'll populate the new table with random data that represents new sales activity for December. We will use the SALES_UPDATE sample table to create the staging table in the examples that follow.

```
-- Create a sample table as a copy of the SALES table.

create table tickit.sales_update as
select * from tickit.sales;

-- Change every fifth row to have updates.

update tickit.sales_update
set qtysold = qtysold*2,
  pricepaid = pricepaid*0.8,
  commission = commission*1.1
where saletime > '2008-11-30'
and mod(sellerid, 5) = 0;

-- Add some new rows to have inserts.
-- This example creates a duplicate of every fourth row.

insert into tickit.sales_update
select (salesid + 172456) as salesid, listid, sellerid, buyerid, eventid, dateid,
  qtysold, pricepaid, commission, getdate() as saletime
from tickit.sales_update
```

```
where saletime > '2008-11-30'  
and mod(sellerid, 4) = 0;
```

Example of a merge that replaces existing rows based on matching keys

The following script uses the SALES_UPDATE table to perform a merge operation on the SALES table with new data for December sales activity. This example replaces rows in the SALES table that have updates. For this example, we will update the qtysold and pricepaid columns, but leave commission and saletime unchanged.

```
MERGE into tickit.sales  
USING tickit.sales_update sales_update  
on ( sales.salesid = sales_update.salesid  
and sales.listid = sales_update.listid  
and sales_update.saletime > '2008-11-30'  
and (sales.qtysold != sales_update.qtysold  
or sales.pricepaid != sales_update.pricepaid))  
WHEN MATCHED THEN  
update SET qtysold = sales_update.qtysold,  
pricepaid = sales_update.pricepaid  
WHEN NOT MATCHED THEN  
INSERT (salesid, listid, sellerid, buyerid, eventid, dateid, qtysold , pricepaid,  
commission, saletime)  
values (sales_update.salesid, sales_update.listid, sales_update.sellerid,  
sales_update.buyerid, sales_update.eventid,  
sales_update.dateid, sales_update.qtysold , sales_update.pricepaid,  
sales_update.commission, sales_update.saletime);  
  
-- Drop the staging table.  
drop table tickit.sales_update;  
  
-- Test to see that commission and salestime were not impacted.  
SELECT sales.salesid, sales.commission, sales.salestime, sales_update.commission,  
sales_update.salestime  
FROM tickit.sales  
INNER JOIN tickit.sales_update sales_update  
ON  
sales.salesid = sales_update.salesid  
AND sales.listid = sales_update.listid  
AND sales_update.saletime > '2008-11-30'  
AND (sales.commission != sales_update.commission  
OR sales.salestime != sales_update.salestime);
```

Example of a merge that specifies a column list without using MERGE

The following example performs a merge operation to update SALES with new data for December sales activity. We need sample data that includes both updates and inserts, along with rows that have not changed. For this example, we want to update the QTYSOLD and PRICEPAID columns but leave COMMISSION and SALETIME unchanged. The following script uses the SALES_UPDATE table to perform a merge operation on the SALES table.

```
-- Create a staging table and populate it with rows from SALES_UPDATE for Dec
create temp table stagesales as select * from sales_update
where saletime > '2008-11-30';

-- Start a new transaction
begin transaction;

-- Update the target table using an inner join with the staging table
-- The join includes a redundant predicate to collocate on the distribution key -- A
  filter on saletime enables a range-restricted scan on SALES

update sales
set qtysold = stagesales.qtysold,
pricepaid = stagesales.pricepaid
from stagesales
where sales.salesid = stagesales.salesid
and sales.listid = stagesales.listid
and stagesales.saletime > '2008-11-30'
and (sales.qtysold != stagesales.qtysold
or sales.pricepaid != stagesales.pricepaid);

-- Delete matching rows from the staging table
-- using an inner join with the target table

delete from stagesales
using sales
where sales.salesid = stagesales.salesid
and sales.listid = stagesales.listid;

-- Insert the remaining rows from the staging table into the target table
insert into sales
select * from stagesales;

-- End transaction and commit
end transaction;
```

```
-- Drop the staging table
drop table stagesales;
```

Performing a deep copy

A deep copy recreates and repopulates a table by using a bulk insert, which automatically sorts the table. If a table has a large unsorted Region, a deep copy is much faster than a vacuum. We recommend that you only make concurrent updates during a deep copy operation if you can track them. After the process has completed, move the delta updates into the new table. A VACUUM operation supports concurrent updates automatically.

You can choose one of the following methods to create a copy of the original table:

- Use the original table DDL.

If the CREATE TABLE DDL is available, this is the fastest and preferred method. If you create a new table, you can specify all table and column attributes, including primary key and foreign keys. You can find the original DDL by using the SHOW TABLE function.

- Use CREATE TABLE LIKE.

If the original DDL is not available, you can use CREATE TABLE LIKE to recreate the original table. The new table inherits the encoding, distribution key, sort key, and not-null attributes of the parent table. The new table doesn't inherit the primary key and foreign key attributes of the parent table, but you can add them using [ALTER TABLE](#).

- Create a temporary table and truncate the original table.

If you must retain the primary key and foreign key attributes of the parent table. If the parent table has dependencies, you can use CREATE TABLE ... AS (CTAS) to create a temporary table. Then truncate the original table and populate it from the temporary table.

Using a temporary table improves performance significantly compared to using a permanent table, but there is a risk of losing data. A temporary table is automatically dropped at the end of the session in which it is created. TRUNCATE commits immediately, even if it is inside a transaction block. If the TRUNCATE succeeds but the session shuts down before the following INSERT completes, the data is lost. If data loss is unacceptable, use a permanent table.

After you create a copy of a table, you might have to grant access to the new table. You can use [GRANT](#) to define access privileges. To view and grant all of a table's access privileges, you must be one of the following:

- A superuser.
- The owner of the table you want to copy.
- A user with the `ACCESS SYSTEM TABLE` privilege to see the table's privileges, and with the `grant` privilege for all relevant permissions.

Additionally, you might have to grant usage permission for the schema your deep copy is in. Granting usage permission is necessary if your deep copy's schema is different from the original table's schema, and also isn't the `public` schema. To view and grant usage privileges you must be one of the following:

- A superuser.
- A user who can grant the `USAGE` permission for the deep copy's schema.

To perform a deep copy using the original table DDL

1. (Optional) Recreate the table DDL by running a script called `v_generate_tbl_ddl`.
2. Create a copy of the table using the original `CREATE TABLE` DDL.
3. Use an `INSERT INTO ... SELECT` statement to populate the copy with data from the original table.
4. Check for permissions granted on the old table. You can see these permissions in the `SVV_RELATION_PRIVILEGES` system view.
5. If necessary, grant the permissions of the old table to the new table.
6. Grant usage permission to every group and user that has privileges in the original table. This step isn't necessary if your deep copy table is in the `public` schema, or is in the same schema as the original table.
7. Drop the original table.
8. Use an `ALTER TABLE` statement to rename the copy to the original table name.

The following example performs a deep copy on the `SAMPLE` table using a duplicate of `SAMPLE` named `sample_copy`.

```
--Create a copy of the original table in the sample_namespace namespace using the
original CREATE TABLE DDL.
create table sample_namespace.sample_copy ( ... );

--Populate the copy with data from the original table in the public namespace.
insert into sample_namespace.sample_copy (select * from public.sample);

--Check SVV_RELATION_PRIVILEGES for the original table's privileges.
select * from svv_relation_privileges where namespace_name = 'public' and relation_name
= 'sample' order by identity_type, identity_id, privilege_type;

--Grant the original table's privileges to the copy table.
grant DELETE on table sample_namespace.sample_copy to group group1;
grant INSERT, UPDATE on table sample_namespace.sample_copy to group group2;
grant SELECT on table sample_namespace.sample_copy to user1;
grant INSERT, SELECT, UPDATE on table sample_namespace.sample_copy to user2;

--Grant usage permission to every group and user that has privileges in the original
table.
grant USAGE on schema sample_namespace to group group1, group group2, user1, user2;

--Drop the original table.
drop table public.sample;

--Rename the copy table to match the original table's name.
alter table sample_namespace.sample_copy rename to sample;
```

To perform a deep copy using CREATE TABLE LIKE

1. Create a new table using CREATE TABLE LIKE.
2. Use an INSERT INTO ... SELECT statement to copy the rows from the current table to the new table.
3. Check for permissions granted on the old table. You can see these permissions in the SVV_RELATION_PRIVILEGES system view.
4. If necessary, grant the permissions of the old table to the new table.
5. Grant usage permission to every group and user that has privileges in the original table. This step isn't necessary if your deep copy table is in the public schema, or is in the same schema as the original table.
6. Drop the current table.

7. Use an ALTER TABLE statement to rename the new table to the original table name.

The following example performs a deep copy on the SAMPLE table using CREATE TABLE LIKE.

```
--Create a copy of the original table in the sample_namespace namespace using CREATE
TABLE LIKE.
create table sample_namespace.sample_copy (like public.sample);

--Populate the copy with data from the original table.
insert into sample_namespace.sample_copy (select * from public.sample);

--Check SVV_RELATION_PRIVILEGES for the original table's privileges.
select * from svv_relation_privileges where namespace_name = 'public' and relation_name
= 'sample' order by identity_type, identity_id, privilege_type;

--Grant the original table's privileges to the copy table.
grant DELETE on table sample_namespace.sample_copy to group group1;
grant INSERT, UPDATE on table sample_namespace.sample_copy to group group2;
grant SELECT on table sample_namespace.sample_copy to user1;
grant INSERT, SELECT, UPDATE on table sample_namespace.sample_copy to user2;

--Grant usage permission to every group and user that has privileges in the original
table.
grant USAGE on schema sample_namespace to group group1, group group2, user1, user2;

--Drop the original table.
drop table public.sample;

--Rename the copy table to match the original table's name.
alter table sample_namespace.sample_copy rename to sample;
```

To perform a deep copy by creating a temporary table and truncating the original table

1. Use CREATE TABLE AS to create a temporary table with the rows from the original table.
2. Truncate the current table.
3. Use an INSERT INTO ... SELECT statement to copy the rows from the temporary table to the original table.
4. Drop the temporary table.

The following example performs a deep copy on the SALES table by creating a temporary table and truncating the original table. Since the original table remains, you don't need to grant permissions to the copy table.

```
--Create a temp table copy using CREATE TABLE AS.  
create temp table salestemp as select * from sales;  
  
--Truncate the original table.  
truncate sales;  
  
--Copy the rows from the temporary table to the original table.  
insert into sales (select * from salestemp);  
  
--Drop the temporary table.  
drop table salestemp;
```

Analyzing tables

The ANALYZE operation updates the statistical metadata that the query planner uses to choose optimal plans.

In most cases, you don't need to explicitly run the ANALYZE command. Amazon Redshift monitors changes to your workload and automatically updates statistics in the background. In addition, the COPY command performs an analysis automatically when it loads data into an empty table.

To explicitly analyze a table or the entire database, run the [ANALYZE](#) command.

Automatic analyze

Amazon Redshift continuously monitors your database and automatically performs analyze operations in the background. To minimize impact to your system performance, automatic analyze runs during periods when workloads are light.

Automatic analyze is enabled by default. To turn off automatic analyze, set the `auto_analyze` parameter to **false** by modifying your cluster's parameter group.

To reduce processing time and improve overall system performance, Amazon Redshift skips automatic analyze for any table where the extent of modifications is small.

An analyze operation skips tables that have up-to-date statistics. If you run ANALYZE as part of your extract, transform, and load (ETL) workflow, automatic analyze skips tables that have current

statistics. Similarly, an explicit ANALYZE skips tables when automatic analyze has updated the table's statistics.

Analysis of new table data

By default, the COPY command performs an ANALYZE after it loads data into an empty table. You can force an ANALYZE regardless of whether a table is empty by setting STATUPDATE ON. If you specify STATUPDATE OFF, an ANALYZE is not performed. Only the table owner or a superuser can run the ANALYZE command or run the COPY command with STATUPDATE set to ON.

Amazon Redshift also analyzes new tables that you create with the following commands:

- CREATE TABLE AS (CTAS)
- CREATE TEMP TABLE AS
- SELECT INTO

Amazon Redshift returns a warning message when you run a query against a new table that was not analyzed after its data was initially loaded. No warning occurs when you query a table after a subsequent update or load. The same warning message is returned when you run the EXPLAIN command on a query that references tables that have not been analyzed.

Whenever adding data to a nonempty table significantly changes the size of the table, you can explicitly update statistics. You do so either by running an ANALYZE command or by using the STATUPDATE ON option with the COPY command. To view details about the number of rows that have been inserted or deleted since the last ANALYZE, query the [PG_STATISTIC_INDICATOR](#) system catalog table.

You can specify the scope of the [ANALYZE](#) command to one of the following:

- The entire current database
- A single table
- One or more specific columns in a single table
- Columns that are likely to be used as predicates in queries

The ANALYZE command gets a sample of rows from the table, does some calculations, and saves resulting column statistics. By default, Amazon Redshift runs a sample pass for the DISTKEY

column and another sample pass for all of the other columns in the table. If you want to generate statistics for a subset of columns, you can specify a comma-separated column list. You can run `ANALYZE` with the `PREDICATE COLUMNS` clause to skip columns that aren't used as predicates.

`ANALYZE` operations are resource intensive, so run them only on tables and columns that actually require statistics updates. You don't need to analyze all columns in all tables regularly or on the same schedule. If the data changes substantially, analyze the columns that are frequently used in the following:

- Sorting and grouping operations
- Joins
- Query predicates

To reduce processing time and improve overall system performance, Amazon Redshift skips `ANALYZE` for any table that has a low percentage of changed rows, as determined by the [analyze_threshold_percent](#) parameter. By default, the analyze threshold is set to 10 percent. You can change the analyze threshold for the current session by running a [SET](#) command.

Columns that are less likely to require frequent analysis are those that represent facts and measures and any related attributes that are never actually queried, such as large `VARCHAR` columns. For example, consider the `LISTING` table in the `TICKIT` database.

```
select "column", type, encoding, distkey, sortkey
from pg_table_def where tablename = 'listing';
```

column	type	encoding	distkey	sortkey
listid	integer	none	t	1
sellerid	integer	none	f	0
eventid	integer	mostly16	f	0
dateid	smallint	none	f	0
numtickets	smallint	mostly8	f	0
priceperticket	numeric(8,2)	bytedict	f	0
totalprice	numeric(8,2)	mostly32	f	0
listtime	timestamp with...	none	f	0

If this table is loaded every day with a large number of new records, the `LISTID` column, which is frequently used in queries as a join key, must be analyzed regularly. If `TOTALPRICE` and `LISTTIME`

are the frequently used constraints in queries, you can analyze those columns and the distribution key on every weekday.

```
analyze listing(listid, totalprice, listtime);
```

Suppose that the sellers and events in the application are much more static, and the date IDs refer to a fixed set of days covering only two or three years. In this case, the unique values for these columns don't change significantly. However, the number of instances of each unique value will increase steadily.

In addition, consider the case where the NUMTICKETS and PRICEPERTICKET measures are queried infrequently compared to the TOTALPRICE column. In this case, you can run the ANALYZE command on the whole table once every weekend to update statistics for the five columns that are not analyzed daily:

Predicate columns

As a convenient alternative to specifying a column list, you can choose to analyze only the columns that are likely to be used as predicates. When you run a query, any columns that are used in a join, filter condition, or group by clause are marked as predicate columns in the system catalog. When you run ANALYZE with the PREDICATE COLUMNS clause, the analyze operation includes only columns that meet the following criteria:

- The column is marked as a predicate column.
- The column is a distribution key.
- The column is part of a sort key.

If none of a table's columns are marked as predicates, ANALYZE includes all of the columns, even when PREDICATE COLUMNS is specified. If no columns are marked as predicate columns, it might be because the table has not yet been queried.

You might choose to use PREDICATE COLUMNS when your workload's query pattern is relatively stable. When the query pattern is variable, with different columns frequently being used as predicates, using PREDICATE COLUMNS might temporarily result in stale statistics. Stale statistics can lead to suboptimal query runtime plans and long runtimes. However, the next time you run ANALYZE using PREDICATE COLUMNS, the new predicate columns are included.

To view details for predicate columns, use the following SQL to create a view named PREDICATE_COLUMNS.

```

CREATE VIEW predicate_columns AS
WITH predicate_column_info as (
SELECT ns.nspname AS schema_name, c.relname AS table_name, a.attnum as col_num,
      a.attname as col_name,
      CASE
        WHEN 10002 = s.stakind1 THEN array_to_string(stavalues1, '|||')
        WHEN 10002 = s.stakind2 THEN array_to_string(stavalues2, '|||')
        WHEN 10002 = s.stakind3 THEN array_to_string(stavalues3, '|||')
        WHEN 10002 = s.stakind4 THEN array_to_string(stavalues4, '|||')
        ELSE NULL::varchar
      END AS pred_ts
FROM pg_statistic s
JOIN pg_class c ON c.oid = s.starelid
JOIN pg_namespace ns ON c.relnamespace = ns.oid
JOIN pg_attribute a ON c.oid = a.attrelid AND a.attnum = s.staattnum)
SELECT schema_name, table_name, col_num, col_name,
      pred_ts NOT LIKE '2000-01-01%' AS is_predicate,
      CASE WHEN pred_ts NOT LIKE '2000-01-01%' THEN (split_part(pred_ts,
'|||',1))::timestamp ELSE NULL::timestamp END as first_predicate_use,
      CASE WHEN pred_ts NOT LIKE '%||2000-01-01%' THEN (split_part(pred_ts,
'|||',2))::timestamp ELSE NULL::timestamp END as last_analyze
FROM predicate_column_info;

```

Suppose that you run the following query against the LISTING table. Note that LISTID, LISTTIME, and EVENTID are used in the join, filter, and group by clauses.

```

select s.buyerid,l.eventid, sum(l.totalprice)
from listing l
join sales s on l.listid = s.listid
where l.listtime > '2008-12-01'
group by l.eventid, s.buyerid;

```

When you query the PREDICATE_COLUMNS view, as shown in the following example, you see that LISTID, EVENTID, and LISTTIME are marked as predicate columns.

```

select * from predicate_columns
where table_name = 'listing';

```

```

schema_name | table_name | col_num | col_name          | is_predicate |
first_predicate_use | last_analyze

```

```

-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
public   | listing   |      1 | listid     | true   | 2017-05-05
19:27:59 | 2017-05-03 18:27:41
public   | listing   |      2 | sellerid   | false  |
| 2017-05-03 18:27:41
public   | listing   |      3 | eventid    | true   | 2017-05-16
20:54:32 | 2017-05-03 18:27:41
public   | listing   |      4 | dateid     | false  |
| 2017-05-03 18:27:41
public   | listing   |      5 | numtickets | false  |
| 2017-05-03 18:27:41
public   | listing   |      6 | priceperticket | false |
| 2017-05-03 18:27:41
public   | listing   |      7 | totalprice | false  |
| 2017-05-03 18:27:41
public   | listing   |      8 | listtime   | true   | 2017-05-16
20:54:32 | 2017-05-03 18:27:41

```

Keeping statistics current improves query performance by enabling the query planner to choose optimal plans. Amazon Redshift refreshes statistics automatically in the background, and you can also explicitly run the `ANALYZE` command. If you choose to explicitly run `ANALYZE`, do the following:

- Run the `ANALYZE` command before running queries.
- Run the `ANALYZE` command on the database routinely at the end of every regular load or update cycle.
- Run the `ANALYZE` command on any new tables that you create and any existing tables or columns that undergo significant change.
- Consider running `ANALYZE` operations on different schedules for different types of tables and columns, depending on their use in queries and their propensity to change.
- To save time and cluster resources, use the `PREDICATE COLUMNS` clause when you run `ANALYZE`.

You don't have to explicitly run the `ANALYZE` command after restoring a snapshot to a provisioned cluster or serverless namespace, nor after resuming a paused provisioned cluster. Amazon Redshift preserves system table information in these cases, making manual `ANALYZE` commands unnecessary. Amazon Redshift will continue to run automatic analyze operations as needed.

An analyze operation skips tables that have up-to-date statistics. If you run ANALYZE as part of your extract, transform, and load (ETL) workflow, automatic analyze skips tables that have current statistics. Similarly, an explicit ANALYZE skips tables when automatic analyze has updated the table's statistics.

ANALYZE command history

It's useful to know when the last ANALYZE command was run on a table or database. When an ANALYZE command is run, Amazon Redshift runs multiple queries that look like this:

```
padb_fetch_sample: select * from table_name
```

Query STL_ANALYZE to view the history of analyze operations. If Amazon Redshift analyzes a table using automatic analyze, the `is_background` column is set to `t` (true). Otherwise, it is set to `f` (false). The following example joins STV_TBL_PERM to show the table name and runtime details.

```
select distinct a.xid, trim(t.name) as name, a.status, a.rows, a.modified_rows,
  a.starttime, a.endtime
from stl_analyze a
join stv_tbl_perm t on t.id=a.table_id
where name = 'users'
order by starttime;
```

xid	name	status	rows	modified_rows	starttime	endtime
1582	users	Full	49990	49990	2016-09-22 22:02:23	2016-09-22 22:02:28
244287	users	Full	24992	74988	2016-10-04 22:50:58	2016-10-04 22:51:01
244712	users	Full	49984	24992	2016-10-04 22:56:07	2016-10-04 22:56:07
245071	users	Skipped	49984	0	2016-10-04 22:58:17	2016-10-04 22:58:17
245439	users	Skipped	49984	1982	2016-10-04 23:00:13	2016-10-04 23:00:13

(5 rows)

Alternatively, you can run a more complex query that returns all the statements that ran in every completed transaction that included an ANALYZE command:

```
select xid, to_char(starttime, 'HH24:MM:SS.MS') as starttime,
datediff(sec,starttime,endtime ) as secs, substring(text, 1, 40)
from svl_statementtext
where sequence = 0
and xid in (select xid from svl_statementtext s where s.text like 'padb_fetch_sample
%' )
order by xid desc, starttime;
```

xid	starttime	secs	substring
1338	12:04:28.511	4	Analyze date
1338	12:04:28.511	1	padb_fetch_sample: select count(*) from
1338	12:04:29.443	2	padb_fetch_sample: select * from date
1338	12:04:31.456	1	padb_fetch_sample: select * from date
1337	12:04:24.388	1	padb_fetch_sample: select count(*) from
1337	12:04:24.388	4	Analyze sales
1337	12:04:25.322	2	padb_fetch_sample: select * from sales
1337	12:04:27.363	1	padb_fetch_sample: select * from sales
...			

Vacuuming tables

Amazon Redshift can automatically sort and perform a VACUUM DELETE operation on tables in the background. To clean up tables after a load or a series of incremental updates, you can also run the [VACUUM](#) command, either against the entire database or against individual tables.

Note

Only users with the necessary table permissions can effectively vacuum a table. If VACUUM is run without the necessary table permissions, the operation completes successfully but has no effect. For a list of valid table permissions to effectively run VACUUM, see [VACUUM](#). For this reason, we recommend vacuuming individual tables as needed. We also recommend this approach because vacuuming the entire database is potentially an expensive operation.

Automatic table sort

Amazon Redshift automatically sorts data in the background to maintain table data in the order of its sort key. Amazon Redshift keeps track of your scan queries to determine which sections of the table will benefit from sorting.

Depending on the load on the system, Amazon Redshift automatically initiates the sort. This automatic sort lessens the need to run the `VACUUM` command to keep data in sort key order. If you need data fully sorted in sort key order, for example after a large data load, then you can still manually run the `VACUUM` command. To determine whether your table will benefit by running `VACUUM SORT`, monitor the `vacuum_sort_benefit` column in [SVV_TABLE_INFO](#).

Amazon Redshift tracks scan queries that use the sort key on each table. Amazon Redshift estimates the maximum percentage of improvement in scanning and filtering of data for each table (if the table was fully sorted). This estimate is visible in the `vacuum_sort_benefit` column in [SVV_TABLE_INFO](#). You can use this column, along with the `unsorted` column, to determine when queries can benefit from manually running `VACUUM SORT` on a table. The `unsorted` column reflects the physical sort order of a table. The `vacuum_sort_benefit` column specifies the impact of sorting a table by manually running `VACUUM SORT`.

For example, consider the following query:

```
select "table", unsorted, vacuum_sort_benefit from svv_table_info order by 1;
```

table	unsorted	vacuum_sort_benefit
sales	85.71	5.00
event	45.24	67.00

For the table “sales”, even though the table is ~86% physically unsorted, the query performance impact from the table being 86% unsorted is only 5%. This might be either because only a small portion of the table is accessed by queries, or very few queries accessed the table. For the table “event”, the table is ~45% physically unsorted. But the query performance impact of 67% indicates that either a larger portion of the table was accessed by queries, or the number of queries accessing the table was large. The table “event” can potentially benefit from running `VACUUM SORT`.

Automatic vacuum delete

When you perform a delete, the rows are marked for deletion, but not removed. Amazon Redshift automatically runs a VACUUM DELETE operation in the background based on the number of deleted rows in database tables. Amazon Redshift schedules the VACUUM DELETE to run during periods of reduced load and pauses the operation during periods of high load.

Topics

- [VACUUM frequency](#)
- [Sort stage and merge stage](#)
- [Vacuum threshold](#)
- [Vacuum types](#)
- [Minimizing vacuum times](#)

VACUUM frequency

You should vacuum as often as necessary to maintain consistent query performance. Consider these factors when determining how often to run your VACUUM command:

- Run VACUUM during time periods when you expect minimal activity on the cluster, such as evenings or during designated database administration windows.
- Run VACUUM commands outside of maintenance windows. For more information, see [Schedule around maintenance windows](#).
- A large unsorted region results in longer vacuum times. If you delay vacuuming, the vacuum will take longer because more data has to be reorganized.
- VACUUM is an I/O intensive operation, so the longer it takes for your vacuum to complete, the more impact it will have on concurrent queries and other database operations running on your cluster.
- VACUUM takes longer for tables that use interleaved sorting. To evaluate whether interleaved tables must be re-sorted, query the [SVV_INTERLEAVED_COLUMNS](#) view.

Sort stage and merge stage

Amazon Redshift performs a vacuum operation in two stages: first, it sorts the rows in the unsorted region, then, if necessary, it merges the newly sorted rows at the end of the table with the existing

rows. When vacuuming a large table, the vacuum operation proceeds in a series of steps consisting of incremental sorts followed by merges. If the operation fails or if Amazon Redshift goes offline during the vacuum, the partially vacuumed table or database will be in a consistent state, but you must manually restart the vacuum operation. Incremental sorts are lost, but merged rows that were committed before the failure do not need to be vacuumed again. If the unsorted region is large, the lost time might be significant. For more information about the sort and merge stages, see [Reduce the volume of merged rows](#).

Users can access tables while they are being vacuumed. You can perform queries and write operations while a table is being vacuumed, but when DML and a vacuum run concurrently, both might take longer. If you run UPDATE and DELETE statements during a vacuum, system performance might be reduced. Incremental merges temporarily block concurrent UPDATE and DELETE operations, and UPDATE and DELETE operations in turn temporarily block incremental merge steps on the affected tables. DDL operations, such as ALTER TABLE, are blocked until the vacuum operation finishes with the table.

Note

Various modifiers to VACUUM control the way that it works. You can use them to tailor the vacuum operation for the current need. For example, using VACUUM RECLUSTER shortens the vacuum operation by not performing a full merge operation. For more information, see [VACUUM](#).

Vacuum threshold

By default, VACUUM skips the sort phase for any table where more than 95 percent of the table's rows are already sorted. Skipping the sort phase can significantly improve VACUUM performance. To change the default sort threshold for a single table, include the table name and the *TO threshold* PERCENT parameter when you run the VACUUM command.

Vacuum types

For information about different vacuum types, see [VACUUM](#).

Minimizing vacuum times

Amazon Redshift automatically sorts data and runs VACUUM DELETE in the background. This lessens the need to run the VACUUM command. Vacuuming is potentially a time consuming

process. Depending on the nature of your data, we recommend the following practices to minimize vacuum times.

Topics

- [Decide whether to reindex](#)
- [Reduce the size of the unsorted region](#)
- [Reduce the volume of merged rows](#)
- [Load your data in sort key order](#)
- [Use time series tables to reduce stored data](#)

Decide whether to reindex

You can often significantly improve query performance by using an interleaved sort style, but over time performance might degrade if the distribution of the values in the sort key columns changes.

When you initially load an empty interleaved table using COPY or CREATE TABLE AS, Amazon Redshift automatically builds the interleaved index. If you initially load an interleaved table using INSERT, you need to run VACUUM REINDEX afterwards to initialize the interleaved index.

Over time, as you add rows with new sort key values, performance might degrade if the distribution of the values in the sort key columns changes. If your new rows fall primarily within the range of existing sort key values, you don't need to reindex. Run VACUUM SORT ONLY or VACUUM FULL to restore the sort order.

The query engine is able to use sort order to efficiently select which data blocks need to be scanned to process a query. For an interleaved sort, Amazon Redshift analyzes the sort key column values to determine the optimal sort order. If the distribution of key values changes, or skews, as rows are added, the sort strategy will no longer be optimal, and the performance benefit of sorting will degrade. To reanalyze the sort key distribution you can run a VACUUM REINDEX. The reindex operation is time consuming, so to decide whether a table will benefit from a reindex, query the [SVV_INTERLEAVED_COLUMNS](#) view.

For example, the following query shows details for tables that use interleaved sort keys.

```
select tbl as tbl_id, stv_tbl_perm.name as table_name,
col, interleaved_skew, last_reindex
from svv_interleaved_columns, stv_tbl_perm
where svv_interleaved_columns.tbl = stv_tbl_perm.id
```

```
and interleaved_skew is not null;
```

```
tbl_id | table_name | col | interleaved_skew | last_reindex
-----+-----+-----+-----+-----
100048 | customer   | 0   | 3.65 | 2015-04-22 22:05:45
100068 | lineorder  | 1   | 2.65 | 2015-04-22 22:05:45
100072 | part       | 0   | 1.65 | 2015-04-22 22:05:45
100077 | supplier   | 1   | 1.00 | 2015-04-22 22:05:45
(4 rows)
```

The value for `interleaved_skew` is a ratio that indicates the amount of skew. A value of 1 means that there is no skew. If the skew is greater than 1.4, a `VACUUM REINDEX` will usually improve performance unless the skew is inherent in the underlying set.

You can use the date value in `last_reindex` to determine how long it has been since the last reindex.

Reduce the size of the unsorted region

The unsorted region grows when you load large amounts of new data into tables that already contain data or when you do not vacuum tables as part of your routine maintenance operations. To avoid long-running vacuum operations, use the following practices:

- Run vacuum operations on a regular schedule.

If you load your tables in small increments (such as daily updates that represent a small percentage of the total number of rows in the table), running `VACUUM` regularly will help ensure that individual vacuum operations go quickly.

- Run the largest load first.

If you need to load a new table with multiple `COPY` operations, run the largest load first. When you run an initial load into a new or truncated table, all of the data is loaded directly into the sorted region, so no vacuum is required.

- Truncate a table instead of deleting all of the rows.

Deleting rows from a table does not reclaim the space that the rows occupied until you perform a vacuum operation; however, truncating a table empties the table and reclaims the disk space, so no vacuum is required. Alternatively, drop the table and re-create it.

- Truncate or drop test tables.

If you are loading a small number of rows into a table for test purposes, don't delete the rows when you are done. Instead, truncate the table and reload those rows as part of the subsequent production load operation.

- Perform a deep copy.

If a table that uses a compound sort key table has a large unsorted region, a deep copy is much faster than a vacuum. A deep copy recreates and repopulates a table by using a bulk insert, which automatically re-sorts the table. If a table has a large unsorted region, a deep copy is much faster than a vacuum. The trade off is that you cannot make concurrent updates during a deep copy operation, which you can do during a vacuum. For more information, see [Amazon Redshift best practices for designing queries](#).

Reduce the volume of merged rows

If a vacuum operation needs to merge new rows into a table's sorted region, the time required for a vacuum will increase as the table grows larger. You can improve vacuum performance by reducing the number of rows that must be merged.

Before a vacuum, a table consists of a sorted region at the head of the table, followed by an unsorted region, which grows whenever rows are added or updated. When a set of rows is added by a COPY operation, the new set of rows is sorted on the sort key as it is added to the unsorted region at the end of the table. The new rows are ordered within their own set, but not within the unsorted region.

The following diagram illustrates the unsorted region after two successive COPY operations, where the sort key is CUSTID. For simplicity, this example shows a compound sort key, but the same principles apply to interleaved sort keys, except that the impact of the unsorted region is greater for interleaved tables.

A vacuum restores the table's sort order in two stages:

1. Sort the unsorted region into a newly-sorted region.

The first stage is relatively cheap, because only the unsorted region is rewritten. If the range of sort key values of the newly sorted region is higher than the existing range, only the new rows need to be rewritten, and the vacuum is complete. For example, if the sorted region contains ID values 1 to 500 and subsequent copy operations add key values greater than 500, then only the unsorted region needs to be rewritten.

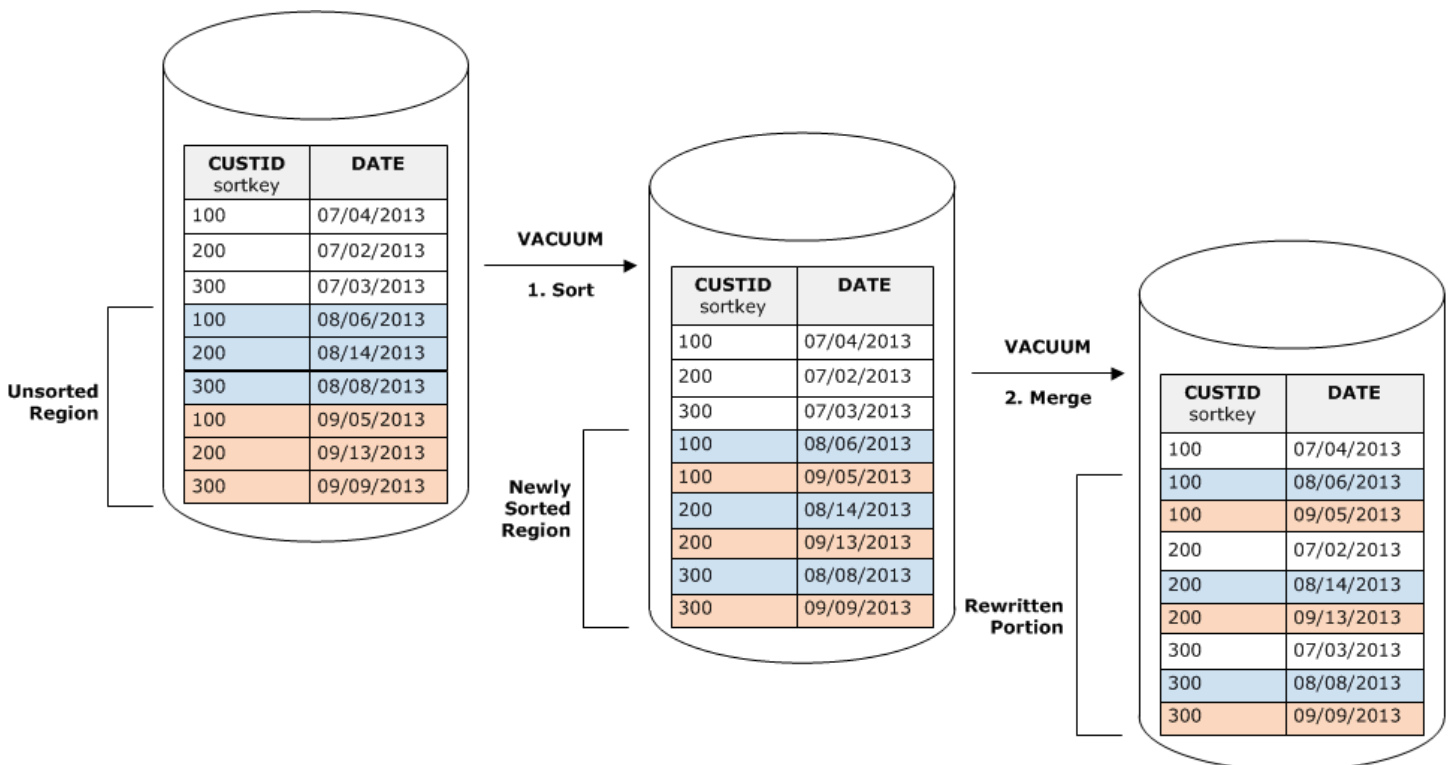

2. Merge the newly-sorted region with the previously-sorted region.

If the keys in the newly sorted region overlap the keys in the sorted region, then VACUUM needs to merge the rows. Starting at the beginning of the newly-sorted region (at the lowest sort key),

the vacuum writes the merged rows from the previously sorted region and the newly sorted region into a new set of blocks.

The extent to which the new sort key range overlaps the existing sort keys determines the extent to which the previously-sorted region will need to be rewritten. If the unsorted keys are scattered throughout the existing sort range, a vacuum might need to rewrite existing portions of the table.

The following diagram shows how a vacuum would sort and merge rows that are added to a table where CUSTID is the sort key. Because each copy operation adds a new set of rows with key values that overlap the existing keys, almost the entire table needs to be rewritten. The diagram shows single sort and merge, but in practice, a large vacuum consists of a series of incremental sort and merge steps.

If the range of sort keys in a set of new rows overlaps the range of existing keys, the cost of the merge stage continues to grow in proportion to the table size as the table grows while the cost of the sort stage remains proportional to the size of the unsorted region. In such a case, the cost of the merge stage overshadows the cost of the sort stage, as the following diagram shows.

To determine what proportion of a table was remerged, query `SVV_VACUUM_SUMMARY` after the vacuum operation completes. The following query shows the effect of six successive vacuums as `CUSTSALES` grew larger over time.

```
select * from svv_vacuum_summary
where table_name = 'custsales';
```

table_name	xid	sort_	merge_	elapsed_	row_	sortedrow_	block_
	max_merge_	partitions	increments	time	delta	delta	delta
	partitions						
custsales	7072	3	2	143918314	0	88297472	1524
	47						
custsales	7122	3	3	164157882	0	88297472	772
	47						
custsales	7212	3	4	187433171	0	88297472	767
	47						
custsales	7289	3	4	255482945	0	88297472	770
	47						

```

custsales | 7420 |           3 |           5 | 316583833 | 0 | 88297472 | 769
|         47
custsales | 9007 |           3 |           6 | 306685472 | 0 | 88297472 | 772
|         47
(6 rows)

```

The `merge_increments` column gives an indication of the amount of data that was merged for each vacuum operation. If the number of merge increments over consecutive vacuums increases in proportion to the growth in table size, it indicates that each vacuum operation is remerging an increasing number of rows in the table because the existing and newly sorted regions overlap.

Load your data in sort key order

If you load your data in sort key order using a `COPY` command, you might reduce or even remove the need to vacuum.

`COPY` automatically adds new rows to the table's sorted region when all of the following are true:

- The table uses a compound sort key with only one sort column.
- The sort column is NOT NULL.
- The table is 100 percent sorted or empty.
- All the new rows are higher in sort order than the existing rows, including rows marked for deletion. In this instance, Amazon Redshift uses the first eight bytes of the sort key to determine sort order.

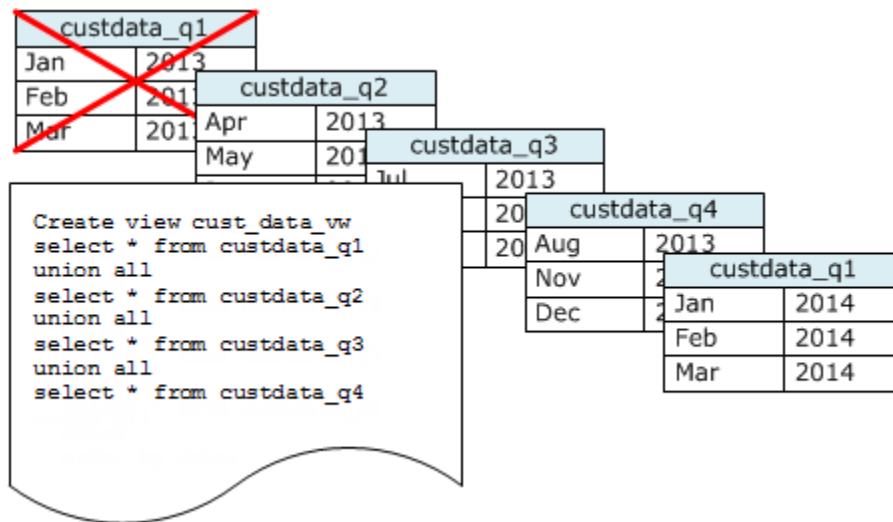

For example, suppose you have a table that records customer events using a customer ID and time. If you sort on customer ID, it's likely that the sort key range of new rows added by incremental loads will overlap the existing range, as shown in the previous example, leading to an expensive vacuum operation.

If you set your sort key to a timestamp column, your new rows will be appended in sort order at the end of the table, as the following diagram shows, reducing or even removing the need to vacuum.

Use time series tables to reduce stored data

If you maintain data for a rolling time period, use a series of tables, as the following diagram illustrates.

Create a new table each time you add a set of data, then delete the oldest table in the series. You gain a double benefit:

- You avoid the added cost of deleting rows, because a DROP TABLE operation is much more efficient than a mass DELETE.
- If the tables are sorted by timestamp, no vacuum is needed. If each table contains data for one month, a vacuum will at most have to rewrite one month's worth of data, even if the tables are not sorted by timestamp.

You can create a UNION ALL view for use by reporting queries that hides the fact that the data is stored in multiple tables. If a query filters on the sort key, the query planner can efficiently skip all the tables that aren't used. A UNION ALL can be less efficient for other types of queries, so you should evaluate query performance in the context of all queries that use the tables.

Managing concurrent write operations

Amazon Redshift allows tables to be read while they are being incrementally loaded or modified.

In some traditional data warehousing and business intelligence applications, the database is available to users only when the nightly load is complete. In such cases, no updates are allowed during regular work hours, when analytic queries are run and reports are generated; however, an increasing number of applications remain live for long periods of the day or even all day, making the notion of a load window obsolete.

Amazon Redshift supports these types of applications by allowing tables to be read while they are being incrementally loaded or modified. Queries simply see the latest committed version,

or *snapshot*, of the data, rather than waiting for the next version to be committed. If you want a particular query to wait for a commit from another write operation, you have to schedule it accordingly.

The following topics describe some of the key concepts and use cases that involve transactions, database snapshots, updates, and concurrent behavior.

Topics

- [Serializable isolation](#)
- [Write and read/write operations](#)
- [Concurrent write examples](#)

Serializable isolation

Some applications require not only concurrent querying and loading, but also the ability to write to multiple tables or the same table concurrently. In this context, *concurrently* means overlapping, not scheduled to run at precisely the same time. Two transactions are considered to be concurrent if the second one starts before the first commits. Concurrent operations can originate from different sessions that are controlled either by the same user or by different users.

Note

Amazon Redshift supports a default *automatic commit* behavior in which each separately run SQL command commits individually. If you enclose a set of commands in a transaction block (defined by [BEGIN](#) and [END](#) statements), the block commits as one transaction, so you can roll it back if necessary. Exceptions to this behavior are the TRUNCATE and VACUUM commands, which automatically commit all outstanding changes made in the current transaction.

Some SQL clients issue BEGIN and COMMIT commands automatically, so the client controls whether a group of statements are run as a transaction or each individual statement is run as its own transaction. Check the documentation for the interface you are using. For example, when using the Amazon Redshift JDBC driver, a JDBC `PreparedStatement` with a query string that contains multiple (semicolon separated) SQL commands runs all the statements as a single transaction. In contrast, if you use SQL Workbench/J and set `AUTO COMMIT ON`, then if you run multiple statements, each statement runs as its own transaction.

Concurrent write operations are supported in Amazon Redshift in a protective way, using write locks on tables and the principle of *serializable isolation*. Serializable isolation preserves the illusion that a transaction running against a table is the only transaction that is running against that table. For example, two concurrently running transactions, T1 and T2, must produce the same results as at least one of the following:

- T1 and T2 run serially in that order.
- T2 and T1 run serially in that order.

Concurrent transactions are invisible to each other; they cannot detect each other's changes. Each concurrent transaction will create a snapshot of the database at the beginning of the transaction. A database snapshot is created within a transaction on the first occurrence of most SELECT statements, DML commands such as COPY, DELETE, INSERT, UPDATE, and TRUNCATE, and the following DDL commands:

- ALTER TABLE (to add or drop columns)
- CREATE TABLE
- DROP TABLE
- TRUNCATE TABLE

If any serial execution of the concurrent transactions produces the same results as their concurrent execution, those transactions are deemed "serializable" and can be run safely. If no serial execution of those transactions can produce the same results, the transaction that runs a statement that might break the ability to serialize is stopped and rolled back.

System catalog tables (PG) and other Amazon Redshift system tables (STL and STV) are not locked in a transaction. Therefore, changes to database objects that arise from DDL and TRUNCATE operations are visible on commit to any concurrent transactions.

For example, suppose that table A exists in the database when two concurrent transactions, T1 and T2, start. Suppose that T2 returns a list of tables by selecting from the PG_TABLES catalog table. Then T1 drops table A and commits, and then T2 lists the tables again. Table A is now no longer listed. If T2 tries to query the dropped table, Amazon Redshift returns a "relation does not exist" error. The catalog query that returns the list of tables to T2 or checks that table A exists isn't subject to the same isolation rules as operations performed on user tables.

Transactions for updates to these tables run in a read committed isolation mode. PG-prefix catalog tables don't support snapshot isolation.

Serializable isolation for system tables and catalog tables

A database snapshot is also created in a transaction for any SELECT query that references a user-created table or Amazon Redshift system table (STL or STV). SELECT queries that don't reference any table don't create a new transaction database snapshot. INSERT, DELETE, and UPDATE statements that operate solely on system catalog tables (PG) also don't create a new transaction database snapshot.

How to fix serializable isolation errors

ERROR:1023 DETAIL: Serializable isolation violation on a table in Redshift

When Amazon Redshift detects a serializable isolation error, you see an error message such as the following.

```
ERROR:1023 DETAIL: Serializable isolation violation on table in Redshift
```

To address a serializable isolation error, you can try the following methods:

- Retry the canceled transaction.

Amazon Redshift detected that a concurrent workload is not serializable. It suggests gaps in the application logic, which can usually be worked around by retrying the transaction that encountered the error. If the issue persists, try one of the other methods.

- Move any operations that don't have to be in the same atomic transaction outside of the transaction.

This method applies when individual operations inside two transactions cross-reference each other in a way that can affect the outcome of the other transaction. For example, the following two sessions each start a transaction.

```
Session1_Redshift=# begin;
```

```
Session2_Redshift=# begin;
```

The result of a `SELECT` statement in each transaction might be affected by an `INSERT` statement in the other. In other words, suppose that you run the following statements serially, in any order. In every case, the result is one of the `SELECT` statements returning one more row than if the transactions were run concurrently. There is no order in which the operations can run serially that produces the same result as when run concurrently. Thus, the last operation that is run results in a serializable isolation error.

```
Session1_Redshift=# select * from tab1;
Session1_Redshift=# insert into tab2 values (1);
```

```
Session2_Redshift=# insert into tab1 values (1);
Session2_Redshift=# select * from tab2;
```

In many cases, the result of the `SELECT` statements isn't important. In other words, the atomicity of the operations in the transactions isn't important. In these cases, move the `SELECT` statements outside of their transactions, as shown in the following examples.

```
Session1_Redshift=# begin;
Session1_Redshift=# insert into tab1 values (1)
Session1_Redshift=# end;
Session1_Redshift=# select * from tab2;
```

```
Session2_Redshift # select * from tab1;
Session2_Redshift=# begin;
Session2_Redshift=# insert into tab2 values (1)
Session2_Redshift=# end;
```

In these examples, there are no cross-references in the transactions. The two `INSERT` statements don't affect each other. In these examples, there is at least one order in which the transactions can run serially and produce the same result as if run concurrently. This means that the transactions are serializable.

- Force serialization by locking all tables in each session.

The [LOCK](#) command blocks operations that can result in serializable isolation errors. When you use the `LOCK` command, be sure to do the following:

- Lock all tables affected by the transaction, including those affected by read-only `SELECT` statements inside the transaction.

- Lock tables in the same order, regardless of the order that operations are performed in.
- Lock all tables at the beginning of the transaction, before performing any operations.
- Use snapshot isolation for concurrent transactions

Use an `ALTER DATABASE` command with snapshot isolation. For more information about the `SNAPSHOT` parameter for `ALTER DATABASE`, see [Parameters](#).

ERROR:1018 DETAIL: Relation does not exist

When you run concurrent Amazon Redshift operations in different sessions, you see an error message such as the following.

```
ERROR: 1018 DETAIL: Relation does not exist.
```

Transactions in Amazon Redshift follow snapshot isolation. After a transaction begins, Amazon Redshift takes a snapshot of the database. For the entire lifecycle of the transaction, the transaction operates on the state of the database as reflected in the snapshot. If the transaction reads from a table that doesn't exist in the snapshot, it throws the 1018 error message shown previously. Even when another concurrent transaction creates a table after the transaction has taken the snapshot, the transaction can't read from the newly created table.

To address this serialization isolation error, you can try to move the start of the transaction to a point where you know the table exists.

If the table is created by another transaction, this point is at least after that transaction has been committed. Also, ensure that no concurrent transaction has been committed that might have dropped the table.

```
session1 = # BEGIN;  
session1 = # DROP TABLE A;  
session1 = # COMMIT;
```

```
session2 = # BEGIN;
```

```
session3 = # BEGIN;  
session3 = # CREATE TABLE A (id INT);  
session3 = # COMMIT;
```

```
session2 = # SELECT * FROM A;
```

The last operation that is run as the read operation by session2 results in a serializable isolation error. This error happens when session2 takes a snapshot and the table has already been dropped by a committed session1. In other words, even though a concurrent session3 has created the table, session2 doesn't see the table because it's not in the snapshot.

To resolve this error, you can reorder the sessions as follows.

```
session1 = # BEGIN;  
session1 = # DROP TABLE A;  
session1 = # COMMIT;
```

```
session3 = # BEGIN;  
session3 = # CREATE TABLE A (id INT);  
session3 = # COMMIT;
```

```
session2 = # BEGIN;  
session2 = # SELECT * FROM A;
```

Now when session2 takes its snapshot, session3 has already been committed, and the table is in the database. Session2 can read from the table without any error.

Write and read/write operations

You can manage the specific behavior of concurrent write operations by deciding when and how to run different types of commands. The following commands are relevant to this discussion:

- COPY commands, which perform loads (initial or incremental)
- INSERT commands that append one or more rows at a time
- UPDATE commands, which modify existing rows
- DELETE commands, which remove rows

COPY and INSERT operations are pure write operations, but DELETE and UPDATE operations are read/write operations. (For rows to be deleted or updated, they have to be read first.) The results of concurrent write operations depend on the specific commands that are being run concurrently.

COPY and INSERT operations against the same table are held in a wait state until the lock is released, then they proceed as normal.

UPDATE and DELETE operations behave differently because they rely on an initial table read before they do any writes. Given that concurrent transactions are invisible to each other, both UPDATES and DELETES have to read a snapshot of the data from the last commit. When the first UPDATE or DELETE releases its lock, the second UPDATE or DELETE needs to determine whether the data that it is going to work with is potentially stale. It will not be stale, because the second transaction does not obtain its snapshot of data until after the first transaction has released its lock.

Potential deadlock situation for concurrent write transactions

Whenever transactions involve updates of more than one table, there is always the possibility of concurrently running transactions becoming deadlocked when they both try to write to the same set of tables. A transaction releases all of its table locks at once when it either commits or rolls back; it does not relinquish locks one at a time.

For example, suppose that transactions T1 and T2 start at roughly the same time. If T1 starts writing to table A and T2 starts writing to table B, both transactions can proceed without conflict; however, if T1 finishes writing to table A and needs to start writing to table B, it will not be able to proceed because T2 still holds the lock on B. Conversely, if T2 finishes writing to table B and needs to start writing to table A, it will not be able to proceed either because T1 still holds the lock on A. Because neither transaction can release its locks until all its write operations are committed, neither transaction can proceed.

In order to avoid this kind of deadlock, you need to schedule concurrent write operations carefully. For example, you should always update tables in the same order in transactions and, if specifying locks, lock tables in the same order before you perform any DML operations.

Concurrent write examples

The following pseudo-code examples demonstrate how transactions either proceed or wait when they are run concurrently.

Concurrent COPY operations into the same table

Transaction 1 copies rows into the LISTING table:

```
begin;  
copy listing from ...;
```

```
end;
```

Transaction 2 starts concurrently in a separate session and attempts to copy more rows into the LISTING table. Transaction 2 must wait until transaction 1 releases the write lock on the LISTING table, then it can proceed.

```
begin;  
[waits]  
copy listing from ;  
end;
```

The same behavior would occur if one or both transactions contained an INSERT command instead of a COPY command.

Concurrent DELETE operations from the same table

Transaction 1 deletes rows from a table:

```
begin;  
delete from listing where ...;  
end;
```

Transaction 2 starts concurrently and attempts to delete rows from the same table. It will succeed because it waits for transaction 1 to complete before attempting to delete rows.

```
begin  
[waits]  
delete from listing where ;  
end;
```

The same behavior would occur if one or both transactions contained an UPDATE command to the same table instead of a DELETE command.

Concurrent transactions with a mixture of read and write operations

In this example, transaction 1 deletes rows from the USERS table, reloads the table, runs a COUNT(*) query, and then ANALYZE, before committing:

```
begin;  
delete one row from USERS table;
```

```
copy ;
select count(*) from users;
analyze ;
end;
```

Meanwhile, transaction 2 starts. This transaction attempts to copy additional rows into the USERS table, analyze the table, and then run the same COUNT(*) query as the first transaction:

```
begin;
[waits]
copy users from ...;
select count(*) from users;
analyze;
end;
```

The second transaction will succeed because it must wait for the first to complete. Its COUNT query will return the count based on the load it has completed.

Tutorial: Loading data from Amazon S3

In this tutorial, you walk through the process of loading data into your Amazon Redshift database tables from data files in an Amazon S3 bucket from beginning to end.

In this tutorial, you do the following:

- Download data files that use comma-separated value (CSV), character-delimited, and fixed width formats.
- Create an Amazon S3 bucket and then upload the data files to the bucket.
- Launch an Amazon Redshift cluster and create database tables.
- Use COPY commands to load the tables from the data files on Amazon S3.
- Troubleshoot load errors and modify your COPY commands to correct the errors.

Estimated time: 60 minutes

Estimated cost: \$1.00 per hour for the cluster

Prerequisites

You need the following prerequisites:

- An AWS account to launch an Amazon Redshift cluster and to create a bucket in Amazon S3.
- Your AWS credentials (IAM role) to load test data from Amazon S3. If you need a new IAM role, go to [Creating IAM roles](#).
- An SQL client such as the Amazon Redshift console query editor.

This tutorial is designed so that it can be taken by itself. In addition to this tutorial, we recommend completing the following tutorials to gain a more complete understanding of how to design and use Amazon Redshift databases:

- [Amazon Redshift Getting Started Guide](#) walks you through the process of creating an Amazon Redshift cluster and loading sample data.

Overview

You can add data to your Amazon Redshift tables either by using an INSERT command or by using a COPY command. At the scale and speed of an Amazon Redshift data warehouse, the COPY command is many times faster and more efficient than INSERT commands.

The COPY command uses the Amazon Redshift massively parallel processing (MPP) architecture to read and load data in parallel from multiple data sources. You can load from data files on Amazon S3, Amazon EMR, or any remote host accessible through a Secure Shell (SSH) connection. Or you can load directly from an Amazon DynamoDB table.

In this tutorial, you use the COPY command to load data from Amazon S3. Many of the principles presented here apply to loading from other data sources as well.

To learn more about using the COPY command, see these resources:

- [Amazon Redshift best practices for loading data](#)
- [Loading data from Amazon EMR](#)
- [Loading data from remote hosts](#)
- [Loading data from an Amazon DynamoDB table](#)

Step 1: Create a cluster

If you already have a cluster that you want to use, you can skip this step.

For the exercises in this tutorial, use a four-node cluster.

To create a cluster

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.

Using the navigation menu, choose the **Provisioned clusters dashboard**.

Important

Make sure that you have the necessary permissions to perform the cluster operations. For information on granting the necessary permissions, see [Authorizing Amazon Redshift to access AWS services](#).

2. At top right, choose the AWS Region in which you want to create the cluster. For the purposes of this tutorial, choose **US West (Oregon)**.
3. On the navigation menu, choose **Clusters**, then choose **Create cluster**. The **Create cluster** page appears.
4. On the **Create cluster** page enter parameters for your cluster. Choose your own values for the parameters, except change the following values:
 - Choose **dc2.large** for the node type.
 - Choose **4** for the **Number of nodes**.
 - In the **Cluster permissions** section, choose an IAM role from **Available IAM roles**. This role should be one that you previously created and that has access to Amazon S3. Then choose **Associate IAM role** to add it to the list of **Associated IAM roles** for the cluster.
5. Choose **Create cluster**.

Follow the [Amazon Redshift Getting Started Guide](#) steps to connect to your cluster from a SQL client and test a connection. You don't need to complete the remaining Getting Started steps to create tables, upload data, and try example queries.

Step 2: Download the data files

In this step, you download a set of sample data files to your computer. In the next step, you upload the files to an Amazon S3 bucket.

To download the data files

1. Download the zipped file: [LoadingDataSampleFiles.zip](#).
2. Extract the files to a folder on your computer.
3. Verify that your folder contains the following files.

```

part-csv.tbl-005
part-csv.tbl-006
part-csv.tbl-007
```

Step 3: Upload the files to an Amazon S3 bucket

In this step, you create an Amazon S3 bucket and upload the data files to the bucket.

To upload the files to an Amazon S3 bucket

1. Create a bucket in Amazon S3.

For more information about creating a bucket, see [Creating a bucket](#) in the *Amazon Simple Storage Service User Guide*.

- a. Sign in to the AWS Management Console and open the Amazon S3 console at <https://console.aws.amazon.com/s3/>.
- b. Choose **Create bucket**.
- c. Choose an AWS Region.

Create the bucket in the same Region as your cluster. If your cluster is in the US West (Oregon) Region, choose **US West (Oregon) Region (us-west-2)**.

- d. In the **Bucket Name** box of the **Create bucket** dialog box, enter a bucket name.

The bucket name you choose must be unique among all existing bucket names in Amazon S3. One way to help ensure uniqueness is to prefix your bucket names with the name of your organization. Bucket names must comply with certain rules. For more information, go to [Bucket restrictions and limitations](#) in the *Amazon Simple Storage Service User Guide*.

- e. Choose the recommended defaults for the rest of the options.
- f. Choose **Create bucket**.

When Amazon S3 successfully creates your bucket, the console displays your empty bucket in the **Buckets** panel.

2. Create a folder.
 - a. Choose the name of the new bucket.
 - b. Choose the **Create Folder** button.
 - c. Name the new folder **load**.

Note

The bucket that you created is not in a sandbox. In this exercise, you add objects to a real bucket. You're charged a nominal amount for the time that you store the

objects in the bucket. For more information about Amazon S3 pricing, go to the [Amazon S3 pricing](#) page.

3. Upload the data files to the new Amazon S3 bucket.
 - a. Choose the name of the data folder.
 - b. In the Upload wizard, choose **Add files**.

Follow the Amazon S3 console instructions to upload all of the files you downloaded and extracted,

- c. Choose **Upload**.

User Credentials

The Amazon Redshift COPY command must have access to read the file objects in the Amazon S3 bucket. If you use the same user credentials to create the Amazon S3 bucket and to run the Amazon Redshift COPY command, the COPY command has all necessary permissions. If you want to use different user credentials, you can grant access by using the Amazon S3 access controls. The Amazon Redshift COPY command requires at least ListBucket and GetObject permissions to access the file objects in the Amazon S3 bucket. For more information about controlling access to Amazon S3 resources, go to [Managing access permissions to your Amazon S3 resources](#).

Step 4: Create the sample tables

For this tutorial, you use a set of five tables based on the Star Schema Benchmark (SSB) schema. The following diagram shows the SSB data model.

The SSB tables might already exist in the current database. If so, drop the tables to remove them from the database before you create them using the CREATE TABLE commands in the next step. The tables used in this tutorial might have different attributes than the existing tables.

To create the sample tables

1. To drop the SSB tables, run the following commands in your SQL client.

```
drop table part cascade;
drop table supplier;
drop table customer;
drop table dwdate;
drop table lineorder;
```

2. Run the following CREATE TABLE commands in your SQL client.

```
CREATE TABLE part
(
  p_partkey      INTEGER NOT NULL,
  p_name        VARCHAR(22) NOT NULL,
```

```
p_mfgr      VARCHAR(6),
p_category  VARCHAR(7) NOT NULL,
p_brand1    VARCHAR(9) NOT NULL,
p_color     VARCHAR(11) NOT NULL,
p_type      VARCHAR(25) NOT NULL,
p_size      INTEGER NOT NULL,
p_container VARCHAR(10) NOT NULL
);

CREATE TABLE supplier
(
  s_suppkey  INTEGER NOT NULL,
  s_name     VARCHAR(25) NOT NULL,
  s_address  VARCHAR(25) NOT NULL,
  s_city     VARCHAR(10) NOT NULL,
  s_nation   VARCHAR(15) NOT NULL,
  s_region   VARCHAR(12) NOT NULL,
  s_phone    VARCHAR(15) NOT NULL
);

CREATE TABLE customer
(
  c_custkey  INTEGER NOT NULL,
  c_name     VARCHAR(25) NOT NULL,
  c_address  VARCHAR(25) NOT NULL,
  c_city     VARCHAR(10) NOT NULL,
  c_nation   VARCHAR(15) NOT NULL,
  c_region   VARCHAR(12) NOT NULL,
  c_phone    VARCHAR(15) NOT NULL,
  c_mktsegment VARCHAR(10) NOT NULL
);

CREATE TABLE dwdate
(
  d_datekey  INTEGER NOT NULL,
  d_date     VARCHAR(19) NOT NULL,
  d_dayofweek VARCHAR(10) NOT NULL,
  d_month    VARCHAR(10) NOT NULL,
  d_year     INTEGER NOT NULL,
  d_yearmonthnum INTEGER NOT NULL,
  d_yearmonth VARCHAR(8) NOT NULL,
  d_daynuminweek INTEGER NOT NULL,
  d_daynuminmonth INTEGER NOT NULL,
  d_daynuminyear INTEGER NOT NULL,
```

```
d_monthnuminyear    INTEGER NOT NULL,
d_weeknuminyear     INTEGER NOT NULL,
d_sellingseason     VARCHAR(13) NOT NULL,
d_lastdayinweekfl   VARCHAR(1) NOT NULL,
d_lastdayinmonthfl  VARCHAR(1) NOT NULL,
d_holidayfl        VARCHAR(1) NOT NULL,
d_weekdayfl         VARCHAR(1) NOT NULL
);
CREATE TABLE lineorder
(
  lo_orderkey        INTEGER NOT NULL,
  lo_linenumbers    INTEGER NOT NULL,
  lo_custkey         INTEGER NOT NULL,
  lo_partkey         INTEGER NOT NULL,
  lo_suppkey         INTEGER NOT NULL,
  lo_orderdate       INTEGER NOT NULL,
  lo_orderpriority   VARCHAR(15) NOT NULL,
  lo_shippriority    VARCHAR(1) NOT NULL,
  lo_quantity        INTEGER NOT NULL,
  lo_extendedprice   INTEGER NOT NULL,
  lo_ordertotalprice INTEGER NOT NULL,
  lo_discount        INTEGER NOT NULL,
  lo_revenue         INTEGER NOT NULL,
  lo_supplycost      INTEGER NOT NULL,
  lo_tax             INTEGER NOT NULL,
  lo_commitdate      INTEGER NOT NULL,
  lo_shipmode        VARCHAR(10) NOT NULL
);
```

Step 5: Run the COPY commands

You run COPY commands to load each of the tables in the SSB schema. The COPY command examples demonstrate loading from different file formats, using several COPY command options, and troubleshooting load errors.

COPY command syntax

The basic [COPY](#) command syntax is as follows.

```
COPY table_name [ column_list ] FROM data_source CREDENTIALS access_credentials
[options]
```

To run a COPY command, you provide the following values.

Table name

The target table for the COPY command. The table must already exist in the database. The table can be temporary or persistent. The COPY command appends the new input data to any existing rows in the table.

Column list

By default, COPY loads fields from the source data to the table columns in order. You can optionally specify a *column list*, that is a comma-separated list of column names, to map data fields to specific columns. You don't use column lists in this tutorial. For more information, see [Column List](#) in the COPY command reference.

Data source

You can use the COPY command to load data from an Amazon S3 bucket, an Amazon EMR cluster, a remote host using an SSH connection, or an Amazon DynamoDB table. For this tutorial, you load from data files in an Amazon S3 bucket. When loading from Amazon S3, you must provide the name of the bucket and the location of the data files. To do this, provide either an object path for the data files or the location of a manifest file that explicitly lists each data file and its location.

- Key prefix

An object stored in Amazon S3 is uniquely identified by an object key, which includes the bucket name, folder names, if any, and the object name. A *key prefix* refers to a set of objects with the same prefix. The object path is a key prefix that the COPY command uses to load all objects that share the key prefix. For example, the key prefix `custdata.txt` can refer to a single file or to a set of files, including `custdata.txt.001`, `custdata.txt.002`, and so on.

- Manifest file

In some cases, you might need to load files with different prefixes, for example from multiple buckets or folders. In others, you might need to exclude files that share a prefix. In these cases, you can use a manifest file. A *manifest file* explicitly lists each load file and its unique object key. You use a manifest file to load the PART table later in this tutorial.

Credentials

To access the AWS resources that contain the data to load, you must provide AWS access credentials for a user with sufficient privileges. These credentials include an IAM role Amazon Resource Name (ARN). To load data from Amazon S3, the credentials must include ListBucket and GetObject permissions. Additional credentials are required if your data is encrypted. For more information, see [Authorization parameters](#) in the COPY command reference. For more information about managing access, go to [Managing access permissions to your Amazon S3 resources](#).

Options

You can specify a number of parameters with the COPY command to specify file formats, manage data formats, manage errors, and control other features. In this tutorial, you use the following COPY command options and features:

- Key prefix

For information on how to load from multiple files by specifying a key prefix, see [Load the PART table using NULL AS](#).

- CSV format

For information on how to load data that is in CSV format, see [Load the PART table using NULL AS](#).

- NULL AS

For information on how to load PART using the NULL AS option, see [Load the PART table using NULL AS](#).

- Character-delimited format

For information on how to use the DELIMITER option, see [Load the SUPPLIER table using REGION](#).

- REGION

For information on how to use the REGION option, see [Load the SUPPLIER table using REGION](#).

- Fixed-format width

For information on how to load the CUSTOMER table from fixed-width data, see [Load the CUSTOMER table using MANIFEST](#).

- MAXERROR

For information on how to use the MAXERROR option, see [Load the CUSTOMER table using MANIFEST](#).

- ACCEPTINVCHARS

For information on how to use the ACCEPTINVCHARS option, see [Load the CUSTOMER table using MANIFEST](#).

- MANIFEST

For information on how to use the MANIFEST option, see [Load the CUSTOMER table using MANIFEST](#).

- DATEFORMAT

For information on how to use the DATEFORMAT option, see [Load the DWDATE table using DATEFORMAT](#).

- GZIP, LZOP and BZIP2

For information on how to compress your files, see [Load the LINEORDER table using multiple files](#).

- COMPUPDATE

For information on how to use the COMPUPDATE option, see [Load the LINEORDER table using multiple files](#).

- Multiple files

For information on how to load multiple files, see [Load the LINEORDER table using multiple files](#).

Loading the SSB tables

You use the following COPY commands to load each of the tables in the SSB schema. The command to each table demonstrates different COPY options and troubleshooting techniques.

To load the SSB tables, follow these steps:

1. [Replace the bucket name and AWS credentials](#)
2. [Load the PART table using NULL AS](#)
3. [Load the SUPPLIER table using REGION](#)

4. [Load the CUSTOMER table using MANIFEST](#)
5. [Load the DWDATA table using DATEFORMAT](#)
6. [Load the LINEORDER table using multiple files](#)

Replace the bucket name and AWS credentials

The COPY commands in this tutorial are presented in the following format.

```
copy table from 's3://<your-bucket-name>/load/key_prefix'  
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'  
options;
```

For each COPY command, do the following:

1. Replace *<your-bucket-name>* with the name of a bucket in the same region as your cluster.

This step assumes the bucket and the cluster are in the same region. Alternatively, you can specify the region using the [REGION](#) option with the COPY command.

2. Replace *<aws-account-id>* and *<role-name>* with your own AWS account and IAM role. The segment of the credentials string that is enclosed in single quotation marks must not contain any spaces or line breaks. Note that the ARN might differ slightly in format than the sample. It's best to copy the ARN for the role from the IAM console, to ensure that it's accurate, when you run the COPY commands.

Load the PART table using NULL AS

In this step, you use the CSV and NULL AS options to load the PART table.

The COPY command can load data from multiple files in parallel, which is much faster than loading from a single file. To demonstrate this principle, the data for each table in this tutorial is split into eight files, even though the files are very small. In a later step, you compare the time difference between loading from a single file and loading from multiple files. For more information, see [Loading data files](#).

Key prefix

You can load from multiple files by specifying a key prefix for the file set, or by explicitly listing the files in a manifest file. In this step, you use a key prefix. In a later step, you use a manifest file. The

key prefix 's3://amzn-s3-demo-bucket/load/part-csv.tbl' loads the following set of the files in the load folder.

```
part-csv.tbl-000
part-csv.tbl-001
part-csv.tbl-002
part-csv.tbl-003
part-csv.tbl-004
part-csv.tbl-005
part-csv.tbl-006
part-csv.tbl-007
```

CSV format

CSV, which stands for comma separated values, is a common format used for importing and exporting spreadsheet data. CSV is more flexible than comma-delimited format because it enables you to include quoted strings within fields. The default quotation mark character for COPY from CSV format is a double quotation mark ("), but you can specify another quotation mark character by using the QUOTE AS option. When you use the quotation mark character within the field, escape the character with an additional quotation mark character.

The following excerpt from a CSV-formatted data file for the PART table shows strings enclosed in double quotation marks ("LARGE ANODIZED BRASS"). It also shows a string enclosed in two double quotation marks within a quoted string ("MEDIUM ""BURNISHED"" TIN").

```
15,dark sky,MFGR#3,MFGR#47,MFGR#3438,indigo,"LARGE ANODIZED BRASS",45,LG CASE
22,floral beige,MFGR#4,MFGR#44,MFGR#4421,medium,"PROMO, POLISHED BRASS",19,LG DRUM
23,bisque slate,MFGR#4,MFGR#41,MFGR#4137,firebrick,"MEDIUM ""BURNISHED"" TIN",42,JUMBO
JAR
```

The data for the PART table contains characters that cause COPY to fail. In this exercise, you troubleshoot the errors and correct them.

To load data that is in CSV format, add csv to your COPY command. Run the following command to load the PART table.

```
copy part from 's3://<your-bucket-name>/load/part-csv.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
csv;
```

You might get an error message similar to the following.

```
An error occurred when executing the SQL command:
copy part from 's3://amzn-s3-demo-bucket/load/part-csv.tbl'
credentials' ...

ERROR: Load into table 'part' failed. Check 'stl_load_errors' system table for
details. [SQL State=XX000]

Execution time: 1.46s

1 statement(s) failed.
1 statement(s) failed.
```

To get more information about the error, query the `STL_LOAD_ERRORS` table. The following query uses the `SUBSTRING` function to shorten columns for readability and uses `LIMIT 10` to reduce the number of rows returned. You can adjust the values in `substring(filename,22,25)` to allow for the length of your bucket name.

```
select query, substring(filename,22,25) as filename,line_number as line,
substring(colname,0,12) as column, type, position as pos, substring(raw_line,0,30) as
line_text,
substring(raw_field_value,0,15) as field_text,
substring(err_reason,0,45) as reason
from stl_load_errors
order by query desc
limit 10;
```

query	filename	line	column	type	pos
333765	part-csv.tbl-000	1			0
line_text		field_text		reason	
15,NUL next,			Missing newline: Unexpected character 0x2c f		

NULL AS

The `part-csv.tbl` data files use the NUL terminator character (`\x000` or `\x0`) to indicate NULL values.

Note

Despite very similar spelling, NUL and NULL are not the same. NUL is a UTF-8 character with codepoint `x0000` that is often used to indicate end of record (EOR). NULL is a SQL value that represents an absence of data.

By default, COPY treats a NUL terminator character as an EOR character and terminates the record, which often results in unexpected results or an error. There is no single standard method of indicating NULL in text data. Thus, the NULL AS COPY command option enables you to specify which character to substitute with NULL when loading the table. In this example, you want COPY to treat the NUL terminator character as a NULL value.

Note

The table column that receives the NULL value must be configured as *nullable*. That is, it must not include the NOT NULL constraint in the CREATE TABLE specification.

To load PART using the NULL AS option, run the following COPY command.

```
copy part from 's3://<your-bucket-name>/load/part-csv.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
csv
null as '\000';
```

To verify that COPY loaded NULL values, run the following command to select only the rows that contain NULL.

```
select p_partkey, p_name, p_mfgr, p_category from part where p_mfgr is null;
```

```
p_partkey | p_name | p_mfgr | p_category
-----+-----+-----+-----
      15 | NUL next |      | MFGR#47
      81 | NUL next |      | MFGR#23
     133 | NUL next |      | MFGR#44
(2 rows)
```

Load the SUPPLIER table using REGION

In this step, you use the DELIMITER and REGION options to load the SUPPLIER table.

Note

The files for loading the SUPPLIER table are provided in an AWS sample bucket. You don't need to upload files for this step.

Character-Delimited Format

The fields in a character-delimited file are separated by a specific character, such as a pipe character (|), a comma (,) or a tab (\t). Character-delimited files can use any single ASCII character, including one of the nonprinting ASCII characters, as the delimiter. You specify the delimiter character by using the DELIMITER option. The default delimiter is a pipe character (|).

The following excerpt from the data for the SUPPLIER table uses pipe-delimited format.

```
1|1|257368|465569|41365|19950218|2-HIGH|0|17|2608718|9783671|4|2504369|92072|2|
19950331|TRUCK
1|2|257368|201928|8146|19950218|2-HIGH|0|36|6587676|9783671|9|5994785|109794|6|
19950416|MAIL
```

REGION

Whenever possible, you should locate your load data in the same AWS region as your Amazon Redshift cluster. If your data and your cluster are in the same region, you reduce latency and avoid cross-region data transfer costs. For more information, see [Amazon Redshift best practices for loading data](#)

If you must load data from a different AWS region, use the REGION option to specify the AWS region in which the load data is located. If you specify a region, all of the load data, including manifest files, must be in the named region. For more information, see [REGION](#).

If your cluster is in the US East (N. Virginia) Region, run the following command to load the SUPPLIER table from pipe-delimited data in an Amazon S3 bucket located in the US West (Oregon) Region. For this example, do not change the bucket name.

```
copy supplier from 's3://awssampleduswest2/ssbgz/supplier.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
```

```
delimiter '|'
gzip
region 'us-west-2';
```

If your cluster is *not* in the US East (N. Virginia) region, run the following command to load the SUPPLIER table from pipe-delimited data in an Amazon S3 bucket located in the US East (N. Virginia) region. For this example, do not change the bucket name.

```
copy supplier from 's3://awssampledbsbgsz/supplier.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
delimiter '|'
gzip
region 'us-east-1';
```

Load the CUSTOMER table using MANIFEST

In this step, you use the FIXEDWIDTH, MAXERROR, ACCEPTINVCHARS, and MANIFEST options to load the CUSTOMER table.

The sample data for this exercise contains characters that cause errors when COPY attempts to load them. You use the MAXERRORS option and the STL_LOAD_ERRORS system table to troubleshoot the load errors and then use the ACCEPTINVCHARS and MANIFEST options to eliminate the errors.

Fixed-Width Format

Fixed-width format defines each field as a fixed number of characters, rather than separating fields with a delimiter. The following excerpt from the data for the CUSTOMER table uses fixed-width format.

1	Customer#000000001	IVhzIApeRb	MOROCCO	0MOROCCO	AFRICA	25-705
2	Customer#000000002	XSTf4,NCwDVaWNe6tE	JORDAN	6JORDAN	MIDDLE EAST	23-453
3	Customer#000000003	MG9kdTD	ARGENTINA5	ARGENTINA	AMERICA	11-783

The order of the label/width pairs must match the order of the table columns exactly. For more information, see [FIXEDWIDTH](#).

The fixed-width specification string for the CUSTOMER table data is as follows.

```
fixedwidth 'c_custkey:10, c_name:25, c_address:25, c_city:10, c_nation:15,
c_region :12, c_phone:15,c_mktsegment:10'
```

To load the CUSTOMER table from fixed-width data, run the following command.

```
copy customer
from 's3://<your-bucket-name>/load/customer-fw.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
fixedwidth 'c_custkey:10, c_name:25, c_address:25, c_city:10, c_nation:15,
c_region :12, c_phone:15,c_mktsegment:10';
```

You should get an error message, similar to the following.

```
An error occurred when executing the SQL command:
copy customer
from 's3://amzn-s3-demo-bucket/load/customer-fw.tbl'
credentials'...

ERROR: Load into table 'customer' failed. Check 'stl_load_errors' system table for
details. [SQL State=XX000]

Execution time: 2.95s

1 statement(s) failed.
```

MAXERROR

By default, the first time COPY encounters an error, the command fails and returns an error message. To save time during testing, you can use the MAXERROR option to instruct COPY to skip a specified number of errors before it fails. Because we expect errors the first time we test loading the CUSTOMER table data, add `maxerror 10` to the COPY command.

To test using the FIXEDWIDTH and MAXERROR options, run the following command.

```
copy customer
from 's3://<your-bucket-name>/load/customer-fw.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
fixedwidth 'c_custkey:10, c_name:25, c_address:25, c_city:10, c_nation:15,
c_region :12, c_phone:15,c_mktsegment:10'
maxerror 10;
```

This time, instead of an error message, you get a warning message similar to the following.

```
Warnings:
Load into table 'customer' completed, 112497 record(s) loaded successfully.
```

Load into table 'customer' completed, 7 record(s) could not be loaded. Check 'stl_load_errors' system table for details.

The warning indicates that COPY encountered seven errors. To check the errors, query the STL_LOAD_ERRORS table, as shown in the following example.

```
select query, substring(filename,22,25) as filename,line_number as line,
substring(colname,0,12) as column, type, position as pos, substring(raw_line,0,30) as
line_text,
substring(raw_field_value,0,15) as field_text,
substring(err_reason,0,45) as error_reason
from stl_load_errors
order by query desc, filename
limit 7;
```

The results of the STL_LOAD_ERRORS query should look similar to the following.

query	filename	line	column	type	pos	line_text	field_text	error_reason
334489	customer-fw.tbl.log	2	c_custkey	int4	-1	customer-fw.tbl	customer-f	Invalid digit, Value 'c', Pos 0, Type: Integ
334489	customer-fw.tbl.log	6	c_custkey	int4	-1	Complete	Complete	Invalid digit, Value 'C', Pos 0, Type: Integ
334489	customer-fw.tbl.log	3	c_custkey	int4	-1	#Total rows	#Total row	Invalid digit, Value '#', Pos 0, Type: Integ
334489	customer-fw.tbl.log	5	c_custkey	int4	-1	#Status	#Status	Invalid digit, Value '#', Pos 0, Type: Integ
334489	customer-fw.tbl.log	1	c_custkey	int4	-1	#Load file	#Load file	Invalid digit, Value '#', Pos 0, Type: Integ
334489	customer-fw.tbl000	1	c_address	varchar	34	1	Customer#000000001	.Mayag.ezR String contains invalid or unsupported UTF8
334489	customer-fw.tbl000	1	c_address	varchar	34	1	Customer#000000001	.Mayag.ezR String contains invalid or unsupported UTF8

(7 rows)

By examining the results, you can see that there are two messages in the error_reasons column:

- Invalid digit, Value '#', Pos 0, Type: Integ

These errors are caused by the `customer-fw.tbl.log` file. The problem is that it is a log file, not a data file, and should not be loaded. You can use a manifest file to avoid loading the wrong file.

- String contains invalid or unsupported UTF8

The `VARCHAR` data type supports multibyte UTF-8 characters up to three bytes. If the load data contains unsupported or invalid characters, you can use the `ACCEPTINVCHARS` option to replace each invalid character with a specified alternative character.

Another problem with the load is more difficult to detect—the load produced unexpected results. To investigate this problem, run the following command to query the `CUSTOMER` table.

```
select c_custkey, c_name, c_address
from customer
order by c_custkey
limit 10;
```

c_custkey	c_name	c_address
2	Customer#000000002	XSTf4,NCwDVaWNe6tE
2	Customer#000000002	XSTf4,NCwDVaWNe6tE
3	Customer#000000003	MG9kdTD
3	Customer#000000003	MG9kdTD
4	Customer#000000004	XxVSJsL
4	Customer#000000004	XxVSJsL
5	Customer#000000005	KvpyuHCplrB84WgAi
5	Customer#000000005	KvpyuHCplrB84WgAi
6	Customer#000000006	sKZz0CsnMD7mp4Xd0YrBvx
6	Customer#000000006	sKZz0CsnMD7mp4Xd0YrBvx

(10 rows)

The rows should be unique, but there are duplicates.

Another way to check for unexpected results is to verify the number of rows that were loaded. In our case, 100000 rows should have been loaded, but the load message reported loading 112497 records. The extra rows were loaded because the `COPY` loaded an extraneous file, `customer-fw.tbl0000.bak`.

In this exercise, you use a manifest file to avoid loading the wrong files.

ACCEPTINVCHARS

By default, when COPY encounters a character that is not supported by the column's data type, it skips the row and returns an error. For information about invalid UTF-8 characters, see [Multibyte character load errors](#).

You could use the MAXERRORS option to ignore errors and continue loading, then query STL_LOAD_ERRORS to locate the invalid characters, and then fix the data files. However, MAXERRORS is best used for troubleshooting load problems and should generally not be used in a production environment.

The ACCEPTINVCHARS option is usually a better choice for managing invalid characters. ACCEPTINVCHARS instructs COPY to replace each invalid character with a specified valid character and continue with the load operation. You can specify any valid ASCII character, except NULL, as the replacement character. The default replacement character is a question mark (?). COPY replaces multibyte characters with a replacement string of equal length. For example, a 4-byte character would be replaced with '????'.

COPY returns the number of rows that contained invalid UTF-8 characters. It also adds an entry to the STL_REPLACEMENTS system table for each affected row, up to a maximum of 100 rows per node slice. Additional invalid UTF-8 characters are also replaced, but those replacement events are not recorded.

ACCEPTINVCHARS is valid only for VARCHAR columns.

For this step, you add the ACCEPTINVCHARS with the replacement character '^'.

MANIFEST

When you COPY from Amazon S3 using a key prefix, there is a risk that you might load unwanted tables. For example, the 's3://amzn-s3-demo-bucket/load/' folder contains eight data files that share the key prefix customer-fw.tbl: customer-fw.tbl0000, customer-fw.tbl0001, and so on. However, the same folder also contains the extraneous files customer-fw.tbl.log and customer-fw.tbl-0001.bak.

To ensure that you load all of the correct files, and only the correct files, use a manifest file. The manifest is a text file in JSON format that explicitly lists the unique object key for each source file to be loaded. The file objects can be in different folders or different buckets, but they must be in the same region. For more information, see [MANIFEST](#).

The following shows the `customer-fw-manifest` text.

```
{
  "entries": [
    {"url": "s3://<your-bucket-name>/load/customer-fw.tbl-000"},
    {"url": "s3://<your-bucket-name>/load/customer-fw.tbl-001"},
    {"url": "s3://<your-bucket-name>/load/customer-fw.tbl-002"},
    {"url": "s3://<your-bucket-name>/load/customer-fw.tbl-003"},
    {"url": "s3://<your-bucket-name>/load/customer-fw.tbl-004"},
    {"url": "s3://<your-bucket-name>/load/customer-fw.tbl-005"},
    {"url": "s3://<your-bucket-name>/load/customer-fw.tbl-006"},
    {"url": "s3://<your-bucket-name>/load/customer-fw.tbl-007"}
  ]
}
```

To load the data for the `CUSTOMER` table using the manifest file

1. Open the file `customer-fw-manifest` in a text editor.
2. Replace `<your-bucket-name>` with the name of your bucket.
3. Save the file.
4. Upload the file to the load folder on your bucket.
5. Run the following `COPY` command.

```
copy customer from 's3://<your-bucket-name>/load/customer-fw-manifest'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
fixedwidth 'c_custkey:10, c_name:25, c_address:25, c_city:10, c_nation:15,
  c_region :12, c_phone:15,c_mktsegment:10'
maxerror 10
acceptinvchars as '^'
manifest;
```

Load the `DWDATE` table using `DATEFORMAT`

In this step, you use the `DELIMITER` and `DATEFORMAT` options to load the `DWDATE` table.

When loading `DATE` and `TIMESTAMP` columns, `COPY` expects the default format, which is `YYYY-MM-DD` for dates and `YYYY-MM-DD HH:MI:SS` for timestamps. If the load data does not use a default format, you can use `DATEFORMAT` and `TIMEFORMAT` to specify the format.

The following excerpt shows date formats in the DWDATE table. Notice that the date formats in column two are inconsistent.

```
19920104 1992-01-04          Sunday January 1992 199201 Jan1992 1 4 4 1...
19920112 January 12, 1992 Monday January 1992 199201 Jan1992 2 12 12 1...
19920120 January 20, 1992 Tuesday January 1992 199201 Jan1992 3 20 20 1...
```

DATEFORMAT

You can specify only one date format. If the load data contains inconsistent formats, possibly in different columns, or if the format is not known at load time, you use DATEFORMAT with the 'auto' argument. When 'auto' is specified, COPY recognizes any valid date or time format and convert it to the default format. The 'auto' option recognizes several formats that are not supported when using a DATEFORMAT and TIMEFORMAT string. For more information, see [Using automatic recognition with DATEFORMAT and TIMEFORMAT](#).

To load the DWDATE table, run the following COPY command.

```
copy dwdate from 's3://<your-bucket-name>/load/dwdate-tab.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
delimiter '\t'
dateformat 'auto';
```

Load the LINEORDER table using multiple files

This step uses the GZIP and COMPUPDATE options to load the LINEORDER table.

In this exercise, you load the LINEORDER table from a single data file and then load it again from multiple files. Doing this enables you to compare the load times for the two methods.

Note

The files for loading the LINEORDER table are provided in an AWS sample bucket. You don't need to upload files for this step.

GZIP, LZOP and BZIP2

You can compress your files using either gzip, lzop, or bzip2 compression formats. When loading from compressed files, COPY uncompresses the files during the load process. Compressing your files saves storage space and shortens upload times.

COMPUPDATE

When COPY loads an empty table with no compression encodings, it analyzes the load data to determine the optimal encodings. It then alters the table to use those encodings before beginning the load. This analysis process takes time, but it occurs, at most, once per table. To save time, you can skip this step by turning COMPUPDATE off. To enable an accurate evaluation of COPY times, you turn COMPUPDATE off for this step.

Multiple Files

The COPY command can load data very efficiently when it loads from multiple files in parallel instead of from a single file. You can split your data into files so that the number of files is a multiple of the number of slices in your cluster. If you do, Amazon Redshift divides the workload and distributes the data evenly among the slices. The number of slices per node depends on the node size of the cluster. For more information about the number of slices that each node size has, go to [About clusters and nodes](#) in the *Amazon Redshift Management Guide*.

For example, the dc2.large compute nodes used in this tutorial have two slices each, so the four-node cluster has eight slices. In previous steps, the load data was contained in eight files, even though the files are very small. In this step, you compare the time difference between loading from a single large file and loading from multiple files.

The files you use for this tutorial contain about 15 million records and occupy about 1.2 GB. These files are very small in Amazon Redshift scale, but sufficient to demonstrate the performance advantage of loading from multiple files. The files are large enough that the time required to download them and then upload them to Amazon S3 is excessive for this tutorial. Thus, you load the files directly from an AWS sample bucket.

The following screenshot shows the data files for LINEORDER.

To evaluate the performance of COPY with multiple files

1. Run the following command to COPY from a single file. Do not change the bucket name.

```
copy lineorder from 's3://awssampledload/load/lo/lineorder-single.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
gzip
compupdate off
region 'us-east-1';
```

2. Your results should be similar to the following. Note the execution time.

```
Warnings:
Load into table 'lineorder' completed, 14996734 record(s) loaded successfully.

0 row(s) affected.
copy executed successfully

Execution time: 51.56s
```

3. Run the following command to COPY from multiple files. Do not change the bucket name.

```
copy lineorder from 's3://awssampledload/load/lo/lineorder-multi.tbl'
credentials 'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
```

```
gzip
compupdate off
region 'us-east-1';
```

4. Your results should be similar to the following. Note the execution time.

```
Warnings:
Load into table 'lineorder' completed, 14996734 record(s) loaded successfully.

0 row(s) affected.
copy executed successfully

Execution time: 17.7s
```

5. Compare execution times.

In our example, the time to load 15 million records decreased from 51.56 seconds to 17.7 seconds, a reduction of 65.7 percent.

These results are based on using a four-node cluster. If your cluster has more nodes, the time savings is multiplied. For typical Amazon Redshift clusters, with tens to hundreds of nodes, the difference is even more dramatic. If you have a single node cluster, there is little difference between the execution times.

Step 6: Vacuum and analyze the database

Whenever you add, delete, or modify a significant number of rows, you should run a `VACUUM` command and then an `ANALYZE` command. A *vacuum* recovers the space from deleted rows and restores the sort order. The `ANALYZE` command updates the statistics metadata, which enables the query optimizer to generate more accurate query plans. For more information, see [Vacuuming tables](#).

If you load the data in sort key order, a vacuum is fast. In this tutorial, you added a significant number of rows, but you added them to empty tables. That being the case, there is no need to resort, and you didn't delete any rows. `COPY` automatically updates statistics after loading an empty table, so your statistics should be up-to-date. However, as a matter of good housekeeping, you complete this tutorial by vacuuming and analyzing your database.

To vacuum and analyze the database, run the following commands.

```
vacuum;  
analyze;
```

Step 7: Clean up your resources

Your cluster continues to accrue charges as long as it is running. When you have completed this tutorial, you should return your environment to the previous state by following the steps in [Step 5: Revoke access and delete your sample cluster](#) in the *Amazon Redshift Getting Started Guide*.

If you want to keep the cluster, but recover the storage used by the SSB tables, run the following commands.

```
drop table part;  
drop table supplier;  
drop table customer;  
drop table dwwdate;  
drop table lineorder;
```

Next

[Summary](#)

Summary

In this tutorial, you uploaded data files to Amazon S3 and then used COPY commands to load the data from the files into Amazon Redshift tables.

You loaded data using the following formats:

- Character-delimited
- CSV
- Fixed-width

You used the STL_LOAD_ERRORS system table to troubleshoot load errors, and then used the REGION, MANIFEST, MAXERROR, ACCEPTINVCHARS, DATEFORMAT, and NULL AS options to resolve the errors.

You applied the following best practices for loading data:

- [Use a COPY command to load data](#)
- [Loading data files](#)
- [Use a single COPY command to load from multiple files](#)
- [Compressing your data files](#)
- [Verify data files before and after a load](#)

For more information about Amazon Redshift best practices, see the following links:

- [Amazon Redshift best practices for loading data](#)
- [Amazon Redshift best practices for designing tables](#)
- [Amazon Redshift best practices for designing queries](#)

Unloading data in Amazon Redshift

To unload data from database tables to a set of files in an Amazon S3 bucket, you can use the [UNLOAD](#) command with a SELECT statement. You can unload text data in either delimited format or fixed-width format, regardless of the data format that was used to load it. You can also specify whether to create compressed GZIP files.

You can limit the access users have to your Amazon S3 bucket by using temporary security credentials.

Topics

- [Unloading data to Amazon S3](#)
- [Unloading encrypted data files](#)
- [Unloading data in delimited or fixed-width format](#)
- [Reloading unloaded data](#)

Unloading data to Amazon S3

Amazon Redshift splits the results of a select statement across a set of files, one or more files per node slice, to simplify parallel reloading of the data. Alternatively, you can specify that [UNLOAD](#) should write the results serially to one or more files by adding the PARALLEL OFF option. You can limit the size of the files in Amazon S3 by specifying the MAXFILESIZE parameter. UNLOAD automatically encrypts data files using Amazon S3 server-side encryption (SSE-S3).

You can use any select statement in the UNLOAD command that Amazon Redshift supports, except for a select that uses a LIMIT clause in the outer select. For example, you can use a select statement that includes specific columns or that uses a where clause to join multiple tables. If your query contains quotation marks (enclosing literal values, for example), you need to escape them in the query text (\'). For more information, see the [SELECT](#) command reference. For more information about using a LIMIT clause, see the [Usage notes](#) for the UNLOAD command.

For example, the following UNLOAD command sends the contents of the VENUE table to the Amazon S3 bucket s3://amzn-s3-demo-bucket/ticket/unload/.

```
unload ('select * from venue')
to 's3://amzn-s3-demo-bucket/ticket/unload/venue_'
```

```
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

The file names created by the previous example include the prefix 'venue_'.

```
venue_0000_part_00  
venue_0001_part_00  
venue_0002_part_00  
venue_0003_part_00
```

By default, UNLOAD writes data in parallel to multiple files, according to the number of slices in the cluster. To write data to a single file, specify `PARALLEL OFF`. UNLOAD writes the data serially, sorted absolutely according to the `ORDER BY` clause, if one is used. The maximum size for a data file is 6.2 GB. If the data size is greater than the maximum, UNLOAD creates additional files, up to 6.2 GB each.

The following example writes the contents `VENUE` to a single file. Only one file is required because the file size is less than 6.2 GB.

```
unload ('select * from venue')  
to 's3://amzn-s3-demo-bucket/ticket/unload/venue_'  
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
parallel off;
```

Note

The UNLOAD command is designed to use parallel processing. We recommend leaving `PARALLEL` enabled for most cases, especially if the files will be used to load tables using a `COPY` command.

Assuming the total data size for `VENUE` is 5 GB, the following example writes the contents of `VENUE` to 50 files, each 100 MB in size.

```
unload ('select * from venue')  
to 's3://amzn-s3-demo-bucket/ticket/unload/venue_'  
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
parallel off  
maxfilesize 100 mb;
```

If you include a prefix in the Amazon S3 path string, UNLOAD will use that prefix for the file names.

```
unload ('select * from venue')
to 's3://amzn-s3-demo-bucket/ticket/unload/venue_'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

You can create a manifest file that lists the unload files by specifying the MANIFEST option in the UNLOAD command. The manifest is a text file in JSON format that explicitly lists the URL of each file that was written to Amazon S3.

The following example includes the manifest option.

```
unload ('select * from venue')
to 's3://amzn-s3-demo-bucket/ticket/venue_'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
manifest;
```

The following example shows a manifest for four unload files.

```
{
  "entries": [
    {"url": "s3://amzn-s3-demo-bucket/ticket/venue_0000_part_00"},
    {"url": "s3://amzn-s3-demo-bucket/ticket/venue_0001_part_00"},
    {"url": "s3://amzn-s3-demo-bucket/ticket/venue_0002_part_00"},
    {"url": "s3://amzn-s3-demo-bucket/ticket/venue_0003_part_00"}
  ]
}
```

The manifest file can be used to load the same files by using a COPY with the MANIFEST option. For more information, see [Using a manifest to specify data files](#).

After you complete an UNLOAD operation, confirm that the data was unloaded correctly by navigating to the Amazon S3 bucket where UNLOAD wrote the files. You will see one or more numbered files per slice, starting with the number zero. If you specified the MANIFEST option, you will also see a file ending with 'manifest'. For example:

```
amzn-s3-demo-bucket/ticket/venue_0000_part_00
amzn-s3-demo-bucket/ticket/venue_0001_part_00
amzn-s3-demo-bucket/ticket/venue_0002_part_00
amzn-s3-demo-bucket/ticket/venue_0003_part_00
```

```
amzn-s3-demo-bucket/ticket/venue_manifest
```

You can programmatically get a list of the files that were written to Amazon S3 by calling an Amazon S3 list operation after the UNLOAD completes. You can also query `STL_UNLOAD_LOG`.

The following query returns the pathname for files that were created by an UNLOAD. The [PG_LAST_QUERY_ID](#) function returns the most recent query.

```
select query, substring(path,0,40) as path
from stl_unload_log
where query=2320
order by path;
```

query	path
2320	s3://amzn-s3-demo-bucket/venue0000_part_00
2320	s3://amzn-s3-demo-bucket/venue0001_part_00
2320	s3://amzn-s3-demo-bucket/venue0002_part_00
2320	s3://amzn-s3-demo-bucket/venue0003_part_00

(4 rows)

If the amount of data is very large, Amazon Redshift might split the files into multiple parts per slice. For example:

```
venue_0000_part_00
venue_0000_part_01
venue_0000_part_02
venue_0001_part_00
venue_0001_part_01
venue_0001_part_02
...
```

The following UNLOAD command includes a quoted string in the select statement, so the quotation marks are escaped (`=\'OH\'`).

```
unload ('select venuename, venuecity from venue where venuestate=\'OH\' ')
to 's3://amzn-s3-demo-bucket/ticket/venue/ '
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

By default, UNLOAD will fail rather than overwrite existing files in the destination bucket. To overwrite the existing files, including the manifest file, specify the `ALLOWOVERWRITE` option.

```
unload ('select * from venue')
to 's3://amzn-s3-demo-bucket/venue_pipe_'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
manifest
allowoverwrite;
```

Unloading encrypted data files

UNLOAD automatically creates files using Amazon S3 server-side encryption with AWS managed encryption keys (SSE-S3). You can also specify server-side encryption with an AWS Key Management Service key (SSE-KMS) or client-side encryption with a customer managed key. UNLOAD doesn't support Amazon S3 server-side encryption using a customer managed key. For more information, see [Protecting data using server-side encryption](#).

To unload to Amazon S3 using server-side encryption with an AWS KMS key, use the `KMS_KEY_ID` parameter to provide the key ID as shown in the following example.

```
unload ('select venueName, venueCity from venue')
to 's3://amzn-s3-demo-bucket/encrypted/venue_'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
KMS_KEY_ID '1234abcd-12ab-34cd-56ef-1234567890ab'
encrypted;
```

If you want to provide your own encryption key, you can create client-side encrypted data files in Amazon S3 by using the UNLOAD command with the ENCRYPTED option. UNLOAD uses the same envelope encryption process that Amazon S3 client-side encryption uses. You can then use the COPY command with the ENCRYPTED option to load the encrypted files.

The process works like this:

1. You create a base64 encoded 256-bit AES key that you will use as your private encryption key, or *root symmetric key*.
2. You issue an UNLOAD command that includes your root symmetric key and the ENCRYPTED option.
3. UNLOAD generates a one-time-use symmetric key (called the *envelope symmetric key*) and an initialization vector (IV), which it uses to encrypt your data.
4. UNLOAD encrypts the envelope symmetric key using your root symmetric key.

5. UNLOAD then stores the encrypted data files in Amazon S3 and stores the encrypted envelope key and IV as object metadata with each file. The encrypted envelope key is stored as object metadata `x-amz-meta-x-amz-key` and the IV is stored as object metadata `x-amz-meta-x-amz-iv`.

For more information about the envelope encryption process, see the [Client-side data encryption with the AWS SDK for Java and Amazon S3](#) article.

To unload encrypted data files, add the root key value to the credentials string and include the ENCRYPTED option. If you use the MANIFEST option, the manifest file is also encrypted.

```
unload ('select venueName, venueCity from venue')
to 's3://amzn-s3-demo-bucket/encrypted/venue_'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
master_symmetric_key '<root_key>'
manifest
encrypted;
```

To unload encrypted data files that are GZIP compressed, include the GZIP option along with the root key value and the ENCRYPTED option.

```
unload ('select venueName, venueCity from venue')
to 's3://amzn-s3-demo-bucket/encrypted/venue_'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
master_symmetric_key '<root_key>'
encrypted gzip;
```

To load the encrypted data files, add the MASTER_SYMMETRIC_KEY parameter with the same root key value and include the ENCRYPTED option.

```
copy venue from 's3://amzn-s3-demo-bucket/encrypted/venue_'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
master_symmetric_key '<root_key>'
encrypted;
```

Unloading data in delimited or fixed-width format

You can unload data in delimited format or fixed-width format. The default output is pipe-delimited (using the '|' character).

The following example specifies a comma as the delimiter:

```
unload ('select * from venue')
to 's3://amzn-s3-demo-bucket/ticket/venue/comma'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter ',';
```

The resulting output files look like this:

```
20,Air Canada Centre,Toronto,ON,0
60,Rexall Place,Edmonton,AB,0
100,U.S. Cellular Field,Chicago,IL,40615
200,Al Hirschfeld Theatre,New York City,NY,0
240,San Jose Repertory Theatre,San Jose,CA,0
300,Kennedy Center Opera House,Washington,DC,0
...
```

To unload the same result set to a tab-delimited file, issue the following command:

```
unload ('select * from venue')
to 's3://amzn-s3-demo-bucket/ticket/venue/tab'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter as '\t';
```

Alternatively, you can use a `FIXEDWIDTH` specification. This specification consists of an identifier for each table column and the width of the column (number of characters). The `UNLOAD` command will fail rather than truncate data, so specify a width that is at least as long as the longest entry for that column. Unloading fixed-width data works similarly to unloading delimited data, except that the resulting output contains no delimiting characters. For example:

```
unload ('select * from venue')
to 's3://amzn-s3-demo-bucket/ticket/venue/fw'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
fixedwidth '0:3,1:100,2:30,3:2,4:6';
```

The fixed-width output looks like this:

```
20 Air Canada Centre      Toronto      ON0
60 Rexall Place          Edmonton    AB0
```

```

100U.S. Cellular Field      Chicago      IL40615
200Al Hirschfeld Theatre  New York CityNY0
240San Jose Repertory TheatreSan Jose      CA0
300Kennedy Center Opera HouseWashington    DC0

```

For more details about FIXEDWIDTH specifications, see the [UNLOAD](#) command.

Reloading unloaded data

To reload the results of an unload operation, you can use a COPY command.

The following example shows a simple case in which the VENUE table is unloaded using a manifest file, truncated, and reloaded.

```

unload ('select * from venue order by venueid')
to 's3://amzn-s3-demo-bucket/ticket/venue/reload_'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
manifest
delimiter '|';

truncate venue;

copy venue
from 's3://amzn-s3-demo-bucket/ticket/venue/reload_manifest'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
manifest
delimiter '|';

```

After it is reloaded, the VENUE table looks like this:

```

select * from venue order by venueid limit 5;

```

venueid	venue name	venue city	venue state	venue seats
1	Toyota Park	Bridgeview	IL	0
2	Columbus Crew Stadium	Columbus	OH	0
3	RFK Stadium	Washington	DC	0
4	CommunityAmerica Ballpark	Kansas City	KS	0
5	Gillette Stadium	Foxborough	MA	68756

(5 rows)

User-defined functions

You can create a custom scalar user-defined function (UDF) using either a SQL SELECT clause or a Python program. The new function is stored in the database and is available for any user with sufficient privileges to run. You run a custom scalar UDF in much the same way as you run existing Amazon Redshift functions.

For Python UDFs, in addition to using the standard Python functionality, you can import your own custom Python modules. For more information, see [Python language support for UDFs](#). Note that Python 3 isn't available for Python UDFs. To get Python 3 support for Amazon Redshift UDFs, use [Scalar Lambda UDFs](#) instead.

You can also create AWS Lambda UDFs that use custom functions defined in Lambda as part of your SQL queries. Lambda UDFs enable you to write complex UDFs and integrate with third-party components. They also can help you overcome some of the limitations of current Python and SQL UDFs. For example, they can help you access network and storage resources and write more full-fledged SQL statements. You can create Lambda UDFs in any of the programming languages supported by Lambda, such as Java, Go, PowerShell, Node.js, C#, Python, and Ruby. Or you can use a custom runtime.

By default, all users can run UDFs. For more information about privileges, see [UDF security and permissions](#).

Topics

- [UDF security and permissions](#)
- [Preventing UDF naming conflicts](#)
- [Scalar SQL UDFs](#)
- [Scalar Python UDFs](#)
- [Scalar Lambda UDFs](#)
- [Use case examples for user-defined functions \(UDFs\)](#)

UDF security and permissions

To create a UDF, you must have permission for usage on language for SQL or plpythonu (Python). By default, USAGE ON LANGUAGE SQL is granted to PUBLIC, but you must explicitly grant USAGE ON LANGUAGE PLPYTHONU to specific users or groups.

To revoke usage for SQL, first revoke usage from PUBLIC. Then grant usage on SQL only to the specific users or groups permitted to create SQL UDFs. The following example revokes usage on SQL from PUBLIC. Then it grants usage to the user group `udf_devs`.

```
revoke usage on language sql from PUBLIC;
grant usage on language sql to group udf_devs;
```

To run a UDF, you must have permission to do so for each function. By default, permission to run new UDFs is granted to PUBLIC. To restrict usage, revoke this permission from PUBLIC for the function. Then grant the privilege to specific individuals or groups.

The following example revokes execution on function `f_py_greater` from PUBLIC. Then it grants usage to the user group `udf_devs`.

```
revoke execute on function f_py_greater(a float, b float) from PUBLIC;
grant execute on function f_py_greater(a float, b float) to group udf_devs;
```

Superusers have all privileges by default.

For more information, see [GRANT](#) and [REVOKE](#).

Preventing UDF naming conflicts

You can avoid potential conflicts and unexpected results considering your UDF naming conventions before implementation. Because function names can be overloaded, they can collide with existing and future Amazon Redshift function names. This topic discusses overloading and presents a strategy for avoiding conflict.

Overloading function names

A function is identified by its name and *signature*, which is the number of input arguments and the data types of the arguments. Two functions in the same schema can have the same name if they have different signatures. In other words, the function names can be *overloaded*.

When you run a query, the query engine determines which function to call based on the number of arguments you provide and the data types of the arguments. You can use overloading to simulate functions with a variable number of arguments, up to the limit allowed by the [CREATE FUNCTION](#) command.

Avoiding conflict with built-in Amazon Redshift functions

We recommend that you name all UDFs using the prefix `f_`. Amazon Redshift reserves the `f_` prefix exclusively for UDFs and by prefixing your UDF names with `f_`, you ensure that your UDF name won't conflict with any existing or future Amazon Redshift built-in SQL function names. For example, by naming a new UDF `f_sum`, you avoid conflict with the Amazon Redshift `SUM` function. Similarly, if you name a new function `f_fibonacci`, you avoid conflict if Amazon Redshift adds a function named `FIBONACCI` in a future release.

You can create a UDF with the same name and signature as an existing Amazon Redshift built-in SQL function without the function name being overloaded if the UDF and the built-in function exist in different schemas. Because built-in functions exist in the system catalog schema, `pg_catalog`, you can create a UDF with the same name in another schema, such as `public` or a user-defined schema. In some cases, you might call a function that is not explicitly qualified with a schema name. If so, Amazon Redshift searches the `pg_catalog` schema first by default. Thus, a built-in function runs before a new UDF with the same name.

You can change this behavior by setting the search path to place `pg_catalog` at the end. If you do so, your UDFs take precedence over built-in functions, but the practice can cause unexpected results. Adopting a unique naming strategy, such as using the reserved prefix `f_`, is a more reliable practice. For more information, see [SET](#) and [search_path](#).

Scalar SQL UDFs

A scalar SQL UDF incorporates a SQL `SELECT` clause that runs when the function is called and returns a single value. The [CREATE FUNCTION](#) command defines the following parameters:

- (Optional) Input arguments. Each argument must have a data type.
- One return data type.
- One SQL `SELECT` clause. In the `SELECT` clause, refer to the input arguments using `$1`, `$2`, and so on, according to the order of the arguments in the function definition.

The input and return data types can be any standard Amazon Redshift data type.

Don't include a `FROM` clause in your `SELECT` clause. Instead, include the `FROM` clause in the SQL statement that calls the SQL UDF.

The `SELECT` clause can't include any of the following types of clauses:

- FROM
- INTO
- WHERE
- GROUP BY
- ORDER BY
- LIMIT

Scalar SQL function example

The following example creates a function that compares two numbers and returns the larger value. For more information, see [CREATE FUNCTION](#).

```
create function f_sql_greater (float, float)
  returns float
stable
as $$
  select case when $1 > $2 then $1
           else $2
  end
$$ language sql;
```

The following query calls the new `f_sql_greater` function to query the `SALES` table and return either `COMMISSION` or 20 percent of `PRICEPAID`, whichever is greater.

```
select f_sql_greater(commission, pricepaid*0.20) from sales;
```

Scalar Python UDFs

A scalar Python UDF incorporates a Python program that runs when the function is called and returns a single value. The [CREATE FUNCTION](#) command defines the following parameters:

- (Optional) Input arguments. Each argument must have a name and a data type.
- One return data type.
- One executable Python program.

The input and return data types can be SMALLINT, INTEGER, BIGINT, DECIMAL, REAL, DOUBLE PRECISION, BOOLEAN, CHAR, VARCHAR, DATE, or TIMESTAMP. In addition, Python UDFs can use the data type ANYELEMENT, which Amazon Redshift automatically converts to a standard data type based on the arguments supplied at runtime. For more information, see [ANYELEMENT data type](#)

When an Amazon Redshift query calls a scalar UDF, the following steps occur at runtime:

1. The function converts the input arguments to Python data types.

For a mapping of Amazon Redshift data types to Python data types, see [Python UDF data types](#).

2. The function runs the Python program, passing the converted input arguments.
3. The Python code returns a single value. The data type of the return value must correspond to the RETURNS data type specified by the function definition.
4. The function converts the Python return value to the specified Amazon Redshift data type, then returns that value to the query.

Note

Python 3 isn't available for Python UDFs. To get Python 3 support for Amazon Redshift UDFs, use [Scalar Lambda UDFs](#) instead.

Scalar Python UDF example

The following example creates a function that compares two numbers and returns the larger value. Note that the indentation of the code between the double dollar signs (\$\$) is a Python requirement. For more information, see [CREATE FUNCTION](#).

```
create function f_py_greater (a float, b float)
  returns float
stable
as $$
  if a > b:
    return a
  return b
$$ language plpythonu;
```

The following query calls the new `f_greater` function to query the `SALES` table and return either `COMMISSION` or 20 percent of `PRICEPAID`, whichever is greater.

```
select f_py_greater (commission, pricepaid*0.20) from sales;
```

Python UDF data types

Python UDFs can use any standard Amazon Redshift data type for the input arguments and the function's return value. In addition to the standard data types, UDFs support the data type `ANYELEMENT`, which Amazon Redshift automatically converts to a standard data type based on the arguments supplied at runtime. Scalar UDFs can return a data type of `ANYELEMENT`. For more information, see [ANYELEMENT data type](#).

During execution, Amazon Redshift converts the arguments from Amazon Redshift data types to Python data types for processing. It then converts the return value from the Python data type to the corresponding Amazon Redshift data type. For more information about Amazon Redshift data types, see [Data types](#).

The following table maps Amazon Redshift data types to Python data types.

Amazon Redshift data type	Python data type
smallint	int
integer	
bigint	
short	
long	
decimal or numeric	decimal
double	float
real	
boolean	bool
char	string

Amazon Redshift data type	Python data type
varchar	
timestamp	datetime

ANYELEMENT data type

ANYELEMENT is a *polymorphic data type*. This means that if a function is declared using ANYELEMENT for an argument's data type, the function can accept any standard Amazon Redshift data type as input for that argument when the function is called. The ANYELEMENT argument is set to the data type actually passed to it when the function is called.

If a function uses multiple ANYELEMENT data types, they must all resolve to the same actual data type when the function is called. All ANYELEMENT argument data types are set to the actual data type of the first argument passed to an ANYELEMENT. For example, a function declared as `f_equal(anyelement, anyelement)` will take any two input values, so long as they are of the same data type.

If the return value of a function is declared as ANYELEMENT, at least one input argument must be ANYELEMENT. The actual data type for the return value is the same as the actual data type supplied for the ANYELEMENT input argument.

Python language support for UDFs

You can create a custom UDF based on the Python programming language. The [Python 2.7 standard library](#) is available for use in UDFs, with the exception of the following modules:

- ScrolledText
- Tix
- Tkinter
- tk
- turtle
- smtpd

In addition to the Python Standard Library, the following modules are part of the Amazon Redshift implementation:

- [numpy 1.8.2](#)
- [pandas 0.14.1](#)
- [python-dateutil 2.2](#)
- [pytz 2014.7](#)
- [scipy 0.12.1](#)
- [six 1.3.0](#)
- [wsgiref 0.1.2](#)

You can also import your own custom Python modules and make them available for use in UDFs by executing a [CREATE LIBRARY](#) command. For more information, see [Example: Importing custom Python library modules](#).

 **Important**

Amazon Redshift blocks all network access and write access to the file system through UDFs.

 **Note**

Python 3 isn't available for Python UDFs. To get Python 3 support for Amazon Redshift UDFs, use [Scalar Lambda UDFs](#) instead.

Example: Importing custom Python library modules

You define scalar functions using Python language syntax. You can use the Python Standard Library modules and Amazon Redshift preinstalled modules. You can also create your own custom Python library modules and import the libraries into your clusters, or use existing libraries from Python or third parties.

You cannot create a library that contains a module with the same name as a Python Standard Library module or an Amazon Redshift preinstalled Python module. If an existing user-installed library uses the same Python package as a library you create, you must drop the existing library before installing the new library.

You must be a superuser or have `USAGE ON LANGUAGE plpythonu` privilege to install custom libraries; however, any user with sufficient privileges to create functions can use the installed libraries. You can query the [PG_LIBRARY](#) system catalog to view information about the libraries installed on your cluster.

Importing a custom Python module into your cluster

This section provides an example of importing a custom Python module into your cluster. To perform the steps in this section, you must have an Amazon S3 bucket, where you upload the library package. You then install the package in your cluster. For more information about creating buckets, go to [Creating a bucket](#) in the *Amazon Simple Storage Service User Guide*.

In this example, let's suppose that you create UDFs to work with positions and distances in your data. Connect to your Amazon Redshift cluster from a SQL client tool, and run the following commands to create the functions.

```
CREATE FUNCTION f_distance (x1 float, y1 float, x2 float, y2 float) RETURNS float
IMMUTABLE as $$
    def distance(x1, y1, x2, y2):
        import math
        return math.sqrt((y2 - y1) ** 2 + (x2 - x1) ** 2)

    return distance(x1, y1, x2, y2)
$$ LANGUAGE plpythonu;

CREATE FUNCTION f_within_range (x1 float, y1 float, x2 float, y2 float) RETURNS bool
IMMUTABLE as $$
    def distance(x1, y1, x2, y2):
        import math
        return math.sqrt((y2 - y1) ** 2 + (x2 - x1) ** 2)

    return distance(x1, y1, x2, y2) < 20
$$ LANGUAGE plpythonu;
```

Note that a few lines of code are duplicated in the previous functions. This duplication is necessary because a UDF cannot reference the contents of another UDF, and both functions require the same functionality. However, instead of duplicating code in multiple functions, you can create a custom library and configure your functions to use it.

To do so, first create the library package by following these steps:

1. Create a folder named **geometry**. This folder is the top level package of the library.

2. In the **geometry** folder, create a file named `__init__.py`. Note that the file name contains two double underscore characters. This file indicates to Python that the package can be initialized.
3. Also in the **geometry** folder, create a folder named **trig**. This folder is the subpackage of the library.
4. In the **trig** folder, create another file named `__init__.py` and a file named `line.py`. In this folder, `__init__.py` indicates to Python that the subpackage can be initialized and that `line.py` is the file that contains library code.

Your folder and file structure should be the same as the following:

```
geometry/  
  __init__.py  
  trig/  
    __init__.py  
    line.py
```

For more information about package structure, go to [Modules](#) in the Python tutorial on the Python website.

5. The following code contains a class and member functions for the library. Copy and paste it into `line.py`.

```
class LineSegment:  
    def __init__(self, x1, y1, x2, y2):  
        self.x1 = x1  
        self.y1 = y1  
        self.x2 = x2  
        self.y2 = y2  
    def angle(self):  
        import math  
        return math.atan2(self.y2 - self.y1, self.x2 - self.x1)  
    def distance(self):  
        import math  
        return math.sqrt((self.y2 - self.y1) ** 2 + (self.x2 - self.x1) ** 2)
```

After you have created the package, do the following to prepare the package and upload it to Amazon S3.

1. Compress the contents of the **geometry** folder into a .zip file named **geometry.zip**. Do not include the **geometry** folder itself; only include the contents of the folder as shown following:

```
geometry.zip
  __init__.py
  trig/
    __init__.py
    line.py
```

2. Upload **geometry.zip** to your Amazon S3 bucket.

Important

If the Amazon S3 bucket does not reside in the same region as your Amazon Redshift cluster, you must use the REGION option to specify the region in which the data is located. For more information, see [CREATE LIBRARY](#).

3. From your SQL client tool, run the following command to install the library. Replace *<bucket_name>* with the name of your bucket, and replace *<access key id>* and *<secret key>* with an access key and secret access key from your AWS Identity and Access Management (IAM) user credentials.

```
CREATE LIBRARY geometry LANGUAGE plpythonu FROM 's3://<bucket_name>/geometry.zip'
  CREDENTIALS 'aws_access_key_id=<access key id>;aws_secret_access_key=<secret key>';
```

After you install the library in your cluster, you need to configure your functions to use the library. To do this, run the following commands.

```
CREATE OR REPLACE FUNCTION f_distance (x1 float, y1 float, x2 float, y2 float) RETURNS
float IMMUTABLE as $$
  from trig.line import LineSegment

  return LineSegment(x1, y1, x2, y2).distance()
$$ LANGUAGE plpythonu;

CREATE OR REPLACE FUNCTION f_within_range (x1 float, y1 float, x2 float, y2 float)
RETURNS bool IMMUTABLE as $$
  from trig.line import LineSegment

  return LineSegment(x1, y1, x2, y2).distance() < 20
```

```
$$ LANGUAGE plpythonu;
```

In the preceding commands, `import trig/line` eliminates the duplicated code from the original functions in this section. You can reuse the functionality provided by this library in multiple UDFs. Note that to import the module, you only need to specify the path to the subpackage and module name (`trig/line`).

Python UDF constraints

Within the constraints listed in this topic, you can use UDFs anywhere you use the Amazon Redshift built-in scalar functions. For more information, see [SQL functions reference](#).

Amazon Redshift Python UDFs have the following constraints:

- Python UDFs cannot access the network or read or write to the file system.
- The total size of user-installed Python libraries cannot exceed 100 MB.
- Amazon Redshift can only run one Python UDF at a time for provisioned clusters using automatic workload management (WLM) and for serverless workgroups. If you try to run more than one UDF concurrently, Amazon Redshift queues the remaining Python UDFs to run in the workload management queues. SQL UDFs don't have a concurrency limit when using automatic WLM.
- When using manual WLM for provisioned clusters, the number of Python UDFs that can run concurrently per cluster is limited to one-fourth of the cluster's total concurrency level. For example, a provisioned cluster with a concurrency of 15 can run a maximum of three concurrent Python UDFs.
- When using Python UDFs, Amazon Redshift doesn't support the SUPER and HLLSKETCH data types.

Logging errors and warnings in Python UDFs

You can use the Python logging module to create user-defined error and warning messages in your UDFs. Following query execution, you can query the [SVL_UDF_LOG](#) system view to retrieve logged messages.

Note

UDF logging consumes cluster resources and might affect system performance. We recommend implementing logging only for development and troubleshooting.

During query execution, the log handler writes messages to the SVL_UDF_LOG system view, along with the corresponding function name, node, and slice. The log handler writes one row to the SVL_UDF_LOG per message, per slice. Messages are truncated to 4096 bytes. The UDF log is limited to 500 rows per slice. When the log is full, the log handler discards older messages and adds a warning message to SVL_UDF_LOG.

Note

The Amazon Redshift UDF log handler escapes newlines (\n), pipe (|) characters, and backslash (\) characters with a backslash (\) character.

By default, the UDF log level is set to WARNING. Messages with a log level of WARNING, ERROR, and CRITICAL are logged. Messages with lower severity INFO, DEBUG, and NOTSET are ignored. To set the UDF log level, use the Python logger method. For example, the following sets the log level to INFO.

```
logger.setLevel(logging.INFO)
```

For more information about using the Python logging module, see [Logging facility for Python](#) in the Python documentation.

The following example creates a function named f_pyerror that imports the Python logging module, instantiates the logger, and logs an error.

```
CREATE OR REPLACE FUNCTION f_pyerror()  
RETURNS INTEGER  
VOLATILE AS  
$$  
import logging  
  
logger = logging.getLogger()  
logger.setLevel(logging.INFO)  
logger.info('Your info message here')  
return 0  
$$ language plpythonu;
```

The following example queries SVL_UDF_LOG to view the message logged in the previous example.

```
select funcname, node, slice, trim(message) as message
```

```
from svl_udf_log;

  funcname | query | node | slice | message
-----+-----+-----+-----+-----
  f_pyerror | 12345 |    1 |     1 | Your info message here
```

Scalar Lambda UDFs

Amazon Redshift can use custom functions defined in AWS Lambda as part of SQL queries. You can write scalar Lambda UDFs in any programming languages supported by Lambda, such as Java, Go, PowerShell, Node.js, C#, Python, and Ruby. Or you can use a custom runtime.

The [CREATE EXTERNAL FUNCTION](#) command creates the following parameters:

- (Optional) A list of arguments with data type.
- One return data type.
- One function name of the external function that is called by Amazon Redshift.
- One IAM role that the Amazon Redshift cluster is authorized to assume and call to Lambda.
- One Lambda function name that the Lambda UDF invokes.

For information about `CREATE EXTERNAL FUNCTION`, see [CREATE EXTERNAL FUNCTION](#).

The input and return data types for this function can be any standard Amazon Redshift data type.

Amazon Redshift ensures that the external function can send and receive batched arguments and results.

Lambda UDFs are defined and managed in Lambda, and you can control the access privileges to invoke these UDFs in Amazon Redshift. You can invoke multiple Lambda functions in the same query or invoke the same function multiple times.

Use Lambda UDFs in any clauses of the SQL statements where scalar functions are supported. You can also use Lambda UDFs in any SQL statement such as `SELECT`, `UPDATE`, `INSERT`, or `DELETE`.

Note

Using Lambda UDFs can incur additional charges from the Lambda service. Whether it does so depends on factors such as the numbers of Lambda requests (UDF invocations) and the total duration of the Lambda program execution. However, there is no additional charge

to use Lambda UDFs in Amazon Redshift. For information about AWS Lambda pricing, see [AWS Lambda Pricing](#).

The number of Lambda requests varies depending on the specific SQL statement clause where the Lambda UDF is used. For example, suppose the function is used in a WHERE clause such as the following.

```
SELECT a, b FROM t1 WHERE lambda_multiply(a, b) = 64; SELECT a, b  
FROM t1 WHERE a*b = lambda_multiply(2, 32)
```

In this case, Amazon Redshift calls the first SELECT statement for each and calls the second SELECT statement only once.

However, using a UDF in the projection part of the query might only invoke the Lambda function once for every qualified or aggregated row in the result set.

UDF security and permissions

To create a Lambda UDF, make sure that you have permissions for usage on the LANGUAGE EXFUNC. You must explicitly grant USAGE ON LANGUAGE EXFUNC or revoke USAGE ON LANGUAGE EXFUNC to specific users, groups, or public.

The following example grants usage on EXFUNC to PUBLIC.

```
grant usage on language exfunc to PUBLIC;
```

The following example revokes usage on exfunc from PUBLIC and then grants usage to the user group lambda_udf_devs.

```
revoke usage on language exfunc from PUBLIC;  
grant usage on language exfunc to group lambda_udf_devs;
```

To run a Lambda UDF, make sure that you have permission for each function called. By default, permission to run new Lambda UDFs is granted to PUBLIC. To restrict usage, revoke this permission from PUBLIC for the function. Then, grant the privilege to specific users or groups.

The following example revokes execution on the function exfunc_sum from PUBLIC. Then, it grants usage to the user group lambda_udf_devs.

```
revoke execute on function exfunc_sum(int, int) from PUBLIC;  
grant execute on function exfunc_sum(int, int) to group lambda_udf_devs;
```

Superusers have all privileges by default.

For more information about granting and revoking privileges, see [GRANT](#) and [REVOKE](#).

Configuring the authorization parameter for Lambda UDFs

The CREATE EXTERNAL FUNCTION command requires authorization to invoke Lambda functions in AWS Lambda. To start authorization, specify an AWS Identity and Access Management (IAM) role when you run the CREATE EXTERNAL FUNCTION command. For more information about IAM roles, see [IAM roles](#) in the *IAM User Guide*.

If there is an existing IAM role with permissions to invoke Lambda functions attached to your cluster, then you can substitute your role Amazon Resource Name (ARN) in the IAM_ROLE parameter for the command. Following sections describe the steps for using an IAM role in the CREATE EXTERNAL FUNCTION command.

Creating an IAM role for Lambda

The IAM role requires permission to invoke Lambda functions. While creating the IAM role, provide the permission in one of the following ways:

- Attach the `AWSLambdaRole` policy on the **Attach permissions policy** page while creating an IAM role. The `AWSLambdaRole` policy grants permissions to invoke Lambda functions which is the minimal requirement. For more information and other policies, see [Identity-based IAM policies for AWS Lambda](#) in the *AWS Lambda Developer Guide*.
- Create your own custom policy to attach to your IAM role with the `lambda:InvokeFunction` permission of either all resources or a particular Lambda function with the ARN of that function. For more information on how to create a policy, see [Creating IAM policies](#) in the *IAM User Guide*.

The following example policy enables invoking Lambda on a particular Lambda function.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "Invoke",
      "Effect": "Allow",
      "Action": [
        "lambda:InvokeFunction"
      ]
    }
  ]
}
```

```
        "Resource": "arn:aws:lambda:us-west-2:123456789012:function:my-function"
    }
  ]
}
```

For more information on resources for Lambda functions, see [Resources and conditions for Lambda actions](#) in the *IAM API Reference*.

After creating your custom policy with the required permissions, you can attach your policy to the IAM role on the **Attach permissions policy** page while creating an IAM role.

For steps to create an IAM role, see [Authorizing Amazon Redshift to access other AWS services on your behalf](#) in the *Amazon Redshift Management Guide*.

If you don't want to create a new IAM role, you can add the permissions mentioned previously to your existing IAM role.

Associating an IAM role with the cluster

Attach the IAM role to your cluster. You can add a role to a cluster or view the roles associated with a cluster by using the Amazon Redshift Management Console, CLI, or API. For more information, see [Associating an IAM Role With a Cluster](#) in the *Amazon Redshift Management Guide*.

Including the IAM role in the command

Include the IAM role ARN in the CREATE EXTERNAL FUNCTION command. When you create an IAM role, IAM returns an Amazon Resource Name (ARN) for the role. To specify an IAM role, provide the role ARN with the IAM_ROLE parameter. The following shows the syntax for the IAM_ROLE parameter.

```
IAM_ROLE 'arn:aws:iam::aws-account-id:role/role-name'
```

To invoke Lambda functions which reside in other accounts within the same Region, see [Chaining IAM roles in Amazon Redshift](#).

Using the JSON interface between Amazon Redshift and AWS Lambda

Amazon Redshift uses a common interface for all Lambda functions that Amazon Redshift communicates to.

The following table shows the list of input fields that the designated Lambda functions that you can expect for the JSON payload.

Field name	Description	Value range
request_id	A universally unique identifier (UUID) that uniquely identifies each invoke request.	A valid UUID.
cluster	The full Amazon Resource Name (ARN) of the cluster.	A valid cluster ARN.
user	The name of the user that makes the call.	A valid user name.
database	The name of the database that the query is running on.	A valid database name.
external_function	The fully qualified name of the external function that makes the call.	A valid fully qualified function name.
query_id	The query ID of the query that is making the call.	A valid query ID.
num_records	The number of arguments in the payload.	A value of 1 - 2 ⁶⁴ .
arguments	The data payload in the specified format.	The data in array format must be a JSON array. Each element is a record that is an array if the number of arguments is larger than 1. By using an array, Amazon

Field name	Description	Value range
		Redshift preserves the order of the records in the payload.

The order of the JSON array determines the order of batch processing. The Lambda function must process the arguments iteratively and produce the exact number of records. The following is an example of a payload.

```
{
  "request_id" : "23FF1F97-F28A-44AA-AB67-266ED976BF40",
  "cluster" : "arn:aws:redshift:xxxx",
  "user" : "adminuser",
  "database" : "db1",
  "external_function": "public.foo",
  "query_id" : 5678234,
  "num_records" : 4,
  "arguments" : [
    [ 1, 2 ],
    [ 3, null],
    null,
    [ 4, 6]
  ]
}
```

The return output of the Lambda function contains the following fields.

Field name	Description	Value range
success	The indication of success or failure for the function.	A value of "true" or "false".
error_msg	The error message if the success value is "false" (if the function fails); otherwise, this field is ignored.	A valid message.

Field name	Description	Value range
num_records	The number of records in the payload.	A value of 1 - 2^64.
results	The results of the call in the specified format.	N/A

The following is an example of the Lambda function output.

```
{
  "success": true, // true indicates the call succeeded
  "error_msg" : "my function isn't working", // shall only exist when success != true
  "num_records": 4, // number of records in this payload
  "results" : [
    1,
    4,
    null,
    7
  ]
}
```

When you call Lambda functions from SQL queries, Amazon Redshift ensures the security of the connection with the following considerations:

- GRANT and REVOKE permissions. For more information about UDF security and permissions, see [UDF security and permissions](#).
- Amazon Redshift only submits the minimum set of data to the designated Lambda function.
- Amazon Redshift only calls the designated Lambda function with the designated IAM role.

Use case examples for user-defined functions (UDFs)

You can use user-defined functions to solve business problems by integrating Amazon Redshift with other components. Following are some examples of how others have used UDFs for their use cases:

- [Accessing external components using Amazon Redshift Lambda UDFs](#) – describes how Amazon Redshift Lambda UDFs work and walks through creating a Lambda UDF.

- [Translate and analyze text using SQL functions with Amazon Redshift, Amazon Translate, and Amazon Comprehend](#) – provides prebuilt Amazon Redshift Lambda UDFs that you can install with a few clicks to translate, redact, and analyze text fields.
- [Access Amazon Location Service from Amazon Redshift](#) – describes how to use Amazon Redshift Lambda UDFs to integrate with Amazon Location Service.
- [Data Tokenization with Amazon Redshift and Protegrity](#) – describes how to integrate Amazon Redshift Lambda UDFs with the Protegrity Serverless product.
- [Amazon Redshift UDFs](#) – a collection of Amazon Redshift SQL, Lambda, and Python UDFs.

Creating stored procedures in Amazon Redshift

This topic describes how to create and use stored procedures in Amazon Redshift. A stored procedure is a collection of SQL statements that multiple programs can use.

You can define an Amazon Redshift stored procedure using the PostgreSQL procedural language PL/pgSQL to perform a set of SQL queries and logical operations. The procedure is stored in the database and available for any user with sufficient database privileges.

Unlike a user-defined function (UDF), a stored procedure can incorporate data definition language (DDL) and data manipulation language (DML) in addition to SELECT queries. A stored procedure doesn't need to return a value. You can use procedural language, including looping and conditional expressions, to control logical flow.

For details about SQL commands to create and manage stored procedures, see the following command topics:

- [CREATE PROCEDURE](#)
- [ALTER PROCEDURE](#)
- [DROP PROCEDURE](#)
- [SHOW PROCEDURE](#)
- [CALL](#)
- [GRANT](#)
- [REVOKE](#)
- [ALTER DEFAULT PRIVILEGES](#)

Topics

- [Overview of stored procedures in Amazon Redshift](#)
- [PL/pgSQL language reference](#)

Overview of stored procedures in Amazon Redshift

This topic describes details about the purpose and use of stored procedures.

Stored procedures are commonly used to encapsulate logic for data transformation, data validation, and business-specific logic. By combining multiple SQL steps into a stored procedure, you can reduce round trips between your applications and the database.

For fine-grained access control, you can create stored procedures to perform functions without giving a user access to the underlying tables. For example, only the owner or a superuser can truncate a table, and a user needs write privileges to insert data into a table. Instead of granting a user privileges on the underlying tables, you can create a stored procedure that performs the task. You then give the user privileges to run the stored procedure.

A stored procedure with the `DEFINER` security attribute runs with the privileges of the stored procedure's owner. By default, a stored procedure has `INVOKER` security, which means the procedure uses the privileges of the user that calls the procedure.

To create a stored procedure, use the [CREATE PROCEDURE](#) command. To run a procedure, use the [CALL](#) command. Examples follow later in this section.

Note

Some clients might display the following error when creating an Amazon Redshift stored procedure.

```
ERROR: 42601: [Amazon](500310) unterminated dollar-quoted string at or near "$$
```

This error occurs due to the inability of the client to correctly parse the `CREATE PROCEDURE` statement with semicolons delimiting statements and with dollar sign (\$) quoting. This results in only a part of the statement sent to the Amazon Redshift server. You can often work around this error by using the `Run as batch` or `Execute selected` option of the client.

For example, when using an Aginity client, use the `Run entire script as batch` option. When you use SQL Workbench/J, we recommend version 124. When you use SQL Workbench/J version 125, consider specifying an alternate delimiter as a workaround. `CREATE PROCEDURE` contains SQL statements delimited with a semicolon (;). Defining an alternate delimiter such as a slash (/) and placing it at the end of the `CREATE PROCEDURE` statement sends the statement to the Amazon Redshift server for processing. Following is an example.

```
CREATE OR REPLACE PROCEDURE test()  
AS $$
```

```
BEGIN
  SELECT 1 a;
END;
$$
LANGUAGE plpgsql
;
```

For more information, see [Alternate delimiter](#) in the SQL Workbench/J documentation. Or use a client with better support for parsing CREATE PROCEDURE statements, such as the [query editor in the Amazon Redshift console](#) or TablePlus.

- [Trapping errors](#)
- [Logging stored procedures](#)
- [Stored procedure limitations](#)

The following example shows a procedure with no output arguments. By default, arguments are input (IN) arguments.

```
CREATE OR REPLACE PROCEDURE test_sp1(f1 int, f2 varchar)
AS $$
BEGIN
  RAISE INFO 'f1 = %, f2 = %', f1, f2;
END;
$$ LANGUAGE plpgsql;

call test_sp1(5, 'abc');
INFO: f1 = 5, f2 = abc
CALL
```

Note

When you write stored procedures, we recommend a best practice for securing sensitive values:

Don't hardcode any sensitive information in stored procedure logic. For example, don't assign a user password in a CREATE USER statement in the body of a stored procedure. This poses a security risk, because hardcoded values can be recorded as schema metadata in catalog tables. Instead, pass sensitive values, such as passwords, as arguments to the stored procedure, by means of parameters.

For more information about stored procedures, see [CREATE PROCEDURE](#) and [Creating stored procedures in Amazon Redshift](#). For more information about catalog tables, see [System catalog tables](#).

The following example shows a procedure with output arguments. Arguments are input (IN), input and output (INOUT), and output (OUT).

```
CREATE OR REPLACE PROCEDURE test_sp2(f1 IN int, f2 INOUT varchar(256), out_var OUT
  varchar(256))
AS $$
DECLARE
  loop_var int;
BEGIN
  IF f1 is null OR f2 is null THEN
    RAISE EXCEPTION 'input cannot be null';
  END IF;
  DROP TABLE if exists my_etl;
  CREATE TEMP TABLE my_etl(a int, b varchar);
  FOR loop_var IN 1..f1 LOOP
    insert into my_etl values (loop_var, f2);
    f2 := f2 || '+' || f2;
  END LOOP;
  SELECT INTO out_var count(*) from my_etl;
END;
$$ LANGUAGE plpgsql;

call test_sp2(2, '2019');

      f2          | column2
-----+-----
```

```
2019+2019+2019+2019 | 2
(1 row)
```

Naming stored procedures

This topic describes details about stored procedure names.

If you define a procedure with the same name and different input argument data types or signature, you create a new procedure. As a result, the procedure name is overloaded. For more information, see [Overloading procedure names](#). Amazon Redshift doesn't enable procedure overloading based on output arguments. You can't have two procedures with the same name and input argument data types but different output argument types.

The owner or a superuser can replace the body of a stored procedure with a new one with the same signature. To change the signature or return types of a stored procedure, drop the stored procedure and recreate it. For more information, see [DROP PROCEDURE](#) and [CREATE PROCEDURE](#).

You can avoid potential conflicts and unexpected results by considering your naming conventions for stored procedures before implementing them. Because you can overload procedure names, they can collide with existing and future Amazon Redshift procedure names.

Overloading procedure names

A procedure is identified by its name and signature, which is the number of input arguments and the data types of the arguments. Two procedures in the same schema can have the same name if they have different signatures. In other words, you can overload procedure names.

When you run a procedure, the query engine determines which procedure to call based on the number of arguments that you provide and the data types of the arguments. You can use overloading to simulate procedures with a variable number of arguments, up to the limit allowed by the CREATE PROCEDURE command. For more information, see [CREATE PROCEDURE](#).

Preventing naming conflicts

We recommend that you name all procedures using the prefix `sp_`. Amazon Redshift reserves the `sp_` prefix exclusively for stored procedures. By prefixing your procedure names with `sp_`, you make sure that your procedure name won't conflict with any existing or future Amazon Redshift procedure name.

Security and privileges for stored procedures

This topic describes the database credentials needed to create and run stored procedures.

By default, all users have privileges to create a procedure. To create a procedure, you must have `USAGE` privilege on the language `PL/pgSQL`, which is granted to `PUBLIC` by default. Only superusers and owners have the privilege to call a procedure by default. Superusers can run `REVOKE USAGE` on `PL/pgSQL` from a user if they want to prevent the user from creating a stored procedure.

To call a procedure, you must be granted `EXECUTE` privilege on the procedure. By default, `EXECUTE` privilege for new procedures is granted to the procedure owner and superusers. For more information, see [GRANT](#).

The user creating a procedure is the owner by default. The owner has `CREATE`, `DROP`, and `EXECUTE` privileges on the procedure by default. Superusers have all privileges.

The `SECURITY` attribute controls a procedure's privileges to access database objects. When you create a stored procedure, you can set the `SECURITY` attribute to either `DEFINER` or `INVOKER`. If you specify `SECURITY INVOKER`, the procedure uses the privileges of the user invoking the procedure. If you specify `SECURITY DEFINER`, the procedure uses the privileges of the owner of the procedure. `INVOKER` is the default.

Because a `SECURITY DEFINER` procedure runs with the privileges of the user that owns it, you must make sure that the procedure can't be misused. To make sure that `SECURITY DEFINER` procedures can't be misused, do the following:

- Grant `EXECUTE` on `SECURITY DEFINER` procedures to specific users, and not to `PUBLIC`.
- Qualify all database objects that the procedure must access with the schema names. For example, use `myschema.mytable` instead of just `mytable`.
- If you can't qualify an object name by its schema, set `search_path` when creating the procedure by using the `SET` option. Set `search_path` to exclude any schemas that are writable by untrusted users. This approach prevents any callers of this procedure from creating objects (for example, tables or views) that mask objects intended to be used by the procedure. For more information about the `SET` option, see [CREATE PROCEDURE](#).

The following example sets `search_path` to `admin` to ensure that the `user_creds` table is accessed from the `admin` schema and not from `public` or any other schema in the caller's `search_path`.

```
CREATE OR REPLACE PROCEDURE sp_get_credentials(userid int, o_creds OUT varchar)
AS $$
BEGIN
    SELECT creds INTO o_creds
    FROM user_creds
    WHERE user_id = $1;
END;
$$ LANGUAGE plpgsql
SECURITY DEFINER
-- Set a secure search_path
SET search_path = admin;
```

Returning a result set from a stored procedure

This topic describes how stored procedures return data.

You can return a result set using a cursor or a temp table.

Returning a cursor

To return a cursor, create a procedure with an `INOUT` argument defined with a `refcursor` data type. When you call the procedure, give the cursor a name. Then you can fetch the results from the cursor by name.

The following example creates a procedure named `get_result_set` with an `INOUT` argument named `rs_out` using the `refcursor` data type. The procedure opens the cursor using a `SELECT` statement.

```
CREATE OR REPLACE PROCEDURE get_result_set (param IN integer, rs_out INOUT refcursor)
AS $$
BEGIN
    OPEN rs_out FOR SELECT * FROM fact_tbl where id >= param;
END;
$$ LANGUAGE plpgsql;
```

The following `CALL` command opens the cursor with the name `mycursor`. Use cursors only within transactions.

```
BEGIN;  
CALL get_result_set(1, 'mycursor');
```

After the cursor is opened, you can fetch from the cursor, as the following example shows.

```
FETCH ALL FROM mycursor;
```

id	secondary_id	name
1	1	Joe
1	2	Ed
2	1	Mary
1	3	Mike

(4 rows)

In the end, the transaction is either committed or rolled back.

```
COMMIT;
```

A cursor returned by a stored procedure is subject to the same constraints and performance considerations as described in `DECLARE CURSOR`. For more information, see [Cursor constraints](#).

The following example shows the calling of the `get_result_set` stored procedure using a `refcursor` data type from JDBC. The literal `'mycursor'` (the name of the cursor) is passed to the `prepareStatement`. Then the results are fetched from the `ResultSet`.

```
static void refcursor_example(Connection conn) throws SQLException {  
    conn.setAutoCommit(false);  
    PreparedStatement proc = conn.prepareStatement("CALL get_result_set(1,  
'mycursor')");  
    proc.execute();  
    ResultSet rs = statement.executeQuery("fetch all from mycursor");  
    while (rs.next()) {  
        int n = rs.getInt(1);  
        System.out.println("n " + n);  
    }  
}
```

Using a temp table

To return results, you can return a handle to a temp table containing result rows. The client can supply a name as a parameter to the stored procedure. Inside the stored procedure, dynamic SQL can be used to operate on the temp table. The following shows an example.

```
CREATE PROCEDURE get_result_set(param IN integer, tmp_name INOUT varchar(256)) as $$
DECLARE
    row record;
BEGIN
    EXECUTE 'drop table if exists ' || tmp_name;
    EXECUTE 'create temp table ' || tmp_name || ' as select * from fact_tbl where id <= '
    || param;
END;
$$ LANGUAGE plpgsql;

CALL get_result_set(2, 'myresult');
    tmp_name
-----
    myresult
(1 row)

SELECT * from myresult;
 id | secondary_id | name
-----+-----+-----
  1 |              | Joe
  2 |              | Mary
  1 |              | Ed
  1 |              | Mike
(4 rows)
```

Managing transactions

You can create a stored procedure with default transaction management behavior or nonatomic behavior.

Default mode stored procedure transaction management

The default transaction mode automatic commit behavior causes each SQL command that runs separately to commit individually. A call to a stored procedure is treated as a single SQL command. The SQL statements inside a procedure behave as if they are in a transaction block that implicitly

begins when the call starts and ends when the call finishes. A nested call to another procedure is treated like any other SQL statement and operates within the context of the same transaction as the caller. For more information about automatic commit behavior, see [Serializable isolation](#).

However, suppose that you call a stored procedure from within a user specified transaction block (defined by BEGIN...COMMIT). In this case, all statements in the stored procedure run in the context of the user-specified transaction. The procedure doesn't commit implicitly on exit. The caller controls the procedure commit or rollback.

If any error is encountered while running a stored procedure, all changes made in the current transaction are rolled back.

You can use the following transaction control statements in a stored procedure:

- COMMIT – commits all work done in the current transaction and implicitly begins a new transaction. For more information, see [COMMIT](#).
- ROLLBACK – rolls back the work done in the current transaction and implicitly begins a new transaction. For more information, see [ROLLBACK](#).

TRUNCATE is another statement that you can issue from within a stored procedure and influences transaction management. In Amazon Redshift, TRUNCATE issues a commit implicitly. This behavior stays the same in the context of stored procedures. When a TRUNCATE statement is issued from within a stored procedure, it commits the current transaction and begins a new one. For more information, see [TRUNCATE](#).

All statements that follow a COMMIT, ROLLBACK, or TRUNCATE statement run in the context of a new transaction. They do so until a COMMIT, ROLLBACK, or TRUNCATE statement is encountered or the stored procedure exits.

When you use a COMMIT, ROLLBACK, or TRUNCATE statement from within a stored procedure, the following constraints apply:

- If the stored procedure is called from within a transaction block, it can't issue a COMMIT, ROLLBACK, or TRUNCATE statement. This restriction applies within the stored procedure's own body and within any nested procedure call.
- If the stored procedure is created with SET config options, it can't issue a COMMIT, ROLLBACK, or TRUNCATE statement. This restriction applies within the stored procedure's own body and within any nested procedure call.

- Any cursor that is open (explicitly or implicitly) is closed automatically when a COMMIT, ROLLBACK, or TRUNCATE statement is processed. For constraints on explicit and implicit cursors, see [Stored procedure limitations](#).

Additionally, you can't run COMMIT or ROLLBACK using dynamic SQL. However, you can run TRUNCATE using dynamic SQL. For more information, see [Dynamic SQL](#).

When working with stored procedures, consider that the BEGIN and END statements in PL/pgSQL are only for grouping. They don't start or end a transaction. For more information, see [Block](#).

The following example demonstrates transaction behavior when calling a stored procedure from within an explicit transaction block. The two insert statements issued from outside the stored procedure and the one from within it are all part of the same transaction (3382). The transaction is committed when the user issues the explicit commit.

```
CREATE OR REPLACE PROCEDURE sp_insert_table_a(a int) LANGUAGE plpgsql
AS $$
BEGIN
  INSERT INTO test_table_a values (a);
END;
$$;

Begin;
  insert into test_table_a values (1);
  Call sp_insert_table_a(2);
  insert into test_table_a values (3);
Commit;

select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
```

userid	xid	pid	type	stmt_text
103	3382	599	UTILITY	Begin;
103	3382	599	QUERY	insert into test_table_a values (1);
103	3382	599	UTILITY	Call sp_insert_table_a(2);
103	3382	599	QUERY	INSERT INTO test_table_a values (\$1)
103	3382	599	QUERY	insert into test_table_a values (3);
103	3382	599	UTILITY	COMMIT

In contrast, take an example when the same statements are issued from outside of an explicit transaction block and the session has autocommit set to ON. In this case, each statement runs in its own transaction.

```
insert into test_table_a values (1);
Call sp_insert_table_a(2);
insert into test_table_a values (3);

select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
```

userid	xid	pid	type	stmt_text
103	3388	599	QUERY	insert into test_table_a values (1);
103	3388	599	UTILITY	COMMIT
103	3389	599	UTILITY	Call sp_insert_table_a(2);
103	3389	599	QUERY	INSERT INTO test_table_a values (\$1)
103	3389	599	UTILITY	COMMIT
103	3390	599	QUERY	insert into test_table_a values (3);
103	3390	599	UTILITY	COMMIT

The following example issues a TRUNCATE statement after inserting into test_table_a. The TRUNCATE statement issues an implicit commit that commits the current transaction (3335) and starts a new one (3336). The new transaction is committed when the procedure exits.

```
CREATE OR REPLACE PROCEDURE sp_truncate_proc(a int, b int) LANGUAGE plpgsql
AS $$
BEGIN
  INSERT INTO test_table_a values (a);
  TRUNCATE test_table_b;
  INSERT INTO test_table_b values (b);
END;
$$;

Call sp_truncate_proc(1,2);

select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
```

```

userid | xid  | pid  | type  |
-----+-----+-----+-----+
stmt_text
-----+-----+-----+-----+
103 | 3335 | 23636 | UTILITY | Call sp_truncate_proc(1,2);
103 | 3335 | 23636 | QUERY   | INSERT INTO test_table_a values ( $1 )
103 | 3335 | 23636 | UTILITY | TRUNCATE test_table_b
103 | 3335 | 23636 | UTILITY | COMMIT
103 | 3336 | 23636 | QUERY   | INSERT INTO test_table_b values ( $1 )
103 | 3336 | 23636 | UTILITY | COMMIT

```

The following example issues a TRUNCATE from a nested call. The TRUNCATE commits all work done so far in the outer and inner procedures in a transaction (3344). It starts a new transaction (3345). The new transaction is committed when the outer procedure exits.

```

CREATE OR REPLACE PROCEDURE sp_inner(c int, d int) LANGUAGE plpgsql
AS $$
BEGIN
  INSERT INTO inner_table values (c);
  TRUNCATE outer_table;
  INSERT INTO inner_table values (d);
END;
$$;

CREATE OR REPLACE PROCEDURE sp_outer(a int, b int, c int, d int) LANGUAGE plpgsql
AS $$
BEGIN
  INSERT INTO outer_table values (a);
  Call sp_inner(c, d);
  INSERT INTO outer_table values (b);
END;
$$;

Call sp_outer(1, 2, 3, 4);

select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;

userid | xid  | pid  | type  |
-----+-----+-----+-----+
stmt_text

```

```

-----+-----+-----+-----
+-----+-----+-----+-----+
103 | 3344 | 23636 | UTILITY | Call sp_outer(1, 2, 3, 4);
103 | 3344 | 23636 | QUERY   | INSERT INTO outer_table values ( $1 )
103 | 3344 | 23636 | UTILITY | CALL sp_inner( $1 , $2 )
103 | 3344 | 23636 | QUERY   | INSERT INTO inner_table values ( $1 )
103 | 3344 | 23636 | UTILITY | TRUNCATE outer_table
103 | 3344 | 23636 | UTILITY | COMMIT
103 | 3345 | 23636 | QUERY   | INSERT INTO inner_table values ( $1 )
103 | 3345 | 23636 | QUERY   | INSERT INTO outer_table values ( $1 )
103 | 3345 | 23636 | UTILITY | COMMIT

```

The following example shows that cursor `cur1` was closed when the `TRUNCATE` statement committed.

```

CREATE OR REPLACE PROCEDURE sp_open_cursor_truncate()
LANGUAGE plpgsql
AS $$
DECLARE
    rec RECORD;
    cur1 cursor for select * from test_table_a order by 1;
BEGIN
    open cur1;
    TRUNCATE table test_table_b;
    Loop
        fetch cur1 into rec;
        raise info '%', rec.c1;
        exit when not found;
    End Loop;
END
$$;

call sp_open_cursor_truncate();
ERROR: cursor "cur1" does not exist
CONTEXT: PL/pgSQL function "sp_open_cursor_truncate" line 8 at fetch

```

The following example issues a `TRUNCATE` statement and can't be called from within an explicit transaction block.

```

CREATE OR REPLACE PROCEDURE sp_truncate_atomic() LANGUAGE plpgsql
AS $$
BEGIN

```

```

TRUNCATE test_table_b;
END;
$$;

Begin;
  Call sp_truncate_atomic();
ERROR: TRUNCATE cannot be invoked from a procedure that is executing in an atomic
context.
HINT: Try calling the procedure as a top-level call i.e. not from within an explicit
transaction block.
Or, if this procedure (or one of its ancestors in the call chain) was created with SET
config options, recreate the procedure without them.
CONTEXT: SQL statement "TRUNCATE test_table_b"
PL/pgSQL function "sp_truncate_atomic" line 2 at SQL statement

```

The following example shows that a user who is not a superuser or the owner of a table can issue a TRUNCATE statement on the table. The user does this using a Security Definer stored procedure. The example shows the following actions:

- The user1 creates table test_tbl.
- The user1 creates stored procedure sp_truncate_test_tbl.
- The user1 grants EXECUTE privilege on the stored procedure to user2.
- The user2 runs the stored procedure to truncate table test_tbl. The example shows the row count before and after the TRUNCATE command.

```

set session_authorization to user1;
create table test_tbl(id int, name varchar(20));
insert into test_tbl values (1,'john'), (2, 'mary');
CREATE OR REPLACE PROCEDURE sp_truncate_test_tbl() LANGUAGE plpgsql
AS $$
DECLARE
  tbl_rows int;
BEGIN
  select count(*) into tbl_rows from test_tbl;
  RAISE INFO 'RowCount before Truncate: %', tbl_rows;
  TRUNCATE test_tbl;
  select count(*) into tbl_rows from test_tbl;
  RAISE INFO 'RowCount after Truncate: %', tbl_rows;
END;
$$ SECURITY DEFINER;

```

```
grant execute on procedure sp_truncate_test_tbl() to user2;
reset session_authorization;

set session_authorization to user2;
call sp_truncate_test_tbl();
INFO: RowCount before Truncate: 2
INFO: RowCount after Truncate: 0
CALL
reset session_authorization;
```

The following example issues COMMIT twice. The first COMMIT commits all work done in transaction 10363 and implicitly starts transaction 10364. Transaction 10364 is committed by the second COMMIT statement.

```
CREATE OR REPLACE PROCEDURE sp_commit(a int, b int) LANGUAGE plpgsql
AS $$
BEGIN
  INSERT INTO test_table values (a);
  COMMIT;
  INSERT INTO test_table values (b);
  COMMIT;
END;
$$;

call sp_commit(1,2);

select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
userid |  xid  | pid  | type  |
          stmt_text
-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
100 | 10363 | 3089 | UTILITY | call sp_commit(1,2);
100 | 10363 | 3089 | QUERY   | INSERT INTO test_table values ( $1 )
100 | 10363 | 3089 | UTILITY | COMMIT
100 | 10364 | 3089 | QUERY   | INSERT INTO test_table values ( $1 )
100 | 10364 | 3089 | UTILITY | COMMIT
```

The following example issues a ROLLBACK statement if `sum_vals` is greater than 2. The first ROLLBACK statement rolls back all the work done in transaction 10377 and starts a new transaction 10378. Transaction 10378 is committed when the procedure exits.

```
CREATE OR REPLACE PROCEDURE sp_rollback(a int, b int) LANGUAGE plpgsql
AS $$
DECLARE
    sum_vals int;
BEGIN
    INSERT INTO test_table values (a);
    SELECT sum(c1) into sum_vals from test_table;
    IF sum_vals > 2 THEN
        ROLLBACK;
    END IF;

    INSERT INTO test_table values (b);
END;
$$;

call sp_rollback(1, 2);

select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
```

userid	xid	pid	type	stmt_text
100	10377	3089	UTILITY	call sp_rollback(1, 2);
100	10377	3089	QUERY	INSERT INTO test_table values (\$1)
100	10377	3089	QUERY	SELECT sum(c1) from test_table
100	10377	3089	QUERY	Undoing 1 transactions on table 133646 with current xid 10377 : 10377
100	10378	3089	QUERY	INSERT INTO test_table values (\$1)
100	10378	3089	UTILITY	COMMIT

Nonatomic mode stored procedure transaction management

A stored procedure created in NONATOMIC mode has different transaction control behavior from a procedure created in default mode. Similar to the automatic commit behavior of SQL commands outside stored procedures, each SQL statement inside a NONATOMIC procedure runs in its own

transaction and commits automatically. If a user begins an explicit transaction block within a NONATOMIC stored procedure, then the SQL statements within the block do not automatically commit. The transaction block controls commit or rollback of statements within it.

In NONATOMIC stored procedures, you can open an explicit transaction block inside the procedure using the `START TRANSACTION` statement. However, if there is already an open transaction block, this statement will do nothing because Amazon Redshift does not support sub transactions. The previous transaction continues.

When you work with cursor FOR loops inside a NONATOMIC procedure, make sure you open an explicit transaction block before iterating through the results of a query. Otherwise, the cursor is closed when the SQL statement inside the loop is automatically committed.

Some of the considerations when using NONATOMIC mode behavior are as follows:

- Each SQL statement inside the stored procedure is automatically committed if there is no open transaction block, and the session has autocommit set to ON.
- You can issue a `COMMIT/ROLLBACK/TRUNCATE` statement to end the transaction if the stored procedure is called from within a transaction block. This is not possible in default mode.
- You can issue a `START TRANSACTION` statement to begin a transaction block inside the stored procedure.

The following examples demonstrate transaction behavior when working with NONATOMIC stored procedures. The session for all the following examples has autocommit set to ON.

In the following example, a NONATOMIC stored procedure has two `INSERT` statements. When the procedure is called outside of a transaction block, every `INSERT` statement within the procedure automatically commits.

```
CREATE TABLE test_table_a(v int);
CREATE TABLE test_table_b(v int);

CREATE OR REPLACE PROCEDURE sp_nonatomic_insert_table_a(a int, b int) NONATOMIC AS
$$
BEGIN
    INSERT INTO test_table_a values (a);
    INSERT INTO test_table_b values (b);
END;
$$
```

```
LANGUAGE plpgsql;
```

```
Call sp_nonatomic_insert_table_a(1,2);
```

```
Select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
```

userid	xid	pid	type	stmt_text
1	1792	1073807554	UTILITY	Call sp_nonatomic_insert_table_a(1,2);
1	1792	1073807554	QUERY	INSERT INTO test_table_a values (\$1)
1	1792	1073807554	UTILITY	COMMIT
1	1793	1073807554	QUERY	INSERT INTO test_table_b values (\$1)
1	1793	1073807554	UTILITY	COMMIT

```
(5 rows)
```

However, when the procedure is called from within a BEGIN..COMMIT block, all the statements are part of the same transaction (xid=1799).

```
Begin;
```

```
INSERT INTO test_table_a values (10);
```

```
Call sp_nonatomic_insert_table_a(20,30);
```

```
INSERT INTO test_table_b values (40);
```

```
Commit;
```

```
Select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
```

userid	xid	pid	type	stmt_text
1	1799	1073914035	UTILITY	Begin;
1	1799	1073914035	QUERY	INSERT INTO test_table_a values (10);
1	1799	1073914035	UTILITY	Call sp_nonatomic_insert_table_a(20,30);
1	1799	1073914035	QUERY	INSERT INTO test_table_a values (\$1)
1	1799	1073914035	QUERY	INSERT INTO test_table_b values (\$1)
1	1799	1073914035	QUERY	INSERT INTO test_table_b values (40);
1	1799	1073914035	UTILITY	COMMIT

```
(7 rows)
```

In this example, two INSERT statements are between START TRANSACTION...COMMIT. When the procedure is called outside of a transaction block, the two INSERT statements are in the same transaction (xid=1866).

```
CREATE OR REPLACE PROCEDURE sp_nonatomic_txn_block(a int, b int) NONATOMIC AS
$$
BEGIN
    START TRANSACTION;
    INSERT INTO test_table_a values (a);
    INSERT INTO test_table_b values (b);
    COMMIT;
END;
$$
LANGUAGE plpgsql;
```

```
Call sp_nonatomic_txn_block(1,2);
```

```
Select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
```

userid	xid	pid	type	stmt_text
1	1865	1073823998	UTILITY	Call sp_nonatomic_txn_block(1,2);
1	1866	1073823998	QUERY	INSERT INTO test_table_a values (\$1)
1	1866	1073823998	QUERY	INSERT INTO test_table_b values (\$1)
1	1866	1073823998	UTILITY	COMMIT

(4 rows)

When the procedure is called from within a BEGIN...COMMIT block, the START TRANSACTION inside the procedure does nothing because there is already an open transaction. The COMMIT inside the procedure commits the current transaction (xid=1876) and starts a new one.

```
Begin;
    INSERT INTO test_table_a values (10);
    Call sp_nonatomic_txn_block(20,30);
    INSERT INTO test_table_b values (40);
Commit;
```

```
Select userid, xid, pid, type, trim(text) as stmt_text
from svl_statementtext where pid = pg_backend_pid() order by xid , starttime ,
sequence;
```

userid	xid	pid	type	stmt_text
1	1876	1073832133	UTILITY	Begin;
1	1876	1073832133	QUERY	INSERT INTO test_table_a values (10);
1	1876	1073832133	UTILITY	Call sp_nonatomic_txn_block(20,30);
1	1876	1073832133	QUERY	INSERT INTO test_table_a values (\$1)
1	1876	1073832133	QUERY	INSERT INTO test_table_b values (\$1)
1	1876	1073832133	UTILITY	COMMIT
1	1878	1073832133	QUERY	INSERT INTO test_table_b values (40);
1	1878	1073832133	UTILITY	COMMIT

(8 rows)

This example shows how to work with cursor loops. Table `test_table_a` has three values. The objective is to iterate through the three values and insert them into table `test_table_b`. If a `NONATOMIC` stored procedure is created in the following way, it will throw the error cursor "cur1" does not exist after executing `INSERT` statement in the first loop. This is because the auto commit of the `INSERT` closes the open cursor.

```
insert into test_table_a values (1), (2), (3);

CREATE OR REPLACE PROCEDURE sp_nonatomic_cursor() NONATOMIC
LANGUAGE plpgsql
AS $$
DECLARE
    rec RECORD;
    cur1 cursor for select * from test_table_a order by 1;
BEGIN
    open cur1;
    Loop
        fetch cur1 into rec;
        exit when not found;
        raise info '%', rec.v;
        insert into test_table_b values (rec.v);
    End Loop;
END
$$;

CALL sp_nonatomic_cursor();

INFO: 1
ERROR: cursor "cur1" does not exist
```

```
CONTEXT: PL/pgSQL function "sp_nonatomic_cursor" line 7 at fetch
```

To make the cursor loop work, put it between `START TRANSACTION...COMMIT`.

```
insert into test_table_a values (1), (2), (3);

CREATE OR REPLACE PROCEDURE sp_nonatomic_cursor() NONATOMIC
LANGUAGE plpgsql
AS $$
DECLARE
    rec RECORD;
    cur1 cursor for select * from test_table_a order by 1;
BEGIN
    START TRANSACTION;
    open cur1;
    Loop
        fetch cur1 into rec;
        exit when not found;
        raise info '%', rec.v;
        insert into test_table_b values (rec.v);
    End Loop;
    COMMIT;
END
$$;

CALL sp_nonatomic_cursor();

INFO:  1
INFO:  2
INFO:  3
CALL
```

Trapping errors

This topic describes how Amazon Redshift handles errors.

When a query or command in a stored procedure causes an error, subsequent queries don't run and the transaction is rolled back. But you can handle errors using an `EXCEPTION` block.

Note

The default behavior is that an error will cause subsequent queries not to run, even when there are no additional error-generating conditions in the stored procedure.

```
[ <<label>> ]  
[ DECLARE  
  declarations ]  
BEGIN  
  statements  
EXCEPTION  
  WHEN OTHERS THEN  
    statements  
END;
```

When an exception occurs, and you add an exception-handling block, you can write RAISE statements and most other PL/pgSQL statements. For example, you can raise an exception with a custom message or insert a record into a logging table.

When entering the exception-handling block, the current transaction is rolled back and a new transaction is created to run the statements in the block. If the statements in the block run without error, the transaction is committed and the exception is re-thrown. Lastly, the stored procedure exits.

The only supported condition in an exception block is OTHERS, which matches every error type except query cancellation. Also, if an error occurs in an exception-handling block, it can be caught by an outer exception-handling block.

When an error occurs inside the NONATOMIC procedure, the error is not re-thrown if it is handled by an exception block. See the PL/pgSQL statement RAISE to throw an exception caught by the exception handling block. This statement is only valid in exception handling blocks. For more information see [RAISE](#).

Controlling what happens after an error in a stored procedure, with the CONTINUE handler

The CONTINUE handler is a type of exception handler that controls the flow of execution within a NONATOMIC stored procedure. By using it, you can catch and handle exceptions without ending the existing statement block. Normally, when an error occurs in a stored procedure, the flow is interrupted and the error is returned to the caller. However, in some use cases, the error condition

isn't severe enough to warrant interrupting the flow. You might want to handle the error gracefully, using error-handling logic of your choosing in a separate transaction, and then continue running statements that follow the error. The following shows the syntax.

```
[ DECLARE
  declarations ]
BEGIN
  statements
EXCEPTION
  [ CONTINUE_HANDLER | EXIT_HANDLER ] WHEN OTHERS THEN
  handler_statements
END;
```

There are several system tables available to help you gather information about various types of errors. For more information, see [STL_LOAD_ERRORS](#), [STL_ERROR](#), and [SYS_STREAM_SCAN_ERRORS](#). There are also additional system tables you can use to troubleshoot errors. More information about these can be found at [System tables and views reference](#).

Example

The following example shows how to write statements in the exception-handling block. The stored procedure is using default transaction management behavior.

```
CREATE TABLE employee (firstname varchar, lastname varchar);
INSERT INTO employee VALUES ('Tomas','Smith');
CREATE TABLE employee_error_log (message varchar);

CREATE OR REPLACE PROCEDURE update_employee_sp() AS
$$
BEGIN
  UPDATE employee SET firstname = 'Adam' WHERE lastname = 'Smith';
  EXECUTE 'select invalid';
EXCEPTION WHEN OTHERS THEN
  RAISE INFO 'An exception occurred.';
  INSERT INTO employee_error_log VALUES ('Error message: ' || SQLERRM);
END;
$$
LANGUAGE plpgsql;

CALL update_employee_sp();

INFO:  An exception occurred.
```

```
ERROR: column "invalid" does not exist
CONTEXT: SQL statement "select invalid"
PL/pgSQL function "update_employee_sp" line 3 at execute statement
```

In this example, if we call `update_employee_sp`, the informational message *An exception occurred.* is raised and the error message is inserted in the logging table's `employee_error_log` log. The original exception is thrown again before the stored procedure exits. The following queries show records that result from running the example.

```
SELECT * from employee;

firstname | lastname
-----+-----
Tomas     | Smith

SELECT * from employee_error_log;

      message
-----
Error message: column "invalid" does not exist
```

For more information about RAISE, including formatting help and a list of additional levels, see [Supported PL/pgSQL statements](#).

The following example shows how to write statements in the exception-handling block. The stored procedure is using NONATOMIC transaction management behavior. In this example, there is no error thrown back to caller after the procedure call completes. The UPDATE statement is not rolled back due to the error in the next statement. The informational message is raised and the error message is inserted in the logging table.

```
CREATE TABLE employee (firstname varchar, lastname varchar);
INSERT INTO employee VALUES ('Tomas','Smith');
CREATE TABLE employee_error_log (message varchar);

-- Create the SP in NONATOMIC mode
CREATE OR REPLACE PROCEDURE update_employee_sp_2() NONATOMIC AS
$$
BEGIN
    UPDATE employee SET firstname = 'Adam' WHERE lastname = 'Smith';
    EXECUTE 'select invalid';
EXCEPTION WHEN OTHERS THEN
```

```

    RAISE INFO 'An exception occurred.';
    INSERT INTO employee_error_log VALUES ('Error message: ' || SQLERRM);
END;
$$
LANGUAGE plpgsql;

CALL update_employee_sp_2();
INFO: An exception occurred.
CALL

SELECT * from employee;

  firstname | lastname
-----+-----
   Adam    | Smith
(1 row)

SELECT * from employee_error_log;

          message
-----
Error message: column "invalid" does not exist
(1 row)

```

This example shows how to create a procedure with two sub blocks. When the stored procedure is called, the error from the first sub block is handled by its exception handling block. After the first sub block completes, the procedure continues to execute the second sub block. You can see from the result that no error is thrown when the procedure call completes. The UPDATE and INSERT operations on table employee are committed. Error messages from both exception blocks are inserted in the logging table.

```

CREATE TABLE employee (firstname varchar, lastname varchar);
INSERT INTO employee VALUES ('Tomas', 'Smith');
CREATE TABLE employee_error_log (message varchar);

CREATE OR REPLACE PROCEDURE update_employee_sp_3() NONATOMIC AS
$$
BEGIN
    BEGIN
        UPDATE employee SET firstname = 'Adam' WHERE lastname = 'Smith';
        EXECUTE 'select invalid1';
    EXCEPTION WHEN OTHERS THEN

```

```

        RAISE INFO 'An exception occurred in the first block.';
        INSERT INTO employee_error_log VALUES ('Error message: ' || SQLERRM);
    END;
BEGIN
    INSERT INTO employee VALUES ('Edie','Robertson');
    EXECUTE 'select invalid2';
EXCEPTION WHEN OTHERS THEN
    RAISE INFO 'An exception occurred in the second block.';
    INSERT INTO employee_error_log VALUES ('Error message: ' || SQLERRM);
END;
END;
$$
LANGUAGE plpgsql;

CALL update_employee_sp_3();
INFO: An exception occurred in the first block.
INFO: An exception occurred in the second block.
CALL

SELECT * from employee;

  firstname | lastname
-----+-----
   Adam     | Smith
   Edie     | Robertson
(2 rows)

SELECT * from employee_error_log;

          message
-----
Error message: column "invalid1" does not exist
Error message: column "invalid2" does not exist
(2 rows)

```

The following example shows how to use the CONTINUE exception handler. This sample creates two tables and uses them in a stored procedure. The CONTINUE handler controls the flow of execution in a stored procedure with NONATOMIC transaction-management behavior.

```

CREATE TABLE tbl_1 (a int);
CREATE TABLE tbl_error_logging(info varchar, err_state varchar, err_msg varchar);

CREATE OR REPLACE PROCEDURE sp_exc_handling_1() NONATOMIC AS

```

```
$$
BEGIN
  INSERT INTO tbl_1 VALUES (1);
  -- Expect an error for the insert statement following, because of the invalid value
  INSERT INTO tbl_1 VALUES ("val");
  INSERT INTO tbl_1 VALUES (2);
EXCEPTION CONTINUE_HANDLER WHEN OTHERS THEN
  INSERT INTO tbl_error_logging VALUES ('Encountered error', SQLSTATE, SQLERRM);
END;
$$ LANGUAGE plpgsql;
```

Call the stored procedure:

```
CALL sp_exc_handling_1();
```

Flow proceeds like so:

1. An error occurs because an attempt is made to insert an incompatible data type in a column. Control passes to the EXCEPTION block. When the exception-handling block is entered, the current transaction is rolled back and a new implicit transaction is created to run the statements in it.
2. If the statements in CONTINUE_HANDLER run without error, control passes to the statement immediately following the statement causing the exception. (If a statement in CONTINUE_HANDLER raises a new exception, you can handle it with an exception handler within the EXCEPTION block.)

After you call the sample stored procedure, the tables contain the following records:

- If you run `SELECT * FROM tbl_1;`, it returns two records. These contain the values 1 and 2.
- If you run `SELECT * FROM tbl_error_logging;`, it returns one record with these values: *Encountered error, 42703, and column "val" does not exist in tbl_1.*

The following additional error-handling example uses both an EXIT handler and a CONTINUE handler. It creates two tables: a data table and a logging table. It also creates a stored procedure that demonstrates error handling:

```
CREATE TABLE tbl_1 (a int);
CREATE TABLE tbl_error_logging(info varchar, err_state varchar, err_msg varchar);
```

```
CREATE OR REPLACE PROCEDURE sp_exc_handling_2() NONATOMIC AS
$$
BEGIN
    INSERT INTO tbl_1 VALUES (1);
    BEGIN
        INSERT INTO tbl_1 VALUES (100);
        -- Expect an error for the insert statement following, because of the invalid
value
        INSERT INTO tbl_1 VALUES ("val");
        INSERT INTO tbl_1 VALUES (101);
    EXCEPTION EXIT_HANDLER WHEN OTHERS THEN
        INSERT INTO tbl_error_logging VALUES ('Encountered error', SQLSTATE, SQLERRM);
    END;
    INSERT INTO tbl_1 VALUES (2);
    -- Expect an error for the insert statement following, because of the invalid value
    INSERT INTO tbl_1 VALUES ("val");
    INSERT INTO tbl_1 VALUES (3);
EXCEPTION CONTINUE_HANDLER WHEN OTHERS THEN
    INSERT INTO tbl_error_logging VALUES ('Encountered error', SQLSTATE, SQLERRM);
END;
$$ LANGUAGE plpgsql;
```

After you create the stored procedure, call it with the following:

```
CALL sp_exc_handling_2();
```

When an error occurs in the inner exception block, which is bracketed by the inner set of BEGIN and END, it's handled by the EXIT handler. Any errors that occur in the outer block are handled by the CONTINUE handler.

After you call the sample stored procedure, the tables contain the following records:

- If you run `SELECT * FROM tbl_1;`, it returns four records, with the values 1, 2, 3, and 100.
- If you run `SELECT * FROM tbl_error_logging;`, it returns two records. They have these values: *Encountered error*, *42703*, and *column "val" does not exist in tbl_1*.

If the table **tbl_error_logging** doesn't exist, it raises an exception.

The following example shows how to use the CONTINUE exception handler with the FOR loop. This sample creates three tables and uses them in a FOR loop within a stored procedure. The FOR loop is result set variant, meaning that it iterates over the results of a query:

```
CREATE TABLE tbl_1 (a int);
INSERT INTO tbl_1 VALUES (1), (2), (3);
CREATE TABLE tbl_2 (a int);
CREATE TABLE tbl_error_logging(info varchar, err_state varchar, err_msg varchar);

CREATE OR REPLACE PROCEDURE sp_exc_handling_loop() NONATOMIC AS
$$
DECLARE
  rec RECORD;
BEGIN
  FOR rec IN SELECT a FROM tbl_1
  LOOP
    IF rec.a = 2 THEN
      -- Expect an error for the insert statement following, because of the
      invalid value
      INSERT INTO tbl_2 VALUES("val");
    ELSE
      INSERT INTO tbl_2 VALUES (rec.a);
    END IF;
  END LOOP;
EXCEPTION CONTINUE_HANDLER WHEN OTHERS THEN
  INSERT INTO tbl_error_logging VALUES ('Encountered error', SQLSTATE, SQLERRM);
END;
$$ LANGUAGE plpgsql;
```

Call the stored procedure:

```
CALL sp_exc_handling_loop();
```

After you call the sample stored procedure, the tables contain the following records:

- If you run `SELECT * FROM tbl_2;`, it returns two records. These contain the values 1 and 3.
- If you run `SELECT * FROM tbl_error_logging;`, it returns one record with these values: *Encountered error, 42703, and column "val" does not exist in tbl_2.*

Usage notes regarding the CONTINUE handler:

- CONTINUE_HANDLER and EXIT_HANDLER keywords can be used only in NONATOMIC stored procedures.
- CONTINUE_HANDLER and EXIT_HANDLER keywords are optional. EXIT_HANDLER is the default.

Logging stored procedures

This topic describes the stored procedures and views that Amazon Redshift uses for stored procedure logging.

Details about stored procedures are logged in the following system tables and views:

- [SVL_STORED_PROC_CALL](#) – details are logged about the stored procedure call's start time and end time, and whether the call is ended before completion. For more information, see [SVL_STORED_PROC_CALL](#).
- [SVL_STORED_PROC_MESSAGES](#) – messages in stored procedures emitted by the RAISE query are logged with the corresponding logging level. For more information, see [SVL_STORED_PROC_MESSAGES](#).
- [SVL_QLOG](#) – the query ID of the procedure call is logged for each query called from a stored procedure. For more information, see [SVL_QLOG](#).
- [STL_UTILITYTEXT](#) – stored procedure calls are logged after they are completed. For more information, see [STL_UTILITYTEXT](#).
- [PG_PROC_INFO](#) – this system catalog view shows information about stored procedures. For more information, see [PG_PROC_INFO](#).

Stored procedure limitations

This topic describes limitations for Amazon Redshift stored procedures.

The following considerations apply when you use Amazon Redshift stored procedures.

Differences between Amazon Redshift and PostgreSQL for stored procedure support

The following are differences between stored procedure support in Amazon Redshift and PostgreSQL:

- Amazon Redshift doesn't support subtransactions, and hence has limited support for exception handling blocks.

Considerations and limits

The following are considerations on stored procedures in Amazon Redshift:

- The maximum number of stored procedures for a database is 10,000.
- The maximum size of the source code for a procedure is 2 MB.
- The maximum number of explicit and implicit cursors that you can open concurrently in a user session is one. FOR loops that iterate over the result set of a SQL statement open implicit cursors. Nested cursors aren't supported.
- Explicit and implicit cursors have the same restrictions on the result set size as standard Amazon Redshift cursors. For more information, see [Cursor constraints](#).
- The maximum number of levels for nested calls is 16.
- The maximum number of procedure parameters is 32 for input arguments and 32 for output arguments.
- The maximum number of variables in a stored procedure is 1,024.
- Any SQL command that requires its own transaction context isn't supported inside a stored procedure. Examples include:
 - PREPARE
 - CREATE/DROP DATABASE
 - CREATE EXTERNAL TABLE
 - VACUUM
 - SET LOCAL
 - ALTER TABLE APPEND
- The `registerOutParameter` method call through the Java Database Connectivity (JDBC) driver isn't supported for the `refcursor` data type. For an example of using the `refcursor` data type, see [Returning a result set from a stored procedure](#).

PL/pgSQL language reference

Stored procedures in Amazon Redshift are based on the PostgreSQL PL/pgSQL procedural language, with some important differences. In this reference, you can find details of PL/pgSQL syntax as implemented by Amazon Redshift. For more information about PL/pgSQL, see [PL/pgSQL - SQL procedural language](#) in the PostgreSQL documentation.

Topics

- [PL/pgSQL reference conventions](#)
- [Structure of PL/pgSQL](#)

- [Supported PL/pgSQL statements](#)

PL/pgSQL reference conventions

In this section, you can find the conventions that are used to write the syntax for the PL/pgSQL stored procedure language.

Character	Description
CAPS	Words in capital letters are keywords.
[]	Brackets denote optional arguments. Multiple arguments in brackets indicate that you can choose any number of the arguments. In addition, arguments in brackets on separate lines indicate that the Amazon Redshift parser expects the arguments to be in the order that they are listed in the syntax.
{ }	Braces indicate that you are required to choose one of the arguments inside the braces.
	Pipes indicate that you can choose between the arguments.
<i>red italics</i>	Words in red italics indicate placeholders. Insert the appropriate value in place of the word in red italics.
...	An ellipsis indicates that you can repeat the preceding element.
'	Words in single quotation marks indicate that you must type the quotes.

Structure of PL/pgSQL

PL/pgSQL is a procedural language with many of the same constructs as other procedural languages.

Topics

- [Block](#)
- [Variable declaration](#)

- [Alias declaration](#)
- [Built-in variables](#)
- [Record types](#)

Block

PL/pgSQL is a block-structured language. The complete body of a procedure is defined in a block, which contains variable declarations and PL/pgSQL statements. A statement can also be a nested block, or subblock.

End declarations and statements with a semicolon. Follow the END keyword in a block or subblock with a semicolon. Don't use semicolons after the keywords DECLARE and BEGIN.

You can write all keywords and identifiers in mixed uppercase and lowercase. Identifiers are implicitly converted to lowercase unless enclosed in double quotation marks.

A double hyphen (--) starts a comment that extends to the end of the line. A /* starts a block comment that extends to the next occurrence of */. You can't nest block comments. However, you can enclose double-hyphen comments in a block comment, and a double hyphen can hide the block comment delimiters /* and */.

Any statement in the statement section of a block can be a subblock. You can use subblocks for logical grouping or to localize variables to a small group of statements.

```
[ <<label>> ]  
[ DECLARE  
  declarations ]  
BEGIN  
  statements  
END [ label ];
```

The variables declared in the declarations section preceding a block are initialized to their default values every time the block is entered. In other words, they're not initialized only once per function call.

The following shows an example.

```
CREATE PROCEDURE update_value() AS $$
```

```
DECLARE
  value integer := 20;
BEGIN
  RAISE NOTICE 'Value here is %', value; -- Value here is 20
  value := 50;
  --
  -- Create a subblock
  --
  DECLARE
    value integer := 80;
  BEGIN
    RAISE NOTICE 'Value here is %', value; -- Value here is 80
  END;

  RAISE NOTICE 'Value here is %', value; -- Value here is 50
END;
$$ LANGUAGE plpgsql;
```

Use a label to identify the block to use in an EXIT statement or to qualify the names of the variables declared in the block.

Don't confuse the use of BEGIN/END for grouping statements in PL/pgSQL with the database commands for transaction control. The BEGIN and END in PL/pgSQL are only for grouping. They don't start or end a transaction.

Variable declaration

Declare all variables in a block, except for loop variables, in the block's DECLARE section. Variables can use any valid Amazon Redshift data type. For supported data types, see [Data types](#).

PL/pgSQL variables can be any Amazon Redshift supported data type, plus RECORD and refcursor. For more information about RECORD, see [Record types](#). For more information about refcursor, see [Cursors](#).

```
DECLARE
name [ CONSTANT ] type [ NOT NULL ] [ { DEFAULT | := } expression ];
```

Following, you can find example variable declarations.

```
customerID integer;
numberofitems numeric(6);
```

```
link varchar;  
oneroW RECORD;
```

The loop variable of a FOR loop iterating over a range of integers is automatically declared as an integer variable.

The DEFAULT clause, if given, specifies the initial value assigned to the variable when the block is entered. If the DEFAULT clause is not given, then the variable is initialized to the SQL NULL value. The CONSTANT option prevents the variable from being assigned to, so that its value remains constant for the duration of the block. If NOT NULL is specified, an assignment of a null value results in a runtime error. All variables declared as NOT NULL must have a non-null default value specified.

The default value is evaluated every time the block is entered. For example, assigning now() to a variable of type timestamp causes the variable to have the time of the current function call, not the time when the function was precompiled.

```
quantity INTEGER DEFAULT 32;  
url VARCHAR := 'http://mysite.com';  
user_id CONSTANT INTEGER := 10;
```

The refcursor data type is the data type of cursor variables within stored procedures. A refcursor value can be returned from within a stored procedure. For more information, see [Returning a result set from a stored procedure](#).

Alias declaration

If stored procedure's signature omits the argument name, you can declare an alias for the argument.

```
name ALIAS FOR $n;
```

Built-in variables

The following built-in variables are supported:

- FOUND
- SQLSTATE

- SQLERRM
- GET DIAGNOSTICS integer_var := ROW_COUNT;

FOUND is a special variable of type Boolean. FOUND starts out false within each procedure call. FOUND is set by the following types of statements:

- SELECT INTO

Sets FOUND to true if it returns a row, false if no row is returned.

- UPDATE, INSERT, and DELETE

Sets FOUND to true if at least one row is affected, false if no row is affected.

- FETCH

Sets FOUND to true if it returns a row, false if no row is returned.

- FOR statement

Sets FOUND to true if the FOR statement iterates one or more times, and otherwise false. This applies to all three variants of the FOR statement: integer FOR loops, record-set FOR loops, and dynamic record-set FOR loops.

FOUND is set when the FOR loop exits. Inside the runtime of the loop, FOUND isn't modified by the FOR statement. However, it can be changed by running other statements within the loop body.

The following shows an example.

```
CREATE TABLE employee(empname varchar);
CREATE OR REPLACE PROCEDURE show_found()
AS $$
DECLARE
    myrec record;
BEGIN
    SELECT INTO myrec * FROM employee WHERE empname = 'John';
    IF NOT FOUND THEN
        RAISE EXCEPTION 'employee John not found';
    END IF;
END;
$$ LANGUAGE plpgsql;
```

Within an exception handler, the special variable `SQLSTATE` contains the error code that corresponds to the exception that was raised. The special variable `SQLERRM` contains the error message associated with the exception. These variables are undefined outside exception handlers and display an error if used.

The following shows an example.

```
CREATE OR REPLACE PROCEDURE sqlstate_sqlerrm() AS
$$
BEGIN
    UPDATE employee SET firstname = 'Adam' WHERE lastname = 'Smith';
    EXECUTE 'select invalid';
    EXCEPTION WHEN OTHERS THEN
        RAISE INFO 'error message SQLERRM %', SQLERRM;
        RAISE INFO 'error message SQLSTATE %', SQLSTATE;
END;
$$ LANGUAGE plpgsql;
```

`ROW_COUNT` is used with the `GET DIAGNOSTICS` command. It shows the number of rows processed by the last SQL command sent down to the SQL engine.

The following shows an example.

```
CREATE OR REPLACE PROCEDURE sp_row_count() AS
$$
DECLARE
    integer_var int;
BEGIN
    INSERT INTO tbl_row_count VALUES(1);
    GET DIAGNOSTICS integer_var := ROW_COUNT;
    RAISE INFO 'rows inserted = %', integer_var;
END;
$$ LANGUAGE plpgsql;
```

Record types

A `RECORD` type is not a true data type, only a placeholder. Record type variables assume the actual row structure of the row that they are assigned during a `SELECT` or `FOR` command. The substructure of a record variable can change each time it is assigned a value. Until a record variable is first assigned to, it has no substructure. Any attempt to access a field in it throws a runtime error.

```
name RECORD;
```

The following shows an example.

```
CREATE TABLE tbl_record(a int, b int);
INSERT INTO tbl_record VALUES(1, 2);
CREATE OR REPLACE PROCEDURE record_example()
LANGUAGE plpgsql
AS $$
DECLARE
    rec RECORD;
BEGIN
    FOR rec IN SELECT a FROM tbl_record
    LOOP
        RAISE INFO 'a = %', rec.a;
    END LOOP;
END;
$$;
```

Supported PL/pgSQL statements

PL/pgSQL statements augment SQL commands with procedural constructs, including looping and conditional expressions, to control logical flow. Most SQL commands can be used, including data manipulation language (DML) such as COPY, UNLOAD, and INSERT, and data definition language (DDL) such as CREATE TABLE. For a list of comprehensive SQL commands, see [SQL commands](#). In addition, the following PL/pgSQL statements are supported by Amazon Redshift.

Topics

- [Assignment](#)
- [SELECT INTO](#)
- [No-op](#)
- [Dynamic SQL](#)
- [Return](#)
- [Conditionals: IF](#)
- [Conditionals: CASE](#)
- [Loops](#)
- [Cursors](#)

- [RAISE](#)
- [Transaction control](#)

Assignment

The assignment statement assigns a value to a variable. The expression must return a single value.

```
identifier := expression;
```

Using the nonstandard = for assignment, instead of :=, is also accepted.

If the data type of the expression doesn't match the variable's data type or the variable has a size or precision, the result value is implicitly converted.

The following shows examples.

```
customer_number := 20;  
tip := subtotal * 0.15;
```

SELECT INTO

The SELECT INTO statement assigns the result of multiple columns (but only one row) into a record variable or list of scalar variables.

```
SELECT INTO target select_expressions FROM ...;
```

In the preceding syntax, *target* can be a record variable or a comma-separated list of simple variables and record fields. The *select_expressions* list and the remainder of the command are the same as in regular SQL.

If a variable list is used as *target*, the selected values must exactly match the structure of the target, or a runtime error occurs. When a record variable is the target, it automatically configures itself to the row type of the query result columns.

The INTO clause can appear almost anywhere in the SELECT statement. It usually appears just after the SELECT clause, or just before FROM clause. That is, it appears just before or just after the *select_expressions* list.

If the query returns zero rows, NULL values are assigned to *target*. If the query returns multiple rows, the first row is assigned to *target* and the rest are discarded. Unless the statement contains an ORDER BY, the first row is not deterministic.

To determine whether the assignment returned at least one row, use the special FOUND variable.

```
SELECT INTO customer_rec * FROM cust WHERE custname = lname;
IF NOT FOUND THEN
  RAISE EXCEPTION 'employee % not found', lname;
END IF;
```

To test whether a record result is null, you can use the IS NULL conditional. There is no way to determine whether any additional rows might have been discarded. The following example handles the case where no rows have been returned.

```
CREATE OR REPLACE PROCEDURE select_into_null(return_webpage OUT varchar(256))
AS $$
DECLARE
  customer_rec RECORD;
BEGIN
  SELECT INTO customer_rec * FROM users WHERE user_id=3;
  IF customer_rec.webpage IS NULL THEN
    -- user entered no webpage, return "http://"
    return_webpage = 'http://';
  END IF;
END;
$$ LANGUAGE plpgsql;
```

No-op

The no-op statement (NULL;) is a placeholder statement that does nothing. A no-op statement can indicate that one branch of an IF-THEN-ELSE chain is empty.

```
NULL;
```

Dynamic SQL

To generate dynamic commands that can involve different tables or different data types each time they are run from a PL/pgSQL stored procedure, use the EXECUTE statement.

```
EXECUTE command-string [ INTO target ];
```

In the preceding, *command-string* is an expression yielding a string (of type text) that contains the command to be run. This *command-string* value is sent to the SQL engine. No substitution of PL/pgSQL variables is done on the command string. The values of variables must be inserted in the command string as it is constructed.

Note

You can't use COMMIT and ROLLBACK statements from within dynamic SQL. For information about using COMMIT and ROLLBACK statements within a stored procedure, see [Managing transactions](#).

When working with dynamic commands, you often have to handle escaping of single quotation marks. We recommend enclosing fixed text in quotation marks in your function body using dollar quoting. Dynamic values to insert into a constructed query require special handling because they might themselves contain quotation marks. The following example assumes dollar quoting for the function as a whole, so the quotation marks don't need to be doubled.

```
EXECUTE 'UPDATE tbl SET '  
  || quote_ident(colname)  
  || ' = '  
  || quote_literal(newvalue)  
  || ' WHERE key = '  
  || quote_literal(keyvalue);
```

The preceding example shows the functions `quote_ident(text)` and `quote_literal(text)`. This example passes variables that contain column and table identifiers to the `quote_ident` function. It also passes variables that contain literal strings in the constructed command to the `quote_literal` function. Both functions take the appropriate steps to return the input text enclosed in double or single quotation marks respectively, with any embedded special characters properly escaped.

Dollar quoting is only useful for quoting fixed text. Don't write the preceding example in the following format.

```
EXECUTE 'UPDATE tbl SET '
```

```

|| quote_ident(colname)
|| ' = $$'
|| newvalue
|| '$$ WHERE key = '
|| quote_literal(keyvalue);

```

You don't do this because the example breaks if the contents of `newvalue` happen to contain `$$`. The same problem applies to any other dollar-quoting delimiter that you might choose. To safely quote text that is not known in advance, use the `quote_literal` function.

Return

The RETURN statement returns back to the caller from a stored procedure.

```
RETURN;
```

The following shows an example.

```

CREATE OR REPLACE PROCEDURE return_example(a int)
AS $$
BEGIN
  FOR b in 1..10 LOOP
    IF b < a THEN
      RAISE INFO 'b = %', b;
    ELSE
      RETURN;
    END IF;
  END LOOP;
END;
$$ LANGUAGE plpgsql;

```

Conditionals: IF

The IF conditional statement can take the following forms in the PL/pgSQL language that Amazon Redshift uses:

- IF ... THEN

```

IF boolean-expression THEN
  statements
END IF;

```

The following shows an example.

```
IF v_user_id <> 0 THEN
  UPDATE users SET email = v_email WHERE user_id = v_user_id;
END IF;
```

- IF ... THEN ... ELSE

```
IF boolean-expression THEN
  statements
ELSE
  statements
END IF;
```

The following shows an example.

```
IF parentid IS NULL OR parentid = ''
THEN
  return_name = fullname;
  RETURN;
ELSE
  return_name = hp_true_filename(parentid) || '/' || fullname;
  RETURN;
END IF;
```

- IF ... THEN ... ELSIF ... THEN ... ELSE

The key word ELSIF can also be spelled ELSEIF.

```
IF boolean-expression THEN
  statements
[ ELSIF boolean-expression THEN
  statements
[ ELSIF boolean-expression THEN
  statements
  ...] ]
[ ELSE
  statements ]
END IF;
```

The following shows an example.

```
IF number = 0 THEN
    result := 'zero';
ELSIF number > 0 THEN
    result := 'positive';
ELSIF number < 0 THEN
    result := 'negative';
ELSE
    -- the only other possibility is that number is null
    result := 'NULL';
END IF;
```

Conditionals: CASE

The CASE conditional statement can take the following forms in the PL/pgSQL language that Amazon Redshift uses:

- Simple CASE

```
CASE search-expression
WHEN expression [, expression [ ... ]] THEN
    statements
[ WHEN expression [, expression [ ... ]] THEN
    statements
... ]
[ ELSE
    statements ]
END CASE;
```

A simple CASE statement provides conditional execution based on equality of operands.

The *search-expression* value is evaluated one time and successively compared to each *expression* in the WHEN clauses. If a match is found, then the corresponding *statements* run, and then control passes to the next statement after END CASE. Subsequent WHEN expressions aren't evaluated. If no match is found, the ELSE *statements* run. However, if ELSE isn't present, then a CASE_NOT_FOUND exception is raised.

The following shows an example.

```
CASE x
```

```
WHEN 1, 2 THEN
    msg := 'one or two';
ELSE
    msg := 'other value than one or two';
END CASE;
```

- Searched CASE

```
CASE
WHEN boolean-expression THEN
    statements
[ WHEN boolean-expression THEN
    statements
... ]
[ ELSE
    statements ]
END CASE;
```

The searched form of CASE provides conditional execution based on truth of Boolean expressions.

Each WHEN clause's *boolean-expression* is evaluated in turn, until one is found that yields true. Then the corresponding statements run, and then control passes to the next statement after END CASE. Subsequent WHEN *expressions* aren't evaluated. If no true result is found, the ELSE *statements* are run. However, if ELSE isn't present, then a CASE_NOT_FOUND exception is raised.

The following shows an example.

```
CASE
WHEN x BETWEEN 0 AND 10 THEN
    msg := 'value is between zero and ten';
WHEN x BETWEEN 11 AND 20 THEN
    msg := 'value is between eleven and twenty';
END CASE;
```

Loops

Loop statements can take the following forms in the PL/pgSQL language that Amazon Redshift uses:

- Simple loop

```
[<<label>>]
LOOP
  statements
END LOOP [ label ];
```

A simple loop defines an unconditional loop that is repeated indefinitely until terminated by an EXIT or RETURN statement. The optional label can be used by EXIT and CONTINUE statements within nested loops to specify which loop the EXIT and CONTINUE statements refer to.

The following shows an example.

```
CREATE OR REPLACE PROCEDURE simple_loop()
LANGUAGE plpgsql
AS $$
BEGIN
  <<simple_while>>
  LOOP
    RAISE INFO 'I am raised once';
    EXIT simple_while;
    RAISE INFO 'I am not raised';
  END LOOP;
  RAISE INFO 'I am raised once as well';
END;
$$;
```

- Exit loop

```
EXIT [ label ] [ WHEN expression ];
```

If *label* isn't present, the innermost loop is terminated and the statement following the END LOOP runs next. If *label* is present, it must be the label of the current or some outer level of nested loop or block. Then, the named loop or block is terminated and control continues with the statement after the loop or block corresponding END.

If WHEN is specified, the loop exit occurs only if *expression* is true. Otherwise, control passes to the statement after EXIT.

You can use EXIT with all types of loops; it isn't limited to use with unconditional loops.

When used with a BEGIN block, EXIT passes control to the next statement after the end of the block. A label must be used for this purpose. An unlabeled EXIT is never considered to match a BEGIN block.

The following shows an example.

```
CREATE OR REPLACE PROCEDURE simple_loop_when(x int)
LANGUAGE plpgsql
AS $$
DECLARE i INTEGER := 0;
BEGIN
  <<simple_loop_when>>
  LOOP
    RAISE INFO 'i %', i;
    i := i + 1;
    EXIT simple_loop_when WHEN (i >= x);
  END LOOP;
END;
$$;
```

- Continue loop

```
CONTINUE [ label ] [ WHEN expression ];
```

If *label* is not given, the execution jumps to the next iteration of the innermost loop. That is, all statements remaining in the loop body are skipped. Control then returns to the loop control expression (if any) to determine whether another loop iteration is needed. If *label* is present, it specifies the label of the loop whose execution is continued.

If WHEN is specified, the next iteration of the loop is begun only if *expression* is true. Otherwise, control passes to the statement after CONTINUE.

You can use CONTINUE with all types of loops; it isn't limited to use with unconditional loops.

```
CONTINUE mylabel;
```

- WHILE loop

```
[<<label>>]
WHILE expression LOOP
```

```
statements
END LOOP [ label ];
```

The WHILE statement repeats a sequence of statements so long as the *boolean-expression* evaluates to true. The expression is checked just before each entry to the loop body.

The following shows an example.

```
WHILE amount_owed > 0 AND gift_certificate_balance > 0 LOOP
  -- some computations here
END LOOP;

WHILE NOT done LOOP
  -- some computations here
END LOOP;
```

- FOR loop (integer variant)

```
[<<label>>]
FOR name IN [ REVERSE ] expression .. expression LOOP
  statements
END LOOP [ label ];
```

The FOR loop (integer variant) creates a loop that iterates over a range of integer values. The variable name is automatically defined as type integer and exists only inside the loop. Any existing definition of the variable name is ignored within the loop. The two expressions giving the lower and upper bound of the range are evaluated one time when entering the loop. If you specify REVERSE, then the step value is subtracted, rather than added, after each iteration.

If the lower bound is greater than the upper bound (or less than, in the REVERSE case), the loop body doesn't run. No error is raised.

If a label is attached to the FOR loop, then you can reference the integer loop variable with a qualified name, using that label.

The following shows an example.

```
FOR i IN 1..10 LOOP
  -- i will take on the values 1,2,3,4,5,6,7,8,9,10 within the loop
END LOOP;
```

```
FOR i IN REVERSE 10..1 LOOP
  -- i will take on the values 10,9,8,7,6,5,4,3,2,1 within the loop
END LOOP;
```

- FOR loop (result set variant)

```
[<<label>>]
FOR target IN query LOOP
  statements
END LOOP [ label ];
```

The *target* is a record variable or comma-separated list of scalar variables. The target is successively assigned each row resulting from the query, and the loop body is run for each row.

The FOR loop (result set variant) enables a stored procedure to iterate through the results of a query and manipulate that data accordingly.

The following shows an example.

```
CREATE PROCEDURE cs_refresh_reports() AS $$
DECLARE
  reports RECORD;
BEGIN
  FOR reports IN SELECT * FROM cs_reports ORDER BY sort_key LOOP
    -- Now "reports" has one record from cs_reports
    EXECUTE 'INSERT INTO ' || quote_ident(reports.report_name) || ' ' ||
reports.report_query;
  END LOOP;
  RETURN;
END;
$$ LANGUAGE plpgsql;
```

- FOR loop with dynamic SQL

```
[<<label>>]
FOR record_or_row IN EXECUTE text_expression LOOP
  statements
END LOOP;
```

A FOR loop with dynamic SQL enables a stored procedure to iterate through the results of a dynamic query and manipulate that data accordingly.

The following shows an example.

```
CREATE OR REPLACE PROCEDURE for_loop_dynamic_sql(x int)
LANGUAGE plpgsql
AS $$
DECLARE
    rec RECORD;
    query text;
BEGIN
    query := 'SELECT * FROM tbl_dynamic_sql LIMIT ' || x;
    FOR rec IN EXECUTE query
    LOOP
        RAISE INFO 'a %', rec.a;
    END LOOP;
END;
$$;
```

Cursors

Rather than running a whole query at once, you can set up a cursor. A *cursor* encapsulates a query and reads the query result a few rows at a time. One reason for doing this is to avoid memory overrun when the result contains a large number of rows. Another reason is to return a reference to a cursor that a stored procedure has created, which allows the caller to read the rows. This approach provides an efficient way to return large row sets from stored procedures.

To use cursors in a NONATOMIC stored procedure, place the cursor loop between START TRANSACTION...COMMIT.

To set up a cursor, first you declare a cursor variable. All access to cursors in PL/pgSQL goes through cursor variables, which are always of the special data type `refcursor`. A `refcursor` data type simply holds a reference to a cursor.

You can create a cursor variable by declaring it as a variable of type `refcursor`. Or, you can use the cursor declaration syntax following.

```
name CURSOR [ ( arguments ) ] FOR query ;
```

In the preceding, *arguments* (if specified) is a comma-separated list of *name datatype* pairs that each define names to be replaced by parameter values in *query*. The actual values to substitute for these names are specified later, when the cursor is opened.

The following shows examples.

```
DECLARE
  curs1 refcursor;
  curs2 CURSOR FOR SELECT * FROM tenk1;
  curs3 CURSOR (key integer) IS SELECT * FROM tenk1 WHERE unique1 = key;
```

All three of these variables have the data type `refcursor`, but the first can be used with any query. In contrast, the second has a fully specified query already bound to it, and the last has a parameterized query bound to it. The key value is replaced by an integer parameter value when the cursor is opened. The variable `curs1` is said to be *unbound* because it is not bound to any particular query.

Before you can use a cursor to retrieve rows, it must be opened. PL/pgSQL has three forms of the `OPEN` statement, of which two use unbound cursor variables and the third uses a bound cursor variable:

- **Open for select:** The cursor variable is opened and given the specified query to run. The cursor can't be open already. Also, it must have been declared as an unbound cursor (that is, as a simple `refcursor` variable). The `SELECT` query is treated in the same way as other `SELECT` statements in PL/pgSQL.

```
OPEN cursor_name FOR SELECT ...;
```

The following shows an example.

```
OPEN curs1 FOR SELECT * FROM foo WHERE key = mykey;
```

- **Open for execute:** The cursor variable is opened and given the specified query to run. The cursor can't be open already. Also, it must have been declared as an unbound cursor (that is, as a simple `refcursor` variable). The query is specified as a string expression in the same way as in the `EXECUTE` command. This approach gives flexibility so the query can vary from one run to the next.

```
OPEN cursor_name FOR EXECUTE query_string;
```

The following shows an example.

```
OPEN curs1 FOR EXECUTE 'SELECT * FROM ' || quote_ident($1);
```

- **Open a bound cursor:** This form of OPEN is used to open a cursor variable whose query was bound to it when it was declared. The cursor can't be open already. A list of actual argument value expressions must appear if and only if the cursor was declared to take arguments. These values are substituted in the query.

```
OPEN bound_cursor_name [ ( argument_values ) ];
```

The following shows an example.

```
OPEN curs2;  
OPEN curs3(42);
```

After a cursor has been opened, you can work with it by using the statements described following. These statements don't have to occur in the same stored procedure that opened the cursor. You can return a `refcursor` value out of a stored procedure and let the caller operate on the cursor. All portals are implicitly closed at transaction end. Thus, you can use a `refcursor` value to reference an open cursor only until the end of the transaction.

- **FETCH** retrieves the next row from the cursor into a target. This target can be a row variable, a record variable, or a comma-separated list of simple variables, just as with `SELECT INTO`. As with `SELECT INTO`, you can check the special variable `FOUND` to see whether a row was obtained.

```
FETCH cursor INTO target;
```

The following shows an example.

```
FETCH curs1 INTO rowvar;
```

- **CLOSE** closes the portal underlying an open cursor. You can use this statement to release resources earlier than end of the transaction. You can also use this statement to free the cursor variable to be opened again.

```
CLOSE cursor;
```

The following shows an example.

```
CLOSE curs1;
```

RAISE

Use the **RAISE level** statement to report messages and raise errors.

```
RAISE level 'format' [, variable [, ...]];
```

Possible levels are NOTICE, INFO, LOG, WARNING, and EXCEPTION. EXCEPTION raises an error, which normally cancels the current transaction. The other levels generate only messages of different priority levels.

Inside the format string, % is replaced by the next optional argument's string representation. Write %% to emit a literal %. Currently, optional arguments must be simple variables, not expressions, and the format must be a simple string literal.

In the following example, the value of `v_job_id` replaces the % in the string.

```
RAISE NOTICE 'Calling cs_create_job(%)', v_job_id;
```

Use the **RAISE** statement to re-throw the exception caught by an exception handling block. This statement is only valid in exception handling blocks of NONATOMIC mode stored procedures.

```
RAISE;
```

Transaction control

You can work with transaction control statements in the PL/pgSQL language that Amazon Redshift uses. For information about using the statements COMMIT, ROLLBACK, and TRUNCATE within a stored procedure, see [Managing transactions](#).

In NONATOMIC mode stored procedures, use `START TRANSACTION` to start a transaction block.

```
START TRANSACTION;
```

 **Note**

The PL/pgSQL statement `START TRANSACTION` is different from the SQL command `START TRANSACTION` in the following ways:

- Within stored procedures, `START TRANSACTION` is not synonymous with `BEGIN`.
- The PL/pgSQL statement does not support optional isolation level and access permission keywords.

Materialized views in Amazon Redshift

This section describes how to create and use materialized views in Amazon Redshift. A materialized view is a database object that stores the results of a query, which can be used to improve performance and efficiency.

In a data warehouse environment, applications often must perform complex queries on large tables. An example is `SELECT` statements that perform multi-table joins and aggregations on tables that contain billions of rows. Processing these queries can be expensive, in terms of system resources and the time it takes to compute the results.

Materialized views in Amazon Redshift provide a way to address these issues. A *materialized view* contains a precomputed result set, based on an SQL query over one or more base tables. You can issue `SELECT` statements to query a materialized view, in the same way that you can query other tables or views in the database. Amazon Redshift returns the precomputed results from the materialized view, without having to access the base tables at all. From the user standpoint, the query results are returned much faster compared to when retrieving the same data from the base tables.

Materialized views are especially useful for speeding up queries that are predictable and repeated. Instead of performing resource-intensive queries against large tables (such as aggregates or multiple joins), applications can query a materialized view and retrieve a precomputed result set. For example, consider the scenario where a set of queries is used to populate dashboards, such as Amazon QuickSight. This use case is ideal for a materialized view, because the queries are predictable and repeated over and over again.

You can define a materialized view in terms of other materialized views. Use *materialized views on materialized views* to expand the capability of materialized views. In this approach, an existing materialized view plays the same role as a base table for the query to retrieve data.

This approach is especially useful for reusing precomputed joins for different aggregate or `GROUP BY` options. For example, take a materialized view that joins customer information (containing millions of rows) with item order detail information (containing billions of rows). This is an expensive query to compute on demand repeatedly. You can use different `GROUP BY` options for the materialized views created on top of this materialized view and join with other tables. Doing this saves compute time otherwise used to run the expensive underlying join every time. The [STV_MV_DEPS](#) table shows the dependencies of a materialized view on other materialized views.

When you create a materialized view, Amazon Redshift runs the user-specified SQL statement to gather the data from the base table or tables and stores the result set. The following illustration provides an overview of the materialized view `tickets_mv` that an SQL query defines by using two base tables, `events` and `sales`.

You can then use these materialized views in queries to speed them up. In addition, Amazon Redshift can automatically rewrite these queries to use materialized views, even when the query doesn't explicitly reference a materialized view. Automatic rewrite of queries is especially powerful in enhancing performance when you can't change your queries to use materialized views.

To update the data in the materialized view, you can use the `REFRESH MATERIALIZED VIEW` statement at any time to manually refresh materialized views. Amazon Redshift identifies changes that have taken place in the base table or tables, and then applies those changes to the materialized view. Because automatic rewriting of queries requires materialized views to be up to

date, as a materialized view owner, make sure to refresh materialized views whenever a base table changes.

Amazon Redshift provides a few ways to keep materialized views up to date for automatic rewriting. You can configure materialized views with the automatic refresh option to refresh materialized views when base tables of materialized views are updated. This autorefresh operation runs at a time when cluster resources are available to minimize disruptions to other workloads. Because the scheduling of autorefresh is workload-dependent, you can have more control over when Amazon Redshift refreshes your materialized views. You can schedule a materialized view refresh job by using Amazon Redshift scheduler API and console integration. For more information about query scheduling, see [Scheduling a query on the Amazon Redshift console](#).

Doing this is especially useful when there is a service level agreement (SLA) requirement for up-to-date data from a materialized view. You can also manually refresh any materialized views that you can autorefresh. For information on how to create materialized views, see [CREATE MATERIALIZED VIEW](#).

You can issue SELECT statements to query a materialized view. For information on how to query materialized views, see [Materialized view queries](#). The result set eventually becomes stale when data is inserted, updated, and deleted in the base tables. You can refresh the materialized view at any time to update it with the latest changes from the base tables. For information on how to refresh materialized views, see [REFRESH MATERIALIZED VIEW](#).

For details about SQL commands used to create and manage materialized views, see the following command topics:

- [CREATE MATERIALIZED VIEW](#)
- [ALTER MATERIALIZED VIEW](#)
- [REFRESH MATERIALIZED VIEW](#)
- [DROP MATERIALIZED VIEW](#)

For information about system tables and views to monitor materialized views, see the following topics:

- [STV_MV_INFO](#)
- [STL_MV_STATE](#)
- [SVL_MV_REFRESH_STATUS](#)

- [STV_MV_DEPS](#)

Materialized view queries

You can use a materialized view in any SQL query by referencing the materialized view name as the data source, like a table or standard view.

When a query accesses a materialized view, it sees only the data that is stored in the materialized view as of its most recent refresh. Thus, the query might not see all the latest changes from corresponding base tables of the materialized view.

If other users want to query the materialized view, the owner of the materialized view grants the SELECT permission to those users. The other users don't need to have the SELECT permission on the underlying base tables. The owner of the materialized view can also revoke the SELECT permission from other users to prevent them from querying the materialized view.

If the owner of the materialized view no longer has the SELECT permission on the underlying base tables:

- The owner can no longer query the materialized view.
- Other users who have the SELECT permission on the materialized view can no longer query the materialized view.

The following example queries the `tickets_mv` materialized view. For more information on the SQL command used to create a materialized view, see [CREATE MATERIALIZED VIEW](#).

```
SELECT sold
FROM tickets_mv
```

```
WHERE catgroup = 'Concerts';
```

Because the query results are precomputed, there's no need to access the underlying tables (category, event, and sales). Amazon Redshift can return the results directly from tickets_mv.

Automatic query rewriting to use materialized views

You can use automatic query rewriting of materialized views in Amazon Redshift to have Amazon Redshift rewrite queries to use materialized views. Doing this accelerates query workloads even for queries that don't explicitly reference a materialized view. When Amazon Redshift rewrites queries, it only uses materialized views that are up to date.

Usage notes

To check if automatic rewriting of queries is used for a query, you can inspect the query plan or STL_EXPLAIN. The following shows a SELECT statement and the EXPLAIN output of the original query plan.

```
SELECT catgroup, SUM(qtysold) AS sold
FROM category c, event e, sales s
WHERE c.catid = e.catid AND e.eventid = s.eventid
GROUP BY 1;

EXPLAIN
  XN HashAggregate (cost=920021.24..920021.24 rows=1 width=35)
    -> XN Hash Join DS_BCAST_INNER (cost=440004.53..920021.22 rows=4 width=35)
        Hash Cond: ("outer".eventid = "inner".eventid)
        -> XN Seq Scan on sales s (cost=0.00..7.40 rows=740 width=6)
        -> XN Hash (cost=440004.52..440004.52 rows=1 width=37)
            -> XN Hash Join DS_BCAST_INNER (cost=0.01..440004.52 rows=1 width=37)
                Hash Cond: ("outer".catid = "inner".catid)
                -> XN Seq Scan on event e (cost=0.00..2.00 rows=200 width=6)
                -> XN Hash (cost=0.01..0.01 rows=1 width=35)
                    -> XN Seq Scan on category c (cost=0.00..0.01 rows=1
width=35)
```

The following shows the EXPLAIN output after a successful automatic rewriting. This output includes a scan on the materialized view in the query plan that replaces parts of the original query plan.

```
* EXPLAIN
   XN HashAggregate (cost=11.85..12.35 rows=200 width=41)
     -> XN Seq Scan on mv_tbl__tickets_mv__0 derived_table1 (cost=0.00..7.90
rows=790 width=41)
```

Only up-to-date (fresh) materialized views are considered for automatic rewriting of queries, irrespective of the refresh strategy, such as auto, scheduled, or manual. Hence, the original query returns up-to-date results. When a materialized view is explicitly referenced in queries, Amazon Redshift accesses currently stored data in the materialized view. This data might not reflect the latest changes from the base tables of the materialized view.

You can use automatic query rewriting of materialized views that are created on cluster version 1.0.20949 or later.

You can stop automatic query rewriting at the session level by using `SET mv_enable_aqmv_for_session` to `FALSE`.

Limitations

Following are limitations for using automatic query rewriting of materialized views:

- Automatic query rewriting works with materialized views that don't reference or include any of the following:
 - Subqueries
 - Left, right, or full outer joins
 - Set operations
 - Any aggregate functions, except `SUM`, `COUNT`, `MIN`, `MAX`, and `AVG`. (These are the only aggregate functions that work with automatic query rewriting.)
 - Any aggregate functions with `DISTINCT`
 - Any window functions
 - `SELECT DISTINCT` or `HAVING` clauses
 - External tables
 - Other materialized views
- Automatic query rewriting rewrites `SELECT` queries that refer to user-defined Amazon Redshift tables. Amazon Redshift doesn't rewrite the following queries:
 - `CREATE TABLE AS` statements

- SELECT INTO statements
- Queries on catalogs or system tables
- Queries with outer joins or a SELECT DISTINCT clause
- If a query isn't automatically rewritten, check whether you have the SELECT permission on the specified materialized view and the [mv_enable_aqmv_for_session](#) option is set to TRUE.

You can also check if your materialized views are eligible for automatic rewriting of queries by inspecting STV_MV_INFO. For more information, see [STV_MV_INFO](#).

Refreshing a materialized view

This topic describes how to refresh the data in a material view from the underlying tables.

When you create a materialized view, its contents reflect the state of the underlying database table or tables at that time. The data in the materialized view remains unchanged, even when applications change the data in the underlying tables. To update the data in the materialized view, you can use the REFRESH MATERIALIZED VIEW statement at any time to manually refresh materialized views. When you use this statement, Amazon Redshift identifies changes that have taken place in the base table or tables and applies those changes to the materialized view.

Amazon Redshift has two strategies for refreshing a materialized view:

- In many cases, Amazon Redshift can perform an incremental refresh. In an *incremental refresh*, Amazon Redshift quickly identifies the changes to the data in the base tables since the last refresh and updates the data in the materialized view. Incremental refresh is supported on the following SQL constructs used in the query when defining the materialized view:
 - Constructs that contain the clauses SELECT, FROM, [INNER] JOIN, WHERE, GROUP BY, or HAVING.
 - Constructs that contain aggregations, such as SUM, MIN, MAX, AVG, and COUNT.
 - Most built-in SQL functions, specifically the ones that are immutable, given that these have the same input arguments and always produce the same output.

Incremental refresh is also supported for a materialized view that's based on a datashare table.

- If an incremental refresh isn't possible, then Amazon Redshift performs a full refresh. A *full refresh* reruns the underlying SQL statement, replacing all of the data in the materialized view.

- Amazon Redshift automatically chooses the refresh method for a materialized view depending on the SELECT query used to define the materialized view.

Refreshing a materialized view on a materialized view isn't a cascading process. In other words, suppose that you have a materialized view A that depends on materialized view B. In this case, when the REFRESH MATERIALIZED VIEW A is invoked, A is refreshed using the current version of B, even when B is out-of-date. To bring A fully up to date, before refreshing A, first refresh B in a separate transaction.

The following example shows how you can create a full refresh plan for a materialized view programmatically. To refresh the materialized view v, first refresh materialized view u. To refresh materialized view w, first refresh materialized view u and then materialized view v.

```
CREATE TABLE t(a INT);
CREATE MATERIALIZED VIEW u AS SELECT * FROM t;
CREATE MATERIALIZED VIEW v AS SELECT * FROM u;
CREATE MATERIALIZED VIEW w AS SELECT * FROM v;

WITH RECURSIVE recursive_deps (mv_tgt, lvl, mv_dep) AS
( SELECT trim(name) as mv_tgt, 0 as lvl, trim(ref_name) as mv_dep
  FROM stv_mv_deps
  UNION ALL
  SELECT R.mv_tgt, R.lvl+1 as lvl, trim(S.ref_name) as mv_dep
  FROM stv_mv_deps S, recursive_deps R
  WHERE R.mv_dep = S.name
)

SELECT mv_tgt, mv_dep from recursive_deps
ORDER BY mv_tgt, lvl DESC;
```

mv_tgt	mv_dep
v	u
w	u
w	v

(3 rows)

The following example shows an informative message when you run REFRESH MATERIALIZED VIEW on a materialized view that depends on an out-of-date materialized view.

```
create table a(a int);
```

```
create materialized view b as select * from a;
```

```
create materialized view c as select * from b;
```

```
insert into a values (1);
```

```
refresh materialized view c;
```

INFO: Materialized view c is already up to date. However, it depends on another materialized view that is not up to date.

```
REFRESH MATERIALIZED VIEW b;
```

INFO: Materialized view b was incrementally updated successfully.

```
REFRESH MATERIALIZED VIEW c;
```

INFO: Materialized view c was incrementally updated successfully.

Amazon Redshift currently has the following limitations for incremental refresh for materialized views.

Amazon Redshift doesn't support incremental refresh for materialized views that are defined with a query using the following SQL elements:

- OUTER JOIN (RIGHT, LEFT, or FULL).
- The set operations UNION, INTERSECT, EXCEPT, and MINUS.
- The aggregate functions MEDIAN, PERCENTILE_CONT, LISTAGG, STDDEV_SAMP, STDDEV_POP, APPROXIMATE COUNT, APPROXIMATE PERCENTILE, and bitwise aggregate functions.

 **Note**

The COUNT, SUM, and AVG aggregate functions are supported.

- DISTINCT aggregate functions, such as DISTINCT COUNT, DISTINCT SUM, and so on.

- Window functions.
- A query that uses temporary tables for query optimization, such as optimizing common subexpressions.
- Subqueries.
- External tables referencing the following formats in the query that defines the materialized view.
 - Delta Lake
 - Hudi

Incremental refresh is supported on the preview track for materialized views defined using formats other than those listed above. For more information about setting up Preview clusters, see [Creating a preview cluster](#) in the *Amazon Redshift Management Guide*. For information about setting up Preview workgroups, see [Creating a preview workgroup](#) in the *Amazon Redshift Management Guide*.

Autorefreshing a materialized view

Amazon Redshift can automatically refresh materialized views with up-to-date data from its base tables when materialized views are created with or altered to have the autorefresh option. Amazon Redshift autorefreshes materialized views as soon as possible after base tables changes.

To complete refresh of the most important materialized views with minimal impact to active workloads in your cluster, Amazon Redshift considers multiple factors. These factors include current system load, the resources needed for refresh, available cluster resources, and how often the materialized views are used.

Amazon Redshift prioritizes your workloads over autorefresh and might stop autorefresh to preserve the performance of user workload. This approach might delay refresh of some materialized views. In some cases, you might need more deterministic refresh behavior for your materialized views. If so, consider using manual refresh as described in [REFRESH MATERIALIZED VIEW](#) or scheduled refresh using the Amazon Redshift scheduler API operations or the console.

You can set autorefresh for materialized views using `CREATE MATERIALIZED VIEW`. You can also use the `AUTO REFRESH` clause to refresh materialized views automatically. For more information about creating materialized views, see [CREATE MATERIALIZED VIEW](#). You can turn on autorefresh for a current materialized view by using [ALTER MATERIALIZED VIEW](#).

Consider the following when you refresh materialized views:

- You can still refresh a materialized view explicitly using `REFRESH MATERIALIZED VIEW` command even if you haven't enabled autorefresh for the materialized view.
- Amazon Redshift doesn't autorefresh materialized views defined on external tables.
- For refresh status, you can check `SVL_MV_REFRESH_STATUS`, which records queries that were user-initiated or autorefreshed.
- To run `REFRESH` on recompute-only materialized views, make sure that you have the `CREATE` permission on schemas. For more information, see [GRANT](#).

Automated materialized views

This topic describes how Amazon Redshift uses automated materialized views to improve performance. Amazon Redshift creates materialized views automatically based on database activity and performance. Amazon Redshift uses automated materialized views by default.

Materialized views are a powerful tool for improving query performance in Amazon Redshift. They do this by storing a precomputed result set. Similar queries don't have to re-run the same logic each time, because they can retrieve records from the existing result set. Developers and analysts create materialized views after analyzing their workloads to determine which queries would benefit, and whether the maintenance cost of each materialized view is worthwhile. As workloads grow or change, these materialized views must be reviewed to ensure they continue to provide tangible performance benefits.

The Automated Materialized Views (AutoMV) feature in Redshift provides the same performance benefits of user-created materialized views. Amazon Redshift continually monitors the workload using machine learning and creates new materialized views when they are beneficial. AutoMV balances the costs of creating and keeping materialized views up to date against expected benefits to query latency. The system also monitors previously created AutoMVs and drops them when they are no longer beneficial.

AutoMV behavior and capabilities are the same as user-created materialized views. They are refreshed automatically and incrementally, using the same criteria and restrictions. Just like materialized views created by users, [Automatic query rewriting to use materialized views](#) identifies queries that can benefit from system-created AutoMVs. It automatically rewrites those queries to use the AutoMVs, improving query performance. Developers don't need to revise queries to take advantage of AutoMV.

Note

Automated materialized views are refreshed intermittently. Queries rewritten to use AutoMV always return the latest results. When Redshift detects that data isn't up to date, queries aren't rewritten to read from automated materialized views. Instead, queries select the latest data from base tables.

Any workload with queries that are used repeatedly can benefit from AutoMV. Common use cases include:

- *Dashboards* - Dashboards are widely used to provide quick views of key business indicators (KPIs), events, trends, and other metrics. They often have a common layout with charts and tables, but show different views for filtering, or for dimension-selection operations, like drill down. Dashboards often have a common set of queries used repeatedly with different parameters. Dashboard queries can benefit greatly from automated materialized views.
- *Reports* - Reporting queries may be scheduled at various frequencies, based on business requirements and the type of report. Additionally, they can be automated or on-demand. A common characteristic of reporting queries is that they can be long running and resource-intensive. With AutoMV, these queries don't need to be recomputed each time they run, which reduces runtime for each query and resource utilization in Redshift.

To turn off automated materialized views, you update the `auto_mv` parameter group to `false`. For more information, see [Amazon Redshift parameter groups](#) in the Amazon Redshift Cluster Management Guide.

SQL scope and considerations for automated materialized views

- An automated materialized view can be initiated and created by a query or subquery, provided it contains a `GROUP BY` clause or one of the following aggregate functions: `SUM`, `COUNT`, `MIN`, `MAX` or `AVG`. But it cannot contain any of the following:
 - Left, right, or full outer joins
 - Aggregate functions other than `SUM`, `COUNT`, `MIN`, `MAX`, and `AVG`. (These particular functions work with automatic query rewriting.)
 - Any aggregate function that includes `DISTINCT`
 - Any window functions

- SELECT DISTINCT or HAVING clauses
- Other materialized views

It isn't guaranteed that a query that meets the criteria will initiate the creation of an automated materialized view. The system determines from which candidates to create a view, based on its expected benefit to the workload and cost in resources to maintain, which includes the cost to the system to refresh. Each resulting materialized view is usable by automatic query rewriting.

- Even though AutoMV might be initiated by a subquery or individual legs of set operators, the resulting materialized view won't contain subqueries or set operators.
- To determine if AutoMV was used for queries, view the EXPLAIN plan and look for `%_auto_mv_%` in the output. For more information, see [EXPLAIN](#).
- Automated materialized views aren't supported on external tables, such as datashares and federated tables.

Automated materialized views limitations

Following are limitations for working with automated materialized views:

- *Maximum number of AutoMVs* - The limit of automated materialized views is 200 per database in the cluster.
- *Storage space and capacity* - An important characteristic of AutoMV is that it is performed using spare background cycles to help achieve that user workloads are not impacted. If the cluster is busy or running out of storage space, AutoMV ceases its activity. Specifically, at 80% of total cluster capacity, no new automated materialized views are created. At 90% of total capacity, they may be dropped to facilitate that user workloads continue without performance degradation. For more information about determining cluster capacity, see [STV_NODE_STORAGE_CAPACITY](#).

Billing for automated materialized views

Amazon Redshift's automatic optimization capability creates and refreshes automated materialized views. There is no charge for compute resources for this process. Storage of automated materialized views is charged at the regular rate for storage. For more information, see [Amazon Redshift pricing](#).

Additional resources

The following blog post provides further explanation regarding automated materialized views. It details how they're created, maintained, and dropped. It also explains the underlying algorithms that drive these decisions: [Optimize your Amazon Redshift query performance with automated materialized views](#).

This video begins with an explanation of materialized views and shows how they improve performance and conserve resources. It then provides an in-depth explanation of automated materialized views with a process-flow animation and a live demonstration.

Using a user-defined function (UDF) in a materialized view

You can use a scalar UDF in an Amazon Redshift materialized view. Define these either in python or SQL and reference them in the materialized view definition.

Referencing a UDF in a materialized view

The following procedure shows how to use UDFs that perform simple arithmetic comparisons, in a materialized-view definition.

1. Create a table to use in the materialized-view definition.

```
CREATE TABLE base_table (a int, b int);
```

2. Create a scalar user-defined function in python that returns a boolean value indicating whether an integer is larger than a comparison integer.

```
CREATE OR REPLACE FUNCTION udf_python_bool(x1 int, x2 int) RETURNS bool IMMUTABLE
AS $$
    return x1 > x2
$$ LANGUAGE plpythonu;
```

Optionally, create a functionally similar UDF with SQL, which you can use to compare results with the first.

```
CREATE OR REPLACE FUNCTION udf_sql_bool(int, int) RETURNS bool IMMUTABLE
AS $$
    select $1 > $2;
```

```
$$ LANGUAGE SQL;
```

3. Create a materialized view that selects from the table you created and references the UDF.

```
CREATE MATERIALIZED VIEW mv_python_udf AS SELECT udf_python_bool(a, b) AS a FROM  
base_table;
```

Optionally, you can create a materialized view that references the SQL UDF.

```
CREATE MATERIALIZED VIEW mv_sql_udf AS SELECT udf_sql_bool(a, b) AS a FROM  
base_table;
```

4. Add data to the table and refresh the materialized view.

```
INSERT INTO base_table VALUES (1,2), (1,3), (4,2);
```

```
REFRESH MATERIALIZED VIEW mv_python_udf;
```

Optionally, you can refresh the materialized view that references the SQL UDF.

```
REFRESH MATERIALIZED VIEW mv_sql_udf;
```

5. Query data from your materialized view.

```
SELECT * FROM mv_python_udf ORDER BY a;
```

The results of the query are the following:

```
a  
----  
false  
false  
true
```

This returns `true` for the last set of values because the value for column a (4) is greater than the value for column b (2).

6. Optionally, you can query the materialized view that references the SQL UDF. The results for the SQL function match the results from the Python version.

```
SELECT * FROM mv_sql_udf ORDER BY a;
```

The results of the query are the following:

```
a
-----
false
false
true
```

This returns `true` for the last set of values to compare.

7. Use a `DROP` statement with `CASCADE` to drop the user-defined function and the materialized view that references it.

```
DROP FUNCTION udf_python_bool(int, int) CASCADE;
```

```
DROP FUNCTION udf_sql_bool(int, int) CASCADE;
```

Streaming ingestion to a materialized view

This topic describes how to use materialized views for fast access to streaming data.

Streaming ingestion provides low-latency, high-speed data ingestion from [Amazon Kinesis Data Streams](#) or [Amazon Managed Streaming for Apache Kafka](#) to an Amazon Redshift provisioned or Amazon Redshift Serverless database. The data lands in a Redshift materialized view that's configured for the purpose. This results in fast access to external data. Streaming ingestion lowers data-access time and reduces storage cost. You can configure it for your Amazon Redshift cluster or for your Amazon Redshift Serverless workgroup, using a small collection of SQL commands. After it's set up, each materialized-view refresh can ingest hundreds of megabytes of data per second.

How data flows from a streaming service to Redshift

It helps to understand how streaming ingestion works and the database objects utilized in the process. Data flows directly from a data-stream provider to an Amazon Redshift provisioned cluster or to an Amazon Redshift Serverless workgroup. There isn't a temporary landing area, such as an Amazon S3 bucket. The provisioned cluster or workgroup is the stream consumer. In

the Redshift database, the data read from the stream lands in a materialized view. The data is processed as it arrives. For instance, JSON values can be consumed and mapped to a materialized view's data columns, using SQL. When the materialized view is refreshed, Redshift consumes data from allocated Kinesis data shards or Kafka partitions until the view is brought up to date with the stream.

Use cases for Amazon Redshift streaming ingestion involve data that's generated continually and must be processed within a short period, or *latency*, from its origination. This is commonly called *near real-time* analytics. Sources can include IT devices, system-telemetry devices, and click-stream data from a busy website or application.

Data parsing best practices for improving performance

When you configure streaming ingestion, there are options in how you can parse the incoming data. Practices can include performing business logic or formatting as data arrives. We recommend the following best practices to avoid errors or data loss. These derived from internal testing and helping customers troubleshoot configuration and parsing issues.

- **Extracting values from streamed data** – If you use the [JSON_EXTRACT_PATH_TEXT](#) function in your materialized view definition to parse or *shred* streamed JSON, it can significantly impact performance and latency. To explain, for each column extracted using `JSON_EXTRACT_PATH_TEXT`, the incoming JSON is re-parsed. After this, data-type conversion, filtering, and business-logic calculations occur. This means, for example, that if you extract 10 columns from JSON data, each JSON record is parsed 10 times, which includes additional logic. This results in higher ingestion latency. An alternative approach we recommend is to use the [JSON_PARSE function](#) to convert JSON records to Redshift's SUPER data type. After the streamed data lands in the materialized view, use PartiQL to extract individual strings from the SUPER representation of the JSON data. For more information, see [Querying semistructured data](#).

Additionally, note that `JSON_EXTRACT_PATH_TEXT` has a 64KB data-size maximum. Thus, if any JSON record is larger than 64KB, processing it with `JSON_EXTRACT_PATH_TEXT` results in an error.

- **Mapping an Amazon Kinesis Data Streams stream or Amazon MSK topic to multiple materialized views** – We don't recommend creating multiple materialized views to ingest data from a single stream or topic. This is because each materialized view creates a consumer for each shard in the Kinesis Data Streams stream or partition in the Kafka topic. This can result in throttling or exceeding the throughput of the stream or topic. It also can result in higher cost,

because you ingest the same data multiple times. When you configure streaming ingestion, we recommend you create one materialized view for each stream or topic.

If your use case requires that you ingest data from one KDS stream or MSK topic into multiple materialized views, consult the [AWS Big Data blog](#), specifically [Best practices to implement near-real-time analytics using Amazon Redshift Streaming Ingestion with Amazon MSK](#), before you do so.

Streaming ingestion behavior and data types

The following table describes technical behavior details and size limits for various data types. We recommend being familiar with these prior to configuring a materialized view for streaming ingestion.

Feature or behavior	Description
Kafka topic length limit	It isn't possible to use a Kafka topic with a name longer than 128 characters (not including quotation marks). For more information, see Names and identifiers .
Incremental refreshes and JOINS on a materialized view	The materialized view must be incrementally maintainable. Full recompute is not possible for Kinesis or Amazon MSK because they don't preserve stream or topic history past 24 hours or 7 days, by default. You can set longer data retention periods in Kinesis or Amazon MSK. However, this can result in more maintenance and cost. Additionally, JOINS are not currently supported on materialized views created on a Kinesis stream, or on an Amazon MSK topic. After creating a materialized view on your stream or topic, you can create another materialized view in order to join your streaming materialized view to other materialized views, tables, or views. For more information, see REFRESH MATERIALIZED VIEW .
Record parsing	Amazon Redshift streaming ingestion doesn't support parsing records that have been aggregated by the Kinesis Producer Library (KPL Key Concepts - Aggregation). The aggregated records are ingested, but are stored as binary protocol buffer

Feature or behavior	Description
	data. (See Protocol buffers for more information.) Depending on how you push data to Kinesis, you may need to turn off this feature.
Decompression	VARBYTE doesn't support decompression. Because of this, records containing compressed data can't be queried in Redshift. Decompress your data before adding it to the Kinesis stream or Amazon MSK topic.
Maximum record size	<p>The maximum size of any record field Amazon Redshift can ingest from Kinesis or Amazon MSK is slightly less than 1MB. The following points detail the behavior:</p> <ul style="list-style-type: none">• Maximum VARBYTE length – For streaming ingestion, the VARBYTE type supports data to a maximum length of 1,024,000 bytes. Kinesis limits payloads to 1 MB.• Message limits – Default Amazon MSK configuration limits messages to 1 MB. Additionally, if a message includes headers, the amount of data is limited to 1,048,470 bytes. With default settings, there are no problems with ingestion. However, you can change the maximum message size for Kafka, and therefore Amazon MSK, to a larger value. In this case, it may be possible for the key/value field of a Kafka record, or the header, to exceed the size limit. These records can cause an error and are not ingested. <div data-bbox="591 1430 1511 1793" style="border: 1px solid #0070C0; border-radius: 10px; padding: 10px;"><p> Note</p><p>Amazon Redshift supports a maximum size of 1,024,000 bytes for streaming ingestion from Kinesis or Amazon MSK, even though Amazon Redshift supports a maximum size of 16 MB for the VARBYTE data type.</p></div>

Feature or behavior	Description
Error records	<p>In each case where a record can't be ingested to Redshift because the size of the data exceeds the maximum , that record is skipped. Materialized view refresh still succeeds, in this case, and a segment of each error record is written to the SYS_STREAM_SCAN_ERRORS system table. Errors that result from business logic, such as an error in a calculation or an error resulting from a type conversion, are not skipped. Test the logic carefully before you add it to your materialized view definition.</p>
Amazon MSK Multi-VPC private connectivity	<p>Amazon MSK multi-VPC private connectivity isn't currently supported for Redshift streaming ingestion. Alternatively, you can use VPC peering to connect VPCs or AWS Transit Gateway to connect VPCs and on-premises networks through a central hub. Either of these can enable Redshift to communicate with an Amazon MSK cluster or with Amazon MSK Serverless in another VPC.</p>
Auto refresh usage and activation	<p>Auto refresh queries for a materialized view or views are treated as any other user workload. Auto refresh loads data from the stream as it arrives.</p> <p>Auto refresh can be turned on explicitly for a materialized view created for streaming ingestion. To do this, specify <code>AUTO REFRESH</code> in the materialized view definition. Manual refresh is the default. To specify auto refresh for an existing materialized view for streaming ingestion, you can run <code>ALTER MATERIALIZED VIEW</code> to turn it on. For more information, see CREATE MATERIALIZED VIEW or ALTER MATERIALIZED VIEW.</p>

Feature or behavior	Description
Streaming ingestion and Amazon Redshift Serverless	The setup and configuration instructions that apply to Amazon Redshift streaming ingestion on a provisioned cluster also apply to streaming ingestion on Amazon Redshift Serverless. It's important to specify the necessary level of RPUs to support streaming ingestion with auto refresh and other workloads. For more information, see Billing for Amazon Redshift Serverless .
Amazon Redshift nodes in a different availability zone than the Amazon MSK cluster	When you configure streaming ingestion, Amazon Redshift attempts to connect to an Amazon MSK cluster in the same availability one, if rack awareness is enabled for Amazon MSK. If all of your nodes are in different availability zones than your Amazon Redshift cluster, you can incur cross availability zone data-transfer cost. To avoid this, keep at least one Amazon MSK broker cluster node in the same AZ as your Redshift provisioned cluster or workgroup.
Refresh start location	After creating a materialized view, its initial refresh starts from the TRIM_HORIZON of a Kinesis stream, or from offset 0 of an Amazon MSK topic.
Data formats	Supported data formats are limited to those that can be converted from VARBYTE. For more information, see VARBYTE type and VARBYTE operators .
Appending records to a table	You can run ALTER TABLE APPEND to append rows to a target table from an existing source materialized view. This works only if the materialized view is configured for streaming ingestion. For more information, see ALTER TABLE APPEND .

Feature or behavior	Description
Running TRUNCATE or DELETE	<p>You can remove records from a materialized view that's used for streaming ingestion, using the following:</p> <ul style="list-style-type: none">• TRUNCATE – This deletes all of the rows from a materialized view that's configured for streaming ingestion. It doesn't do a table scan. For more information, see TRUNCATE.• DELETE – This deletes all of the rows from a materialized view that's configured for streaming ingestion. For more information, see DELETE.

Getting started with streaming ingestion from Amazon Kinesis Data Streams

This topic describes how to consume streaming data from Kinesis Data Streams using a materialized view.

Setting up Amazon Redshift streaming ingestion involves creating an external schema that maps to the streaming data source and creating a materialized view that references the external schema. Amazon Redshift streaming ingestion supports Kinesis Data Streams as a source. As such, you must have a Kinesis Data Streams source available before configuring streaming ingestion. If you don't have a source, follow the instructions in the Kinesis documentation at [Getting Started with Amazon Kinesis Data Streams](#) or create one on the console using the instructions at [Creating a Stream via the AWS Management Console](#).

Amazon Redshift streaming ingestion uses a materialized view, which is updated directly from the stream when REFRESH is run. The materialized view maps to the stream data source. You can perform filtering and aggregations on the stream data as part of the materialized-view definition. Your streaming ingestion materialized view (the *base* materialized view) can reference only one stream, but you can create additional materialized views that join with the base materialized view and with other materialized views or tables.

Note

Streaming ingestion and Amazon Redshift Serverless - The configuration steps in this topic apply both to provisioned Amazon Redshift clusters and to Amazon Redshift Serverless. For more information, see [Streaming ingestion behavior and data types](#).

Assuming you have a Kinesis Data Streams stream available, the first step is to define a schema in Amazon Redshift with `CREATE EXTERNAL SCHEMA` and to reference a Kinesis Data Streams resource. Following that, to access data in the stream, define the `STREAM` in a materialized view. You can store stream records in the semi-structured `SUPER` format, or define a schema that results in data converted to Redshift data types. When you query the materialized view, the returned records are a point-in-time view of the stream.

1. Create an IAM role with a trust policy that allows your Amazon Redshift cluster or Amazon Redshift Serverless workgroup to assume the role. For information about how to configure the trust policy for the IAM role, see [Authorizing Amazon Redshift to access other AWS services on your behalf](#). After it is created, the role should have the following IAM policy, which provides permission for communication with the Amazon Kinesis data stream.

IAM policy for an unencrypted stream from Kinesis Data Streams

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "ReadStream",
      "Effect": "Allow",
      "Action": [
        "kinesis:DescribeStreamSummary",
        "kinesis:GetShardIterator",
        "kinesis:GetRecords",
        "kinesis:ListShards",
        "kinesis:DescribeStream"
      ],
      "Resource": "arn:aws:kinesis:*:0123456789:stream/*"
    },
    {
      "Sid": "ListStream",
      "Effect": "Allow",
```

```

        "Action": "kinesis:ListStreams",
        "Resource": "*"
    }
]
}

```

IAM policy for an encrypted stream from Kinesis Data Streams

```

{
  "Version": "2012-10-17",
  "Statement": [{
    "Sid": "ReadStream",
    "Effect": "Allow",

    "Resource": "*"
  }
]
}

```

2. Check your VPC and verify that your Amazon Redshift cluster or Amazon Redshift Serverless has a route to get to the Kinesis Data Streams endpoints over the internet using a NAT gateway or internet gateway. If you want traffic between Redshift and Kinesis Data Streams

to remain within the AWS network, consider using a Kinesis Interface VPC Endpoint. For more information, see [Using Amazon Kinesis Data Streams Kinesis Data Streams with Interface VPC Endpoints](#).

3. In Amazon Redshift, create an external schema to map the data from Kinesis to a schema.

```
CREATE EXTERNAL SCHEMA kds
FROM KINESIS
IAM_ROLE { default | 'iam-role-arn' };
```

Streaming ingestion for Kinesis Data Streams doesn't require an authentication type. It uses the IAM role defined in the `CREATE EXTERNAL SCHEMA` statement for making Kinesis Data Streams requests.

Optional: Use the `REGION` keyword to specify the region where the Amazon Kinesis Data Streams or Amazon MSK stream resides.

```
CREATE EXTERNAL SCHEMA kds
FROM KINESIS
REGION 'us-west-2'
IAM_ROLE { default | 'iam-role-arn' };
```

In this sample, the region specifies the location of the source stream. The `IAM_ROLE` is a sample.

4. Create a materialized view to consume the stream data. With a statement like the following, if a record can't be parsed, it causes an error. Use a command like this if you don't want error records to be skipped.

```
CREATE MATERIALIZED VIEW my_view AUTO REFRESH YES AS
SELECT *
FROM kds.my_stream_name;
```

Kinesis stream names are case sensitive and can contain both uppercase and lowercase letters. To ingest from streams with uppercase names, you can set the configuration `enable_case_sensitive_identifier` to `true` at the database level. For more information, see [Names and identifiers](#) and [enable_case_sensitive_identifier](#).

To turn on auto refresh, use `AUTO REFRESH YES`. The default behavior is manual refresh. Note when you use `CAN_JSON_PARSE`, it's possible that records that can't be parsed are skipped.

Metadata columns include the following:

Metadata column	Data type	Description
<code>approximate_arrival_timestamp</code>	timestamp without time zone	The approximate time that the record was inserted into the Kinesis stream
<code>partition_key</code>	varchar(256)	The key used by Kinesis to assign the record to a shard
<code>shard_id</code>	char(20)	The unique identifier of the shard within the stream from which the record was retrieved
<code>sequence_number</code>	varchar(128)	The unique identifier of the record from the Kinesis shard
<code>refresh_time</code>	timestamp without time zone	The time the refresh started
<code>kinesis_data</code>	varbyte	The record from the Kinesis stream

It's important to note if you have business logic in your materialized view definition that business-logic errors can cause streaming ingestion to be blocked in some cases. This might lead to you having to drop and re-create the materialized view. To avoid this, we recommend that you keep your logic as simple as possible and perform most of your business-logic checks on the data after it's ingested.

- Refresh the view, which invokes Redshift to read from the stream and load data into the materialized view.

```
REFRESH MATERIALIZED VIEW my_view;
```

6. Query data in the materialized view.

```
select * from my_view;
```

Getting started with streaming ingestion from Amazon Managed Streaming for Apache Kafka (Amazon MSK)

This topic describes how to consume streaming data from Amazon MSK using a materialized view.

The purpose of Amazon Redshift streaming ingestion is to simplify the process for directly ingesting stream data from a streaming service into Amazon Redshift or Amazon Redshift Serverless. This works with Amazon MSK Provisioned and Amazon MSK Serverless, and with Kinesis Data Streams. Amazon Redshift streaming ingestion removes the need to stage a Kinesis Data Streams stream or an Amazon MSK topic in Amazon S3 before ingesting the stream data into Redshift.

On a technical level, streaming ingestion, both from Amazon Kinesis Data Streams and Amazon MSK, provides low-latency, high-speed ingestion of stream or topic data into an Amazon Redshift materialized view. Following setup, using materialized view refresh, you can take in large data volumes.

Set up Amazon Redshift streaming ingestion for Amazon MSK by performing the following steps:

1. Create an external schema that maps to the streaming data source.
2. Create a materialized view that references the external schema.

You must have an Amazon MSK source available, before configuring Amazon Redshift streaming ingestion. If you do not have a source, follow the instructions at [Getting Started Using Amazon MSK](#).

Note

Streaming ingestion and Amazon Redshift Serverless - The configuration steps in this topic apply both to provisioned Amazon Redshift clusters and to Amazon Redshift Serverless. For more information, see [Streaming ingestion behavior and data types](#).

Setting up IAM permissions and performing streaming ingestion from Kafka

Assuming you have an Amazon MSK cluster available, the first step is to define a schema in Redshift with `CREATE EXTERNAL SCHEMA` and to reference the Amazon MSK cluster as the data source. Following that, to access data in the topic, define the `STREAM` in a materialized view. You can store records from your topic using the default Amazon Redshift `VARBYTE` datatype, or define a schema that converts the data to the semi-structured `SUPER` format. When you query the materialized view, the returned records are a point-in-time view of the topic.

1. If you use `AUTHENTICATION NONE` to connect to MSK, no IAM role is required. However, if you use `AUTHENTICATION IAM` or `MTLS` to authenticate with your Amazon MSK cluster, your Amazon Redshift cluster or Amazon Redshift Serverless namespace must have an attached IAM role with appropriate permissions. Create an IAM role with a trust policy that allows your Amazon Redshift cluster or Amazon Redshift Serverless namespace to assume the role. After you create the role, add one of the following permissions to support IAM or MTLS. For mTLS authentication, the certificates that Amazon Redshift uses can be stored in AWS Certificate Manager or AWS Secrets Manager, so you must choose the policy that matches where the certificate is stored. Attach the role to your Amazon Redshift provisioned cluster or Redshift Serverless namespace. For information about how to configure the trust policy for the IAM role, see [Authorizing Amazon Redshift to access other AWS services on your behalf](#).

AUTHENTICATION IAM:

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "MSKIAMPolicy",
      "Effect": "Allow",
      "Action": [
        "kafka-cluster:ReadData",
        "kafka-cluster:DescribeTopic",
```

```

        "kafka-cluster:Connect"
    ],
    "Resource": [
        "arn:aws:kafka:*:0123456789:cluster/MyTestCluster/*",
        "arn:aws:kafka:*:0123456789:topic/MyTestCluster/*"
    ]
},
{
    "Effect": "Allow",
    "Action": [
        "kafka-cluster:AlterGroup",
        "kafka-cluster:DescribeGroup"
    ],
    "Resource": [
        "arn:aws:kafka:*:0123456789:group/MyTestCluster/*"
    ]
}
]
}

```

AUTHENTICATION MTLS: using a certificate stored in AWS Certificate Manager

```

{
    "Version": "2012-10-17",
    "Statement": [
        {
            "Sid": "MSKmTLSACMpolicy",
            "Effect": "Allow",
            "Action": [
                "acm:ExportCertificate"
            ],
            "Resource": [
                "arn:aws:acm:us-east-1:444455556666:certificate/certificate_ID"
            ]
        }
    ]
}

```

AUTHENTICATION MTLS: using a certificate stored in AWS Secrets Manager

```

{
    "Version": "2012-10-17",

```

```

    "Statement": [
      {
        "Sid": "MSKmtlsSecretsManagerpolicy",
        "Effect": "Allow",
        "Action": [
          "secretsmanager:GetSecretValue"
        ],
        "Resource": [
          "arn:aws:secretsmanager:us-east-1:444455556666:secret:secret_ID"
        ]
      }
    ]
  }
}

```

2. Check your VPC and verify that your Amazon Redshift cluster or Amazon Redshift Serverless has a route to get to your Amazon MSK cluster. The inbound security group rules for your Amazon MSK cluster should allow your Amazon Redshift cluster's or your Amazon Redshift Serverless workgroup's security group. The ports you specify depend on the authentication methods configured on your Amazon MSK cluster. For more information, see [Port information](#) and [Access from within AWS but outside the VPC](#).

The following table shows complimentary configuration options to set for streaming ingestion from Amazon MSK:

Amazon Redshift configuration	Amazon MSK configuration	Port to open between Redshift and Amazon MSK
AUTHENTICATION NONE	TLS transport disabled	9092
AUTHENTICATION NONE	TLS transport enabled	9094
AUTHENTICATION IAM	IAM	9098/9198
AUTHENTICATION MTLS	TLS transport enabled	9094

Amazon Redshift authentication is set in the CREATE EXTERNAL SCHEMA statement.

Note

In a case where the Amazon MSK cluster has Mutual Transport Layer Security (mTLS) authentication enabled, configuring Amazon Redshift to use `AUTHENTICATION NONE` directs it to use port 9094 for unauthenticated access. However, this will fail because the port is being used by mTLS authentication. Because of this, we recommend that you switch to `AUTHENTICATION mtls` when you use mTLS.

3. Enable enhanced VPC routing on your Amazon Redshift cluster or Amazon Redshift Serverless workgroup. For more information, see [Enabling enhanced VPC routing](#).
4. In Amazon Redshift, create an external schema to map to the Amazon MSK cluster. The syntax is the following:

```
CREATE EXTERNAL SCHEMA MySchema
FROM MSK
[ IAM_ROLE [ default | 'iam-role-arn' ] ]
AUTHENTICATION [ none | iam | mtls ]
[AUTHENTICATION_ARN 'acm-certificate-arn' | SECRET_ARN 'ssm-secret-arn' ];
```

In the `FROM` clause, `MSK` denotes that the schema maps data from Managed Kafka Services.

`AUTHENTICATION` denotes the authentication type for streaming ingestion with Amazon MSK. There are three types available:

- **none** – Specifies that there is no authentication required. This corresponds to Unauthenticated access on MSK.
- **iam** – Specifies IAM authentication. When you choose this, make sure that the IAM role has permissions for IAM authentication. For more information about setting up the required IAM policies, see [Setting up IAM permissions and performing streaming ingestion from Kafka](#).
- **mtls** – Specifies that mutual transport layer security provides secure communication by facilitating authentication between a client and server. In this case, the client is Redshift and the server is Amazon MSK. For more information about configuring streaming ingestion with mTLS, see [Authentication with mTLS for Redshift streaming ingestion from Amazon MSK](#).

Note that Amazon MSK authentication with a username and password isn't supported for streaming ingestion.

AUTHENTICATION_ARN specifies the ARN of the ACM mutual transport layer security (mTLS) certificate you use to establish an encrypted connection.

SECRET_ARN specifies the arn of the AWS Secrets Manager secret containing the certificate to be used by Amazon Redshift for mTLS.

The following samples show how to set the broker URI for the Amazon MSK cluster when you create the external schema:

```
CREATE EXTERNAL SCHEMA my_schema
FROM MSK
IAM_ROLE 'arn:aws:iam::012345678901:role/my_role'
AUTHENTICATION IAM
URI 'b-1.myTestCluster.123z8u.c2.kafka.us-
west-1.amazonaws.com:9098,b-2.myTestCluster.123z8u.c2.kafka.us-
west-1.amazonaws.com:9098'
```

Using no authentication:

```
CREATE EXTERNAL SCHEMA my_schema
FROM MSK
AUTHENTICATION none
URI 'b-1.myTestCluster.123z8u.c2.kafka.us-
west-1.amazonaws.com:9092,b-2.myTestCluster.123z8u.c2.kafka.us-
west-1.amazonaws.com:9092'
```

Using mTLS

```
CREATE EXTERNAL SCHEMA my_schema
FROM MSK
IAM_ROLE 'arn:aws:iam::012345678901:role/my_role'
AUTHENTICATION MTLS
URI 'b-1.myTestCluster.123z8u.c2.kafka.us-west-1.amazonaws.com:9094,b-
2.myTestCluster.123z8u.c2.kafka.us-west-1.amazonaws.com:9094'
AUTHENTICATION_ARN 'acm-certificate-arn' | [ SECRET_ARN 'ssm-secret-arn' ];
```

For more information on creating an external schema, see [CREATE EXTERNAL SCHEMA](#).

5. Create a materialized view to consume the data from the topic. Use a SQL command such as the following sample.

```
CREATE MATERIALIZED VIEW MyView AUTO REFRESH YES AS
SELECT *
FROM MySchema."mytopic";
```

Kafka topic names are case sensitive and can contain both uppercase and lowercase letters. To ingest from topics with uppercase names, you can set the configuration `enable_case_sensitive_identifier` to `true` at the session or database level. For more information, see [Names and identifiers](#) and [enable_case_sensitive_identifier](#).

To turn on auto refresh, use `AUTO REFRESH YES`. The default behavior is manual refresh.

Metadata columns include the following:

Metadata column	Data type	Description
<code>kafka_partition</code>	<code>bigint</code>	Partition id of the record from the Kafka topic
<code>kafka_offset</code>	<code>bigint</code>	Offset of the record in the Kafka topic for a given partition
<code>kafka_timestamp_type</code>	<code>char(1)</code>	Type of timestamp used in the Kafka record: <ul style="list-style-type: none"> <code>C</code> – Record creation time (<code>CREATE_TIME</code>) on the client side <code>L</code> – Record append time (<code>LOG_APPEND_TIME</code>) on the Kafka server side <code>U</code> – Record creation time is not available (<code>NO_TIMESTAMP_TYPE</code>)
<code>kafka_timestamp</code>	<code>timestamp without time zone</code>	The timestamp value for the record

Metadata column	Data type	Description
kafka_key	varbyte	The key of the Kafka record
kafka_value	varbyte	The record received from Kafka
kafka_headers	super	The header of the record received from Kafka
refresh_time	timestamp without time zone	The time the refresh started

It's important to note if you have business logic in your materialized view definition that results in business logic errors, this can result in ingestion failures in streaming ingestion in some cases. This might lead to you having to drop and re-create the materialized view. To avoid this, we recommend that you keep your business logic simple and run additional logic on the data after you ingest it.

- Refresh the view, which invokes Amazon Redshift to read from the topic and load data into the materialized view.

```
REFRESH MATERIALIZED VIEW MyView;
```

- Query data in the materialized view.

```
select * from MyView;
```

The materialized view is updated directly from the topic when REFRESH is run. You create a materialized view that maps to the Kafka topic data source. You can perform filtering and aggregations on the data as part of the materialized view definition. Your streaming ingestion materialized view (base materialized view) can reference only one Kafka topic, but you can create additional materialized views that join with the base materialized view and with other materialized views or tables.

For more information about limitations for streaming ingestion, see [Streaming ingestion behavior and data types](#).

Authentication with mTLS for Redshift streaming ingestion from Amazon MSK

Mutual transport-layer security (mTLS) provides the means for a server to authenticate a client it's sending information to, and for the client to authenticate the server. The benefit of using mTLS is to provide trusted authentication for a variety of use cases in several industry-vertical applications. These include use cases in financial, retail, government and healthcare industries. In the case of streaming ingestion to Redshift, authentication occurs between a server, in this case Amazon MSK, and an Amazon Redshift provisioned cluster or an Amazon Redshift Serverless workgroup.

This topic provides procedures and SQL-command examples that show ways to create an external schema that uses mTLS to authenticate between the Redshift client and Amazon MSK server. The steps in this topic complement the full set of steps for setting up streaming ingestion from Amazon MSK. These are detailed at [Getting started with streaming ingestion from Amazon Managed Streaming for Apache Kafka \(Amazon MSK\)](#).

Prerequisites for using mTLS for streaming ingestion

This section provides prerequisite steps for using mTLS for streaming ingestion with either AWS Certificate Manager or Amazon SageMaker.

1. As a preliminary step, you must have or create a private certificate authority (PCA), which you can use to issue certificates that, among other functions, enable secure communication through secure communication channels. AWS Private Certificate Authority (Private CA) is an available service that performs this function. For more information, see [Creating a private CA](#) in the *AWS Private Certificate Authority User Guide*. In a later step, you issue a certificate and attach it to your Amazon MSK cluster to enable encrypted communication to Redshift.
2. Create an Amazon MSK cluster that supports mTLS client authentication. For more information about configuring an Amazon MSK cluster, see [To create a cluster that supports client authentication](#) in the *Amazon Managed Streaming for Apache Kafka Developer Guide*.
3. Edit the security settings for the Amazon MSK cluster, turning on TLS client authentication using AWS Certificate Manager (ACM) and selecting the AWS Private CA (PCA) you created previously. For more information, see [Updating security settings of a cluster](#) in the *Amazon Managed Streaming for Apache Kafka Developer Guide*.

Using mTLS for streaming ingestion with AWS Certificate Manager

The following procedure shows how to configure mTLS for Redshift streaming ingestion by leveraging AWS Certificate Manager (ACM) for certificate storage and management:

1. Request a private certificate through ACM. When you do this, select the PCA you created in the Prerequisites section as the certificate authority. ACM stores the signed certificate and attached private key for secure communication. For more information about managing certificates with ACM, see [Issuing and managing certificates](#) in the *AWS Certificate Manager User Guide*.
2. For the IAM role that you use to manage your Redshift cluster or Amazon Redshift Serverless workgroup, attach the permission to export the certificate, which is **acm:ExportCertificate**. For more information about setting up the necessary IAM resources for streaming ingestion with Amazon MSK, see [Setting up IAM permissions and performing streaming ingestion from Kafka](#). Specify the same IAM role in the next step to create the external schema.
3. Get the bootstrap broker URI for the Amazon MSK cluster. Getting the bootstrap broker URI is detailed in [Getting the bootstrap brokers for an Amazon MSK cluster](#) in the *Amazon Managed Streaming for Apache Kafka Developer Guide*.
4. Run a SQL command like the following sample to create an external schema that maps a stream from an Amazon MSK cluster to a Redshift external schema, using `mtls`.

```
CREATE EXTERNAL SCHEMA my_schema
FROM MSK
IAM_ROLE 'arn:aws:iam::012345678901:role/my_role'
AUTHENTICATION mtls
URI 'b-1.myTestCluster.123z8u.c2.kafka.us-
west-1.amazonaws.com:9094,b-2.myTestCluster.123z8u.c2.kafka.us-
west-1.amazonaws.com:9094'
AUTHENTICATION_ARN 'arn:aws:acm:Region:444455556666:certificate/certificate_ID';
```

Important parameters:

- **IAM_ROLE** – The IAM role associated with the cluster, for streaming ingestion.
- **URI** – The bootstrap broker URI for the Amazon MSK cluster. Note that port 9094 is specified for communicating with brokers for TLS encryption.
- **AUTHENTICATION_ARN** – The ARN of the ACM certificate. The ARN is available in the ACM console when you choose the issued certificate.

After performing these configuration steps, you can create a Redshift materialized view that references the schema defined in the sample and then use `REFRESH MATERIALIZED VIEW` to stream data. This is detailed in the getting-started steps for streaming from Amazon MSK at

[Getting started with streaming ingestion from Amazon Managed Streaming for Apache Kafka \(MSK\)](#).

Using mTLS for streaming ingestion with AWS Secrets Manager

You can configure mTLS for Redshift streaming ingestion by leveraging AWS Secrets Manager for certificate management, if you don't want to reference the certificate in ACM. The steps that follow describe how to configure it.

1. Create a certificate signing request and private key with your tool of choice. Then you can use the signing request to generate a signed certificate, using the same AWS Private CA (PCA) that you used to generate the certificate for the Amazon MSK cluster. For more information about issuing a certificate, see [IssueCertificate](#) in the *AWS Private Certificate Authority API Reference*.
2. Extract the certificate using AWS Private Certificate Authority. For more information, see [Retrieve a private certificate](#) in the *AWS Private Certificate Authority User Guide*.
3. Store the certificate and private key generated in the previous step in AWS Secrets Manager. Choose `Other` type of secret and use the plaintext format. The key-value pairs should be in the format `{"certificate": "<cert value>", "privateKey": "<pkey value>"}`, as in the following example. For more information about creating and managing secrets in AWS Secrets Manager, see [Create and manage secrets with AWS Secrets Manager](#) in the *AWS Secrets Manager User Guide*.

```

{"certificate": "-----BEGIN CERTIFICATE-----
k1hds1kfjahksgdfkgioeuyihbflahabhbdslv6akybeoiwv1hoaiusdhbabsbdi
H4hAX8/eE96qCcjkpFT84EdvHzp6fC+/WwM0oX1wUEW1vfMCXNaG5D8SqRq3qA==
-----END CERTIFICATE-----
-----BEGIN CERTIFICATE-----
k1hds1kfjahksgdfkgioeuyihbflahabhbdslv6akybeoiwv1hoaiusdhbabsbdi
wJa1rXUtnFEMI/K7MDENG/bPxRfiCYEXAMPLEKEY
-----END CERTIFICATE-----",
"privateKey": "-----BEGIN PRIVATE KEY-----
k1hds1kfjahksgdfkgioeuyihbflahabhbdslv6akybeoiwv1hoaiusdhbabsbdi
70D4m1dBES3Fj++hDMH9rYRp99RqtC0f0EW0Ue139K0i10sW+cyhAoc9Ci2+Jo/k
17u2N1iGILMQEZuCRtnJ0kFYkw==
-----END PRIVATE KEY-----"}

```

4. In Redshift, run the SQL command to create the external schema. You use the `AUTHENTICATION` type `mtls`. You also specify the URI of the Amazon MSK cluster and the secret ARN in AWS Secrets Manager.

```
CREATE EXTERNAL SCHEMA my_schema
FROM MSK
IAM_ROLE 'arn:aws:iam::012345678901:role/my_role'
AUTHENTICATION mtls
URI 'b-1.myTestCluster.123z8u.c2.kafka.us-
west-1.amazonaws.com:9094,b-2.myTestCluster.123z8u.c2.kafka.us-
west-1.amazonaws.com:9094'
SECRET_ARN 'arn:aws:secretsmanager:us-east-1:012345678910:secret:myMTLSSecret';
```

Important parameters:

- **IAM_ROLE** – The IAM role associated with the cluster, for streaming ingestion.
- **URI** – The bootstrap broker URI for the Amazon MSK cluster. Note that port 9094 is specified for communicating with brokers for TLS encryption.
- **SECRET_ARN** – The ARN of the secret from Secrets Manager, containing the certificate to use for mTLS.

Enabling mTLS authentication for an existing external schema

If you have an existing external schema that you use for streaming ingestion and you want to implement mutual TLS for authentication, you can run a command such as the following, which specifies mTLS authentication and the ACM certificate ARN in ACM.

```
ALTER EXTERNAL SCHEMA schema_name
AUTHENTICATION mtls
AUTHENTICATION_ARN 'arn:aws:acm:Region:444455556666:certificate/certificate_ID';
```

Or you can specify mTLS authentication, with reference to the secret ARN in AWS Secrets Manager.

```
ALTER EXTERNAL SCHEMA schema_name
AUTHENTICATION mtls
SECRET_ARN 'arn:aws:secretsmanager:us-east-1:012345678910:secret:myMTLSSecret';
```

Ingesting streaming data using Kinesis

This procedure demonstrates how to ingest data from a Kinesis stream named *ev_station_data*, which contains consumption data from different EV charging stations, in JSON format. The schema

is well defined. The example shows how to store the data as raw JSON and also how to convert the JSON data to Amazon Redshift data types as it's ingested.

Producer setup

1. Using Amazon Kinesis Data Streams, follow the steps to create a stream named `ev_station_data`. Choose **On-demand** for the **Capacity mode**. For more information, see [Creating a Stream via the AWS Management Console](#).
2. The [Amazon Kinesis Data Generator](#) can help you generate test data for use with your stream. Follow the steps detailed in the tool to get started, and use the following data template for generating your data:

```
{
  "_id" : "{{random.uuid}}",
  "clusterID": "{{random.number(
    {
      "min":1,
      "max":50
    }
  )}}",
  "connectionTime": "{{date.now("YYYY-MM-DD HH:mm:ss")}}",
  "kWhDelivered": "{{commerce.price}}",
  "stationID": "{{random.number(
    {
      "min":1,
      "max":467
    }
  )}}",
  "spaceID": "{{random.word}}-{{random.number(
    {
      "min":1,
      "max":20
    }
  )}}",
  "timezone": "America/Los_Angeles",
  "userID": "{{random.number(
    {
      "min":1000,
      "max":500000
    }
  )}}"
}
```

Each JSON object in the stream data has the following properties:

```
{
  "_id": "12084f2f-fc41-41fb-a218-8cc1ac6146eb",
  "clusterID": "49",
  "connectionTime": "2022-01-31 13:17:15",
  "kWhDelivered": "74.00",
  "stationID": "421",
  "spaceID": "technologies-2",
  "timezone": "America/Los_Angeles",
  "userID": "482329"
}
```

Amazon Redshift setup

These steps show you how to configure the materialized view to ingest data.

1. Create an external schema to map the data from Kinesis to a Redshift object.

```
CREATE EXTERNAL SCHEMA evdata FROM KINESIS
IAM_ROLE 'arn:aws:iam::0123456789:role/redshift-streaming-role';
```

For information about how to configure the IAM role, see [Getting started with streaming ingestion from Amazon Kinesis Data Streams](#).

2. Create a materialized view to consume the stream data. The following examples show both methods of defining materialized views to ingest the JSON source data.

First, store stream records in semi-structured SUPER format. In this example, the JSON source is stored in Redshift without converting to Redshift types.

```
CREATE MATERIALIZED VIEW ev_station_data AS
  SELECT approximate_arrival_timestamp,
         partition_key,
         shard_id,
         sequence_number,
         case when can_json_parse(kinesis_data) then json_parse(kinesis_data) else null
         end as payload,
         case when not can_json_parse(kinesis_data) then kinesis_data else null end as
         failed_payload
  FROM evdata."ev_station_data" ;
```

In contrast, in the following materialized view definition, the materialized view has a defined schema in Redshift. The materialized view is distributed on the UUID value from the stream and is sorted by the `approximatearrivaltimestamp` value.

```
CREATE MATERIALIZED VIEW ev_station_data_extract DISTKEY(6) sortkey(1) AUTO REFRESH
YES AS
  SELECT refresh_time,
         approximate_arrival_timestamp,
         partition_key,
         shard_id,
         sequence_number,

         json_extract_path_text(from_varbyte(kinesis_data, 'utf-8'), '_id', true)::character(36)
         as ID,

         json_extract_path_text(from_varbyte(kinesis_data, 'utf-8'), 'clusterID', true)::varchar(30)
         as clusterID,

         json_extract_path_text(from_varbyte(kinesis_data, 'utf-8'), 'connectionTime', true)::varchar(100)
         as connectionTime,

         json_extract_path_text(from_varbyte(kinesis_data, 'utf-8'), 'kWhDelivered', true)::DECIMAL(10,2)
         as kWhDelivered,

         json_extract_path_text(from_varbyte(kinesis_data, 'utf-8'), 'stationID', true)::DECIMAL(10,2)
         as stationID,

         json_extract_path_text(from_varbyte(kinesis_data, 'utf-8'), 'spaceID', true)::varchar(100)
         as spaceID,
         json_extract_path_text(from_varbyte(kinesis_data,
         'utf-8'), 'timezone', true)::varchar(30)as timezone,

         json_extract_path_text(from_varbyte(kinesis_data, 'utf-8'), 'userID', true)::varchar(30)
         as userID
  FROM evdata."ev_station_data"
  WHERE LENGTH(kinesis_data) < 65355;
```

Query the stream

1. Query the refreshed materialized view to get usage statistics.

```
SELECT to_timestamp(connectionTime, 'YYYY-MM-DD HH24:MI:SS') as connectiontime
,SUM(kWhDelivered) AS Energy_Consumed
,count(distinct userID) AS #Users
from ev_station_data_extract
group by to_timestamp(connectionTime, 'YYYY-MM-DD HH24:MI:SS')
order by 1 desc;
```

2. View results.

connectiontime	energy_consumed	#users
2022-02-08 16:07:21+00	4139	10
2022-02-08 16:07:20+00	5571	10

AWS Glue Data Catalog views

This topic describes how to create views in the AWS Glue Data Catalog. You can use views in the Data Catalog to access data in different data sources using the same schema.

By creating views in the Data Catalog, you can create a single common view schema and metadata object to use across engines such as Amazon Athena and Amazon EMR Spark. Doing so lets you use the same views across your data lakes and data warehouses to fit your use cases. Views in the Data Catalog are special in that they are categorized as definer views, where access permissions are defined by the user who created the view instead of the user querying the view. The following are some use cases and benefits of creating views in the Data Catalog:

- Create a view that restricts data access based on the permissions the user needs. For example, you can use views in the Data Catalog to prevent employees who don't work in the HR department from seeing personally identifiable information (PII).
- Make sure that users can't access incomplete records. By applying certain filters onto your view in the Data Catalog, you make sure that data records inside a view in the Data Catalog are always complete.
- Data Catalog views have an included security benefit of making sure that the query definition used to create the view must complete to create the view. This security benefit means that views in the Data Catalog are not susceptible to SQL commands from malicious players.
- Views in the Data Catalog support the same advantages as normal views, such as letting users access a view without making the underlying table available to users.

To create a view in the Data Catalog, you must have a [Spectrum external table](#), an object that's contained within a [Lake Formation-managed datashare](#), or an [Apache Iceberg table](#).

Definitions of Data Catalog views are stored in the AWS Glue Data Catalog. Use AWS Lake Formation to grant access through resource grants, column grants, or tag-based access controls. For more information about granting and revoking access in Lake Formation, see [Granting and revoking permissions on Data Catalog resources](#).

Prerequisites

Before you can create a view in the Data Catalog, make sure that you have the following prerequisites completed:

- Make sure that your IAM role has the following trust policy.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "Service": [
          "glue.amazonaws.com",
          "lakeformation.amazonaws.com"
        ]
      },
      "Action": "sts:AssumeRole"
    }
  ]
}
```

- You also need the following pass role policy.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "Stmt1",
      "Action": [
        "iam:PassRole"
      ],
      "Effect": "Allow",
      "Resource": "*",
      "Condition": {
        "StringEquals": {
          "iam:PassedToService": [
            "glue.amazonaws.com",
            "lakeformation.amazonaws.com"
          ]
        }
      }
    }
  ]
}
```

- Finally, you also need the following permissions.

- `Glue:GetDatabase`
- `Glue:GetDatabases`
- `Glue:CreateTable`
- `Glue:GetTable`
- `Glue:UpdateTable`
- `Glue>DeleteTable`
- `Glue:GetTables`
- `Glue:SearchTables`
- `Glue:BatchGetPartition`
- `Glue:GetPartitions`
- `Glue:GetPartition`
- `Glue:GetTableVersion`
- `Glue:GetTableVersions`

End-to-end example

Start by creating an external schema based on your Data Catalog database.

```
CREATE EXTERNAL SCHEMA IF NOT EXISTS external_schema FROM DATA CATALOG DATABASE
'external_data_catalog_db'
IAM_ROLE 'arn:aws:iam::123456789012:role/sample-role';
```

You can now create a Data Catalog view.

```
CREATE EXTERNAL PROTECTED VIEW external_schema.remote_view
AS SELECT * FROM external_schema.remote_table;
```

You can then start querying your view.

```
SELECT * FROM external_schema.remote_view;
```

For more information about the SQL commands related to views in the Data Catalog, see [CREATE EXTERNAL VIEW](#), [ALTER EXTERNAL VIEW](#), and [DROP EXTERNAL VIEW](#).

Secure logging

Redshift masks metadata logged in the Redshift system logs when a query references a multi-dialect glue view. Multi-dialect means that the view supports the SQL dialects of different query engines, such as Redshift and Amazon EMR. Data in the following tables is masked for all queries with the same query id. The following table lists system views and columns with secure logging applied.

System table	Sensitive columns
<code>SYS_EXTERNAL_QUERY_DETAIL</code>	Columns: <code>source_type</code> , <code>total_partitions</code> , <code>qualified_partitions</code> , <code>scanned_files</code> , <code>returned_rows</code> , <code>returned_bytes</code> , <code>file_format</code> , <code>file_location</code> , <code>external_query_text</code> , <code>warning_message</code> . For more information, see SYS_EXTERNAL_QUERY_DETAIL .
<code>SYS_EXTERNAL_QUERY_ERROR</code>	Columns: <code>file_location</code> , <code>rowid</code> , <code>column_name</code> , <code>original_value</code> , <code>modified_value</code> , <code>trigger</code> , <code>action</code> , <code>action_value</code> , <code>error_code</code> . For more information, see SYS_EXTERNAL_QUERY_ERROR .
<code>SYS_QUERY_DETAIL</code>	Columns: <code>step_name</code> , <code>table_id</code> , <code>table_name</code> , <code>input_bytes</code> , <code>input_rows</code> , <code>output_bytes</code> , <code>output_rows</code> , <code>blocks_read</code> , <code>blocks_write</code> , <code>local_read_IO</code> , <code>remote_read_IO</code> , <code>spilled_block_local_disk</code> , <code>spilled_block_remote_disk</code> . Considerations and limitations

The following are considerations and limitations that apply to views created in the Data Catalog.

- You can't create a Data Catalog view that is based off of another view.
- You can only have 10 base tables in a Data Catalog view.
- The definer of the view must have full `SELECT GRANTABLE` permissions on the base tables.
- Views can only contain Lake Formation objects and built-ins. The following objects are not permitted inside of a view.
 - System tables
 - User-defined functions (UDFs)
 - Redshift tables, views, materialized views, and late binding views that aren't in a Lake Formation managed data share.
- Views can't contain nested Redshift Spectrum tables.
- AWS Glue representations of the base objects of a view must be in the same AWS account and Region as the view.

Querying spatial data in Amazon Redshift

Spatial data describes the position and shape of a geometry in a defined space (a spatial reference system). Amazon Redshift supports spatial data with the GEOMETRY and GEOGRAPHY data types, which contain spatial data and optionally the data's spatial reference system identifier (SRID).

Spatial data contains geometric data that you can use to represent geographic features. Examples of this type of data include weather reports, map directions, tweets with geographic positions, store locations, and airline routes. Spatial data plays an important role in business analytics, reporting, and forecasting.

You can query spatial data with Amazon Redshift SQL functions. Spatial data contains geometric values for an object.

The GEOMETRY data type operations work on the Cartesian plane. Although the spatial reference system identifier (SRID) is stored inside the object, this SRID is merely an identifier of the coordinate system and plays no role in the algorithms used to process the GEOMETRY objects. Conversely, the operations on the GEOGRAPHY data type treat the coordinates inside objects as spherical coordinates on a spheroid. This spheroid is defined by the SRID, which references a geographic spatial reference system. By default, GEOGRAPHY data types are created with spatial reference (SRID) 4326, referencing the World Geodetic System (WGS) 84. For more information about SRIDs, see [Spatial reference system](#) in Wikipedia.

You can use the ST_Transform function to transform the coordinates from various spatial reference systems. After the transformation of the coordinates is done, you can also use a simple cast between the two, as long as the input GEOMETRY is encoded with the geographic SRID. This cast simply copies coordinates without any further transformation. For example:

```
SELECT ST_AsEWKT(ST_GeomFromEWKT('SRID=4326;POINT(10 20)'))::geography;
```

```
st_asewkt
```

```
-----
```

```
SRID=4326;POINT(10 20)
```

To better understand the difference between GEOMETRY and GEOGRAPHY data types, consider calculating the distance between the Berlin airport (BER) and the San Francisco airport (SFO) using the World Geodetic System (WGS) 84. Using the GEOGRAPHY data type, the result is in meters.

When using GEOMETRY data type with SRID 4326, the result is in degrees, which can't convert to meters because the distance of one degree depends on where on the globe geometries are located.

Calculations on the GEOGRAPHY data type are mostly used for realistic round earth calculations such as the precise area of a country without distortion. But they are far more expensive to compute. Therefore, ST_Transform can transform your coordinates to an appropriate local projected coordinate system and do the calculation on the GEOMETRY data type faster.

Using spatial data, you can run queries to do the following:

- Find the distance between two points.
- Check whether one area (polygon) contains another.
- Check whether one linestring intersects another linestring or polygon.

You can use the GEOMETRY data type to hold the values of spatial data. A GEOMETRY value in Amazon Redshift can define two-dimensional (2D), three-dimensional (3DZ), two-dimensional with a measure (3DM), and four-dimensional (4D) geometry primitive data types:

- A two-dimensional (2D) geometry is specified by two Cartesian coordinates (x, y) in a plane.
- A three-dimensional (3DZ) geometry is specified by three Cartesian coordinates (x, y, z) in space.
- A two-dimensional with measure (3DM) geometry is specified by three coordinates (x, y, m), where the first two are Cartesian coordinates in a plane and the third is a measurement.
- A four-dimensional (4D) geometry is specified by four coordinates (x, y, z, m), where the first three are Cartesian coordinates in a space and the fourth is a measurement.

For more information about geometry primitive data types, see [Well-known text representation of geometry](#) in Wikipedia.

You can use the GEOGRAPHY data type to hold the values of spatial data. A GEOGRAPHY value in Amazon Redshift can define two-dimensional (2D), three-dimensional (3DZ), two-dimensional with a measure (3DM), and four-dimensional (4D) geometry primitive data types:

- A two-dimensional (2D) geometry is specified by longitude and latitude coordinates on a spheroid.
- A three-dimensional (3DZ) geometry is specified by longitude, latitude, and altitude coordinates on a spheroid.

- A two-dimensional with measure (3DM) geometry is specified by three coordinates (longitude, latitude, measure), where the first two are angular coordinates on a sphere and the third is a measurement.
- A four-dimensional (4D) geometry is specified by four coordinates (longitude, latitude, altitude, measure), where the first three are longitude, latitude and altitude, and the fourth is a measurement.

For more information about geographic coordinate systems, see [Geographic coordinate system](#) and [Spherical coordinate system](#) in Wikipedia.

The GEOMETRY and GEOGRAPHY data types have the following subtypes:

- POINT
- LINESTRING
- POLYGON
- MULTIPOINT
- MULTILINESTRING
- MULTIPOLYGON
- GEOMETRYCOLLECTION

There are Amazon Redshift SQL functions that support the following representations of geometric data:

- GeoJSON
- Well-known text (WKT)
- Extended well-known text (EWKT)
- Well-known binary (WKB) representation
- Extended well-known binary (EWKB)

You can cast between GEOMETRY and GEOGRAPHY data types.

The following SQL casts a linestring from a GEOMETRY to a GEOGRAPHY.

```
SELECT ST_AsEWKT(ST_GeomFromText('LINESTRING(110 40, 2 3, -10 80, -7 9)')::geography);
```

```
st_asewkt
```

```
-----  
SRID=4326;LINESTRING(110 40,2 3,-10 80,-7 9)
```

The following SQL casts a linestring from a GEOGRAPHY to a GEOMETRY.

```
SELECT ST_AseWKT(ST_GeogFromText('LINESTRING(110 40, 2 3, -10 80, -7 9)')::geometry);
```

```
st_asewkt
```

```
-----  
SRID=4326;LINESTRING(110 40,2 3,-10 80,-7 9)
```

Amazon Redshift provides many SQL functions to query spatial data. Except for the `ST_IsValid` function, spatial functions that accept a GEOMETRY object as an argument expect this GEOMETRY object to be a valid geometry. If the GEOMETRY or GEOGRAPHY object isn't valid, then the behavior of the spatial function is undefined. For more information about validity, see [Geometric validity](#).

For details about SQL functions to query spatial data, see [Spatial functions](#).

For details about loading spatial data, see [Loading a column of the GEOMETRY or GEOGRAPHY data type](#).

Tutorial: Using spatial SQL functions with Amazon Redshift

This tutorial demonstrates how to use some of the spatial SQL functions with Amazon Redshift.

To do this, you query two tables using spatial SQL functions. The tutorial uses data from public datasets that correlate location data of rental accommodations with postal codes in Berlin, Germany.

Topics

- [Prerequisites](#)
- [Step 1: Create tables and load test data](#)
- [Step 2: Query spatial data](#)
- [Step 3: Clean up your resources](#)

Prerequisites

For this tutorial, you need the following resources:

- An existing Amazon Redshift cluster and database that you can access and update. In the existing cluster, you create tables, load sample data, and run SQL queries to demonstrate spatial functions. Your cluster should have at least two nodes. To learn how to create a cluster, follow the steps in [Amazon Redshift Getting Started Guide](#).
- To use the Amazon Redshift query editor, make sure that your cluster is in an AWS Region that supports the query editor. For more information, see [Querying a database using the query editor](#) in the *Amazon Redshift Management Guide*.
- AWS credentials for your Amazon Redshift cluster that allow it to load test data from Amazon S3. For information about how to access other AWS services like Amazon S3, see [Authorizing Amazon Redshift to access AWS services](#).
- The AWS Identity and Access Management (IAM) role named `mySpatialDemoRole`, which has the managed policy `AmazonS3ReadOnlyAccess` attached to read Amazon S3 data. To create a role with permission to load data from an Amazon S3 bucket, see [Authorizing COPY, UNLOAD, and CREATE EXTERNAL SCHEMA operations using IAM roles](#) in the *Amazon Redshift Management Guide*.
- After you create the IAM role `mySpatialDemoRole`, that role needs an association with your Amazon Redshift cluster. For more information on how to create that association, see [Authorizing COPY, UNLOAD, and CREATE EXTERNAL SCHEMA operations using IAM roles](#) in the *Amazon Redshift Management Guide*.

Step 1: Create tables and load test data

The source data used by this tutorial is in files named `accommodations.csv` and `zipcodes.csv`.

The `accommodations.csv` file is open-source data from `insideairbnb.com`. The `zipcodes.csv` file provides postal codes that are open-source data from the national statistics institute of Berlin-Brandenburg in Germany (Amt für Statistik Berlin-Brandenburg). Both data sources are provided under a Creative Commons license. The data is limited to the Berlin, Germany, region. These files are located in an Amazon S3 public bucket to use with this tutorial.

You can optionally download the source data from the following Amazon S3 links:

- [Source data for the accommodations table.](#)
- [Source data for the zipcode table.](#)

Use the following procedure to create tables and load test data.

To create tables and load test data

1. Open the Amazon Redshift query editor. For more information on working with the query editor, see [Querying a database using the query editor](#) in the *Amazon Redshift Management Guide*.
2. Drop any tables used by this tutorial if they already exist in your database. For more information, see [Step 3: Clean up your resources](#).
3. Create the `accommodations` table to store each accommodation's geographical location (longitude and latitude), the name of the listing, and other business data.

This tutorial explores room rentals in Berlin, Germany. The `shape` column stores geographic points of the location of accommodations. The other columns contain information about the rental.

To create the `accommodations` table, run the following SQL statement in the Amazon Redshift query editor.

```
CREATE TABLE public.accommodations (  
  id INTEGER PRIMARY KEY,  
  shape GEOMETRY,  
  name VARCHAR(100),  
  host_name VARCHAR(100),  
  neighbourhood_group VARCHAR(100),  
  neighbourhood VARCHAR(100),  
  room_type VARCHAR(100),  
  price SMALLINT,
```

```
minimum_nights SMALLINT,  
number_of_reviews SMALLINT,  
last_review DATE,  
reviews_per_month NUMERIC(8,2),  
calculated_host_listings_count SMALLINT,  
availability_365 SMALLINT  
);
```

4. Create the zipcode table in the query editor to store Berlin postal codes.

A *postal code* is defined as a polygon in the `wkb_geometry` column. The rest of the columns describe additional spatial metadata about the postal code.

To create the zipcode table, run the following SQL statement in the Amazon Redshift query editor.

```
CREATE TABLE public.zipcode (  
  ogc_field INTEGER PRIMARY KEY NOT NULL,  
  wkb_geometry GEOMETRY,  
  gml_id VARCHAR(256),  
  spatial_name VARCHAR(256),  
  spatial_alias VARCHAR(256),  
  spatial_type VARCHAR(256)  
);
```

5. Load the tables using sample data.

The sample data for this tutorial is provided in an Amazon S3 bucket that allows read access to all authenticated AWS users. Make sure that you provide valid AWS credentials that permit access to Amazon S3.

To load test data to your tables, run the following COPY commands. Replace *account-number* with your own AWS account number. The segment of the credentials string that is enclosed in single quotation marks can't contain any spaces or line breaks.

```
COPY public.accommodations  
FROM 's3://redshift-downloads/spatial-data/accommodations.csv'  
DELIMITER ';'   
IGNOREHEADER 1 REGION 'us-east-1'  
CREDENTIALS 'aws_iam_role=arn:aws:iam::account-number:role/mySpatialDemoRole';
```

```
COPY public.zipcode
FROM 's3://redshift-downloads/spatial-data/zipcode.csv'
DELIMITER ';'
IGNOREHEADER 1 REGION 'us-east-1'
CREDENTIALS 'aws_iam_role=arn:aws:iam::account-number:role/mySpatialDemoRole';
```

6. Verify that each table loaded correctly by running the following commands.

```
select count(*) from accommodations;
```

```
select count(*) from zipcode;
```

The following results show the number of rows in each table of test data.

Table name	Rows
accommodations	22,248
zipcode	190

Step 2: Query spatial data

After your tables are created and loaded, you can query them using SQL SELECT statements. The following queries demonstrate some of the information that you can retrieve. You can write many other queries that use spatial functions to satisfy your needs.

To query spatial data

1. Query to get the count of the total number of listings stored in the `accommodations` table, as shown following. The spatial reference system is World Geodetic System (WGS) 84, which has the unique spatial reference identifier 4326.

```
SELECT count(*) FROM public.accommodations WHERE ST_SRID(shape) = 4326;
```

```
count
-----
```

22248

- Fetch the geometry objects in well-known text (WKT) format with some additional attributes. Additionally, you can validate if this postal code data is also stored in World Geodetic System (WGS) 84, which uses the spatial reference ID (SRID) 4326. Spatial data must be stored in the same spatial reference system to be interoperable.

```
SELECT ogc_field, spatial_name, spatial_type, ST_SRID(wkb_geometry),
       ST_AsText(wkb_geometry)
FROM public.zipcode
ORDER BY spatial_name;
```

(190 rows returned)

- Select the polygon of Berlin Mitte (10117), a borough of Berlin, in GeoJSON format, its dimension, and the number of points in this polygon.

```
SELECT ogc_field, spatial_name, ST_AsGeoJSON(wkb_geometry),
       ST_Dimension(wkb_geometry), ST_NPoints(wkb_geometry)
FROM public.zipcode
WHERE spatial_name='10117';
```

ogc_field	spatial_name	spatial_type	st_dimension	st_npoint
4	10117	{"type": "Polygon", "coordinates": [[[...]]}	331	2

- Run the following SQL command to view how many accommodations are within 500 meters of the Brandenburg Gate.

```
SELECT count(*)
FROM public.accommodations
```

```
WHERE ST_DistanceSphere(shape, ST_GeomFromText('POINT(13.377704 52.516431)', 4326))
< 500;
```

```
count
-----
29
```

- Get the rough location of the Brandenburg Gate from data stored in the accommodations that are listed as nearby by running the following query.

This query requires a subselect. It leads to a different count because the requested location is not the same as the previous query because it is closer to the accommodations.

```
WITH poi(loc) as (
  SELECT st_astext(shape) FROM accommodations WHERE name LIKE '%brandenburg gate%'
)
SELECT count(*)
FROM accommodations a, poi p
WHERE ST_DistanceSphere(a.shape, ST_GeomFromText(p.loc, 4326)) < 500;
```

```
count
-----
60
```

- Run the following query to show the details of all accommodations around the Brandenburg Gate, ordered by price in descending order.

```
SELECT name, price, ST_AsText(shape)
FROM public.accommodations
WHERE ST_DistanceSphere(shape, ST_GeomFromText('POINT(13.377704 52.516431)', 4326))
< 500
ORDER BY price DESC;
```

```

...
(29 rows returned)
```

7. Run the following query to retrieve the most expensive accommodation with its postal code.

```
SELECT
  a.price, a.name, ST_AsText(a.shape),
  z.spatial_name, ST_AsText(z.wkb_geometry)
FROM accommodations a, zipcode z
WHERE price = 9000 AND ST_Within(a.shape, z.wkb_geometry);
```

```
price  name                                st_astext
      spatial_name      st_astext
-----
9000   Ueber den Dächern Berlins Zentrum    POINT(13.334436985013
52.4979779501538)    10777      POLYGON((13.3318284987227
52.4956021172799,...
```

8. Calculate the maximum, minimum, or median price of accommodations by using a subquery.

The following query lists the median price of accommodations by postal code.

```
SELECT
  a.price, a.name, ST_AsText(a.shape),
  z.spatial_name, ST_AsText(z.wkb_geometry)
FROM accommodations a, zipcode z
WHERE
  ST_Within(a.shape, z.wkb_geometry) AND
  price = (SELECT median(price) FROM accommodations)
ORDER BY a.price;
```

```
price name                                st_astext
      spatial_name      st_astext
-----

```

```
(723 rows returned)
```

9. Run the following query to retrieve the number of accommodations listed in Berlin. To find the hot spots, these are grouped by postal code and sorted by the amount of supply.

```
SELECT z.spatial_name as zip, count(*) as numAccommodations
FROM public.accommodations a, public.zipcode z
WHERE ST_Within(a.shape, z.wkb_geometry)
GROUP BY zip
ORDER BY numAccommodations DESC;
```

```
zip    numaccommodations
-----
10245  872
10247  832
10437  733
10115  664
...
(187 rows returned)
```

Step 3: Clean up your resources

Your cluster continues to accrue charges as long as it's running. When you have completed this tutorial, you can delete your sample cluster.

If you want to keep the cluster but recover the storage used by the test data tables, run the following commands to delete the tables.

```
drop table public.accommodations cascade;
```

```
drop table public.zipcode cascade;
```

Loading a shapefile into Amazon Redshift

You can use the COPY command to ingest Esri shapefiles stored in Amazon S3 into Amazon Redshift tables. A *shapefile* stores the geometric location and attribute information of geographic

features in a vector format. The shapefile format can spatially describe spatial objects such as points, lines, and polygons. For more information about a shapefile, see [Shapefile](#) in Wikipedia.

The COPY command supports the data format parameter SHAPEFILE. By default, the first column of the shapefile is either a GEOMETRY or IDENTITY column. All subsequent columns follow the order specified in the shapefile. However, the target table doesn't need to be in this exact layout because you can use COPY column mapping to define the order. For information about the COPY command shapefile support, see [SHAPEFILE](#).

In some cases, the resulting geometry size might be greater than the maximum for storing a geometry in Amazon Redshift. If so, you can use the COPY option SIMPLIFY or SIMPLIFY AUTO to simplify the geometries during ingestion as follows:

- Specify `SIMPLIFY tolerance` to simplify all geometries during ingestion using the Ramer-Douglas-Peucker algorithm and the given tolerance.
- Specify `SIMPLIFY AUTO` without tolerance to simplify only geometries that are larger than the maximum size using the Ramer-Douglas-Peucker algorithm. This approach calculates the minimum tolerance that is large enough to store the object within the maximum size limit.
- Specify `SIMPLIFY AUTO max_tolerance` to simplify only geometries that are larger than the maximum size using the Ramer-Douglas-Peucker algorithm and the automatically calculated tolerance. This approach makes sure that the tolerance doesn't exceed the maximum tolerance.

For information about the maximum size of a GEOMETRY data value, see [Considerations when using spatial data with Amazon Redshift](#).

In some cases, the tolerance is low enough that the record can't shrink below the maximum size of a GEOMETRY data value. In these cases, you can use the MAXERROR option of the COPY command to ignore all or up to a certain number of ingestion errors.

The COPY command also supports loading GZIP shapefiles. To do this, specify the COPY GZIP parameter. With this option, all shapefile components must be independently compressed and share the same compression suffix.

If a projection description file (.prj) exists with the shapefile, Redshift uses it to determine the spatial reference system id (SRID). If the SRID is valid, the resulting geometry has this SRID assigned. If the SRID value associated with the input geometry does not exist, the resulting geometry has the SRID value zero. You can disable automatic detection of the spatial reference system id at the session level by using `SET read_srid_on_shapefile_ingestion` to OFF.

Query the `SYS_SPATIAL_SIMPLIFY` or `SVL_SPATIAL_SIMPLIFY` system views to view which records have been simplified, along with the calculated tolerance. When you specify `SIMPLIFY tolerance`, this view contains a record for each `COPY` operation. Otherwise, it contains a record for each simplified geometry. For more information, see [SYS_SPATIAL_SIMPLIFY](#) or [SVL_SPATIAL_SIMPLIFY](#).

For examples of loading a shapefile, see [Loading a shapefile into Amazon Redshift](#).

Terminology for Amazon Redshift spatial data

The following terms are used to describe some Amazon Redshift spatial functions.

Bounding box

A bounding box of a geometry or geography is defined as the cross product (across dimensions) of the extents of the coordinates of all points in the geometry or geography. For two-dimensional geometries, the bounding box is a rectangle that completely includes all points in the geometry. For example, a bounding box of the polygon `POLYGON((0 0, 1 0, 0 2, 0 0))` is the rectangle that is defined by the points (0, 0) and (1, 2) as its bottom-left and top-right corners. Amazon Redshift precomputes and stores a bounding box inside a geometry to speed up geometric predicates and spatial joins. For example if the bounding boxes of two geometries don't intersect, then these two geometries can't intersect, and they can't be in the result set of a spatial join using the `ST_Intersects` predicate.

You can use spatial functions to add ([AddBBox](#)), drop ([DropBBox](#)), and determine support ([SupportsBBox](#)) for a bounding box. Amazon Redshift supports the precomputation of bounding boxes for all geometry subtypes.

The following example shows how to update existing geometries in a table to store them with a bounding box. If your cluster is at cluster version 1.0.26809 or later, then all new geometries are created with a precomputed bounding box by default.

```
UPDATE my_table SET geom = AddBBox(geom) WHERE SupportsBBox(geom) = false;
```

After you update existing geometries, we recommend you run the `VACUUM` command on the updated table. For more information, see [VACUUM](#).

To set whether geometries are encoded with a bounding box during a session, see [default_geometry_encoding](#).

Geometric validity

Geometric algorithms used by Amazon Redshift assume that the input geometry is a valid geometry. If an input to an algorithm is not valid, then the result is undefined. The following section describes the geometric validity definitions used by Amazon Redshift for each geometry subtype.

Point

A point is considered to be valid if one of the following conditions is true:

- The point is the empty point.
- All point coordinates are finite floating point numbers.

A point can be the empty point.

Linestring

A linestring is considered to be valid if any of the following conditions are true:

- The linestring is empty; that is, it contains no points.
- All points in a nonempty linestring have coordinates that are finite floating point numbers.
- The linestring, if not empty, must be one-dimensional; that is, it can't degenerate to a point.

A linestring can't contain empty points.

A linestring can have duplicate consecutive points.

A linestring can have self-intersections.

Polygon

A polygon is considered to be valid if any of the following conditions are true:

- The polygon is empty; that is, it contains no rings.
- If not empty, a polygon is valid if all of the following conditions are true:
 - All rings of the polygon are valid. A ring is considered to be valid if all the following conditions are true:
 - All points of the ring have coordinates that are finite floating point numbers.
 - The ring is closed; that is, its first point and its last point coincide.
 - The ring doesn't have any self-intersections.
 - The ring is two-dimensional.

- The rings of the polygon have consistent orientations. That is, if you traverse any ring, the interior of the polygon is either to your right or to your left. This means that if a polygon's exterior ring is oriented clockwise or counterclockwise, all the polygon's interior rings must have the same counterclockwise or clockwise orientation.
- All interior rings must be within the exterior ring of the polygon.
- Interior rings can't be nested; that is, an interior ring can't be within another interior ring.
- Interior and exterior rings can only intersect at a finite number of points.
- The interior of the polygon must be simply connected.

A polygon can't contain empty points.

Multipoint

A multipoint is considered to be valid if any of the following conditions are true:

- The multipoint is empty; that is, it contains no points.
- A multipoint is not empty, and all points are valid according to the point validity definition.

A multipoint can contain one or more empty points.

A multipoint can have duplicate points.

Multilinestring

A multilinestring is considered to be valid if any of the following conditions are true:

- The multilinestring is empty; that is, it contains no linestrings.
- All linestrings in a nonempty multilinestring are valid according to the linestring validity definition.

A nonempty multilinestring that consists of only empty linestrings is considered to be valid.

An empty linestring in a multilinestring doesn't affect its validity.

A multilinestring can have linestrings with duplicate consecutive points.

A multilinestring can have self-intersections.

A multilinestring can't contain empty points.

Multipolygon

A multipolygon is considered to be valid if any of the following conditions are true:

- The multipolygon doesn't contain any polygons (it is empty).
- The multipolygon is not empty and all of the following are true:
 - All polygons in the multipolygon are valid.
 - No two polygons in the multipolygon can intersect at an infinite number of points. In particular, this implies that the interior of any two polygons can't intersect and that they can only touch at a finite number of points.

An empty polygon in a multipolygon doesn't invalidate a multipolygon.

A multipolygon can't contain empty points.

Geometry collection

A geometry collection is considered to be valid if any of the following conditions are true:

- The geometry collection is empty; that is, it doesn't contain any geometries.
- All geometries in a nonempty geometry collection are valid.

This definition still applies, although in a recursive manner, for nested geometry collections.

A geometry collection can contain empty points and multipoints with empty points.

Geometric simplicity

Geometric algorithms used by Amazon Redshift assume that the input geometry is a valid geometry. If an input to an algorithm is not valid, then the simplicity check is undefined. The following section describes the geometric simplicity definitions used by Amazon Redshift for each geometry subtype.

Point

A valid point is considered to be simple if any of the following conditions are true:

- A valid point is always considered to be simple.
- An empty point is considered to be simple.

Linestring

A valid linestring is considered to be simple if any of the following conditions are true:

- The linestring is empty.
- The linestring is not empty and all of the following conditions are true:

- It has no duplicate consecutive points.
- It has no self-intersections, except possibly for its first point and last point, which can coincide. In other words, the linestring can't have self-intersections except at boundary points.

Polygon

A valid polygon is considered to be simple if it doesn't contain any duplicate consecutive points.

Multipoint

A valid multipoint is considered to be simple if any of the following conditions are true:

- The multipoint is empty; that is, it contains no points.
- No two nonempty points of the multipoint coincide.

Multilinestring

A valid multilinestring is considered to be simple if any of the following conditions are true:

- The multilinestring is empty.
- The multilinestring is nonempty and all of the following conditions are true:
 - All its linestrings are simple.
 - Any two linestrings of the multilinestring don't intersect, except at points that are boundary points of the two linestrings.

A nonempty multilinestring that consists of empty linestrings only is considered to be empty.

An empty linestring in a multilinestring doesn't affect its simplicity.

A closed linestring in a multilinestring can't intersect with any other linestring in the multilinestring.

A multilinestring can't have linestrings with duplicate consecutive points.

Multipolygon

A valid multipolygon is considered to be simple if it doesn't contain any duplicate consecutive points.

Geometry collection

A valid geometry collection is considered to be simple if any of the following conditions are true:

- The geometry collection is empty; that is, it doesn't contain any geometries.
- All geometries in a nonempty geometry collection are simple.

This definition still applies, although in a recursive manner, for nested geometry collections.

H3

H3 is a hierarchical geospatial indexing grid system, which offers a way to index spatial coordinates down to square meter resolution. Indexed data can be joined across disparate datasets and aggregated at different levels of precision. H3 enables a range of algorithms and optimizations based on the grid, including nearest neighbors, shortest path, gradient smoothing, and more. H3 indexes refer to cells that can be either hexagons or pentagons. The space is subdivided hierarchically given a resolution. H3 supports 16 resolutions from 0–15, inclusive. With 0 being the coarsest and 15 being the finest.

Amazon Redshift provides the following H3 spatial functions:

- [H3_FromLongLat](#)
- [H3_FromPoint](#)
- [H3_Polyfill](#)

Considerations when using spatial data with Amazon Redshift

The following are considerations when using spatial data with Amazon Redshift:

- The maximum size of a GEOMETRY or GEOGRAPHY object is 1,048,447 bytes.
- Amazon Redshift Spectrum doesn't natively support spatial data. Therefore, you can't create or alter an external table with a GEOMETRY or GEOGRAPHY column.
- Data types for Python user-defined functions (UDFs) don't support the GEOMETRY or GEOGRAPHY data type.
- You can't use a GEOMETRY or GEOGRAPHY column as a sort key or a distribution key for an Amazon Redshift table.
- You can't use GEOMETRY or GEOGRAPHY columns in SQL ORDER BY, GROUP BY, or DISTINCT clauses.
- You can't use GEOMETRY or GEOGRAPHY columns in many SQL functions.

- You can't perform an UNLOAD operation on GEOMETRY or GEOGRAPHY columns into every format. You can UNLOAD GEOMETRY or GEOGRAPHY columns to text or comma-separated value (CSV) files. Doing this writes GEOMETRY or GEOGRAPHY data in hexadecimal EWKB format. If the size of the EWKB data is more than 4 MB, then a warning occurs because the data can't later be loaded into a table.
- The supported compression encoding of GEOMETRY or GEOGRAPHY data is RAW.
- When using JDBC or ODBC drivers, use customized type mappings. In this case, the client application must have information on which parameters of a ResultSet object are GEOMETRY or GEOGRAPHY objects. The ResultSetMetadata operation returns type VARCHAR.
- To copy geographic data from a SHAPEFILE, first ingest into a GEOMETRY column, and then cast the objects to GEOGRAPHY objects. .

The following nonspatial functions can accept an input of type GEOMETRY or GEOGRAPHY, or columns of type GEOMETRY or GEOGRAPHY:

- The aggregate function COUNT
- The conditional expressions COALESCE and NVL
- CASE expressions
- The default encoding for GEOMETRY and GEOGRAPHY is RAW. For more information, see [Compression encodings](#).

Querying data with federated queries in Amazon Redshift

By using *federated queries* in Amazon Redshift, you can query and analyze data across operational databases, data warehouses, and data lakes. With the Federated Query feature, you can integrate queries from Amazon Redshift on live data in external databases with queries across your Amazon Redshift and Amazon S3 environments. Federated queries can work with external databases in Amazon RDS for PostgreSQL, Amazon Aurora PostgreSQL-Compatible Edition, Amazon RDS for MySQL, and Amazon Aurora MySQL-Compatible Edition.

You can use federated queries to incorporate live data as part of your business intelligence (BI) and reporting applications. For example, to make data ingestion to Amazon Redshift easier you can use federated queries to do the following:

- Query operational databases directly.
- Apply transformations quickly.
- Load data into the target tables without the need for complex extract, transform, load (ETL) pipelines.

To reduce data movement over the network and improve performance, Amazon Redshift distributes part of the computation for federated queries directly into the remote operational databases. Amazon Redshift also uses its parallel processing capacity to support running these queries, as needed.

When running federated queries, Amazon Redshift first makes a client connection to the RDS or Aurora DB cluster DB instance from the leader node to retrieve table metadata. From a compute node, Amazon Redshift issues subqueries with a predicate pushed down and retrieves the result rows. Amazon Redshift then distributes the result rows among the compute nodes for further processing.

Details about queries sent to the Amazon Aurora PostgreSQL database or Amazon RDS for PostgreSQL database are logged in the system view [SVL_FEDERATED_QUERY](#).

- [Examples of using a federated query](#)
- [Data type differences between Amazon Redshift and supported PostgreSQL and MySQL databases](#)
- [Considerations when accessing federated data with Amazon Redshift](#)

Getting started with using federated queries to PostgreSQL

To create a federated query, you follow this general approach:

1. Set up connectivity from your Amazon Redshift cluster to your Amazon RDS or Aurora PostgreSQL DB instance.

To do this, make sure that your RDS PostgreSQL or Aurora PostgreSQL DB instance can accept connections from your Amazon Redshift cluster. We recommend that your Amazon Redshift cluster and Amazon RDS or Aurora PostgreSQL instance be in the same virtual private cloud (VPC) and subnet group. This way, you can add the security group for the Amazon Redshift cluster to the inbound rules of the security group for your RDS or Aurora PostgreSQL DB instance.

You can also set up VPC peering or other networking that allows Amazon Redshift to make connections to your RDS or Aurora PostgreSQL instance. For more information about VPC networking, see the following.

- [What is VPC peering?](#) in the *Amazon VPC Peering Guide*
- [Working with a DB instance in a VPC](#) in the *Amazon RDS User Guide*

Note

There are cases where you must enable enhanced VPC routing: For example, if your Amazon Redshift cluster is in a different VPC than your RDS or Aurora PostgreSQL instance, or if they're in the same VPC and your routes require it. Otherwise, you might receive timeout errors when you run a federated query.

2. Set up secrets in AWS Secrets Manager for your RDS PostgreSQL and Aurora PostgreSQL databases. Then reference the secrets in AWS Identity and Access Management (IAM) access

policies and roles. For more information, see [Creating a secret and an IAM role to use federated queries](#).

Note

If your cluster uses enhanced VPC routing, you might need to configure an interface VPC endpoint for AWS Secrets Manager. This is necessary when the VPC and subnet of your Amazon Redshift cluster don't have access to the public AWS Secrets Manager endpoint. When you use a VPC interface endpoint, communication between the Amazon Redshift cluster in your VPC and AWS Secrets Manager is routed privately from your VPC to the endpoint interface. For more information, see [Creating an interface endpoint](#) in the *Amazon VPC User Guide*.

3. Apply the IAM role that you previously created to the Amazon Redshift cluster. For more information, see [Creating a secret and an IAM role to use federated queries](#).
4. Connect to your RDS PostgreSQL and Aurora PostgreSQL databases with an external schema. For more information, see [CREATE EXTERNAL SCHEMA](#). For examples on how to use federated query, see [Examples of using a federated query](#).
5. Run your SQL queries referencing the external schema that references your RDS PostgreSQL and Aurora PostgreSQL databases.

Getting started using federated queries to PostgreSQL with AWS CloudFormation

You can use federated queries to query across operational databases. In this getting-started guide, you can automate setup by using a sample AWS CloudFormation stack to enable a federated query from an Amazon Redshift cluster to an Aurora PostgreSQL serverless database. You can get up and running quickly without having to run SQL statements to provision your resources.

The stack creates an external schema, referencing your Aurora PostgreSQL instance, which includes tables with sample data. You can query tables in the external schema from your Redshift cluster.

If instead you want to get started with federated queries by running SQL statements to set up an external schema, without using CloudFormation, see [Getting started with using federated queries to PostgreSQL](#).

Before running the CloudFormation stack for federated queries, make sure that you have an Amazon Aurora PostgreSQL-Compatible Edition serverless database with the Data API turned on. You can turn on the Data API in the database properties. If you can't find the setting, double-check that you are running a serverless instance of Aurora PostgreSQL. Also make sure that you have a Amazon Redshift cluster that uses RA3 nodes. We recommend that both the Redshift cluster and serverless Aurora PostgreSQL instance are in the same virtual private cloud (VPC) and subnet group. This way, you can add the security group for the Amazon Redshift cluster to the inbound rules of the security group for your Aurora PostgreSQL database instance.

For more information about getting started setting up an Amazon Redshift cluster, see [Get started with Amazon Redshift provisioned data warehouses](#). For more information about setting up resources with CloudFormation, see [What is AWS CloudFormation?](#). For more information about setting up an Aurora DB cluster database, see [Creating an Aurora DB cluster Serverless v1 DB cluster](#).

Launching a CloudFormation stack for Redshift federated queries

Use the following procedure to launch your CloudFormation stack for Amazon Redshift to enable federated queries. Before doing so, make sure you have your Amazon Redshift cluster and your serverless Aurora PostgreSQL instance set up.

To launch your CloudFormation stack for federated queries

1. Click [Launch CFN stack](#) here to launch the CloudFormation service in the AWS Management Console.

If you are prompted, sign in.

The stack creation process starts, referencing a CloudFormation template file, which is stored in Amazon S3. A CloudFormation *template* is a text file in JSON format that declares AWS resources that make up a stack.

2. Choose **Next** to enter the stack details.
3. Under **Parameters**, for the cluster, enter the following:
 - The Amazon Redshift cluster name, for example **ra3-consumer-cluster**
 - A specific database name, for example **dev**
 - The name of a database user, for example **consumeruser**

Also enter the parameters for the Aurora DB cluster database, including the user, database name, port, and endpoint. We recommend using a test cluster and test serverless database, because the stack creates several database objects.

Choose **Next**.

The stack options appear.

4. Choose **Next** to accept the default settings.
5. Under **Capabilities**, choose **I acknowledge that AWS CloudFormation might create IAM resources**.
6. Choose **Create stack**.

Choose **Create stack**. CloudFormation provisions the template resources, which takes about 10 minutes, and creates an external schema.

If an error occurs while the stack is created, do the following:

- View the CloudFormation **Events** tab for information that can help you resolve the error.
- Make sure that you entered the correct name, database name, and database user name for the Redshift cluster. Also check the parameters for the Aurora PostgreSQL instance.
- Make sure that your cluster has RA3 nodes.
- Make sure that your database and Redshift cluster are in the same subnet and security group.

Querying data from the external schema

To use the following procedure, make sure that you have the required permissions for running queries on the cluster and the database described.

To query an external database with federated query

1. Connect to the Redshift database that you entered when you created the stack, using a client tool such as the Redshift query editor.
2. Query for the external schema created by the stack.

```
select * from svv_external_schemas;
```

The [SVV_EXTERNAL_SCHEMAS](#) view returns information about available external schemas. In this case, the external schema created by the stack is returned, `myfederated_schema`. You might also have other external schemas returned, if you have any set up. The view also returns the schema's associated database. The database is the Aurora DB cluster database that you entered when you created the stack. The stack adds a table to the Aurora DB cluster database, called `category`, and another table called `sales`.

3. Run SQL queries on tables in the external schema that references your Aurora PostgreSQL database. The following example shows a query.

```
SELECT count(*) FROM myfederated_schema.category;
```

The `category` table returns several records. You can also return records from the `sales` table.

```
SELECT count(*) FROM myfederated_schema.sales;
```

For more examples, see [Examples of using a federated query](#).

Getting started with using federated queries to MySQL

To create a federated query to MySQL databases, you follow this general approach:

1. Set up connectivity from your Amazon Redshift cluster to your Amazon RDS or Aurora MySQL DB instance.

To do this, make sure that your RDS MySQL or Aurora MySQL DB instance can accept connections from your Amazon Redshift cluster. We recommend that your Amazon Redshift cluster and Amazon RDS or Aurora MySQL instance be in the same virtual private cloud (VPC) and subnet group. This way, you can add the security group for the Amazon Redshift cluster to the inbound rules of the security group for your RDS or Aurora MySQL DB instance.

You can also set up VPC peering or other networking that allows Amazon Redshift to make connections to your RDS or Aurora MySQL instance. For more information about VPC networking, see the following.

- [What is VPC peering?](#) in the *Amazon VPC Peering Guide*
- [Working with a DB instance in a VPC](#) in the *Amazon RDS User Guide*

Note

If your Amazon Redshift cluster is in a different VPC than your RDS or Aurora MySQL instance, then enable enhanced VPC routing. Otherwise, you might receive timeout errors when you run a federated query.

2. Set up secrets in AWS Secrets Manager for your RDS MySQL and Aurora MySQL databases. Then reference the secrets in AWS Identity and Access Management (IAM) access policies and roles. For more information, see [Creating a secret and an IAM role to use federated queries](#).

Note

If your cluster uses enhanced VPC routing, you might need to configure an interface VPC endpoint for AWS Secrets Manager. This is necessary when the VPC and subnet of your Amazon Redshift cluster don't have access to the public AWS Secrets Manager endpoint. When you use a VPC interface endpoint, communication between the Amazon Redshift cluster in your VPC and AWS Secrets Manager is routed privately from your VPC to the endpoint interface. For more information, see [Creating an interface endpoint](#) in the *Amazon VPC User Guide*.

3. Apply the IAM role that you previously created to the Amazon Redshift cluster. For more information, see [Creating a secret and an IAM role to use federated queries](#).
4. Connect to your RDS MySQL and Aurora MySQL databases with an external schema. For more information, see [CREATE EXTERNAL SCHEMA](#). For examples on how to use federated queries, see [Example of using a federated query with MySQL](#).
5. Run your SQL queries referencing the external schema that references your RDS MySQL and Aurora MySQL databases.

Creating a secret and an IAM role to use federated queries

The following steps show how to create a secret and an IAM role to use with federated queries.

Prerequisites

Make sure that you have the following prerequisites to create a secret and an IAM role to use with federated queries:

- An RDS PostgreSQL, Aurora PostgreSQL DB instance, RDS MySQL, or Aurora MySQL DB instance with user name and password authentication.
- An Amazon Redshift cluster with a cluster maintenance version that supports federated queries.

To create a secret (user name and password) with AWS Secrets Manager

1. Sign in to the Secrets Manager console with the account that owns your RDS or Aurora DB cluster instance.
2. Choose **Store a new secret**.
3. Choose the **Credentials for RDS database** tile. For **User name** and **Password**, enter values for your instance. Confirm or choose a value for **Encryption key**. Then choose the RDS database that your secret will access.

Note

We recommend using the default encryption key (DefaultEncryptionKey). If you use a custom encryption key, the IAM role that is used to access the secret must be added as a key user.

4. Enter a name for the secret, continue with the creation steps with the default choices, and then choose **Store**.
5. View your secret and note the **Secret ARN** value that you created to identify the secret.

To create a security policy using the secret

1. Sign in to the AWS Management Console and open the IAM console at <https://console.aws.amazon.com/iam/>.
2. Create a policy with JSON similar to the following.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "AccessSecret",
      "Effect": "Allow",
      "Action": [
        "secretsmanager:GetResourcePolicy",
```

```

        "secretsmanager:GetSecretValue",
        "secretsmanager:DescribeSecret",
        "secretsmanager:ListSecretVersionIds"
    ],
    "Resource": "arn:aws:secretsmanager:us-west-2:123456789012:secret:my-
rds-secret-VNenFy"
},
{
    "Sid": "VisualEditor1",
    "Effect": "Allow",
    "Action": [
        "secretsmanager:GetRandomPassword",
        "secretsmanager:ListSecrets"
    ],
    "Resource": "*"
}
]
}

```

To retrieve the secret, you need list and read actions. We recommend that you restrict the resource to the specific secret that you created. To do this, use the Amazon Resource Name (ARN) of the secret to limit the resource. You can also specify the permissions and resources using the visual editor on the IAM console.

3. Give the policy a name and finish creating it.
4. Navigate to **IAM roles**.
5. Create an IAM role for **Redshift - Customizable**.
6. Either attach the IAM policy you just created to an existing IAM role, or create a new IAM role and attach the policy.
7. On the **Trust relationships** tab of your IAM role, confirm that the role contains the trust entity `redshift.amazonaws.com`.
8. Note the **Role ARN** you created. This ARN has access to the secret.

To attach the IAM role to your Amazon Redshift cluster

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**. The clusters for your account in the current AWS Region are listed.

3. Choose the cluster name in the list to view more details about a cluster.
4. For **Actions**, choose **Manage IAM roles**. The **Manage IAM roles** page appears.
5. Add your IAM role to the cluster.

Examples of using a federated query

The following examples show how to run a federated query. Run the SQL using your SQL client connected to the Amazon Redshift database.

Example of using a federated query with PostgreSQL

The following example shows how to set up a federated query that references an Amazon Redshift database, an Aurora PostgreSQL database, and Amazon S3. This example illustrates how federated queries work. To run it on your own environment, change it to fit your environment. For prerequisites for doing this, see [Getting started with using federated queries to PostgreSQL](#).

Create an external schema that references an Aurora PostgreSQL database.

```
CREATE EXTERNAL SCHEMA apg
FROM POSTGRES
DATABASE 'database-1' SCHEMA 'myschema'
URI 'endpoint to aurora hostname'
IAM_ROLE 'arn:aws:iam::123456789012:role/Redshift-SecretsManager-R0'
SECRET_ARN 'arn:aws:secretsmanager:us-west-2:123456789012:secret:federation/test/
dataplane-apg-creds-YbVKQw';
```

Create another external schema that references Amazon S3, which uses Amazon Redshift Spectrum. Also, grant permission to use the schema to public.

```
CREATE EXTERNAL SCHEMA s3
FROM DATA CATALOG
DATABASE 'default' REGION 'us-west-2'
IAM_ROLE 'arn:aws:iam::123456789012:role/Redshift-S3';

GRANT USAGE ON SCHEMA s3 TO public;
```

Show the count of rows in the Amazon Redshift table.

```
SELECT count(*) FROM public.lineitem;
```

```

count
-----
25075099

```

Show the count of rows in the Aurora PostgreSQL table.

```
SELECT count(*) FROM apg.lineitem;
```

```

count
-----
11760

```

Show the count of rows in Amazon S3.

```
SELECT count(*) FROM s3.lineitem_1t_part;
```

```

count
-----
6144008876

```

Create a view of the tables from Amazon Redshift, Aurora PostgreSQL, and Amazon S3. This view is used to run your federated query.

```

CREATE VIEW lineitem_all AS
  SELECT
    l_orderkey,l_partkey,l_suppkey,l_linenumber,l_quantity,l_extendedprice,l_discount,l_tax,l_returnflag,
        l_shipdate::date,l_commitdate::date,l_receiptdate::date,
    l_shipinstruct ,l_shipmode,l_comment
  FROM s3.lineitem_1t_part
  UNION ALL SELECT * FROM public.lineitem
  UNION ALL SELECT * FROM apg.lineitem
  with no schema binding;

```

Show the count of rows in the view `lineitem_all` with a predicate to limit the results.

```
SELECT count(*) from lineitem_all WHERE l_quantity = 10;
```

```

count
-----
123373836

```

Find out how many sales of one item there were in January of each year.

```
SELECT extract(year from l_shipdate) as year,
       extract(month from l_shipdate) as month,
       count(*) as orders
FROM lineitem_all
WHERE extract(month from l_shipdate) = 1
AND l_quantity < 2
GROUP BY 1,2
ORDER BY 1,2;
```

year	month	orders
1992	1	196019
1993	1	1582034
1994	1	1583181
1995	1	1583919
1996	1	1583622
1997	1	1586541
1998	1	1583198
2016	1	15542
2017	1	15414
2018	1	15527
2019	1	151

Example of using a mixed-case name

To query a supported PostgreSQL remote database that has a mixed-case name of a database, schema, table, or column, then set `enable_case_sensitive_identifier` to `true`. For more information about this session parameter, see [enable_case_sensitive_identifier](#).

```
SET enable_case_sensitive_identifier TO TRUE;
```

Typically, the database and schema names are in lowercase. The following example shows how you can connect to a supported PostgreSQL remote database that has lowercase names for database and schema and mixed-case names for table and column.

Create an external schema that references an Aurora PostgreSQL database that has a lowercase database name (`dblower`) and lowercase schema name (`schemalower`).

```
CREATE EXTERNAL SCHEMA apg_lower
```

```
FROM POSTGRES
DATABASE 'dblower' SCHEMA 'schemalower'
URI 'endpoint to aurora hostname'
IAM_ROLE 'arn:aws:iam::123456789012:role/Redshift-SecretsManager-R0'
SECRET_ARN 'arn:aws:secretsmanager:us-west-2:123456789012:secret:federation/test/
dataplane-apg-creds-YbVKQw';
```

In the session where the query runs, set `enable_case_sensitive_identifier` to true.

```
SET enable_case_sensitive_identifier TO TRUE;
```

Run a federated query to select all data from the PostgreSQL database. The table (`MixedCaseTab`) and column (`MixedCaseName`) have mixed-case names. The result is one row (`Harry`).

```
select * from apg_lower."MixedCaseTab";
```

```
MixedCaseName
-----
Harry
```

The following example shows how you can connect to a supported PostgreSQL remote database that has a mixed-case name for the database, schema, table, and column.

Set `enable_case_sensitive_identifier` to true before you create the external schema. If `enable_case_sensitive_identifier` is not set to true before creating the external schema, then a database does not exist error occurs.

Create an external schema that references an Aurora PostgreSQL database that has a mixed-case database (`UpperDB`) and schema (`UpperSchema`) name.

```
CREATE EXTERNAL SCHEMA apg_upper
FROM POSTGRES
DATABASE 'UpperDB' SCHEMA 'UpperSchema'
URI 'endpoint to aurora hostname'
IAM_ROLE 'arn:aws:iam::123456789012:role/Redshift-SecretsManager-R0'
SECRET_ARN 'arn:aws:secretsmanager:us-west-2:123456789012:secret:federation/test/
dataplane-apg-creds-YbVKQw';
```

Run a federated query to select all data from the PostgreSQL database. The table (`MixedCaseTab`) and column (`MixedCaseName`) have mixed-case names. The result is one row (`Harry`).

```
select * from apg_upper."MixedCaseTab";
```

```
MixedCaseName
-----
Harry
```

Example of using a federated query with MySQL

The following example shows how to set up a federated query that references an Aurora MySQL database. This example illustrates how federated queries works. To run it on your own environment, change it to fit your environment. For prerequisites for doing this, see [Getting started with using federated queries to MySQL](#).

This example depends on the following prerequisites:

- A secret that was set up in Secrets Manager for the Aurora MySQL database. This secret is referenced in IAM access policies and roles. For more information, see [Creating a secret and an IAM role to use federated queries](#).
- A security group that is set up linking Amazon Redshift and Aurora MySQL.

Create an external schema that references an Aurora MySQL database.

```
CREATE EXTERNAL SCHEMA amysql
FROM MYSQL
DATABASE 'functional'
URI 'endpoint to remote hostname'
IAM_ROLE 'arn:aws:iam::123456789012:role/Redshift-SecretsManager-R0'
SECRET_ARN 'arn:aws:secretsmanager:us-west-2:123456789012:secret:federation/test/
dataplane-apg-creds-YbVKQw';
```

Run an example SQL select of the Aurora MySQL table to display one row from the employees table in Aurora MySQL.

```
SELECT level FROM amysql.employees LIMIT 1;
```

```
level
-----
      8
```

Data type differences between Amazon Redshift and supported PostgreSQL and MySQL databases

The following table shows the mapping of an Amazon Redshift data type to a corresponding Amazon RDS PostgreSQL or Aurora PostgreSQL data type.

Amazon Redshift data type	RDS PostgreSQL or Aurora PostgreSQL data type	Description
SMALLINT	SMALLINT	Signed two-byte integer
INTEGER	INTEGER	Signed four-byte integer
BIGINT	BIGINT	Signed eight-byte integer
DECIMAL	DECIMAL	Exact numeric of selectable precision
REAL	REAL	Single precision floating-point number
DOUBLE PRECISION	DOUBLE PRECISION	Double precision floating-point number
BOOLEAN	BOOLEAN	Logical Boolean (true/false)
CHAR	CHAR	Fixed-length character string

Amazon Redshift data type	RDS PostgreSQL or Aurora PostgreSQL data type	Description
VARCHAR	VARCHAR	Variable-length character string with a user-defined limit
DATE	DATE	Calendar date (year, month, day)
TIMESTAMP	TIMESTAMP	Date and time (without time zone)
TIMESTAMPTZ	TIMESTAMPTZ	Date and time (with time zone)
GEOMETRY	PostGIS GEOMETRY	Spatial data

The following RDS PostgreSQL and Aurora PostgreSQL data types are converted to VARCHAR(64K) in Amazon Redshift:

- JSON, JSONB
- Arrays
- BIT, BIT VARYING
- BYTEA
- Composite types
- Date and time types INTERVAL, TIME, TIME WITH TIMEZONE
- Enumerated types
- Monetary types
- Network address types
- Numeric types SERIAL, BIGSERIAL, SMALLSERIAL, and MONEY
- Object identifier types
- pg_lsn type
- Pseudotypes
- Range types

- Text search types
- TXID_SNAPSHOT
- UUID
- XML type

The following table shows the mapping of an Amazon Redshift data type to a corresponding Amazon RDS MySQL or Aurora MySQL data type.

Amazon Redshift data type	RDS MySQL or Aurora MySQL data type	Description
BOOLEAN	TINYINT(1)	Logical Boolean (true or false)
SMALLINT	TINYINT(UNSIGNED)	Signed two-byte integer
SMALLINT	SMALLINT	Signed two-byte integer
INTEGER	SMALLINT UNSIGNED	Signed four-byte integer
INTEGER	MEDIUMINT (UNSIGNED)	Signed four-byte integer
INTEGER	INT	Signed four-byte integer
BIGINT	INT UNSIGNED	Signed eight-byte integer
BIGINT	BIGINT	Signed eight-byte integer
DECIMAL	BIGINT UNSIGNED	Exact numeric of selectable precision

Amazon Redshift data type	RDS MySQL or Aurora MySQL data type	Description
DECIMAL	DECIMAL(M,D)	Exact numeric of selectable precision
REAL	FLOAT	Single precision floating-point number
DOUBLE PRECISION	DOUBLE	Double precision floating-point number
CHAR	CHAR	Fixed-length character string
VARCHAR	VARCHAR	Variable-length character string with a user-defined limit
DATE	DATE	Calendar date (year, month, day)
TIME	TIME	Time (without time zone)
TIMESTAMP	TIMESTAMP	Date and time (without time zone)
TIMESTAMP	DATETIME	Time (without time zone)
VARCHAR(4)	YEAR	Variable length character representing year

An error results when TIME data is out of range (00:00:00 – 24:00:00).

The following RDS MySQL and Aurora MySQL data types are converted to VARCHAR(64K) in Amazon Redshift:

- BIT
- BINARY
- VARBINARY
- TINYBLOB, BLOB, MEDIUMBLOB, LONGBLOB
- TINYTEXT, TEXT, MEDIUMTEXT, LONGTEXT
- ENUM
- SET
- SPATIAL

Considerations when accessing federated data with Amazon Redshift

Some Amazon Redshift features don't support access to federated data. You can find related limitations and considerations following.

The following are limitations and considerations when using federated queries with Amazon Redshift:

- Federated queries support read access to external data sources. You can't write or create database objects in the external data source.
- In some cases, you might access an Amazon RDS or Aurora DB cluster database in a different AWS Region than Amazon Redshift. In these cases, you typically incur network latency and billing charges for transferring data across AWS Regions. We recommend using an Aurora global database with a local endpoint in the same AWS Region as your Amazon Redshift cluster. Aurora global databases use dedicated infrastructure for storage-based replication across any two AWS Regions with typical latency of less than 1 second.
- Consider the cost of accessing Amazon RDS or Aurora DB cluster. For example, when using this feature to access Aurora DB cluster, Aurora DB cluster charges are based on IOPS.
- Federated queries don't enable access to Amazon Redshift from RDS or Aurora DB cluster.
- Federated queries are only available in AWS Regions where both Amazon Redshift and Amazon RDS or Aurora DB cluster are available.

- Federated queries currently don't support ALTER SCHEMA. To change a schema, use DROP and then CREATE EXTERNAL SCHEMA.
- Federated queries don't work with concurrency scaling.
- Federated queries currently don't support access through a PostgreSQL foreign data wrapper.
- Federated queries to RDS MySQL or Aurora MySQL support transaction isolation at the READ COMMITTED level.
- If not specified, Amazon Redshift connects to RDS for MySQL or Aurora MySQL on port 3306. Confirm the MySQL port number before creating an external schema for MySQL.
- If not specified, Amazon Redshift connects to RDS PostgreSQL or Aurora PostgreSQL on port 5432. Confirm the PostgreSQL port number before creating an external schema for PostgreSQL.
- When fetching TIMESTAMP and DATE data types from MySQL, zero values are treated as NULL.
- If an Aurora DB cluster database reader endpoint is used, an "invalid snapshot" error can occur. This can be avoided by one of the following methods:
 - Use a specific Aurora DB cluster instance endpoint (instead of using the Aurora DB cluster endpoint). This method uses REPEATABLE READ transaction isolation for the results from the PostgreSQL database.
 - Use an Aurora DB cluster reader endpoint and set `pg_federation_repeatable_read` to false for the session. This method uses READ COMMITTED transaction isolation for the results from the PostgreSQL database. For more information about Aurora DB cluster reader endpoints, see [Types of Aurora DB cluster endpoints](#) in the *Amazon Aurora User Guide*. For information about `pg_federation_repeatable_read`, see [pg_federation_repeatable_read](#).

The following are considerations for transactions when working with federated queries to PostgreSQL databases:

- If a query consists of federated tables, the leader node starts a READ ONLY REPEATABLE READ transaction on the remote database. This transaction remains for the duration of the Amazon Redshift transaction.
- The leader node creates a snapshot of the remote database by calling `pg_export_snapshot` and makes a read lock on the affected tables.
- A compute node starts a transaction and uses the snapshot created at the leader node to issue queries to the remote database.

Supported versions of federated databases

An Amazon Redshift external schema can reference a database in an external RDS PostgreSQL or Aurora PostgreSQL. When it does, these limitations apply:

- When creating an external schema referencing Aurora DB cluster, the Aurora PostgreSQL database must be at version 9.6, or later.
- When creating an external schema referencing Amazon RDS, the Amazon RDS PostgreSQL database must be at version 9.6, or later.

An Amazon Redshift external schema can reference a database in an external RDS MySQL or Aurora MySQL. When it does, these limitations apply:

- When creating an external schema referencing Aurora DB cluster, the Aurora MySQL database must be at version 5.6 or later.
- When creating an external schema referencing Amazon RDS, the RDS MySQL database must be at version 5.6 or later.

Amazon Redshift Spectrum

This section describes how to use Redshift Spectrum to efficiently read data from Amazon S3.

Using Amazon Redshift Spectrum, you can efficiently query and retrieve structured and semistructured data from files in Amazon S3 without having to load the data into Amazon Redshift tables. Redshift Spectrum queries employ massive parallelism to run very fast against large datasets. Much of the processing occurs in the Redshift Spectrum layer, and most of the data remains in Amazon S3. Multiple clusters can concurrently query the same dataset in Amazon S3 without the need to make copies of the data for each cluster.

Amazon Redshift Spectrum overview

This topic describes details for using Redshift Spectrum to efficiently read from Amazon S3.

Amazon Redshift Spectrum resides on dedicated Amazon Redshift servers that are independent of your cluster. Amazon Redshift pushes many compute-intensive tasks, such as predicate filtering

and aggregation, down to the Redshift Spectrum layer. Thus, Redshift Spectrum queries use much less of your cluster's processing capacity than other queries. Redshift Spectrum also scales intelligently. Based on the demands of your queries, Redshift Spectrum can potentially use thousands of instances to take advantage of massively parallel processing.

You create Redshift Spectrum tables by defining the structure for your files and registering them as tables in an external data catalog. The external data catalog can be AWS Glue, the data catalog that comes with Amazon Athena, or your own Apache Hive metastore. You can create and manage external tables either from Amazon Redshift using data definition language (DDL) commands or using any other tool that connects to the external data catalog. Changes to the external data catalog are immediately available to any of your Amazon Redshift clusters.

Optionally, you can partition the external tables on one or more columns. Defining partitions as part of the external table can improve performance. The improvement occurs because the Amazon Redshift query optimizer eliminates partitions that don't contain data for the query.

After your Redshift Spectrum tables have been defined, you can query and join the tables just as you do any other Amazon Redshift table. Redshift Spectrum doesn't support update operations on external tables. You can add Redshift Spectrum tables to multiple Amazon Redshift clusters and query the same data on Amazon S3 from any cluster in the same AWS Region. When you update Amazon S3 data files, the data is immediately available for query from any of your Amazon Redshift clusters.

The AWS Glue Data Catalog that you access might be encrypted to increase security. If the AWS Glue catalog is encrypted, you need the AWS Key Management Service (AWS KMS) key for AWS Glue to access the AWS Glue catalog. AWS Glue catalog encryption is not available in all AWS Regions. For a list of supported AWS Regions, see [Encryption and Secure Access for AWS Glue](#) in the [AWS Glue Developer Guide](#). For more information about AWS Glue Data Catalog encryption, see [Encrypting Your AWS Glue Data Catalog](#) in the [AWS Glue Developer Guide](#).

Note

You can't view details for Redshift Spectrum tables using the same resources that you use for standard Amazon Redshift tables, such as [PG_TABLE_DEF](#), [STV_TBL_PERM](#), [PG_CLASS](#), or [information_schema](#). If your business intelligence or analytics tool doesn't recognize Redshift Spectrum external tables, configure your application to query [SVV_EXTERNAL_TABLES](#) and [SVV_EXTERNAL_COLUMNS](#).

Amazon Redshift Spectrum Regions

Redshift Spectrum is available in AWS Regions where Amazon Redshift is available, unless otherwise specified in Region specific documentation. For AWS Region availability in commercial Regions, see [Service endpoints](#) for the **Redshift API** in the *Amazon Web Services General Reference*.

Amazon Redshift Spectrum limitations

This topic describes limitations for using Redshift Spectrum.

Note the following considerations when you use Redshift Spectrum:

- The Amazon Redshift cluster and the Amazon S3 bucket must be in the same AWS Region.
- Redshift Spectrum doesn't support enhanced VPC routing with provisioned clusters. To access your Amazon S3 data, you might need to perform additional configuration steps. For more information, see [Redshift Spectrum and enhanced VPC routing](#) in the *Amazon Redshift Management Guide*.
- Redshift Spectrum supports Amazon S3 access point aliases. For more information, see [Using a bucket-style alias for your access point](#) in the *Amazon Simple Storage Service User Guide*. However, Redshift Spectrum doesn't support VPC with Amazon S3 access point aliases. For more information, see [Redshift Spectrum and enhanced VPC routing](#) in the *Amazon Redshift Management Guide*.
- You can't perform update or delete operations on external tables. To create a new external table in the specified schema, you can use CREATE EXTERNAL TABLE. For more information about CREATE EXTERNAL TABLE, see [CREATE EXTERNAL TABLE](#). To insert the results of a SELECT query into existing external tables on external catalogs, you can use INSERT (external table). For more information about INSERT (external table), see [INSERT \(external table\)](#).
- Unless you are using an AWS Glue Data Catalog that is enabled for AWS Lake Formation, you can't control user permissions on an external table. Instead, you can grant and revoke permissions on the external schema. For more information about working with AWS Lake Formation, see [Redshift Spectrum and AWS Lake Formation](#).
- To run Redshift Spectrum queries, the database user must have permission to create temporary tables in the database. The following example grants temporary permission on the database spectrumdb to the spectrumusers user group.

```
grant temp on database spectrumdb to group spectrumusers;
```

For more information, see [GRANT](#).

- When using the Athena Data Catalog or AWS Glue Data Catalog as a metadata store, see [Quotas and Limits](#) in the *Amazon Redshift Management Guide*.
- Redshift Spectrum doesn't support Amazon EMR with Kerberos.

Getting started with Amazon Redshift Spectrum

In this tutorial, you learn how to use Amazon Redshift Spectrum to query data directly from files on Amazon S3. If you already have a cluster and a SQL client, you can complete this tutorial with minimal setup.

Note

Redshift Spectrum queries incur additional charges. The cost of running the sample queries in this tutorial is nominal. For more information about pricing, see [Amazon Redshift Spectrum pricing](#).

Prerequisites

To use Redshift Spectrum, you need an Amazon Redshift cluster and a SQL client that's connected to your cluster so that you can run SQL commands. The cluster and the data files in Amazon S3 must be in the same AWS Region.

For information about how to create an Amazon Redshift cluster, see [Get started with Amazon Redshift provisioned data warehouses](#) in the *Amazon Redshift Getting Started Guide*. For information about ways to connect to a cluster, see [Connecting to Amazon Redshift data warehouses](#) in the *Amazon Redshift Getting Started Guide*.

In some of the examples that follow, the sample data is in the US East (N. Virginia) Region (us-east-1), so you need a cluster that is also in us-east-1. Or, you can use Amazon S3 to copy data objects from the following buckets and folders to your bucket in the AWS Region where your cluster is located:

- s3://redshift-downloads/ticket/spectrum/customers/*
- s3://redshift-downloads/ticket/spectrum/sales_partition/*

- `s3://redshift-downloads/ticket/spectrum/sales/*`
- `s3://redshift-downloads/ticket/spectrum/salesevent/*`

Run an Amazon S3 command similar to the following to copy sample data that is located in the US East (N. Virginia) to your AWS Region. Before running the command create your bucket and folders in your bucket to match your Amazon S3 copy command. The output of the Amazon S3 copy command confirms that the files are copied to the *bucket-name* in your desired AWS Region.

```
aws s3 cp s3://redshift-downloads/ticket/spectrum/ s3://bucket-name/ticket/spectrum/ --  
copy-props none --recursive
```

Getting started with Redshift Spectrum using AWS CloudFormation

As an alternative to the following steps, you can access the Redshift Spectrum DataLake AWS CloudFormation template to create a stack with an Amazon S3 bucket that you can query. For more information, see [Launch your AWS CloudFormation stack and then query your data in Amazon S3](#).

Getting started with Redshift Spectrum step by step

To get started using Amazon Redshift Spectrum, follow these steps:

- [Step 1: Create an IAM role for Amazon Redshift](#)
- [Step 2: Associate the IAM role with your cluster](#)
- [Step 3: Create an external schema and an external table](#)
- [Step 4: Query your data in Amazon S3](#)

Step 1. Create an IAM role for Amazon Redshift

Your cluster needs authorization to access your external Data Catalog in AWS Glue or Amazon Athena and your data files in Amazon S3. To provide that authorization, you reference an AWS Identity and Access Management (IAM) role that is attached to your cluster. For more information about using roles with Amazon Redshift, see [Authorizing COPY and UNLOAD Operations Using IAM Roles](#).

Note

In certain cases, you can migrate your Athena Data Catalog to an AWS Glue Data Catalog. You can do this if your cluster is in an AWS Region where AWS Glue is supported and you have Redshift Spectrum external tables in the Athena Data Catalog. To use the AWS Glue Data Catalog with Redshift Spectrum, you might need to change your IAM policies. For more information, see [Upgrading to the AWS Glue Data Catalog](#) in the *Athena User Guide*.

When you create a role for Amazon Redshift, choose one of the following approaches:

- If you are using Redshift Spectrum with either an Athena Data Catalog or AWS Glue Data Catalog, follow the steps outlined in [To create an IAM role for Amazon Redshift](#).
- If you are using Redshift Spectrum with an AWS Glue Data Catalog that is enabled for AWS Lake Formation, follow the steps outlined in these procedures:
 - [To create an IAM role for Amazon Redshift using an AWS Glue Data Catalog enabled for AWS Lake Formation](#)
 - [To grant SELECT permissions on the table to query in the Lake Formation database](#)

To create an IAM role for Amazon Redshift

1. Open the [IAM console](#).
2. In the navigation pane, choose **Roles**.
3. Choose **Create role**.
4. Choose **AWS service** as the trusted entity, and then choose **Redshift** as the use case.
5. Under **Use case for other AWS services**, choose **Redshift - Customizable** and then choose **Next**.
6. The **Add permissions policy** page appears. Choose `AmazonS3ReadOnlyAccess` and `AWSGlueConsoleFullAccess`, if you're using the AWS Glue Data Catalog. Or choose `AmazonAthenaFullAccess` if you're using the Athena Data Catalog. Choose **Next**.

Note

The `AmazonS3ReadOnlyAccess` policy gives your cluster read-only access to all Amazon S3 buckets. To grant access to only the AWS sample data bucket, create a new policy and add the following permissions.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "s3:Get*",
        "s3:List*"
      ],
      "Resource": "arn:aws:s3:::redshift-downloads/*"
    }
  ]
}
```

7. For **Role name**, enter a name for your role, for example **myspectrum_role**.
8. Review the information, and then choose **Create role**.
9. In the navigation pane, choose **Roles**. Choose the name of your new role to view the summary, and then copy the **Role ARN** to your clipboard. This value is the Amazon Resource Name (ARN) for the role that you just created. You use that value when you create external tables to reference your data files on Amazon S3.

To create an IAM role for Amazon Redshift using an AWS Glue Data Catalog enabled for AWS Lake Formation

1. Open the IAM console at <https://console.aws.amazon.com/iam/>.
2. In the navigation pane, choose **Policies**.

If this is your first time choosing **Policies**, the **Welcome to Managed Policies** page appears. Choose **Get Started**.

3. Choose **Create policy**.
4. Choose to create the policy on the **JSON** tab.
5. Paste in the following JSON policy document, which grants access to the Data Catalog but denies the administrator permissions for Lake Formation.

```
{
  "Version": "2012-10-17",
  "Statement": [
```

```

    {
      "Sid": "RedshiftPolicyForLF",
      "Effect": "Allow",
      "Action": [
        "glue:*",
        "lakeformation:GetDataAccess"
      ],
      "Resource": "*"
    }
  ]
}

```

6. When you are finished, choose **Review** to review the policy. The policy validator reports any syntax errors.
7. On the **Review policy** page, for **Name** enter **myspectrum_policy** to name the policy that you are creating. Enter a **Description** (optional). Review the policy **Summary** to see the permissions that are granted by your policy. Then choose **Create policy** to save your work.

After you create a policy, you can provide access to your users.

To provide access, add permissions to your users, groups, or roles:

- Users and groups in AWS IAM Identity Center:

Create a permission set. Follow the instructions in [Create a permission set](#) in the *AWS IAM Identity Center User Guide*.

- Users managed in IAM through an identity provider:

Create a role for identity federation. Follow the instructions in [Creating a role for a third-party identity provider \(federation\)](#) in the *IAM User Guide*.

- IAM users:

- Create a role that your user can assume. Follow the instructions in [Creating a role for an IAM user](#) in the *IAM User Guide*.
- (Not recommended) Attach a policy directly to a user or add a user to a user group. Follow the instructions in [Adding permissions to a user \(console\)](#) in the *IAM User Guide*.

To grant SELECT permissions on the table to query in the Lake Formation database

1. Open the Lake Formation console at <https://console.aws.amazon.com/lakeformation/>.

2. In the navigation pane, choose **Data lake permissions**, and then choose **Grant**.
3. Follow the instructions in [Granting table permissions using the named resource method](#) in the *AWS Lake Formation Developer Guide*. Provide the following information:
 - For **IAM role**, choose the IAM role you created, `myspectrum_role`. When you run the Amazon Redshift Query Editor, it uses this IAM role for permission to the data.

Note

To grant SELECT permission on the table in a Lake Formation–enabled Data Catalog to query, do the following:

- Register the path for the data in Lake Formation.
- Grant users permission to that path in Lake Formation.
- Created tables can be found in the path registered in Lake Formation.

4. Choose **Grant**.

Important

As a best practice, allow access only to the underlying Amazon S3 objects through Lake Formation permissions. To prevent unapproved access, remove any permission granted to Amazon S3 objects outside of Lake Formation. If you previously accessed Amazon S3 objects before setting up Lake Formation, remove any IAM policies or bucket permissions that previously were set up. For more information, see [Upgrading AWS Glue Data Permissions to the AWS Lake Formation Model](#) and [Lake Formation Permissions](#).

Step 2: Associate the IAM role with your cluster

Now you have an IAM role that authorizes Amazon Redshift to access the external Data Catalog and Amazon S3 for you. At this point, you must associate that role with your Amazon Redshift cluster.

To associate an IAM role with a cluster

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.

2. On the navigation menu, choose **Clusters**, then choose the name of the cluster that you want to update.
3. For **Actions**, choose **Manage IAM roles**. The **IAM roles** page appears.
4. Either choose **Enter ARN** and then enter an ARN or an IAM role, or choose an IAM role from the list. Then choose **Add IAM role** to add it to the list of **Attached IAM roles**.
5. Choose **Done** to associate the IAM role with the cluster. The cluster is modified to complete the change.

Step 3: Create an external schema and an external table

Create external tables in an external schema. The external schema references a database in the external data catalog and provides the IAM role ARN that authorizes your cluster to access Amazon S3 on your behalf. You can create an external database in an Amazon Athena Data Catalog, AWS Glue Data Catalog, or an Apache Hive metastore, such as Amazon EMR. For this example, you create the external database in an Amazon Athena Data Catalog when you create the external schema Amazon Redshift. For more information, see [External schemas in Amazon Redshift Spectrum](#).

To create an external schema and an external table

1. To create an external schema, replace the IAM role ARN in the following command with the role ARN you created in [step 1](#). Then run the command in your SQL client.

```
create external schema myspectrum_schema
from data catalog
database 'myspectrum_db'
iam_role 'arn:aws:iam::123456789012:role/myspectrum_role'
create external database if not exists;
```

2. To create an external table, run the following CREATE EXTERNAL TABLE command.

Note

Your cluster and the Amazon S3 bucket must be in the same AWS Region. For this example CREATE EXTERNAL TABLE command, the Amazon S3 bucket with the sample data is located in the US East (N. Virginia) AWS Region. To see the source data, download the [sales_ts.000 file](#).

You can modify this example to run in a different AWS Region. Create an Amazon S3 bucket in your desired AWS Region. Copy the sales data with an Amazon S3 copy command. Then update the location option in the example CREATE EXTERNAL TABLE command to your bucket.

```
aws s3 cp s3://redshift-downloads/ticket/spectrum/sales/ s3://bucket-name/
ticket/spectrum/sales/ --copy-props none --recursive
```

The output of the Amazon S3 copy command confirms that the file was copied to the *bucket-name* in your desired AWS Region.

```
copy: s3://redshift-downloads/ticket/spectrum/sales/sales_ts.000 to
s3://bucket-name/ticket/spectrum/sales/sales_ts.000
```

```
create external table myspectrum_schema.sales(
salesid integer,
listid integer,
sellerid integer,
buyerid integer,
eventid integer,
dateid smallint,
qtsold smallint,
pricepaid decimal(8,2),
commission decimal(8,2),
saletime timestamp)
row format delimited
fields terminated by '\t'
stored as textfile
location 's3://redshift-downloads/ticket/spectrum/sales/'
table properties ('numRows'='172000');
```

Step 4: Query your data in Amazon S3

After your external tables are created, you can query them using the same SELECT statements that you use to query other Amazon Redshift tables. These SELECT statement queries include joining tables, aggregating data, and filtering on predicates.

To query your data in Amazon S3

1. Get the number of rows in the `MYSPECTRUM_SCHEMA.SALES` table.

```
select count(*) from myspectrum_schema.sales;
```

```
count
-----
172462
```

2. Keep your larger fact tables in Amazon S3 and your smaller dimension tables in Amazon Redshift, as a best practice. If you loaded the sample data in [Load data](#), you have a table named `EVENT` in your database. If not, create the `EVENT` table by using the following command.

```
create table event(
eventid integer not null distkey,
venueid smallint not null,
catid smallint not null,
dateid smallint not null sortkey,
eventname varchar(200),
starttime timestamp);
```

3. Load the `EVENT` table by replacing the IAM role ARN in the following `COPY` command with the role ARN you created in [Step 1. Create an IAM role for Amazon Redshift](#). You can optionally download and view the [source data for the allevents_pipe.txt](#) from an Amazon S3 bucket in AWS Region `us-east-1`.

```
copy event from 's3://redshift-downloads/ticket/allevents_pipe.txt'
iam_role 'arn:aws:iam::123456789012:role/myspectrum_role'
delimiter '|' timeformat 'YYYY-MM-DD HH:MI:SS' region 'us-east-1';
```

The following example joins the external Amazon S3 table `MYSPECTRUM_SCHEMA.SALES` with the local Amazon Redshift table `EVENT` to find the total sales for the top 10 events.

```
select top 10 myspectrum_schema.sales.eventid,
sum(myspectrum_schema.sales.pricepaid) from myspectrum_schema.sales, event
where myspectrum_schema.sales.eventid = event.eventid
and myspectrum_schema.sales.pricepaid > 30
group by myspectrum_schema.sales.eventid
```

```
order by 2 desc;
```

```
eventid | sum
-----+-----
    289 | 51846.00
   7895 | 51049.00
   1602 | 50301.00
    851 | 49956.00
   7315 | 49823.00
   6471 | 47997.00
   2118 | 47863.00
    984 | 46780.00
   7851 | 46661.00
   5638 | 46280.00
```

- View the query plan for the previous query. Notice the S3 Seq Scan, S3 HashAggregate, and S3 Query Scan steps that were run against the data on Amazon S3.

```
explain
select top 10 myspectrum_schema.sales.eventid,
       sum(myspectrum_schema.sales.pricepaid)
from myspectrum_schema.sales, event
where myspectrum_schema.sales.eventid = event.eventid
and myspectrum_schema.sales.pricepaid > 30
group by myspectrum_schema.sales.eventid
order by 2 desc;
```

QUERY PLAN

```
-----
XN Limit (cost=1001055770628.63..1001055770628.65 rows=10 width=31)

-> XN Merge (cost=1001055770628.63..1001055770629.13 rows=200 width=31)

      Merge Key: sum(sales.derived_col2)
```

```
-> XN Network (cost=1001055770628.63..1001055770629.13 rows=200 width=31)

      Send to leader

      -> XN Sort (cost=1001055770628.63..1001055770629.13 rows=200

          Sort Key: sum(sales.derived_col2)

          -> XN HashAggregate (cost=1055770620.49..1055770620.99
rows=200 width=31)

              -> XN Hash Join DS_BCAST_INNER
(cost=3119.97..1055769620.49 rows=200000 width=31)

                  Hash Cond: ("outer".derived_col1 = "inner".eventid)

                  -> XN S3 Query Scan sales (cost=3010.00..5010.50
rows=200000 width=31)

                      -> S3 HashAggregate (cost=3010.00..3010.50
rows=200000 width=16)

                          -> S3 Seq Scan myspectrum_schema.sales
location:"s3://redshift-downloads/ticket/spectrum/sales" format:TEXT
(cost=0.00..2150.00 rows=172000 width=16)

                              Filter: (pricepaid > 30.00)

                              -> XN Hash (cost=87.98..87.98 rows=8798 width=4)

                                  -> XN Seq Scan on event (cost=0.00..87.98
rows=8798 width=4)
```

Launch your AWS CloudFormation stack and then query your data in Amazon S3

After you create an Amazon Redshift cluster and connect to the cluster, you can install your Redshift Spectrum DataLake AWS CloudFormation template and then query your data.

CloudFormation installs the Redshift Spectrum Getting Started DataLake template and creates a stack that includes the following:

- A role named `myspectrum_role` associated with your Redshift cluster
- An external schema named `myspectrum_schema`
- An external table named `sales` in an Amazon S3 bucket
- A Redshift table named `event` loaded with data

To launch your Redshift Spectrum Getting Started DataLake CloudFormation stack

1. Choose [Launch CFN stack](#). The CloudFormation console opens with the `DataLake.yml` template selected.

You can also download and customize the Redshift Spectrum Getting Started DataLake CloudFormation [CFN template](#), then open CloudFormation console (<https://console.aws.amazon.com/cloudformation>) and create a stack with the customized template.

2. Choose **Next**.
3. Under **Parameters**, enter the Amazon Redshift cluster name, database name, and your database user name.
4. Choose **Next**.

The stack options appear.

5. Choose **Next** to accept the default settings.
6. Review the information and under **Capabilities**, and choose **I acknowledge that AWS CloudFormation might create IAM resources**.
7. Choose **Create stack**.

If an error occurs while the stack is being created, see the following information:

- View the CloudFormation **Events** tab for information that can help you resolve the error.

- Delete the DataLake CloudFormation stack before trying the operation again.
- Make sure that you are connected to your Amazon Redshift database.
- Make sure that you entered the correct information for the Amazon Redshift cluster name, database name, and database user name.

Query your data in Amazon S3

You query external tables using the same `SELECT` statements that you use to query other Amazon Redshift tables. These `SELECT` statement queries include joining tables, aggregating data, and filtering on predicates.

The following query returns the number of rows in the `myspectrum_schema.sales` external table.

```
select count(*) from myspectrum_schema.sales;
```

```
count
-----
172462
```

Join an external table with a local table

The following example joins the external table `myspectrum_schema.sales` with the local table `event` to find the total sales for the top 10 events.

```
select top 10 myspectrum_schema.sales.eventid, sum(myspectrum_schema.sales.pricepaid)
   from myspectrum_schema.sales, event
  where myspectrum_schema.sales.eventid = event.eventid
 and myspectrum_schema.sales.pricepaid > 30
 group by myspectrum_schema.sales.eventid
 order by 2 desc;
```

```
eventid | sum
-----+-----
    289 | 51846.00
    7895 | 51049.00
    1602 | 50301.00
     851 | 49956.00
    7315 | 49823.00
```

```
6471 | 47997.00
2118 | 47863.00
 984 | 46780.00
7851 | 46661.00
5638 | 46280.00
```

View the query plan

View the query plan for the previous query. Note the S3 Seq Scan, S3 HashAggregate, and S3 Query Scan steps that were run on the data on Amazon S3.

```
explain
select top 10 myspectrum_schema.sales.eventid, sum(myspectrum_schema.sales.pricepaid)
from myspectrum_schema.sales, event
where myspectrum_schema.sales.eventid = event.eventid
and myspectrum_schema.sales.pricepaid > 30
group by myspectrum_schema.sales.eventid
order by 2 desc;
```

QUERY PLAN

```
-----
XN Limit (cost=1001055770628.63..1001055770628.65 rows=10 width=31)

-> XN Merge (cost=1001055770628.63..1001055770629.13 rows=200 width=31)

    Merge Key: sum(sales.derived_col2)

-> XN Network (cost=1001055770628.63..1001055770629.13 rows=200 width=31)

    Send to leader

-> XN Sort (cost=1001055770628.63..1001055770629.13 rows=200 width=31)
```

```

Sort Key: sum(sales.derived_col2)

-> XN HashAggregate (cost=1055770620.49..1055770620.99 rows=200
width=31)

-> XN Hash Join DS_BCAST_INNER (cost=3119.97..1055769620.49
rows=200000 width=31)

Hash Cond: ("outer".derived_col1 = "inner".eventid)

-> XN S3 Query Scan sales (cost=3010.00..5010.50
rows=200000 width=31)

-> S3 HashAggregate (cost=3010.00..3010.50
rows=200000 width=16)

-> S3 Seq Scan spectrum.sales
location:"s3://redshift-downloads/ticket/spectrum/sales" format:TEXT
(cost=0.00..2150.00 rows=172000 width=16)

Filter: (pricepaid > 30.00)

-> XN Hash (cost=87.98..87.98 rows=8798 width=4)

-> XN Seq Scan on event (cost=0.00..87.98
rows=8798 width=4)

```

IAM policies for Amazon Redshift Spectrum

This topic describes the required IAM permissions for using Redshift Spectrum.

By default, Amazon Redshift Spectrum uses the AWS Glue Data Catalog in AWS Regions that support AWS Glue. In other AWS Regions, Redshift Spectrum uses the Athena Data Catalog. Your cluster needs authorization to access your external data catalog in AWS Glue or Athena and your data files in Amazon S3. You provide that authorization by referencing an AWS Identity and Access Management (IAM) role that is attached to your cluster. If you use an Apache Hive metastore to manage your data catalog, you don't need to provide access to Athena.

You can chain roles so that your cluster can assume other roles not attached to the cluster. For more information, see [Chaining IAM roles in Amazon Redshift Spectrum](#).

The AWS Glue catalog that you access might be encrypted to increase security. If the AWS Glue catalog is encrypted, you need the AWS KMS key for AWS Glue to access the AWS Glue Data Catalog. For more information, see [Encrypting Your AWS Glue Data Catalog](#) in the [AWS Glue Developer Guide](#).

Topics

- [Amazon S3 permissions](#)
- [Cross-account Amazon S3 permissions](#)
- [Policies to grant or restrict access using Redshift Spectrum](#)
- [Policies to grant minimum permissions](#)
- [Chaining IAM roles in Amazon Redshift Spectrum](#)
- [Controlling access to the AWS Glue Data Catalog](#)

Amazon S3 permissions

At a minimum, your cluster needs GET and LIST access to your Amazon S3 bucket. If your bucket is not in the same AWS account as your cluster, your bucket must also authorize your cluster to access the data. For more information, see [Authorizing Amazon Redshift to Access Other AWS Services on Your Behalf](#).

Note

The Amazon S3 bucket can't use a bucket policy that restricts access only from specific VPC endpoints.

The following policy grants GET and LIST access to any Amazon S3 bucket. The policy allows access to Amazon S3 buckets for Redshift Spectrum as well as COPY operations.

```
{
  "Version": "2012-10-17",
  "Statement": [{
    "Effect": "Allow",
    "Action": ["s3:Get*", "s3:List*"],
```

```

    "Resource": "*"
  }]
}

```

The following policy grants GET and LIST access to your Amazon S3 bucket named `amzn-s3-demo-bucket`.

```

{
  "Version": "2012-10-17",
  "Statement": [{
    "Effect": "Allow",
    "Action": ["s3:Get*", "s3:List*"],
    "Resource": "arn:aws:s3:::amzn-s3-demo-bucket/*"
  }]
}

```

Cross-account Amazon S3 permissions

To grant Redshift Spectrum permission to access data in an Amazon S3 bucket that belongs to another AWS account, add the following policy to the Amazon S3 bucket. For more information, see [Granting Cross-Account Bucket Permissions](#).

```

{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "Example permissions",
      "Effect": "Allow",
      "Principal": {
        "AWS": "arn:aws:iam::redshift-account:role/spectrumrole"
      },
      "Action": [
        "s3:GetBucketLocation",
        "s3:GetObject",
        "s3:ListMultipartUploadParts",
        "s3:ListBucket",
        "s3:ListBucketMultipartUploads"
      ],
      "Resource": [
        "arn:aws:s3:::bucketname",
        "arn:aws:s3:::bucketname/*"
      ]
    }
  ]
}

```

```

    }
  ]
}

```

Policies to grant or restrict access using Redshift Spectrum

To grant access to an Amazon S3 bucket only using Redshift Spectrum, include a condition that allows access for the user agent `AWS Redshift/Spectrum`. The following policy allows access to Amazon S3 buckets only for Redshift Spectrum. It excludes other access, such as COPY operations.

```

{
  "Version": "2012-10-17",
  "Statement": [{
    "Effect": "Allow",
    "Action": ["s3:Get*", "s3:List*"],
    "Resource": "arn:aws:s3:::amzn-s3-demo-bucket/*",
    "Condition": {"StringEquals": {"aws:UserAgent": "AWS Redshift/
Spectrum"}}
  }]
}

```

Similarly, you might want to create an IAM role that allows access for COPY operations, but excludes Redshift Spectrum access. To do so, include a condition that denies access for the user agent `AWS Redshift/Spectrum`. The following policy allows access to an Amazon S3 bucket with the exception of Redshift Spectrum.

```

{
  "Version": "2012-10-17",
  "Statement": [{
    "Effect": "Allow",
    "Action": ["s3:Get*", "s3:List*"],
    "Resource": "arn:aws:s3:::amzn-s3-demo-bucket/*",
    "Condition": {"StringNotEquals": {"aws:UserAgent": "AWS Redshift/
Spectrum"}}
  }]
}

```

Policies to grant minimum permissions

The following policy grants the minimum permissions required to use Redshift Spectrum with Amazon S3, AWS Glue, and Athena.

```

{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "s3:GetBucketLocation",
        "s3:GetObject",
        "s3:ListMultipartUploadParts",
        "s3:ListBucket",
        "s3:ListBucketMultipartUploads"
      ],
      "Resource": [
        "arn:aws:s3:::bucketname",
        "arn:aws:s3:::bucketname/folder1/folder2/*"
      ]
    },
    {
      "Effect": "Allow",
      "Action": [
        "glue:CreateDatabase",
        "glue>DeleteDatabase",
        "glue:GetDatabase",
        "glue:GetDatabases",
        "glue:UpdateDatabase",
        "glue:CreateTable",
        "glue>DeleteTable",
        "glue:BatchDeleteTable",
        "glue:UpdateTable",
        "glue:GetTable",
        "glue:GetTables",
        "glue:BatchCreatePartition",
        "glue:CreatePartition",
        "glue>DeletePartition",
        "glue:BatchDeletePartition",
        "glue:UpdatePartition",
        "glue:GetPartition",
        "glue:GetPartitions",
        "glue:BatchGetPartition"
      ],
      "Resource": [
        "*"
      ]
    }
  ]
}

```

```
    }  
  ]  
}
```

If you use Athena for your data catalog instead of AWS Glue, the policy requires full Athena access. The following policy grants access to Athena resources. If your external database is in a Hive metastore, you don't need Athena access.

```
{  
  "Version": "2012-10-17",  
  "Statement": [{  
    "Effect": "Allow",  
    "Action": ["athena:*"],  
    "Resource": ["*"]  
  }]  
}
```

Chaining IAM roles in Amazon Redshift Spectrum

When you attach a role to your cluster, your cluster can assume that role to access Amazon S3, Athena, and AWS Glue on your behalf. If a role attached to your cluster doesn't have access to the necessary resources, you can chain another role, possibly belonging to another account. Your cluster then temporarily assumes the chained role to access the data. You can also grant cross-account access by chaining roles. You can chain a maximum of 10 roles. Each role in the chain assumes the next role in the chain, until the cluster assumes the role at the end of chain.

To chain roles, you establish a trust relationship between the roles. A role that assumes another role must have a permissions policy that allows it to assume the specified role. In turn, the role that passes permissions must have a trust policy that allows it to pass its permissions to another role. For more information, see [Chaining IAM Roles in Amazon Redshift](#).

When you run the CREATE EXTERNAL SCHEMA command, you can chain roles by including a comma-separated list of role ARNs.

Note

The list of chained roles must not include spaces.

In the following example, `MyRedshiftRole` is attached to the cluster. `MyRedshiftRole` assumes the role `AcmeData`, which belongs to account `111122223333`.

```
create external schema acme from data catalog
database 'acmedb' region 'us-west-2'
iam_role 'arn:aws:iam::123456789012:role/MyRedshiftRole,arn:aws:iam::111122223333:role/
AcmeData';
```

Controlling access to the AWS Glue Data Catalog

If you use AWS Glue for your data catalog, you can apply fine-grained access control to the AWS Glue Data Catalog with your IAM policy. For example, you might want to expose only a few databases and tables to a specific IAM role.

The following sections describe the IAM policies for various levels of access to data stored in the AWS Glue Data Catalog.

Topics

- [Policy for database operations](#)
- [Policy for table operations](#)
- [Policy for partition operations](#)

Policy for database operations

If you want to give users permissions to view and create a database, they need access rights to both the database and the AWS Glue Data Catalog.

The following example query creates a database.

```
CREATE EXTERNAL SCHEMA example_db
FROM DATA CATALOG DATABASE 'example_db' region 'us-west-2'
IAM_ROLE 'arn:aws:iam::redshift-account:role/spectrumrole'
CREATE EXTERNAL DATABASE IF NOT EXISTS
```

The following IAM policy gives the minimum permissions required for creating a database.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:GetDatabase",
        "glue:CreateDatabase"
      ],
      "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:database/example_db",
        "arn:aws:glue:us-west-2:redshift-account:catalog"
      ]
    }
  ]
}
```

The following example query lists the current databases.

```
SELECT * FROM SVV_EXTERNAL_DATABASES WHERE
databasename = 'example_db1' or databasename = 'example_db2';
```

The following IAM policy gives the minimum permissions required to list the current databases.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:GetDatabases"
      ],
      "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:database/example_db1",
        "arn:aws:glue:us-west-2:redshift-account:database/example_db2",
        "arn:aws:glue:us-west-2:redshift-account:catalog"
      ]
    }
  ]
}
```

```
    ]
  }
}
```

Policy for table operations

If you want to give users permissions to view, create, drop, alter, or take other actions on tables, they need several types of access. They need access to the tables themselves, the databases they belong to, and the catalog.

The following example query creates an external table.

```
CREATE EXTERNAL TABLE example_db.example_tbl0(
  col0 INT,
  col1 VARCHAR(255)
) PARTITIONED BY (part INT) STORED AS TEXTFILE
LOCATION 's3://test/s3/location/';
```

The following IAM policy gives the minimum permissions required to create an external table.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:CreateTable"
      ],
      "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:catalog",
        "arn:aws:glue:us-west-2:redshift-account:database/example_db",
        "arn:aws:glue:us-west-2:redshift-account:table/example_db/example_tbl0"
      ]
    }
  ]
}
```

The following example queries each list the current external tables.

```
SELECT * FROM svv_external_tables
WHERE tablename = 'example_tbl0' OR
tablename = 'example_tbl1';
```

```
SELECT * FROM svv_external_columns
WHERE tablename = 'example_tbl0' OR
tablename = 'example_tbl1';
```

```
SELECT parameters FROM svv_external_tables
WHERE tablename = 'example_tbl0' OR
tablename = 'example_tbl1';
```

The following IAM policy gives the minimum permissions required to list the current external tables.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:GetTables"
      ],
      "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:catalog",
        "arn:aws:glue:us-west-2:redshift-account:database/example_db",
        "arn:aws:glue:us-west-2:redshift-account:table/example_db/
example_tbl0",
        "arn:aws:glue:us-west-2:redshift-account:table/example_db/example_tbl1"
      ]
    }
  ]
}
```

The following example query alters an existing table.

```
ALTER TABLE example_db.example_tbl0
SET TABLE PROPERTIES ('numRows' = '100');
```

The following IAM policy gives the minimum permissions required to alter an existing table.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:GetTable",
        "glue:UpdateTable"
      ],
      "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:catalog",
        "arn:aws:glue:us-west-2:redshift-account:database/example_db",
        "arn:aws:glue:us-west-2:redshift-account:table/example_db/example_tbl0"
      ]
    }
  ]
}
```

The following example query drops an existing table.

```
DROP TABLE example_db.example_tbl0;
```

The following IAM policy gives the minimum permissions required to drop an existing table.

```
{
```

```

"Version": "2012-10-17",
"Statement": [
  {
    "Effect": "Allow",
    "Action": [
      "glue:DeleteTable"
    ],
    "Resource": [
      "arn:aws:glue:us-west-2:redshift-account:catalog",
      "arn:aws:glue:us-west-2:redshift-account:database/example_db",
      "arn:aws:glue:us-west-2:redshift-account:table/example_db/example_tbl0"
    ]
  }
]
}

```

Policy for partition operations

If you want to give users permissions to perform partition-level operations (view, create, drop, alter, and so on), they need permissions to the tables that the partitions belong to. They also need permissions to the related databases and the AWS Glue Data Catalog.

The following example query creates a partition.

```

ALTER TABLE example_db.example_tbl0
ADD PARTITION (part=0) LOCATION 's3://test/s3/location/part=0/';
ALTER TABLE example_db.example_t
ADD PARTITION (part=1) LOCATION 's3://test/s3/location/part=1/';

```

The following IAM policy gives the minimum permissions required to create a partition.

```

{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:GetTable",

```

```

        "glue:BatchCreatePartition"
    ],
    "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:catalog",
        "arn:aws:glue:us-west-2:redshift-account:database/example_db",
        "arn:aws:glue:us-west-2:redshift-account:table/example_db/example_tbl0"
    ]
}

```

The following example query lists the current partitions.

```

SELECT * FROM svv_external_partitions
WHERE schemaname = 'example_db' AND
tablename = 'example_tbl0'

```

The following IAM policy gives the minimum permissions required to list the current partitions.

```

{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:GetPartitions",
        "glue:GetTables",
        "glue:GetTable"
      ],
      "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:catalog",
        "arn:aws:glue:us-west-2:redshift-account:database/example_db",
        "arn:aws:glue:us-west-2:redshift-account:table/example_db/example_tbl0"
      ]
    }
  ]
}

```

The following example query alters an existing partition.

```
ALTER TABLE example_db.example_tbl0 PARTITION(part='0')
SET LOCATION 's3://test/s3/new/location/part=0/';
```

The following IAM policy gives the minimum permissions required to alter an existing partition.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:GetPartition",
        "glue:UpdatePartition"
      ],
      "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:catalog",
        "arn:aws:glue:us-west-2:redshift-account:database/example_db",
        "arn:aws:glue:us-west-2:redshift-account:table/example_db/example_tbl0"
      ]
    }
  ]
}
```

The following example query drops an existing partition.

```
ALTER TABLE example_db.example_tbl0 DROP PARTITION(part='0');
```

The following IAM policy gives the minimum permissions required to drop an existing partition.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": [
        "glue:DeletePartition"
      ],
      "Resource": [
        "arn:aws:glue:us-west-2:redshift-account:catalog",
        "arn:aws:glue:us-west-2:redshift-account:database/example_db",
        "arn:aws:glue:us-west-2:redshift-account:table/example_db/example_tbl0"
      ]
    }
  ]
}
```

Redshift Spectrum and AWS Lake Formation

This topic describes how to use Redshift Spectrum with Lake Formation. Lake Formation is a service for sharing analytics data.

You can use AWS Lake Formation to centrally define and enforce database, table, and column-level access policies to data stored in Amazon S3. After your data is registered with an AWS Glue Data Catalog enabled with Lake Formation, you can query it by using several services, including Redshift Spectrum.

Lake Formation provides the security and governance of the Data Catalog. Within Lake Formation, you can grant and revoke permissions to the Data Catalog objects, such as databases, tables, columns, and underlying Amazon S3 storage.

Important

You can only use Redshift Spectrum with a Lake Formation enabled Data Catalog in AWS Regions where Lake Formation is available. For a list of available Regions, see [AWS Lake Formation endpoints and quotas](#) in the *AWS General Reference*.

By using Redshift Spectrum with Lake Formation, you can do the following:

- Use Lake Formation as a centralized place where you grant and revoke permissions and access control policies on all of your data in the data lake. Lake Formation provides a hierarchy of permissions to control access to databases and tables in a Data Catalog. For more information, see [Overview of Lake Formation permissions](#) in the *AWS Lake Formation Developer Guide*.
- Create external tables and run queries on data in the data lake. Before users in your account can run queries, a data lake account administrator registers your existing Amazon S3 paths containing source data with Lake Formation. The administrator also creates tables and grants permissions to your users. Access can be granted on databases, tables, or columns. The administrator can use data filters in Lake Formation to grant granular access control over your sensitive data stored in Amazon S3. For more information, see [Using data filters for row-level and cell-level security](#).

After the data is registered in the Data Catalog, each time users try to run queries, Lake Formation verifies access to the table for that specific principal. Lake Formation vends temporary credentials to Redshift Spectrum, and the query runs.

- Run Redshift Spectrum queries against an automounted AWS Glue Data Catalog using IAM credentials obtained with `GetCredentials` or `GetClusterCredentials`, and manage Lake Formation permissions by database user (`IAMR:username` or `IAM:username`).

When you use Redshift Spectrum with a Data Catalog enabled for Lake Formation, one of the following must be in place:

- An IAM role associated with the cluster that has permission to the Data Catalog.
- A federated IAM identity configured to manage access to external resources. For more information, see [Using a federated identity to manage Amazon Redshift access to local resources and Amazon Redshift external tables](#).

Important

You can't chain IAM roles when using Redshift Spectrum with a Data Catalog enabled for Lake Formation.

To learn more about the steps required to set up AWS Lake Formation to use with Redshift Spectrum, see [Tutorial: Creating a data lake from a JDBC source in Lake Formation](#) in the *AWS Lake Formation Developer Guide*. Specifically, see [Query the data in the data lake using Amazon Redshift](#)

[Spectrum](#) for details about integration with Redshift Spectrum. The data and AWS resources used in this topic depend on previous steps in the tutorial.

Using data filters for row-level and cell-level security

You can define data filters in AWS Lake Formation to control your Redshift Spectrum queries' row-level and cell-level access to data defined in your Data Catalog. To set this up, you perform the following tasks:

- Create a data filter in Lake Formation with the following information:
 - A column specification with a list of columns to include or exclude from query results.
 - A row filter expression that specifies the rows to include in the query results.

For more information about how to create a data filter, see [Data filters in Lake Formation](#) in the *AWS Lake Formation Developer Guide*.

- Create an external table in Amazon Redshift that references a table in your Lake Formation enabled Data Catalog. For details on how to query a Lake Formation table using Redshift Spectrum, see [Query the data in the data lake using Amazon Redshift Spectrum](#) in the *AWS Lake Formation Developer Guide*.

After the table is defined in Amazon Redshift, you can query the Lake Formation table and access only the rows and columns that are allowed by the data filter.

For a detailed guide on how to set up row-level and cell-level security in Lake Formation, and then query using Redshift Spectrum, see [Use Amazon Redshift Spectrum with row-level and cell-level security policies defined in AWS Lake Formation](#).

Data files for queries in Amazon Redshift Spectrum

This section describes how to create data files in Amazon S3 in a format that Redshift Spectrum supports.

The data files that you use for queries in Amazon Redshift Spectrum are commonly the same types of files that you use for other applications. For example, the same types of files are used with Amazon Athena, Amazon EMR, and Amazon QuickSight. You can query the data in its original format directly from Amazon S3. To do this, the data files must be in a format that Redshift Spectrum supports and be located in an Amazon S3 bucket that your cluster can access.

The Amazon S3 bucket with the data files and the Amazon Redshift cluster must be in the same AWS Region. For information about supported AWS Regions, see [Amazon Redshift Spectrum Regions](#).

Data formats for Redshift Spectrum

Redshift Spectrum supports the following structured and semistructured data formats.

File format	Columnar	Supports parallel reads	Split unit
Parquet	Yes	Yes	Row group
ORC	Yes	Yes	Stripe
RCFile	Yes	Yes	Row group
TextFile	No	Yes	Row
SequenceFile	No	Yes	Row or block
RegexSerde	No	Yes	Row
OpenCSV	No	Yes	Row
AVRO	No	Yes	Block
Ion	No	No	N/A
JSON	No	No	N/A

In the preceding table, the headings indicate the following:

- **Columnar** – Whether the file format physically stores data in a column-oriented structure as opposed to a row-oriented one.
- **Supports parallel reads** – Whether the file format supports reading individual blocks within the file. Reading individual blocks enables the distributed processing of a file across multiple independent Redshift Spectrum requests instead of having to read the full file in a single request.

- **Split unit** – For file formats that can be read in parallel, the split unit is the smallest chunk of data that a single Redshift Spectrum request can process.

 **Note**

Timestamp values in text files must be in the format `yyyy-MM-dd HH:mm:ss.SSSSSS`, as the following timestamp value shows: `2017-05-01 11:30:59.000000`.

We recommend using a columnar storage file format, such as Apache Parquet. With a columnar storage file format, you can minimize data transfer out of Amazon S3 by selecting only the columns that you need.

Compression types for Redshift Spectrum

To reduce storage space, improve performance, and minimize costs, we strongly recommend that you compress your data files. Redshift Spectrum recognizes file compression types based on the file extension.

Redshift Spectrum supports the following compression types and extensions.

Compression Algorithm	File Extension	Supports Parallel Reads
Gzip	.gz	No
Bzip2	.bz2	Yes
Snappy	.snappy	No

You can apply compression at different levels. Most commonly, you compress a whole file or compress individual blocks within a file. Compressing columnar formats at the file level doesn't yield performance benefits.

For Redshift Spectrum to be able to read a file in parallel, the following must be true:

- The file format supports parallel reads.
- The file-level compression, if any, supports parallel reads.

It doesn't matter whether the individual split units within a file are compressed using a compression algorithm that can be read in parallel, because each split unit is processed by a single Redshift Spectrum request. An example of this is Snappy-compressed Parquet files. Individual row groups within the Parquet file are compressed using Snappy, but the top-level structure of the file remains uncompressed. In this case, the file can be read in parallel because each Redshift Spectrum request can read and process individual row groups from Amazon S3.

Encryption for Redshift Spectrum

Redshift Spectrum transparently decrypts data files that are encrypted using the following encryption options:

- Server-side encryption (SSE-S3) using an AES-256 encryption key managed by Amazon S3.
- Server-side encryption with keys managed by AWS Key Management Service (SSE-KMS).

Redshift Spectrum doesn't support Amazon S3 client-side encryption. For more information on server-side encryption, see [Protecting Data Using Server-Side Encryption](#) in the *Amazon Simple Storage Service User Guide*.

Amazon Redshift uses massively parallel processing (MPP) to achieve fast execution of complex queries operating on large amounts of data. Redshift Spectrum extends the same principle to query external data, using multiple Redshift Spectrum instances as needed to scan files. Place the files in a separate folder for each table.

You can optimize your data for parallel processing by doing the following:

- If your file format or compression doesn't support reading in parallel, break large files into many smaller files. We recommend using file sizes between 64 MB and 1 GB.
- Keep all the files about the same size. If some files are much larger than others, Redshift Spectrum can't distribute the workload evenly.

External schemas in Amazon Redshift Spectrum

This topic describes how to create and use external schemas with Redshift Spectrum. External schemas are collections of tables that you use as references to access data outside your Amazon Redshift cluster. These tables contain metadata about the external data that Redshift Spectrum reads.

All external tables must be created in an external schema, which you create using a [CREATE EXTERNAL SCHEMA](#) statement.

Note

Some applications use the term *database* and *schema* interchangeably. In Amazon Redshift, we use the term *schema*.

An Amazon Redshift external schema references an external database in an external data catalog. You can create the external database in Amazon Redshift, in [Amazon Athena](#), in [AWS Glue Data Catalog](#), or in an Apache Hive metastore, such as [Amazon EMR](#). If you create an external database in Amazon Redshift, the database resides in the Athena Data Catalog. To create a database in a Hive metastore, you need to create the database in your Hive application.

Amazon Redshift needs authorization to access the Data Catalog in Athena and the data files in Amazon S3 on your behalf. To provide that authorization, you first create an AWS Identity and Access Management (IAM) role. Then you attach the role to your cluster and provide Amazon Resource Name (ARN) for the role in the Amazon Redshift `CREATE EXTERNAL SCHEMA` statement. For more information about authorization, see [IAM policies for Amazon Redshift Spectrum](#).

Note

If you currently have Redshift Spectrum external tables in the Athena Data Catalog, you can migrate your Athena Data Catalog to an AWS Glue Data Catalog. To use an AWS Glue Data Catalog with Redshift Spectrum, you might need to change your IAM policies. For more information, see [Upgrading to the AWS Glue Data Catalog](#) in the *Amazon Athena User Guide*.

To create an external database at the same time you create an external schema, specify `FROM DATA CATALOG` and include the `CREATE EXTERNAL DATABASE` clause in your `CREATE EXTERNAL SCHEMA` statement.

The following example creates an external schema named `spectrum_schema` using the external database `spectrum_db`.

```
create external schema spectrum_schema from data catalog
```

```
database 'spectrum_db'  
iam_role 'arn:aws:iam::123456789012:role/MySpectrumRole'  
create external database if not exists;
```

If you manage your data catalog using Athena, specify the Athena database name and the AWS Region in which the Athena Data Catalog is located.

The following example creates an external schema using the default `samp1edb` database in the Athena Data Catalog.

```
create external schema athena_schema from data catalog  
database 'samp1edb'  
iam_role 'arn:aws:iam::123456789012:role/MySpectrumRole'  
region 'us-east-2';
```

Note

The `region` parameter references the AWS Region in which the Athena Data Catalog is located, not the location of the data files in Amazon S3.

If you manage your data catalog using a Hive metastore, such as Amazon EMR, your security groups must be configured to allow traffic between the clusters.

In the `CREATE EXTERNAL SCHEMA` statement, specify `FROM HIVE METASTORE` and include the metastore's URI and port number. The following example creates an external schema using a Hive metastore database named `hive_db`.

```
create external schema hive_schema  
from hive metastore  
database 'hive_db'  
uri '172.10.10.10' port 99  
iam_role 'arn:aws:iam::123456789012:role/MySpectrumRole'
```

To view external schemas for your cluster, query the `PG_EXTERNAL_SCHEMA` catalog table or the `SVV_EXTERNAL_SCHEMAS` view. The following example queries `SVV_EXTERNAL_SCHEMAS`, which joins `PG_EXTERNAL_SCHEMA` and `PG_NAMESPACE`.

```
select * from svv_external_schemas
```

For the full command syntax and examples, see [CREATE EXTERNAL SCHEMA](#).

Working with external catalogs in Amazon Redshift Spectrum

The metadata for Amazon Redshift Spectrum external databases and external tables is stored in an external data catalog. By default, Redshift Spectrum metadata is stored in an Athena Data Catalog. You can view and manage Redshift Spectrum databases and tables in your Athena console.

You can also create and manage external databases and external tables using Hive data definition language (DDL) using Athena or a Hive metastore, such as Amazon EMR.

Note

We recommend using Amazon Redshift to create and manage external databases and external tables in Redshift Spectrum.

Viewing Redshift Spectrum databases in Athena and AWS Glue

You can create an external database by including the CREATE EXTERNAL DATABASE IF NOT EXISTS clause as part of your CREATE EXTERNAL SCHEMA statement. In such cases, the external database metadata is stored in your Data Catalog. The metadata for external tables that you create qualified by the external schema is also stored in your Data Catalog.

Athena and AWS Glue maintain a Data Catalog for each supported AWS Region. To view table metadata, log on to the Athena or AWS Glue console. In Athena, choose **Data sources**, your AWS Glue, then view the details of your database. In AWS Glue, choose **Databases**, your external database, then view the details of your database.

If you create and manage your external tables using Athena, register the database using CREATE EXTERNAL SCHEMA. For example, the following command registers the Athena database named `sampledb`.

```
create external schema athena_sample
from data catalog
database 'sampledb'
iam_role 'arn:aws:iam::123456789012:role/mySpectrumRole'
region 'us-east-1';
```

When you query the `SVV_EXTERNAL_TABLES` system view, you see tables in the Athena `sampledb` database and also tables that you created in Amazon Redshift.

```
select * from svv_external_tables;
```

schemaname	tablename	location
athena_sample	elb_logs	s3://athena-examples/elb/plaintext
athena_sample	lineitem_1t_csv	s3://myspectrum/tpch/1000/lineitem_csv
athena_sample	lineitem_1t_part	s3://myspectrum/tpch/1000/lineitem_partition
spectrum	sales	s3://redshift-downloads/tickit/spectrum/sales
spectrum	sales_part	s3://redshift-downloads/tickit/spectrum/sales_part

Registering an Apache Hive metastore database

If you create external tables in an Apache Hive metastore, you can use `CREATE EXTERNAL SCHEMA` to register those tables in Redshift Spectrum.

In the `CREATE EXTERNAL SCHEMA` statement, specify the `FROM HIVE METASTORE` clause and provide the Hive metastore URI and port number. The IAM role must include permission to access Amazon S3 but doesn't need any Athena permissions. The following example registers a Hive metastore.

```
create external schema if not exists hive_schema
from hive metastore
database 'hive_database'
uri 'ip-10-0-111-111.us-west-2.compute.internal' port 9083
iam_role 'arn:aws:iam::123456789012:role/mySpectrumRole';
```

Enabling your Amazon Redshift cluster to access your Amazon EMR cluster

If your Hive metastore is in Amazon EMR, you must give your Amazon Redshift cluster access to your Amazon EMR cluster. To do so, you create an Amazon EC2 security group. You then allow all inbound traffic to the EC2 security group from your Amazon Redshift cluster's security group and

your Amazon EMR cluster's security group. Then you add the EC2 security to both your Amazon Redshift cluster and your Amazon EMR cluster.

View your Amazon Redshift cluster's security group name

To display the security group, do the following:

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose the cluster from the list to open its details.
3. Choose **Properties** and view the **Network and security settings** section.
4. Find your security group in **VPC security group** and take note of it.

View the Amazon EMR master node security group name

1. Open your Amazon EMR cluster. For more information, see [Use security configurations to set up cluster security](#) in the *Amazon EMR Management Guide*.
2. Under **Security and access**, make a note of the Amazon EMR master node security group name.

To create or modify an Amazon EC2 security group to allow connection between Amazon Redshift and Amazon EMR

1. In the Amazon EC2 dashboard, choose **Security groups**. For more information, see [Security group rules](#) in the *Amazon EC2 User Guide*
2. Choose **Create security group**.
3. If you are using VPC, choose the VPC that your Amazon Redshift and Amazon EMR clusters are in.
4. Add an inbound rule.
 1. For **Type**, choose **Custom TCP**.
 2. For **Source**, choose **Custom**.
 3. Enter the name of your Amazon Redshift security group.
5. Add another inbound rule.
 1. For **Type**, choose **TCP**.
 2. For **Port Range**, enter **9083**.

Note

The default port for an EMR HMS is 9083. If your HMS uses a different port, specify that port in the inbound rule and in the external schema definition.

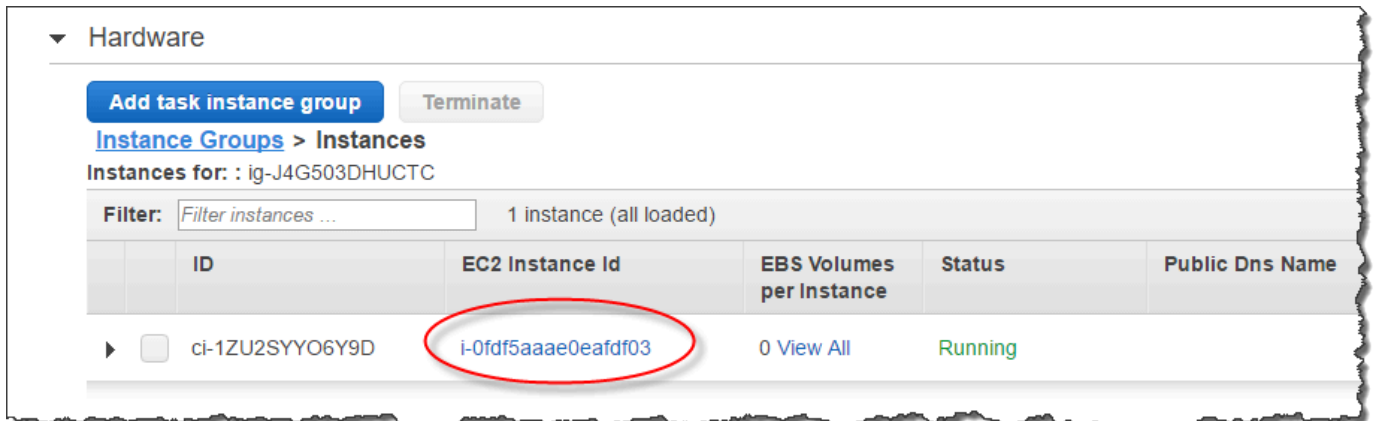

3. For **Source**, choose **Custom**.
6. Enter a security group name and description.
7. Choose **Create security group**.

To add the Amazon EC2 security group you created in the previous procedure to your Amazon Redshift cluster

1. In Amazon Redshift, choose your cluster.
2. Choose **Properties**.
3. View the **Network and security settings** and choose **Edit**.
4. In **VPC security group**, choose the new security group name.
5. Choose **Save changes**.

To add the Amazon EC2 security group to your Amazon EMR cluster

1. In Amazon EMR, choose your cluster. For more information, see [Use security configurations to set up cluster security](#) in the *Amazon EMR Management Guide*.
2. Under **Hardware**, choose the link for the Master node.
3. Choose the link in the **EC2 instance ID** column.

4. For **Actions**, choose **Security, Change security groups**.
5. In **Associated security groups**, choose the new security group, and choose **Add security group**.
6. Choose **Save**.

External tables for Redshift Spectrum

This topic describes how to create and use external tables with Redshift Spectrum. External tables are tables that you use as references to access data outside your Amazon Redshift cluster. These tables contain metadata about the external data that Redshift Spectrum reads.

You create an external table in an external schema. To create external tables, you must be the owner of the external schema or a superuser. To transfer ownership of an external schema, use [ALTER SCHEMA](#) to change the owner. The following example changes the owner of the `spectrum_schema` schema to `newowner`.

```
alter schema spectrum_schema owner to newowner;
```

To run a Redshift Spectrum query, you need the following permissions:

- Usage permission on the schema
- Permission to create temporary tables in the current database

The following example grants usage permission on the schema `spectrum_schema` to the `spectrumusers` user group.

```
grant usage on schema spectrum_schema to group spectrumusers;
```

The following example grants temporary permission on the database `spectrumdb` to the `spectrumusers` user group.

```
grant temp on database spectrumdb to group spectrumusers;
```

You can create an external table in Amazon Redshift, AWS Glue, Amazon Athena, or an Apache Hive metastore. For more information, see [Getting Started Using AWS Glue](#) in the *AWS Glue Developer Guide*, [Getting Started](#) in the *Amazon Athena User Guide*, or [Apache Hive](#) in the *Amazon EMR Developer Guide*.

If your external table is defined in AWS Glue, Athena, or a Hive metastore, you first create an external schema that references the external database. Then you can reference the external table in your `SELECT` statement by prefixing the table name with the schema name, without needing to create the table in Amazon Redshift. For more information, see [External schemas in Amazon Redshift Spectrum](#).

To allow Amazon Redshift to view tables in the AWS Glue Data Catalog, add `glue:GetTable` to the Amazon Redshift IAM role. Otherwise you might get an error similar to the following.

```
RedshiftIamRoleSession is not authorized to perform: glue:GetTable on resource: *;
```

For example, suppose that you have an external table named `lineitem_athena` defined in an Athena external catalog. In this case, you can define an external schema named `athena_schema`, then query the table using the following `SELECT` statement.

```
select count(*) from athena_schema.lineitem_athena;
```

To define an external table in Amazon Redshift, use the [CREATE EXTERNAL TABLE](#) command. The external table statement defines the table columns, the format of your data files, and the location of your data in Amazon S3. Redshift Spectrum scans the files in the specified folder and any

subfolders. Redshift Spectrum ignores hidden files and files that begin with a period, underscore, or hash mark (. , _ , or #) or end with a tilde (~).

The following example creates a table named SALES in the Amazon Redshift external schema named spectrum. The data is in tab-delimited text files.

```
create external table spectrum.sales(  
  salesid integer,  
  listid integer,  
  sellerid integer,  
  buyerid integer,  
  eventid integer,  
  dateid smallint,  
  qty sold smallint,  
  pricepaid decimal(8,2),  
  commission decimal(8,2),  
  saletime timestamp)  
row format delimited  
fields terminated by '\t'  
stored as textfile  
location 's3://redshift-downloads/ticket/spectrum/sales/'  
table properties ('numRows'='172000');
```

To view external tables, query the [SVV_EXTERNAL_TABLES](#) system view.

Pseudocolumns

By default, Amazon Redshift creates external tables with the pseudocolumns `$path`, `$size`, and `$spectrum_oid`. Select the `$path` column to view the path to the data files on Amazon S3, and select the `$size` column to view the size of the data files for each row returned by a query. The `$spectrum_oid` column provides the ability to perform correlated queries with Redshift Spectrum. For an example, see [Example: Performing correlated subqueries in Redshift Spectrum](#). You must delimit the `$path`, `$size`, and `$spectrum_oid` column names with double quotation marks. A `SELECT *` clause doesn't return the pseudocolumns. You must explicitly include the `$path`, `$size`, and `$spectrum_oid` column names in your query, as the following example shows.

```
select "$path", "$size", "$spectrum_oid"  
from spectrum.sales_part where saledate = '2008-12-01';
```

You can disable the creation of pseudocolumns for a session by setting the `spectrum_enable_pseudo_columns` configuration parameter to `false`. For more information,

see [spectrum_enable_pseudo_columns](#). You can also disable only the `$spectrum_oid` pseudocolumn by setting the `enable_spectrum_oid` to `false`. For more information, see [enable_spectrum_oid](#). However, disabling the `$spectrum_oid` pseudocolumn also disables support for correlated queries with Redshift Spectrum.

Important

Selecting `$size`, `$path`, or `$spectrum_oid` incurs charges because Redshift Spectrum scans the data files on Amazon S3 to determine the size of the result set. For more information, see [Amazon Redshift Pricing](#).

Pseudocolumns example

The following example returns the total size of related data files for an external table.

```
select distinct "$path", "$size"
from spectrum.sales_part;
```

<code>\$path</code>	<code>\$size</code>
<code>s3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-01/</code>	1616
<code>s3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-02/</code>	1444
<code>s3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-03/</code>	1644

Partitioning Redshift Spectrum external tables

When you partition your data, you can restrict the amount of data that Redshift Spectrum scans by filtering on the partition key. You can partition your data by any key.

A common practice is to partition the data based on time. For example, you might choose to partition by year, month, date, and hour. If you have data coming from multiple sources, you might partition by a data source identifier and date.

The following procedure describes how to partition your data.

To partition your data

1. Store your data in folders in Amazon S3 according to your partition key.

Create one folder for each partition value and name the folder with the partition key and value. For example, if you partition by date, you might have folders named `saledate=2017-04-01`, `saledate=2017-04-02`, and so on. Redshift Spectrum scans the files in the partition folder and any subfolders. Redshift Spectrum ignores hidden files and files that begin with a period, underscore, or hash mark (. , _ , or #) or end with a tilde (~).

2. Create an external table and specify the partition key in the `PARTITIONED BY` clause.

The partition key can't be the name of a table column. The data type can be `SMALLINT`, `INTEGER`, `BIGINT`, `DECIMAL`, `REAL`, `DOUBLE PRECISION`, `BOOLEAN`, `CHAR`, `VARCHAR`, `DATE`, or `TIMESTAMP` data type.

3. Add the partitions.

Using `ALTER TABLE ... ADD PARTITION`, add each partition, specifying the partition column and key value, and the location of the partition folder in Amazon S3. You can add multiple partitions in a single `ALTER TABLE ... ADD` statement. The following example adds partitions for `'2008-01'` and `'2008-03'`.

```
alter table spectrum.sales_part add
partition(saledate='2008-01-01')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/
saledate=2008-01/'
partition(saledate='2008-03-01')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/
saledate=2008-03/';
```

Note

If you use the AWS Glue catalog, you can add up to 100 partitions using a single `ALTER TABLE` statement.

Partitioning data examples

In this example, you create an external table that is partitioned by a single partition key and an external table that is partitioned by two partition keys.

The sample data for this example is located in an Amazon S3 bucket that gives read access to all authenticated AWS users. Your cluster and your external data files must be in the same AWS

Region. The sample data bucket is in the US East (N. Virginia) Region (us-east-1). To access the data using Redshift Spectrum, your cluster must also be in us-east-1. To list the folders in Amazon S3, run the following command.

```
aws s3 ls s3://redshift-downloads/ticket/spectrum/sales_partition/
```

```
PRE saledate=2008-01/  
PRE saledate=2008-03/  
PRE saledate=2008-04/  
PRE saledate=2008-05/  
PRE saledate=2008-06/  
PRE saledate=2008-12/
```

If you don't already have an external schema, run the following command. Substitute the Amazon Resource Name (ARN) for your AWS Identity and Access Management (IAM) role.

```
create external schema spectrum  
from data catalog  
database 'spectrumdb'  
iam_role 'arn:aws:iam::123456789012:role/myspectrumrole'  
create external database if not exists;
```

Example 1: Partitioning with a single partition key

In the following example, you create an external table that is partitioned by month.

To create an external table partitioned by month, run the following command.

```
create external table spectrum.sales_part(  
salesid integer,  
listid integer,  
sellerid integer,  
buyerid integer,  
eventid integer,  
dateid smallint,  
qtysold smallint,  
pricepaid decimal(8,2),  
commission decimal(8,2),  
saletime timestamp)  
partitioned by (saledate char(10))  
row format delimited  
fields terminated by '|'
```

```
stored as textfile
location 's3://redshift-downloads/ticket/spectrum/sales_partition/'
table properties ('numRows'='172000');
```

To add the partitions, run the following ALTER TABLE command.

```
alter table spectrum.sales_part add
partition(saledate='2008-01')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-01/'

partition(saledate='2008-03')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-03/'

partition(saledate='2008-04')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-04/';
```

To select data from the partitioned table, run the following query.

```
select top 5 spectrum.sales_part.eventid, sum(spectrum.sales_part.pricepaid)
from spectrum.sales_part, event
where spectrum.sales_part.eventid = event.eventid
  and spectrum.sales_part.pricepaid > 30
  and saledate = '2008-01'
group by spectrum.sales_part.eventid
order by 2 desc;
```

```
eventid | sum
-----+-----
  4124 | 21179.00
  1924 | 20569.00
  2294 | 18830.00
  2260 | 17669.00
  6032 | 17265.00
```

To view external table partitions, query the [SVV_EXTERNAL_PARTITIONS](#) system view.

```
select schemaname, tablename, values, location from svv_external_partitions
where tablename = 'sales_part';
```

```
schemaname | tablename | values | location
```

```

-----+-----+-----
+-----
spectrum | sales_part | ["2008-01"] | s3://redshift-downloads/ticket/spectrum/
sales_partition/saledate=2008-01
spectrum | sales_part | ["2008-03"] | s3://redshift-downloads/ticket/spectrum/
sales_partition/saledate=2008-03
spectrum | sales_part | ["2008-04"] | s3://redshift-downloads/ticket/spectrum/
sales_partition/saledate=2008-04

```

Example 2: Partitioning with a multiple partition key

To create an external table partitioned by date and eventid, run the following command.

```

create external table spectrum.sales_event(
salesid integer,
listid integer,
sellerid integer,
buyerid integer,
eventid integer,
dateid smallint,
qtysold smallint,
pricepaid decimal(8,2),
commission decimal(8,2),
saletime timestamp)
partitioned by (salesmonth char(10), event integer)
row format delimited
fields terminated by '|'
stored as textfile
location 's3://redshift-downloads/ticket/spectrum/salesevent/'
table properties ('numRows'='172000');

```

To add the partitions, run the following ALTER TABLE command.

```

alter table spectrum.sales_event add
partition(salesmonth='2008-01', event='101')
location 's3://redshift-downloads/ticket/spectrum/salesevent/salesmonth=2008-01/
event=101/'

partition(salesmonth='2008-01', event='102')
location 's3://redshift-downloads/ticket/spectrum/salesevent/salesmonth=2008-01/
event=102/'

partition(salesmonth='2008-01', event='103')

```

```

location 's3://redshift-downloads/tickit/spectrum/salesevent/salesmonth=2008-01/
event=103/'

partition(salesmonth='2008-02', event='101')
location 's3://redshift-downloads/tickit/spectrum/salesevent/salesmonth=2008-02/
event=101/'

partition(salesmonth='2008-02', event='102')
location 's3://redshift-downloads/tickit/spectrum/salesevent/salesmonth=2008-02/
event=102/'

partition(salesmonth='2008-02', event='103')
location 's3://redshift-downloads/tickit/spectrum/salesevent/salesmonth=2008-02/
event=103/'

partition(salesmonth='2008-03', event='101')
location 's3://redshift-downloads/tickit/spectrum/salesevent/salesmonth=2008-03/
event=101/'

partition(salesmonth='2008-03', event='102')
location 's3://redshift-downloads/tickit/spectrum/salesevent/salesmonth=2008-03/
event=102/'

partition(salesmonth='2008-03', event='103')
location 's3://redshift-downloads/tickit/spectrum/salesevent/salesmonth=2008-03/
event=103/';

```

Run the following query to select data from the partitioned table.

```

select spectrum.sales_event.salesmonth, event.eventname,
       sum(spectrum.sales_event.pricepaid)
from spectrum.sales_event, event
where spectrum.sales_event.eventid = event.eventid
       and salesmonth = '2008-02'
       and (event = '101'
            or event = '102'
            or event = '103')
group by event.eventname, spectrum.sales_event.salesmonth
order by 3 desc;

```

salesmonth	eventname	sum
2008-02	The Magic Flute	5062.00

2008-02	La Sonnambula	3498.00
2008-02	Die Walkure	534.00

Mapping external table columns to ORC columns

You use Amazon Redshift Spectrum external tables to query data from files in ORC format. Optimized row columnar (ORC) format is a columnar storage file format that supports nested data structures. For more information about querying nested data, see [Querying Nested Data with Amazon Redshift Spectrum](#).

When you create an external table that references data in an ORC file, you map each column in the external table to a column in the ORC data. To do so, you use one of the following methods:

- [Mapping by position](#)
- [Mapping by column name](#)

Mapping by column name is the default.

Mapping by position

With position mapping, the first column defined in the external table maps to the first column in the ORC data file, the second to the second, and so on. Mapping by position requires that the order of columns in the external table and in the ORC file match. If the order of the columns doesn't match, then you can map the columns by name.

Important

In earlier releases, Redshift Spectrum used position mapping by default. If you need to continue using position mapping for existing tables, set the table property `orc.schema.resolution` to `position`, as the following example shows.

```
alter table spectrum.orc_example
set table properties('orc.schema.resolution'='position');
```

For example, the table `SPECTRUM.ORB_EXAMPLE` is defined as follows.

```
create external table spectrum.orc_example(
int_col int,
```

```
float_col float,
nested_col struct<
  "int_col" : int,
  "map_col" : map<int, array<float >>
>
) stored as orc
location 's3://example/orc/files/';
```

The table structure can be abstracted as follows.

- 'int_col' : int
- 'float_col' : float
- 'nested_col' : struct
 - o 'int_col' : int
 - o 'map_col' : map
 - key : int
 - value : array
 - value : float

The underlying ORC file has the following file structure.

- ORC file root(id = 0)
 - o 'int_col' : int (id = 1)
 - o 'float_col' : float (id = 2)
 - o 'nested_col' : struct (id = 3)
 - 'int_col' : int (id = 4)
 - 'map_col' : map (id = 5)
 - key : int (id = 6)
 - value : array (id = 7)
 - value : float (id = 8)

In this example, you can map each column in the external table to a column in ORC file strictly by position. The following shows the mapping.

External table column name	ORC column ID	ORC column name
int_col	1	int_col
float_col	2	float_col
nested_col	3	nested_col

External table column name	ORC column ID	ORC column name
nested_col.int_col	4	int_col
nested_col.map_col	5	map_col
nested_col.map_col.key	6	NA
nested_col.map_col.value	7	NA
nested_col.map_col.value.item	8	NA

Mapping by column name

Using name mapping, you map columns in an external table to named columns in ORC files on the same level, with the same name.

For example, suppose that you want to map the table from the previous example, SPECTRUM. ORC_EXAMPLE, with an ORC file that uses the following file structure.

- ORC file root(id = 0)
 - o 'nested_col' : struct (id = 1)
 - 'map_col' : map (id = 2)
 - key : int (id = 3)
 - value : array (id = 4)
 - value : float (id = 5)
 - 'int_col' : int (id = 6)
 - o 'int_col' : int (id = 7)
 - o 'float_col' : float (id = 8)

Using position mapping, Redshift Spectrum attempts the following mapping.

External table column name	ORC column ID	ORC column name
int_col	1	struct
float_col	7	int_col
nested_col	8	float_col

When you query a table with the preceding position mapping, the SELECT command fails on type validation because the structures are different.

You can map the same external table to both file structures shown in the previous examples by using column name mapping. The table columns `int_col`, `float_col`, and `nested_col` map by column name to columns with the same names in the ORC file. The column named `nested_col` in the external table is a `struct` column with subcolumns named `map_col` and `int_col`. The subcolumns also map correctly to the corresponding columns in the ORC file by column name.

Creating external tables for data managed in Apache Hudi

To query data in Apache Hudi Copy On Write (CoW) format, you can use Amazon Redshift Spectrum external tables. A Hudi Copy On Write table is a collection of Apache Parquet files stored in Amazon S3. You can read Copy On Write (CoW) tables in Apache Hudi versions 0.5.2, 0.6.0, 0.7.0, 0.8.0, 0.9.0, 0.10.0, 0.10.1, 0.11.0, and 0.11.1 that are created and modified with insert, delete, and upsert write operations. For example, bootstrap tables are not supported. For more information, see [Copy On Write Table](#) in the open source Apache Hudi documentation.

When you create an external table that references data in Hudi CoW format, you map each column in the external table to a column in the Hudi data. Mapping is done by column.

The data definition language (DDL) statements for partitioned and unpartitioned Hudi tables are similar to those for other Apache Parquet file formats. For Hudi tables, you define `INPUTFORMAT` as `org.apache.hudi.hadoop.HoodieParquetInputFormat`. The `LOCATION` parameter must point to the Hudi table base folder that contains the `.hoodie` folder, which is required to establish the Hudi commit timeline. In some cases, a SELECT operation on a Hudi table might fail with the message `No valid Hudi commit timeline found`. If so, check if the `.hoodie` folder is in the correct location and contains a valid Hudi commit timeline.

Note

Apache Hudi format is only supported when you use an AWS Glue Data Catalog. It's not supported when you use an Apache Hive metastore as the external catalog.

The DDL to define an unpartitioned table has the following format.

```
CREATE EXTERNAL TABLE tbl_name (columns)  
ROW FORMAT SERDE 'org.apache.hadoop.hive.q1.io.parquet.serde.ParquetHiveSerDe'
```

```
STORED AS
INPUTFORMAT 'org.apache.hudi.hadoop.HoodieParquetInputFormat'
OUTPUTFORMAT 'org.apache.hadoop.hive.q1.io.parquet.MapredParquetOutputFormat'
LOCATION 's3://s3-bucket/prefix'
```

The DDL to define a partitioned table has the following format.

```
CREATE EXTERNAL TABLE tbl_name (columns)
PARTITIONED BY(pcolumn1 pcolumn1-type[,...])
ROW FORMAT SERDE 'org.apache.hadoop.hive.q1.io.parquet.serde.ParquetHiveSerDe'
STORED AS
INPUTFORMAT 'org.apache.hudi.hadoop.HoodieParquetInputFormat'
OUTPUTFORMAT 'org.apache.hadoop.hive.q1.io.parquet.MapredParquetOutputFormat'
LOCATION 's3://s3-bucket/prefix'
```

To add partitions to a partitioned Hudi table, run an ALTER TABLE ADD PARTITION command where the LOCATION parameter points to the Amazon S3 subfolder with the files that belong to the partition.

The DDL to add partitions has the following format.

```
ALTER TABLE tbl_name
ADD IF NOT EXISTS PARTITION(pcolumn1=pvalue1[,...])
LOCATION 's3://s3-bucket/prefix/partition-path'
```

Creating external tables for data managed in Delta Lake

To query data in Delta Lake tables, you can use Amazon Redshift Spectrum external tables.

To access a Delta Lake table from Redshift Spectrum, generate a manifest before the query. A Delta Lake *manifest* contains a listing of files that make up a consistent snapshot of the Delta Lake table. In a partitioned table, there is one manifest per partition. A Delta Lake table is a collection of Apache Parquet files stored in Amazon S3. For more information, see [Delta Lake](#) in the open source Delta Lake documentation.

When you create an external table that references data in Delta Lake tables, you map each column in the external table to a column in the Delta Lake table. Mapping is done by column name.

The DDL for partitioned and unpartitioned Delta Lake tables is similar to that for other Apache Parquet file formats. For Delta Lake tables, you define INPUTFORMAT as

`org.apache.hadoop.hive.q1.io.SymlinkTextInputFormat` and `OUTPUTFORMAT` as `org.apache.hadoop.hive.q1.io.HiveIgnoreKeyTextOutputFormat`. The `LOCATION` parameter must point to the manifest folder in the table base folder. If a `SELECT` operation on a Delta Lake table fails, for possible reasons see [Limitations and troubleshooting for Delta Lake tables](#).

The DDL to define an unpartitioned table has the following format.

```
CREATE EXTERNAL TABLE tbl_name (columns)
ROW FORMAT SERDE 'org.apache.hadoop.hive.q1.io.parquet.serde.ParquetHiveSerDe'
STORED AS
INPUTFORMAT 'org.apache.hadoop.hive.q1.io.SymlinkTextInputFormat'
OUTPUTFORMAT 'org.apache.hadoop.hive.q1.io.HiveIgnoreKeyTextOutputFormat'
LOCATION 's3://s3-bucket/prefix/_symlink_format_manifest'
```

The DDL to define a partitioned table has the following format.

```
CREATE EXTERNAL TABLE tbl_name (columns)
PARTITIONED BY(pcolumn1 pcolumn1-type[,...])
ROW FORMAT SERDE 'org.apache.hadoop.hive.q1.io.parquet.serde.ParquetHiveSerDe'
STORED AS
INPUTFORMAT 'org.apache.hadoop.hive.q1.io.SymlinkTextInputFormat'
OUTPUTFORMAT 'org.apache.hadoop.hive.q1.io.HiveIgnoreKeyTextOutputFormat'
LOCATION 's3://s3-bucket>/prefix/_symlink_format_manifest'
```

To add partitions to a partitioned Delta Lake table, run an `ALTER TABLE ADD PARTITION` command where the `LOCATION` parameter points to the Amazon S3 subfolder that contains the manifest for the partition.

The DDL to add partitions has the following format.

```
ALTER TABLE tbl_name
ADD IF NOT EXISTS PARTITION(pcolumn1=pvalue1[,...])
LOCATION
's3://s3-bucket/prefix/_symlink_format_manifest/partition-path'
```

Or run DDL that points directly to the Delta Lake manifest file.

```
ALTER TABLE tbl_name
ADD IF NOT EXISTS PARTITION(pcolumn1=pvalue1[,...])
LOCATION
```

```
's3://s3-bucket/prefix/_symlink_format_manifest/partition-path/manifest'
```

Limitations and troubleshooting for Delta Lake tables

Consider the following when querying Delta Lake tables from Redshift Spectrum:

- If a manifest points to a snapshot or partition that no longer exists, queries fail until a new valid manifest has been generated. For example, this might result from a VACUUM operation on the underlying table,
- Delta Lake manifests only provide partition-level consistency.

The following table explains some potential reasons for certain errors when you query a Delta Lake table.

Error message	Possible reason
Delta Lake manifest in bucket <i>s3-bucket-1</i> cannot contain entries in bucket <i>s3-bucket-2</i> .	The manifest entries point to files in a different Amazon S3 bucket than the specified one.
Delta Lake files are expected to be in the same folder.	The manifest entries point to files that have a different Amazon S3 prefix than the specified one.
File <i>filename</i> listed in Delta Lake manifest <i>manifest-path</i> was not found.	A file listed in the manifest wasn't found in Amazon S3.
Error fetching Delta Lake manifest.	The manifest wasn't found in Amazon S3.
Invalid S3 Path.	An entry in the manifest file isn't a valid Amazon S3 path, or the manifest file has been corrupted.

Using Apache Iceberg tables with Amazon Redshift

This topic describes how to use tables in Apache Iceberg format with Redshift Spectrum or Redshift Serverless. Apache Iceberg is a high-performance format for huge analytic tables.

You can use Redshift Spectrum or Redshift Serverless to query Apache Iceberg tables cataloged in the AWS Glue Data Catalog. Apache Iceberg is an open-source table format for data lakes. For more information, see [Apache Iceberg](#) in the Apache Iceberg documentation.

Amazon Redshift provides transactional consistency for querying Apache Iceberg tables. You can manipulate the data in your tables using ACID (atomicity, consistency, isolation, durability) compliant services such as Amazon Athena and Amazon EMR while running queries using Amazon Redshift. Amazon Redshift can use the table statistics stored in Apache Iceberg metadata to optimize query plans and reduce file scans during query processing. With Amazon Redshift SQL, you can join Redshift tables with data lake tables.

To get started using Iceberg tables with Amazon Redshift:

1. Create an Apache Iceberg table on an AWS Glue Data Catalog database using a compatible service such as Amazon Athena or Amazon EMR. To create an Iceberg table using Athena, see [Using Apache Iceberg tables](#) in the *Amazon Athena User Guide*.
2. Create an Amazon Redshift cluster or Redshift Serverless workgroup with an associated IAM role that allows access to your data lake. For information on how to create clusters or workgroups, see [Get started with Amazon Redshift provisioned data warehouses](#) and [Get started with Redshift Serverless data warehouses](#) in the *Amazon Redshift Getting Started Guide*.
3. Connect to your cluster or workgroup using query editor v2 or a third-party SQL client. For information about how to connect using query editor v2, see [Connecting to an Amazon Redshift data warehouse using SQL client tools](#) in the *Amazon Redshift Management Guide*.
4. Create an external schema in your Amazon Redshift database for a specific Data Catalog database that includes your Iceberg tables. For information about creating an external schema, see [External schemas in Amazon Redshift Spectrum](#).
5. Run SQL queries to access the Iceberg tables in the external schema you created.

Considerations when using Apache Iceberg tables with Amazon Redshift

Consider the following when using Amazon Redshift with Iceberg tables:

- **Iceberg version support** – Amazon Redshift supports running queries against the following versions of Iceberg tables:
 - Version 1 defines how large analytic tables are managed using immutable data files.

- Version 2 adds the ability to support row-level updates and deletes while keeping the existing data files unchanged, and handling table data changes using delete files.

For the difference between version 1 and version 2 tables, see [Format version changes](#) in the Apache Iceberg documentation.

- **Queries only** – Amazon Redshift supports read-only access to Apache Iceberg tables. It supports transactional consistent select queries. You can use a service like Amazon Athena to define and update the schema of Iceberg tables in the AWS Glue Data Catalog.
- **Adding partitions** – You don't need to manually add partitions for your Apache Iceberg tables. New partitions in Apache Iceberg tables are automatically detected by Amazon Redshift and no manual operation is needed to update partitions in the table definition. Any changes in partition specification are also automatically applied to your queries without any user intervention.
- **Ingesting Iceberg data into Amazon Redshift** – You can use INSERT INTO or CREATE TABLE AS commands to import data from your Iceberg table into a local Amazon Redshift table. You currently cannot use the COPY command to ingest the contents of an Apache Iceberg table into a local Amazon Redshift table.
- **Materialized views** – You can create materialized views on Apache Iceberg tables like any other external table in Amazon Redshift. The same considerations for other data lake table formats apply to Apache Iceberg tables. Incremental updates, automatic refreshes, automatic query rewriting, and automatic MVs on data lake tables are currently not supported.
- **AWS Lake Formation fine-grained access control** – Amazon Redshift supports AWS Lake Formation fine-grained access control on Apache Iceberg tables.
- **User-defined data handling parameters** – Amazon Redshift supports user-defined data handling parameters on Apache Iceberg tables. You use user-defined data handling parameters on existing files to tailor the data being queried in external tables to avoid scan errors. These parameters provide capabilities to handle mismatches between the table schema and the actual data on files. You can use user-defined data handling parameters on Apache Iceberg tables as well.
- **Data sharing** – Amazon Redshift data sharing currently doesn't support data lake tables, including Apache Iceberg tables.
- **Time travel queries** – Time travel queries are currently not supported with Apache Iceberg tables.
- **Pricing** – When you access Iceberg tables from a cluster, you are charged Redshift Spectrum pricing. When you access Iceberg tables from a workgroup, you are charged Redshift Serverless

pricing. For information about Redshift Spectrum and Redshift Serverless pricing, see [Amazon Redshift pricing](#).

Supported data types with Apache Iceberg tables

This topic describes the supported data types that Redshift Spectrum can read from tables in Apache Iceberg format.

Amazon Redshift can query Iceberg tables that contain the following data types:

```
binary
boolean
date
decimal
double
float

long
map
string
struct
timestamp without time zone
```

For more information about Iceberg data types, see the [Schemas for Iceberg](#) in the Apache Iceberg documentation.

The following table shows the relationship between Amazon Redshift data types and Iceberg table data types.

Iceberg type	Amazon Redshift type	Notes
boolean	boolean	
-	tinyint	Not supported for Iceberg tables in Amazon Redshift.
-	smallint	Not supported for Iceberg tables in Amazon Redshift.

Iceberg type	Amazon Redshift type	Notes
int	int	In Amazon Redshift SQL statements, this type is INTEGER.
long	bigint	
double	double	
float	float	
decimal(P, S)	decimal(P, S)	P is precision, S is scale.
-	char	Not supported for Iceberg tables in Redshift Spectrum.
string	string	In Amazon Redshift SQL statements, this type is VARCHAR.
binary	binary	
date	date	
time	-	
timestamp	timestamp	
timestamp tz	-	
list<E>	array	
map<K, V>	map	
struct<..>	struct	
fixed(L)	-	The fixed(L) type is not currently supported in Redshift Spectrum.

For more information about data types in Amazon Redshift, see [Data types](#).

Amazon Redshift Spectrum query performance

This topic describes how to improve Redshift Spectrum query performance.

Look at the query plan to find what steps have been pushed to the Amazon Redshift Spectrum layer.

The following steps are related to the Redshift Spectrum query:

- S3 Seq Scan
- S3 HashAggregate
- S3 Query Scan
- Seq Scan PartitionInfo
- Partition Loop

The following example shows the query plan for a query that joins an external table with a local table. Note the S3 Seq Scan and S3 HashAggregate steps that were run against the data on Amazon S3.

```
explain
select top 10 spectrum.sales.eventid, sum(spectrum.sales.pricepaid)
from spectrum.sales, event
where spectrum.sales.eventid = event.eventid
and spectrum.sales.pricepaid > 30
group by spectrum.sales.eventid
order by 2 desc;
```

QUERY PLAN

```
-----
XN Limit (cost=1001055770628.63..1001055770628.65 rows=10 width=31)
```

```
-> XN Merge (cost=1001055770628.63..1001055770629.13 rows=200 width=31)
```

```

Merge Key: sum(sales.derived_col2)

-> XN Network (cost=1001055770628.63..1001055770629.13 rows=200 width=31)

    Send to leader

-> XN Sort (cost=1001055770628.63..1001055770629.13 rows=200 width=31)

    Sort Key: sum(sales.derived_col2)

-> XN HashAggregate (cost=1055770620.49..1055770620.99 rows=200
width=31)

    -> XN Hash Join DS_BCAST_INNER (cost=3119.97..1055769620.49
rows=200000 width=31)

        Hash Cond: ("outer".derived_col1 = "inner".eventid)

-> XN S3 Query Scan sales (cost=3010.00..5010.50
rows=200000 width=31)

    -> S3 HashAggregate (cost=3010.00..3010.50
rows=200000 width=16)

        -> S3 Seq Scan spectrum.sales
location:"s3://redshift-downloads/ticket/spectrum/sales" format:TEXT
(cost=0.00..2150.00 rows=172000 width=16)

            Filter: (pricepaid > 30.00)

-> XN Hash (cost=87.98..87.98 rows=8798 width=4)

    -> XN Seq Scan on event (cost=0.00..87.98
rows=8798 width=4)

```

Note the following elements in the query plan:

- The S3 Seq Scan node shows the filter `pricepaid > 30.00` was processed in the Redshift Spectrum layer.

A filter node under the XN S3 Query Scan node indicates predicate processing in Amazon Redshift on top of the data returned from the Redshift Spectrum layer.

- The S3 HashAggregate node indicates aggregation in the Redshift Spectrum layer for the group by clause (`group by spectrum.sales.eventid`).

Following are ways to improve Redshift Spectrum performance:

- Use Apache Parquet formatted data files. Parquet stores data in a columnar format, so Redshift Spectrum can eliminate unneeded columns from the scan. When data is in text-file format, Redshift Spectrum needs to scan the entire file.
- Use multiple files to optimize for parallel processing. Keep your file sizes larger than 64 MB. Avoid data size skew by keeping files about the same size. For information about Apache Parquet files and configuration recommendations, see [File Format: Configurations](#) in the *Apache Parquet Documentation*.
- Use the fewest columns possible in your queries.
- Put your large fact tables in Amazon S3 and keep your frequently used, smaller dimension tables in your local Amazon Redshift database.
- Update external table statistics by setting the TABLE PROPERTIES numRows parameter. Use [CREATE EXTERNAL TABLE](#) or [ALTER TABLE](#) to set the TABLE PROPERTIES numRows parameter to reflect the number of rows in the table. Amazon Redshift doesn't analyze external tables to generate the table statistics that the query optimizer uses to generate a query plan. If table statistics aren't set for an external table, Amazon Redshift generates a query execution plan. Amazon Redshift generates this plan based on the assumption that external tables are the larger tables and local tables are the smaller tables.
- The Amazon Redshift query planner pushes predicates and aggregations to the Redshift Spectrum query layer whenever possible. When large amounts of data are returned from Amazon S3, the processing is limited by your cluster's resources. Redshift Spectrum scales automatically to process large requests. Thus, your overall performance improves whenever you can push processing to the Redshift Spectrum layer.
- Write your queries to use filters and aggregations that are eligible to be pushed to the Redshift Spectrum layer.

The following are examples of some operations that can be pushed to the Redshift Spectrum layer:

- GROUP BY clauses
- Comparison conditions and pattern-matching conditions, such as LIKE.
- Aggregate functions, such as COUNT, SUM, AVG, MIN, and MAX.
- String functions.

Operations that can't be pushed to the Redshift Spectrum layer include DISTINCT and ORDER BY.

- Use partitions to limit the data that is scanned. Partition your data based on your most common query predicates, then prune partitions by filtering on partition columns. For more information, see [Partitioning Redshift Spectrum external tables](#).

Query [SVL_S3PARTITION](#) to view total partitions and qualified partitions.

- Use AWS Glue's statistics generator to compute column-level statistics for AWS Glue Data Catalog tables. Once AWS Glue generates statistics for tables in the Data Catalog, Amazon Redshift Spectrum automatically uses those statistics to optimize the query plan. For more information about computing column-level statistics using AWS Glue, see [Working with column statistics](#) in the *AWS Glue Developer Guide*.

Data handling options

This topic describes how to configure how Redshift Spectrum handles data in unexpected formats.

You can set table parameters when you create external tables to tailor the data being queried in external tables. Otherwise, scan errors can occur. For more information, see TABLE PROPERTIES in [CREATE EXTERNAL TABLE](#). For examples, see [Data handling examples](#). For a list of errors, see [SVL_SPECTRUM_SCAN_ERROR](#).

You can set the following TABLE PROPERTIES when you create external tables to specify input handling for data being queried in external tables.

- `column_count_mismatch_handling` to identify if the file contains less or more values for a row than the number of columns specified in the external table definition.
- `invalid_char_handling` to specify input handling for invalid characters in columns containing VARCHAR, CHAR, and string data. When you specify REPLACE for `invalid_char_handling`, you can specify the replacement character to use.

- `numeric_overflow_handling` to specify cast overflow handling in columns containing integer and decimal data.
- `surplus_bytes_handling` to specify input handling for surplus bytes in columns containing VARBYTE data.
- `surplus_char_handling` to specify input handling for surplus characters in columns containing VARCHAR, CHAR, and string data.

You can set a configuration option to cancel queries that exceed a maximum number of errors. For more information, see [spectrum_query_maxerror](#).

Example: Performing correlated subqueries in Redshift Spectrum

This topic describes how to perform correlated subqueries in Redshift Spectrum. A correlated subquery is a query that uses values from the outer query.

You can perform correlated subqueries in Redshift Spectrum. The `$spectrum_oid` pseudocolumn provides the ability to perform correlated queries with Redshift Spectrum. To perform a correlated subquery, the pseudocolumn `$spectrum_oid` must be enabled but doesn't appear in the SQL statement. For more information, see [Pseudocolumns](#).

To create the external schema and external tables for this example, see [Getting started with Amazon Redshift Spectrum](#).

Following is an example of a correlated subquery in Redshift Spectrum.

```
select *
from myspectrum_schema.sales s
where exists
( select *
from myspectrum_schema.listing l
where l.listid = s.listid )
order by salesid
limit 5;
```

```
salesid listid sellerid buyerid eventid dateid qtysold pricepaid
commission saletime
```

Metrics in Amazon Redshift Spectrum

This topic describes system views that you can use to monitor Redshift Spectrum queries.

You can monitor Amazon Redshift Spectrum queries using the following system views:

- [SVL_S3QUERY](#)

Use the SVL_S3QUERY view to get details about Redshift Spectrum queries (S3 queries) at the segment and node slice level.

- [SVL_S3QUERY_SUMMARY](#)

Use the SVL_S3QUERY_SUMMARY view to get a summary of all Amazon Redshift Spectrum queries (S3 queries) that have been run on the system.

The following are some things to look for in SVL_S3QUERY_SUMMARY:

- The number of files that were processed by the Redshift Spectrum query.
- The number of bytes scanned from Amazon S3. The cost of a Redshift Spectrum query is reflected in the amount of data scanned from Amazon S3.
- The number of bytes returned from the Redshift Spectrum layer to the cluster. A large amount of data returned might affect system performance.
- The maximum duration and average duration of Redshift Spectrum requests. Long-running requests might indicate a bottleneck.

Query troubleshooting in Amazon Redshift Spectrum

This topic is a reference for common issues you might encounter with Amazon Redshift Spectrum queries.

To view errors generated by Redshift Spectrum queries, query the [SVL_S3LOG](#) system table.

Topics

- [Retries exceeded](#)
- [Access throttled](#)
- [Resource limit exceeded](#)
- [No rows returned for a partitioned table](#)
- [Not authorized error](#)
- [Incompatible data formats](#)
- [Syntax error when using Hive DDL in Amazon Redshift](#)
- [Permission to create temporary tables](#)
- [Invalid range](#)
- [Invalid Parquet version number](#)

Retries exceeded

If an Amazon Redshift Spectrum request times out, the request is canceled and resubmitted. After five failed retries, the query fails with the following error.

```
error: Spectrum Scan Error: Retries exceeded
```

Possible causes include the following:

- Large file sizes (greater than 1 GB). Check your file sizes in Amazon S3 and look for large files and file size skew. Break up large files into smaller files, between 100 MB and 1 GB. Try to make files about the same size.
- Slow network throughput. Try your query later.

Access throttled

Amazon Redshift Spectrum is subject to the service quotas of other AWS services. Under high usage, Redshift Spectrum requests might be required to slow down, resulting in the following error.

```
error: Spectrum Scan Error: Access throttled
```

Two types of throttling can happen:

- Access throttled by Amazon S3.
- Access throttled by AWS KMS.

The error context provides more details about the type of throttling. Following, you can find causes and possible resolutions for this throttling.

Access throttled by Amazon S3

Amazon S3 might throttle a Redshift Spectrum request if the read request rate on a [prefix](#) is too high. For information about a GET/HEAD request rate that you can achieve in Amazon S3, see [Optimizing Amazon S3 Performance](#) in *Amazon Simple Storage Service User Guide*. The Amazon S3 GET/HEAD request rate takes into account all GET/HEAD requests on a prefix so different applications accessing the same prefix share the total requests rate.

If your Redshift Spectrum requests frequently get throttled by Amazon S3, reduce the number of Amazon S3 GET/HEAD requests that Redshift Spectrum makes to Amazon S3. To do this, try merging small files into larger files. We recommend using file sizes of 64 MB or larger.

Also consider partitioning your Redshift Spectrum tables to benefit from early filtering and to reduce the number of files accessed in Amazon S3. For more information, see [Partitioning Redshift Spectrum external tables](#).

Access throttled by AWS KMS

If you store your data in Amazon S3 using server-side encryption (SSE-S3 or SSE-KMS), Amazon S3 calls an API operation to AWS KMS for each file that Redshift Spectrum accesses. These requests count toward your cryptographic operations quota; for more information, see [AWS KMS Request Quotas](#). For more information on SSE-S3 and SSE-KMS, see [Protecting Data Using Server-Side Encryption](#) and [Protecting Data Using Server-Side Encryption with KMS keys Stored in AWS KMS](#) in *Amazon Simple Storage Service User Guide*.

A first step to reduce the number of requests that Redshift Spectrum makes to AWS KMS is to reduce the number of files accessed. To do this, try merging small files into larger files. We recommend using file sizes of 64 MB or larger.

If your Redshift Spectrum requests frequently get throttled by AWS KMS, consider requesting a quota increase for your AWS KMS request rate for cryptographic operations. To request a quota increase, see [AWS Service Limits](#) in the *Amazon Web Services General Reference*.

Resource limit exceeded

Redshift Spectrum enforces an upper bound on the amount of memory a request can use. A Redshift Spectrum request that requires more memory fails, resulting in the following error.

```
error: Spectrum Scan Error: Resource limit exceeded
```

There are two common reasons that can cause a Redshift Spectrum request to overrun its memory allowance:

- Redshift Spectrum processes a large chunk of data that can't be split in smaller chunks.
- A large aggregation step is processed by Redshift Spectrum.

We recommend using a file format that supports parallel reads with split sizes of 128 MB or less. See [Data files for queries in Amazon Redshift Spectrum](#) for supported file formats and generic guidelines for data file creation. When using file formats or compression algorithms that don't support parallel reads, we recommend keeping file sizes between 64 MB and 128 MB.

No rows returned for a partitioned table

If your query returns zero rows from a partitioned external table, check whether a partition has been added for this external table. Redshift Spectrum only scans files in an Amazon S3 location that has been explicitly added using `ALTER TABLE ... ADD PARTITION`. Query the [SVV_EXTERNAL_PARTITIONS](#) view to find existing partitions. Run `ALTER TABLE ... ADD PARTITION` for each missing partition.

Not authorized error

Verify that the IAM role for the cluster allows access to the Amazon S3 file objects. If your external database is on Amazon Athena, verify that the IAM role allows access to Athena resources. For more information, see [IAM policies for Amazon Redshift Spectrum](#).

Incompatible data formats

For a columnar file format, such as Apache Parquet, the column type is embedded with the data. The column type in the CREATE EXTERNAL TABLE definition must match the column type of the data file. If there is a mismatch, you receive an error similar to the following:

```
File 'https://s3bucket/location/file has an incompatible Parquet schema
for column 's3://s3bucket/location.col1'. Column type: VARCHAR, Par
```

The error message might be truncated due to the limit on message length. To retrieve the complete error message, including column name and column type, query the [SVL_S3LOG](#) system view.

The following example queries SVL_S3LOG for the last query completed.

```
select message
from svl_s3log
where query = pg_last_query_id()
order by query,segment,slice;
```

The following is an example of a result that shows the full error message.

```
message
-----
Spectrum Scan Error. File 'https://s3bucket/location/file has an incompatible
Parquet schema for column ' s3bucket/location.col1'.
Column type: VARCHAR, Parquet schema:\noptional int64 l_orderkey [i:0 d:1 r:0]\n
```

To correct the error, alter the external table to match the column type of the Parquet file.

Syntax error when using Hive DDL in Amazon Redshift

Amazon Redshift supports data definition language (DDL) for CREATE EXTERNAL TABLE that is similar to Hive DDL. However, the two types of DDL aren't always exactly the same. If you copy Hive DDL to create or alter Amazon Redshift external tables, you might encounter syntax errors. The following are examples of differences between Amazon Redshift and Hive DDL:

- Amazon Redshift requires single quotation marks (') where Hive DDL supports double quotation marks (").
- Amazon Redshift doesn't support the STRING data type. Use VARCHAR instead.

Permission to create temporary tables

To run Redshift Spectrum queries, the database user must have permission to create temporary tables in the database. The following example grants temporary permission on the database `spectrumdb` to the `spectrumusers` user group.

```
grant temp on database spectrumdb to group spectrumusers;
```

For more information, see [GRANT](#).

Invalid range

Redshift Spectrum expects that files in Amazon S3 that belong to an external table are not overwritten during a query. If this happens, it can result in the following error.

```
Error: HTTP response error code: 416 Message: InvalidRange The requested range is not satisfiable
```

To avoid the error, make sure Amazon S3 files are not overwritten while they are queried with Redshift Spectrum.

Invalid Parquet version number

Redshift Spectrum checks the metadata of each Apache Parquet file it accesses. If the check fails, it can result in an error similar to the following:

```
File 'https://s3.region.amazonaws.com/s3bucket/location/file' has an invalid version number
```

There are two common reasons that can cause the check to fail:

- The Parquet file has been overwritten during the query (see [Invalid range](#)).
- The Parquet file is corrupt.

Tutorial: Querying nested data with Amazon Redshift Spectrum

This tutorial demonstrates how to query nested data with Redshift Spectrum. Nested data is data that contains nested fields. Nested fields are fields that are joined together as a single entity, such as arrays, structs, or objects.

Topics

- [Overview](#)
- [Step 1: Create an external table that contains nested data](#)
- [Step 2: Query your nested data in Amazon S3 with SQL extensions](#)
- [Nested data use cases](#)
- [Nested data limitations \(preview\)](#)
- [Serializing complex nested JSON](#)

Overview

Amazon Redshift Spectrum supports querying nested data in Parquet, ORC, JSON, and Ion file formats. Redshift Spectrum accesses the data using external tables. You can create external tables that use the complex data types `struct`, `array`, and `map`.

For example, suppose that your data file contains the following data in Amazon S3 in a folder named `customers`. Although there isn't a single root element, each JSON object in this sample data represents a row in a table.

```
{
  "id": 1,
  "name": {"given": "John", "family": "Smith"},
  "phones": ["123-457789"],
  "orders": [{"shipdate": "2018-03-01T11:59:59.000Z", "price": 100.50},
             {"shipdate": "2018-03-01T09:10:00.000Z", "price": 99.12}]
}
{"id": 2,
 "name": {"given": "Jenny", "family": "Doe"},
 "phones": ["858-8675309", "415-9876543"],
 "orders": []
}
{"id": 3,
 "name": {"given": "Andy", "family": "Jones"},
 "phones": [],
 "orders": [{"shipdate": "2018-03-02T08:02:15.000Z", "price": 13.50}]
}
```

You can use Amazon Redshift Spectrum to query nested data in files. The following tutorial shows you how to do so with Apache Parquet data.

Prerequisites

If you are not using Redshift Spectrum yet, follow the steps in the [Getting started with Amazon Redshift Spectrum](#) before continuing.

To create an external schema, replace the IAM role ARN in the following command with the role ARN you created in [Create an IAM role](#). Then run the command in your SQL client.

```
create external schema spectrum
from data catalog
database 'myspectrum_db'
iam_role 'arn:aws:iam::123456789012:role/myspectrum_role'
create external database if not exists;
```

Step 1: Create an external table that contains nested data

You can view the [source data](#) by downloading it from Amazon S3.

To create the external table for this tutorial, run the following command.

```
CREATE EXTERNAL TABLE spectrum.customers (
  id      int,
  name    struct<given:vvarchar(20), family:vvarchar(20)>,
  phones  array<vvarchar(20)>,
  orders  array<struct<shipdate:timestamp, price:double precision>>
)
STORED AS PARQUET
LOCATION 's3://redshift-downloads/ticket/spectrum/customers/';
```

In the example preceding, the external table `spectrum.customers` uses the `struct` and `array` data types to define columns with nested data. Amazon Redshift Spectrum supports querying nested data in Parquet, ORC, JSON, and Ion file formats. The `STORED AS` parameter is `PARQUET` for Apache Parquet files. The `LOCATION` parameter has to refer to the Amazon S3 folder that contains the nested data or files. For more information, see [CREATE EXTERNAL TABLE](#).

You can nest `array` and `struct` types at any level. For example, you can define a column named `toparray` as shown in the following example.

```
toparray array<struct<nestedarray:
  array<struct<morenestedarray:
    array<string>>>>>
```

You can also nest struct types as shown for column `x` in the following example.

```
x struct<a: string,
      b: struct<c: integer,
              d: struct<e: string>
            >
      >
```

Step 2: Query your nested data in Amazon S3 with SQL extensions

Redshift Spectrum supports querying `array`, `map`, and `struct` complex types through extensions to the Amazon Redshift SQL syntax.

Extension 1: Access to columns of structs

You can extract data from `struct` columns using a dot notation that concatenates field names into paths. For example, the following query returns given and family names for customers. The given name is accessed by the long path `c.name.given`. The family name is accessed by the long path `c.name.family`.

```
SELECT c.id, c.name.given, c.name.family
FROM   spectrum.customers c;
```

The preceding query returns the following data.

```
id | given | family
---|-----|-----
1  | John  | Smith
2  | Jenny | Doe
3  | Andy  | Jones
(3 rows)
```

A `struct` can be a column of another `struct`, which can be a column of another `struct`, at any level. The paths that access columns in such deeply nested structs can be arbitrarily long. For example, see the definition for the column `x` in the following example.

```
x struct<a: string,
      b: struct<c: integer,
              d: struct<e: string>
            >
      >
```

>

You can access the data in `e` as `x.b.d.e`.

Extension 2: Ranging over arrays in a FROM clause

You can extract data from `array` columns (and, by extension, map columns) by specifying the `array` columns in a `FROM` clause in place of table names. The extension applies to the `FROM` clause of the main query, and also the `FROM` clauses of subqueries.

You can reference `array` elements by position, such as `c.orders[0]`. (preview)

By combining ranging over `arrays` with joins, you can achieve various kinds of unnesting, as explained in the following use cases.

Unnesting using inner joins

The following query selects customer IDs and order ship dates for customers that have orders. The SQL extension in the `FROM` clause `c.orders o` depends on the alias `c`.

```
SELECT c.id, o.shipdate
FROM   spectrum.customers c, c.orders o
```

For each customer `c` that has orders, the `FROM` clause returns one row for each order `o` of the customer `c`. That row combines the customer row `c` and the order row `o`. Then the `SELECT` clause keeps only the `c.id` and `o.shipdate`. The result is the following.

```
id|      shipdate
--|-----
1 |2018-03-01 11:59:59
1 |2018-03-01 09:10:00
3 |2018-03-02 08:02:15
(3 rows)
```

The alias `c` provides access to the customer fields, and the alias `o` provides access to the order fields.

The semantics are similar to standard SQL. You can think of the `FROM` clause as running the following nested loop, which is followed by `SELECT` choosing the fields to output.

```
for each customer c in spectrum.customers
```

```
for each order o in c.orders
  output c.id and o.shipdate
```

Therefore, if a customer doesn't have an order, the customer doesn't appear in the result.

You can also think of this as the FROM clause performing a JOIN with the customers table and the orders array. In fact, you can also write the query as shown in the following example.

```
SELECT c.id, o.shipdate
FROM spectrum.customers c INNER JOIN c.orders o ON true
```

Note

If a schema named `c` exists with a table named `orders`, then `c.orders` refers to the table `orders`, and not the array column of customers.

Unnesting using left joins

The following query outputs all customer names and their orders. If a customer hasn't placed an order, the customer's name is still returned. However, in this case, the order columns are NULL, as shown in the following example for Jenny Doe.

```
SELECT c.id, c.name.given, c.name.family, o.shipdate, o.price
FROM spectrum.customers c LEFT JOIN c.orders o ON true
```

The preceding query returns the following data.

id	given	family	shipdate	price
1	John	Smith	2018-03-01 11:59:59	100.5
1	John	Smith	2018-03-01 09:10:00	99.12
2	Jenny	Doe		
3	Andy	Jones	2018-03-02 08:02:15	13.5

(4 rows)

Extension 3: Accessing an array of scalars directly using an alias

When an alias `p` in a FROM clause ranges over an array of scalars, the query refers to the values of `p` as `p`. For example, the following query produces pairs of customer names and phone numbers.

```
SELECT c.name.given, c.name.family, p AS phone
FROM   spectrum.customers c LEFT JOIN c.phones p ON true
```

The preceding query returns the following data.

```
given | family | phone
-----|-----|-----
John  | Smith  | 123-4577891
Jenny | Doe    | 858-8675309
Jenny | Doe    | 415-9876543
Andy  | Jones  |
(4 rows)
```

Extension 4: Accessing elements of maps

Redshift Spectrum treats the map data type as an array type that contains struct types with a key column and a value column. The key must be a scalar; the value can be any data type.

For example, the following code creates an external table with a map for storing phone numbers.

```
CREATE EXTERNAL TABLE spectrum.customers2 (
  id      int,
  name    struct<given:varchar(20), family:varchar(20)>,
  phones  map<varchar(20), varchar(20)>,
  orders  array<struct<shipdate:timestamp, price:double precision>>
)
STORED AS PARQUET
LOCATION 's3://redshift-downloads/ticket/spectrum/customers/';
```

Because a map type behaves like an array type with columns key and value, you can think of the preceding schemas as if they were the following.

```
CREATE EXTERNAL TABLE spectrum.customers3 (
  id      int,
  name    struct<given:varchar(20), family:varchar(20)>,
  phones  array<struct<key:varchar(20), value:varchar(20)>>,
  orders  array<struct<shipdate:timestamp, price:double precision>>
)
STORED AS PARQUET
LOCATION 's3://redshift-downloads/ticket/spectrum/customers/';
```

The following query returns the names of customers with a mobile phone number and returns the number for each name. The map query is treated as the equivalent of querying a nested array of struct types. The following query only returns data if you have created the external table as described previously.

```
SELECT c.name.given, c.name.family, p.value
FROM   spectrum.customers c, c.phones p
WHERE  p.key = 'mobile';
```

Note

The key for a map is a string for Ion and JSON file types.

Nested data use cases

This topic describes use cases for nested data. Nested data is data that contains nested fields. Nested fields are fields that are joined together as a single entity, such as arrays, structs, or objects.

You can combine the extensions described previously with the usual SQL features. The following use cases illustrate some common combinations. These examples help demonstrate how you can use nested data. They aren't part of the tutorial.

Topics

- [Ingesting nested data](#)
- [Aggregating nested data with subqueries](#)
- [Joining Amazon Redshift and nested data](#)

Ingesting nested data

You can use a CREATE TABLE AS statement to ingest data from an external table that contains complex data types. The following query extracts all customers and their phone numbers from the external table, using LEFT JOIN, and stores them in the Amazon Redshift table CustomerPhones.

```
CREATE TABLE CustomerPhones AS
SELECT  c.name.given, c.name.family, p AS phone
FROM    spectrum.customers c LEFT JOIN c.phones p ON true;
```

Aggregating nested data with subqueries

You can use a subquery to aggregate nested data. The following example illustrates this approach.

```
SELECT c.name.given, c.name.family, (SELECT COUNT(*) FROM c.orders o) AS ordercount
FROM spectrum.customers c;
```

The following data is returned.

given	family	ordercount
Jenny	Doe	0
John	Smith	2
Andy	Jones	1

(3 rows)

Note

When you aggregate nested data by grouping by the parent row, the most efficient way is the one shown in the previous example. In that example, the nested rows of `c.orders` are grouped by their parent row `c`. Alternatively, if you know that `id` is unique for each customer and `o.shipdate` is never null, you can aggregate as shown in the following example. However, this approach generally isn't as efficient as the previous example.

```
SELECT c.name.given, c.name.family, COUNT(o.shipdate) AS ordercount
FROM spectrum.customers c LEFT JOIN c.orders o ON true
GROUP BY c.id, c.name.given, c.name.family;
```

You can also write the query by using a subquery in the FROM clause that refers to an alias (`c`) of the ancestor query and extracts array data. The following example demonstrates this approach.

```
SELECT c.name.given, c.name.family, s.count AS ordercount
FROM spectrum.customers c, (SELECT count(*) AS count FROM c.orders o) s;
```

Joining Amazon Redshift and nested data

You can also join Amazon Redshift data with nested data in an external table. For example, suppose that you have the following nested data in Amazon S3.

```
CREATE EXTERNAL TABLE spectrum.customers2 (  
  id      int,  
  name    struct<given:varchar(20), family:varchar(20)>,  
  phones  array<varchar(20)>,  
  orders  array<struct<shipdate:timestamp, item:int>>  
)
```

Suppose also that you have the following table in Amazon Redshift.

```
CREATE TABLE prices (  
  id int,  
  price double precision  
)
```

The following query finds the total number and amount of each customer's purchases based on the preceding. The following example is only an illustration. It only returns data if you have created the tables described previously.

```
SELECT  c.name.given, c.name.family, COUNT(o.date) AS ordercount, SUM(p.price) AS  
        ordersum  
FROM    spectrum.customers2 c, c.orders o, prices p ON o.item = p.id  
GROUP BY c.id, c.name.given, c.name.family;
```

Nested data limitations (preview)

This topic describes limitations for reading nested data with Redshift Spectrum. Nested data is data that contains nested fields. Nested fields are fields that are joined together as a single entity, such as arrays, structs, or objects.

Note

The limitations marked (preview) in the following list only apply to preview clusters and preview workgroups created in the following Regions.

- US East (Ohio) (us-east-2)
- US East (N. Virginia) (us-east-1)
- US West (N. California) (us-west-1)
- Asia Pacific (Tokyo) (ap-northeast-1)

- Europe (Ireland) (eu-west-1)
- Europe (Stockholm) (eu-north-1)

For information about setting up Preview clusters, see [Creating a preview cluster](#) in the *Amazon Redshift Management Guide*. For information about setting up Preview workgroups, see [Creating a preview workgroup](#) in the *Amazon Redshift Management Guide*.

The following limitations apply to nested data:

- An `array` or `map` type can contain other `array` or `map` types as long as queries on the nested arrays or maps don't return scalar values. (preview)
- Amazon Redshift Spectrum supports complex data types only as external tables.
- Subquery result columns must be top-level. (preview)
- If an `OUTER JOIN` expression refers to a nested table, it can refer only to that table and its nested arrays (and maps). If an `OUTER JOIN` expression doesn't refer to a nested table, it can refer to any number of non-nested tables.
- If a `FROM` clause in a subquery refers to a nested table, it can't refer to any other table.
- If a subquery depends on a nested table that refers to a parent table, the subquery can only use the parent table in the `FROM` clause. You can't use the parent in any other clauses, such as a `SELECT` or `WHERE` clause. For example, the following query doesn't run because the subquery's `SELECT` clause refers to the parent table `c`.

```
SELECT c.name.given
FROM   spectrum.customers c
WHERE  (SELECT COUNT(c.id) FROM c.phones p WHERE p LIKE '858%') > 1;
```

The following query works because the parent `c` is used only in the `FROM` clause of the subquery.

```
SELECT c.name.given
FROM   spectrum.customers c
WHERE  (SELECT COUNT(*) FROM c.phones p WHERE p LIKE '858%') > 1;
```

- A subquery that accesses nested data anywhere other than the `FROM` clause must return a single value. The only exceptions are `(NOT) EXISTS` operators in a `WHERE` clause.
- `(NOT) IN` is not supported.

- The maximum nesting depth for all nested types is 100. This restriction applies to all file formats (Parquet, ORC, Ion, and JSON).
- Aggregation subqueries that access nested data can only refer to `arrays` and `maps` in their `FROM` clause, not to an external table.
- Querying the pseudocolumns of nested data in a Redshift Spectrum table is not supported. For more information, see [Pseudocolumns](#).
- When extracting data from array or map columns by specifying them in a `FROM` clause, you can only select values from those columns if the values are `scalar`. For example, the following queries both try to `SELECT` elements from inside an array. The query that selects `arr.a` works because `arr.a` is a `scalar` value. The second query doesn't work because `array` is an array extracted from `s3.nested` table in the `FROM` clause. (preview)

```
SELECT array_column FROM s3.nested_table;

array_column
-----
[{"a":1}, {"b":2}]

SELECT arr.a FROM s3.nested_table t, t.array_column arr;

arr.a
-----
1

--This query fails to run.
SELECT array FROM s3.nested_table tab, tab.array_column array;
```

You can't use an array or map in the `FROM` clause that itself comes from another array or map. To select arrays or other complex structures that are nested inside other arrays, consider using indexes in the `SELECT` statement.

Serializing complex nested JSON

This topic demonstrates how to serialize nested data in JSON format. Nested data is data that contains nested fields. Nested fields are fields that are joined together as a single entity, such as arrays, structs, or objects.

An alternate to methods demonstrated in this tutorial is to query top-level nested collection columns as serialized JSON. You can use the serialization to inspect, convert, and ingest nested data as JSON with Redshift Spectrum. This method is supported for ORC, JSON, Ion, and Parquet formats. Use the session configuration parameter `json_serialization_enable` to configure the serialization behavior. When set, complex JSON data types are serialized to `VARCHAR(65535)`. The nested JSON can be accessed with [JSON functions](#). For more information, see [json_serialization_enable](#).

For example, without setting `json_serialization_enable`, the following queries that access nested columns directly fail.

```
SELECT * FROM spectrum.customers LIMIT 1;

=> ERROR:  Nested tables do not support '*' in the SELECT clause.

SELECT name FROM spectrum.customers LIMIT 1;

=> ERROR:  column "name" does not exist in customers
```

Setting `json_serialization_enable` enables querying top-level collections directly.

```
SET json_serialization_enable TO true;

SELECT * FROM spectrum.customers order by id LIMIT 1;

id | name | phones | orders
---+-----+-----+-----
1 | {"given": "John", "family": "Smith"} | ["123-457789"] | [{"shipdate": "2018-03-01T11:59:59.000Z", "price": 100.50}, {"shipdate": "2018-03-01T09:10:00.000Z", "price": 99.12}]

SELECT name FROM spectrum.customers order by id LIMIT 1;

name
-----
{"given": "John", "family": "Smith"}
```

Consider the following items when serializing nested JSON.

- When collection columns are serialized as VARCHAR(65535), their nested subfields can't be accessed directly as part of the query syntax (for example, in the filter clause). However, JSON functions can be used to access nested JSON.
- The following specialized representations are not supported:
 - ORC unions
 - ORC maps with complex type keys
 - Ion datagrams
 - Ion SEXP
- Timestamps are returned as ISO serialized strings.
- Primitive map keys are promoted to string (for example, 1 to "1").
- Top-level null values are serialized as NULLs.
- If the serialization overflows the maximum VARCHAR size of 65535, the cell is set to NULL.

Serializing complex types containing JSON strings

By default, string values contained in nested collections are serialized as escaped JSON strings. Escaping might be undesirable when the strings are valid JSON. Instead you might want to write nested subelements or fields that are VARCHAR directly as JSON. Enable this behavior with the `json_serialization_parse_nested_strings` session-level configuration. When both `json_serialization_enable` and `json_serialization_parse_nested_strings` are set, valid JSON values are serialized inline without escape characters. When the value is not valid JSON, it is escaped as if the `json_serialization_parse_nested_strings` configuration value was not set. For more information, see [json_serialization_parse_nested_strings](#).

For example, assume the data from the previous example contained JSON as a structs complex type in the name VARCHAR(20) field:

```
name
-----
{"given": "{\"first\": \"John\", \"middle\": \"James\"}", "family": "Smith"}
```

When `json_serialization_parse_nested_strings` is set, the name column is serialized as follows:

```
SET json_serialization_enable TO true;
SET json_serialization_parse_nested_strings TO true;
```

```
SELECT name FROM spectrum.customers order by id LIMIT 1;
```

```
name
```

```
-----
```

```
{"given": {"first":"John","middle":"James"}, "family": "Smith"}
```

Instead of being escaped like this:

```
SET json_serialization_enable TO true;
```

```
SELECT name FROM spectrum.customers order by id LIMIT 1;
```

```
name
```

```
-----
```

```
{"given": "{\"first\": \"John\", \"middle\": \"James\"}", "family": "Smith"}
```

HyperLogLog sketches

This topic describes how to use HyperLogLog sketches in Amazon Redshift. HyperLogLog is an algorithm for the count-distinct problem, approximating the number of distinct elements in a data set. HyperLogLog sketches are arrays of uniqueness data about a data set.

HyperLogLog is an algorithm used for estimating the cardinality of a multiset. *Cardinality* refers to the number of distinct values in a multiset. For example, in the set of {4,3,6,2,2,6,4,3,6,2,2,3}, the cardinality is 4 with distinct values of 4, 3, 6, and 2.

The precision of the HyperLogLog algorithm (also known as *m* value) can affect the accuracy of the estimated cardinality. During the cardinality estimation, Amazon Redshift uses a default precision value of 15. This value can be up to 26 for smaller datasets. Thus, the average relative error ranges between 0.01–0.6%.

When calculating the cardinality of a multiset, the HyperLogLog algorithm generates a construct called an HLL sketch. An *HLL sketch* encapsulates information about the distinct values in a multiset. The Amazon Redshift data type HLLSKETCH represents such sketch values. This data type can be used to store sketches in an Amazon Redshift table. Additionally, Amazon Redshift supports operations that can be applied to HLLSKETCH values as aggregate and scalar functions. You can use these functions to extract the cardinality of an HLLSKETCH and combine multiple HLLSKETCH values.

The HLLSKETCH data type offers significant query performance benefits when extracting the cardinality from large datasets. You can preaggregate these datasets using HLLSKETCH values and store them in tables. Amazon Redshift can extract the cardinality directly from the stored HLLSKETCH values without accessing the underlying datasets.

When processing HLL sketches, Amazon Redshift performs optimizations that minimize the memory footprint of the sketch and maximize the precision of the extracted cardinality. Amazon Redshift uses two representations for HLL sketches, sparse and dense. An HLLSKETCH starts in sparse format. As new values are inserted into it, its size increases. After its size reaches the size of the dense representation, Amazon Redshift automatically converts the sketch from sparse to dense.

Amazon Redshift imports, exports, and prints an HLLSKETCH as JSON when the sketch is in a sparse format. Amazon Redshift imports, exports, and prints an HLLSKETCH as a Base64 string when the sketch is in a dense format. For more information about UNLOAD, see [Unloading the](#)

[HLLSKETCH data type](#). To import text or comma-separated value (CSV) data into Amazon Redshift, use the COPY command. For more information, see [Loading the HLLSKETCH data type](#).

For information about functions used with HyperLogLog, see [HyperLogLog functions](#).

Topics

- [Considerations](#)
- [Limitations](#)
- [Examples](#)

Considerations

This topic describes usage details for HyperLogLog in Amazon Redshift.

The following are considerations for using HyperLogLog in Amazon Redshift:

- The following non-HyperLogLog functions can accept an input of type HLLSKETCH or columns of type HLLSKETCH:
 - The aggregate function COUNT
 - The conditional expressions COALESCE and NVL
 - CASE expressions
- The supported encoding is RAW.
- You can perform an UNLOAD operation on table with HLLSKETCH columns into text or CSV. You can use the UNLOAD HLLSKETCH columns to write HLLSKETCH data. Amazon Redshift shows the data in a JSON format for a sparse representation or a Base64 format for a dense representation. For more information about UNLOAD, see [Unloading the HLLSKETCH data type](#).

The following shows the format used for a sparse HyperLogLog sketch represented in a JSON format.

```
{"version":1,"logm":15,"sparse":{"indices":  
[15099259,33107846,37891580,50065963],"values":[2,3,2,1]}}
```

- You can import text or CSV data into Amazon Redshift using the COPY command. For more information, see [Loading the HLLSKETCH data type](#).
- The default encoding for HLLSKETCH is RAW. For more information, see [Compression encodings](#).

Limitations

This topic describes limitations for HyperLogLog in Amazon Redshift.

The following are limitations for using HyperLogLog in Amazon Redshift:

- Amazon Redshift tables don't support an HLLSKETCH column as a sort key or a distribution key for an Amazon Redshift table.
- Amazon Redshift doesn't support HLLSKETCH columns in ORDER BY, GROUP BY, or DISTINCT clauses.
- You can only UNLOAD HLLSKETCH columns to text or CSV format. Amazon Redshift then writes the HLLSKETCH data in either a JSON format or a Base64 format. For more information about UNLOAD, see [UNLOAD](#).
- Amazon Redshift only supports HyperLogLog sketches with a precision (logm value) of 15.
- JDBC and ODBC drivers don't support the HLLSKETCH data type. Therefore, the result set uses VARCHAR to represent the HLLSKETCH values.
- Amazon Redshift Spectrum doesn't natively support the HLLSKETCH data. Therefore, you can't create or alter an external table with an HLLSKETCH column.
- Data types for Python user-defined functions (UDFs) don't support the HLLSKETCH data type. For more information about Python UDFs, see [Scalar Python UDFs](#).

Examples

This section contains examples for using HyperLogLog with Amazon Redshift.

Topics

- [Example: Return cardinality in a subquery](#)
- [Example: Return an HLLSKETCH type from combined sketches in a subquery](#)
- [Example: Return a HyperLogLog sketch from combining multiple sketches](#)
- [Example: Generate HyperLogLog sketches over S3 data using external tables](#)

Example: Return cardinality in a subquery

The following example returns the cardinality for each sketch in a subquery for a table named *Sales*.

```
CREATE TABLE Sales (customer VARCHAR, country VARCHAR, amount BIGINT);
INSERT INTO Sales VALUES ('David Joe', 'Greece', 14.5), ('David Joe', 'Greece',
19.95), ('John Doe', 'USA', 29.95), ('John Doe', 'USA', 19.95), ('George Spanos',
'Greece', 9.95), ('George Spanos', 'Greece', 2.95);
```

The following query generates an HLL sketch for the customers of each country and extracts the cardinality. This shows unique customers from each country.

```
SELECT hll_cardinality(sketch), country
FROM (SELECT hll_create_sketch(customer) AS sketch, country
      FROM Sales
      GROUP BY country) AS hll_subquery;
```

```
hll_cardinality | country
-----+-----
              1 | USA
              2 | Greece
...

```

Example: Return an HLLSKETCH type from combined sketches in a subquery

The following example returns a single HLLSKETCH type that represents the combination of individual sketches from a subquery. The sketches are combined by using the HLL_COMBINE aggregate function.

```
SELECT hll_combine(sketch)
FROM (SELECT hll_create_sketch(customer) AS sketch
      FROM Sales
      GROUP BY country) AS hll_subquery
```

```
hll_combine
-----
{"version":1,"logm":15,"sparse":{"indices":[29808639,35021072,47612452],"values":
[1,1,1]}}
(1 row)
```

Example: Return a HyperLogLog sketch from combining multiple sketches

For the following example, suppose that the table `page-users` stores preaggregated sketches for each page that users visited on a given website. Each row in this table contains a HyperLogLog sketch that represents all user IDs that show the visited pages.

```
page_users
-- +-----+-----+-----+
-- | _PARTITIONTIME | page          | sketch |
-- +-----+-----+-----+
-- | 2019-07-28     | homepage     | CHAQkAQYA... |
-- | 2019-07-28     | Product A    | CHAQxPnYB... |
-- +-----+-----+-----+
```

The following example unions the preaggregated multiple sketches and generates a single sketch. This sketch encapsulates the collective cardinality that each sketch encapsulates.

```
SELECT hll_combine(sketch) as sketch
FROM page_users
```

The output looks similar to the following.

```
-- +-----+
-- | sketch |
-- +-----+
-- | CHAQ3sGoCxgCIAuCB4iAIBgTIBgqgIAgAwY.... |
-- +-----+
```

When a new sketch is created, you can use the `HLL_CARDINALITY` function to get the collective distinct values, as shown following.

```
SELECT hll_cardinality(sketch)
FROM (
  SELECT
    hll_combine(sketch) as sketch
  FROM page_users
) AS hll_subquery
```

The output looks similar to the following.

```
-- +-----+
-- | count |
-- +-----+
-- | 54356 |
-- +-----+
```

Example: Generate HyperLogLog sketches over S3 data using external tables

The following examples cache HyperLogLog sketches to avoid directly accessing Amazon S3 for cardinality estimation.

You can preaggregate and cache HyperLogLog sketches in external tables defined to hold Amazon S3 data. By doing this, you can extract cardinality estimates without accessing the underlying base data.

For example, suppose that you have unloaded a set of tab-delimited text files into Amazon S3. You run the following query to define an external table named `sales` in the Amazon Redshift external schema named `spectrum`. The Amazon S3 bucket for this example is in the US East (N. Virginia) AWS Region.

```
create external table spectrum.sales(
  salesid integer,
  listid integer,
  sellerid smallint,
  buyerid smallint,
  eventid integer,
  dateid integer,
  qtysold integer,
  pricepaid decimal(8,2),
  commission decimal(8,2),
  saletime timestamp)
row format delimited
fields terminated by '\t' stored as textfile
location 's3://redshift-downloads/ticket/spectrum/sales/';
```

Suppose that you want to compute the distinct buyers who purchased an item on arbitrary dates. To do so, the following example generates sketches for the buyer IDs for each day of the year and stores the result in the Amazon Redshift table `h11_sales`.

```
CREATE TABLE hll_sales AS
SELECT saletime, hll_create_sketch(buyerid) AS sketch
FROM spectrum.sales
GROUP BY saletime;

SELECT TOP 5 * FROM hll_sales;
```

The output looks similar to the following.

```
-- hll_sales

-- | saletime          | sketch
-- |                  |
-- +-----+
+-----+
-- | 7/22/2008 8:30    | {"version":1,"logm":15,"sparse":{"indices":[9281416],"values":
[1]}}
-- | 2/19/2008 0:38    | {"version":1,"logm":15,"sparse":{"indices":[48735497],"values":
[3]}}
-- | 11/5/2008 4:49    | {"version":1,"logm":15,"sparse":{"indices":[27858661],"values":
[1]}}
-- | 10/27/2008 4:08   | {"version":1,"logm":15,"sparse":{"indices":[65295430],"values":
[2]}}
-- | 2/16/2008 9:37    | {"version":1,"logm":15,"sparse":{"indices":[56869618],"values":
[2]}}
-- +-----+
+-----+
```

The following query shows the estimated number of distinct buyers that purchased an item during the Friday after Thanksgiving in 2008.

```
SELECT hll_cardinality(hll_combine(sketch)) as distinct_buyers
FROM hll_sales
WHERE trunc(saletime) = '2008-11-28';
```

The output looks similar to the following.

```
distinct_buyers
-----
386
```

Suppose that you want the number of distinct users who bought an item on a certain range of dates. An example might be from the Friday after Thanksgiving to the following Monday. To get this, the following query uses the `hll_combine` aggregate function. This function enables you to avoid double-counting buyers who purchased an item on more than one day of the selected range.

```
SELECT hll_cardinality(hll_combine(sketch)) as distinct_buyers
FROM hll_sales
WHERE saletime BETWEEN '2008-11-28' AND '2008-12-01';
```

The output looks similar to the following.

```
distinct_buyers
-----
1166
```

To keep the `hll_sales` table up-to-date, run the following query at the end of each day. Doing this generates an HyperLogLog sketch based on the IDs of buyers that purchased an item today and adds it to the `hll_sales` table.

```
INSERT INTO hll_sales
SELECT saletime, hll_create_sketch(buyerid)
FROM spectrum.sales
WHERE TRUNC(saletime) = to_char(GETDATE(), 'YYYY-MM-DD')
GROUP BY saletime;
```

Cross-database queries

This topic describes *cross-database queries*, which are queries that operate on multiple Amazon Redshift databases within a single Amazon Redshift cluster.

By using cross-database queries in Amazon Redshift, you can query across databases in an Amazon Redshift cluster. With cross-database queries, you can query data from any database in the Amazon Redshift cluster, regardless of which database you are connected to. Cross-database queries eliminate data copies and simplify your data organization to support multiple business groups from the same data warehouse.

With cross-database queries, you can do the following:

- **Query data across databases in your Amazon Redshift cluster.**

Not only can you query from databases that you are connected to, you can also read from any other databases that you have permissions to.

When you query database objects on any other unconnected databases, you have read access only to those database objects. You can use cross-database queries to access data from any of the databases on your Amazon Redshift cluster without having to connect to that specific database. Doing this can help you query and join data that is spread across multiple databases in your Amazon Redshift cluster quickly and easily.

You can also join datasets from multiple databases in a single query and analyze the data using business intelligence (BI) or analytics tools. You can continue to set up granular table-level access controls for users by using standard Amazon Redshift SQL commands. By doing so, you can help ensure that users see only the relevant subsets of the data that they have permissions for.

- **Query objects.**

You can query other database objects using fully qualified object names expressed with the three-part notation. The full path to any database object consists of three components: database name, schema, and name of the object. You can access any object from any other database using the full path notation, *database_name.schema_name.object_name*. To access a particular column, use *database_name.schema_name.object_name.column_name*.

You can also create an alias for a schema in another database using the external schema notation. This external schema references to another database and schema

pair. Query can access the other database object using the external schema notation, *external_schema_name.object_name*.

In the same read-only query, you can query various database objects, such as user tables, regular views, materialized views, and late-binding views from other databases.

- **Manage permissions.**

Users with access privileges for objects in any databases in an Amazon Redshift cluster can query those objects. You grant privileges to users and user groups using the [GRANT](#) command. You can also revoke privileges using the [REVOKE](#) command when a user no longer requires the access to specific database objects.

- **Work with metadata and BI tools.**

You can create an external schema to refer to a schema in another Amazon Redshift database within the same Amazon Redshift cluster. For information, see [CREATE EXTERNAL SCHEMA](#) command.

After external schema references are created, Amazon Redshift shows the tables under the schema of the other database in [SVV_EXTERNAL_TABLES](#) and [SVV_EXTERNAL_COLUMNS](#) for the tools to explore the metadata.

To integrate cross-database query with BI tools, you can use the following system views. These help you view information about the metadata of objects in the connected and other databases on the Amazon Redshift cluster.

Following are system views that show all Amazon Redshift objects and external objects of all databases in your Amazon Redshift cluster:

- [SVV_ALL_COLUMNS](#)
- [SVV_ALL_SCHEMAS](#)
- [SVV_ALL_TABLES](#)

Following are system views that show all Amazon Redshift objects of all databases in your Amazon Redshift cluster:

- [SVV_REDSHIFT_COLUMNS](#)
- [SVV_REDSHIFT_DATABASES](#)
- [SVV_REDSHIFT_FUNCTIONS](#)
- [SVV_REDSHIFT_SCHEMAS](#)

- [SVV_REDSHIFT_TABLES](#)

Topics

- [Considerations](#)
- [Limitations](#)
- [Cross-database query examples](#)
- [Using cross-database queries with the query editor](#)

Considerations

This topic describes usage details for cross-database queries in Amazon Redshift.

When you work with the cross-database query feature in Amazon Redshift, consider the following:

- Amazon Redshift supports cross-database query on the ra3.4xlarge, ra3.16xlarge, and ra3.xlplus node types.
- Amazon Redshift supports joining data from tables or views across one or more databases in the same Amazon Redshift cluster.
- Amazon Redshift Serverless supports the same cross-database capabilities as Amazon Redshift clusters, so you can join data from tables or views across one or more databases in a serverless namespace.
- All queries in a transaction on the connected database read data in the same state of the other database as the data was at the beginning of the transaction. This approach helps to provide query transactional consistency across databases. Amazon Redshift supports transactional consistency for cross-database queries.
- To get metadata across databases, use SVV_ALL* and SVV_REDSHIFT* metadata views. You can't use the three-part notation or external schemas to query cross-database metadata tables or views under information_schema and pg_catalog.

Limitations

This topic describes limitations for cross-database queries in Amazon Redshift.

When you work with the cross-database query feature in Amazon Redshift, be aware of the limitations following:

- When you query database objects on any other unconnected databases, you have read access only to those database objects.
- You can't query views that are created on other databases that refer to objects of yet another database.
- You can only create late-binding and materialized views on objects of other databases in the cluster. You can't create regular views on objects of other databases in the cluster.
- Amazon Redshift doesn't support tables with column-level privileges for cross-database queries.
- Amazon Redshift doesn't support query catalog objects on AWS Glue or federated databases. To query these objects, first create external schemas that refer to those external data sources in each database.
- Running cross-database queries on tables with interleaved sort keys isn't supported.

Cross-database query examples

This topic contains examples for how to use cross-database queries. Cross-database queries are queries that operate on multiple databases within a single Amazon Redshift cluster.

Use the following examples to help learn how to set up a cross-database query that references an Amazon Redshift database.

To start, create databases `db1` and `db2` and users `user1` and `user2` in your Amazon Redshift cluster. For more information, see [CREATE DATABASE](#) and [CREATE USER](#).

```
--As user1 on db1
CREATE DATABASE db1;

CREATE DATABASE db2;

CREATE USER user1 PASSWORD 'Redshift01';

CREATE USER user2 PASSWORD 'Redshift01';
```

As `user1` on `db1`, create a table, grant access privileges to `user2`, and insert values into `table1`. For more information, see [GRANT](#) and [INSERT](#).

```
--As user1 on db1
CREATE TABLE table1 (c1 int, c2 int, c3 int);
```

```
GRANT SELECT ON table1 TO user2;

INSERT INTO table1 VALUES (1,2,3),(4,5,6),(7,8,9);
```

As `user2` on `db2`, run a cross-database query in `db2` using the three-part notation.

```
--As user2 on db2
SELECT * from db1.public.table1 ORDER BY c1;
c1 | c2 | c3
----+-----+----
1  | 2  | 3
4  | 5  | 6
7  | 8  | 9
(3 rows)
```

As `user2` on `db2`, create an external schema and run a cross-database query in `db2` using the external schema notation.

```
--As user2 on db2
CREATE EXTERNAL SCHEMA db1_public_sch
FROM REDSHIFT DATABASE 'db1' SCHEMA 'public';

SELECT * FROM db1_public_sch.table1 ORDER BY c1;

c1 | c2 | c3
----+-----+----
1  | 2  | 3
4  | 5  | 6
7  | 8  | 9
(3 rows)
```

To create different views and grant permissions to those views, as `user1` on `db1`, do the following.

```
--As user1 on db1
CREATE VIEW regular_view AS SELECT c1 FROM table1;

GRANT SELECT ON regular_view TO user2;

CREATE MATERIALIZED VIEW mat_view AS SELECT c2 FROM table1;
```

```
GRANT SELECT ON mat_view TO user2;

CREATE VIEW late_bind_view AS SELECT c3 FROM public.table1 WITH NO SCHEMA BINDING;

GRANT SELECT ON late_bind_view TO user2;
```

As `user2` on `db2`, run the following cross-database query using the three-part notation to view the particular view.

```
--As user2 on db2
SELECT * FROM db1.public.regular_view;
c1
----
1
4
7
(3 rows)

SELECT * FROM db1.public.mat_view;
c2
----
8
5
2
(3 rows)

SELECT * FROM db1.public.late_bind_view;
c3
----
3
6
9
(3 rows)
```

As `user2` on `db2`, run the following cross-database query using the external schema notation to query the late-binding view.

```
--As user2 on db2
SELECT * FROM db1_public_sch.late_bind_view;
c3
```

```

----
3
6
9
(3 rows)

```

As user2 on db2, run the following command using connected tables in a single query.

```

--As user2 on db2
CREATE TABLE table1 (a int, b int, c int);

INSERT INTO table1 VALUES (1,2,3), (4,5,6), (7,8,9);

SELECT a AS col_1, (db1.public.table1.c2 + b) AS sum_col2, (db1.public.table1.c3 + c)
  AS sum_col3 FROM db1.public.table1, table1 WHERE db1.public.table1.c1 = a;
col_1 | sum_col2 | sum_col3
-----+-----+-----
1     | 4        | 6
4     | 10       | 12
7     | 16       | 18
(3 rows)

```

The following example lists all databases on the cluster.

```

select database_name, database_owner, database_type
from svv_redshift_databases
where database_name in ('db1', 'db2');

database_name | database_owner | database_type
-----+-----+-----
db1           |                | 100 | local
db2           |                | 100 | local
(2 rows)

```

The following example lists all Amazon Redshift schemas of all databases on the cluster.

```

select database_name, schema_name, schema_owner, schema_type
from svv_redshift_schemas
where database_name in ('db1', 'db2');

database_name | schema_name | schema_owner | schema_type
-----+-----+-----+-----

```

```

db1      | pg_catalog      |          1 | local
db1      | public          |          1 | local
db1      | information_schema |          1 | local
db2      | pg_catalog      |          1 | local
db2      | public          |          1 | local
db2      | information_schema |          1 | local
(6 rows)

```

The following example lists all Amazon Redshift tables or views of all databases on the cluster.

```

select database_name, schema_name, table_name, table_type
from svv_redshift_tables
where database_name in ('db1', 'db2') and schema_name in ('public');

```

```

database_name | schema_name |      table_name      | table_type
-----+-----+-----+-----
db1           | public     | late_bind_view      | VIEW
db1           | public     | mat_view            | VIEW
db1           | public     | mv_tbl__mat_view__0 | TABLE
db1           | public     | regular_view        | VIEW
db1           | public     | table1              | TABLE
db2           | public     | table2              | TABLE
(6 rows)

```

The following example lists all Amazon Redshift and external schemas of all databases on the cluster.

```

select database_name, schema_name, schema_owner, schema_type
from svv_all_schemas where database_name in ('db1', 'db2') ;

```

```

database_name |      schema_name      | schema_owner | schema_type
-----+-----+-----+-----
db1           | pg_catalog            |          1 | local
db1           | public                |          1 | local
db1           | information_schema    |          1 | local
db2           | pg_catalog            |          1 | local
db2           | public                |          1 | local
db2           | information_schema    |          1 | local
db2           | db1_public_sch       |          1 | external
(7 rows)

```

The following example lists all Amazon Redshift and external tables of all databases on the cluster.

```
select database_name, schema_name, table_name, table_type
from svv_all_tables
where database_name in ('db1', 'db2') and schema_name in ('public');
```

database_name	schema_name	table_name	table_type
db1	public	regular_view	VIEW
db1	public	mv_tbl__mat_view__0	TABLE
db1	public	mat_view	VIEW
db1	public	late_bind_view	VIEW
db1	public	table1	TABLE
db2	public	table2	TABLE

(6 rows)

Using cross-database queries with the query editor

This topic explains how to use cross-database queries with the query editor. Cross-database queries are queries that operate on multiple databases within a single Amazon Redshift cluster.

You can use cross-database queries to access data from any of the databases on your Amazon Redshift cluster without having to connect to that specific database. When you run cross-database queries on any other unconnected databases, you have read access only to those database objects.

You can query other database objects using fully qualified object names expressed with three-part notation. The full path to any database object consists of three components: database name, schema, and name of the object. An example is *database_name.schema_name.object_name*.

To use cross-database queries with the query editor v2

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. Create a cluster to use cross-database queries in Amazon Redshift query editor v2. For more information, see [Creating a cluster](#) in the *Amazon Redshift Management Guide*.
3. Enable access to the query editor with the appropriate permissions. For more information, see [Querying a database using the query editor v2](#) in the *Amazon Redshift Management Guide*.
4. On the navigation menu, choose **Query editor v2**, then connect to a database in your cluster.

When you connect to the query editor v2 for the first time, Amazon Redshift shows the resources for the connected database by default.

5. Choose the other databases that you have access to view database objects for these other databases. To view objects, make sure that you have the appropriate permissions. After you choose a database, Amazon Redshift shows the list of schemas from the database.

Select a schema to see the list of database objects within that schema.

 **Note**

Amazon Redshift doesn't directly support query catalog objects that are part of AWS Glue or federated databases. To query these, first create external schemas that refer to those external data sources in each database.

Amazon Redshift cross-database queries with three-part notation don't support metadata tables under the schemas `information_schema` and `pg_catalog` because these metadata views are specific to a database.

6. (Optional) Filter the list of tables or views for the schema that you selected.

Data sharing in Amazon Redshift

With Amazon Redshift, you can securely share data across Amazon Redshift clusters or with other AWS services. Data sharing lets you share live data, without having to create a copy or move it. Database administrators and data engineers can use data sharing to provide secure, read-only access to data for analytics purposes, while maintaining control over the data. Data analysts, business intelligence professionals, and data scientists can leverage shared data to gain insights without duplicating or moving data. Common use cases include sharing data with partners, enabling cross-functional analysis, and facilitating data democratization within an organization. The following sections cover the details of configuring and managing data sharing in Amazon Redshift.

With Amazon Redshift *data sharing*, you can securely share access to live data across Amazon Redshift clusters, workgroups, AWS accounts, and AWS Regions without manually moving or copying the data. Since the data is live, all users can see the most up-to-date and consistent information in Amazon Redshift as soon as it's updated.

You can share data across provisioned clusters, serverless workgroups, Availability Zones, AWS accounts, and AWS Regions. You can share between cluster types as well as between provisioned clusters and serverless.

You can share database objects for both reads and writes across different Amazon Redshift clusters or Amazon Redshift Serverless workgroups within the same AWS account, or from one AWS account to another. You can write data across regions as well. You can grant permissions such as SELECT, INSERT, and UPDATE for different tables and USAGE and CREATE for different schemas. The data is live and available to all warehouses as soon as a write transaction is committed.

For more information about configuring capabilities for data sharing in the PREVIEW_2023 track, see [Sharing write access to data \(Preview\)](#).

Note

Multi-warehouse writes through data sharing is not currently available on ra3.xlplus clusters. To use this feature, create ra3.4xl clusters, ra3.16xl clusters, or Amazon Redshift Serverless workgroups.

Data sharing overview

With Amazon Redshift, you can securely share live data across Amazon Redshift clusters, simplifying data sharing workflows and reducing the need for complex extract, transform, and load (ETL) processes. Data sharing lets you share live data across Amazon Redshift clusters, enabling real-time access to the latest data without the need for copying or replicating the data. Database administrators, data analysts, and data engineers might be interested in this feature to streamline data access and collaboration within or across teams and organizations. It enables use cases such as sharing live production data with analytics teams, providing real-time reporting across distributed data sources, and simplifying data governance by centrally controlling access permissions. The following sections will cover the details of configuring and managing data sharing in Amazon Redshift.

With *data sharing*, you can securely and easily share live data across Amazon Redshift clusters.

For information about how to get started working with data sharing and manage datashares using the AWS Management Console, see [Managing data sharing tasks](#).

Data sharing use cases for Amazon Redshift

Amazon Redshift data sharing is especially useful for these use cases:

- **Supporting different kinds of business-critical workloads** – Use a central extract, transform, and load (ETL) cluster that shares data with multiple business intelligence (BI) or analytic clusters. This approach provides read workload isolation and chargeback for individual workloads. You can size and scale your individual workload compute according to the workload-specific requirements of price and performance.
- **Enabling cross-group collaboration** – Enable seamless collaboration across teams and business groups for broader analytics, data science, and cross-product impact analysis.
- **Delivering data as a service** – Share data as a service across your organization.
- **Sharing data between environments** – Share data among development, test, and production environments. You can improve team agility by sharing data at different levels of granularity.
- **Licensing access to data in Amazon Redshift** – List Amazon Redshift data sets in the AWS Data Exchange catalog that customers can find, subscribe to, and query in minutes.

Data sharing write-access use cases (preview)

Datasharing for writes has several important use cases:

- **Update business source data on the producer** – You can share data as a service across your organization, but then consumers can also perform actions on the source data. For instance, they can communicate back up-to-date values or acknowledge receipt of data. These are just a couple possible business use cases.
- **Insert additional records on the producer** – Consumers can add records to the original source data. These can be marked as from the consumer, if needed.

For information specifically regarding how to perform write operations on a datashare, see [Sharing write access to data \(Preview\)](#).

Data sharing at different levels in Amazon Redshift

With Amazon Redshift, you can share data at different levels. These levels include databases, schemas, tables, views (including regular, late-binding, and materialized views), and SQL user-defined functions (UDFs). You can create multiple datashares for a given database. A datashare can contain objects from multiple schemas in the database on which sharing is created.

By having this flexibility in sharing data, you get fine-grained access control. You can tailor this control for different users and businesses that need access to Amazon Redshift data.

Consistency management for data sharing in Amazon Redshift

Amazon Redshift provides transactional consistency on all producer and consumer clusters and shares up-to-date and consistent views of the data with all consumers.

You can continuously update data on the producer cluster. All queries on a consumer cluster within a transaction read the same state of the shared data. Amazon Redshift doesn't consider the data that was changed by another transaction on the producer cluster that was committed after the beginning of the transaction on the consumer cluster. After the data change is committed on the producer cluster, new transactions on the consumer cluster can immediately query the updated data.

The strong consistency removes the risks of lower-fidelity business reports that might contain invalid results during sharing of data. This factor is especially important for financial analysis

or where the results might be used to prepare datasets that are used to train machine learning models.

Considerations when using data sharing in Amazon Redshift

Following are considerations for working with Amazon Redshift data sharing. For information on data sharing limitations, see [Limitations for data sharing](#).

- Cross-region data sharing includes additional cross-region data-transfer charges. These data-transfer charges don't apply within the same region, only across regions. For more information, see [Managing cost control for cross-Region data sharing](#).
- When you read data from a datashare, you remain connected to your local cluster database. For more information about setting up and reading from a database created from a datashare, see [Querying datashare objects](#).
- The consumer is charged for all compute and cross-region data transfer fees required to query the producer's data. The producer is charged for the underlying storage of data in their provisioned cluster or serverless namespace.
- The performance of the queries on shared data depends on the compute capacity of the consumer clusters.

Cluster encryption management for data sharing

To share data across AWS account, both the producer and consumer clusters must be encrypted.

In Amazon Redshift, you can turn on database encryption for your clusters to help protect data at rest. When you turn on encryption for a cluster, the data blocks and system metadata are encrypted for the cluster and its snapshots. You can turn on encryption when you launch your cluster, or you can modify an unencrypted cluster to use AWS Key Management Service (AWS KMS) encryption. For more information about Amazon Redshift database encryption, see [Amazon Redshift database encryption](#) in the *Amazon Redshift Management Guide*.

To protect data in transit, all data is encrypted in transit through the encryption schema of the producer cluster. The consumer cluster adopts this encryption schema when data is loaded. The consumer cluster then operates as a normal encrypted cluster. Communications between the producer and consumer are also encrypted using a shared key schema. For more information about encryption in transit, [Encryption in transit](#).

Limitations for data sharing

The following are limitations when working with datashares in Amazon Redshift:

- Data sharing is supported for all provisioned ra3 cluster types (ra3.16xlarge, ra3.4xlarge, and ra3.xlplus) and Amazon Redshift Serverless. It isn't supported for other cluster types.
- For cross-account and cross-Region data sharing, both the producer and consumer clusters and serverless namespaces must be encrypted. This is for security purposes. However, they don't need to share the same encryption key.
- You can only share SQL UDFs through datashares. Python and Lambda UDFs aren't supported.
- If the producer database has specific collation, use the same collation settings for the consumer database.
- Amazon Redshift doesn't support adding external schemas, tables, or late-binding views on external tables to datashares.
- Amazon Redshift doesn't support nested SQL user-defined functions on producer clusters.
- Amazon Redshift doesn't support sharing tables with interleaved sort keys and views that refer to tables with interleaved sort keys.
- Consumers can't add datashare objects to another datashare. Additionally, consumers can't add views referencing datashare objects to another datashare.
- Amazon Redshift doesn't support accessing a datashare object which had a concurrent DDL occur between the Prepare and Execute of the access.
- Amazon Redshift doesn't support sharing stored procedures through datashares.
- Amazon Redshift doesn't support sharing metadata system views and system tables.

Regions where data sharing is available

The following table lists availability for data-sharing capabilities.

Region	Same-region data sharing	Cross-region data sharing	AWS Lake Formation governed data shares
US East (N. Virginia) (us-east-1)	Yes	Yes	Yes

Region	Same-region data sharing	Cross-region data sharing	AWS Lake Formation governed data shares
US East (Ohio) (us-east-2)	Yes	Yes	Yes
US West (N. California) (us-west-1)	Yes	Yes	Yes
US West (Oregon) (us-west-2)	Yes	Yes	Yes
Asia Pacific (Hong Kong) (ap-east-1)	Yes	No	No
Asia Pacific (Mumbai) (ap-south-1)	Yes	Yes	Yes
Asia Pacific (Hyderabad) (ap-south-2)	Yes	No	No
Asia Pacific (Tokyo) (ap-northeast-1)	Yes	Yes	Yes
Asia Pacific (Singapore) (ap-southeast-1)	Yes	Yes	Yes
Asia Pacific (Sydney) (ap-southeast-2)	Yes	Yes	Yes
Asia Pacific (Jakarta); (ap-southeast-3)	Yes	No	No
Asia Pacific (Melbourne) (ap-southeast-4)	Yes	No	No

Region	Same-region data sharing	Cross-region data sharing	AWS Lake Formation governed data shares
Asia Pacific (Seoul) (ap-northeast-2)	Yes	Yes	Yes
Asia Pacific (Osaka) (ap-northeast-3)	Yes	No	No
China (Beijing) (cn-north-1)	Yes	No	No
Africa (Cape Town) (af-south-1)	Yes	Yes	No
Canada West (Calgary) (ca-west-1)	Yes	No	No
Canada (Central) (ca-central-1)	Yes	Yes	Yes
Europe (Frankfurt) (eu-central-1)	Yes	Yes	Yes
Europe (Zurich) (eu-central-2)	Yes	No	No
Europe (Ireland) (eu-west-1)	Yes	Yes	Yes
Europe (London) (eu-west-2)	Yes	Yes	Yes
Europe (Paris) (eu-west-3)	Yes	Yes	Yes
Europe (Milan) (eu-south-1)	Yes	No	No

Region	Same-region data sharing	Cross-region data sharing	AWS Lake Formation governed data shares
Europe (Spain) (eu-south-2)	Yes	No	No
Europe (Stockholm) (eu-north-1)	Yes	Yes	Yes
Middle East (UAE) (me-central-1)	Yes	No	No
Middle East (Bahrain) (me-south-1)	Yes	No	No
Israel (Tel Aviv) (il-central-1)	Yes	No	No
South America (São Paulo) (sa-east-1)	Yes	Yes	Yes
AWS GovCloud (US-East) (us-gov-east-1)	Yes	No	Yes
AWS GovCloud (US-West) (us-gov-west-1)	Yes	No	Yes

Regional availability for multi-warehouse writes for data sharing

In the PREVIEW_2023 track, data sharing has the capability for write operations and more granular sharing capabilities. For more information about how to configure these, see [Sharing write access to data \(Preview\)](#). For information about regions where preview capabilities are available, see [Regions where data sharing is available \(preview\)](#).

Datashares for Amazon Redshift data sharing

A *datashare* is the unit of sharing data in Amazon Redshift. Use datashares to share data in the same AWS account or different AWS accounts. Also, share data for read purposes across different Amazon Redshift clusters.

Each datashare is associated with a specific database in your Amazon Redshift cluster.

A producer cluster administrator can create datashares and add datashare objects to share data with other clusters, referred to as *outbound* shares. A consumer cluster administrator can receive datashares from other clusters, referred to as *inbound* shares. For details on producers and consumers, see [Datashare producers and consumers](#).

Datashare objects are objects from specific databases on a cluster that producer cluster administrators can add to datashares to be shared with data consumers. Datashare objects are read-only for data consumers. Examples of datashare objects are tables, views, and user-defined functions. You can add datashare objects to datashares while creating datashares or editing a datashare at any time.

Data sharing continues to work when clusters are resized or when the producer cluster is paused.

There are different types of datashares.

Topics

- [Standard datashares](#)
- [AWS Data Exchange datashares](#)
- [AWS Lake Formation-managed datashares](#)
- [Datashare producers and consumers](#)
- [Datashares for Amazon Redshift details](#)
- [Querying datashares](#)

Standard datashares

With standard datashares, you can share data across provisioned clusters, serverless workgroups, Availability Zones, AWS accounts, and AWS Regions. You can share between cluster types as well as between provisioned clusters and Amazon Redshift Serverless.

To share data, note the following provisioned cluster, serverless namespace, and AWS account identifiers:

- Provisioned cluster namespaces are identifiers that identify Amazon Redshift provisioned clusters. A namespace globally unique identifier (GUID) is automatically created during provisioned cluster creation and attached to the cluster. A namespace Amazon Resource Name (ARN) is in the `arn:{partition}:redshift:{region}:{account-id}:namespace:{namespace-guid}` format. You can see the namespace of a provisioned cluster on the cluster details page on the Amazon Redshift console.

In the data sharing workflow, the namespace GUID value and the cluster namespace ARN are used to share data with clusters in the AWS account. You can also find the namespace for the current cluster by using the `current_namespace` function.

- Serverless namespaces are identifiers that identify Amazon Redshift Serverless. A namespace globally unique identifier (GUID) is automatically created during Amazon Redshift Serverless creation and attached to the instance. A serverless namespace ARN is in the `arn:{partition}:redshift-serverless:{region}:{account-id}:namespace/{namespace-guid}` format.
- AWS accounts can be consumers for datashares and are each represented by a 12-digit AWS account ID.

For *standard datashares*, consider the following:

- When a producer cluster is deleted, Amazon Redshift deletes the datashares created by the producer cluster. When a producer cluster is backed up and restored, the created datashares still persist on the restored cluster. However, datashare permissions granted to other clusters are no longer valid on the restored cluster. Re-grant usage permissions of datashares to desired consumer clusters. The consumer database on the consumer cluster points to the datashare from the original cluster where the snapshot is taken. To query the shared data from the restored cluster, the consumer cluster administrator creates a different database. Or the administrator can drop and recreate an existing consumer database to use the datashare from the newly restored cluster.
- When a consumer cluster is deleted and restored from a snapshot, the previous access shared to this cluster would no longer be valid and visible. If access to datashares is still required on the restored consumer cluster, the producer cluster administrator must grant usage of datashares to the restored consumer cluster again. The consumer cluster administrator must drop any stale consumer databases created from the inactive datashares. Then the administrator must recreate the consumer database from the datashare, after the producer re-granted the permissions. As

the cluster namespace GUID is different on a restored cluster from the original cluster, re-grant datashare permissions when the consumer or producer cluster is restored from backup.

AWS Data Exchange datashares

You can use AWS Data Exchange datashares to manage billing for Amazon Redshift data sharing.

An AWS Data Exchange datashare is a unit of licensing for sharing your data through AWS Data Exchange. AWS manages all billing and payments associated with subscriptions to AWS Data Exchange and use of Amazon Redshift data sharing. Approved data providers can add AWS Data Exchange datashares to AWS Data Exchange products. When customers subscribe to a product with AWS Data Exchange datashares, they get access to the datashares in the product.

AWS Data Exchange for Amazon Redshift makes it convenient to license access to your Amazon Redshift data through AWS Data Exchange. When a customer subscribes to a product with AWS Data Exchange datashares, AWS Data Exchange automatically adds the customer as a data consumer on all AWS Data Exchange datashares included with the product. Invoices are automatically generated, and payments are centrally collected and automatically disbursed through AWS Marketplace Entitlement Service.

Providers can license data in Amazon Redshift at a granular level, such as schemas, tables, views, and user-defined functions. You can use the same AWS Data Exchange datashare across multiple AWS Data Exchange products. Any objects added to the AWS Data Exchange datashare is available to consumers. Producers can view all AWS Data Exchange datashares managed by AWS Data Exchange on their behalf using Amazon Redshift API operations, SQL commands, and the Amazon Redshift console. Customers who subscribe to a product AWS Data Exchange datashares have read-only access to the objects in the datashares.

Customers who want to consume third-party producer data can browse the AWS Data Exchange catalog to discover and subscribe to datasets in Amazon Redshift. After their AWS Data Exchange subscription is active, they can create a database from the datashare in their cluster and query the data in Amazon Redshift.

How AWS Data Exchange datashares work

Managing AWS Data Exchange datashares as a producer administrator

If you are a data producer (also known as a provider on AWS Data Exchange), you can create AWS Data Exchange datashares that connect to your Amazon Redshift databases. To add AWS Data

Exchange datashares to products on AWS Data Exchange, you must be a registered AWS Data Exchange provider.

For more information on how to get started with AWS Data Exchange datashares, see [Sharing licensed Amazon Redshift data on AWS Data Exchange](#).

Using AWS Data Exchange datashares as a consumer with an active AWS Data Exchange subscription

If you are a consumer with an active AWS Data Exchange subscription (also known as a subscriber on AWS Data Exchange), you can browse the AWS Data Exchange catalog on the AWS Data Exchange console to discover products containing AWS Data Exchange datashares.

After you subscribe to a product that contains AWS Data Exchange datashares, create a database from the datashare within your cluster. You can then query the data in Amazon Redshift directly without extracting, transforming, and loading the data.

For more information on how to get started with AWS Data Exchange datashares, see [Sharing licensed Amazon Redshift data on AWS Data Exchange](#).

For *AWS Data Exchange datashares*, consider the following:

- When a producer cluster is deleted, Amazon Redshift deletes the datashares created by the producer cluster. When a producer cluster is backed up and restored, the created datashares still persist on the restored cluster. For data subscribers to be able to continue accessing the data, create the AWS Data Exchange datashares again and publish them to the product's data sets. The consumer database on the consumer cluster points to the datashare from the original cluster where the snapshot is taken. To query the shared data from the restored cluster, the consumer cluster administrator creates a different database, or drops and recreates an existing consumer database to use the newly created AWS Data Exchange datashare from the newly restored cluster.
- When a consumer cluster is deleted and restored from a snapshot, the previous access shared to this cluster remains valid and visible. Consumer cluster administrator must drop any stale consumer databases created from the inactive datashares and recreate the consumer database from the datashare after the producer re-grants the permissions. As the cluster namespace GUID is different on a restored cluster from the original cluster, re-grant datashare permissions when the producer cluster is restored from backup.

- We recommend that you don't delete your cluster if you have any AWS Data Exchange datashares. Performing this type of alteration can breach data product terms in AWS Data Exchange.

Considerations when using AWS Data Exchange for Amazon Redshift

When using AWS Data Exchange for Amazon Redshift, consider the following:

- Both producers and consumers must use the RA3 instance types to use Amazon Redshift datashares. Producers must use the RA3 instance types with the latest Amazon Redshift cluster version.
- Both the producer and consumer clusters must be encrypted.
- You must be registered as an AWS Data Exchange provider to list products on AWS Data Exchange, including products that contain AWS Data Exchange datashares. For more information, see [Getting started as a provider](#).
- You don't need to be a registered AWS Data Exchange provider to find, subscribe to, and query Amazon Redshift data through AWS Data Exchange.
- To control access to your data, create AWS Data Exchange datashares with the publicly accessible setting turned on. To alter an AWS Data Exchange datashare to turn off the publicly accessible setting, set the session variable to allow `ALTER DATASHARE SET PUBLICACCESSIBLE FALSE`. For more information, see [ALTER DATASHARE usage notes](#).
- Producers can't manually add or remove consumers from AWS Data Exchange datashares because access to the datashares is granted based on having an active subscription to an AWS Data Exchange product that contains the AWS Data Exchange datashare.
- Producers can't view the SQL queries that consumers run. They can only view metadata, such as the number of queries or the objects consumers query, through Amazon Redshift tables that only the producer can access. For more information, see [Monitoring and auditing data sharing in Amazon Redshift](#).
- We recommend that you make your datashares publicly accessible. If you don't, subscribers on AWS Data Exchange with publicly accessible consumer clusters won't be able to use your datashare.
- We recommend that you don't delete an AWS Data Exchange datashare shared to other AWS accounts using the `DROP DATASHARE` statement. If you do, the AWS accounts that have access to the datashare will lose access. This action is irreversible. Performing this type of alteration can

breach data product terms in AWS Data Exchange. If you want to delete an AWS Data Exchange datashare, see [DROP DATASHARE usage notes](#).

- For cross-Region data sharing, you can create AWS Data Exchange datashares to share licensed data.
- When consuming data from a different Region, the consumer pays the Cross-Region data transfer fee from the producer Region to the consumer Region.

AWS Lake Formation-managed datashares

With Amazon Redshift, you can access and share live data across AWS accounts and Amazon Redshift clusters through AWS Lake Formation-managed datashares. AWS Lake Formation datashares enable data providers to securely share live data from their Amazon S3 data lake with any consumer, including other AWS accounts and Amazon Redshift clusters.

Using AWS Lake Formation, you can centrally define and enforce database, table, column, and row-level access permissions of Amazon Redshift datashares and restrict user access to objects within a datashare. By sharing data through Lake Formation, you can define permissions in Lake Formation and apply those permissions to any datashare and its objects. For example, if you have a table containing employee information, you can use Lake Formation's column-level filters to prevent employees who don't work in the HR department from seeing personally identifiable information (PII), such as a social security number. For more information about data filters, see [Data filtering and cell-level security in Lake Formation](#) in the *AWS Lake Formation Developer Guide*.

You can also use tags in Lake Formation to configure permissions on Lake Formation resources. For more information, see [Lake Formation Tag-based access control](#).

Amazon Redshift currently supports data sharing via Lake Formation when sharing within the same account or across accounts. Cross-Region sharing is currently not supported.

The following is a high-level overview of how to use Lake Formation to control datashare permissions:

1. In Amazon Redshift, the producer cluster or workgroup administrator creates a datashare on the producer cluster or workgroup and grants usage to a Lake Formation account.
2. The producer cluster or workgroup administrator authorizes the Lake Formation account to access the datashare.
3. The Lake Formation administrator discovers and registers the datashares. They must also discover the AWS Glue ARNs they have access to and associate the datashares with an AWS

Glue Data Catalog ARN. If you're using the AWS CLI you can discover and accept datashares with the Redshift CLI operations `describe-data-shares` and `associate-data-share-consumer`. To register a datashare, use the Lake Formation CLI operation `register-resource`.

4. The Lake Formation administrator creates a federated database in the AWS Glue Data Catalog, and configures Lake Formation permissions to control user access to objects within the datashare. For more information about federated databases in AWS Glue, see [Managing permissions for data in an Amazon Redshift datashare](#).
5. The Lake Formation administrator discovers the AWS Glue databases they have access to and associates the datashare with an AWS Glue Data Catalog ARN.
6. The Redshift administrator discovers the AWS Glue database ARNs they have access to, creates an external database in the Amazon Redshift consumer cluster using a AWS Glue database ARN, and grants usage to [database users authenticated with IAM credentials](#) to start querying the Amazon Redshift database.
7. Database users can use the views `SVV_EXTERNAL_TABLES` and `SVV_EXTERNAL_COLUMNS` to find all of the tables or columns within the AWS Glue database that they have access to, and then they can query the AWS Glue database's tables.
8. When the producer cluster or workgroup administrator decides to no longer share the data with the consumer cluster, the producer cluster administrator can revoke usage, deauthorize, or delete the datashare from Redshift. The associated permissions and objects in Lake Formation are not automatically deleted.

For more information about sharing a datashare with AWS Lake Formation as a producer cluster or workgroup administrator, see [Working with Lake Formation-managed datashares as a producer](#). To consume the shared data from the producer cluster or workgroup, see [Working with Lake Formation-managed datashares as a consumer](#).

Considerations and limitations when using AWS Lake Formation with Amazon Redshift

The following are considerations and limitations for sharing Amazon Redshift data via Lake Formation. For information on data sharing considerations and limitations, see [Considerations when using data sharing in Amazon Redshift](#). For information about Lake Formation limitations, see [Notes on working with Amazon Redshift datashares in Lake Formation](#).

- Sharing a datashare to Lake Formation across Regions is currently unsupported.

- If column-level filters are defined for a user on a shared relation, performing a `SELECT *` operation returns only the columns the user has access to.
- Cell-level filters from Lake Formation are unsupported.
- If you created and shared a view and its tables to Lake Formation, you can configure filters to manage access of the tables, Amazon Redshift enforces Lake Formation defined policies when consumer cluster users access shared objects. When a user accesses a view shared with Lake Formation, Redshift enforces only the Lake Formation policies defined on the view and not the tables contained within the view. However, when users directly access the table, Redshift enforces the defined Lake Formation policies on the table.
- You can't create materialized views on the consumer based on a shared table if the table has Lake Formation filters configured.
- The Lake Formation administrator must have [data lake administrator](#) permissions and the [required permissions to accept a datashare](#).
- The producer consumer cluster must be an RA3 cluster with the latest Amazon Redshift cluster version or a serverless workgroup to share datashares via Lake Formation.
- Both the producer and consumer clusters must be encrypted.
- Redshift row-level and column-level access control policies implemented in the producer cluster or workgroup are ignored when the datashare is shared to Lake Formation. The Lake Formation administrator must configure these policies in Lake Formation. The producer cluster or workgroup administrator can turn off RLS for a table by using the [ALTER TABLE](#) command.
- Sharing datashares via Lake Formation is only available to users who have access to both Redshift and Lake Formation.

Datashare producers and consumers

Data producers (also known as data sharing producers or datashare producers) are clusters that you want to share data from. Producer cluster administrators and database owners can create datashares using the `CREATE DATASHARE` command. You can add objects such as schemas, tables, views, and SQL user-defined functions (UDFs) from a database that you want the producer cluster to share with consumer clusters.

Data producers (also known as providers on AWS Data Exchange) for AWS Data Exchange datashares can license data through AWS Data Exchange. Approved providers can add AWS Data Exchange datashares to AWS Data Exchange products.

When a customer subscribes to a product with AWS Data Exchange datashares, AWS Data Exchange automatically adds the customer as a data consumer on all AWS Data Exchange datashares included with the product. AWS Data Exchange also removes all customers from AWS Data Exchange datashares when their subscription ends. AWS Data Exchange also automatically manages billing, invoicing, payment collection, and payment distribution for paid products with AWS Data Exchange datashares. For more information, see [AWS Data Exchange datashares](#). To register as an AWS Data Exchange data provider, see [Getting started as a provider](#).

Data consumers (also known as data sharing consumers or datashare consumers) are clusters that receive datashares from producer clusters.

Amazon Redshift clusters that share data can be in the same or different AWS accounts or different AWS Regions, so you can share data across organizations and collaborate with other parties. Consumer cluster administrators receive the datashares that they are granted usage for and review the contents of each datashare. To consume shared data, the consumer cluster administrator creates an Amazon Redshift database from the datashare. The administrator then assigns permissions for the database to users and roles in the consumer cluster. After permissions are granted, users and roles can list the shared objects as part of the standard metadata queries, along with the local data on the consumer cluster. They can start querying immediately.

If you are a *consumer with an active AWS Data Exchange subscription* (also known as subscribers on AWS Data Exchange), you can find, subscribe to, and query granular, up-to-date data in Amazon Redshift without the need to extract, transform, and load the data. For more information, see [AWS Data Exchange datashares](#).

Datashares for Amazon Redshift details

With Amazon Redshift, you can securely share live data across Amazon Redshift clusters without having to copy or transfer data. Datashares for Amazon Redshift enables you to share live query results, including updates to the source data, with any Amazon Redshift cluster in the same or different AWS accounts and AWS Regions.

Topics

Datashare status values in Amazon Redshift

This topic describes the possible statuses that datashares can have in Amazon Redshift.

With cross-account datashares, there are different statuses of datashares that require your actions. Your datashare can have a status of active, action required, or inactive.

Following describes each datashare status and its required action:

- When a producer cluster administrator creates a datashare, the datashare status on the producer cluster is **Pending authorization**. The producer cluster administrator can authorize data consumers to access the datashare. There isn't any action for the consumer cluster administrator.
- When a producer cluster administrator authorizes the datashare, the datashare status becomes **Authorized** on the producer cluster. There isn't any action for the producer cluster administrator. When there is at least one association with a data consumer for the datashare, the datashare status changes from **Authorized** to **Active**.

The datashare share status then becomes **Available (Action required on the Amazon Redshift console)** on the consumer cluster. The consumer cluster administrator can associate the datashare with data consumers or reject the datashare. The consumer cluster administrator can also use the AWS CLI command `describeDatashareforConsumer` to view the status of datashares. Or the administrator can use the CLI command `describeDatashare` and provide the datashare Amazon Resource Name (ARN) to view the status of the datashare.

- When the consumer cluster administrator associates a datashare with data consumers, the datashare status becomes **Active** on the producer cluster. When there is at least one association with a data consumer for the datashare, the datashare status changes from **Authorized** to **Active**. There isn't any action required for the producer cluster administrator.

The datashare status becomes **Active** on the consumer cluster. There isn't any action required for the consumer cluster administrator.

- When the consumer cluster administrator removes a consumer association from a datashare, the datashare status becomes either **Active** or **Authorized**. It becomes **Active** when there is at least one association exists for the datashare with another data consumer. It becomes **Authorized** when there isn't any consumer association with the datashare on the producer cluster. There isn't any action for the producer cluster administrator.

The datashare status becomes **Action required** on the consumer cluster if all associations are removed. The consumer cluster administrator can reassociate a datashare with data consumers when the datashare is available to the consumers.

- When a consumer cluster administrator declines a datashare, the datashare status on the producer cluster becomes **Action required** and **Declined** on the consumer cluster. The producer cluster administrator can reauthorize the datashare. There isn't any action for the consumer cluster administrator.
- When the producer cluster administrator removes authorization from a datashare, the datashare's status becomes **Action required** on the producer cluster. The producer cluster administrator can choose to reauthorize the datashare, if necessary. There isn't any action required for the consumer cluster administrator.

Data sharing within and between clusters

You only need datashares when you are sharing data between different Amazon Redshift provisioned clusters or serverless workgroups. Within the same cluster, you can query another database using simple three-part notation `database . schema . table` as long as you have the required permissions on the objects in the other database.

Managing permissions for datashares in Amazon Redshift

As a producer cluster administrator, you retain control for the datasets you are sharing. You can add new objects to or remove them from the datashare. You can also grant or revoke access to datashares as a whole for the consumer clusters, AWS accounts, or AWS Regions. When permissions are revoked, consumer clusters immediately lose access to the shared objects and stop seeing them in the list of INBOUND datashares in `SVV_DATASHARES`.

The following example creates the datashare `salesshare`, adds the schema `public`, and adds the table `public.tickit_sales_redshift` to `salesshare`. It also grants usage permissions on `salesshare` to the specified cluster namespace.

```
CREATE DATASHARE salesshare;  
  
ALTER DATASHARE salesshare ADD SCHEMA public;  
  
ALTER DATASHARE salesshare ADD TABLE public.tickit_sales_redshift;
```

```
GRANT USAGE ON DATASHARE salesshare TO NAMESPACE
'13b8833d-17c6-4f16-8fe4-1a018f5ed00d';
```

For CREATE DATASHARE, superusers and database owners can create datashares. For more information, see [CREATE DATASHARE](#). For ALTER DATASHARE, the owner of the datashare with the required permissions on the datashare objects to be added or removed can alter the datashare. For information, see [ALTER DATASHARE](#).

As a producer administrator, when you drop a datashare, it stops being listed on consumer clusters. The databases and schema references created on the consumer cluster from the dropped datashare continue to exist with no objects in them. The consumer cluster administrator must delete these databases manually.

On the consumer side, a consumer cluster administrator can determine which users and roles should get access to the shared data by creating a database from the datashare. Depending on the options you choose when creating the database, you can control access to it as follows. For more information about creating a database from a datashare, see [CREATE DATABASE](#).

For more information about setting up a datashare and reading data from a consumer, see [Sharing read access to data within an AWS account](#).

Creating the database without the WITH PERMISSIONS clause

An administrator can control access at the database or schema level. To control access at the schema level, the administrator must create an external schema from the Amazon Redshift database created from the datashare.

The following example grants permissions to access a shared table at the database level and schema level.

```
GRANT USAGE ON DATABASE sales_db TO Bob;

CREATE EXTERNAL SCHEMA sales_schema FROM REDSHIFT DATABASE sales_db SCHEMA 'public';

GRANT USAGE ON SCHEMA sales_schema TO ROLE Analyst_role;
```

To further restrict access, you can create views on top of shared objects, exposing only the necessary data. You can then use these views to give access to the users and roles.

Once the users are granted access to the database or schema, they will have access to all shared objects in that database or schema.

Creating the database with the WITH PERMISSIONS clause

After granting usage rights on the database or schema, an administrator can further control access using the same permission granting process as they would on a local database or schema. Without individual object permissions, users can't access any objects in the datashared database or schema even after being granted the USAGE permission.

The following example grants permissions to access a shared table at the database level.

```
GRANT USAGE ON DATABASE sales_db TO Bob;  
GRANT USAGE FOR SCHEMAS IN DATABASE sales_db TO Bob;  
GRANT SELECT ON sales_db.public.tickit_sales_redshift TO Bob;
```

After being granted access to the database or schema, users still need to be given the relevant permissions for any objects in the database or schema that you want them to access.

Granular sharing using WITH PERMISSIONS

Enabling clusters or Serverless workgroups to query the datashare

This step assumes the datashare is originating from another cluster or Amazon Redshift Serverless namespace in your account, or it is coming from another account and has been associated with the namespace you are using.

1. The consumer database administrator can create a database from the datashare.

```
CREATE DATABASE my_ds_db [WITH PERMISSIONS] FROM DATASHARE my_datashare OF  
  NAMESPACE 'abc123def';
```

If you create a database WITH PERMISSIONS you can grant granular permissions on datashare objects to different users and roles. Without this, all users and roles granted USAGE permission on the datashare database are granted all permissions on all objects within the datashare database.

2. The following shows how to grant permissions to a Redshift database user or role. You must be connected to a local database to run these statements. You cannot run these statements if you execute a USE command on the datashare database before running the grant statements.

```
GRANT USAGE ON DATABASE my_ds_db TO ROLE data_eng;  
GRANT CREATE, USAGE ON SCHEMA my_ds_db.my_shared_schema TO ROLE data_eng;  
GRANT ALL ON ALL TABLES IN SCHEMA my_ds_db.my_shared_schema TO ROLE data_eng;
```

```
GRANT USAGE ON DATABASE my_ds_db TO bi_user;
GRANT USAGE ON SCHEMA my_ds_db.my_shared_schema TO bi_user;
GRANT SELECT ON my_ds_db.my_shared_schema.table1 TO bi_user;
```

Working with views in Amazon Redshift data sharing

A producer cluster can share regular, late-binding, and materialized views. When sharing regular or late-binding views, you don't have to share the base tables. The following table shows how views are supported with data sharing.

View name	Can this view be added to a datashare ?	Can a consumer create this view on datashare objects across clusters?
Regular view	Yes	No
Late-binding view	Yes	Yes
Materialized view	Yes	Yes, but only with a complete refresh

The following query shows the output of a regular view that is supported with data sharing. For information about regular view definition, see [CREATE VIEW](#).

```
SELECT * FROM tickit_db.public.myevent_regular_vw
ORDER BY eventid LIMIT 5;
```

```
eventid | eventname
-----+-----
    3835 | LeAnn Rimes
    3967 | LeAnn Rimes
    4856 | LeAnn Rimes
    4948 | LeAnn Rimes
    5131 | LeAnn Rimes
```

The following query shows the output of a late-binding view that is supported with data sharing. For information about late-binding view definition, see [CREATE VIEW](#).

```
SELECT * FROM tickit_db.public.event_lbv
ORDER BY eventid LIMIT 5;
```

eventid	venueid	catid	dateid	eventname	starttime
1	305	8	1851	Gotterdammerung	2008-01-25 14:30:00
2	306	8	2114	Boris Godunov	2008-10-15 20:00:00
3	302	8	1935	Salome	2008-04-19 14:30:00
4	309	8	2090	La Cenerentola (Cinderella)	2008-09-21 14:30:00
5	302	8	1982	Il Trovatore	2008-06-05 19:00:00

The following query shows the output of a materialized view that is supported with data sharing. For information about materialized view definition, see [CREATE MATERIALIZED VIEW](#).

```
SELECT * FROM tickit_db.public.tickets_mv;
```

catgroup	qtysold
Concerts	195444
Shows	149905

You can maintain common tables across all tenants in a producer cluster. You can also share subsets of data filtered by dimension columns, such as `tenant_id` (`account_id` or `namespace_id`), to consumer clusters. To do this, you can define a view on the base table with a filter on these ID columns, for example `current_aws_account = tenant_id`. On the consumer side, when you query the view, you see only the rows that qualify for your account. To do this, you can use the Amazon Redshift context functions `current_aws_account` and `current_namespace`.

The following query returns the account ID in which the current Amazon Redshift cluster resides. You can run this query if you are connected to Amazon Redshift.

```
select current_user, current_aws_account;

current_user | current_aws_account
```

```

-----+-----
dwuser      |      111111111111
(1row)

```

The following query returns the namespace of the current Amazon Redshift cluster. You can run this query if you are connected to the database.

```

select current_user, current_namespace;

current_user | current_namespace
-----+-----
dwuser      | 86b5169f-01dc-4a6f-9fbb-e2e24359e9a8
(1 row)

```

Incremental refresh for materialized views in a datashare

Amazon Redshift supports incremental refresh for materialized views in a consumer datashare when the base tables are shared. Incremental refresh is an operation where Amazon Redshift identifies changes in the base table or tables that happened after the previous refresh and updates only the corresponding records in the materialized view. For more information about this behavior, see [CREATE MATERIALIZED VIEW](#).

Managing access to data sharing API operations with IAM policies

To control the access to the data sharing API operations, use IAM action-based policies. For information about how to manage IAM policies, see [Managing IAM policies](#) in the *IAM User Guide*.

For information on the permissions required to use the data sharing API operations, see [Permissions required to use the data sharing API operations](#) in the *Amazon Redshift Management Guide*.

To make cross-account data sharing more secure, you can use a conditional key `ConsumerIdentifier` for the `AuthorizeDataShare` and `DeauthorizeDataShare` API operations. By doing this, you can explicitly control which AWS accounts can make calls to the two API operations.

You can deny authorizing or deauthorizing data sharing for any consumer that isn't your own account. To do so, specify the AWS account number in the IAM policy.

```
{
```

```

"Version": "2012-10-17",
"Statement": [
  {
    "Sid": "VisualEditor0",
    "Effect": "Deny",
    "Action": [
      "redshift:AuthorizeDataShare",
      "redshift:DeauthorizeDataShare"
    ],
    "Resource": "*",
    "Condition": {
      "StringNotEquals": {
        "redshift:ConsumerIdentifier": "555555555555"
      }
    }
  }
]
}

```

You can allow a producer with a DataShareArn **testshare2** to explicitly share with a consumer with an AWS account of 111122223333 in the IAM policy.

```

{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "VisualEditor0",
      "Effect": "Allow",
      "Action": [
        "redshift:AuthorizeDataShare",
        "redshift:DeauthorizeDataShare"
      ],
      "Resource": "arn:aws:redshift:us-east-1:666666666666:datashare:af06285e-8a45-4ee9-b598-648c218c8ff1/testshare2",
      "Condition": {
        "StringEquals": {
          "redshift:ConsumerIdentifier": "111122223333"
        }
      }
    }
  ]
}

```

Querying datashares

Accessing shared data in Amazon Redshift

You can discover shared data using standard SQL interfaces, JDBC or ODBC drivers, and the Data API. You can also query data with high performance from familiar business intelligence (BI) and analytic tools. You can perform queries by referring to the objects from other Amazon Redshift databases that are both local to and remote from your cluster that you have permissions to access.

You can do so simply by staying connected to local databases in your cluster. Then you can create consumer databases from datashares to consume shared data.

After you have done so, you can perform cross-database queries joining the datasets. You can query objects in consumer databases using the 3-part notation (*consumer_database_name.schema_name.table_name*). You can also query using external schema links to schemas in the consumer database. You can query both local data and data shared from other clusters within the same query. Such a query can reference objects from the current connected database and from other nonconnected databases, including consumer databases created from datashares.

Accessing metadata for datashares in Amazon Redshift

To help cluster administrators discover datashares, Amazon Redshift provides a set of metadata views to list datashares. These views list datashares created in your cluster and also those received from other clusters within the same account, from other accounts, or other AWS Regions. These views display the following information:

- Datashares that are shared and received by the clusters
- Contents of database objects in the datashares, including the basic share metadata, objects, and consumers

Use `SVV_DATASHARES` to view a list of all datashares created in your cluster (outbound) and shared from others (inbound). For more information, see [SVV_DATASHARES](#).

Use `SVV_DATASHARE_CONSUMERS` to view a list of data consumers. For more information, see [SVV_DATASHARE_CONSUMERS](#).

Use `SVV_DATASHARE_OBJECTS` to view a list of objects in all datashares created in your cluster (outbound) and shared from others (inbound). For more information, see [SVV_DATASHARE_OBJECTS](#).

Integrating Amazon Redshift data sharing with business intelligence tools

To integrate data sharing with business intelligence (BI) tools, we recommend that you use the Amazon Redshift JDBC or ODBC drivers.

Amazon Redshift JDBC and ODBC drivers support the `GetCatalogs` API operation in the drivers, which returns the list of all databases including those created from datashares. The drivers also support downstream operations, such as `GetSchemas`, `GetTables`, and so on, that return data from all the databases that `GetCatalogs` returns. The drivers provide this support even when the catalog isn't explicitly specified in the call. For more information about JDBC or ODBC drivers, see [Configuring connections in Amazon Redshift](#) in the *Amazon Redshift Management Guide*.

You can't connect to consumer databases created from datashares directly. Connect to local databases on your cluster. If you have a connection switching user interface in your tool, the list of databases should include only the local cluster databases. The list should exclude consumer databases created from datashares to provide the best experience. You can use an option in the `SVV_REDSHIFT_DATABASES` view to filter databases.

Monitoring and auditing data sharing in Amazon Redshift

With Amazon Redshift, you can monitor and audit data sharing activities to ensure compliance and security.

By auditing data sharing, producers can track the datashare evolution. For example, auditing helps track when datashares are created, objects are added or removed, and permissions are granted or revoked to Amazon Redshift clusters, AWS accounts, or AWS Regions.

In addition to auditing, producers and consumers track datashare usage at various granularities, such as account, cluster, and object levels. For more information about tracking usage and auditing views, see [SVL_DATASHARE_CHANGE_LOG](#) and [SVL_DATASHARE_USAGE_PRODUCER](#).

You can monitor datashares by querying system views.

1. The producer cluster administrator who wants to share data creates an Amazon Redshift datashare. The producer cluster administrator then adds the needed database objects. These

might be schemas, tables, and views to the datashare and specifies a list of consumers that the objects to be shared with.

Use the following system views to see consolidated views for tracking changes to and usage of datashares on producer and/or consumer clusters:

- [SYS_DATASHARE_CHANGE_LOG](#)
- [SYS_DATASHARE_USAGE_CONSUMER](#)
- [SYS_DATASHARE_USAGE_PRODUCER](#)

Use the following system views to see datashare objects and data consumer information for outbound datashares:

- [SVV_DATASHARES](#)
 - [SVV_DATASHARE_CONSUMERS](#)
 - [SVV_DATASHARE_OBJECTS](#)
2. The consumer cluster administrators look at the datashares for which they're granted use and review the contents of each datashare by viewing inbound datashares using [SVV_DATASHARES](#).

To consume shared data, each consumer cluster administrator creates an Amazon Redshift database from the datashare. The administrator then assigns permissions to appropriate users and roles in the consumer cluster. Users and roles can list the shared objects as part of the standard metadata queries by viewing the following metadata system views and can start querying data immediately.

- [SVV_REDSHIFT_COLUMNS](#)
- [SVV_REDSHIFT_DATABASES](#)
- [SVV_REDSHIFT_FUNCTIONS](#)
- [SVV_REDSHIFT_SCHEMAS](#)
- [SVV_REDSHIFT_TABLES](#)

To view objects of both Amazon Redshift local and shared schemas and external schemas, use the following metadata system views to query them.

- [SVV_ALL_COLUMNS](#)
- [SVV_ALL_SCHEMAS](#)
- [SVV_ALL_TABLES](#)

Integrating Amazon Redshift data sharing with AWS CloudTrail

Data sharing is integrated with AWS CloudTrail. CloudTrail is a service that provides a record of actions taken by a user, a role, or an AWS service in Amazon Redshift. CloudTrail captures all API calls for data sharing as events. The calls captured include calls from the AWS CloudTrail console and code calls to the data sharing operations. For more information about Amazon Redshift integration with AWS CloudTrail, see [Logging with CloudTrail](#).

For more information about CloudTrail, see [How CloudTrail works](#).

Managing data sharing tasks

With Amazon Redshift, you can securely share data across Amazon Redshift clusters, enabling data consumers to query and access live data without copying or replicating it. Data sharing lets you create and configure datashares, which are producer-side objects that reference the database objects you want to share.

You can get started with data sharing by using either the SQL interface or the Amazon Redshift console.

Topics

- [Managing data sharing using the SQL interface](#)
- [Managing data sharing using the console](#)
- [Managing data sharing with AWS CloudFormation](#)
- [Managing data sharing with writes using the console \(preview\)](#)

Managing data sharing using the SQL interface

With Amazon Redshift, you can control data access and sharing between databases and clusters using the SQL interface. Managing data sharing allows you to create datashares, which are producer-consumer relationships between a producer database and one or more consumer databases or clusters.

You can share data for read purposes across different Amazon Redshift clusters within or across AWS accounts, or across AWS Regions.

Topics

Sharing read access to data within an AWS account

With Amazon Redshift, you can share read access to data across different database users or groups within the same AWS account. This feature allows you to control data access privileges at a granular level, ensuring that only authorized users or groups can read specific data sets.

To share data for read purposes as a producer cluster administrator or database owner

1. Create datashares in your cluster. For more information, see [CREATE DATASHARE](#).

```
CREATE DATASHARE salesshare;
```

Cluster superuser and database owners can create datashares. Each datashare is associated with a database during creation. Only objects from that database can be shared in that datashare. Multiple datashares can be created on the same database with the same or different granularity of objects. There is no limit on the number of datashares a cluster can create.

You can also use the Amazon Redshift console to create datashares. For more information, see [Creating datashares](#).

2. Delegate permissions to operate on the datashare. For more information, see [GRANT](#) or [REVOKE](#).

The following example grants permissions to `dbuser` on `salesshare`.

```
GRANT ALTER, SHARE ON DATASHARE salesshare TO dbuser;
```

Cluster superusers and the owners of the datashare can grant or revoke modification permissions on the datashare to additional users.

3. Add objects to or remove objects from datashares. To add objects to a datashare, add the schema before adding objects. When you add a schema, Amazon Redshift doesn't add all

the objects under it. Make sure to add these explicitly. For more information, see [ALTER DATASHARE](#).

```
ALTER DATASHARE salesshare ADD SCHEMA PUBLIC;
ALTER DATASHARE salesshare ADD TABLE public.tickit_sales_redshift;
ALTER DATASHARE salesshare ADD ALL TABLES IN SCHEMA PUBLIC;
```

You can also add views to a datashare.

```
CREATE VIEW public.sales_data_summary_view AS SELECT * FROM
public.tickit_sales_redshift;
ALTER DATASHARE salesshare ADD TABLE public.sales_data_summary_view;
```

Use ALTER DATASHARE to share schemas, and tables, views, and functions in a given schema. Superusers, datashare owners, or users who have ALTER or ALL permission on the datashare can alter the datashare to add objects to or remove objects from it. Users should have the permissions to add or remove objects from the datashare. Users should also be the owners of the objects or have SELECT, USAGE, or ALL permissions on the objects.

You can also use GRANT to add objects to the datashare. This example shows how:

```
GRANT SELECT ON TABLE public.tickit_sales_redshift TO DATASHARE salesshare;
```

This syntax is functionally equivalent to ALTER DATASHARE salesshare ADD TABLE public.tickit_sales_redshift;.

Use the INCLUDENEW clause to add any new tables, views, or SQL user-defined functions (UDFs) created in a specified schema to the datashare. Only superusers can change this property for each datashare-schema pair.

```
ALTER DATASHARE salesshare ADD SCHEMA PUBLIC;
ALTER DATASHARE salesshare SET INCLUDENEW = TRUE FOR SCHEMA PUBLIC;
```

You can also use the Amazon Redshift console to add or remove objects from datashares. For more information, see [Adding datashare objects to datashares](#), [Removing datashare objects from datashares](#), and [Editing datashares created in your account](#).

4. Add consumers to or remove consumers from datashares. The following example adds the consumer cluster namespace to salesshare. The namespace is the namespace globally

unique identifier (GUID) of the consumer cluster in the account. For more information, see [GRANT](#) or [REVOKE](#).

```
GRANT USAGE ON DATASHARE salesshare TO NAMESPACE
'13b8833d-17c6-4f16-8fe4-1a018f5ed00d';
```

You can only grant permissions to one datashare consumer in a GRANT statement.

Cluster superusers and the owners of datashare objects or users that have SHARE permission on the datashare can add consumers to or remove consumers from a datashare. To do so, they use GRANT USAGE or REVOKE USAGE.

To find the namespace of the cluster that you currently see, you can use the SELECT CURRENT_NAMESPACE command. To find the namespace of a different cluster within the same AWS account, go to the Amazon Redshift console cluster details page. On that page, find the newly added namespace field.

You can also use the Amazon Redshift console to add or remove data consumers for datashares. For more information, see [Adding data consumers to datashares](#) and [Removing data consumers from datashares](#).

5. (Optional) Add security restrictions to the datashare. The following example shows that the consumer cluster with a public IP access is allowed to read the datashare. For more information, see [ALTER DATASHARE](#).

```
ALTER DATASHARE salesshare SET PUBLICACCESSIBLE = TRUE;
```

You can modify properties about the type of consumers after datashare creation. For example, you can define that clusters that want to consume data from a given datashare can't be publicly accessible. Queries from consumer clusters that don't meet security restrictions specified in datashare are rejected at query runtime.

You can also use the Amazon Redshift console to edit datashares. For more information, see [Editing datashares created in your account](#).

6. List datashares created in the cluster and look into the contents of the datashare.

The following example displays the information of a datashare named salesshare. For more information, see [DESC DATASHARE](#) and [SHOW DATASHARES](#).

```
DESC DATASHARE salesshare;
```

producer_account	producer_namespace	share_type	share_name
object_type	object_name	include_new	
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_users_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_venue_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_category_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_date_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_event_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_listing_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_sales_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
schema	public	t	
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
view	public.sales_data_summary_view		

The following example displays the outbound datashares in a producer cluster.

```
SHOW DATASHARES LIKE 'sales%';
```

The output looks similar to the following.

share_name	share_owner	source_database	consumer_database	share_type
createdate	is_publicaccessible	share_acl	producer_account	producer_namespace
salesshare	100	dev		OUTBOUND
2020-12-09 02:27:08	True		123456789012	
				13b8833d-17c6-4f16-8fe4-1a018f5ed00d

For more information, see [DESC DATASHARE](#) and [SHOW DATASHARES](#).

You can also use [SVV_DATASHARES](#), [SVV_DATASHARE_CONSUMERS](#), and [SVV_DATASHARE_OBJECTS](#) to view the datashares, the objects within the datashare, and the datashare consumers.

7. Drop datashares. For more information, see [DROP DATASHARE](#).

You can delete the datashare objects at any point using [DROP DATASHARE](#). Cluster superusers and owners of datashare can drop datashares.

The following example drops a datashare named salesshare.

```
DROP DATASHARE salesshare;
```

You can also use the Amazon Redshift console to delete datashares. For more information, see [Deleting datashares created in your account](#).

8. Use ALTER DATASHARE to remove objects from datashares at any point from the datashare. Use REVOKE USAGE ON to revoke permissions on the datashare to certain consumers. It revokes USAGE permissions on objects within a datashare and instantly stops access to all consumer clusters. Listing datashares and the metadata queries, such as listing databases and tables, doesn't return the shared objects after access is revoked.

```
ALTER DATASHARE salesshare REMOVE TABLE public.tickit_sales_redshift;
```

You can also use the Amazon Redshift console to edit datashares. For more information, see [Editing datashares created in your account](#).

9. Revoke access to the datashare from namespaces if you don't want to share the data with the consumers anymore.

```
REVOKE USAGE ON DATASHARE salesshare FROM NAMESPACE  
'13b8833d-17c6-4f16-8fe4-1a018f5ed00d';
```

You can also use the Amazon Redshift console to edit datashares. For more information, see [Editing datashares created in your account](#).

To share data for read purposes as a consumer cluster administrator

1. List the datashares that are made available to you and view the content of datashares. For more information, see [DESC DATASHARE](#) and [SHOW DATASHARES](#).

The following example displays the information of inbound datashares of a specified producer namespace. When you run `DESC DATASHARE` as a consumer cluster administrator, you must specify the `NAMESPACE` option to view inbound datashares.

```
DESC DATASHARE salesshare OF NAMESPACE '13b8833d-17c6-4f16-8fe4-1a018f5ed00d';
```

producer_account	producer_namespace	share_type	share_name
object_type	object_name	include_new	
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_users_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_venue_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_category_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_date_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_event_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_listing_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_sales_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
schema	public		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
view	public.sales_data_summary_view		

Only cluster superusers can do this. You can also use `SVV_DATASHARES` to view the datashares and `SVV_DATASHARE_OBJECTS` to view the objects within the datashare.

The following example displays the inbound datashares in a consumer cluster.

```
SHOW DATASHARES LIKE 'sales%';
```

```

share_name | share_owner | source_database | consumer_database | share_type
| createdate | is_publicaccessible | share_acl | producer_account |
producer_namespace
-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
salesshare |          |          |          | INBOUND
|          |          |          |          |
|          |          |          |          | 123456789012 |
13b8833d-17c6-4f16-8fe4-1a018f5ed00d

```

2. As a database superuser, you can create local databases that reference to the datashares. For more information, see [CREATE DATABASE](#).

```

CREATE DATABASE sales_db FROM DATASHARE salesshare OF NAMESPACE
'13b8833d-17c6-4f16-8fe4-1a018f5ed00d';

```

If you want more granular control over access to the objects in the local database, use the `WITH PERMISSIONS` clause when creating the database. This lets you grant object-level permissions for objects in the database in step 4.

```

CREATE DATABASE sales_db WITH PERMISSIONS FROM DATASHARE salesshare OF NAMESPACE
'13b8833d-17c6-4f16-8fe4-1a018f5ed00d';

```

You can see databases that you created from the datashare by querying the [SVV_REDSHIFT_DATABASES](#) view. You can't connect to these databases created from datashares, and they are read-only. However, you can connect to a local database on your consumer cluster and perform a cross-database query to query the data from the databases created from datashares. You can't create a datashare on top of database objects created from an existing datashare. However, you can copy the data into a separate table on the consumer cluster, perform any processing needed, and then share the new objects that were created.

You can also use the Amazon Redshift console to create databases from datashares. For more information, see [Creating databases from datashares](#).

3. (Optional) Create external schemas to refer to and assign granular permissions to specific schemas in the consumer database imported on the consumer cluster. For more information, see [CREATE EXTERNAL SCHEMA](#).

```
CREATE EXTERNAL SCHEMA sales_schema FROM REDSHIFT DATABASE 'sales_db' SCHEMA
'public';
```

4. Grant permissions on databases and schema references created from the datashares to users and roles in the consumer cluster as needed. For more information, see [GRANT](#) or [REVOKE](#).

```
GRANT USAGE ON DATABASE sales_db TO Bob;
```

```
GRANT USAGE ON SCHEMA sales_schema TO ROLE Analyst_role;
```

If you created your database without `WITH PERMISSIONS`, you can only assign permissions on the entire database created from the datashare to your users and roles. In some cases, you need fine-grained controls on a subset of database objects created from the datashare. If so, you can create an external schema reference that points to specific schemas in the datashare (as described in the previous step) and provide granular permissions at schema level.

You can also create late-binding views on top of shared objects and use these to assign granular permissions. You can also consider having producer clusters create additional datashares for you with the granularity required.

If you created your database with `WITH PERMISSIONS` in step 2, you must assign object-level permissions for objects in the shared database. A user with only the `USAGE` permission can't access any objects in a database created with `WITH PERMISSIONS` until they're granted additional object-level permissions..

```
GRANT SELECT ON sales_db.public.ticket_sales_redshift to Bob;
```

5. Query data in the shared objects in the datashares.

Users and roles with permissions on consumer databases and schemas on consumer clusters can explore and navigate the metadata of any shared objects. They can also explore and navigate local objects in a consumer cluster. To do this, they use JDBC or ODBC drivers or `SVV_ALL` and `SVV_REDSHIFT` views.

Producer clusters might have many schemas in the database, tables, and views within each schema. The users on the consumer side can see only the subset of objects that are made available through the datashare. These users can't see the entire metadata from the producer cluster. This approach helps provide granular metadata security control with data sharing.

You continue to connect to local cluster databases. But now, you can also read from the databases and schemas that are created from the datashare using the three-part database.schema.table notation. You can perform queries that span across any and all databases that are visible to you. These can be local databases on the cluster or databases created from the datashares. Consumer clusters can't connect to the databases created from the datashares.

You can access the data using full qualification. For more information, see [Cross-database query examples](#).

```
SELECT * FROM sales_db.public.tickit_sales_redshift ORDER BY 1,2 LIMIT 5;
```

salesid	listid	sellerid	buyerid	eventid	dateid	qtysold	pricepaid	commission	saletime
1	1	36861	21191	7872	1875	4	728.00		
109.20	2008-02-18	02:36:48							
2	4	8117	11498	4337	1983	2	76.00		
11.40	2008-06-06	05:00:16							
3	5	1616	17433	8647	1983	2	350.00		
52.50	2008-06-06	08:26:17							
4	5	1616	19715	8647	1986	1	175.00		
26.25	2008-06-09	08:38:52							
5	6	47402	14115	8240	2069	2	154.00		
23.10	2008-08-31	09:17:02							

You can only use SELECT statements on shared objects. However, you can create tables in the consumer cluster by querying the data from the shared objects in a different local database.

In addition to queries, consumers can create views on shared objects. Only late-binding views or materialized views are supported. Amazon Redshift doesn't support regular views on shared data. Views that consumers create can span across multiple local databases or databases created from datashares. For more information, see [CREATE VIEW](#).

```
// Connect to a local cluster database

// Create a view on shared objects and access it.
CREATE VIEW sales_data
AS SELECT *
```

```
FROM sales_db.public.tickit_sales_redshift
WITH NO SCHEMA BINDING;

SELECT * FROM sales_data;
```

Sharing write access to data (Preview)

You can share database objects for both reads and writes across different Amazon Redshift clusters or Amazon Redshift Serverless workgroups within the same AWS account, across accounts, and across regions. The procedures in this topic show how to set up data sharing that includes write permissions. You can grant permissions such as SELECT, INSERT, and UPDATE for different tables and USAGE and CREATE for schemas. The data is live and available to all warehouses as soon as a write transaction is committed. Producer account administrators can determine whether or not specific namespaces or regions get read-only, read-and-write, or any access to the data.

The sections that follow show how to configure data sharing. The procedures assume you're working in a database in a provisioned cluster or Amazon Redshift Serverless workgroup.

Read-only data sharing vs. data sharing for reads and writes

Previously, objects in datashares were read only in all circumstances. Writing to an object in a datashare is a new feature. Objects in datashares are only write-enabled when a producer specifically grants write privileges like INSERT or CREATE on objects to the datashare. Additionally, for cross-account sharing, a producer has to authorize the datashare for writes and the consumer has to associate specific clusters and workgroups for writes. Details follow in subsequent sections in this topic.

Permissions you can grant to datashares (preview)

Different object types and various permissions you can grant to them in a data sharing context.

Schemas:

- USAGE
- CREATE

Tables:

- SELECT

- INSERT
- UPDATE
- DELETE
- TRUNCATE
- DROP
- REFERENCES

Functions:

- EXECUTE

Databases:

- CREATE

Requirements and limitations for datasharing in preview

- *Connections* – You must be connected directly to a datashare database or run the USE command to write to datashares. However, we will soon enable the ability to do this with three-part notation.
- *Availability* – You must use Serverless workgroups, ra3.4xl clusters, or ra3.16xl clusters to use this feature. Support for ra3.xlplus clusters is planned.
- *Metadata Discovery* – When you're a consumer connected directly to a datashare database through the Redshift JDBC, ODBC, or Python drivers, you can view catalog data in the following ways:
 - SQL [SHOW](#) commands.
 - Querying information_schema tables and views.
 - Querying [SVV metadata views](#).
- *Data API* – You cannot connect to datashare databases via the Data API. Support for this will be coming soon.
- *Permissions visibility* – Consumers cannot see the permissions granted to the datashares. We will be adding this soon.

- *Encryption* – For cross-account data sharing, both the producer and consumer cluster must be encrypted.
- *Isolation level* – Your database's isolation level must be snapshot isolation in order to allow other Serverless workgroups and clusters to write to it.
- *Auto operations* – Consumers writing to datashare objects will not trigger an auto analyze operation. As a result, the producer must manually run analyze after data is inserted into the table to have table statistics updated. Without this, query plans may not be optimal.
- *Multi-statement queries and transactions* – Multi-statement queries outside of a transaction block aren't currently supported. As a result, if you are using a query editor like dbeaver and you have multiple write queries, you need to wrap your queries in an explicit BEGIN...END transaction statement.

SQL statements supported

These statements are supported for the public preview release of data sharing with writes:

- BEGIN | START TRANSACTION
- END | COMMIT | ROLLBACK
- COPY without COMPUPDATE
- { CREATE | DROP } SCHEMA
- { CREATE | DROP | SHOW } TABLE
- CREATE TABLE table_name AS
- DELETE
- { GRANT | REVOKE } privilege_name ON OBJECT_TYPE object_name TO consumer_user
- INSERT
- SELECT
- INSERT INTO SELECT
- TRUNCATE
- UPDATE
- Super data type columns

Unsupported statement types – The following aren't supported:

- Multi-statement queries to consumer warehouses when writing to producers.

- Concurrency scaling queries writing from consumers to producers.
- Auto-copy jobs writing from consumers to producers.
- Streaming jobs writing from consumers to producers.
- Consumers creating zero-ETL integration tables on producer clusters. For more information about zero-ETL integrations, see [Working with zero-ETL integrations](#).
- Writing to a table with an interleaved sort key.

Sharing data within an account with write permissions as the producer account administrator (preview)

Previously, objects in datashares were read only in all circumstances. Writing to an object in a datashare is a new feature. Objects in datashares are only write-enabled when a producer specifically grants write privileges like INSERT or CREATE on objects to the datashare. Details follow in subsequent sections in this topic.

If you're looking for the existing documentation for read-only datashares, that's available at [Sharing data across clusters in Amazon Redshift](#).

To start data sharing, the administrator on the producer creates a datashare and adds objects to it:

1. The producer database owner or [superuser](#) creates a datashare. A datashare is a logical container of database objects, permissions, and consumers. (Consumers are clusters or Amazon Redshift Serverless namespaces in your account and other accounts.) Each datashare is associated with the database it's created in and only objects from that database can be added. The following command creates a datashare:

```
CREATE DATASHARE my_datashare [PUBLICACCESSIBLE = TRUE];
```

Setting PUBLICACCESSIBLE = TRUE allows consumers to query your datashare from publicly accessible clusters and provisioned workgroups. Leave this out or explicitly set it to false if you do not want to allow it.

The datashare owner must grant USAGE on the schemas they want to add to the datashare. The GRANT command is new. It's used to grant various actions on the schema, including CREATE and USAGE. The schemas hold shared objects:

```
CREATE SCHEMA myshared_schema1;  
CREATE SCHEMA myshared_schema2;
```

```
GRANT USAGE ON SCHEMA myshared_schema1 TO DATASHARE my_datashare;  
GRANT CREATE, USAGE ON SCHEMA myshared_schema2 TO DATASHARE my_datashare;
```

Alternatively, the administrator can continue to run ALTER commands to add a schema to the datashare. Only USAGE permissions are granted when a schema is added this way.

```
ALTER DATASHARE my_datashare ADD SCHEMA myshared_schema1;
```

2. After the administrator adds schemas, they can grant datashare permissions on objects in the schema. These can be both read and write permissions. The GRANT ALL sample shows how to grant all permissions.

```
GRANT SELECT, INSERT ON TABLE myshared_schema1.table1, myshared_schema1.table2,  
myshared_schema2.table1  
TO DATASHARE my_datashare;  
  
GRANT ALL ON TABLE myshared_schema1.table4 TO DATASHARE my_datashare;
```

You can continue to run commands like ALTER DATASHARE to add tables. When you do, only SELECT permissions are granted on the objects added.

```
ALTER DATASHARE my_datashare ADD TABLE myshared_schema1.table1,  
myshared_schema1.table2, myshared_schema2.table1;
```

3. The administrator grants usage on the datashare to a specific namespace in the account. You can find the namespace ID as part of the ARN in the cluster details page, in the Amazon Redshift Serverless namespace details page, or by running the command `SELECT current_namespace;`. For more information, see [CURRENT_NAMESPACE](#).

```
GRANT USAGE ON DATASHARE my_datashare TO NAMESPACE '86b5169f-012a-234b-9fbb-  
e2e24359e9a8';
```

Sharing write permissions to data across accounts (preview)

With Amazon Redshift, you can share data across AWS accounts and grant write permissions, enabling collaboration and data sharing between teams or organizations. Cross-account data sharing allows you to establish a data provider account that creates and manages databases, schemas, and tables, which can then be securely shared with data consumer accounts. The

following sections demonstrate the process of configuring cross-account data sharing and granting write access in Amazon Redshift.

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

If you haven't created a datashare yet on the PREVIEW_2023 track, go to [Sharing write access to data \(Preview\)](#) to get started.

Associating shared data as the consumer data security administrator (preview)

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

If you haven't created a datashare yet on the PREVIEW_2023 track, go to [Sharing write access to data \(Preview\)](#) to get started.

Prerequisites: The steps in this section are performed after the producer administrator grants specific actions on the shared database objects and, if the datashare is being shared with another account, the producer security administrator authorizes access.

The consumer security administrator determines the following:

- Whether or not all namespaces in an account, namespaces in specific regions in the account, or specific namespaces have access to the datashare.
- If namespaces have access to the datashare, whether or not those namespace have write permissions.

The consumer security administrator can associate the datashare via the console, the CLI, or via API. If by CLI, the administrator uses the following command:

```
associate-data-share-consumer
--data-share-arn <value>
--consumer-identifier <value>
[--allow-writes | --no-allow-writes]
```

For more information about the command, see [associate-data-share-consumer](#).

The consumer security administrator must explicitly set `allow-writes` to true when associating a datashare with a namespace, to allow use of INSERT and UPDATE commands. If they don't, the users can perform only read operations, such as SELECT, USAGE, or EXECUTE privileges.

You can change the association of a namespace for a datashare by calling `associate-data-share-consumer` again, with a different value. The old association is overwritten by the new association, so if you originally associate and set `allow-writes`, but associate and specify `no-allow-writes`, or simply do not specify a value, the consumer will have their write permissions revoked.

Authorizing datashares for writes as the producer security administrator (preview)

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

If you haven't created a datashare yet on the PREVIEW_2023 track, go to [Sharing write access to data \(Preview\)](#) to get started.

Note

This only applies when the datashare is shared between accounts.

The producer security administrator determines the following:

- Whether or not another account can have access to the datashare.
- If an account has access to the datashare, whether or not that account has write permissions.

The following IAM permissions are required to authorize a datashare:

redshift:AuthorizeDataShare

You can authorize usage and writes using either a CLI call or with the API:

```
authorize-data-share
--data-share-arn <value>
--consumer-identifier <value>
[--allow-writes | --no-allow-writes]
```

For more information about the command, see [authorize-data-share](#).

The consumer identifier can be either:

- A twelve digit AWS account ID.
- The namespace identifier ARN.

Note that write permissions aren't granted at the authorizing step. Authorizing a datashare for writes just allows the account to have write permissions that were granted by the datashare administrator. If an administrator does not allow writes, the only permissions available to the specific consumer are SELECT, USAGE, and EXECUTE.

You can change the authorization of a datashare consumer by calling `authorize-data-share` again, but with a different value. The old authorization is overwritten by the new authorization. So if you originally authorize and allow writes, but re-authorize and specify `no-allow-writes` or simply do not specify a value, the consumer will have their write permissions revoked.

Regions where data sharing is available (preview)

With Amazon Redshift, you can share data across Amazon Redshift clusters in the same or different AWS Regions, enabling cross-Region analytics, data residency, and disaster recovery scenarios. Regions where data sharing is available refers to the AWS Regions that support sharing data from a datashare, which is an Amazon Redshift object containing one or more database objects that can be shared across accounts or clusters. The following sections provide details on configuring and managing data shares in Amazon Redshift across Regions.

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track.

The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

With Amazon Redshift, you can share live data across Amazon Redshift clusters in the same or different AWS regions where data sharing is available.

If you haven't created a datashare yet on the PREVIEW_2023 track, go to [Sharing write access to data \(Preview\)](#) to get started.

The following regions have data sharing available, in preview:

- US East (N. Virginia) (us-east-1)
- US East (Ohio) (us-east-2)
- US West (Oregon) (us-west-2)
- Asia Pacific (Tokyo) (ap-northeast-1)
- Europe (Ireland) (eu-west-1)
- Europe (Stockholm) (eu-north-1)

Sharing data across AWS accounts

You can share data for read purposes across AWS accounts. Sharing data across AWS accounts works similarly to sharing data within an account. The difference is that there is a two-way handshake required in sharing data across AWS accounts. A producer account administrators can either authorize consumer accounts to access datashares or choose not to authorize any access. To use an authorized datashare, a consumer account administrator can associate the datashare. The administrator can associate the datashare with an entire AWS account or with specific clusters in the consumer account, or decline the datashare. For more information about sharing data within an account, see [Sharing read access to data within an AWS account](#).

A datashare can have data consumers that are either cluster namespaces in the same account or different AWS accounts. You don't need to create separate datashares for sharing within an account and cross-account sharing.

For cross-account data sharing, both the producer and consumer cluster must be encrypted.

When sharing data with AWS accounts, producer cluster administrators share with the AWS account as an entity. A consumer cluster administrator can decide which cluster namespaces in the consumer account get access to a datashare.

Topics

- [Producer cluster administrator actions](#)
- [Consumer account administrator actions](#)
- [Consumer cluster administrator actions](#)

Producer cluster administrator actions

With Amazon Redshift, you can perform administrative tasks on producer clusters to manage data ingestion and load processing.

If you are a producer cluster administrator or database owner – follow these steps:

1. Create datashares in your cluster and add datashare objects to the datashares. For more detailed steps on how to create datashares and add datashare objects to datashares, see [Sharing read access to data within an AWS account](#). For information about the CREATE DATASHARE and ALTER DATASHARE, see [CREATE DATASHARE](#) and [ALTER DATASHARE](#).

The following example adds different datashare objects to the datashare salesshare.

```
-- Add schema to datashare
ALTER DATASHARE salesshare ADD SCHEMA PUBLIC;

-- Add table under schema to datashare
ALTER DATASHARE salesshare ADD TABLE public.ticket_sales_redshift;

-- Add view to datashare
ALTER DATASHARE salesshare ADD TABLE public.sales_data_summary_view;

-- Add all existing tables and views under schema to datashare (does not include
  future table)
ALTER DATASHARE salesshare ADD ALL TABLES in schema public;
```

You can also use the Amazon Redshift console to create or edit datashares. For more information, see [Creating datashares](#) and [Editing datashares created in your account](#).

2. Delegate permissions to operate on the datashare. For more information, see [GRANT](#) or [REVOKE](#).

The following example grants permissions to `dbuser` on `salessshare`.

```
GRANT ALTER, SHARE ON DATASHARE salessshare TO dbuser;
```

Cluster superusers and the owners of the datashare can grant or revoke modification permissions on the datashare to additional users.

3. Add consumers to or remove consumers from datashares. The following example adds the AWS account ID to `salessshare`. For more information, see [GRANT](#) or [REVOKE](#).

```
GRANT USAGE ON DATASHARE salessshare TO ACCOUNT '123456789012';
```

You can only grant permissions to one data consumer in a GRANT statement.

Cluster superusers and the owners of datashare objects, or users that have SHARE permissions on the datashare, can add consumers to or remove consumers from a datashare. To do so, they use GRANT USAGE or REVOKE USAGE.

You can also use the Amazon Redshift console to add or remove data consumers for datashares. For more information, see [Adding data consumers to datashares](#) and [Removing data consumers from datashares](#).

4. (Optional) Revoke access to the datashare from AWS accounts if you don't want to share the data with the consumers anymore.

```
REVOKE USAGE ON DATASHARE salessshare FROM ACCOUNT '123456789012';
```

If you are a producer account administrator – follow these steps:

After granting usage to the AWS account, the datashare status is `pending_authorization`. The producer account administrator should authorize datashares using the Amazon Redshift console and choose the data consumers.

Sign in to the <https://console.aws.amazon.com/redshiftv2/>. Then choose which data consumers to authorize to access datashares or to remove authorization from. Authorized data consumers receive notifications to take actions on datashares. If you are adding a cluster namespace as a data

consumer, you don't have to perform authorization. After data consumers are authorized, they can access datashare objects and create a consumer database to query the data. For more information, see [Authorizing or removing authorization from datashares](#).

Consumer account administrator actions

With Amazon Redshift, you can manage consumer accounts and control their access to your data warehousing resources.

If you are a consumer account administrator – follow these steps:

To associate one or more datashares that are shared from other accounts with your entire AWS account or specific cluster namespaces in your account, use the Amazon Redshift console.

Sign in to the <https://console.aws.amazon.com/redshiftv2/>. Then, associate one or more datashares that are shared from other accounts with your entire AWS account or specific cluster namespaces in your account. For more information, see [Associating datashares](#).

After the AWS account or specific cluster namespaces are associated, the datashares become available for consumption. You can also change datashare association at any time. When changing association from individual cluster namespaces to an AWS account, Amazon Redshift overwrites the cluster namespaces with the AWS account information. When changing association from an AWS account to specific cluster namespaces, Amazon Redshift overwrites the AWS account information with the cluster namespace information. All cluster namespaces in the account get access to the data.

Consumer cluster administrator actions

With Amazon Redshift, you can perform administrative tasks on consumer clusters to manage data ingestion and load processing.

If you are a consumer cluster administrator – follow these steps:

1. List the datashares made available to you and view the content of datashares. The content of datashares is available only when the producer cluster administrator has authorized the datashares and the consumer cluster administrator has accepted and associated the datashares. For more information, see [DESC DATASHARE](#) and [SHOW DATASHARES](#).

The following example displays the information of inbound datashares of a specified producer namespace. When you run the `DESC DATAHSARE` as a consumer cluster administrator, you must

specify the NAMESPACE and account ID to view inbound datashares. For outbound datashares, specify the datashare name.

```
SHOW DATASHARES LIKE 'sales%';
```

```
share_name | share_owner | source_database | consumer_database | share_type
| createdate | is_publicaccessible | share_acl | producer_account |
producer_namespace
-----+-----+-----+-----+-----+-----

schema         | public
(8 rows)
```

Only cluster superusers can do this. You can also use `SVV_DATASHARES` to view the datashares and `SVV_DATASHARE_OBJECTS` to view the objects within the datashare.

The following example displays the inbound datashares in a consumer cluster.

```
SELECT * FROM SVV_DATASHARES WHERE share_name LIKE 'sales%';
```

share_name	share_owner	source_database	consumer_database	share_type	createdate	is_publicaccessible	share_acl	producer_account	producer_namespace
salesshare				INBOUND				123456789012	'dd8772e1-d792-4fa4-996b-1870577efc0d'

```
SELECT * FROM SVV_DATASHARE_OBJECTS WHERE share_name LIKE 'sales%';
```

share_type	share_name	object_type	object_name	producer_account	producer_namespace
INBOUND	salesshare	table	public.tickit_users_redshift	123456789012	dd8772e1-d792-4fa4-996b-1870577efc0d
INBOUND	salesshare	table	public.tickit_venue_redshift	123456789012	dd8772e1-d792-4fa4-996b-1870577efc0d
INBOUND	salesshare	table	public.tickit_category_redshift	123456789012	dd8772e1-d792-4fa4-996b-1870577efc0d
INBOUND	salesshare	table	public.tickit_date_redshift	123456789012	dd8772e1-d792-4fa4-996b-1870577efc0d
INBOUND	salesshare	table	public.tickit_event_redshift	123456789012	dd8772e1-d792-4fa4-996b-1870577efc0d
INBOUND	salesshare	table	public.tickit_listing_redshift	123456789012	dd8772e1-d792-4fa4-996b-1870577efc0d
INBOUND	salesshare	table	public.tickit_sales_redshift	123456789012	dd8772e1-d792-4fa4-996b-1870577efc0d
INBOUND	salesshare	schema	public	123456789012	dd8772e1-d792-4fa4-996b-1870577efc0d

(8 rows)

2. Create local databases that reference to the datashares. Specify the NAMESPACE and account ID when creating the database from the datashare. For more information, see [CREATE DATABASE](#).

```
CREATE DATABASE sales_db FROM DATASHARE saleshare OF ACCOUNT '123456789012'  
NAMESPACE 'dd8772e1-d792-4fa4-996b-1870577efc0d';
```

If you want more granular control over access to the objects in the local database, use the WITH PERMISSIONS clause when creating the database. This lets you grant object-level permissions for objects in the database in step 4.

```
CREATE DATABASE sales_db WITH PERMISSIONS FROM DATASHARE saleshare OF ACCOUNT  
'123456789012' NAMESPACE 'dd8772e1-d792-4fa4-996b-1870577efc0d';
```

You can see databases that you created from the datashare by querying [SVV_REDSHIFT_DATABASES](#) view. You can't connect to these databases created from datashares, and they are read-only. However, you can connect to a local database on your consumer cluster and perform a cross-database query on the data from the databases created from datashares. You can't create a datashare on top of database objects created from an existing datashare. However, you can copy the data into a separate table on the consumer cluster, perform any processing needed, and then share the new objects created.

3. (Optional) Create external schemas to refer and assign granular permissions to specific schemas in the consumer database imported on the consumer cluster. For more information, see [CREATE EXTERNAL SCHEMA](#).

```
CREATE EXTERNAL SCHEMA sales_schema FROM REDSHIFT DATABASE 'sales_db' SCHEMA  
'public';
```

4. Grant permissions on databases and schema references created from the datashares to user or roles in the consumer cluster as needed. For more information, see [GRANT](#) or [REVOKE](#).

```
GRANT USAGE ON DATABASE sales_db TO Bob;
```

```
GRANT USAGE ON SCHEMA sales_schema TO ROLE Analyst_role;
```

If you created your database without WITH PERMISSIONS, you can only assign permissions on the entire database created from the datashare to your users or roles. In some cases, you need fine-grained controls on a subset of database objects created from the datashare. If so,

you can create an external schema reference pointing to specific schemas in the datashare, as described in the previous step. You can then provide granular permissions at the schema level. You can also create late-binding views on top of shared objects and use these to assign granular permissions. You can also consider having producer clusters create additional datashares for you with the granularity required. You can create as many schema references to the database created from the datashare as you need.

If you created your database with `WITH PERMISSIONS` in step 2, you must assign object-level permissions for objects in the shared database. A user with only the `USAGE` permission can't access any objects in a database created with `WITH PERMISSIONS` until they're granted additional object-level permissions..

```
GRANT SELECT ON sales_db.public.ticket_sales_redshift to Bob;
```

5. Query data in the shared objects in the datashares.

Users and roles with permissions on consumer databases and schemas on consumer clusters can explore and navigate the metadata of any shared objects. They can also explore and navigate local objects in a consumer cluster. To do this, use JDBC or ODBC drivers or `SVV_ALL` and `SVV_REDSHIFT` views.

Producer clusters might have many schemas in the database, tables, and views within each schema. The users on the consumer side can see only the subset of objects that are made available through the datashare. These users can't see all the metadata from the producer cluster. This approach helps provide granular metadata security control with data sharing.

You continue to connect to local cluster databases. But now, you can also read from the databases and schemas that are created from the datashare using the three-part `database.schema.table` notation. You can perform queries that span across any and all databases that are visible to you. These can be local databases on the cluster or databases created from the datashares. Consumer clusters can't connect to the databases created from the datashares.

You can access the data using full qualification. For more information, see [Cross-database query examples](#).

```
SELECT * FROM sales_db.public.ticket_sales_redshift;
```

You can only use `SELECT` statements on shared objects. However, you can create tables in the consumer cluster by querying the data from the shared objects in a different local database.

In addition to performing queries, consumers can create views on shared objects. Only late-binding views and materialized views are supported. Amazon Redshift doesn't support regular views on shared data. Views that consumers create can span across multiple local databases or databases created from datashares. For more information, see [CREATE VIEW](#).

```
// Connect to a local cluster database

// Create a view on shared objects and access it.
CREATE VIEW sales_data
AS SELECT *
FROM sales_db.public.tickit_sales_redshift
WITH NO SCHEMA BINDING;

SELECT * FROM sales_data;
```

Sharing data across AWS Regions

You can share data for read purposes across Amazon Redshift clusters in AWS Regions. With cross-Region data sharing, you can share data across AWS Regions without the need to copy data manually. You don't have to unload your data into Amazon S3 and copy the data into a new Amazon Redshift cluster or perform cross-Region snapshot copy.

With cross-Region data sharing, you can share data across clusters in the same AWS account, or in different AWS accounts even when the clusters are in different Regions. When sharing data with Amazon Redshift clusters that are in the same AWS account but different AWS Regions, follow the same workflow as sharing data within an AWS account. For more information, see [Sharing read access to data within an AWS account](#).

If clusters sharing data are in different AWS accounts and AWS Regions, you can follow the same workflow as sharing data across AWS accounts and include Region-level associations on the consumer cluster. Cross-Region data sharing supports datashare association with the entire AWS account, the entire AWS Region, or specific cluster namespaces within an AWS Region. For more information about sharing data across AWS accounts, see [Sharing data across AWS accounts](#).

When consuming data from a different Region, the consumer pays the Cross-Region data transfer fee from the producer region to the consumer region.

To use the datashare, a consumer account administrator can associate the datashare in one of the following three ways.

- Association with an entire AWS account spanning all its AWS Regions
- Association with a specific AWS Region in an AWS account
- Association with specific cluster namespaces within an AWS Region

When the administrator chooses the entire AWS account, all existing and future cluster namespaces across different AWS Regions in the account have access to the datashares. A consumer account administrator can also choose specific AWS Regions or cluster namespaces within a Region to grant them access to the datashares.

If you are a producer cluster administrator or database owner, create a datashare, add database objects and data consumers to the datashare, and grant permissions to data consumers. For more information, see [Producer cluster administrator actions](#).

If you are a producer account administrator, authorize datashares using the AWS Command Line Interface (AWS CLI) or the Amazon Redshift console and choose the data consumers.

If you are a consumer account administrator – follow these steps:

To associate one or more datashares that are shared from other accounts to your entire AWS account or specific AWS Regions or cluster namespaces within an AWS Region, use the Amazon Redshift console.

With cross-Region datasharing, you can add clusters in a specific AWS Region using the AWS Command Line Interface (AWS CLI) or Amazon Redshift console.

To specify one or more AWS Regions, you can use the `associate-data-share-consumer` CLI command with the optional `consumer-region` option.

With the CLI, the following example associates the `Salesshare` with the entire AWS account with the `associate-entire-account` option. You can only associate one Region at a time.

```
aws redshift associate-data-share-consumer
--region {PRODUCER_REGION}
--data-share-arn arn:aws:redshift:{PRODUCER_REGION}:{PRODUCER_ACCOUNT}:datashare:
{PRODUCER_CLUSTER_NAMESPACE}/Salesshare
--associate-entire-account
```

The following example associates the `Salesshare` with the US East (Ohio) Region (`us-east-2`).

```
aws redshift associate-data-share-consumer
```

```
--region {PRODUCER_REGION}
--data-share-arn arn:aws:redshift:{PRODUCER_REGION}:0123456789012:datashare:
{PRODUCER_CLUSTER_NAMESPACE}/Salesshare
--consumer-region 'us-east-2'
```

The following example associates the Salesshare with a specific consumer cluster namespace in another AWS account in the Asia Pacific (Sydney) Region (ap-southeast-2).

```
aws redshift associate-data-share-consumer
--data-share-arn arn:aws:redshift:{PRODUCER_REGION}:{PRODUCER_ACCOUNT}:datashare:
{PRODUCER_CLUSTER_NAMESPACE}/Salesshare
--consumer-arn 'arn:aws:redshift:ap-southeast-2:{CONSUMER_ACCOUNT}:namespace:
{ConsumerImmutableClusterId}'
```

You can use the Amazon Redshift console to associate datashares with your entire AWS account or specific AWS Regions or cluster namespaces within an AWS Region. To do this, sign in to the <https://console.aws.amazon.com/redshiftv2/>. Then associate one or more datashares that are shared from other accounts with your entire AWS account, the entire AWS Region, or a specific cluster namespace within an AWS Region. For more information, see [Associating datashares](#).

After the AWS account or specific cluster namespaces are associated, the datashares become available for consumption. You can also change datashare association at any time. When changing association from individual cluster namespaces to an AWS account, Amazon Redshift overwrites the cluster namespaces with the AWS account information. When changing association from an AWS account to specific cluster namespaces, Amazon Redshift overwrites the AWS account information with the cluster namespace information. When changing association from an entire AWS account to specific AWS Regions and cluster namespaces, Amazon Redshift overwrites the AWS account information with the specific Region and cluster namespace information.

If you are a consumer cluster administrator, you can create local databases that reference to the datashares and grant permissions on databases created from the datashares to user or roles in the consumer cluster as needed. You can also create views on shared objects and create external schemas to refer and assign granular permissions to specific schemas in the consumer database imported on the consumer cluster. For more information, see [Consumer cluster administrator actions](#).

Managing cost control for cross-Region data sharing

With Amazon Redshift, you can manage cost control for cross-Region data sharing by configuring data sharing to limit the amount of data that is transferred between AWS Regions. Managing cost

control for cross-Region data sharing allows you to set data transfer limits, monitor data transfer usage, and receive notifications when approaching or exceeding those limits.

When consuming data from a different Region, the consumer pays the Cross-Region data transfer fee from the producer Region to the consumer Region. The price of data transfer is different for different Regions. The charge is based on the bytes of data scanned for every successful query run. For more information about Amazon Redshift pricing, see [Amazon Redshift pricing](#).

You are charged for the number of bytes, rounded up to the next megabyte, with a 10MB minimum per query. You can set cost controls on your query usage and view the amount of data being transferred per query on your cluster.

To monitor and control your usage and associated cost of using cross-Region data sharing, you can create daily, weekly, monthly usage limits, and define actions that Amazon Redshift automatically takes if those limits are reached to help maintain your budget with predictability. For more information about usage limits in Amazon Redshift, see [Managing usage limits in Amazon Redshift](#).

Depending on the usage limits you set, actions that Amazon Redshift takes can be to log an event to a system table, send a CloudWatch alarm and notify an administrator with an Amazon SNS, or to turn off cross-Region data sharing for further usage. For more information about the actions, see [Managing usage limits in Amazon Redshift](#).

To create usage limits in the Amazon Redshift console, choose **Configure usage limit** under **Actions** for your cluster. You can monitor your usage trends and get alerts on usage exceeding your defined limits with automatically generated CloudWatch metrics from the **Cluster performance** or **Monitoring** tabs. You can also create, modify, and delete usage limits programmatically by using the AWS CLI or Amazon Redshift API operations. For more information, see [Managing usage limits in Amazon Redshift](#).

Sharing licensed Amazon Redshift data on AWS Data Exchange

When creating AWS Data Exchange datashares and adding them to an AWS Data Exchange product, providers can license data in Amazon Redshift that consumers can discover, subscribe to, and query up-to-date data in Amazon Redshift when they have active AWS Data Exchange subscriptions.

With AWS Data Exchange datashares added to an AWS Data Exchange product, consumers automatically have access to a product's datashares when their subscription starts and retain their access as long as their subscription is active.

Working with AWS Data Exchange datashares as a producer

With Amazon Redshift, you can share live data products with AWS Data Exchange as a producer by creating and managing datashares.

If you are a producer cluster administrator, follow these steps to manage AWS Data Exchange datashares on the Amazon Redshift console:

1. Create datashares in your cluster to share data on AWS Data Exchange and grant access to AWS Data Exchange to the datashares.

Cluster superuser and database owners can create datashares. Each datashare is associated with a database during creation. Only objects from that database can be shared in that datashare. Multiple datashares can be created on the same database with the same or different granularity of objects. There is no limit on the number of datashares you can create on a cluster.

You can also use the Amazon Redshift console to create datashares. For more information, see [Creating datashares](#).

Use the `MANAGEDBY ADX` option to implicitly grant access of the datashare to AWS Data Exchange when running the `CREATE DATASHARE` statement. This indicates that AWS Data Exchange manages this datashare. You can only use the `MANAGEDBY ADX` option when you create a new datashare. You can't use the `ALTER DATASHARE` statement to modify an existing datashare to add the `MANAGEDBY ADX` option. Once a datashare is created with the `MANAGEDBY ADX` option, only AWS Data Exchange can access and manage the datashare.

```
CREATE DATASHARE salesshare
[[SET] MANAGEDBY [=] {ADX} ];
```

2. Add objects to the datashares. Producer administrator continues to manage datashare objects that are available in an AWS Data Exchange datashare.

To add objects to a datashare, add the schema before adding objects. When you add a schema, Amazon Redshift doesn't add all the objects under it. You must add them explicitly. For more information, see [ALTER DATASHARE](#).

```
ALTER DATASHARE salesshare ADD SCHEMA PUBLIC;  
ALTER DATASHARE salesshare ADD TABLE public.tickit_sales_redshift;  
ALTER DATASHARE salesshare ADD ALL TABLES IN SCHEMA PUBLIC;
```

You can also add views to a datashare.

```
CREATE VIEW public.sales_data_summary_view AS SELECT * FROM  
public.tickit_sales_redshift;  
ALTER DATASHARE salesshare ADD TABLE public.sales_data_summary_view;
```

Use ALTER DATASHARE to share schemas, and tables, views, and functions in a given schema. Superusers, datashare owners, or users who have ALTER or ALL permissions on the datashare can alter the datashare to add objects to or remove objects from it. Users should have the permissions to add or remove objects from the datashare. Users should also be the owners of the objects or have SELECT, USAGE, or ALL permissions on the objects.

Use the INCLUDENEW clause to add any new tables, views, or SQL user-defined functions (UDFs) created in a specified schema to the datashare. Only superusers can change this property for each datashare-schema pair.

```
ALTER DATASHARE salesshare ADD SCHEMA PUBLIC;  
ALTER DATASHARE salesshare SET INCLUDENEW = TRUE FOR SCHEMA PUBLIC;
```

You can also use the Amazon Redshift console to add or remove objects from datashares. For more information, see [Adding datashare objects to datashares](#), [Removing datashare objects from datashares](#), and [Editing AWS Data Exchange datashares](#).

3. To authorize access to the datashares for AWS Data Exchange, do one of the following:
 - Explicitly authorize access to the datashare for AWS Data Exchange by using the ADX keyword in the `aws redshift authorize-data-share` API. This allows AWS Data Exchange to recognize the datashare in the service account and manage associating consumers to the datashare.

```
aws redshift authorize-data-share
--data-share-arn arn:aws:redshift:us-east-1:{PRODUCER_ACCOUNT}:datashare:
{PRODUCER_CLUSTER_NAMESPACE}/salesshare
--consumer-identifier ADX
```

You can use a conditional key `ConsumerIdentifier` for the `AuthorizeDataShare` and `DeauthorizeDataShare` APIs to explicitly allow or deny AWS Data Exchange to make calls to the two APIs in the IAM policy.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "VisualEditor0",
      "Effect": "Deny",
      "Action": [
        "redshift:AuthorizeDataShare",
        "redshift:DeauthorizeDataShare"
      ],
      "Resource": "*",
      "Condition": {
        "StringEqualsIgnoreCase": {
          "redshift:ConsumerIdentifier": "ADX"
        }
      }
    }
  ]
}
```

- Use the Amazon Redshift console to authorize or remove authorization of AWS Data Exchange datashares. For more information, see [Authorizing or removing authorization from datashares](#).
- Optionally, you can implicitly authorize access to the AWS Data Exchange datashare when importing the datashare into an AWS Data Exchange dataset.

To remove authorization for access to the AWS Data Exchange datashares, use the `ADX` keyword in the `aws redshift deauthorize-data-share` API operation. By doing this, you allow AWS Data Exchange to recognize the datashare in the service account and manage removing association from the datashare.

```
aws redshift deauthorize-data-share
--data-share-arn arn:aws:redshift:us-east-1:{PRODUCER_ACCOUNT}:datashare:
{PRODUCER_CLUSTER_NAMESPACE}/salesshare
--consumer-identifier ADX
```

- List datashares created in the cluster and look into the contents of the datashare.

The following example displays the information of a datashare named salesshare. For more information, see [DESC DATASHARE](#) and [SHOW DATASHARES](#).

```
DESC DATASHARE salesshare;
```

producer_account	producer_namespace	share_type	share_name
object_type	object_name	include_new	
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_users_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_venue_redshift

table	public.tickit_category_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_date_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_event_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_listing_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
table	public.tickit_sales_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
schema	public	t	
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	OUTBOUND	salesshare
view	public.sales_data_summary_view		

The following example displays the outbound datashares in a producer cluster.

```
SHOW DATASHARES LIKE 'sales%';
```

The output looks similar to the following.

```

share_name | share_owner | source_database | consumer_database | share_type |
createdate | is_publicaccessible | share_acl | producer_account |
producer_namespace
-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
salesshare | 100 | dev | | OUTBOUND
| 2020-12-09 02:27:08 | True | | 123456789012 |
13b8833d-17c6-4f16-8fe4-1a018f5ed00d

```

For more information, see [DESC DATASHARE](#) and [SHOW DATASHARES](#).

You can also use [SVV_DATASHARES](#), [SVV_DATASHARE_CONSUMERS](#), and [SVV_DATASHARE_OBJECTS](#) to view the datashares, the objects within the datashare, and the datashare consumers.

- Drop datashares. We recommend that you don't delete an AWS Data Exchange datashare shared to other AWS accounts using the DROP DATASHARE statement. Those accounts will lose access to the datashare. This action is irreversible. This might breach data product offer terms in AWS Data Exchange. If you want to delete an AWS Data Exchange datashare, see [DROP DATASHARE usage notes](#).

The following example drops a datashare named salesshare.

```

DROP DATASHARE salesshare;
ERROR: Drop of ADX-managed datashare salesshare requires session variable
datashare_break_glass_session_var to be set to value '620c871f890c49'

```

To allow dropping an AWS Data Exchange datashare, set the `datashare_break_glass_session_var` variable and run the DROP DATASHARE statement again. If you want to delete an AWS Data Exchange datashare, see [DROP DATASHARE usage notes](#).

You can also use the Amazon Redshift console to delete datashares. For more information, see [Deleting AWS Data Exchange datashares created in your account](#).

- Use ALTER DATASHARE to remove objects from datashares at any point from the datashare. Use REVOKE USAGE ON to revoke permissions on the datashare to certain consumers. It revokes USAGE permissions on objects within a datashare and instantly stops access to all consumer clusters. Listing datashares and the metadata queries, such as listing databases and tables, doesn't return the shared objects after access is revoked.

```
ALTER DATASHARE salesshare REMOVE TABLE public.tickit_sales_redshift;
```

You can also use the Amazon Redshift console to edit datashares. For more information, see [Editing AWS Data Exchange datashares](#).

7. Grant or revoke GRANT USAGE from AWS Data Exchange datashares. You can't grant or revoke GRANT USAGE for AWS Data Exchange datashare. The following example shows an error when the GRANT USAGE permission is granted to an AWS account for a datashare that AWS Data Exchange manages.

```
CREATE DATASHARE salesshare MANAGEDBY ADX;
```

```
GRANT USAGE ON DATASHARE salesshare TO ACCOUNT '012345678910';  
ERROR: Permission denied to add/remove consumer to/from datashare salesshare.  
Datashare consumers are managed by ADX.
```

For more information, see [GRANT](#) or [REVOKE](#).

If you are a producer cluster administrator, follow these steps to create and publish a datashare product on the AWS Data Exchange console:

- When the AWS Data Exchange datashare has been created, the producer creates a new dataset, imports assets, creates a revision, and creates and publishes a new product.

Use the Amazon Redshift console to create datasets. For more information, see [Creating data sets on AWS Data Exchange](#).

For more information, see [Providing data products on AWS Data Exchange](#).

Working with AWS Data Exchange datashares as a consumer

With Amazon Redshift, you can access and analyze datasets from AWS Data Exchange without having to store or manage copies of the data.

If you are a consumer, follow these steps to discover data products that contain AWS Data Exchange datashares and query Amazon Redshift data:

1. On the AWS Data Exchange console, discover and subscribe to data products that contains AWS Data Exchange datashares.

Once your subscription starts, you can access licensed Amazon Redshift data that is imported as assets to datasets that contain AWS Data Exchange datashares.

For more information on how to get started with using data products that contain AWS Data Exchange datashares, see [Subscribing to data products on AWS Data Exchange](#).

2. On the Amazon Redshift console, create an Amazon Redshift cluster, if needed.

For information on how to create a cluster, see [Creating a cluster](#).

3. List the datashares that are made available to you and view the content of datashares. For more information, see [DESC DATASHARE](#) and [SHOW DATASHARES](#).

The following example displays the information of inbound datashares of a specified producer namespace. When you run `DESC DATASHARE` as a consumer cluster administrator, you must specify the `ACCOUNT` and `NAMESPACE` option to view inbound datashares.

```
DESC DATASHARE salesshare of ACCOUNT '123456789012' NAMESPACE
'13b8833d-17c6-4f16-8fe4-1a018f5ed00d';
```

producer_account	producer_namespace	share_type	share_name
object_type	object_name	include_new	
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_users_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_venue_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_category_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_date_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_event_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_listing_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
table	public.tickit_sales_redshift		
123456789012	13b8833d-17c6-4f16-8fe4-1a018f5ed00d	INBOUND	salesshare
schema	public		

```
123456789012 | 13b8833d-17c6-4f16-8fe4-1a018f5ed00d | INBOUND | salesshare
| view | public.sales_data_summary_view |
```

Only cluster superusers can do this. You can also use `SVV_DATASHARES` to view the datashares and `SVV_DATASHARE_OBJECTS` to view the objects within the datashare.

The following example displays the inbound datashares in a consumer cluster.

```
SHOW DATASHARES LIKE 'sales%';
```

```
share_name | share_owner | source_database | consumer_database | share_type
| createdate | is_publicaccessible | share_acl | producer_account |
producer_namespace
-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
salesshare | | | | INBOUND
| | t | | 123456789012 |
13b8833d-17c6-4f16-8fe4-1a018f5ed00d
```

4. Create local databases that reference to the datashares. You must specify the `ACCOUNT` and `NAMESPACE` option to create local databases for AWS Data Exchange datashares. For more information, see [CREATE DATABASE](#).

```
CREATE DATABASE sales_db FROM DATASHARE salesshare OF ACCOUNT '123456789012'
NAMESPACE '13b8833d-17c6-4f16-8fe4-1a018f5ed00d';
```

If you want more granular control over access to the objects in the local database, use the `WITH PERMISSIONS` clause when creating the database. This lets you grant object-level permissions for objects in the database in step 6.

```
CREATE DATABASE sales_db WITH PERMISSIONS FROM DATASHARE salesshare OF ACCOUNT
'123456789012' NAMESPACE '13b8833d-17c6-4f16-8fe4-1a018f5ed00d';
```

You can see databases that you created from the datashare by querying the [SVV_REDSHIFT_DATABASES](#) view. You can't connect to these databases created from datashares, and they are read-only. However, you can connect to a local database on your consumer cluster and perform a cross-database query on the data from the databases created from datashares. You can't create a datashare on top of database objects created from an

existing datashare. However, you can copy the data into a separate table on the consumer cluster, perform any processing needed, and then share the new objects that were created.

You can also use the Amazon Redshift console to create databases from datashares. For more information, see [Creating databases from datashares](#).

5. (Optional) Create external schemas to refer to and assign granular permissions to specific schemas in the consumer database imported on the consumer cluster. For more information, see [CREATE EXTERNAL SCHEMA](#).

```
CREATE EXTERNAL SCHEMA sales_schema FROM REDSHIFT DATABASE 'sales_db' SCHEMA 'public';
```

6. Grant permissions on databases and schema references created from the datashares to user or roles in the consumer cluster as needed. For more information, see [GRANT](#) or [REVOKE](#).

```
GRANT USAGE ON DATABASE sales_db TO Bob;
```

```
GRANT USAGE ON SCHEMA sales_schema TO ROLE Analyst_role;
```

If you created your database without `WITH PERMISSIONS`, you can only assign permissions on the entire database created from the datashare to your users and roles. In some cases, you need fine-grained controls on a subset of database objects created from the datashare. If so, you can create an external schema reference that points to specific schemas in the datashare (as described in the previous step) and provide granular permissions at schema level.

You can also create late-binding views on top of shared objects and use these to assign granular permissions. You can also consider having producer clusters create additional datashares for you with the granularity required. You can create as many schema references to the database created from the datashare as you need.

If you created your database with `WITH PERMISSIONS` in step 4, you must assign object-level permissions for objects in the shared database. A user with only the `USAGE` permission can't access any objects in a database created with `WITH PERMISSIONS` until they're granted additional object-level permissions..

```
GRANT SELECT ON sales_db.public.tickit_sales_redshift to Bob;
```

7. Query data in the shared objects in the datashares.

Users and roles with permissions on consumer databases and schemas on consumer clusters can explore and navigate the metadata of any shared objects. They can also explore and navigate local objects in a consumer cluster. To do this, they use JDBC or ODBC drivers or SVV_ALL and SVV_REDSHIFT views.

Producer clusters might have many schemas in the database, tables, and views within each schema. The users on the consumer side can see only the subset of objects that are made available through the datashare. These users can't see the entire metadata from the producer cluster. This approach helps provide granular metadata security control with data sharing.

You continue to connect to local cluster databases. But now, you can also read from the databases and schemas that are created from the datashare using the three-part database.schema.table notation. You can perform queries that span across any and all databases that are visible to you. These can be local databases on the cluster or databases created from the datashares. Consumer clusters can't connect to the databases created from the datashares.

You can access the data using full qualification. For more information, see [Cross-database query examples](#).

```
SELECT * FROM sales_db.public.tickit_sales_redshift ORDER BY 1,2 LIMIT 5;
```

salesid	listid	sellerid	buyerid	eventid	dateid	qtysold	pricepaid	commission	saletime
1	1	36861	21191	7872	1875	4	728.00	109.20	2008-02-18 02:36:48
2	4	8117	11498	4337	1983	2	76.00	11.40	2008-06-06 05:00:16
3	5	1616	17433	8647	1983	2	350.00	52.50	2008-06-06 08:26:17
4	5	1616	19715	8647	1986	1	175.00	26.25	2008-06-09 08:38:52
5	6	47402	14115	8240	2069	2	154.00	23.10	2008-08-31 09:17:02

You can only use SELECT statements on shared objects. However, you can create tables in the consumer cluster by querying the data from the shared objects in a different local database.

In addition to queries, consumers can create views on shared objects. Only late-binding views or materialized views are supported. Amazon Redshift doesn't support regular views on shared data. Views that consumers create can span across multiple local databases or databases created from datashares. For more information, see [CREATE VIEW](#).

```
// Connect to a local cluster database

// Create a view on shared objects and access it.
CREATE VIEW sales_data
AS SELECT *
FROM sales_db.public.tickit_sales_redshift
WITH NO SCHEMA BINDING;

SELECT * FROM sales_data;
```

Working with AWS Lake Formation-managed datashares

With Amazon Redshift, you can access and analyze data shared through AWS Lake Formation datashares. AWS Lake Formation datashares enable secure data sharing across AWS accounts and Amazon Redshift clusters without having to copy or move the underlying data.

Sharing data to AWS Lake Formation lets you centrally define AWS Lake Formation permissions of Amazon Redshift datashares and restrict user access to objects within a datashare.

Topics

- [Working with Lake Formation-managed datashares as a producer](#)
- [Working with Lake Formation-managed datashares as a consumer](#)

Working with Lake Formation-managed datashares as a producer

With Amazon Redshift, you can securely share live data across AWS accounts and Amazon Redshift clusters using AWS Lake Formation-managed datashares as a producer. A Lake Formation-managed datashare is an object that allows you to share live data from your Amazon Redshift cluster with other AWS accounts and services.

As a producer cluster or workgroup administrator, follow these steps to share datashares to Lake Formation:

1. Create datashares in your cluster and authorize AWS Lake Formation to access the datashares.

Only cluster superuser and database owners can create datashares. Each datashare is associated with a database during creation. Only objects from that database can be shared in that datashare. Multiple datashares can be created on the same database with the same or different granularity of objects. There is no limit on the number of datashares you can create on a cluster.

```
CREATE DATASHARE salesshare;
```

2. Add objects to the datashare. The producer cluster or workgroup administrator continues to manage datashare objects that are available. To add objects to a datashare, add the schema before adding objects. When you add a schema, Amazon Redshift doesn't add all the objects under it. You must add them explicitly. For more information, see [ALTER DATASHARE](#).

```
ALTER DATASHARE salesshare ADD SCHEMA PUBLIC;  
ALTER DATASHARE salesshare ADD TABLE public.tickit_sales_redshift;  
ALTER DATASHARE salesshare ADD ALL TABLES IN SCHEMA PUBLIC;
```

You can also add views to a datashare. Supported views are standard views, late binding views, and materialized views.

```
CREATE VIEW public.sales_data_summary_view AS SELECT * FROM  
public.tickit_sales_redshift;  
ALTER DATASHARE salesshare ADD TABLE public.tickit_sales_redshift;
```

Use ALTER DATASHARE to share schemas, tables, and views, in a given schema. Superusers, datashare owners, or users who have ALTER or ALL permissions on the datashare can alter the datashare to add objects to or remove objects from it. Database users should be the owners of the objects or have SELECT, USAGE, or ALL permissions on the objects.

Use the INCLUDENEW clause to add any new tables and views created in a specified schema to the datashare. Only superusers can change this property for each datashare-schema pair.

```
ALTER DATASHARE salesshare ADD SCHEMA PUBLIC;  
ALTER DATASHARE salesshare SET INCLUDENEW = TRUE FOR SCHEMA PUBLIC;
```

3. Grant access of the datashare to a Lake Formation administrator account.

```
GRANT USAGE ON DATASHARE salesshare TO ACCOUNT '012345678910' VIA DATA CATALOG;
```

To revoke usage, use the following command.

```
REVOKE USAGE ON DATASHARE salesshare FROM ACCOUNT '012345678910' VIA DATA CATALOG;
```

4. Authorize access to the datashare for Lake Formation by using the `aws redshift authorize-data-share` API operation. Doing so lets Lake Formation recognize the datashare in the service account and manage associating consumers to the datashare.

```
aws redshift authorize-data-share
--data-share-arn arn:aws:redshift:us-east-1:{PRODUCER_ACCOUNT}:datashare:
{PRODUCER_CLUSTER_NAMESPACE}/salesshare
--consumer-identifier {"DataCatalog/<consumer-account-id>"}
```

To remove authorization from Lake Formation-managed datashares, use the `aws redshift deauthorize-data-share` API operation. By doing so, you allow AWS Lake Formation to recognize the datashare in the service account and remove authorization.

```
aws redshift deauthorize-data-share
--data-share-arn arn:aws:redshift:us-east-1:{PRODUCER_ACCOUNT}:datashare:
{PRODUCER_CLUSTER_NAMESPACE}/salesshare
--consumer-identifier {"DataCatalog/<consumer-account-id>"}
```

At any time, if the producer cluster or workgroup administrator decides that there is no longer a need to share data with the consumer cluster or workgroup, they can use `DROP DATASHARE` to delete the datashare, `deauthorize` the datashare, or `revoke` datashare permissions. The associated permissions and objects in Lake Formation are not automatically deleted.

```
DROP DATASHARE salesshare;
```

After authorizing the Lake Formation account to manage the datashare, the Lake Formation administrator can discover the shared datashare, associate the datashare with an Data Catalog ARN, and create a database in the AWS Glue Data Catalog linking to the datashare. To associate datashares using the AWS CLI, use the command [associate-data-share-consumer](#). To share a datashare across AWS Regions, specify the `--region` parameter in the `associate-data-share-consumer` command or use the AWS console to choose your data consumers.

The following example demonstrates how to share a Lake Formation-managed datashare across Regions.

```
aws redshift associate-data-share-consumer --region <region-1>
--data-share-arn 'arn:aws:redshift:us-
east-1:12345678912:datashare:035c45ea-61ce-86f0-8b75-19ac6102c3b7/sample_share'
--consumer-arn 'arn:aws:glue:<region-1>:111912345678:catalog'
```

The Lake Formation administrator must also create local resources that define how objects within the datashare should map to objects within Lake Formation. For more information about discovering datashares and creating local resources, see [Managing permissions for data in an Amazon Redshift datashare](#).

Working with Lake Formation-managed datashares as a consumer

With Amazon Redshift, you can access and analyze data shared with you through AWS Lake Formation datashares. A datashare is a data product that contains a collection of data objects, such as tables or databases, from different data sources.

After the AWS Lake Formation administrator discovers the datashare invitation and creates a database in the AWS Glue Data Catalog that links to the datashare, the consumer cluster or workgroup administrator can associate the cluster with the datashare and the database in the AWS Glue Data Catalog, create a database local to the consumer cluster or workgroup, and grant access to users and roles in the Amazon Redshift consumer cluster or workgroup to start querying. Follow these steps to set up querying permissions.

1. On the Amazon Redshift console, create a Redshift cluster to serve as the consumer cluster or workgroup, if needed. For information on how to create a cluster, see [Creating a cluster](#).
2. To list which databases in the AWS Glue Data Catalog consumer cluster or workgroup users have access to, run the [SHOW DATABASES](#) command.

```
SHOW DATABASES FROM DATA CATALOG [ACCOUNT <account-id>,<account-id2>] [LIKE
<expression>]
```

Doing so lists the resources that are available from the Data Catalog, such as the AWS Glue database's ARN, database name, and information about the datashare.

3. Using the AWS Glue database ARN from SHOW DATABASES, create a local database in the consumer cluster or workgroup. For more information, see [CREATE DATABASE](#).

```
CREATE DATABASE lf_db FROM ARN <lake-formation-database-ARN> WITH [NO] DATA CATALOG
SCHEMA [<schema>];
```

- Grant access on databases and schema references created from the datashares to users and roles in the consumer cluster or workgroup as needed. For more information, see [GRANT](#) or [REVOKE](#). Note that users created from the [CREATE USER](#) command cannot access objects in datashare that have been shared to Lake Formation. Only users with access to both Redshift and Lake Formation can access datashares that have been shared with Lake Formation.

```
GRANT USAGE ON DATABASE sales_db TO IAM:Bob;
```

As a consumer cluster or workgroup administrator, you can only assign permissions on the entire database created from the datashare to your users and roles. In some cases, you need fine-grained controls on a subset of database objects created from the datashare.

You can also create late-binding views on top of shared objects and use these to assign granular permissions. You can also consider having producer clusters or workgroups create additional datashares for you with the granularity required. You can create as many schema references to the database created from the datashare.

- Database users can use the views `SVV_EXTERNAL_TABLES` and `SVV_EXTERNAL_COLUMNS` to find all of the shared tables or columns within the AWS Glue database

```
SELECT * from svv_external_tables WHERE redshift_database_name = 'lf_db';

SELECT * from svv_external_columns WHERE redshift_database_name = 'lf_db';
```

- Query data in the shared objects in the datashares.

Users and roles with permissions on consumer databases and schemas on consumer clusters or workgroups can explore and navigate the metadata of any shared objects. They can also explore and navigate local objects in a consumer cluster or workgroup. To do so, they can use the JDBC or ODBC drivers or the `SVV_ALL` and `SVV_EXTERNAL` views.

```
SELECT * FROM lf_db.schema.table;
```

You can only use `SELECT` statements on shared objects. However, you can create tables in the consumer cluster by querying the data from the shared objects in a different local database.

```
// Connect to a local cluster database

// Create a view on shared objects and access it.

CREATE VIEW sales_data
AS SELECT *
FROM sales_db.public.tickit_sales_redshift
WITH NO SCHEMA BINDING;

SELECT * FROM sales_data;
```

Managing data sharing using the console

With Amazon Redshift, you can manage data sharing with writes using the console to control access and govern data across Amazon Redshift clusters and AWS accounts. The following sections provide step-by-step instructions on configuring and managing data sharing with writes using the Amazon Redshift console.

Use the Amazon Redshift console to manage datashares created in your account or shared from other accounts.

You need permissions to create, edit, or delete datashares. For information, see [Managing permissions for datashares in Amazon Redshift](#).

- If you are a producer cluster administrator, you can create datashares, add data consumers, add datashare objects, create databases from datashares, edit datashares, or delete datashares from the **CLUSTERS** tab.

From the navigation menu, navigate the **Clusters** tab, choose a cluster from the cluster list. Then do one of the following:

- Choose the **Datashares** tab, choose a datashare from the **Datashares created in my namespace** section. Then do one of the following:
 - [Creating datashares](#)

When a datashare is created, you can add datashare objects or data consumers. For more information, see [Adding datashare objects to datashares](#) and [Adding data consumers to datashares](#).

- [Editing datashares created in your account](#)
- [Deleting datashares created in your account](#)
- Choose **Datashares** and choose a datashare from the **Datashares from other clusters** section. Then do one of the following:
 - [Creating datashares](#)
 - [Creating databases from datashares](#)
- Choose **Databases** and choose a database from the **Databases** section. Then choose **Create datashare**. For more information, see [Creating databases from datashares](#).

 **Note**

To view databases and objects within databases or to view datashares in the cluster, connect to a database. For more information, see [Connecting to a database](#).

Connecting to a database

With Amazon Redshift, you can establish a connection to your data warehouse cluster and execute SQL queries, load data, or perform administrative tasks. Connecting to a database refers to the process of creating a secure channel between a client application or tool and the Amazon Redshift cluster. The following sections will provide step-by-step instructions on how to connect to an Amazon Redshift database.

Connect to a database to view databases and objects within databases in this cluster or to view datashares.

The user credentials used to connect to a specified database must have the necessary permissions to view all datashares.

If there is no local connection, do one of the following:

- In the cluster details page, from the **Databases** tab, in the **Databases** or **Datashare objects** section, choose **Connect to database** to view database objects in the cluster.
- In the cluster details page, from the **Datashares** tab, do one of the following:
 - In the **Datashares from other clusters** section, choose **Connect to database** to view datashares from other clusters.

- In the **Datashares created in my cluster** section, choose **Connect to database** to view datashares in your cluster.
- On the **Connect to database** window, do one of the following:
 - If you choose **Create a new connection**, choose **AWS Secrets Manager** to use a stored secret to authenticate access for the connection.

Or, choose **Temporary credentials** to use database credentials to authenticate access for the connection. Specify values for **Database name** and **Database user**.

Choose **Connect**.

- Choose **Use a recent connection** to connect to another database that you have the necessary permissions.

Amazon Redshift automatically makes the connection.

After database connection is established, you can start creating datashares, querying datashares, or creating databases from datashares.

Creating datashares

With Amazon Redshift, you can share live data across Amazon Redshift clusters or AWS accounts using datashares. A datashare is a consumer-producer object that allows you to share live data from your Amazon Redshift cluster with other clusters or AWS accounts. Creating datashares enables secure data sharing while maintaining control over access and ensuring data remains up-to-date. The following sections provide details on creating datashares and adding database objects such as schemas, tables, and views to share live data securely.

Creating datashares

As a producer cluster administrator, you can create datashares from the **Databases** or **Datashares** tabs in the cluster details page.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. In the cluster details page, do one of the following:

- From the **Databases** tab, in the **Database** section, choose a database. The database details page appears.

Choose **Create datashare**. You can only create a datashare from a local database. If you haven't connected to the database, the Connect to database page appears. Follow the steps in [Connecting to a database](#) to connect to a database. If there is a recent connection, the Create datashare page appears.

- From the **Datashares** tab, in the **Datashares** section, connect to a database if you don't have a database connection.

In the **Datashares created in my cluster** section, choose **Create datashare**. The Create datashare page appears.

4. In the **Datashare information** section, choose one of the following:

- Choose **Datashare** to create datashares to share data for read purpose across different Amazon Redshift clusters or in the same AWS account or different AWS accounts.
- Choose **AWS Data Exchange datashare** to create datashares to license your data through AWS Data Exchange.

5. Specify values for **Datashare name**, **Database name**, and **Publicly accessible**.

When you change the database name, make a new database connection.

6. In the **Datashare objects** section, choose **Add**. The add datashare page appears. To add objects to a datashare, follow [Adding datashare objects to datashares](#).

7. In the **Data consumers** section, you can choose to publish to a Redshift account, or publish to the AWS Glue Data Catalog, which starts the process of sharing data via Lake Formation. Publishing your datashare to Redshift accounts means sharing your data with another Redshift account that acts as the consumer cluster.

 **Note**

Once the datashare is created, you can't edit the configuration to publish to the other option.

8. Choose **Create datashare**.

Amazon Redshift creates the datashare. After the datashare is created, you can create databases from the datashare.

Adding datashare objects to datashares

Add one or more objects to the datashare. Datashare objects are read-only for data consumers.

You can create a datashare without adding datashare objects and add objects later.

A datashare becomes active only when you add at least one object to the datashare.

1. Choose the datashare you want to add objects to from the datashare list.
2. Choose **Add**. The add datashare objects page appears.
3. Add at least one schema to the datashare before adding other datashare objects. Add multiple schemas by choosing **Add and repeat**.
4. You can choose to add all existing objects of chosen object types from the specified schema or add specific individual objects from the specified schema. Choose the **Object types**, such as tables and views or user-defined functions.
5. You can choose **Add and repeat** to add the specified schemas and datashare objects and continue to add another and objects.

Adding data consumers to datashares

You can add one or more data consumers to the datashares. Data consumers can be cluster namespaces that uniquely identified Amazon Redshift clusters or AWS accounts.

You must explicitly choose to turn off or turn on sharing your datashare to clusters with public access.

- Choose **Add cluster namespaces to the datashare**. Namespaces are globally unique identifier (GUID) for Amazon Redshift cluster.
- Choose **Add AWS accounts** to the datashare. The specified AWS accounts must have access permissions to the datashare.

Authorizing or removing authorization from datashares

As a producer cluster administrator, choose which data consumers to authorize to access datashares or to remove authorization from. Authorized data consumers receive notifications to take actions on datashares. If you are adding a cluster namespace as a data consumer, you don't have to perform authorization.

Prerequisite: To authorize or remove authorization for the datashare, there must be at least one data consumer added to the datashare.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Datashares**. The datashare list page appears.
3. Choose **In my account**.
4. In the **Datashares in my account** section, do one of the following:
 - Choose one or more consumer clusters that you want to authorize. The Authorize data consumers page appears. Then choose **Authorize**.

If you chose **Publish to AWS Glue Data Catalog** when creating the datashare, you can only grant authorization of the datashare to a Lake Formation account.

For AWS Data Exchange datashare, you can only authorize one datashare at a time.

When you authorize an AWS Data Exchange datashare, you are sharing the datashare with the AWS Data Exchange service and allowing AWS Data Exchange to manage access to the datashare on your behalf. AWS Data Exchange allows access to consumers by adding consumer accounts as data consumers to the AWS Data Exchange datashare when they subscribe to the products. AWS Data Exchange doesn't have read access to the datashare.

- Choose one or more consumer clusters that you want to remove authorization from. Then choose **Remove authorization**.

After data consumers are authorized, they can access datashare objects and create a consumer database to query the data.

After authorization is removed, data consumers lose access to the datashare immediately.

Managing datashares from other accounts as a consumer

With Amazon Redshift, you can consume datashares from other AWS accounts, enabling cross-account data sharing and collaboration. A datashare is a secure way to share live data across Amazon Redshift clusters, even if they are in different AWS accounts. The following sections provide detailed steps for configuring access, querying shared data, and monitoring datashare activity as a consumer.

Associating datashares

As a consumer cluster administrator, you can associate one or more datashares that are shared from other accounts to your entire AWS account or specific cluster namespaces in your account.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Datashares**. The datashare list page appears.
3. Choose **From other accounts**.
4. In the **Datashares from other accounts** section, choose the datashare that you want to associate and choose **Associate**. When the Associate datashare page appears, choose one of the following Association types:
 - Choose **Entire AWS account** to associate all existing and future cluster namespaces across different AWS Regions in your AWS account with the datashare. Then choose **Associate**.

If the datashare is published to the AWS Glue Data Catalog, you can only associate the datashare with the entire AWS account.

- Choose **Specific AWS Regions and cluster namespaces** to associate one or more AWS Regions and specific cluster namespaces with the datashare.
 - a. Choose **Add Region** to add specific AWS Regions and cluster namespaces to the datashare. The **Add AWS Region** page appears.
 - b. Choose an **AWS Region**.
 - c. Do one of the following:
 - Choose **Add all cluster namespaces** to add all existing and future cluster namespaces in this Region to the datashare.
 - Choose **Add specific cluster namespaces** to add one or more specific cluster namespaces in this Region to the datashare.
 - Choose one or more cluster namespaces and choose **Add AWS Region**.
 - d. Choose **Associate**.

If you're associating the datashare with a Lake Formation account, go to the Lake Formation console to create a database, then define permissions over the database. For more information, see [Setting up permissions for Amazon Redshift datashares](#) in the AWS Lake Formation Developer Guide. Once you create a AWS Glue database or a federated database, you can use query editor v2

or any preferred SQL client with your consumer cluster to query the data. For more information, see [Working with Lake Formation-managed datashares as a consumer](#).

After the datashare is associated, the datashares become available.

You can also change datashare association at any time. When changing association from specific AWS Regions and cluster namespaces to the entire AWS account, Amazon Redshift overwrites the specific Region and cluster namespaces information with AWS account information. All the AWS Regions and cluster namespaces in the AWS account then have access to the datashare.

When changing association from specific cluster namespaces to all cluster namespaces in the specified AWS Region, all cluster namespaces in this Region then have access to the datashare.

Removing association of datashare from data consumers

As a consumer cluster administrator, you can remove association of datashares from data consumers.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Datashares**. The datashare list page appears.
3. Choose **From other accounts**.
4. In the **Datashares from other accounts** section, choose the datashare to remove association from data consumers.
5. In the **Data consumers** section, choose one or more data consumers to remove association from. Then choose **Remove association**.
6. When the Remove association page appears, choose **Remove association**.

After association is removed, data consumers will lose access to the datashare. You can change the data consumer association at any time.

Declining datashares

As a consumer cluster administrator, you can reject any datashare whose state is [available or active](#). After you reject a datashare, consumer cluster users lose access to the datashare. Amazon Redshift doesn't return the rejected datashare if you call the `DescribeDataSharesForConsumer` API operation. If the producer cluster administrator runs the `DescribeDataSharesForProducer` API operation, they will see that the datashare was rejected. Once a datashare is rejected, the producer

cluster administrator can authorize the datashare to a consumer cluster again, and the consumer cluster administrator can choose to associate their AWS account with the datashare or reject it.

If your AWS account has an association to a datashare and a pending association to a datashare that's managed by Lake Formation, rejecting the datashare association that's managed by Lake Formation also rejects the original datashare. To reject a specific association, the producer cluster administrator can remove authorization from a specified datashare. This action doesn't affect other datashares.

To reject a datashare, use the AWS console, the API operation `RejectDataShare`, or `reject-datashare` in the AWS CLI.

To reject a datashare using the AWS console:

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. In the navigation menu, choose **Datashares**.
3. Choose **From other accounts**.
4. In the **Datashares from other accounts** section, choose the datashare you want to decline. When the **Decline datashare** page appears, choose **Decline**.

After you decline the datashares, you can't revert the change. Amazon Redshift removes the datashares from the list. To see the datashare again, the producer administrator must authorize it again.

Managing existing datashares

With Amazon Redshift, you can manage existing datashares to control access to your data in an Amazon Redshift cluster. The following sections provide step-by-step guidance on managing datashares in your Amazon Redshift environment.

Viewing datashares

View datashares from the **DATASHARES** or **CLUSTERS** tab.

- Use the **DATASHARES** tab to list datashares in your account or from other accounts.
 - To view datashares created in your account, choose **In my account**, then choose the datashare you want to view.

- To view datashares that are shared from other accounts, choose **From other accounts**, then choose the datashare you want to view.
- Use the **CLUSTERS** tab to list datashares in your cluster or from other clusters.

Connect to a database. For more information, see [Connecting to a database](#).

Then choose a datashare either from the **Datashares from other clusters** or **Datashares created in my cluster** section to view its details.

Removing datashare objects from datashares

You can remove one or more objects from a datashare by using the following procedure.

To remove one or more objects from a datashare

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**.
4. In the **Datashares created in my account** section, choose **Connect to database**. For more information, see [Connecting to a database](#).
5. Choose the datashare you want to edit, then choose **Edit**. The datashare details page appears.
6. To remove one or more datashare objects to the datashare, do one of the following:
 - To remove schemas from the datashare, choose one or more schemas. Then choose **Remove**. Amazon Redshift removes the specified schemas and all the objects of the specified schemas from the datashare.
 - To remove tables and views from the datashare, choose one or more tables and views. Then choose **Remove**. Alternatively, choose **Remove by schema** to remove all tables and views in the specified schemas.
 - To remove user-defined functions from the datashare, choose one or more user-defined functions. Then choose **Remove**. Alternatively, choose **Remove by schema** to remove all user-defined functions in the specified schemas.

Removing data consumers from datashares

You can remove one or more data consumers from a datashare. Data consumers can be cluster namespaces that uniquely identified Amazon Redshift clusters or AWS accounts.

Choose one or more data consumers either from the cluster namespace IDs or AWS account, then choose **Remove**.

Amazon Redshift removes the specified data consumers from the datashare. They lose access to the datashare immediately.

Editing datashares created in your account

Edit datashares created in your account using the console. Connect to a database first to see the list of datashares created in your account.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**.
4. In the **Datashares created in my account** section, choose **Connect to database**. For more information, see [Connecting to a database](#).
5. Choose the datashare you want to edit, then choose **Edit**. The datashare details page appears.
6. Make any changes in the **Datashare objects** or **Data consumers** section.

Note

If you chose to publish your datashare to the AWS Glue Data Catalog, you can't edit the configuration to publish the datashare to other Amazon Redshift accounts.

7. Choose **Save changes**.

Amazon Redshift updates your datashare with the changes.

Deleting datashares created in your account

Delete datashares created in your account using the console. Connect to a database first to see the list of datashares created in your account.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**. The datashare list appears.
4. In the **Datashares created in my account** section, choose **Connect to database**. For more information, see [Connecting to a database](#).
5. Choose one or more datashares you want to delete, then choose **Delete**. The Delete datashares page appears.

Deleting a datashare shared with Lake Formation doesn't automatically remove the associated permissions in Lake Formation. To remove them, go to the Lake Formation console.

6. Type **Delete** to confirm deleting the specified datashares.
7. Choose **Delete**.

After datashares are deleted, datashare consumers lose access to the datashares.

Querying datashares

With Amazon Redshift, you can query data across datashares from producer clusters to securely access live data without copying or transferring it. The following sections cover the details of setting up and querying datashares in your Amazon Redshift environment.

Creating databases from datashares

To start querying data in the datashare, create a database from a datashare. You can create only one database from a specified datashare.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**. The datashare list appears.
4. In the **Datashares from other clusters** section, choose **Connect to database**. For more information, see [Connecting to a database](#).
5. Choose a datashare that you want to create databases from, then choose **Create database from datashare**. The Create database from datashare page appears.

6. In the **Database name**, specify a database name. The database name must be 1–64 alphanumeric characters (lowercase only) and it can't be a reserved word.
7. Choose **Create**.

After the database is created, you can query data in the database.

Managing AWS Data Exchange datashares

With Amazon Redshift, you can securely share and receive live data from AWS Data Exchange without having to create and manage data extracts or pipelines. Managing AWS Data Exchange datashares allows you to subscribe to third-party data products and integrate live data streams directly into your Amazon Redshift data warehouse. The following sections demonstrate managing AWS Data Exchange datashares within your Amazon Redshift clusters.

Creating data sets on AWS Data Exchange

Create data sets on AWS Data Exchange.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**.
4. In the **Datashares created in my account** section, choose an AWS Data Exchange datashare.
5. Choose **Create data set on AWS Data Exchange**. For more information, see [Publishing a new product](#).

Editing AWS Data Exchange datashares

Edit AWS Data Exchange datashares using the console. Connect to a database first to see the list of datashares created in your account.

For AWS Data Exchange datashares, you can't make changes to data consumers.

To edit the publicly accessible setting for AWS Data Exchange datashares, use the Query editor v2. Amazon Redshift generates a random one-time value to set the session variable to allow turning this setting off. For more information, see [ALTER DATASHARE usage notes](#).

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. From the navigator menu, choose **Editor**, then **Query editor v2**.
4. If this is the first time you use the Query editor v2, configure your AWS account. By default, an AWS owned key is used to encrypt resources. For more information about configuring your AWS account, see [Configuring your AWS account](#) in the *Amazon Redshift Management Guide*.
5. To connect to the cluster that your AWS Data Exchange datashare is in, choose **Database** and the cluster name in the tree-view panel. If prompted, enter the connection parameters.
6. Copy the following SQL statement. The following example changes the publicly accessible setting of the salesshare datashare.

```
ALTER DATASHARE salesshare SET PUBLICACCESSIBLE FALSE;
```

7. To run the copied SQL statement, choose **Queries** and paste the copied SQL statement in the query area. Then choose **Run**.

An error appears following:

```
ALTER DATASHARE salesshare SET PUBLICACCESSIBLE FALSE;  
ERROR: Alter of ADX-managed datashare salesshare requires session variable  
datashare_break_glass_session_var to be set to value 'c670ba4db22f4b'
```

The value 'c670ba4db22f4b' is a random one-time value that Amazon Redshift generates when an unrecommended operation occurs.

8. Copy and paste the following sample statement into the query area. Then run the command. The SET datashare_break_glass_session_var command applies a permission to allow an unrecommended operation for an AWS Data Exchange datashare.

```
SET datashare_break_glass_session_var to 'c670ba4db22f4b';
```

9. Run the ALTER DATASHARE statement again.

```
ALTER DATASHARE salesshare;
```

Amazon Redshift updates your datashare with the changes.

Deleting AWS Data Exchange datashares created in your account

Delete AWS Data Exchange datashares created in your account using the console. Connect to a database first to see the list of datashares created in your account.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. From the navigator menu, choose **Editor**, then **Query editor v2**.
4. If this is the first time you use the Query editor v2, configure your AWS account. By default, an AWS owned key is used to encrypt resources. For more information about configuring your AWS account, see [Configuring your AWS account](#) in the *Amazon Redshift Management Guide*.
5. To connect to the cluster that your AWS Data Exchange datashare is in, choose **Database** and the cluster name in the tree-view panel. If prompted, enter the connection parameters.
6. Copy the following SQL statement. The following example drops the salesshare datashare.

```
DROP DATASHARE salesshare
```

7. To run the copied SQL statement, choose **Queries** and paste the copied SQL statement in the query area. Then choose **Run**.

An error appears following:

```
ERROR: Drop of ADX-managed datashare salesshare requires session variable  
datashare_break_glass_session_var to be set to value '620c871f890c49'
```

The value '620c871f890c49' is a random one-time value that Amazon Redshift generates when an unrecommended operation occurs.

8. Copy and paste the following sample statement into the query area. Then run the command. The `SET datashare_break_glass_session_var` command applies a permission to allow an unrecommended operation for an AWS Data Exchange datashare.

```
SET datashare_break_glass_session_var to '620c871f890c49';
```

9. Run the `DROP DATASHARE` statement again.

```
DROP DATASHARE salesshare;
```

After the datashare is deleted, datashare consumers lose access to the datashare.

Deleting a shared AWS Data Exchange datashare can breach data product terms in AWS Data Exchange.

Managing data sharing with AWS CloudFormation

You can automate data sharing setup by using an AWS CloudFormation stack, which provisions AWS resources. The CloudFormation stack sets up data sharing between two Amazon Redshift clusters in the same AWS account. Thus, you can start data sharing without running SQL statements to provision your resources.

The stack creates a datashare on the cluster that you designate. The datashare includes a table and sample read-only data. This data can be read by your other Amazon Redshift cluster.

If you want to start sharing data in an AWS account by running SQL statements to set up a datashare and grant permissions, without using CloudFormation, see [Sharing read access to data within an AWS account](#).

Before running the data sharing CloudFormation stack, you must be logged in with a user that has permission to create an IAM role and a Lambda function. You also need two Amazon Redshift clusters in the same account. You use one, the *producer*, to share the sample data, and the other, the *consumer*, to read it. The primary requirement for these clusters is that each use RA3 nodes. For additional requirements, see [Considerations when using data sharing in Amazon Redshift](#).

For more information about getting started setting up an Amazon Redshift cluster, see [Get started with Amazon Redshift provisioned data warehouses](#). For more information about automating setup with CloudFormation, see [What is AWS CloudFormation?](#)

Important

Before launching your CloudFormation stack, make sure you have two Amazon Redshift clusters in the same account and that the clusters use RA3 nodes. Make sure each cluster has a database and a superuser. For more information, see [CREATE DATABASE](#) and [superuser](#).

To launch your CloudFormation stack for Amazon Redshift data sharing:

1. Click [Launch CFN stack](#), which takes you to the CloudFormation service in the AWS Management Console.

If you are prompted, sign in.

The stack creation process starts, referencing a CloudFormation template file, which is stored in Amazon S3. A CloudFormation *template* is a text file in JSON format that declares AWS resources that make up a stack. For more information about CloudFormation templates, see [Learn template basics](#).

2. Choose **Next** to enter the stack details.
3. Under **Parameters**, for each cluster, enter the following:
 - Your Amazon Redshift cluster name, for example **ra3-consumer-cluster**
 - Your database name, for example **dev**
 - The name of your database user, for example **consumeruser**

We recommend using test clusters, because the stack creates several database objects.

Choose **Next**.

4. The stack options appear.

Choose **Next** to accept the default settings.

5. Under **Capabilities**, choose **I acknowledge that AWS CloudFormation might create IAM resources**.
6. Choose **Create stack**.

CloudFormation takes about 10 minutes to build the Amazon Redshift stack using the template, creating a datashare called `myproducer_share`. The stack creates the datashare in the database specified in the stack details. Only objects from that database can be shared.

If an error occurs while the stack is created, do the following:

- Make sure that you entered the correct cluster name, database name, and database user name for each Redshift cluster.
- Make sure that your cluster has RA3 nodes.

- Make sure you are logged in with a user that has permission to create an IAM role and a Lambda function. For more information about creating IAM roles, see [Creating IAM roles](#). For more information about policies for Λ function creation, see [Function development](#).

Querying the datashare that you created

To use the following procedure, make sure that you have the required permissions for running queries on each cluster described.

To query your datashare:

1. Connect to the producer cluster on the database entered when your CloudFormation stack was created, using a client tool such as the Amazon Redshift query editor v2.
2. Query for datashares.

```
SHOW DATASHARES;
```

```
+-----+-----+-----+-----+
+-----+-----+-----+-----+-----+
+-----+
|  share_name   | share_owner | source_database | consumer_database | share_type
| createdate   | is_publicaccessible | share_acl | producer_account |
producer_namespace
+-----+-----+-----+-----+-----+
+-----+-----+-----+-----+-----+
+-----+
| myproducer_share | 100          | sample_data_dev | myconsumer_db      | INBOUND
| NULL          | true         | NULL          | producer-acct    | your-
producer-namespace
+-----+-----+-----+-----+-----+
+-----+-----+-----+-----+-----+
+-----+
```

The preceding command returns the name of the datashare created by the stack, called `myproducer_share`. It also returns the name of the database associated with the datashare, `myconsumer_db`.

Copy the producer namespace identifier to use in a later step.

3. Describe objects in the datashare.

```
DESC DATASHARE myproducer_share;
```

```
+-----+-----+-----+
+-----+-----+-----+
+-----+
| producer_account | producer_namespace | share_type |
share_name | object_type | object_name | include_new |
+-----+-----+-----+
+-----+-----+-----+
+-----+
| producer-acct | your-producer-namespace | OUTBOUND |
myproducer_share | schema | myproducer_schema | true
|
| producer-acct | your-producer-namespace | OUTBOUND |
myproducer_share | table | myproducer_schema.tickit_sales | NULL
|
| producer-acct | your-producer-namespace | OUTBOUND |
myproducer_share | view | myproducer_schema.ticket_sales_view | NULL
|
+-----+-----+-----+
+-----+-----+-----+
+-----+

```

When you describe the datashare, it returns properties for tables and views. The stack adds tables and views with sample data to the producer database, for example `tickit_sales` and `tickit_sales_view`. For more information about the TICKIT sample database, see [Sample database](#).

You don't have to delegate permissions on the datashare to run queries. The stack grants the necessary permissions.

4. Connect to the consumer cluster using your client tool. Describe the datashare, specifying the producer's namespace.

```
DESC DATASHARE myproducer_share OF NAMESPACE '<namespace id>'; --specify the unique
  identifier for the producer namespace
```

```
+-----+-----+-----+
+-----+-----+-----+
+-----+

```

```

| producer_account |          producer_namespace          | share_type |
share_name      | object_type |          object_name          | include_new |
+-----+-----+-----+-----+
+-----+-----+-----+-----+
| producer-acct | your-producer-namespace | INBOUND |
myproducer_share | schema      | myproducer_schema | NULL
|
| producer-acct | your-producer-namespace | INBOUND |
myproducer_share | table       | myproducer_schema.tickit_sales | NULL
|
| producer-acct | your-producer-namespace | INBOUND |
myproducer_share | view        | myproducer_schema.ticket_sales_view | NULL
|
+-----+-----+-----+-----+
+-----+-----+-----+-----+
+-----+-----+

```

5. You can query tables in the datashare by specifying the datashare's database and schema. For more information, see [Cross-database query examples](#). The following queries return sales and seller data from the SALES table in the TICKIT sample database. For more information, see [Sample database](#).

```
SELECT * FROM myconsumer_db.myproducer_schema.tickit_sales_view;
```

```

+-----+-----+-----+-----+-----+-----+-----+-----+
+-----+-----+
| salesid | listid | sellerid | buyerid | eventid | dateid | qty sold | pricepaid |
commission | saletime |
+-----+-----+-----+-----+-----+-----+-----+-----+
+-----+-----+
| 1 | 1 | 36861 | 21191 | 7872 | 1875 | 4 | 728 |
109.2 | 2008-02-18 02:36:48 |
| 2 | 4 | 8117 | 11498 | 4337 | 1983 | 2 | 76 |
11.4 | 2008-06-06 05:00:16 |
| 3 | 5 | 1616 | 17433 | 8647 | 1983 | 2 | 350 |
52.5 | 2008-06-06 08:26:17 |
| 4 | 5 | 1616 | 19715 | 8647 | 1986 | 1 | 175 |
26.25 | 2008-06-09 08:38:52 |
| 5 | 6 | 47402 | 14115 | 8240 | 2069 | 2 | 154 |
23.1 | 2008-08-31 09:17:02 |
+-----+-----+-----+-----+-----+-----+-----+-----+
+-----+-----+

```

Note

The query runs against the view in the shared schema. You can't connect directly to databases created from datashares. They are read-only.

6. To run a query that includes aggregations, use the following example.

```
SELECT * FROM myconsumer_db.myproducer_schema.tickit_sales ORDER BY 1,2 LIMIT 5;
```

salesid	listid	sellerid	buyerid	eventid	dateid	qtysold	pricepaid	commission	saletime
1	1	36861	21191	7872	1875	4	728	109.2	2008-02-18 02:36:48
2	4	8117	11498	4337	1983	2	76	11.4	2008-06-06 05:00:16
3	5	1616	17433	8647	1983	2	350	52.5	2008-06-06 08:26:17
4	5	1616	19715	8647	1986	1	175	26.25	2008-06-09 08:38:52
5	6	47402	14115	8240	2069	2	154	23.1	2008-08-31 09:17:02

The query returns sales and seller data from the sample TICKIT data.

For more examples of datashare queries, see [Sharing read access to data within an AWS account](#).

Managing data sharing with writes using the console (preview)

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use

this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

With Amazon Redshift, you can manage data sharing with writes using the console to control access and govern data across Amazon Redshift clusters and AWS accounts. The following sections provide step-by-step instructions on configuring and managing data sharing with writes using the Amazon Redshift console.

For more information about setting up PREVIEW_2023 track, see either of the following:

- For Amazon Redshift Serverless preview: [Creating a preview workgroup](#)
- For Amazon Redshift provisioned clusters preview: [Creating a preview cluster](#)

For more information about getting started with data sharing, go to [Sharing write access to data \(Preview\)](#).

Use the Amazon Redshift console to manage datashares created in your account or shared from other accounts.

Connecting to a database (preview)

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

With Amazon Redshift, you can connect to databases across AWS accounts and Amazon Redshift clusters using data sharing.

For more information about getting started with data sharing, go to [Sharing write access to data \(Preview\)](#).

Connect to a database to view databases and objects within databases in this cluster or to view datashares.

The user credentials used to connect to a specified database must have the necessary permissions to view all datashares.

If there is no local connection, do one of the following:

- In the cluster details page, from the **Databases** tab, in the **Databases** or **Datashare objects** section, choose **Connect to database** to view database objects in the cluster.
- In the cluster details page, from the **Datashares** tab, do one of the following:
 - In the **Datashares from other clusters** section, choose **Connect to database** to view datashares from other clusters.
 - In the **Datashares created in my cluster** section, choose **Connect to database** to view datashares in your cluster.
- On the **Connect to database** window, do one of the following:
 - If you choose **Create a new connection**, choose **AWS Secrets Manager** to use a stored secret to authenticate access for the connection.

Or, choose **Temporary credentials** to use database credentials to authenticate access for the connection. Specify values for **Database name** and **Database user**.

Choose **Connect**.

- Choose **Use a recent connection** to connect to another database that you have the necessary permissions.

Amazon Redshift automatically makes the connection.

After database connection is established, you can start creating datashares, querying datashares, or creating databases from datashares.

Creating datashares and adding objects (preview)

Creating datashares

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

With Amazon Redshift, you can share live data across Amazon Redshift clusters or AWS accounts using datashares. A datashare is a consumer-producer object that allows you to share live data from your Amazon Redshift cluster with other clusters or AWS accounts. Creating datashares enables secure data sharing while maintaining control over access and ensuring data remains up-to-date. The following sections provide details on creating datashares and adding database objects such as schemas, tables, and views to share live data securely.

For more information about getting started with data sharing, go to [Sharing write access to data \(Preview\)](#).

As a producer cluster administrator, you can create datashares from the **Databases** or **Datashares** tabs in the cluster details page.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. In the cluster details page, do one of the following:
 - From the **Databases** tab, in the **Database** section, choose a database. The database details page appears.

Choose **Create datashare**. You can only create a datashare from a local database. If you haven't connected to the database, the **Connect to database** page appears. Follow the steps in [Connecting to a database \(preview\)](#) to connect to a database. If there is a recent connection, the **Create datashare** page appears.

- From the **Datashares** tab, in the **Datashares** section, connect to a database if you don't have a database connection.

In the **Datashares created in my cluster** section, choose **Create datashare**. The **Create datashare** page appears.

4. From here, you can add database objects of various types. Select the **Add** button to add objects. A dialog appears. Perform the following steps:
 1. Choose a schema, or more than one schema. Doing this makes objects from the schemas available to add.
 2. Select **Objects types** from the schemas.

From here you can choose a couple options to **Add objects**:

- **Add specific objects from schemas** – If you choose this, it lists individual objects by name. You can select objects and add them to the datashare. For example, you can add specific **Tables** and **Stored procedures**, if you like. Then the tables and stored procedures from the schema you selected are included in the datashare. Setting permissions is explained further in subsequent steps. Continue with **Views** and other types, selecting objects to add.
 - **Add all existing objects from the selected object types to the schema** – This adds all of the objects.
3. You can also choose whether you want to **Add future objects**. When you choose to include datashare objects added to the schema, it means that objects added to the schema are added to the datashare automatically.
 4. Choose **Add** to complete the section and add the objects. They're listed under the **Datashare objects**.
 5. After you add objects, you can select individual objects and edit their permissions. If you select a schema, a dialog appears that asks if you would like to add **Scoped permissions**. This makes it so each existing or added object to the schema has a pre-selected set of permissions, appropriate for the object type. For instance, the administrator can set that all added tables have **SELECT** and **UPDATE** permissions, for instance.
 6. After you configure schema permissions you can walk through additional object types and select their permissions. For instance, you can add **UPDATE** permissions to a specific table.
 7. In the **Data consumers** section, you can add namespaces or add **AWS** accounts as consumers of the datashare.
 8. Choose **Create datashare** to save your changes.

After you create the datashare, it appears in the list under **Datashares created in my namespace**. If you choose a datashare from the list, you can view its consumers, its objects, and other properties.

Adding data consumers to datashares

You can add one or more data consumers to the datashares. Data consumers can be cluster namespaces that uniquely identified Amazon Redshift clusters or **AWS** accounts.

You must explicitly choose to turn off or turn on sharing your datashare to clusters with public access.

- Choose **Add cluster namespaces to the datashare**. Namespaces are globally unique identifier (GUID) for Amazon Redshift cluster.
- Choose **Add AWS accounts** to the datashare. The specified AWS accounts must have access permissions to the datashare.

Authorizing or removing authorization from datashares (preview)

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

With Amazon Redshift, you can control access to datashares by authorizing or revoking authorization for specified consumers. Datashares allow you to share live data across Amazon Redshift clusters in the same or different AWS accounts, providing a seamless way to distribute and consume analytical data. The following sections provide step-by-step instructions for authorizing and revoking consumer access to your datashares in Amazon Redshift.

For more information about getting started with data sharing, go to [Sharing write access to data \(Preview\)](#).

As a producer cluster administrator, choose which data consumers to authorize to access datashares or to remove authorization from. Authorized data consumers receive notifications to take actions on datashares. If you are adding a cluster namespace as a data consumer, you don't have to perform authorization.

Prerequisite: To authorize or remove authorization for the datashare, there must be at least one data consumer added to the datashare.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Datashares**. From here you can see a list called **Datashares consumers**. Choose one or more consumer clusters that you want to authorize. Then choose **Authorize**.
3. The **Authorize account** dialog appears. You can choose among a couple authorization types.

- **Read-only on [cluster name or workgroup name]** – This means that no write permissions are available on the consumer, even if the datashare creator granted write permissions.
- **Read and write on [cluster name or workgroup name]** – This means that all permissions granted by the creator, including write permissions, are available on the consumer.

4. Choose **Save**.

You can also authorize AWS Data Exchange as a consumer.

1. If you chose **Publish to AWS Glue Data Catalog** when creating the datashare, you can only grant authorization of the datashare to a Lake Formation account.

For AWS Data Exchange datashare, you can only authorize one datashare at a time.

When you authorize an AWS Data Exchange datashare, you are sharing the datashare with the AWS Data Exchange service and allowing AWS Data Exchange to manage access to the datashare on your behalf. AWS Data Exchange allows access to consumers by adding consumer accounts as data consumers to the AWS Data Exchange datashare when they subscribe to the products. AWS Data Exchange doesn't have read access to the datashare.

2. Choose **Save**.

After data consumers are authorized, they can access datashare objects and create a consumer database to query the data.

Removing authorization:

Choose one or more consumer clusters that you want to remove authorization from. Then choose **Remove authorization**.

After authorization is removed, data consumers lose access to the datashare immediately.

Associating or declining datashares as a consumer (preview)

With Amazon Redshift you can associate or decline datashares shared by other AWS accounts, enabling seamless and secure data sharing across organizational boundaries. Datashares are shareable database objects that encapsulate data from one or more Amazon Redshift databases. The following sections demonstrate the process of associating with or declining datashares, empowering you to unlock the full potential of shared data resources within your Amazon Redshift environment.

Associating datashares

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

For more information about getting started with data sharing, go to [Sharing write access to data \(Preview\)](#).

As a consumer cluster administrator, you can associate one or more datashares that are shared from other accounts to your entire AWS account or specific cluster namespaces in your account.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Datashares**. The datashare list page appears. Choose **From other accounts**.
3. In the **Datashares from other accounts** section, choose the datashare that you want to associate and choose **Associate**. When the **Associate** datashare page appears, choose one of the following association types:
 - Choose **Entire AWS account** to associate all existing and future cluster namespaces across different AWS Regions in your AWS account with the datashare.

If the datashare is published to the AWS Glue Data Catalog, you can only associate the datashare with the entire AWS account.

4. From here you can choose **Allowed permissions**. The choices are:
 - **Read-only** – If you choose read only, write permissions like UPDATE or INSERT aren't available on the consumer, even if these permissions were granted and authorized on the producer.
 - **Read and write** – Consumer datashare users will have all of the permissions, both read and write, that were granted and authorized by the producer.
5. Or choose **Specific AWS Regions and cluster namespaces** to associate one or more AWS Regions and specific cluster namespaces with the datashare. Choose **Add Region** to add

specific AWS Regions and cluster namespaces to the datashare. The **Add AWS Region** page appears.

6. Choose an **AWS Region**.
7. Do one of the following:
 - Choose **Add all cluster namespaces** to add all existing and future cluster namespaces in this Region to the datashare.
 - Choose **Add specific cluster namespaces** to add one or more specific cluster namespaces in this Region to the datashare.
 - Choose one or more cluster namespaces and choose **Add AWS Region**.
8. Choose **Associate**.

It's possible for the producer to go back and change settings for an authorization, which can affect association settings on consumers.

If you're associating the datashare with a Lake Formation account, go to the Lake Formation console to create a database, then define permissions over the database. For more information, see [Setting up permissions for Amazon Redshift datashares](#) in the AWS Lake Formation Developer Guide. Once you create a AWS Glue database or a federated database, you can use query editor v2 or any preferred SQL client with your consumer cluster to query the data. .

After the datashare is associated, the datashares become available.

You can also change datashare association at any time. When changing association from specific AWS Regions and cluster namespaces to the entire AWS account, Amazon Redshift overwrites the specific Region and cluster namespaces information with AWS account information. All the AWS Regions and cluster namespaces in the AWS account then have access to the datashare.

When changing association from specific cluster namespaces to all cluster namespaces in the specified AWS Region, all cluster namespaces in this Region then have access to the datashare.

Removing association of datashare from data consumers

As a consumer cluster administrator, you can remove association of datashares from data consumers.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.

2. On the navigation menu, choose **Datashares**. The datashare list page appears.
3. Choose **From other accounts**.
4. In the **Datashares from other accounts** section, choose the datashare to remove association from data consumers.
5. In the **Data consumers** section, choose one or more data consumers to remove association from. Then choose **Remove association**.
6. When the Remove association page appears, choose **Remove association**.

After association is removed, data consumers will lose access to the datashare. You can change the data consumer association at any time.

Declining datashares

As a consumer cluster administrator, you can reject any datashare whose state is available or active. After you reject a datashare, consumer cluster users lose access to the datashare. Amazon Redshift doesn't return the rejected datashare if you call the `DescribeDataSharesForConsumer` API operation. If the producer cluster administrator runs the `DescribeDataSharesForProducer` API operation, they will see that the datashare was rejected. Once a datashare is rejected, the producer cluster administrator can authorize the datashare to a consumer cluster again, and the consumer cluster administrator can choose to associate their AWS account with the datashare or reject it.

If your AWS account has an association to a datashare and a pending association to a datashare that's managed by Lake Formation, rejecting the datashare association that's managed by Lake Formation also rejects the original datashare. To reject a specific association, the producer cluster administrator can remove authorization from a specified datashare. This action doesn't affect other datashares.

To reject a datashare, use the AWS console, the API operation `RejectDataShare`, or `reject-datashare` in the AWS CLI.

To reject a datashare using the AWS console:

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. In the navigation menu, choose **Datashares**.
3. Choose **From other accounts**.

4. In the **Datashares from other accounts** section, choose the datashare you want to decline. When the **Decline datashare** page appears, choose **Decline**.

After you decline the datashares, you can't revert the change. Amazon Redshift removes the datashares from the list. To see the datashare again, the producer administrator must authorize it again.

Managing existing datashares (preview)

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

With Amazon Redshift, you can manage existing datashares to control access to your data in an Amazon Redshift cluster. The following sections provide step-by-step guidance on modifying datashare objects, managing datashare permissions, and updating datashare properties to effectively control and audit data access in your Amazon Redshift environment.

For more information about getting started with data sharing, go to [Sharing write access to data \(Preview\)](#).

Viewing datashares

View datashares from the **DATASHARES** or **CLUSTERS** tab.

- Use the **DATASHARES** tab to list datashares in your account or from other accounts.
 - To view datashares created in your account, choose **In my account**, then choose the datashare you want to view.
 - To view datashares that are shared from other accounts, choose **From other accounts**, then choose the datashare you want to view.
- Use the **CLUSTERS** tab to list datashares in your cluster or from other clusters.

Connect to a database. For more information, see [Connecting to a database \(preview\)](#).

Then choose a datashare either from the **Datashares from other clusters** or **Datashares created in my cluster** section to view its details.

Removing datashare objects from datashares

You can remove one or more objects from a datashare by using the following procedure.

To remove one or more objects from a datashare

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**.
4. In the **Datashares created in my account** section, choose **Connect to database**. For more information, see [Connecting to a database \(preview\)](#).
5. Choose the datashare you want to edit, then choose **Edit**. The datashare details page appears.
6. To remove one or more datashare objects to the datashare, do one of the following:
 - To remove schemas from the datashare, choose one or more schemas. Then choose **Remove**. Amazon Redshift removes the specified schemas and all the objects of the specified schemas from the datashare.
 - To remove tables and views from the datashare, choose one or more tables and views. Then choose **Remove**. Alternatively, choose **Remove by schema** to remove all tables and views in the specified schemas.
 - To remove user-defined functions from the datashare, choose one or more user-defined functions. Then choose **Remove**. Alternatively, choose **Remove by schema** to remove all user-defined functions in the specified schemas.

Removing data consumers from datashares

You can remove one or more data consumers from a datashare. Data consumers can be cluster namespaces that uniquely identified Amazon Redshift clusters or AWS accounts.

Choose one or more data consumers either from the cluster namespace IDs or AWS account, then choose **Remove**.

Amazon Redshift removes the specified data consumers from the datashare. They lose access to the datashare immediately.

Editing datashares created in your account

Edit datashares created in your account using the console. Connect to a database first to see the list of datashares created in your account.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**.
4. In the **Datashares created in my account** section, choose **Connect to database**.
5. Choose the datashare you want to edit, then choose **Edit**. The datashare details page appears.
6. Make any changes in the **Datashare objects** or **Data consumers** section.

Note

If you chose to publish your datashare to the AWS Glue Data Catalog, you can't edit the configuration to publish the datashare to other Amazon Redshift accounts.

7. Choose **Save changes**.

Amazon Redshift updates your datashare with the changes.

Deleting datashares created in your account

Delete datashares created in your account using the console. Connect to a database first to see the list of datashares created in your account.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**. The datashare list appears.
4. In the **Datashares created in my account** section, choose **Connect to database**.

5. Choose one or more datashares you want to delete, then choose **Delete**. The Delete datashares page appears.

Deleting a datashare shared with Lake Formation doesn't automatically remove the associated permissions in Lake Formation. To remove them, go to the Lake Formation console.

6. Type **Delete** to confirm deleting the specified datashares.
7. Choose **Delete**.

After datashares are deleted, datashare consumers lose access to the datashares.

Querying datashares (preview)

This is prerelease documentation for the multi-data warehouse writes through data sharing feature for Amazon Redshift, which is available in public preview in the PREVIEW_2023 track. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta Service Participation in [AWS Service Terms](#).

With Amazon Redshift, you can query data across datashares from producer clusters to securely access live data without copying or transferring it. The following sections cover the details of setting up and querying datashares in your Amazon Redshift environment.

For more information about getting started with data sharing, go to [Sharing write access to data \(Preview\)](#).

Creating databases from datashares

To start querying data in the datashare, create a database from a datashare. You can create only one database from a specified datashare.

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Clusters**, then choose your cluster. The cluster details page appears.
3. Choose **Datashares**. The datashare list appears.
4. In the **Datashares from other clusters** section, choose **Connect to database**. For more information, see [Connecting to a database \(preview\)](#).

5. Choose a datashare that you want to create databases from, then choose **Create database from datashare**. The Create database from datashare page appears.
6. In the **Database name**, specify a database name. The database name must be 1–64 alphanumeric characters (lowercase only) and it can't be a reserved word.
7. Choose **Create**.

After the database is created, you can query data in the database or perform write operations, if they have been granted, authorized, and associated by the consumer administrator.

Semistructured data in Amazon Redshift

By using *semistructured data support* in Amazon Redshift, you can ingest and store semistructured data in your Amazon Redshift data warehouses. Using the SUPER data type and PartiQL language, Amazon Redshift expands data warehouse capability to integrate with both SQL and NoSQL data sources. This way, Amazon Redshift enables efficient analytics on relational and semistructured stored data such as JSON.

Amazon Redshift offers two forms of semistructured data support: the SUPER data type and Amazon Redshift Spectrum.

Use the SUPER data type if you need to insert or update small batches of JSON data with low latency. Also, use SUPER when your query requires strong consistency, predictable query performance, complex query support, and ease of use with evolving schemas and schemaless data.

In contrast, use Amazon Redshift Spectrum with an open file format if your data query requires integration with other AWS services and with data mainly stored in Amazon S3 for archival purposes.

Use cases for the SUPER data type

Semistructured data support using the SUPER data type in Amazon Redshift provides superior performance, flexibility, and ease of use. The following use cases help demonstrate how you can use semistructured data support with SUPER.

Rapid and flexible insertion of JSON data – Amazon Redshift supports rapid transactions that can parse JSON and store it as a SUPER value. The insert transactions can operate up to five times faster than performing the same insertions into tables that have shredded the attributes of SUPER into conventional columns. For example, suppose that the incoming JSON is of the form {"a":..., "b":..., "c":..., ...}. You can accelerate the insert performance many times by storing the incoming JSON into a table TJ with a single SUPER column S, instead of storing it into a conventional table TR with columns "a", "b", "c", and so on. When there are hundreds of attributes in the JSON, the performance advantage of SUPER data type becomes substantial.

Also, SUPER data type doesn't need a regular schema. You don't need to introspect and clean up the incoming JSON before storing it. For example, suppose an incoming JSON has a string "c" attribute and others that have an integer "c" attribute, without the SUPER data type. In this case, you have to either separate c_string and c_int columns or clean up the data. In contrast, with the

SUPER data type, all JSON data is stored during ingestion without the loss of information. Later, you can use the PartiQL extension of SQL to analyze the information.

Flexible queries for discovery – After you have stored your semistructured data (such as JSON) into a SUPER data value, you can query it without imposing a schema. You can use PartiQL dynamic typing and lax semantics to run your queries and discover the deeply nested data you need, without the need to impose a schema before query.

Flexible queries for extract, load, transform (ETL) operations into conventional materialized views – After you have stored your schemaless and semistructured data into SUPER, you can use PartiQL materialized views to introspect the data and shred them into materialized views.

The materialized views with the shredded data are a good example of performance and usability advantages to your classic analytics cases. When you perform analytics on the shredded data, the columnar organization of Amazon Redshift materialized views provides better performance. Furthermore, users and business intelligence (BI) tools that require a conventional schema for ingested data can use views (either materialized or virtual) as the conventional schema presentation of the data.

After your PartiQL materialized views have extracted the data found in JSON or SUPER into conventional columnar materialized views, you can query the materialized views. For more information on how the SUPER data type works with materialized views, see [SUPER data type and materialized views](#).

You can apply dynamic data masking policies to `scalar` values on the paths of SUPER type columns. For more information about dynamic data masking, see [Dynamic data masking](#). For information about the using dynamic data masking with the SUPER data type, see [Using dynamic data masking with SUPER data type paths](#). (preview)

For information about the SUPER data type, see [SUPER type](#).

For examples of using the SUPER data type, see the subsections for this topic, beginning with [SUPER sample dataset](#).

Concepts for SUPER data type use

Following, you can find some Amazon Redshift SUPER data type concepts.

Understand what the SUPER data type is in Amazon Redshift – The *SUPER* data type is an Amazon Redshift data type that enables the storage of schemaless arrays and structures that

contain Amazon Redshift scalars and possibly nested arrays and structures. The SUPER data type can natively store different formats of semistructured data, such as JSON or data originating from document-oriented sources. You can add a new SUPER column to store semistructured data and write queries that access the SUPER column, along with the usual scalar columns. For more information about the SUPER data type, see [SUPER type](#).

Ingest schemaless JSON into SUPER – With the flexible semistructured SUPER data type, Amazon Redshift can receive and ingest schemaless JSON into a SUPER value. For example, Amazon Redshift can ingest the JSON value [10.5, "first"] into a SUPER value [10.5, 'first'], that is an array containing the Amazon Redshift decimal 10.5 and varchar 'first'. Amazon Redshift can ingest the JSON into a SUPER value using the COPY command or the JSON parse function, such as `json_parse('[10.5, "first"]')`. Both COPY and `json_parse` ingest JSON using strict parsing semantics by default. You can also construct SUPER values including arrays and structures, using the database data themselves.

The SUPER column requires no schema modifications while ingesting the irregular structures of schemaless JSON. For example, while analyzing a click-stream, you initially store in the SUPER column "click" structures with attributes "IP" and "time". You can add an attribute "customer id" without changing your schema in order to ingest such changes.

The native format used for the SUPER data type is a binary format that requires lesser space than the JSON value in its textual form. This enables faster ingestion and runtime processing of SUPER values at query.

Query SUPER data with PartiQL – PartiQL is a backward-compatible extension of SQL-92 that many AWS services currently use. With the use of PartiQL, familiar SQL constructs seamlessly combine access to both the classic, tabular SQL data and the semistructured data of SUPER. You can perform object and array navigation and unnest arrays. PartiQL extends the standard SQL language to declaratively express and process nested and multivalued data.

PartiQL is an extension of SQL where the nested and schemaless data of SUPER columns are first-class citizens. PartiQL doesn't require all query expressions to be type-checked during query compilation time. This approach enables query expressions that contain the SUPER data type to be dynamically typed during query execution when the actual types of the data inside the SUPER columns are accessed. Also, PartiQL operates in a lax mode where type inconsistencies don't cause failures but return null. The combination of schemaless and lax query processing makes PartiQL ideal for extract, load, transfer (ELT) applications where your SQL query evaluates the JSON data that are ingested in the SUPER columns.

Integrate with Redshift Spectrum – Amazon Redshift supports multiple aspects of PartiQL when running Redshift Spectrum queries over JSON, Parquet, and other formats that have nested data. Redshift Spectrum only supports nested data that has schemas. For example, with Redshift Spectrum you can declare that your JSON data have an attribute *nested_schemaful_example* in a schema `ARRAY<STRUCT<a:INTEGER, b:DECIMAL(5,2)>>`. The schema of this attribute determines that the data always contains an array, which contains a structure with integer *a* and decimal *b*. If the data changes to include more attributes, the type also changes. In contrast, the SUPER data type requires no schema. You can store arrays with structure elements that have different attributes or types. Also, some values can be stored outside arrays.

For information about functions that support the SUPER data type, see the following:

- [ABS function](#)
- [CEILING \(or CEIL\) function](#)
- [FLOOR function](#)
- [ROUND function](#)
- [SIGN function](#)
- [TRUNC function](#)

Considerations for SUPER data

When working with SUPER data, consider the following:

- Use JDBC driver version 1.2.50, ODBC driver version 1.4.17 or later, and Amazon Redshift Python driver version 2.0.872 or later.

For information about JDBC drivers, see [Configuring a JDBC connection](#).

For information about ODBC drivers, see [Configuring an ODBC connection](#).

- Find the schema examples used in the following topics at [SUPER sample dataset](#).
- All the SQL code examples used in the following topics are included with the same S3 prefix for download. These include the data definition language (DDL) and COPY statements, and also certain TPC-H modified queries that work with SUPER.

To view or download the SQL files, do one of the following:

- Download the [SUPER tutorial SQL file](#) and [TPC-H file](#).

- Using the Amazon S3 CLI, run the following command. You can use your own target path.

```
aws s3 cp s3://redshift-downloads/semistructured/tutorialscripts/semistructured-
tutorial.sql /target/path
aws s3 cp s3://redshift-downloads/semistructured/tutorialscripts/
super_tpch_queries.sql /target/path
```

For more information about SUPER configurations, see [SUPER configurations](#).

SUPER sample dataset

You can explore and analyze the SUPER sample dataset, which contains data related to fictional product sales across various categories, regions, and time periods. The following sections provide details on accessing, querying, and manipulating the SUPER sample dataset within your Amazon Redshift cluster.

The table schema and data model used for ingestion and query examples are defined as follows.

```
/*customer-orders-lineitem*/
CREATE TABLE customer_orders_lineitem
(c_custkey bigint
 ,c_name varchar
 ,c_address varchar
 ,c_nationkey smallint
 ,c_phone varchar
 ,c_acctbal decimal(12,2)
 ,c_mktsegment varchar
 ,c_comment varchar
 ,c_orders super
);

/* Datamodel of documents to be stored in c_orders Super column would be as follows*/
ARRAY < STRUCT < o_orderkey:bigint
                                ,o_orderstatus:string
                                ,o_totalprice:double
                                ,o_orderdate:string
                                ,o_orderpriority:string
                                ,o_clerk:string
                                ,o_shippriority:int
                                ,o_comment:string
                                ,o_lineitems:ARRAY < STRUCT < l_partkey:bigint
```

```

,l_commitdate:string
,l_receiptdate:string
,l_shipinstruct:string
,l_shipmode:string
,l_comment:string
> >

```

```
> >
```

```

/*part*/
CREATE TABLE part
(
  p_partkey bigint
  ,p_name varchar
  ,p_mfgr varchar
  ,p_brand varchar
  ,p_type varchar
  ,p_size int
  ,p_container varchar
  ,p_retailprice decimal(12,2)
  ,p_comment varchar
);

/*region-nations*/
CREATE TABLE region_nations
(
  r_regionkey smallint
  ,r_name varchar
  ,r_comment varchar
  ,r_nations super
);

/* Datamodel of documents to be stored in r_nations Super column would be as follows*/
ARRAY < STRUCT < n_nationkey:int,n_name:string,n_comment:string > >

/*supplier-partsupp*/

```

```
CREATE TABLE supplier_partsupp
(
  s_suppkey bigint
  ,s_name varchar
  ,s_address varchar
  ,s_nationkey smallint
  ,s_phone varchar
  ,s_acctbal double precision
  ,s_comment varchar
  ,s_partsupps super
);

/* Datamodel of documents to be stored in s_partsupps Super column would be as
follows*/
ARRAY < STRUCT <
ps_partkey:bigint,ps_availqty:int,ps_supplycost:double,ps_comment:string > >
```

Loading semistructured data into Amazon Redshift

Use the SUPER data type to persist and query hierarchical and generic data in Amazon Redshift. Amazon Redshift introduces the `json_parse` function to parse data in JSON format and convert it into the SUPER representation. Amazon Redshift also supports loading SUPER columns using the COPY command. The supported file formats are JSON, Avro, text, comma-separated value (CSV) format, Parquet, and ORC.

For information on the tables used in the following examples, see [SUPER sample dataset](#).

For information about the `json_parse` function, see [JSON_PARSE function](#).

The default encoding for SUPER data type is ZSTD.

Parsing JSON documents to SUPER columns

You can insert or update JSON data into a SUPER column using the `json_parse` function. The function parses data in JSON format and converts it into the SUPER data type, which you can use in INSERT or UPDATE statements.

The following example inserts JSON data into a SUPER column. If the `json_parse` function is missing in the query, Amazon Redshift treats the value as a single string instead of a JSON-formatted string that must be parsed.

If you update a SUPER data column, Amazon Redshift requires the complete document to be passed to column values. Amazon Redshift doesn't support partial update.

```
INSERT INTO region_nations VALUES(0,
  'lar deposits. blithely final packages cajole. regular waters are final requests.
regular accounts are according to',
  'AFRICA',
  JSON_PARSE('{"r_nations":[
    {"n_comment":" haggles. carefully final deposits detect slyly again",
      "n_nationkey":0,
      "n_name":"ALGERIA"
    },
    {"n_comment":"ven packages wake quickly. regul",
      "n_nationkey":5,
      "n_name":"ETHIOPIA"
    },
    {"n_comment":" pending excuses haggles furiously deposits. pending, express pinto
beans wake fluffily past t",
      "n_nationkey":14,
      "n_name":"KENYA"
    },
    {"n_comment":"rns. blithely bold courts among the closely regular packages use
furiously bold platelets?",
      "n_nationkey":15,
      "n_name":"MOROCCO"
    },
    {"n_comment":"s. ironic, unusual asymptotes wake blithely r",
      "n_nationkey":16,
      "n_name":"MOZAMBIQUE"
    }
  ]
}')));
```

Using COPY to load SUPER columns in Amazon Redshift

In the following sections, you can learn about different ways to use the COPY command to load JSON data into Amazon Redshift.

Copying data from JSON and Avro

By using semistructured data support in Amazon Redshift, you can load a JSON document without shredding the attributes of its JSON structures into multiple columns.

Amazon Redshift provides two methods to ingest JSON document using COPY, even with a JSON structure that is fully or partially unknown:

1. Store the data deriving from a JSON document into a single SUPER data column using the `noshred` option. This method is useful when the schema isn't known or is expected to change. Thus, this method makes it easier to store the entire tuple in a single SUPER column.
2. Shred the JSON document into multiple Amazon Redshift columns using the `auto` or `jsonpaths` option. Attributes can be Amazon Redshift scalars or SUPER values.

You can use these options with the JSON or Avro formats.

The maximum size for a JSON object before shredding is 4 MB.

Copying a JSON document into a single SUPER data column

To copy a JSON document into a single SUPER data column, create a table with a single SUPER data column.

```
CREATE TABLE region_nations_noshred (rdata SUPER);
```

Copy the data from Amazon S3 into the single SUPER data column. To ingest the JSON source data into a single SUPER data column, specify the `noshred` option in the `FORMAT JSON` clause.

```
COPY region_nations_noshred FROM 's3://redshift-downloads/semistructured/tpch-nested/
data/json/region_nation'
REGION 'us-east-1' IAM_ROLE 'arn:aws:iam::xxxxxxxxxxxx:role/Redshift-S3'
FORMAT JSON 'noshred';
```

After COPY has successfully ingested the JSON, your table has a `rdata SUPER` data column that contains the data of the entire JSON object. The ingested data maintains all the properties of the JSON hierarchy. However, the leaves are converted to Amazon Redshift scalar types for efficient query processing.

Use the following query to retrieve the original JSON string.

```
SELECT rdata FROM region_nations_noshred;
```

When Amazon Redshift generates a SUPER data column, it becomes accessible using JDBC as a string through JSON serialization. For more information, see [Serializing complex nested JSON](#).

Copying a JSON document into multiple SUPER data columns

You can shred a JSON document into multiple columns that can be either SUPER data columns or Amazon Redshift scalar types. Amazon Redshift spreads different portions of the JSON object to different columns.

```
CREATE TABLE region_nations
(
  r_regionkey smallint
  ,r_name varchar
  ,r_comment varchar
  ,r_nations super
);
```

To copy the data of the previous example into the table, specify the AUTO option in the FORMAT JSON clause to split the JSON value across multiple columns. COPY matches the top-level JSON attributes with column names and allows nested values to be ingested as SUPER values, such as JSON arrays and objects.

```
COPY region_nations FROM 's3://redshift-downloads/semistructured/tpch-nested/data/json/
region_nation'
REGION 'us-east-1' IAM_ROLE 'arn:aws:iam::xxxxxxxxxxxx:role/Redshift-S3'
FORMAT JSON 'auto';
```

When the JSON attribute names are in mixed upper and lower cases, specify the `auto ignorecase` option in the FORMAT JSON clause. For more information about the COPY command, see [Load from JSON data using the 'auto ignorecase' option](#).

In some cases, there is a mismatch between column names and JSON attributes or the attribute to load is nested more than a level deep. If so, use a `jsonpaths` file to manually map JSON attributes to Amazon Redshift columns.

```
CREATE TABLE nations
(
  regionkey smallint
  ,name varchar
  ,comment super
  ,nations super
);
```

Suppose that you want to load data to a table where the column names don't match the JSON attributes. In the following example, the `nations` table is such a table. You can create a `jsonpaths` file that maps the paths of attributes to the table columns by their position in the `jsonpaths` array.

```
{
  "jsonpaths": [
    "$.r_regionkey",
    "$.r_name",
    "$.r_comment",
    "$.r_nations"
  ]
}
```

The location of the `jsonpaths` file is used as the argument to `FORMAT JSON`.

```
COPY nations FROM 's3://redshift-downloads/semistructured/tpch-nested/data/json/
region_nation'
REGION 'us-east-1' IAM_ROLE 'arn:aws:iam::xxxxxxxxxxxx:role/Redshift-S3'
FORMAT JSON 's3://redshift-downloads/semistructured/tpch-nested/data/jsonpaths/
nations_jsonpaths.json';
```

Use the following query to access the table that shows data spread to multiple columns. The `SUPER` data columns are printed using the JSON format.

```
SELECT r_regionkey,r_name,r_comment,r_nations[0].n_nationkey FROM region_nations ORDER
BY 1,2,3 LIMIT 1;
```

`Jsonpaths` files map fields in the JSON document to table columns. You can extract additional columns, such as distribution and sort keys, while still loading the complete document as a `SUPER` column. The following query loads the complete document to the `nations` column. The `name` column is the sort key and the `regionkey` column is the distribution key.

```
CREATE TABLE nations_sorted (
  regionkey smallint,
  name varchar,
  nations super
) DISTKEY(regionkey) SORTKEY(name);
```

The root `jsonpath "$"` maps to the root of the document as follows:

```
{"jsonpaths": [  
    "$.r_regionkey",  
    "$.r_name",  
    "$"  
  ]  
}
```

The location of the jsonpaths file is used as the argument to FORMAT JSON.

```
COPY nations_sorted FROM 's3://redshift-downloads/semistructured/tpch-nested/data/json/  
region_nation'  
REGION 'us-east-1' IAM_ROLE 'arn:aws:iam:xxxxxxxxxxxx:role/Redshift-S3'  
FORMAT JSON 's3://redshift-downloads/semistructured/tpch-nested/data/jsonpaths/  
nations_sorted_jsonpaths.json';
```

Copying data from text and CSV

Amazon Redshift represents SUPER columns in text and CSV formats as serialized JSON. Valid JSON formatting is required for SUPER columns to load with the correct type information. Unquote objects, arrays, numbers, booleans, and null values. Wrap string values in double quotes. SUPER columns use standard escaping rules for text and CSV formats. For CSV, delimiters are escaped according to the CSV standard. For text, if the chosen delimiter might also appear in a SUPER field, use the ESCAPE option during COPY and UNLOAD.

```
COPY region_nations FROM 's3://redshift-downloads/semistructured/tpch-nested/data/csv/  
region_nation'  
REGION 'us-east-1' IAM_ROLE 'arn:aws:iam:xxxxxxxxxxxx:role/Redshift-S3'  
FORMAT CSV;
```

```
COPY region_nations FROM 's3://redshift-downloads/semistructured/tpch-nested/data/text/  
region_nation'  
REGION 'us-east-1' IAM_ROLE 'arn:aws:iam:xxxxxxxxxxxx:role/Redshift-S3'  
DELIMITER ','  
ESCAPE;
```

Copying data from columnar-format Parquet and ORC

If your semistructured or nested data is already available in either Apache Parquet or Apache ORC format, you can use the COPY command to ingest data into Amazon Redshift.

The Amazon Redshift table structure should match the number of columns and the column data types of the Parquet or ORC files. By specifying SERIALIZETOJSON in the COPY command, you can load any column type in the file that aligns with a SUPER column in the table as SUPER. This includes structure and array types.

```
COPY region_nations FROM 's3://redshift-downloads/semistructured/tpch-nested/data/parquet/region_nation'  
REGION 'us-east-1' IAM_ROLE 'arn:aws:iam::xxxxxxxxxxxx:role/Redshift-S3'  
FORMAT PARQUET SERIALIZETOJSON;
```

The following example uses an ORC format.

```
COPY region_nations FROM 's3://redshift-downloads/semistructured/tpch-nested/data/orc/region_nation'  
IAM_ROLE 'arn:aws:iam::xxxxxxxxxxxx:role/Redshift-S3'  
FORMAT ORC SERIALIZETOJSON;
```

When the attributes of the date or time data types are in ORC, Amazon Redshift converts them to varchar upon encoding them in SUPER.

Unloading semistructured data

With Amazon Redshift, you can export semistructured data from your Amazon Redshift cluster to Amazon S3 in a variety of formats, including text, Apache Parquet, Apache ORC, and Avro. The following sections will guide you through the process of configuring and executing unload operations for your semistructured data in Amazon Redshift.

CSV or text formats

You can unload tables with SUPER data columns to Amazon S3 in a comma-separated value (CSV) or text format. Using a combination of navigation and unnest clauses, Amazon Redshift unloads hierarchical data in SUPER data format to Amazon S3 in CSV or text formats. Subsequently, you can create external tables against unloaded data and query them using Redshift Spectrum. For information on using UNLOAD and the required IAM permissions, see [UNLOAD](#).

Before running the following example, populate the region_nations table using the processes in [Loading semistructured data into Amazon Redshift](#). For information on the tables used in the following example, see [SUPER sample dataset](#).

The following example unloads data into Amazon S3.

```
UNLOAD ('SELECT * FROM region_nations')
TO 's3://xxxxxx/'
IAM_ROLE 'arn:aws:iam::xxxxxxxxxxxx:role/Redshift-S3-Write'
DELIMITER AS '|'
GZIP
ALLOWOVERWRITE;
```

Unlike other data types where a user-defined string represents a null value, Amazon Redshift exports the SUPER data columns using the JSON format and represents it as *null* as determined by the JSON format. As a result, SUPER data columns ignore the NULL [AS] option used in UNLOAD commands.

Parquet format

You can unload tables with SUPER data columns to Amazon S3 in the Parquet format. Amazon Redshift represents SUPER columns in Parquet as the JSON data type. This enables semistructured data to be represented in Parquet. You can query these columns using Redshift Spectrum or ingest them back to Amazon Redshift using the COPY command. For information on using UNLOAD and the required IAM permissions, see [UNLOAD](#).

The following example unloads data into Amazon S3 in the Parquet format.

```
UNLOAD ('SELECT * FROM region_nations')
TO 's3://xxxxxx/'
IAM_ROLE 'arn:aws:iam::xxxxxxxxxxxx:role/Redshift-S3-Write'
FORMAT PARQUET;
```

Querying semistructured data

With Amazon Redshift, you can query and analyze semistructured data, such as JSON, Avro, or Ion, alongside your structured data. Semistructured data refers to data that has a flexible schema, allowing for hierarchical or nested structures. The following sections demonstrate querying semistructured data using Amazon Redshift's support for open data formats, allowing you to unlock valuable information from complex data structures.

Amazon Redshift uses the PartiQL language to offer SQL-compatible access to relational, semistructured, and nested data.

PartiQL operates with dynamic types. This approach enables intuitive filtering, joining, and aggregation on the combination of structured, semistructured, and nested datasets. The PartiQL syntax uses dotted notation and array subscript for path navigation when accessing nested data. It also enables the FROM clause items to iterate over arrays and use for unnest operations. Following, you can find descriptions of the different query patterns that combine the use of the SUPER data type with path and array navigation, unnesting, unpivoting, and joins.

For information on the tables used in the following example, see [SUPER sample dataset](#).

Topics

- [Navigation](#)
- [Unnesting queries](#)
- [Object unpivoting](#)
- [Dynamic typing](#)
- [Lax semantics](#)
- [Types of introspection](#)
- [Order by](#)

Navigation

Amazon Redshift uses PartiQL to enable navigation into arrays and structures using the [...] bracket and dot notation respectively. Furthermore, you can mix navigation into structures using the dot notation and arrays using the bracket notation. For example, the following example assumes that the `c_orders` SUPER data column is an array with a structure and an attribute is named `o_orderkey`.

To ingest data in the `customer_orders_lineitem` table, run the following command. Replace the IAM role with your own credentials.

```
COPY customer_orders_lineitem FROM 's3://redshift-downloads/semistructured/tpch-nested/
data/json/customer_orders_lineitem'
REGION 'us-east-1' IAM_ROLE 'arn:aws:iam::xxxxxxxxxxxx:role/Redshift-S3'
FORMAT JSON 'auto';

SELECT c_orders[0].o_orderkey FROM customer_orders_lineitem;
```

Amazon Redshift also uses a table alias as a prefix to the notation. The following example is the same query as the previous example.

```
SELECT cust.c_orders[0].o_orderkey FROM customer_orders_lineitem AS cust;
```

You can use the dot and bracket notations in all types of queries, such as filtering, join, and aggregation. You can use these notations in a query in which there are normally column references. The following example uses a SELECT statement that filters results.

```
SELECT count(*) FROM customer_orders_lineitem WHERE c_orders[0]. o_orderkey IS NOT NULL;
```

The following example uses the bracket and dot navigation in both GROUP BY and ORDER BY clauses.

```
SELECT c_orders[0].o_orderdate,
       c_orders[0].o_orderstatus,
       count(*)
FROM customer_orders_lineitem
WHERE c_orders[0].o_orderkey IS NOT NULL
GROUP BY c_orders[0].o_orderstatus,
         c_orders[0].o_orderdate
ORDER BY c_orders[0].o_orderdate;
```

Unnesting queries

To unnest queries, Amazon Redshift uses the PartiQL syntax to iterate over SUPER arrays. It does this by navigating the array using the FROM clause of a query. Using the previous example, the following example iterates over the attribute values for `c_orders`.

```
SELECT c.*, o FROM customer_orders_lineitem c, c.c_orders o;
```

The unnesting syntax is an extension of the FROM clause. In standard SQL, the FROM clause `x (AS) y` means that `y` iterates over each tuple in relation `x`. In this case, `x` refers to a relation and `y` refers to an alias for relation `x`. Similarly, the PartiQL syntax of unnesting using the FROM clause `item x (AS) y` means that `y` iterates over each (SUPER) value in (SUPER) array expression `x`. In this case, `x` is a SUPER expression and `y` is an alias for `x`.

The left operand can also use the dot and bracket notation for regular navigation. In the previous example, `customer_orders_lineitem c` is the iteration over the `customer_order_lineitem` base table and `c.c_orders o` is the iteration over the `c.c_orders` array. To iterate over the `o_lineitems` attribute, which is an array within an array, you add multiple clauses.

```
SELECT c.*, o, l FROM customer_orders_lineitem c, c.c_orders o, o.o_lineitems l;
```

Amazon Redshift also supports an array index when iterating over the array using the `AT` keyword. The clause `x AS y AT z` iterates over array `x` and generates the field `z`, which is the array index. The following example shows how an array index works.

```
SELECT c_name,
       orders.o_orderkey AS orderkey,
       index AS orderkey_index
FROM customer_orders_lineitem c, c.c_orders AS orders AT index
ORDER BY orderkey_index;
```

c_name	orderkey	orderkey_index
Customer#000008251	3020007	0
Customer#000009452	4043971	0

(2 rows)

The following example iterates over a scalar array.

```
CREATE TABLE bar AS SELECT json_parse('{"scalar_array": [1, 2.3, 45000000]}') AS data;
SELECT index, element FROM bar AS b, b.data.scalar_array AS element AT index;
```

index	element
0	1
1	2.3
2	45000000

(3 rows)

The following example iterates over an array of multiple levels. The example uses multiple `unnest` clauses to iterate into the innermost arrays. The `f.multi_level_array AS array` iterates over `multi_level_array`. The `array AS element` is the iteration over the arrays within `multi_level_array`.

```
CREATE TABLE foo AS SELECT json_parse('[[[1.1, 1.2], [2.1, 2.2], [3.1, 3.2]]]') AS
multi_level_array;

SELECT array, element FROM foo AS f, f.multi_level_array AS array, array AS element;
```

array	element
[1.1,1.2]	1.1
[1.1,1.2]	1.2
[2.1,2.2]	2.1
[2.1,2.2]	2.2
[3.1,3.2]	3.1
[3.1,3.2]	3.2

(6 rows)

For more information about the FROM clause, see [FROM clause](#).

Object unpivoting

To perform object unpivoting, Amazon Redshift uses the PartiQL syntax to iterate over SUPER objects. It does this using the FROM clause of a query with the UNPIVOT keyword. In this case, the expression is the `c.c_orders[0]` object. The example query iterates over each attribute returned by the object.

```
SELECT attr as attribute_name, json_typeof(val) as value_type
FROM customer_orders_lineitem c, UNPIVOT c.c_orders[0] AS val AT attr
WHERE c_custkey = 9451;
```

attribute_name	value_type
o_orderstatus	string
o_clerk	string
o_lineitems	array
o_orderdate	string
o_shippriority	number
o_totalprice	number
o_orderkey	number
o_comment	string
o_orderpriority	string

(9 rows)

As with unnesting, the unpivoting syntax is also an extension of the FROM clause. The difference is that the unpivoting syntax uses the UNPIVOT keyword to indicate that it's iterating over an object instead of an array. It uses the AS `value_alias` for iteration over all the values inside an object and uses the AT `attribute_alias` for iterating over all the attributes. Consider the following syntax fragment:

```
UNPIVOT expression AS value_alias [ AT attribute_alias ]
```

Amazon Redshift supports using object unpivoting and array unnesting in a single FROM clause as follows:

```
SELECT attr as attribute_name, val as object_value
FROM customer_orders_lineitem c, c.c_orders AS o, UNPIVOT o AS val AT attr
WHERE c_custkey = 9451;
```

When you use object unpivoting, Amazon Redshift doesn't support correlated unpivoting. Specifically, suppose that you have a case where there are multiple examples of unpivoting in different query levels and the inner unpivoting references the outer one. Amazon Redshift doesn't support this type of multiple unpivoting.

For more information about the FROM clause, see [FROM clause](#). For examples that show how to query structured data, with PIVOT and UNPIVOT, see [PIVOT and UNPIVOT examples](#).

Dynamic typing

Dynamic typing doesn't require explicit casting of data that is extracted from the dot and bracket paths. Amazon Redshift uses dynamic typing to process schemaless SUPER data without the need to declare the data types before you use them in your query. Dynamic typing uses the results of navigating into SUPER data columns without having to explicitly cast them into Amazon Redshift types. Dynamic typing is most useful in joins and GROUP BY clauses. The following example uses a SELECT statement that requires no explicit casting of the dot and bracket expressions to the usual Amazon Redshift types. For information about type compatibility and conversion, see [Type compatibility and conversion](#).

```
SELECT c_orders[0].o_orderkey
FROM customer_orders_lineitem
WHERE c_orders[0].o_orderstatus = 'P';
```

The equality sign in this query evaluates to `true` when `c_orders[0].o_orderstatus` is the string `'P'`. In all other cases, the equality sign evaluates to `false`, including the cases where the arguments of the equality are different types.

Dynamic and static typing

Without using dynamic typing, you can't determine whether `c_orders[0].o_orderstatus` is a string, an integer, or a structure. You can only determine that `c_orders[0].o_orderstatus` is a SUPER data type, which can be an Amazon Redshift scalar, an array, or a structure. The static type of `c_orders[0].o_orderstatus` is a SUPER data type. Conventionally, a type is implicitly a static type in SQL.

Amazon Redshift uses dynamic typing to the processing of schemaless data. When the query evaluates the data, `c_orders[0].o_orderstatus` turns out to be a specific type. For example, evaluating `c_orders[0].o_orderstatus` on the first record of `customer_orders_lineitem` may result into an integer. Evaluating on the second record may result into a string. These are the dynamic types of the expression.

When using an SQL operator or function with dot and bracket expressions that have dynamic types, Amazon Redshift produces results similar to using standard SQL operator or function with the respective static types. In this example, when the dynamic type of the path expression is a string, the comparison with the string `'P'` is meaningful. Whenever the dynamic type of `c_orders[0].o_orderstatus` is any other data type except being a string, the equality returns false. Other functions return null when mistyped arguments are used.

The following example writes the previous query with static typing:

```
SELECT c_custkey
FROM customer_orders_lineitem
WHERE CASE WHEN JSON_TYPEOF(c_orders[0].o_orderstatus) = 'string'
          THEN c_orders[0].o_orderstatus::VARCHAR = 'P'
          ELSE FALSE END;
```

Note the following distinction between equality predicates and comparison predicates. In the previous example, if you replace the equality predicate with a less-than-or-equal predicate, the semantics produce null instead of false.

```
SELECT c_orders[0]. o_orderkey
FROM customer_orders_lineitem
WHERE c_orders[0].o_orderstatus <= 'P';
```

In this example, if `c_orders[0].o_orderstatus` is a string, Amazon Redshift returns true if it is alphabetically equal to or smaller than 'P'. Amazon Redshift returns false if it is alphabetically larger than 'P'. However, if `c_orders[0].o_orderstatus` is not a string, Amazon Redshift returns null since Amazon Redshift can't compare values of different types, as shown in the following query:

```
SELECT c_custkey
FROM customer_orders_lineitem
WHERE CASE WHEN JSON_TYPEOF(c_orders[0].o_orderstatus) = 'string'
          THEN c_orders[0].o_orderstatus::VARCHAR <= 'P'
          ELSE NULL END;
```

Dynamic typing doesn't exclude from comparisons of types that are minimally comparable. For example, you can convert both CHAR and VARCHAR Amazon Redshift scalar types to SUPER. They are comparable as strings, including ignoring trailing white-space characters similar to Amazon Redshift CHAR and VARCHAR types. Similarly, integers, decimals, and floating-point values are comparable as SUPER values. Specifically for decimal columns, each value can also have a different scale. Amazon Redshift still considers them as dynamic types.

Amazon Redshift also supports equality on objects and arrays that are evaluated as deep equal, such as evaluating deep into objects or arrays and comparing all attributes. Use deep equal with caution, because the process of performing deep equal can be time-consuming.

Using dynamic typing for joins

For joins, dynamic typing automatically matches values with different dynamic types without performing a long CASE WHEN analysis to find out what data types may appear. For example, assume that your organization changed the format that it was using for part keys over time.

The initial integer part keys issued are replaced by string part keys, such as 'A55', and later replaced again by array part keys, such as ['X', 10] combining a string and a number. Amazon Redshift doesn't have to perform a lengthy case analysis about part keys and can use joins as shown in the following example.

```
SELECT c.c_name
      ,l.l_extendedprice
      ,l.l_discount
FROM customer_orders_lineitem c
     ,c.c_orders o
     ,o.o_lineitems l
```

```

    ,supplier_partsupp s
    ,s.s_partsupps ps
WHERE l.l_partkey = ps.ps_partkey
AND c.c_nationkey = s.s_nationkey
ORDER BY c.c_name;

```

The following example shows how complex and inefficient the same query can be without using dynamic typing:

```

SELECT c.c_name
    ,l.l_extendedprice
    ,l.l_discount
FROM customer_orders_lineitem c
    ,c.c_orders o
    ,o.o_lineitems l
    ,supplier_partsupp s
    ,s.s_partsupps ps
WHERE CASE WHEN IS_INTEGER(l.l_partkey) AND IS_INTEGER(ps.ps_partkey)
            THEN l.l_partkey::integer = ps.ps_partkey::integer
            WHEN IS_VARCHAR(l.l_partkey) AND IS_VARCHAR(ps.ps_partkey)
            THEN l.l_partkey::varchar = ps.ps_partkey::varchar
            WHEN IS_ARRAY(l.l_partkey) AND IS_ARRAY(ps.ps_partkey)
            AND IS_VARCHAR(l.l_partkey[0]) AND IS_VARCHAR(ps.ps_partkey[0])
            AND IS_INTEGER(l.l_partkey[1]) AND IS_INTEGER(ps.ps_partkey[1])
            THEN l.l_partkey[0]::varchar = ps.ps_partkey[0]::varchar
            AND l.l_partkey[1]::integer = ps.ps_partkey[1]::integer
            ELSE FALSE END
AND c.c_nationkey = s.s_nationkey
ORDER BY c.c_name;

```

Lax semantics

By default, navigation operations on SUPER values return null instead of returning an error out when the navigation is invalid. Object navigation is invalid if the SUPER value is not an object or if the SUPER value is an object but doesn't contain the attribute name used in the query. For example, the following query accesses an invalid attribute name in the SUPER data column cdata:

```

SELECT c.c_orders.something FROM customer_orders_lineitem c;

```

Array navigation returns null if the SUPER value is not an array or the array index is out of bounds. The following query returns null because c_orders[1][1] is out of bounds.

```
SELECT c.c_orders[1][1] FROM customer_orders_lineitem c;
```

Lax semantics is especially useful when using dynamic typing to cast a SUPER value. Casting a SUPER value to the wrong type returns null instead of an error if the cast is invalid. For example, the following query returns null because it can't cast the string value 'Good' of the object attribute `o_orderstatus` to INTEGER. Amazon Redshift returns an error for a VARCHAR to INTEGER cast but not for a SUPER cast.

```
SELECT c.c_orders.o_orderstatus::integer FROM customer_orders_lineitem c;
```

Types of introspection

SUPER data columns support inspection functions that return the dynamic type and other type information about the SUPER value. The most common example is the `JSON_TYPEOF` scalar function that returns a VARCHAR with values boolean, number, string, object, array, or null, depending on the dynamic type of the SUPER value. Amazon Redshift supports the following boolean functions for SUPER data columns:

- `DECIMAL_PRECISION`
- `DECIMAL_SCALE`
- `IS_ARRAY`
- `IS_BIGINT`
- `IS_CHAR`
- `IS_DECIMAL`
- `IS_FLOAT`
- `IS_INTEGER`
- `IS_OBJECT`
- `IS_SCALAR`
- `IS_SMALLINT`
- `IS_VARCHAR`
- `JSON_TYPEOF`

All these functions return false if the input value is null. `IS_SCALAR`, `IS_OBJECT`, and `IS_ARRAY` are mutually exclusive and cover all possible values except for null.

To infer the types corresponding to the data, Amazon Redshift uses the `JSON_TYPEOF` function that returns the type of (the top level of) the SUPER value as shown in the following example:

```
SELECT JSON_TYPEOF(r_nations) FROM region_nations;
 json_typeof
-----
 array
(1 row)
```

```
SELECT JSON_TYPEOF(r_nations[0].n_nationkey) FROM region_nations;
 json_typeof
-----
 number
```

Amazon Redshift sees this as a single long string, similar to inserting this value into a VARCHAR column instead of a SUPER. Since the column is SUPER, the single string is still a valid SUPER value and the difference is noted in `JSON_TYPEOF`:

```
SELECT IS_VARCHAR(r_nations[0].n_name) FROM region_nations;
 is_varchar
-----
 true
(1 row)
```

```
SELECT r_nations[4].n_name FROM region_nations
WHERE CASE WHEN IS_INTEGER(r_nations[4].n_nationkey)
            THEN r_nations[4].n_nationkey::INTEGER = 15
            ELSE false END;
```

Order by

Amazon Redshift doesn't define SUPER comparisons among values with different dynamic types. A SUPER value that is a string is neither smaller nor larger than a SUPER value that is a number. To use ORDER BY clauses with SUPER columns, Amazon Redshift defines a total ordering among different types to be observed when Amazon Redshift ranks SUPER values using ORDER BY clauses. The order among dynamic types is boolean, number, string, array, object. The following example shows the orders of different types:

```
INSERT INTO region_nations VALUES
```

```
(100, 'name1', 'comment1', 'AWS'),
(200, 'name2', 'comment2', 1),
(300, 'name3', 'comment3', ARRAY(1, 'abc', null)),
(400, 'name4', 'comment4', -2.5),
(500, 'name5', 'comment5', 'Amazon');

SELECT r_nations FROM region_nations order by r_nations;
```

```
r_nations
-----
-2.5
1
"Amazon"
"AWS"
[1, "abc", null]
(5 rows)
```

For more information about the ORDER BY clause, see [ORDER BY clause](#).

Operators and functions

With Amazon Redshift, you can perform advanced analytics on large datasets using SUPER data using operators and functions. Operators and functions for SUPER data are SQL constructs that enable complex analysis and manipulation of semi-structured data stored in Amazon Redshift tables.

The following sections will cover the syntax, examples, and best practices for using operators and functions for SUPER data in Amazon Redshift to unlock the full potential of your semi-structured data.

Arithmetic operators

SUPER values support all basic arithmetic operators `+`, `-`, `*`, `/`, `%` using dynamic typing. The resultant type of the operation remains as SUPER. For all operators, except for the binary operator `+`, the input operands must be numbers. Otherwise, Amazon Redshift returns null. The distinction between decimals and floating-point values is retained when Amazon Redshift runs these operators and the dynamic type doesn't change. However, decimal scale changes when you use multiplications and divisions. Arithmetic overflows still cause query errors, they aren't changed to null. Binary operator `+` performs addition if the inputs are numbers or concatenation if the inputs are string. If one operand is a string and the other operand is a number, the result is null. Unary

prefix operators + and - returns null if the SUPER value is not a number as shown in the following example:

```
SELECT (c_orders[0]. o_orderkey + 0.5) * c_orders[0]. o_orderkey / 10 AS math FROM
customer_orders_lineitem;
      math
-----
1757958232200.1500
(1 row)
```

Dynamic typing allows decimal values in SUPER to have different scales. Amazon Redshift treats decimal values as if they are different static types and allows all mathematical operations. Amazon Redshift computes the resulting scale dynamically based on the scales of the operands. If one of the operands is a floating-point number, then Amazon Redshift promotes the other operand to a floating-point number and generates the result as a floating-point number.

Arithmetic functions

Amazon Redshift supports the following arithmetic functions for SUPER columns. They return null if the input isn't a number:

- FLOOR. For more information, see [FLOOR function](#).
- CEIL and CEILING. For more information, see [CEILING \(or CEIL\) function](#).
- ROUND. For more information, see [ROUND function](#).
- TRUNC. For more information, see [TRUNC function](#).
- ABS. For more information, see [ABS function](#).

The following example uses arithmetic functions to query data:

```
SELECT x, FLOOR(x), CEIL(x), ROUND(x)
FROM (
  SELECT (c_orders[0]. o_orderkey + 0.5) * c_orders[0].o_orderkey / 10 AS x
  FROM customer_orders_lineitem
);
```

x	floor	ceil	round
1389636795898.0500	1389636795898	1389636795899	1389636795898

The ABS function retains the scale of the input decimal while FLOOR, CEIL. The ROUND eliminates the scale of the input decimal.

Array functions

Amazon Redshift supports the following array composition and utility functions array, array_concat, subarray, array_flatten, get_array_length, and split_to_array.

You can construct SUPER arrays from values in Amazon Redshift data types using the ARRAY function, including other SUPER values. The following example uses the variadic function ARRAY:

```
SELECT ARRAY(1, c.c_custkey, NULL, c.c_name, 'abc') FROM customer_orders_lineitem c;
           array
-----
[1,8401,null,""Customer#000008401"", ""abc""]
[1,9452,null,""Customer#000009452"", ""abc""]
[1,9451,null,""Customer#000009451"", ""abc""]
[1,8251,null,""Customer#000008251"", ""abc""]
[1,5851,null,""Customer#000005851"", ""abc""]
(5 rows)
```

The following example uses array concatenation with the ARRAY_CONCAT function:

```
SELECT ARRAY_CONCAT(JSON_PARSE('[10001,10002]'), JSON_PARSE('[10003,10004]'));
           array_concat
-----
[10001,10002,10003,10004]
(1 row)
```

The following example uses array manipulation with the SUBARRAY function which returns a subset of the input array.

```
SELECT SUBARRAY(ARRAY('a', 'b', 'c', 'd', 'e', 'f'), 2, 3);
           subarray
-----
["c","d","e"]
(1 row)
```

The following example merges multiple levels of arrays into a single array using ARRAY_FLATTEN:

```
SELECT x, ARRAY_FLATTEN(x) FROM (SELECT ARRAY(1, ARRAY(2, ARRAY(3, ARRAY())))) AS x);
```

```

      x          | array_flatten
-----+-----
 [1,[2,[3,[]]]] | [1,2,3]
(1 row)

```

Array functions `ARRAY_CONCAT` and `ARRAY_FLATTEN` use dynamic typing rules. They return a null instead of an error if the input isn't an array. The `GET_ARRAY_LENGTH` function returns the length of a SUPER array given an object or array path.

```

SELECT c_name
FROM customer_orders_lineitem
WHERE GET_ARRAY_LENGTH(c_orders) = (
    SELECT MAX(GET_ARRAY_LENGTH(c_orders))
    FROM customer_orders_lineitem
);

```

The following example splits a string to an array of strings using `SPLIT_TO_ARRAY`. The function uses a delimiter as an optional parameter. If no delimiter is absent, then the default is a comma.

```
SELECT SPLIT_TO_ARRAY('12|345|6789', '|');
```

```

      split_to_array
-----
 ["12","345","6789"]
(1 row)

```

SUPER configurations

You can configure your SUPER data for specific scenarios. The following sections provide details on choosing and applying the appropriate SUPER configurations based on your data format requirements.

Topics

- [Lax and strict modes for SUPER](#)
- [Accessing JSON fields with uppercase and mixedcase field names or attributes](#)
- [Parsing options for SUPER](#)

Lax and strict modes for SUPER

When you query SUPER data, the path expression may not match the actual SUPER data structure. If you try to access a non-existent member of an object or element of an array, Amazon Redshift returns a NULL value if your query is run in the default lax mode. If you run your query in the strict mode, Amazon Redshift returns an error. The following session parameters can be set to set the lax mode on or off.

The following example uses session parameters to enable lax mode.

```
SET navigate_super_null_on_error=ON;  --default lax mode for navigation

SET cast_super_null_on_error=ON;  --default lax mode for casting

SET parse_super_null_on_error=OFF;  --default strict mode for ingestion
```

Accessing JSON fields with uppercase and mixedcase field names or attributes

When your JSON attribute names are in uppercase or mixedcase, you must be able to navigate SUPER type structures in a case sensitive way. To do that, you can configure `enable_case_sensitive_identifier` to TRUE and wrap the uppercase and mixedcase attribute names with double quotation marks. You can also configure `enable_case_sensitive_super_attribute` to TRUE. In this case, you can use uppercase and mixedcase attribute names in your queries without wrapping them in double quotation marks.

The following example illustrates how to set `enable_case_sensitive_identifier` to query data.

```
SET enable_case_sensitive_identifier to TRUE;

-- Accessing JSON attribute names with uppercase and mixedcase names
SELECT json_table.data."ITEMS"."Name",
       json_table.data."price"
FROM
  (SELECT json_parse('{"ITEMS":{"Name":"TV"}, "price": 345}') AS data) AS json_table;

Name | price
-----+-----
"TV" | 345
```

```
(1 row)
```

```
RESET enable_case_sensitive_identifier;
```

```
-- After resetting the above configuration, the following query accessing JSON
attribute names with uppercase and mixedcase names should return null (if in lax
mode).
```

```
SELECT json_table.data."ITEMS"."Name",
       json_table.data."price"
```

```
FROM
```

```
  (SELECT json_parse('{"ITEMS":{"Name":"TV"}, "price": 345}') AS data) AS json_table;
```

```
name | price
```

```
-----+-----
```

```
      | 345
```

```
(1 row)
```

The following example illustrates how to set `enable_case_sensitive_super_attribute` to query data.

```
SET enable_case_sensitive_super_attribute to TRUE;
```

```
-- Accessing JSON attribute names with uppercase and mixedcase names
```

```
SELECT json_table.data.ITEMS.Name,
       json_table.data.price
```

```
FROM
```

```
  (SELECT json_parse('{"ITEMS":{"Name":"TV"}, "price": 345}') AS data) AS json_table;
```

```
name | price
```

```
-----+-----
```

```
"TV" | 345
```

```
(1 row)
```

```
RESET enable_case_sensitive_super_attribute;
```

```
-- After resetting enable_case_sensitive_super_attribute, the query now returns NULL
for ITEMS.Name (if in lax mode).
```

```
SELECT json_table.data.ITEMS.Name,
       json_table.data.price
```

```
FROM
```

```
  (SELECT json_parse('{"ITEMS":{"Name":"TV"}, "price": 345}') AS data) AS json_table;
```

```
name | price
-----+-----
      | 345
(1 row)
```

Parsing options for SUPER

When you use the `JSON_PARSE` function to parse JSON strings into SUPER values, certain restrictions apply:

- The same attribute name cannot appear in the same object, but can appear in a nested object. The `json_parse_dedup_attributes` configuration option allows `JSON_PARSE` to keep only the last occurrence of duplicate attributes instead of returning an error.
- String values cannot exceed the system max varchar size of 65535 bytes. The `json_parse_truncate_strings` configuration option allows `JSON_PARSE()` to automatically truncate strings that are longer than this limit without returning an error. This behavior affects string values only and not attribute names.

For more information about the `JSON_PARSE` function, see [JSON_PARSE function](#).

The following example shows how to set the `json_parse_dedup_attributes` configuration option to the default behavior of returning an error for duplicate attributes.

```
SET json_parse_dedup_attributes=OFF; --default behavior of returning error instead of
de-duplicating attributes
```

The following example shows how to set the `json_parse_truncate_strings` configuration option for the default behavior of returning an error for strings that are longer than this limit.

```
SET json_parse_truncate_strings=OFF; --default behavior of returning error instead of
truncating strings
```

Limitations

With Amazon Redshift, you can work with the SUPER data type to store and query semi-structured data like JSON, Avro, or Ion. The SUPER data type limitations refer to the constraints and boundaries when using this data type in Amazon Redshift. The following sections provide details

on the specific limitations of the SUPER data type, such as maximum size, nesting levels, and data types supported within semi-structured data.

- You can't define SUPER columns as either a distribution or sort key.
- An individual SUPER object can hold up to 16 MB of data.
- An individual value within a SUPER object is limited to the maximum length of the corresponding Amazon Redshift type. For example, a single string value loaded to SUPER is limited to the maximum VARCHAR length of 65535 bytes.
- You can't perform partial update or transform operations on SUPER columns.
- You can't use the SUPER data type and its alias in right joins or full outer joins.
- The SUPER data type doesn't support XML as inbound or outbound serialization format.
- In the FROM clause of a subquery (that is correlated or not) that references a table variable for unnesting, the query can only refer to its parent table and not other tables.
- Casting limitations

SUPER values can be cast to and from other data types, with the following exceptions:

- Amazon Redshift doesn't differentiate integers and decimals of scale 0.
- If the scale isn't zero, SUPER data type has the same behavior as other Amazon Redshift data types, except that Amazon Redshift converts SUPER-related errors to null, as shown in the following example.

```
SELECT 5::bool;
  bool
-----
  True
(1 row)

SELECT 5::decimal::bool;
ERROR:  cannot cast type numeric to boolean

SELECT 5::super::bool;
  bool
-----
  True
(1 row)

SELECT 5.0::bool;
ERROR:  cannot cast type numeric to boolean
```

```
SELECT 5.0::super::bool;
   bool
-----
(1 row)
```

- Amazon Redshift doesn't cast the date and time types to SUPER data type. Amazon Redshift can only cast the date and time data types from SUPER data type, as shown in the following example.

```
SELECT o.o_orderdate FROM customer_orders_lineitem c,c.c_orders o;
   order_date
-----
"2001-09-08"
(1 row)

SELECT JSON_TYPEOF(o.o_orderdate) FROM customer_orders_lineitem c,c.c_orders o;
   json_typeof
-----
   string
(1 row)

SELECT o.o_orderdate::date FROM customer_orders_lineitem c,c.c_orders o;
   order_date
-----
   2001-09-08
(1 row)

--date/time cannot be cast to super
SELECT '2019-09-09'::date::super;
ERROR:  cannot cast type date to super
```

- Cast from non-scalar values (object and array) to string returns NULL. To properly serialize these non-scalar values, don't cast them. Instead, use `json_serialize` to cast non-scalar values. The `json_serialize` function returns a varchar. Typically, you don't need to cast non-scalar values to varchar since Amazon Redshift implicitly serializes as shown in the following first example.

```
SELECT r_nations FROM region_nations WHERE r_regionkey=300;
```

```

    r_nations
    -----
    [1,"abc",null]
    (1 row)

SELECT r_nations::varchar FROM region_nations WHERE r_regionkey=300;
    r_nations
    -----
    (1 row)

SELECT JSON_SERIALIZE(r_nations) FROM region_nations WHERE r_regionkey=300;
    json_serialize
    -----
    [1,"abc",null]
    (1 row)

```

- For case-insensitive databases, Amazon Redshift doesn't support the SUPER data type. For case-insensitive columns, Amazon Redshift doesn't cast them to the SUPER type. Thus, Amazon Redshift doesn't support SUPER columns interacting with case-insensitive columns that trigger casting.
- Amazon Redshift doesn't support volatile functions, such as RANDOM () or TIMEOFDAY (), in subqueries that unnest an outer table or a left-hand side (LHS) of IN functions with such subqueries.

SUPER data type and materialized views

With Amazon Redshift, you can use the SUPER data type to enhance the performance and flexibility of materialized views. The SUPER data type lets you store a superset of columns from the base tables in a materialized view, letting you query the materialized view directly without joining the base tables. The following sections show you how to create and use materialized views with the SUPER data type in Amazon Redshift.

Amazon Redshift extends the capability of materialized views to work with the SUPER data type and PartiQL in materialized views. SQL and PartiQL queries can be precomputed using incremental materialized views. For more information about materialized views, see [Materialized views in Amazon Redshift](#).

Once you have stored your schemaless and semistructured data into SUPER, you can use PartiQL materialized views to introspect the data and shred them into materialized views.

Accelerating PartiQL queries

You can use materialized views to accelerate PartiQL queries that navigate and/or unnest hierarchical data in SUPER columns. Create one or more materialized views to shred the SUPER values into multiple columns and utilize the columnar organization of Amazon Redshift analytical queries. Consequently, queries make use of the materialized views.

The materialized view essentially extracts and normalizes the nested data. The level of normalization depends on how much effort you put into turning the SUPER data into conventional columnar data.

Shredding into SUPER columns with materialized views

With Amazon Redshift, you can improve query performance and reduce storage requirements by shredding data into SUPER columns using materialized views. Shredding refers to the process of breaking down complex data types like semi-structured JSON or XML into smaller, flatter columns. SUPER columns are a specialized form of columnar storage optimized for rapidly scanning shredded data.

The following sections describe the steps and considerations for shredding data into SUPER columns using materialized views in Amazon Redshift.

The following example shows a materialized view that shreds the nested data with the resulting columns still being the SUPER data type.

```
SELECT c.c_name, o.o_orderstatus
FROM customer_orders_lineitem c, c.c_orders o;
```

The following example shows a materialized view that creates conventional Amazon Redshift scalar columns from the shredded data.

```
SELECT c.c_name, c.c_orders[0].o_totalprice
FROM customer_orders_lineitem c;
```

You can create a single materialized view `super_mv` to accelerate both queries.

To answer the first query, you must materialize the attribute `o_orderstatus`. You can omit the attribute `c_name` because it doesn't involve nested navigation nor unnesting. You must also include

in the materialized view the attribute `c_custkey` of `customer_orders_lineitem` to be able to join the base table with the materialized view.

To answer the second query, you must also materialize the attribute `o_totalprice` and the array index `o_idx` of `c_orders`. Hence, you can access the index 0 of `c_orders`.

```
CREATE MATERIALIZED VIEW super_mv distkey(c_custkey) sortkey(c_custkey) AS (  
  SELECT c_custkey, o.o_orderstatus, o.o_totalprice, o_idx  
  FROM customer_orders_lineitem c, c.c_orders o AT o_idx  
);
```

The attributes `o_orderstatus` and `o_totalprice` of the materialized view `super_mv` are SUPER.

The materialized view `super_mv` will be refreshed incrementally upon changes to the base table `customer_orders_lineitem`.

```
REFRESH MATERIALIZED VIEW super_mv;  
INFO: Materialized view super_mv was incrementally updated successfully.
```

To rewrite the first PartiQL query as a regular SQL query, join `customer_orders_lineitem` with `super_mv` as follows.

```
SELECT c.c_name, v.o_orderstatus  
FROM customer_orders_lineitem c  
JOIN super_mv v ON c.c_custkey = v.c_custkey;
```

Similarly, you can rewrite the second PartiQL query. The following example uses a filter on `o_idx = 0`.

```
SELECT c.c_name, v.o_totalprice  
FROM customer_orders_lineitem c  
JOIN super_mv v ON c.c_custkey = v.c_custkey  
WHERE v.o_idx = 0;
```

In the `CREATE MATERIALIZED VIEW` command, specify `c_custkey` as distribution key and sort key for `super_mv`. Amazon Redshift performs an efficient merge join, assuming that `c_custkey` is also the distribution key and sort key of `customer_orders_lineitem`. If that isn't the case, you can specify `c_custkey` as the sort key and distribution key of `customer_orders_lineitem` as follows.

```
ALTER TABLE customer_orders_lineitem
ALTER DISTKEY c_custkey, ALTER SORTKEY (c_custkey);
```

Use the EXPLAIN statement to verify that Amazon Redshift performs a merge join on the rewritten queries.

```
EXPLAIN
  SELECT c.c_name, v.o_orderstatus
  FROM customer_orders_lineitem c JOIN super_mv v ON c.c_custkey = v.c_custkey;

QUERY PLAN

-----
XN Merge Join DS_DIST_NONE (cost=0.00..34701.82 rows=1470776 width=27)
Merge Cond: ("outer".c_custkey = "inner".c_custkey)
-> XN Seq Scan on mv_tbl__super_mv__0 derived_table2 (cost=0.00..14999.86
rows=1499986 width=13)
-> XN Seq Scan on customer_orders_lineitem c (cost=0.00..999.96 rows=99996
width=30)
(4 rows)
```

Creating Amazon Redshift scalar columns out of shredded data

Schemaless data stored in SUPER can affect the performance of Amazon Redshift. For instance, filter predicates or join conditions as range-restricted scans can't effectively use zone maps. Users and BI tools can use materialized views as the conventional presentation of the data and increase performance of analytical queries.

The following query scans the materialized view `super_mv` and filters on `o_orderstatus`.

```
SELECT c.c_name, v.o_totalprice
FROM customer_orders_lineitem c
JOIN super_mv v ON c.c_custkey = v.c_custkey
WHERE v.o_orderstatus = 'F';
```

Inspect `stl_scan` to verify that Amazon Redshift can't effectively use zone maps on the range-restricted scan over `o_orderstatus`.

```
SELECT slice, is_rrscan FROM stl_scan
WHERE query = pg_last_query_id() AND perm_table_name LIKE '%super_mv%';
```

```

slice | is_rrscan
-----+-----
    0 | f
    1 | f
    5 | f
    4 | f
    2 | f
    3 | f
(6 rows)

```

The following example adapts the materialized view `super_mv` to create scalar columns out of the shredded data. In this case, Amazon Redshift casts `o_orderstatus` from `SUPER` to `VARCHAR`. In addition, specify `o_orderstatus` as the sort key for `super_mv`.

```

CREATE MATERIALIZED VIEW super_mv distkey(c_custkey) sortkey(c_custkey, o_orderstatus)
AS (
  SELECT c_custkey, o.o_orderstatus::VARCHAR AS o_orderstatus, o.o_totalprice, o_idx
  FROM customer_orders_lineitem c, c.c_orders o AT o_idx
);

```

After re-running the query, verify that Amazon Redshift can now use zone maps.

```

SELECT v.o_totalprice
FROM super_mv v
WHERE v.o_orderstatus = 'F';

```

You can verify that the range-restricted scan now uses zone maps as follows.

```

SELECT slice, is_rrscan FROM stl_scan
WHERE query = pg_last_query_id() AND perm_table_name LIKE '%super_mv%';

slice | is_rrscan
-----+-----
    0 | t
    1 | t
    2 | t
    3 | t
    4 | t
    5 | t
(6 rows)

```

Limitations for using the SUPER data type with materialized views

With Amazon Redshift, you can create materialized views with the SUPER data type to pre-compute complex queries and improve query performance. The SUPER data type lets you store the result set of a query as a flat data structure, enabling faster access and processing.

The following sections provide details on limitations and best practices for using the SUPER data type with materialized views in Amazon Redshift.

Materialized views in Amazon Redshift don't have any specific limitations with respect to PartiQL or SUPER.

For information about general SQL limitations when creating materialized views, see [Limitations](#).

For information about general SQL limitations on incremental refresh of materialized views, see [Limitations for incremental refresh](#).

Machine learning

Amazon Redshift machine learning (Amazon Redshift ML) is a robust, cloud-based service that makes it easier for analysts and data scientists of all skill levels to use machine learning technology. You provide the data that you want to train a model, and metadata associated with data inputs to Amazon Redshift. Then Amazon Redshift ML creates models that capture patterns in the input data. You can then use these models to generate predictions for new input data without incurring additional costs.

How Amazon Redshift ML works with Amazon SageMaker

Amazon Redshift works with Amazon SageMaker Autopilot to automatically obtain the best model and make the prediction function available in Amazon Redshift.

The following diagram illustrates how Amazon Redshift ML works.

The general workflow is as follows:

1. Amazon Redshift exports the training data into Amazon S3.
2. Amazon SageMaker Autopilot preprocesses the training data. *Preprocessing* performs important functions, such as imputing missing values. It recognizes that certain columns are categorical (such as the postal code), properly formats them for training, and performs numerous other tasks. Choosing the best preprocessors to apply on the training dataset is a problem in itself, and Amazon SageMaker Autopilot automates its solution.

3. Amazon SageMaker Autopilot finds the algorithm and algorithm hyperparameters that deliver the model with the most accurate predictions.
4. Amazon Redshift registers the prediction function as a SQL function in your Amazon Redshift cluster.
5. When you run CREATE MODEL statements, Amazon Redshift uses Amazon SageMaker for training. Therefore, there is an associated cost for training your model. This is a separate line item for Amazon SageMaker in your AWS bill. You also pay for the storage used in Amazon S3 for storing your training data. Inference using models created with CREATE MODEL that you can compile and run on your Redshift cluster aren't charged. There are no additional Amazon Redshift charges for using Amazon Redshift ML.

Machine learning overview

With Amazon Redshift, you can leverage machine learning capabilities to gain valuable insights from your data. This Machine Learning (ML) overview shows you how to explore, visualize, and prepare your data for ML model training and deployment. The following sections will guide you through the process of utilizing Amazon Redshift ML to unlock the potential of your data through machine learning.

By using Amazon Redshift ML, you can train machine learning models using SQL statements and invoke them in SQL queries for prediction.

To help you learn how to use Amazon Redshift ML, you can watch the following video: [Amazon Redshift ML](#).

For information about the prerequisites for setting up your Redshift cluster, permissions, and ownership for using Amazon Redshift ML, read the following sections. These sections also describe how simple training and predictions work in Amazon Redshift ML.

How machine learning can solve a problem

A machine learning model generates predictions by finding patterns in your training data and then applying these patterns to new data. In machine learning, you train these models by learning the patterns that best explain your data. Then you use the models to make predictions (also called inferences) on new data. Machine learning is typically an iterative process where you can continue to improve the accuracy of the predictions by changing parameters and improving your training data. If data changes, retraining new models with the new dataset happens.

To address various business goals, there are different fundamental machine learning approaches.

Supervised learning in Amazon Redshift ML

Amazon Redshift supports supervised learning, which is the most common approach to advanced enterprise analytics. Supervised learning is the preferred machine learning approach when you have an established set of data and an understanding of how specific input data predicts various business outcomes. These outcomes are sometimes called labels. In particular, your dataset is a table with attributes that comprise features (inputs) and targets (outputs). For example, suppose that you have a table that provides the age and postal code for past and present customers. Suppose that you also have a field “active” that is true for present customers and false for customers who have suspended their membership. The goal of supervised machine learning is to spot the patterns of age and postal code leading to customer churn, as represented by customers whose targets are “False.” You can use this model to predict customers who are likely to churn, such as suspending their membership, and potentially offer retention incentives.

Amazon Redshift supports supervised learning that includes regression, binary classification, and multiclass classification. Regression refers to the problem of predicting continuous values, such as the total spending of customers. Binary classification refers to the problem of predicting one of two outcomes, such as predicting whether a customer churns or not. Multiclass classification refers to the problem of predicting one of many outcomes, such as predicting the item a customer might be interested. Data analysts and data scientists can use it to perform supervised learning to tackle problems ranging from forecasting, personalization, or customer churn prediction. You can also use supervised learning in problems such as prediction of which sales will close, revenue prediction, fraud detection, and customer life-time value prediction.

Unsupervised learning in Amazon Redshift ML

Unsupervised learning uses machine learning algorithms to analyze and group unlabeled training data. The algorithms discover hidden patterns or groupings. The goal is to model the underlying structure or distribution in the data to learn more about the data.

Amazon Redshift supports the K-Means clustering algorithm to solve an unsupervised learning problem. This algorithm solves clustering problems where you want to discover groupings in the data. The K-Means algorithm attempts to find discrete groupings within the data. Unclassified data is grouped and partitioned based on its similarities and differences. By grouping, the K-Means algorithm iteratively determines the best centroids and assigns each member to the closest centroid. Members nearest the same centroid belong to the same group. Members of a group are as similar as possible to other members in the same group, and as different as possible from members of other groups. For example, the K-Means clustering algorithm can be used to classify cities impacted by a pandemic or classify cities based on the popularity of consumer products.

When using the K-Means algorithm, you specify an input *k* that specifies the number of clusters to find in the data. The output of this algorithm is a set of *k* centroids. Each data point belongs to one of the *k* clusters that is closest to it. Each cluster is described by its centroid. The centroid can be thought of as the multi-dimensional average of the cluster. The K-Means algorithm compares the distances to see how different the clusters are from each other. A larger distance generally indicates a greater difference between the clusters.

Preprocessing the data is important for K-Means, as it ensures that the features of the model stay on the same scale and produce reliable results. Amazon Redshift supports some K-Means preprocessors for the CREATE MODEL statement, such as StandardScaler, MinMax, and NumericPassthrough. If you don't want to apply any preprocessing for K-means, choose NumericPassthrough explicitly as a transformer. For more information about K-Means parameters, see [CREATE MODEL with K-MEANS parameters](#).

To help you learn how to perform unsupervised training with K-Means clustering, you can watch the following video: [Unsupervised training with K-Means clustering](#).

Terms and concepts for Amazon Redshift ML

The following terms are used to describe some Amazon Redshift ML concepts:

- *Machine learning* in Amazon Redshift trains a model with one SQL command. Amazon Redshift ML and Amazon SageMaker manage all the data conversions, permissions, resource usage, and discovery of the proper model.

- *Training* is the phase when Amazon Redshift creates a machine learning model by running a specified subset of data into the model. Amazon Redshift automatically launches a training job in Amazon SageMaker and generates a model.
- *Prediction* (also called *inference*) is the use of the model in Amazon Redshift SQL queries to predict outcomes. At inference time, Amazon Redshift uses a model-based prediction function as part of a larger query to produce predictions. The predictions are computed locally, at the Redshift cluster, thus providing high throughput, low latency, and zero additional cost.
- With *bring your own model (BYOM)*, you can use a model trained outside of Amazon Redshift with Amazon SageMaker for in-database inference locally in Amazon Redshift. Amazon Redshift ML supports using BYOM in local inference.
- *Local inference* is used when models are pretrained in Amazon SageMaker, compiled by Amazon SageMaker Neo, and localized in Amazon Redshift ML. To import models that are supported for local inference to Amazon Redshift, use the CREATE MODEL command. Amazon Redshift imports the pretrained SageMaker models by calling Amazon SageMaker Neo. You compile the model there and import the compiled model into Amazon Redshift. Use local inference for faster speed and lower costs.
- *Remote inference* is used when Amazon Redshift invokes a model endpoint deployed in SageMaker. Remote inference provides the flexibility to invoke all types of custom models and deep learning models, such as TensorFlow models that you built and deployed in Amazon SageMaker.

Also important are the following:

- *Amazon SageMaker* is a fully managed machine learning service. With Amazon SageMaker, data scientists and developers can easily build, train, and directly deploy models into a production-ready hosted environment. For information about Amazon SageMaker, see [What is Amazon SageMaker](#) in the *Amazon SageMaker Developer Guide*.
- *Amazon SageMaker Autopilot* is a feature set that automatically trains and tunes the best machine learning models for classification or regression, based on your data. You maintain full control and visibility. Amazon SageMaker Autopilot supports input data in tabular format. Amazon SageMaker Autopilot provides automatic data cleaning and preprocessing, automatic algorithm selection for linear regression, binary classification, and multiclass classification. It also supports automatic hyperparameter optimization (HPO), distributed training, automatic instance, and cluster size selection. For information about Amazon SageMaker Autopilot, see

[Automate model development with Amazon SageMaker Autopilot](#) in the *Amazon SageMaker Developer Guide*.

Machine learning for novices and experts

With Amazon Redshift, you can leverage Machine Learning (ML) capabilities to gain insights from your data, whether you are a novice or an expert in ML. Machine Learning is an Amazon Redshift feature that enables you to create, train, and deploy ML models using SQL commands, without the need for extensive ML expertise or complex data engineering.

The following sections guide you through the process of utilizing Machine Learning, empowering you to unlock the full potential of your data with Amazon Redshift.

Amazon Redshift ML enables you to train models with one single SQL `CREATE MODEL` command. The `CREATE MODEL` command creates a model that Amazon Redshift uses to generate model-based predictions with familiar SQL constructs.

Amazon Redshift ML is especially useful when you don't have expertise in machine learning, tools, languages, algorithms, and APIs. With Amazon Redshift ML, you don't have to perform the undifferentiated heavy lifting required for integrating with an external machine learning service. Amazon Redshift saves you the time to format and move data, manage permission controls, or build custom integrations, workflows, and scripts. You can easily use popular machine learning algorithms and simplify training needs that require frequent iteration from training to prediction. Amazon Redshift automatically discovers the best algorithm and tunes the best model for your problem. You can make predictions from within the Amazon Redshift cluster without the need to move data out of Amazon Redshift nor to interface with and pay for another service.

Amazon Redshift ML supports data analysts and data scientists in using machine learning. It also makes it possible for machine learning experts to use their knowledge to guide the `CREATE MODEL` statement to use only the aspects that they specify. By doing so, you can speed up the time that `CREATE MODEL` needs to find the best candidate, improve the accuracy of the model, or both.

The `CREATE MODEL` statement offers flexibility in how you can specify the parameters to training job. Using this flexibility, both machine learning novices or experts can choose their preferred preprocessors, algorithms, problem types, and hyperparameters. For example, a user interested in customer churn might specify for the `CREATE MODEL` statement that the problem type is a binary classification, which works well for customer churn. Then the `CREATE MODEL` statement narrows down its search for the best model into binary classification models. Even with the user choice of

the problem type, there are still many options that the CREATE MODEL statement can work with. For example, the CREATE MODEL discovers and applies the best preprocessing transformations and discovers the best hyperparameter settings.

Amazon Redshift ML makes training easier by automatically finding the best model using Amazon SageMaker Autopilot. Behind the scenes, Amazon SageMaker Autopilot automatically trains and tunes the best machine learning model based on your supplied data. Amazon SageMaker Neo then compiles the training model and makes it available for prediction in your Redshift cluster. When you run a machine learning inference query using a trained model, the query can use the massively parallel processing capabilities of Amazon Redshift. At the same time, the query can use machine learning–based prediction.

- As a *machine learning beginner*, with general knowledge of different aspects of machine learning such as preprocessors, algorithms, and hyperparameters, use the CREATE MODEL statement for only the aspects that you specify. Then you can shorten the time that CREATE MODEL needs to find the best candidate or improve the accuracy of the model. Also, you can increase the business value of the predictions by introducing additional domain knowledge such as the problem type or the objective. For example, in a customer churn scenario, if the outcome “customer is not active” is rare, then the F1 objective is often preferred to the Accuracy objective. Because high Accuracy models might predict “customer is active” all the time, this results in high accuracy but little business value. For information about F1 objectives, see [AutoMLJobObjective](#) in the *Amazon SageMaker API Reference*.

For more information about the basic options for the CREATE MODEL statement, see [Simple CREATE MODEL](#).

- As a *machine learning advanced practitioner*, you can specify the problem type and preprocessors for certain (but not all) features. Then CREATE MODEL follows your suggestions on the specified aspects. At the same time, CREATE MODEL still discovers the best preprocessors for the remaining features and the best hyperparameters. For more information about how you can constrain one or more aspects of the training pipeline, see [CREATE MODEL with user guidance](#).
- As a *machine learning expert*, you can take full control of training and hyperparameter tuning. Then the CREATE MODEL statement doesn't attempt to discover the optimal preprocessors, algorithms, and hyperparameters because you make all the choices. For more information about how to use CREATE MODEL with AUTO OFF, see [CREATE XGBoost models with AUTO OFF](#).
- As a *data engineer*, you can bring a pretrained XGBoost model in Amazon SageMaker and import it into Amazon Redshift for local inference. With bring your own model (BYOM), you can use a model trained outside of Amazon Redshift with Amazon SageMaker for in-database inference

locally in Amazon Redshift. Amazon Redshift ML supports using BYOM in either local or remote inference.

For more information about how to use the CREATE MODEL statement for local or remote inference, see [Bring your own model \(BYOM\) - local inference](#).

As an Amazon Redshift ML user, you can choose any of the following options to train and deploy your model:

- Problem types, see [CREATE MODEL with user guidance](#).
- Objectives, see [CREATE MODEL with user guidance](#) or [CREATE XGBoost models with AUTO OFF](#).
- Model types, see [CREATE XGBoost models with AUTO OFF](#).
- Preprocessors, see [CREATE MODEL with user guidance](#).
- Hyperparameters, see [CREATE XGBoost models with AUTO OFF](#).
- Bring your own model (BYOM), see [Bring your own model \(BYOM\) - local inference](#).

Costs for using Amazon Redshift ML

With Amazon Redshift, you can leverage machine learning capabilities to gain insights from your data without the need for extensive data engineering or machine learning expertise. The following sections describe the costs associated with using Amazon Redshift ML, helping you plan and optimize your expenses while leveraging this powerful machine learning integration.

Amazon Redshift ML uses your existing cluster resources for prediction so you can avoid additional Amazon Redshift charges. There is no additional Amazon Redshift charge for creating or using a model. Prediction happens locally in your Redshift cluster, so you don't have to pay extra unless you need to resize your cluster. Amazon Redshift ML uses Amazon SageMaker for training your model, which does have an additional associated cost.

There is no additional charge for prediction functions that run within your Amazon Redshift cluster. The CREATE MODEL statement uses Amazon SageMaker and incurs an additional cost. The cost increases with the number of cells in your training data. The number of cells is the product of the number of records (in the training query or table times) times the number of columns. For example, when a SELECT query of the CREATE MODEL statement creates 10,000 records and 5 columns, then the number of cells it creates is 50,000.

In some cases, the training data produced by the SELECT query of the CREATE MODEL exceeds the MAX_CELLS limit that you provided (or the default 1 million if you didn't provide a limit). In these cases, CREATE MODEL randomly chooses approximately MAX_CELLS (that is the "number of columns" records from the training dataset). CREATE MODEL then performs training using these randomly chosen tuples. The random sampling ensures that the reduced training dataset doesn't have any bias. Thus, by setting the MAX_CELLS, you can control your training costs.

When using the CREATE MODEL statement, you can use the MAX_CELLS and MAX_RUNTIME options to control the costs, time, and potential model accuracy.

MAX_RUNTIME specifies the maximum amount of time the training can take in SageMaker when the AUTO ON or OFF option is used. Training jobs often complete sooner than MAX_RUNTIME, depending on the size of the dataset. After a model is trained, Amazon Redshift does additional work in the background to compile and install your models in your cluster. Thus, CREATE MODEL can take longer than MAX_RUNTIME to complete. However, MAX_RUNTIME limits the amount of computation and time used in SageMaker to train your model. You can check the status of your model at any time using SHOW MODEL.

When you run CREATE MODEL with AUTO ON, Amazon Redshift ML uses SageMaker Autopilot to automatically and intelligently explore different models (or candidates) to find the best one. MAX_RUNTIME limits the amount of time and computation spent. If MAX_RUNTIME is set too low, there might not be enough time to explore even one candidate. If you see the error "Autopilot candidate has no models," rerun the CREATE MODEL with a larger MAX_RUNTIME value. For more information about this parameter, see [MaxAutoMLJobRuntimeInSeconds](#) in the *Amazon SageMaker API Reference*.

When you run CREATE MODEL with AUTO OFF, MAX_RUNTIME corresponds to a limit on how long the training job is run in SageMaker. Training jobs often complete sooner, depending on the size of the dataset and other parameters used, such as num_rounds in MODEL_TYPE XGBOOST.

You can also control costs or reduce training time by specifying a smaller MAX_CELLS value when you run CREATE MODEL. A *cell* is an entry in the database. Each row corresponds to as many cells as there are columns, which can be of fixed or varying width. MAX_CELLS limits the number of cells, and thus the number of training examples used to train your model. By default, MAX_CELLS is set to 1 million cells. Reducing MAX_CELLS reduces the number of rows from the result of the SELECT query in CREATE MODEL that Amazon Redshift exports and sends to SageMaker to train a model. Reducing MAX_CELLS thus reduces the size of the dataset used to train models both with AUTO ON and AUTO OFF. This approach helps reduce the costs and time to train models. To

see information about training and billing times of a specific training job, choose **Training jobs** in Amazon SageMaker.

Increasing MAX_RUNTIME and MAX_CELLS often improves model quality by allowing SageMaker to explore more candidates. This way, SageMaker can take more time to train each candidate and use more data to train better models. If you want faster iteration or exploration of your dataset, use lower MAX_RUNTIME and MAX_CELLS. If you want improved accuracy of models, use higher MAX_RUNTIME and MAX_CELLS.

For more information about costs associated with various cell numbers and free trial details, see [Amazon Redshift pricing](#).

Getting started with Amazon Redshift ML

Amazon Redshift ML makes it easy for SQL users to create, train, and deploy machine learning models using familiar SQL commands. With Amazon Redshift ML, you can use your data in your Redshift cluster to train model with Amazon SageMaker. Later, the models are localized and predictions can be made within an Amazon Redshift database. Amazon Redshift ML currently supports the machine learning algorithms XGBoost (AUTO ON and OFF) and multilayer perceptron (AUTO ON), K-Means (AUTO OFF), and Linear Learner.

Cluster and configure setup for Amazon Redshift ML administration

Before you work with Amazon Redshift ML, complete the cluster setup and configure permissions for using Amazon Redshift ML.

Cluster setup for using Amazon Redshift ML

Before you work with Amazon Redshift ML, complete the following prerequisites.

As an Amazon Redshift administrator, do the following one-time setup.

To perform one-time cluster setup for Amazon Redshift ML

1. Create a Redshift cluster using the AWS Management Console or the AWS Command Line Interface (AWS CLI). Make sure to attach the AWS Identity and Access Management (IAM) policy while creating the cluster. For more information about permissions required to use Amazon Redshift ML with Amazon SageMaker, see [Permissions required to use Amazon Redshift machine learning \(ML\) with Amazon SageMaker](#).
2. Create the IAM role required for using Amazon Redshift ML in one of the following ways:
 - A simple operation is to create an IAM role with `AmazonS3FullAccess` and `AmazonSageMakerFullAccess` policies for use with Amazon Redshift ML. If you plan to also create Forecast models, attach the `AmazonForecastFullAccess` policy to your role as well.
 - We recommend that you create an IAM role through the Amazon Redshift console that has the `AmazonRedshiftAllCommandsFullAccess` policy with permissions to run SQL commands, such as `CREATE MODEL`. Amazon Redshift uses a seamless API-based mechanism to programmatically create IAM roles in your AWS account on your behalf. Amazon Redshift automatically attaches existing AWS managed policies to the IAM role. This approach means that you can stay within the Amazon Redshift console and don't have to switch to the IAM console for role creation. For more information, see [Creating an IAM role as default for Amazon Redshift](#).

When an IAM role is created as the default for your cluster, include `redshift` as part of the resource name or use a Redshift-specific tag to tag those resources.

If your cluster has enhanced Amazon VPC routing turned on, you can use an IAM role created through the Amazon Redshift console. This IAM role has the `AmazonRedshiftAllCommandsFullAccess` policy attached and adds the following permissions to the policy. These additional permissions allow Amazon Redshift to create and delete an elastic network interface (ENI) in your account and attach it to compilation tasks running on Amazon EC2 or Amazon ECS. Doing this enables objects in your Amazon S3 buckets to be accessed only from within a virtual private cloud (VPC) with internet access blocked.

```
{
  "Effect": "Allow",
  "Action": [
    "ec2:DescribeVpcEndpoints",
    "ec2:DescribeDhcpOptions",
    "ec2:DescribeVpcs",
```

```

    "ec2:DescribeSubnets",
    "ec2:DescribeSecurityGroups",
    "ec2:DescribeNetworkInterfaces",
    "ec2:DeleteNetworkInterfacePermission",
    "ec2:DeleteNetworkInterface",
    "ec2:CreateNetworkInterfacePermission",
    "ec2:CreateNetworkInterface",
    "ec2:ModifyNetworkInterfaceAttribute"
  ],
  "Resource": "*"
}

```

- If you want to create an IAM role with a more restrictive policy, you can use the policy following. You can also modify this policy to meet your needs.

The Amazon S3 bucket `redshift-downloads/redshift-ml/` is the location where the sample data used for other steps and examples is stored. You can remove it if you don't need to load data from Amazon S3. Or, replace it with other Amazon S3 buckets that you use to load data into Amazon Redshift.

The *your-account-id*, *your-role*, and `amzn-s3-demo-bucket` values are the ones that you specify as part of your `CREATE MODEL` command.

(Optional) Use the AWS KMS keys section of the sample policy if you specify an AWS KMS key while using Amazon Redshift ML. The *your-kms-key* value is the key that you use as part of your `CREATE MODEL` command.

        "s3:AbortMultipartUpload",
        "s3:GetObject",
        "s3:DeleteObject",
        "s3:PutObject"
    ],
    "Resource": [
        "arn:aws:iam::<your-account-id>:role/<your-role>",
        "arn:aws:s3:::amzn-s3-demo-bucket/*",
        "arn:aws:s3:::redshift-downloads/*"
    ]
},
{
    "Effect": "Allow",
    "Action": [
        "s3:GetBucketLocation",
        "s3:ListBucket"
    ],
    "Resource": [
        "arn:aws:s3:::amzn-s3-demo-bucket",
        "arn:aws:s3:::redshift-downloads"
    ]
}
// Optional section needed if you use AWS KMS keys.
,{
    "Effect": "Allow",
    "Action": [
        "kms:CreateGrant",
        "kms:Decrypt",
        "kms:DescribeKey",
        "kms:Encrypt",
        "kms:GenerateDataKey*"
    ],
    "Resource": [
        "arn:aws:kms:<your-region>:<your-account-id>:key/<your-kms-key>"
    ]
}

```

```
]
}
```

3. To allow Amazon Redshift and SageMaker to assume the role to interact with other services, add the following trust policy to the IAM role.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Principal": {
        "Service": [
          "redshift.amazonaws.com",
          "sagemaker.amazonaws.com",
          "forecast.amazonaws.com"
        ]
      },
      "Action": "sts:AssumeRole"
    }
  ]
}
```

4. (Optional) Create an Amazon S3 bucket and an AWS KMS key. These are for Amazon Redshift to use to store the training data sent to Amazon SageMaker and receive the trained model from Amazon SageMaker.
5. (Optional) Create different combinations of IAM roles and Amazon S3 buckets for controlling access to different user groups.
6. (Optional) When you turn on VPC routing for your Redshift cluster, create an Amazon S3 endpoint and a SageMaker endpoint for the VPC that your Redshift cluster is in. Doing this makes it possible for traffic to run through your VPC between services during CREATE MODEL. For more information about VPC routing, see [Enhanced VPC routing in Amazon Redshift](#).

For more information about permissions required to specify a private VPC for your hyperparameter tuning job, see [Permissions required to use Amazon Redshift ML with Amazon SageMaker](#).

For information on how to use the CREATE MODEL statement to start creating models for different use cases, see [CREATE MODEL](#).

Managing permissions and ownership

Just as with other database objects, such as tables or functions, Amazon Redshift binds creating and using ML models to access control mechanisms. There are separate permissions for creating a model that runs prediction functions.

The following examples use two user groups, `retention_analyst_grp` (model creator) and `marketing_analyst_grp` (model user) to illustrate how Amazon Redshift manages access control. The retention analyst creates machine learning models that the other set of users can use through acquired permissions.

A superuser can GRANT USER or GROUP permission to create machine learning models using the following statement.

```
GRANT CREATE MODEL TO GROUP retention_analyst_grp;
```

Users or groups with this permission can create a model in any schema in the cluster if a user has the usual CREATE permission on the SCHEMA. The machine learning model is part of the schema hierarchy in a similar way to tables, views, procedures, and user-defined functions.

Assuming a schema `demo_ml` already exists, grant the two user groups the permission on the schema as follows.

```
GRANT CREATE, USAGE ON SCHEMA demo_ml TO GROUP retention_analyst_grp;
```

```
GRANT USAGE ON SCHEMA demo_ml TO GROUP marketing_analyst_grp;
```

To let other users use your machine learning inference function, grant the EXECUTE permission. The following example uses the EXECUTE permission to grant the `marketing_analyst_grp` GROUP the permission to use the model.

```
GRANT EXECUTE ON MODEL demo_ml.customer_churn_auto_model TO GROUP  
marketing_analyst_grp;
```

Use the REVOKE statement with CREATE MODEL and EXECUTE to revoke those permissions from users or groups. For more information on permission control commands, see [GRANT](#) and [REVOKE](#).

Using model explainability with Amazon Redshift ML

With model explainability in Amazon Redshift ML, you use feature importance values to help understand how each attribute in your training data contributes to the predicted result.

Model explainability helps improve your machine learning (ML) models by explaining the predictions that your models make. Model explainability helps explain how these models make predictions using a feature attribution approach.

Amazon Redshift ML incorporates model explainability to provide model explanation functionality to Amazon Redshift ML users. For more information about model explainability, see [What Is Fairness and Model Explainability for Machine Learning Predictions?](#) in the *Amazon SageMaker Developer Guide*.

Model explainability also monitors the inferences that models make in production for feature attribution drift. It also provides tools to help you generate model governance reports that you can use to inform risk and compliance teams, and external regulators.

When you specify the AUTO ON or AUTO OFF option when using the CREATE MODEL statement, after the model training job finishes, SageMaker creates the explanation output. You can use the EXPLAIN_MODEL function to query the explainability report in a JSON format. For more information, see [Machine learning functions](#).

Amazon Redshift ML probability metrics

In supervised learning problems, class labels are outcomes of predictions that use the input data. For example, if you're using a model to predict whether a customer would resubscribe to a streaming service, possible labels are likely and unlikely. Redshift ML provides the capability of probability metrics, which assign a probability to each label to indicate its likelihood. This helps you make more informed decisions based on the predicted outcomes. In Amazon Redshift ML, probability metrics are available when creating AUTO ON models with a problem type of either binary classification or multiclass classification. If you omit the AUTO ON parameter, Redshift ML assumes that the model should have AUTO ON.

Create the model

When creating a model, Amazon Redshift automatically detects the model type and problem type. If it is a classification problem, Redshift automatically creates a second inference function that you can use to output probabilities relative to each label. This second inference function's name is your

specified inference function name followed by the string `_probabilities`. For example, if you name your inference function as `customer_churn_predict`, then the second inference function's name is `customer_churn_predict_probabilities`. You can then query this function to get the probabilities of each label.

```
CREATE MODEL customer_churn_model
FROM customer_activity
    PROBLEM_TYPE BINARY_CLASSIFICATION
TARGET churn
FUNCTION customer_churn_predict
IAM_ROLE {default}
AUTO ON
SETTINGS ( S3_BUCKET 'amzn-s3-demo-bucket'
```

Get probabilities

Once the probability function is ready, running the command returns a [SUPER type](#) that contains arrays of the returned probabilities and their associated labels. For example, the result `"probabilities" : [0.7, 0.3], "labels" : ["False.", "True."]` means that the False label has a probability of 0.7, and the True label has a probability of 0.3.

```
SELECT customer_churn_predict_probabilities(Account_length, Area_code,
      VMail_message, Day_mins, Day_calls, Day_charge,Eve_mins, Eve_calls,
      Eve_charge, Night_mins, Night_calls, Night_charge,Intl_mins, Intl_calls,
      Intl_charge, Cust_serv_calls)
FROM customer_activity;

customer_churn_predict_probabilities
-----
{"probabilities" : [0.7, 0.3], "labels" : ["False.", "True."]}
{"probabilities" : [0.8, 0.2], "labels" : ["False.", "True."]}
{"probabilities" : [0.75, 0.25], "labels" : ["True.", "False"]}
```

The probabilities and labels arrays are always sorted by their probabilities in descending order. You can write a query to return just the predicted label with the highest probability by unnesting the SUPER returned results of the probability function.

```
SELECT prediction.labels[0], prediction.probabilities[0]
      FROM (SELECT customer_churn_predict_probabilities(Account_length,
      Area_code,
```

```

        VMail_message, Day_mins, Day_calls, Day_charge, Eve_mins, Eve_calls,
        Eve_charge, Night_mins, Night_calls, Night_charge, Intl_mins, Intl_calls,
        Intl_charge, Cust_serv_calls) AS prediction
FROM customer_activity);

```

labels	probabilities
"False."	0.7
"False."	0.8
"True."	0.75

To make the queries simpler, you can store the results of the prediction function in a table.

```

CREATE TABLE churn_auto_predict_probabilities AS
    (SELECT customer_churn_predict_probabilities(Account_length, Area_code,
        VMail_message, Day_mins, Day_calls, Day_charge, Eve_mins, Eve_calls,
        Eve_charge, Night_mins, Night_calls, Night_charge, Intl_mins,
        Intl_calls, Intl_charge, Cust_serv_calls) AS prediction
FROM customer_activity);

```

You can query the table with the results to return only predictions that have a probability higher than 0.7.

```

SELECT prediction.labels[0], prediction.probabilities[0]
FROM churn_auto_predict_probabilities
WHERE prediction.probabilities[0] > 0.7;

```

labels	probabilities
"False."	0.8
"True."	0.75

Using index notation, you can get the probability of a specific label. The following example returns probabilities of all the True . labels.

```

SELECT label, index, p.prediction.probabilities[index]
FROM churn_auto_predict_probabilities p, p.prediction.labels AS label AT index
WHERE label='True.';

```

label	index	probabilities
-------	-------	---------------

```
"True." | 0 | 0.3
"True." | 0 | 0.2
"True." | 0 | 0.75
```

The following example returns all rows that have a True. label with a probability greater than 0.7, indicating that the customer is likely to churn.

```
SELECT prediction.labels[0], prediction.proBABILITIES[0]
FROM churn_auto_predict_probabilities
WHERE prediction.proBABILITIES[0] > 0.7 AND prediction.labels[0] = "True.";
```

```
labels      | probabilities
-----+-----
"True."    | 0.75
```

Tutorials for Amazon Redshift ML

You can use Amazon Redshift ML to train machine learning models using SQL statements, and then invoke the models in SQL queries for prediction. Machine learning in Amazon Redshift trains a model with one SQL command. Amazon Redshift automatically launches a training job in Amazon SageMaker and generates a model. Once a model is created, you can perform predictions in Amazon Redshift using the model's prediction function.

Follow the steps in these tutorials to learn about Amazon Redshift ML features:

[Tutorial: Building customer churn models](#)

In this tutorial, you use Amazon Redshift ML to create a customer churn model with the CREATE MODEL command, and run prediction queries for user scenarios. Then, you implement queries using the SQL function that the CREATE MODEL command generates.

[Tutorial: Building remote inference models](#)

The following tutorial goes over the steps of how to create a [Random Cut Forest model](#) that has been previously trained and deployed in Amazon SageMaker, outside of Amazon Redshift.

[Tutorial: Building K-means clustering models](#)

In this tutorial, you use Amazon Redshift ML to create, train, and deploy a machine learning model based on the [K-means algorithm](#).

[Tutorial: Building multi-class classification models](#)

In this tutorial, you use Amazon Redshift ML to create a machine learning model that solves multi-class classification problems. The multi-class classification algorithm classifies data points into one of three or more classes. Then, you implement queries using the SQL function that the CREATE MODEL command generates.

[Tutorial: Building XGBoost models](#)

In this tutorial, you create a model with data from Amazon S3 and run prediction queries with the model using Amazon Redshift ML. The XGBoost algorithm is an optimized implementation of the gradient boosted trees algorithm.

[Tutorial: Building regression models](#)

In this tutorial, you use Amazon Redshift ML to create a machine learning regression model and run prediction queries on the model. Regression models allow you to predict numerical outcomes, such as the price of a house, or how many people will use a city's bike rental service.

[Tutorial: Building regression models with linear learner](#)

In this tutorial, you create a linear learner model with data from Amazon S3 and run prediction queries with the model using Amazon Redshift ML. The SageMaker linear learner algorithm solves either regression or multi-class classification problems.

[Tutorial: Building multi-class classification models with linear learner](#)

In this tutorial, you create a linear learner model with data from Amazon S3, and then run prediction queries with the model using Amazon Redshift ML. The SageMaker linear learner algorithm solves either regression or classification problems.

Tutorial: Building customer churn models

In this tutorial, you use Amazon Redshift ML to create a customer churn model with the CREATE MODEL command, and run prediction queries for user scenarios. Then, you implement queries using the SQL function that the CREATE MODEL command generates.

You can use a simple CREATE MODEL command to export training data, train a model, import the model, and prepare an Amazon Redshift prediction function. Use the CREATE MODEL statement to specify training data either as a table or SELECT statement.

This example uses historical information to construct a machine learning model of a mobile operator's customer churn. First, SageMaker trains your machine learning model and then tests your model using the profile information of an arbitrary customer. After the model is validated, Amazon SageMaker deploys the model and the prediction function to Amazon Redshift. You can use the prediction function to predict whether a customer is going to churn or not.

Use case examples

You can solve other binary classification problems using Amazon Redshift ML, such as predicting if a sales lead will close or not. You could also predict whether a financial transaction is fraudulent or not.

Tasks

- Prerequisites
- Step 1: Load the data from Amazon S3 to Amazon Redshift
- Step 2: Create the machine learning model
- Step 3: Perform predictions with the model

Prerequisites

To complete this tutorial, you must have the following prerequisites:

- You must set up an Amazon Redshift cluster for Amazon Redshift ML. To do so, use the documentation for [Cluster and configure setup for Amazon Redshift ML administration](#).
- The Amazon Redshift cluster that you use to create the model, and the Amazon S3 bucket that you use to stage the training data and store the model artifacts must be in the same AWS Region.
- To download the SQL commands and the sample dataset used in this documentation, do one of the following:
 - Download the [SQL commands](#), [Customer activity file](#), and [Abalone file](#).
 - Using the AWS CLI for Amazon S3, run the following command. You can use your own target path.

```
aws s3 cp s3://redshift-downloads/redshift-ml/tutorial-scripts/redshift-ml-tutorial.sql </target/path>
aws s3 cp s3://redshift-downloads/redshift-ml/customer_activity/customer_activity.csv </target/path>
aws s3 cp s3://redshift-downloads/redshift-ml/abalone_xgb/abalone_xgb.csv </target/path>
```

Step 1: Load the data from Amazon S3 to Amazon Redshift

Use the [Amazon Redshift query editor v2](#) to edit and run queries and visualize results.

Running the following queries creates a table named `customer_activity` and ingests the sample dataset from Amazon S3.

```
DROP TABLE IF EXISTS customer_activity;

CREATE TABLE customer_activity (
  state varchar(2),
  account_length int,
  area_code int,
  phone varchar(8),
  intl_plan varchar(3),
  vMail_plan varchar(3),
  vMail_message int,
```

```
day_mins float,  
day_calls int,  
day_charge float,  
total_charge float,  
eve_mins float,  
eve_calls int,  
eve_charge float,  
night_mins float,  
night_calls int,  
night_charge float,  
intl_mins float,  
intl_calls int,  
intl_charge float,  
cust_serv_calls int,  
churn varchar(6),  
record_date date  
);  
  
COPY customer_activity  
FROM 's3://redshift-downloads/redshift-ml/customer_activity/'  
REGION 'us-east-1' IAM_ROLE default  
FORMAT AS CSV IGNOREHEADER 1;
```

Step 2: Create the machine learning model

Churn is our target input in this model. All other inputs for the model are attributes that help to create a function to predict churn.

The following example uses the CREATE MODEL operation to deliver a model that predicts whether a customer will be active, using inputs such as the customer's age, postal code, spending, and cases. In the following example, replace amzn-s3-demo-bucket with your own Amazon S3 bucket.

```
CREATE MODEL customer_churn_auto_model  
FROM  
  (  
    SELECT state,  
           account_length,  
           area_code,  
           total_charge/account_length AS average_daily_spend,  
           cust_serv_calls/account_length AS average_daily_cases,  
           churn  
    FROM customer_activity  
    WHERE record_date < '2020-01-01'
```

```
    )
TARGET churn FUNCTION ml_fn_customer_churn_auto
IAM_ROLE default SETTINGS (
  S3_BUCKET 'amzn-s3-demo-bucket'
);
```

The SELECT query in the preceding example creates the training data. The TARGET clause specifies which column is the machine learning label that the CREATE MODEL operation uses to learn how to predict. The target column “churn” indicates whether the customer still has an active membership or has suspended the membership. The S3_BUCKET field is the name of the Amazon S3 bucket that you previously created. The Amazon S3 bucket is used to share training data and artifacts between Amazon Redshift and Amazon SageMaker. The remaining columns are the features that are used for the prediction.

For a summary of the syntax and features of a basic use case of the CREATE MODEL command, see [Simple CREATE MODEL](#).

Add permissions for server-side encryption (optional)

Amazon Redshift by default uses Amazon SageMaker Autopilot for training. In particular, Amazon Redshift securely exports the training data to the customer-specified Amazon S3 bucket. If you don't specify a KMS_KEY_ID, then the data is encrypted using server-side encryption SSE-S3 by default.

When you encrypt your input using server-side encryption with a AWS KMS managed key (SSE-MMS), then add the following permissions:

```
{
  "Effect": "Allow",
  "Action": [
    "kms:Encrypt"
    "kms:Decrypt"
  ]
}
```

For more information about Amazon SageMaker roles, see [Amazon SageMaker roles](#) in the *Amazon SageMaker Developer Guide*.

Check the status of model training (optional)

You can use the SHOW MODEL command to know when your model is ready.

Use the following operation to check the status of the model.

```
SHOW MODEL customer_churn_auto_model;
```

The following is an example of the output of the previous operation.

```
+-----+
+-----+
+
|      Key      |
|      Value    |

```

```
+-----  
+-----  
+
```

When the model training is complete, the `model_state` variable becomes `Model is Ready`, and the prediction function becomes available.

Step 3: Perform predictions with the model

You can use SQL statements to view the predictions made by the prediction model. In this example, the prediction function created by the `CREATE MODEL` operation is named `m1_fn_customer_churn_auto`. The input arguments for the prediction function correspond to the types of the features, such as `varchar` for the `state` and `integer` for `account_length`. The output of the prediction function is the same type as the `TARGET` column of the `CREATE MODEL` statement.

1. You trained the model on data from before `2020-01-01`, so now you use the prediction function on the testing set. The following query displays the predictions of whether customers who signed up after `2020-01-01` will go through churn or not.

```
SELECT  
    phone,  
    m1_fn_customer_churn_auto(  
        state,  
        account_length,  
        area_code,  
        total_charge / account_length,  
        cust_serv_calls / account_length  
    ) AS active  
FROM  
    customer_activity  
WHERE  
    record_date > '2020-01-01';
```

2. The following example uses the same prediction function for a different use case. In this case, Amazon Redshift predicts the proportion of churners and non-churners among customers from different states where the record date is greater than `2020-01-01`.

```
WITH predicted AS (  
    SELECT  
        state,
```

```
        ml_fn_customer_churn_auto(
            state,
            account_length,
            area_code,
            total_charge / account_length,
            cust_serv_calls / account_length
        ) :: varchar(6) AS active
    FROM
        customer_activity
    WHERE
        record_date > '2020-01-01'
)
SELECT
    state,
    SUM(
        CASE
            WHEN active = 'True.' THEN 1
            ELSE 0
        END
    ) AS churners,
    SUM(
        CASE
            WHEN active = 'False.' THEN 1
            ELSE 0
        END
    ) AS nonchurners,
    COUNT(*) AS total_per_state
FROM
    predicted
GROUP BY
    state
ORDER BY
    state;
```

3. The following example uses the prediction function for the use case of predicting the percentage of customers who churn in a state. In this case, Amazon Redshift predicts the churn percentage where the record date is greater than 2020-01-01.

```
WITH predicted AS (
    SELECT
        state,
        ml_fn_customer_churn_auto(
            state,
```

```
        account_length,  
        area_code,  
        total_charge / account_length,  
        cust_serv_calls / account_length  
    ) :: varchar(6) AS active  
FROM  
    customer_activity  
WHERE  
    record_date > '2020-01-01'  
)  
SELECT  
    state,  
    CAST((CAST((SUM(  
        CASE  
            WHEN active = 'True.' THEN 1  
            ELSE 0  
        END  
    )) AS FLOAT) / CAST(COUNT(*) AS FLOAT)) AS DECIMAL (3, 2)) AS pct_churn,  
    COUNT(*) AS total_customers_per_state  
FROM  
    predicted  
GROUP BY  
    state  
ORDER BY  
    3 DESC;
```

Tutorial: Building remote inference models

The following tutorial goes over the steps of how to create a [Random Cut Forest model](#) that has been previously trained and deployed in Amazon SageMaker, outside of Amazon Redshift. The Random Cut Forest algorithm detects anomalous data points within a dataset. Creating a model with remote inference allows you to bring your Random Cut Forest SageMaker model into Amazon Redshift. Then, in Amazon Redshift, you use SQL to perform predictions on a remote SageMaker endpoint.

You can use a CREATE MODEL command to import a machine learning model from an Amazon SageMaker endpoint and prepare an Amazon Redshift prediction function. When using the CREATE MODEL operation, you provide the SageMaker machine learning model's endpoint name.

In this tutorial, you create an Amazon Redshift machine learning model using a SageMaker model endpoint. Once your machine learning model is ready, you can use it to perform predictions in Amazon Redshift. First, you train and create an endpoint in Amazon SageMaker, and then you get the endpoint name. Then, you use the CREATE MODEL command to create a model with Amazon Redshift ML. Finally, you perform predictions on the model using the prediction function that the CREATE MODEL command generates.

Use case examples

You can use Random Cut Forest models and remote inference for anomaly detection in other datasets, such as predicting a rapid increase or decrease in e-commerce transactions. You could also predict significant changes in weather or seismic activity.

Tasks

- Prerequisites
- Step 1: Deploy the Amazon SageMaker model
- Step 2: Get the SageMaker model endpoint
- Step 3: Load the data from Amazon S3 to Amazon Redshift
- Step 4: Create a model with Amazon Redshift ML
- Step 5: Perform predictions with the model

Prerequisites

To complete this tutorial, you must have the following prerequisites:

- You have completed the [Administrative setup](#) for Amazon Redshift ML.
- You have downloaded the [NYC taxi dataset](#), [created an Amazon S3 bucket](#), and [uploaded the data into the Amazon S3 bucket](#).
- You must train, deploy the SageMaker model and endpoint, and get the name of the SageMaker endpoint. Use [this AWS CloudFormation template](#) to provision all the SageMaker resources in your AWS account automatically.

Step 1: Deploy the Amazon SageMaker model

1. To deploy the model, go to the Amazon SageMaker console, choose **Notebook instances** under **Notebook** in the navigation pane.
2. Choose **Open Jupyter** for the Jupyter notebook that was created by the CloudFormation template.
3. Choose `bring-your-own-model-remote-inference.ipynb`.
4. Set up the parameters to store the training input and output in Amazon S3 by replacing the following lines with your Amazon S3 bucket and prefix.

```
data_location=f"s3://{bucket}/{prefix}/",  
output_path=f"s3://{bucket}/{prefix}/output",
```

5. Choose the **fast-forward** button to run all cells.

Step 2: Get the SageMaker model endpoint

On the Amazon SageMaker console, under **Inference** in the navigation pane, choose **Endpoints** and find your model name. You must copy your model's endpoint name when you create the remote inference model in Amazon Redshift.

Step 3: Load the data from Amazon S3 to Amazon Redshift

Use the [Amazon Redshift query editor v2](#) to run the following SQL commands in Amazon Redshift. These commands drop the `rcf_taxi_data` table if it exists, create a table of the same name, and load the sample dataset into the table.

```
DROP TABLE IF EXISTS public.rcf_taxi_data CASCADE;  
  
CREATE TABLE public.rcf_taxi_data (ride_timestamp timestamp, nbr_passengers int);
```

```

COPY public.rcf_taxi_data
FROM
  's3://sagemaker-sample-files/datasets/tabular/anomaly_benchmark_taxi/
NAB_nyc_taxi.csv'
IAM_ROLE default
IGNOREHEADER 1
FORMAT AS CSV;

```

Step 4: Create a model with Amazon Redshift ML

Run the following query to create a model in Amazon Redshift ML using the SageMaker model endpoint you got in the previous step. Replace *randomcutforest-xxxxxxxx* with your own SageMaker endpoint's name.

```

CREATE MODEL public.remote_random_cut_forest
FUNCTION remote_fn_rcf(int)
RETURNS decimal(10, 6) SAGEMAKER '<randomcutforest-xxxxxxxx>' IAM_ROLE default;

```

Check the model status (optional)

You can use the SHOW MODEL command to know when your model is ready.

To check the model status, use the following SHOW MODEL operation.

```
SHOW MODEL public.remote_random_cut_forest
```

The output shows the SageMaker endpoint and function name.

Model Name	remote_random_cut_forest
Schema Name	public
Owner	awsuser
Creation Time	Wed, 15.06.2022 17:58:21
Model State	READY
PARAMETERS:	
Endpoint	<randomcutforest-xxxxxxxx>
Function Name	remote_fn_rcf
Inference Type	Remote

Function Parameter Types	int4
IAM Role	default-aws-iam-role
+-----+-----+	

Step 5: Perform predictions with the model

The Amazon SageMaker Random Cut Forest algorithm is designed to detect anomalous data points within a dataset. In this example, your model is designed to detect spikes in taxi rides due to important events. You can use the model to predict anomalous events by generating an anomaly score for each data point.

Use the following query to compute anomaly scores across the entire taxi dataset. Note that you reference the function that you used in your CREATE MODEL statement in the previous step.

```
SELECT
    ride_timestamp,
    nbr_passengers,
    public.remote_fn_rcf(nbr_passengers) AS score
FROM
    public.rcf_taxi_data;
```

Check for high and low anomalies (optional)

Run the following query to find any data points with scores greater than three standard deviations from the mean score.

```
WITH score_cutoff AS (
    SELECT
        STDDEV(public.remote_fn_rcf(nbr_passengers)) AS std,
        AVG(public.remote_fn_rcf(nbr_passengers)) AS mean,
        (mean + 3 * std) AS score_cutoff_value
    FROM
        public.rcf_taxi_data
)
SELECT
    ride_timestamp,
    nbr_passengers,
    public.remote_fn_rcf(nbr_passengers) AS score
FROM
    public.rcf_taxi_data
WHERE
    score > (
```

```
        SELECT
            score_cutoff_value
        FROM
            score_cutoff
    )
ORDER BY
    2 DESC;
```

Run the following query to find any data points with scores greater than three standard deviations from the mean score.

```
WITH score_cutoff AS (
    SELECT
        STDDEV(public.remote_fn_rcf(nbr_passengers)) AS std,
        AVG(public.remote_fn_rcf(nbr_passengers)) AS mean,
        (mean - 3 * std) AS score_cutoff_value
    FROM
        public.rcf_taxi_data
)
SELECT
    ride_timestamp,
    nbr_passengers,
    public.remote_fn_rcf(nbr_passengers) AS score
FROM
    public.rcf_taxi_data
WHERE
    score < (
        SELECT
            score_cutoff_value
        FROM
            score_cutoff
    )
ORDER BY
    2 DESC;
```

Tutorial: Building K-means clustering models

In this tutorial, you use Amazon Redshift ML to create, train, and deploy a machine learning model based on the [K-means algorithm](#). This algorithm solves clustering problems where you want to discover groupings in the data. K-means helps in grouping data that has not been labeled yet. To learn more about K-means clustering, see [How K-means Clustering Works](#) in the Amazon SageMaker Developer Guide.

You will use a CREATE MODEL operation to create a K-means model from a Amazon Redshift cluster. You can use a CREATE MODEL command to export training data, train a model, import the model, and prepare an Amazon Redshift prediction function. Use the CREATE MODEL operation to specify training data either as a table or a SELECT statement.

In this tutorial, you use K-means on the [Global Database of Events, Language, and Tone \(GDELT\)](#) dataset, which monitors world news across the world, and the data is stored for every second of every day. K-means will group events that have similar tone, actors, or locations. The data is stored as multiple files on Amazon Simple Storage Service, in two different folders. The folders are historical, which cover the years 1979–2013, and daily updates, which cover the years 2013 and later. For this example, we use the historical format and bring in 1979 data.

Use case examples

You can solve other clustering problems with Amazon Redshift ML, such as grouping customers who have similar viewing habits on a streaming service. You could also use Redshift ML to predict the optimal number of shipping centers for a delivery service.

Tasks

- Prerequisites
- Step 1: Load the data from Amazon S3 to Amazon Redshift
- Step 2: Create the machine learning model
- Step 3: Perform predictions with the model

Prerequisites

To complete this tutorial, you must complete the [Administrative setup](#) for Amazon Redshift ML.

Step 1: Load the data from Amazon S3 to Amazon Redshift

1. Use the [Amazon Redshift query editor v2](#) to run the following query. The query drops the `gdelt_data` table in the public schema if it exists and creates a table of the same name in the public schema.

```
DROP TABLE IF EXISTS gdelt_data CASCADE;
```

```
CREATE TABLE gdelt_data (  
    GlobalEventId bigint,  
    SqlDate bigint,  
    MonthYear bigint,  
    Year bigint,  
    FractionDate double precision,  
    Actor1Code varchar(256),  
    Actor1Name varchar(256),  
    Actor1CountryCode varchar(256),  
    Actor1KnownGroupCode varchar(256),  
    Actor1EthnicCode varchar(256),  
    Actor1Religion1Code varchar(256),  
    Actor1Religion2Code varchar(256),  
    Actor1Type1Code varchar(256),  
    Actor1Type2Code varchar(256),  
    Actor1Type3Code varchar(256),  
    Actor2Code varchar(256),  
    Actor2Name varchar(256),  
    Actor2CountryCode varchar(256),  
    Actor2KnownGroupCode varchar(256),  
    Actor2EthnicCode varchar(256),  
    Actor2Religion1Code varchar(256),  
    Actor2Religion2Code varchar(256),  
    Actor2Type1Code varchar(256),  
    Actor2Type2Code varchar(256),  
    Actor2Type3Code varchar(256),  
    IsRootEvent bigint,  
    EventCode bigint,  
    EventBaseCode bigint,  
    EventRootCode bigint,  
    QuadClass bigint,
```

```
GoldsteinScale double precision,
NumMentions bigint,
NumSources bigint,
NumArticles bigint,
AvgTone double precision,
Actor1Geo_Type bigint,
Actor1Geo_FullName varchar(256),
Actor1Geo_CountryCode varchar(256),
Actor1Geo_ADM1Code varchar(256),
Actor1Geo_Lat double precision,
Actor1Geo_Long double precision,
Actor1Geo_FeatureID bigint,
Actor2Geo_Type bigint,
Actor2Geo_FullName varchar(256),
Actor2Geo_CountryCode varchar(256),
Actor2Geo_ADM1Code varchar(256),
Actor2Geo_Lat double precision,
Actor2Geo_Long double precision,
Actor2Geo_FeatureID bigint,
ActionGeo_Type bigint,
ActionGeo_FullName varchar(256),
ActionGeo_CountryCode varchar(256),
ActionGeo_ADM1Code varchar(256),
ActionGeo_Lat double precision,
ActionGeo_Long double precision,
ActionGeo_FeatureID bigint,
DATEADDED bigint
);
```

2. The following query loads the sample data into the `gdelt_data` table.

```
COPY gdelt_data
FROM 's3://gdelt-open-data/events/1979.csv'
REGION 'us-east-1'
IAM_ROLE default
CSV
DELIMITER '\t';
```

Examine the training data (optional)

To see what data your model will be trained on, use the following query.

```
SELECT
    AvgTone,
    EventCode,
    NumArticles,
    Actor1Geo_Lat,
    Actor1Geo_Long,
    Actor2Geo_Lat,
    Actor2Geo_Long
FROM
    gdelt_data LIMIT 100;
```

Step 2: Create the machine learning model

The following example uses the CREATE MODEL command to create a model that groups the data into seven clusters. The K value is the number of clusters that your data points are divided into. The model classifies your data points into clusters where data points are more similar to each other. By clustering the data points into groups, the K-Means algorithm iteratively determines the best cluster center. The algorithm then assigns each data point to the closest cluster center. Members nearest the same cluster center belong to the same group. Members of a group are as similar as possible to other members in the same group, and as different as possible from members of other groups. The K value is subjective and depends on methods that measure the similarities among data points. You can change the K value to smooth out cluster sizes if the clusters are unevenly distributed.

In the following example, replace `amzn-s3-demo-bucket` with your own Amazon S3 bucket.

```
CREATE MODEL news_data_clusters
FROM
    (
        SELECT
            AvgTone,
            EventCode,
            NumArticles,
            Actor1Geo_Lat,
            Actor1Geo_Long,
            Actor2Geo_Lat,
            Actor2Geo_Long
        FROM
            gdelt_data
    ) FUNCTION news_monitoring_cluster
IAM_ROLE default
```

```
AUTO OFF
MODEL_TYPE KMEANS
PREPROCESSORS 'none'
HYPERPARAMETERS DEFAULT
EXCEPT
(K '7')
SETTINGS (S3_BUCKET 'amzn-s3-demo-bucket');
```

Check the status of model training (optional)

You can use the SHOW MODEL command to know when your model is ready.

To check the model status, use the following SHOW MODEL operation and find if the Model State is Ready.

```
SHOW MODEL NEWS_DATA_CLUSTERS;
```

When the model is ready, the output of the previous operation should show that the Model State is Ready. The following is an example of the output of the SHOW MODEL operation.

```

+-----+
+-----+
+

```

Step 3: Perform predictions with the model

Identify the clusters

You can find discrete groupings identified in the data by your model, otherwise known as clusters. A cluster is the set of data points that is closer to its cluster center than any other cluster center. Since the K value represents the number of clusters in the model, it also represents the number of cluster centers. The following query identifies the clusters by showing the cluster associated with each `globaleventid`.

```
SELECT
  globaleventid,
  news_monitoring_cluster (
    AvgTone,
    EventCode,
    NumArticles,
    Actor1Geo_Lat,
    Actor1Geo_Long,
    Actor2Geo_Lat,
    Actor2Geo_Long
  ) AS cluster
FROM
  gdelt_data;
```

Check the distribution of data

You can check the distribution of data across clusters to see if the K value that you chose caused the data to be somewhat evenly distributed. Use the following query to determine if the data is evenly distributed across your clusters.

```
SELECT
  events_cluster,
  COUNT(*) AS nbr_events
FROM
  (
    SELECT
      globaleventid,
      news_monitoring_cluster(
        AvgTone,
        EventCode,
        NumArticles,
        Actor1Geo_Lat,
```

```
        Actor1Geo_Long,  
        Actor2Geo_Lat,  
        Actor2Geo_Long  
    ) AS events_cluster  
FROM  
    gdelt_data  
)  
GROUP BY  
    1;
```

Note that you can change the K value to smooth out cluster sizes if the clusters are unevenly distributed.

Determine the cluster centers

A data point is closer to its cluster center than it is to any other cluster center. Thus, finding the cluster centers helps you define the clusters.

Run the following query to determine the centers of the clusters based on the number of articles by event code.

```
SELECT  
    news_monitoring_cluster (  
        AvgTone,  
        EventCode,  
        NumArticles,  
        Actor1Geo_Lat,  
        Actor1Geo_Long,  
        Actor2Geo_Lat,  
        Actor2Geo_Long  
    ) AS events_cluster,  
    eventcode,  
    SUM(numArticles) AS numArticles  
FROM  
    gdelt_data  
GROUP BY  
    1,  
    2;
```

Show information about data points in a cluster

Use the following query to return the data for the points assigned to the fifth cluster. The selected articles must have two actors.

```
SELECT
  news_monitoring_cluster (
    AvgTone,
    EventCode,
    NumArticles,
    Actor1Geo_Lat,
    Actor1Geo_Long,
    Actor2Geo_Lat,
    Actor2Geo_Long
  ) AS events_cluster,
  eventcode,
  actor1name,
  actor2name,
  SUM(numarticles) AS totalarticles
FROM
  gdelt_data
WHERE
  events_cluster = 5
  AND actor1name <> ' '
  AND actor2name <> ' '
GROUP BY
  1,
  2,
  3,
  4
ORDER BY
  5 desc;
```

Show data about events with actors of the same ethnic code

The following query counts the number of articles written about events with a positive tone. The query also requires that the two actors have the same ethnic code and it returns which cluster each event is assigned to.

```
SELECT
  news_monitoring_cluster (
    AvgTone,
    EventCode,
    NumArticles,
    Actor1Geo_Lat,
    Actor1Geo_Long,
    Actor2Geo_Lat,
    Actor2Geo_Long
```

```
    ) AS events_cluster,
    SUM(numarticles) AS total_articles,
    eventcode AS event_code,
    Actor1EthnicCode AS ethnic_code
FROM
    gdelt_data
WHERE
    Actor1EthnicCode = Actor2EthnicCode
    AND Actor1EthnicCode <> ' '
    AND Actor2EthnicCode <> ' '
    AND AvgTone > 0
GROUP BY
    1,
    3,
    4
HAVING
    (total_articles) > 4
ORDER BY
    1,
    2 ASC;
```

Tutorial: Building multi-class classification models

In this tutorial, you use Amazon Redshift ML to create a machine learning model that solves multi-class classification problems. The multi-class classification algorithm classifies data points into one

of three or more classes. Then, you implement queries using the SQL function that the CREATE MODEL command generates.

You can use a CREATE MODEL command to export training data, train a model, import the model, and prepare an Amazon Redshift prediction function. Use the CREATE MODEL operation to specify training data either as a table or a SELECT statement.

To follow along with the tutorial, you use the public dataset [E-Commerce Sales Forecast](#), which includes sales data of an online UK retailer. The model you generate will target the most active customers for a special customer loyalty program. With multi-class classification, you can use the model to predict how many months a customer will be active over a 13-month period. The prediction function designates customers who are predicted to be active for 7 or more months for admission to the program.

Use case examples

You can solve other multi-class classification problems with Amazon Redshift ML, such as predicting the best-selling product from a product line. You could also predict which fruit an image contains, such as selecting apples or pears or oranges.

Tasks

- Prerequisites
- Step 1: Load the data from Amazon S3 to Amazon Redshift
- Step 2: Create the machine learning model
- Step 3: Perform predictions with the model

Prerequisites

To complete this tutorial, you must complete the [Administrative setup](#) for Amazon Redshift ML.

Step 1: Load the data from Amazon S3 to Amazon Redshift

Use the [Amazon Redshift query editor v2](#) to run the following queries. These queries load the sample data into Amazon Redshift.

1. The following query creates a table named `ecommerce_sales`.

```
CREATE TABLE IF NOT EXISTS ecommerce_sales (  
    invoiceno VARCHAR(30),
```

```
stockcode VARCHAR(30),
description VARCHAR(60),
quantity DOUBLE PRECISION,
invoicedate VARCHAR(30),
unitprice DOUBLE PRECISION,
customerid BIGINT,
country VARCHAR(25)
);
```

2. The following query copies the sample data from the [E-Commerce Sales Forecast dataset](#) into the `ecommerce_salestable`.

```
COPY ecommerce_sales
FROM
    's3://redshift-ml-multiclass/ecommerce_data.txt'
IAM_ROLE default
DELIMITER '\t'
IGNOREHEADER 1
REGION 'us-east-1'
MAXERROR 100;
```

Split the data

When you create a model in Amazon Redshift ML, SageMaker automatically splits your data into training and test sets, so that SageMaker can determine the model accuracy. By manually splitting the data at this step, you will be able to verify the accuracy of the model by allocating an additional prediction set.

Use the following SQL statement to split the data into three sets for training, validation, and prediction.

```
--creates table with all data
CREATE TABLE ecommerce_sales_data AS (
    SELECT
        t1.stockcode,
        t1.description,
        t1.invoicedate,
        t1.customerid,
        t1.country,
        t1.sales_amt,
        CAST(RANDOM() * 100 AS INT) AS data_group_id
    FROM
```

```

    (
        SELECT
            stockcode,
            description,
            invoicedate,
            customerid,
            country,
            SUM(quantity * unitprice) AS sales_amt
        FROM
            ecommerce_sales
        GROUP BY
            1,
            2,
            3,
            4,
            5
    ) t1
);

--creates training set
CREATE TABLE ecommerce_sales_training AS (
    SELECT
        a.customerid,
        a.country,
        a.stockcode,
        a.description,
        a.invoicedate,
        a.sales_amt,
        (b.nbr_months_active) AS nbr_months_active
    FROM
        ecommerce_sales_data a
    INNER JOIN (
        SELECT
            customerid,
            COUNT(
                DISTINCT(
                    DATE_PART(y, CAST(invoicedate AS DATE)) || '-' || LPAD(
                        DATE_PART(mon, CAST(invoicedate AS DATE)),
                        2,
                        '00'
                    )
                )
            ) AS nbr_months_active
        FROM

```

```

        ecommerce_sales_data
    GROUP BY
        1
    ) b ON a.customerid = b.customerid
WHERE
    a.data_group_id < 80
);

--creates validation set
CREATE TABLE ecommerce_sales_validation AS (
    SELECT
        a.customerid,
        a.country,
        a.stockcode,
        a.description,
        a.invoicedate,
        a.sales_amt,
        (b.nbr_months_active) AS nbr_months_active
    FROM
        ecommerce_sales_data a
    INNER JOIN (
        SELECT
            customerid,
            COUNT(
                DISTINCT(
                    DATE_PART(y, CAST(invoicedate AS DATE)) || '-' || LPAD(
                        DATE_PART(mon, CAST(invoicedate AS DATE)),
                        2,
                        '00'
                    )
                )
            ) AS nbr_months_active
        FROM
            ecommerce_sales_data
        GROUP BY
            1
    ) b ON a.customerid = b.customerid
WHERE
    a.data_group_id BETWEEN 80
    AND 90
);

--creates prediction set
CREATE TABLE ecommerce_sales_prediction AS (

```

```
SELECT
    customerid,
    country,
    stockcode,
    description,
    invoicedate,
    sales_amt
FROM
    ecommerce_sales_data
WHERE
    data_group_id > 90);
```

Step 2: Create the machine learning model

In this step, you use the CREATE MODEL statement to create your machine learning model using multi-class classification.

The following query creates the multi-class classification model with the training set using the CREATE MODEL operation. Replace amzn-s3-demo-bucket with your own Amazon S3 bucket.

```
CREATE MODEL ecommerce_customer_activity
FROM
    (
        SELECT
            customerid,
            country,
            stockcode,
            description,
            invoicedate,
            sales_amt,
            nbr_months_active
        FROM
            ecommerce_sales_training
    ) TARGET nbr_months_active FUNCTION predict_customer_activity IAM_ROLE default
PROBLEM_TYPE MULTICLASS_CLASSIFICATION SETTINGS (
    S3_BUCKET 'amzn-s3-demo-bucket',
    S3_GARBAGE_COLLECT OFF
);
```

In this query, you specify the problem type as `Multiclass_Classification`. The target that you predict for the model is `nbr_months_active`. When SageMaker finishes training the model,

it creates the function `predict_customer_activity`, which you will use to make predictions in Amazon Redshift.

Show the status of model training (optional)

You can use the `SHOW MODEL` command to know when your model is ready.

Use the following query to return various metrics of the model, including model state and accuracy.

```
SHOW MODEL ecommerce_customer_activity;
```

When the model is ready, the output of the previous operation should show that the Model State is Ready. The following is an example of the output of the `SHOW MODEL` operation.

```

| bucket                              |                                     |
|   Max Runtime                       |                                     | 5400
|                                     |                                     |
+-----+
+-----+
+

```

Step 3: Perform predictions with the model

The following query shows which customers qualify for your customer loyalty program. If the model predicts that the customer will be active for at least seven months, then the model selects the customer for the loyalty program.

```

SELECT
  customerid,
  predict_customer_activity(
    customerid,
    country,

```

```

        stockcode,
        description,
        invoicedate,
        sales_amt
    ) AS predicted_months_active
FROM
    ecommerce_sales_prediction
WHERE
    predicted_months_active >= 7
GROUP BY
    1,
    2
LIMIT
    10;

```

Run prediction queries against the validation data (optional)

Run the following prediction queries against the validation data to see the model's level of accuracy.

```

SELECT
    CAST(SUM(t1.match) AS decimal(7, 2)) AS predicted_matches,
    CAST(SUM(t1.nonmatch) AS decimal(7, 2)) AS predicted_non_matches,
    CAST(SUM(t1.match + t1.nonmatch) AS decimal(7, 2)) AS total_predictions,
    predicted_matches / total_predictions AS pct_accuracy
FROM
    (
        SELECT
            customerid,
            country,
            stockcode,
            description,
            invoicedate,
            sales_amt,
            nbr_months_active,
            predict_customer_activity(
                customerid,
                country,
                stockcode,
                description,
                invoicedate,
                sales_amt
            ) AS predicted_months_active,

```

```
        CASE
            WHEN nbr_months_active = predicted_months_active THEN 1
            ELSE 0
        END AS match,
        CASE
            WHEN nbr_months_active <> predicted_months_active THEN 1
            ELSE 0
        END AS nonmatch
    FROM
        ecommerce_sales_validation
)t1;
```

Predict how many customers miss entry (optional)

The following query compares the number of customers that are predicted to be active for only 5 or 6 months. The model predicts that these customers will miss out on the loyalty program. The query then compares the amount that barely miss the program to the number that are predicted to be eligible for the loyalty program. This query could be used to inform a decision on whether to lower the threshold for the loyalty program. You can also determine if there is a significant amount of customers that are predicted to barely miss out on the program. You could then encourage those customers to increase their activity to get a loyalty program membership.

```
SELECT
    predict_customer_activity(
        customerid,
        country,
        stockcode,
        description,
        invoicedate,
        sales_amt
    ) AS predicted_months_active,
    COUNT(customerid)
FROM
    ecommerce_sales_prediction
WHERE
    predicted_months_active BETWEEN 5 AND 6
GROUP BY
    1
ORDER BY
    1 ASC
LIMIT
    10)
```

```
UNION
(SELECT
    NULL AS predicted_months_active,
    COUNT (customerid)
FROM
    ecommerce_sales_prediction
WHERE
    predict_customer_activity(
        customerid,
        country,
        stockcode,
        description,
        invoicedate,
        sales_amt
    ) >=7);
```

Tutorial: Building XGBoost models

In this tutorial, you create a model with data from Amazon S3 and run prediction queries with the model using Amazon Redshift ML. The XGBoost algorithm is an optimized implementation of the gradient boosted trees algorithm. XGBoost handles more data types, relationships, and distributions than other gradient boosted trees algorithms. You can use XGBoost for regression, binary classification, multi-class classification, and ranking problems. For more information about the XGBoost algorithm, see [XGBoost algorithm](#) in the Amazon SageMaker Developer Guide.

The Amazon Redshift ML `CREATE MODEL` operation with the `AUTO OFF` option currently supports XGBoost as the `MODEL_TYPE`. You can provide relevant information such as the objective and hyperparameters as part of the `CREATE MODEL` command, based on your use case.

In this tutorial, you use the [banknote authentication dataset](#), which is a binary classification problem to predict whether a given banknote is genuine or forged.

Use case examples

You can solve other binary classification problems using Amazon Redshift ML, such as predicting whether a patient is healthy or has a disease. You could also predict whether an email is spam or not spam.

Tasks

- Prerequisites
- Step 1: Load the data from Amazon S3 to Amazon Redshift
- Step 2: Create the machine learning model
- Step 3: Perform predictions with the model

Prerequisites

To complete this tutorial, you must complete the [Administrative setup](#) for Amazon Redshift ML.

Step 1: Load the data from Amazon S3 to Amazon Redshift

Use the [Amazon Redshift query editor v2](#) to run the following queries.

The following query creates two tables, loads the data from Amazon S3, and splits the data into a training set and a testing set. You will use the training set to train your model and create the prediction function. Then, you will test the prediction function on the testing set.

```
--create training set table
CREATE TABLE banknoteauthentication_train(
  variance FLOAT,
  skewness FLOAT,
  curtosis FLOAT,
  entropy FLOAT,
  class INT
```

```
);

--Load into training table
COPY banknoteauthentication_train
FROM
    's3://redshiftbucket-ml-sagemaker/banknote_authentication/train_data/' IAM_ROLE
    default REGION 'us-west-2' IGNOREHEADER 1 CSV;

--create testing set table
CREATE TABLE banknoteauthentication_test(
    variance FLOAT,
    skewness FLOAT,
    curtosis FLOAT,
    entropy FLOAT,
    class INT
);

--Load data into testing table
COPY banknoteauthentication_test
FROM
    's3://redshiftbucket-ml-sagemaker/banknote_authentication/test_data/'
    IAM_ROLE default
    REGION 'us-west-2'
    IGNOREHEADER 1
    CSV;
```

Step 2: Create the machine learning model

The following query creates the XGBoost model in Amazon Redshift ML from the training set you created in the previous step. Replace `amzn-s3-demo-bucket` with your own `S3_BUCKET`, which will store your input datasets and other Redshift ML artifacts.

```
CREATE MODEL model_banknoteauthentication_xgboost_binary
FROM
    banknoteauthentication_train
    TARGET class
    FUNCTION func_model_banknoteauthentication_xgboost_binary
    IAM_ROLE default
    AUTO OFF
    MODEL_TYPE xgboost
    OBJECTIVE 'binary:logistic'
    PREPROCESSORS 'none'
    HYPERPARAMETERS DEFAULT
```

```
EXCEPT(NUM_ROUND '100')
SETTINGS(S3_BUCKET 'amzn-s3-demo-bucket');
```

Show the status of model training (optional)

You can use the SHOW MODEL command to know when your model is ready.

Use the following query to monitor the progress of the model training.

```
SHOW MODEL model_banknoteauthentication_xgboost_binary;
```

If the model is READY, the SHOW MODEL operation also provides the `train:error` metric, as shown in the following example of the output. The `train:error` metric is a measure of accuracy of your model that measures to six decimal places. A value of 0 is most accurate and a value of 1 is least accurate.

```

| objective          | binary:logistic              |     |
+-----+-----+-----+
```

Step 3: Perform predictions with the model

Check the accuracy of the model

The following prediction query uses the prediction function created in the previous step to check the accuracy of your model. Run this query on the testing set to make sure the model does not correspond too closely to the training set. This close correspondence is also known as overfitting, and overfitting could cause the model to make unreliable predictions.

```
WITH predict_data AS (
  SELECT
    class AS label,
    func_model_banknoteauthentication_xgboost_binary (variance, skewness, curtosis,
entropy) AS predicted,
    CASE
      WHEN label IS NULL THEN 0
      ELSE label
    END AS actual,
    CASE
      WHEN actual = predicted THEN 1 :: INT
      ELSE 0 :: INT
    END AS correct
  FROM
    banknoteauthentication_test
),
aggr_data AS (
  SELECT
    SUM(correct) AS num_correct,
    COUNT(*) AS total
  FROM
    predict_data
)
SELECT
  (num_correct :: FLOAT / total :: FLOAT) AS accuracy
FROM
  aggr_data;
```

Predict the amount of original and counterfeit banknotes

The following prediction query returns the predicted amount of original and counterfeit banknotes in the testing set.

```
WITH predict_data AS (
  SELECT
    func_model_banknoteauthentication_xgboost_binary(variance, skewness, curtosis,
entropy) AS predicted
  FROM
    banknoteauthentication_test
)
SELECT
  CASE
    WHEN predicted = '0' THEN 'Original banknote'
    WHEN predicted = '1' THEN 'Counterfeit banknote'
    ELSE 'NA'
  END AS banknote_authentication,
  COUNT(1) AS count
FROM
  predict_data
GROUP BY
  1;
```

Find the average observation for an original and a counterfeit banknote

The following prediction query returns the average value of each feature for banknotes that are predicted to be original and counterfeit in the testing set.

```
WITH predict_data AS (
  SELECT
    func_model_banknoteauthentication_xgboost_binary(variance, skewness, curtosis,
entropy) AS predicted,
    variance,
    skewness,
    curtosis,
    entropy
  FROM
    banknoteauthentication_test
)
SELECT
  CASE
    WHEN predicted = '0' THEN 'Original banknote'
```

```
        WHEN predicted = '1' THEN 'Counterfeit banknote'
        ELSE 'NA'
    END AS banknote_authentication,
    TRUNC(AVG(variance), 2) AS avg_variance,
    TRUNC(AVG(skewness), 2) AS avg_skewness,
    TRUNC(AVG(kurtosis), 2) AS avg_kurtosis,
    TRUNC(AVG(entropy), 2) AS avg_entropy
FROM
    predict_data
GROUP BY
    1
ORDER BY
    2;
```

Tutorial: Building regression models

In this tutorial, you use Amazon Redshift ML to create a machine learning regression model and run prediction queries on the model. Regression models allow you to predict numerical outcomes, such as the price of a house, or how many people will use a city's bike rental service. You use the CREATE MODEL command in Amazon Redshift with your training data. Then, Amazon Redshift ML compiles the model, imports the trained model to Redshift, and prepares a SQL prediction function. You can use the prediction function in SQL queries in Amazon Redshift.

In this tutorial, you will use Amazon Redshift ML to build a regression model that predicts the number of people that use the city of Toronto's bike sharing service at any given hour of a day.

The inputs for the model include holidays and weather conditions. You will use a regression model, because you want a numerical outcome for this problem.

You can use the CREATE MODEL command to export training data, train a model, and make the model available in Amazon Redshift as a SQL function. Use the CREATE MODEL operation to specify training data either as a table or a SELECT statement.

Use case examples

You can solve other regression problems with Amazon Redshift ML, such as predicting a customer's lifetime value. You could also use Redshift ML to predict the most profitable price and the resulting revenue of a product.

Tasks

- Prerequisites
- Step 1: Load the data from Amazon S3 to Amazon Redshift
- Step 2: Create the machine learning model
- Step 3: Validate the model

Prerequisites

To complete this tutorial, you must complete the [Administrative setup](#) for Amazon Redshift ML.

Step 1: Load the data from Amazon S3 to Amazon Redshift

Use the [Amazon Redshift query editor v2](#) to run the following queries.

1. You must create three tables to load the three public datasets into Amazon Redshift. The datasets are [Toronto Bike Ridership Data](#), [historical weather data](#), and [historical holidays data](#). Run the following query in the Amazon Redshift query editor to create tables named `ridership`, `weather`, and `holiday`.

```
CREATE TABLE IF NOT EXISTS ridership (  
    trip_id INT,  
    trip_duration_seconds INT,  
    trip_start_time timestamp,  
    trip_stop_time timestamp,  
    from_station_name VARCHAR(50),  
    to_station_name VARCHAR(50),
```

```
    from_station_id SMALLINT,  
    to_station_id SMALLINT,  
    user_type VARCHAR(20)  
);  
  
CREATE TABLE IF NOT EXISTS weather (  
    longitude_x DECIMAL(5, 2),  
    latitude_y DECIMAL(5, 2),  
    station_name VARCHAR(20),  
    climate_id BIGINT,  
    datetime_utc TIMESTAMP,  
    weather_year SMALLINT,  
    weather_month SMALLINT,  
    weather_day SMALLINT,  
    time_utc VARCHAR(5),  
    temp_c DECIMAL(5, 2),  
    temp_flag VARCHAR(1),  
    dew_point_temp_c DECIMAL(5, 2),  
    dew_point_temp_flag VARCHAR(1),  
    rel_hum SMALLINT,  
    rel_hum_flag VARCHAR(1),  
    precip_amount_mm DECIMAL(5, 2),  
    precip_amount_flag VARCHAR(1),  
    wind_dir_10s_deg VARCHAR(10),  
    wind_dir_flag VARCHAR(1),  
    wind_spd_kmh VARCHAR(10),  
    wind_spd_flag VARCHAR(1),  
    visibility_km VARCHAR(10),  
    visibility_flag VARCHAR(1),  
    stn_press_kpa DECIMAL(5, 2),  
    stn_press_flag VARCHAR(1),  
    hmdx SMALLINT,  
    hmdx_flag VARCHAR(1),  
    wind_chill VARCHAR(10),  
    wind_chill_flag VARCHAR(1),  
    weather VARCHAR(10)  
);  
  
CREATE TABLE IF NOT EXISTS holiday (holiday_date DATE, description VARCHAR(100));
```

2. The following query loads the sample data into the tables that you created in the previous step.

```
COPY ridership  
FROM
```

```
's3://redshift-ml-bikesharing-data/bike-sharing-data/ridership/'
IAM_ROLE default
FORMAT CSV
IGNOREHEADER 1
DATEFORMAT 'auto'
TIMEFORMAT 'auto'
REGION 'us-west-2'
gzip;

COPY weather
FROM
  's3://redshift-ml-bikesharing-data/bike-sharing-data/weather/'
  IAM_ROLE default
  FORMAT csv
  IGNOREHEADER 1
  DATEFORMAT 'auto'
  TIMEFORMAT 'auto'
  REGION 'us-west-2'
  gzip;

COPY holiday
FROM
  's3://redshift-ml-bikesharing-data/bike-sharing-data/holiday/'
  IAM_ROLE default
  FORMAT csv
  IGNOREHEADER 1
  DATEFORMAT 'auto'
  TIMEFORMAT 'auto'
  REGION 'us-west-2'
  gzip;
```

3. The following query performs transformations on the `ridership` and `weather` datasets to remove bias or anomalies. Removing bias and anomalies results in improved model accuracy. The query simplifies the tables by creating two new views called `ridership_view` and `weather_view`.

```
CREATE
OR REPLACE VIEW ridership_view AS
SELECT
  trip_time,
  trip_count,
  TO_CHAR(trip_time, 'hh24') :: INT trip_hour,
  TO_CHAR(trip_time, 'dd') :: INT trip_day,
```

```

    TO_CHAR(trip_time, 'mm') :: INT trip_month,
    TO_CHAR(trip_time, 'yy') :: INT trip_year,
    TO_CHAR(trip_time, 'q') :: INT trip_quarter,
    TO_CHAR(trip_time, 'w') :: INT trip_month_week,
    TO_CHAR(trip_time, 'd') :: INT trip_week_day
FROM
  (
    SELECT
      CASE
        WHEN TRUNC(r.trip_start_time) < '2017-07-01' :: DATE THEN
          CONVERT_TIMEZONE(
            'US/Eastern',
            DATE_TRUNC('hour', r.trip_start_time)
          )
        ELSE DATE_TRUNC('hour', r.trip_start_time)
      END trip_time,
      COUNT(1) trip_count
    FROM
      ridership r
    WHERE
      r.trip_duration_seconds BETWEEN 60
      AND 60 * 60 * 24
    GROUP BY
      1
  );

CREATE
OR REPLACE VIEW weather_view AS
SELECT
  CONVERT_TIMEZONE(
    'US/Eastern',
    DATE_TRUNC('hour', datetime_utc)
  ) daytime,
  ROUND(AVG(temp_c)) temp_c,
  ROUND(AVG(precip_amount_mm)) precip_amount_mm
FROM
  weather
GROUP BY
  1;

```

4. The following query creates a table that combines all the relevant input attributes from `ridership_view` and `weather_view` into the `trip_data` table.

```

CREATE TABLE trip_data AS
SELECT
    r.trip_time,
    r.trip_count,
    r.trip_hour,
    r.trip_day,
    r.trip_month,
    r.trip_year,
    r.trip_quarter,
    r.trip_month_week,
    r.trip_week_day,
    w.temp_c,
    w.precip_amount_mm,CASE
        WHEN h.holiday_date IS NOT NULL THEN 1
        WHEN TO_CHAR(r.trip_time, 'D') :: INT IN (1, 7) THEN 1
        ELSE 0
    END is_holiday,
    ROW_NUMBER() OVER (
        ORDER BY
            RANDOM()
    ) serial_number
FROM
    ridership_view r
    JOIN weather_view w ON (r.trip_time = w.daytime)
    LEFT OUTER JOIN holiday h ON (TRUNC(r.trip_time) = h.holiday_date);

```

View the sample data (optional)

The following query shows entries from the table. You can run this operation to make sure the table was made correctly.

```

SELECT *
FROM trip_data
LIMIT 5;

```

The following is an example of the output of the previous operation.

```

+-----+-----+-----+-----+-----+-----+

Show the correlation between attributes (optional)

Determining correlation helps you measure the strength of association between attributes. The level of association can help you determine what affects your target output. In this tutorial, the target output is `trip_count`.

The following query creates or replaces the `sp_correlation` procedure. You use the stored procedure called `sp_correlation` to show the correlation between an attribute and other attributes in a table in Amazon Redshift.

```

CREATE OR REPLACE PROCEDURE sp_correlation(source_schema_name in varchar(255),
  source_table_name in varchar(255), target_column_name in varchar(255),
  output_temp_table_name inout varchar(255)) AS $$
DECLARE
  v_sql varchar(max);
  v_generated_sql varchar(max);
  v_source_schema_name varchar(255)=lower(source_schema_name);
  v_source_table_name varchar(255)=lower(source_table_name);

```

```

v_target_column_name varchar(255)=lower(target_column_name);
BEGIN
EXECUTE 'DROP TABLE IF EXISTS ' || output_temp_table_name;
v_sql = '
SELECT
  'CREATE temp table ' || output_temp_table_name || ' AS SELECT ' || outer_calculation ||
  ' FROM (SELECT COUNT(1) number_of_items, SUM(' || v_target_column_name || ')
sum_target, SUM(POW(' || v_target_column_name || ',2)) sum_square_target, POW(SUM(' ||
v_target_column_name || '),2) square_sum_target, ' ||
inner_calculation ||
  ' FROM (SELECT ' ||
column_name ||
  ' FROM ' || v_source_table_name || '))'
FROM
(
SELECT
  DISTINCT
  LISTAGG(outer_calculation,',' OVER () outer_calculation
  ,LISTAGG(inner_calculation,',' OVER () inner_calculation
  ,LISTAGG(column_name,',' OVER () column_name
FROM
(
SELECT
  CASE WHEN atttypid=16 THEN 'DECODE(' || column_name || ',true,1,0)' ELSE
column_name END column_name
  ,atttypid
  , 'CAST(DECODE(number_of_items * sum_square_' || rn || ' - square_sum_' ||
rn || ',0,null,(number_of_items*sum_target_' || rn || ' - sum_target * sum_' || rn ||
  ')/SQRT((number_of_items * sum_square_target - square_sum_target) *
(number_of_items * sum_square_' || rn ||
  ' - square_sum_' || rn || '))) AS numeric(5,2)) ' || column_name
outer_calculation
  , 'sum(' || column_name || ') sum_' || rn || ', ' ||
  'SUM(trip_count*' || column_name || ') sum_target_' || rn || ', ' ||
  'SUM(POW(' || column_name || ',2)) sum_square_' || rn || ', ' ||
  'POW(SUM(' || column_name || '),2) square_sum_' || rn inner_calculation
FROM
(
SELECT
  row_number() OVER (order by a.attnum) rn
  ,a.attname::VARCHAR column_name
  ,a.atttypid
FROM pg_namespace AS n
INNER JOIN pg_class AS c ON n.oid = c.relnamespace

```

```

        INNER JOIN pg_attribute AS a ON c.oid = a.attrelid
    WHERE a.attnum > 0
        AND n.nspname = '||v_source_schema_name||'
        AND c.relname = '||v_source_table_name||'
        AND a.atttypid IN (16,20,21,23,700,701,1700)
    )
)
)';
EXECUTE v_sql INTO v_generated_sql;
EXECUTE v_generated_sql;
END;
$$ LANGUAGE plpgsql;

```

The following query shows the correlation between the target column, `trip_count`, and other numeric attributes in our dataset.

```

call sp_correlation(
    'public',
    'trip_data',
    'trip_count',
    'tmp_corr_table'
);

SELECT
    *
FROM
    tmp_corr_table;

```

The following example shows the output of the previous `sp_correlation` operation.

```

+-----+-----+-----+-----+-----+-----+
+-----+-----+-----+-----+-----+-----+
+-----+
| trip_count | trip_hour | trip_day | trip_month | trip_year | trip_quarter |
| trip_month_week | trip_week_day | temp_c | precip_amount_mm | is_holiday |
serial_number |
+-----+-----+-----+-----+-----+-----+
+-----+-----+-----+-----+-----+-----+
+-----+

|          0 |         0.02 |         0.53 |        -0.07 |        -0.13 |          0 |

```

```
+-----+-----+-----+-----+-----+-----+
+-----+-----+-----+-----+-----+-----+
+-----+
```

Step 2: Create the machine learning model

1. The following query splits your data into a training set and a validation set by designating 80% of the dataset for training and 20% for validation. The training set is the input for the ML model to identify the best possible algorithm for the model. After the model is created, you use the validation set to validate the model accuracy.

```
CREATE TABLE training_data AS
SELECT
    trip_count,
    trip_hour,
    trip_day,
    trip_month,
    trip_year,
    trip_quarter,
    trip_month_week,
    trip_week_day,
    temp_c,
    precip_amount_mm,
    is_holiday
FROM
    trip_data
WHERE
    serial_number > (
        SELECT
            COUNT(1) * 0.2
        FROM
            trip_data
    );

CREATE TABLE validation_data AS
SELECT
    trip_count,
    trip_hour,
    trip_day,
    trip_month,
    trip_year,
    trip_quarter,
```

```
trip_month_week,  
trip_week_day,  
temp_c,  
precip_amount_mm,  
is_holiday,  
trip_time  
FROM  
trip_data  
WHERE  
serial_number <= (  
    SELECT  
        COUNT(1) * 0.2  
    FROM  
        trip_data  
);
```

2. The following query creates a regression model to predict the `trip_count` value for any input date and time. In the following example, replace `amzn-s3-demo-bucket` with your own S3 bucket.

```
CREATE MODEL predict_rental_count  
FROM  
training_data TARGET trip_count FUNCTION predict_rental_count  
IAM_ROLE default  
PROBLEM_TYPE regression  
OBJECTIVE 'mse'  
SETTINGS (  
    s3_bucket 'amzn-s3-demo-bucket',  
    s3_garbage_collect off,  
    max_runtime 5000  
);
```

Step 3: Validate the model

1. Use the following query to output aspects of the model, and find the mean square error metric in the output. Mean square error is a typical accuracy metric for regression problems.

```
show model predict_rental_count;
```

2. Run the following prediction queries against the validation data to compare the predicted trip count to the actual trip count.

```

SELECT
    trip_time,
    actual_count,
    predicted_count,
    (actual_count - predicted_count) difference
FROM
    (
        SELECT
            trip_time,
            trip_count AS actual_count,
            PREDICT_RENTAL_COUNT (
                trip_hour,
                trip_day,
                trip_month,
                trip_year,
                trip_quarter,
                trip_month_week,
                trip_week_day,
                temp_c,
                precip_amount_mm,
                is_holiday
            ) predicted_count
        FROM
            validation_data
    )
LIMIT
    5;

```

3. The following query calculates the mean square error and root mean square error based on your validation data. You use mean square error and root mean square error to measure the distance between the predicted numeric target and the actual numeric answer. A good model has a low score in both metrics. The following query returns the value of both metrics.

```

SELECT
    ROUND(
        AVG(POWER((actual_count - predicted_count), 2)),
        2
    ) mse,
    ROUND(
        SQRT(AVG(POWER((actual_count - predicted_count), 2))),
        2
    ) rmse

```

```

FROM
  (
    SELECT
      trip_time,
      trip_count AS actual_count,
      PREDICT_RENTAL_COUNT (
        trip_hour,
        trip_day,
        trip_month,
        trip_year,
        trip_quarter,
        trip_month_week,
        trip_week_day,
        temp_c,
        precip_amount_mm,
        is_holiday
      ) predicted_count
    FROM
      validation_data
  );

```

4. The following query calculates the percent error in trip count for each trip time on 2017-01-01. The query orders the trip times from the time with the lowest percent error to the time with the highest percent error.

```

SELECT
  trip_time,
  CAST(ABS(((actual_count - predicted_count) / actual_count)) * 100 AS DECIMAL
  (7,2)) AS pct_error
FROM
  (
    SELECT
      trip_time,
      trip_count AS actual_count,
      PREDICT_RENTAL_COUNT (
        trip_hour,
        trip_day,
        trip_month,
        trip_year,
        trip_quarter,
        trip_month_week,
        trip_week_day,
        temp_c,

```

```
        precip_amount_mm,  
        is_holiday  
    ) predicted_count  
FROM  
    validation_data  
)  
WHERE  
    trip_time LIKE '2017-01-01 %:%:%:%%'  
ORDER BY  
    2 ASC;
```

Tutorial: Building regression models with linear learner

In this tutorial, you create a linear learner model with data from Amazon S3 and run prediction queries with the model using Amazon Redshift ML. The SageMaker linear learner algorithm solves either regression or multi-class classification problems. To learn more about regression and multi-class classification problems, see [Problem types for the machine learning paradigms](#) in the Amazon SageMaker Developer Guide. In this tutorial, you solve a regression problem. The linear learner algorithm trains many models in parallel, and automatically determines the most optimized model. You use the CREATE MODEL operation in Amazon Redshift, which creates your linear learner model using SageMaker and sends a prediction function to Amazon Redshift. For more information about the linear learner algorithm, see [Linear Learner Algorithm](#) in the Amazon SageMaker Developer Guide.

You can use a CREATE MODEL command to export training data, train a model, import the model, and prepare an Amazon Redshift prediction function. Use the CREATE MODEL operation to specify training data either as a table or a SELECT statement.

Linear learner models optimize either continuous objectives or discrete objectives. Continuous objectives are used for regression, while discrete variables are used for classification. Some methods provide a solution for only continuous objectives, such as the regression method. The linear learner algorithm provides an increase in speed over naive hyperparameter optimization techniques, such as the Naive Bayes technique. A naive optimization technique assumes that each input variable is independent. To use the linear learner algorithm, you must provide columns representing the dimensions of the inputs, and rows representing the observations. For more information about the linear learner algorithm, see the [Linear Learner Algorithm](#) in the Amazon SageMaker Developer Guide.

In this tutorial, you build a linear learner model that predicts the age of abalone. You use the CREATE MODEL command on the [Abalone dataset](#) to determine the relationship between the physical measurements of abalone. Then, you use the model to determine the age of abalone.

Use case examples

You can solve other regression problems with linear learner and Amazon Redshift ML, such as predicting the price of a house. You could also use Redshift ML to predict the number of people who will use a city's bike rental service.

Tasks

- Prerequisites
- Step 1: Load the data from Amazon S3 to Amazon Redshift
- Step 2: Create the machine learning model
- Step 3: Validate the model

Prerequisites

To complete this tutorial, you must complete the [Administrative setup](#) for Amazon Redshift ML.

Step 1: Load the data from Amazon S3 to Amazon Redshift

Use the [Amazon Redshift query editor v2](#) to run the following queries. These queries load the sample data into Redshift and divide the data into a training set and a validation set.

1. The following query creates the `abalone_dataset` table.

```
CREATE TABLE abalone_dataset (  
    id INT IDENTITY(1, 1),  
    Sex CHAR(1),  
    Length float,  
    Diameter float,  
    Height float,  
    Whole float,  
    Shucked float,  
    Viscera float,  
    Shell float,  
    Rings integer  
);
```

2. The following query copies the sample data from the [Abalone dataset](#) in Amazon S3 to the `abalone_dataset` table you created previously in Amazon Redshift.

```
COPY abalone_dataset  
FROM  
    's3://redshift-ml-multiclass/abalone.csv' REGION 'us-east-1' IAM_ROLE default CSV  
IGNOREHEADER 1 NULL AS 'NULL';
```

3. By manually splitting the data, you will be able to verify the accuracy of the model by allocating an additional prediction set. The following query splits the data into two sets. The `abalone_training` table is for training and the `abalone_validation` table is for validation.

```
CREATE TABLE abalone_training as  
SELECT  
    *  
FROM  
    abalone_dataset  
WHERE  
    mod(id, 10) < 8;  
  
CREATE TABLE abalone_validation as  
SELECT  
    *  
FROM  
    abalone_dataset  
WHERE  
    mod(id, 10) >= 8;
```

Step 2: Create the machine learning model

In this step, you use the CREATE MODEL statement to create your machine learning model with the linear learner algorithm.

The following query creates the linear learner model with the CREATE MODEL operation using your S3 bucket. Replace amzn-s3-demo-bucket with your own S3 bucket.

```
CREATE MODEL model_abalone_ring_prediction
FROM
  (
    SELECT
      Sex,
      Length,
      Diameter,
      Height,
      Whole,
      Shucked,
      Viscera,
      Shell,
      Rings AS target_label
    FROM
      abalone_training
  ) TARGET target_label FUNCTION f_abalone_ring_prediction IAM_ROLE default
MODEL_TYPE LINEAR_LEARNER PROBLEM_TYPE REGRESSION OBJECTIVE 'MSE' SETTINGS (
  S3_BUCKET 'amzn-s3-demo-bucket',
  MAX_RUNTIME 15000
);
```

Show the status of model training (optional)

You can use the SHOW MODEL command to know when your model is ready.

Use the following query to monitor the progress of the model training.

```
SHOW MODEL model_abalone_ring_prediction;
```

When the model is ready, the output of the previous operation should look similar to the following example. Note that the output provides the `validation:mse` metric, which is the mean square error. You will use the mean square error to validate the accuracy of the model in the next step.

+-----+
+-----+
+

```

Step 3: Validate the model

1. The following prediction query validates the accuracy of the model on the `abalone_validation` dataset by calculating mean square error and root mean square error.

```

SELECT
    ROUND(AVG(POWER((tgt_label - predicted), 2)), 2) mse,
    ROUND(SQRT(AVG(POWER((tgt_label - predicted), 2))), 2) rmse
FROM
    (
        SELECT
            Sex,
            Length,
            Diameter,
            Height,
            Whole,
            Shucked,
            Viscera,
            Shell,
            Rings AS tgt_label,
            f_abalone_ring_prediction(
                Sex,
                Length,
                Diameter,
                Height,
                Whole,
                Shucked,

```

```

        Viscera,
        Shell
    ) AS predicted,
    CASE
        WHEN tgt_label = predicted then 1
        ELSE 0
    END AS match,
    CASE
        WHEN tgt_label <> predicted then 1
        ELSE 0
    END AS nonmatch
FROM
    abalone_validation
) t1;

```

The output of the previous query should look like the following example. The value of the mean square error metric should be similar to the `validation:mse` metric shown by the `SHOW MODEL` operation's output.

```

+-----+-----+
| mse |      rmse      |
+-----+-----+
| 5.1 | 2.2600000000000002 |
+-----+-----+

```

2. Use the following query to run the `EXPLAIN_MODEL` operation on your prediction function. The operation will return a model explainability report. For more information about the `EXPLAIN_MODEL` operation, see the [EXPLAIN_MODEL function](#) in the Amazon Redshift Database Developer Guide.

```

SELECT
    EXPLAIN_MODEL ('model_abalone_ring_prediction');

```

The following information is an example of the model explainability report produced by the previous `EXPLAIN_MODEL` operation. The values for each of the inputs are Shapley values. The Shapley values represent the effect each input has on the prediction of your model, with higher-valued inputs having more impact on the prediction. In this example, the higher-valued inputs have more impact on predicting the age of abalone.

```
{
```

```

"explanations": {
  "kernel_shap": {
    "label0": {
      "expected_value" :10.290688514709473,
      "global_shap_values": {
        "diameter" :0.6856910187882492,
        "height" :0.4415323937124035,
        "length" :0.21507476107609084,
        "sex" :0.448611774505744,
        "shell" :1.70426496893776,
        "shucked" :2.1181392924386994,
        "viscera" :0.342220754059912,

      }
    }
  }
},
"version" : "1.0"
};

```

3. Use the following query to calculate the percentage of correct predictions that the model makes about abalone that are not yet mature. Abalone that are immature have 10 rings or less, and a correct prediction is accurate to within one ring of the actual number of rings.

```

SELECT
  TRUNC(
    SUM(
      CASE
        WHEN ROUND(
          f_abalone_ring_prediction(
            Sex,
            Length,
            Diameter,
            Height,
            Whole,
            Shucked,
            Viscera,
            Shell
          ),
          0
        ) BETWEEN Rings - 1
        AND Rings + 1 THEN 1
      ELSE 0
    )
  )

```

```
        END
      ) / CAST(COUNT(SHELL) AS FLOAT),
      4
    ) AS prediction_pct
FROM
  abalone_validation
WHERE
  Rings <= 10;
```

Tutorial: Building multi-class classification models with linear learner

In this tutorial, you create a linear learner model with data from Amazon S3, and then run prediction queries with the model using Amazon Redshift ML. The SageMaker linear learner algorithm solves either regression or classification problems. To learn more about regression and multi-class classification problems, see [Problem types for the machine learning paradigms](#) in the Amazon SageMaker Developer Guide. In this tutorial, you solve a multi-class classification problem. The linear learner algorithm trains many models in parallel, and automatically determines the most optimized model. You use the CREATE MODEL operation in Amazon Redshift, which creates your linear learner model using SageMaker and sends the prediction function to Amazon Redshift. For more information about the linear learner algorithm, see the [Linear Learner Algorithm](#) in the Amazon SageMaker Developer Guide.

You can use a CREATE MODEL command to export training data, train a model, import the model, and prepare an Amazon Redshift prediction function. Use the CREATE MODEL operation to specify training data either as a table or a SELECT statement.

Linear learner models optimize either continuous objectives or discrete objectives. Continuous objectives are used for regression, while discrete variables are used for classification. Some methods provide a solution for only continuous objectives, such as a regression method. The linear learner algorithm provides an increase in speed over naive hyperparameter optimization techniques, such as the Naive Bayes technique. A naive optimization technique assumes that each input variable is independent. The linear learner algorithm trains many models in parallel and selects the most optimized model. A similar algorithm is XGBoost, which combines estimates from a set of simpler and weaker models to make predictions. To learn more about XGBoost, see [XGBoost algorithm](#) in the Amazon SageMaker Developer Guide.

To use the linear learner algorithm, you must provide columns representing the dimensions of the inputs, and rows representing the observations. For more information about the linear learner algorithm, see the [Linear Learner Algorithm](#) in the Amazon SageMaker Developer Guide.

In this tutorial, you build a linear learner model that predicts the types of cover for a given area. You use the CREATE MODEL command on the [Coverture dataset](#) from the UCI Machine Learning Repository. Then, you use the prediction function created by the command to determine the types of cover in a wilderness area. A forest cover type is usually a type of tree. The inputs that Redshift ML will use to create the model include soil type, distance to roadways, and wilderness area designation. For more information about the dataset, see the [Coverture Dataset](#) from the UCI Machine Learning Repository.

Use case examples

You can solve other multi-class classification problems with linear learner with Amazon Redshift ML, such as predicting the species of a plant from an image. You could also predict the quantity of a product that a customer will purchase.

Tasks

- Prerequisites
- Step 1: Load the data from Amazon S3 to Amazon Redshift
- Step 2: Create the machine learning model
- Step 3: Validate the model

Prerequisites

To complete this tutorial, you must complete the [Administrative setup](#) for Amazon Redshift ML.

Step 1: Load the data from Amazon S3 to Amazon Redshift

Use the [Amazon Redshift query editor v2](#) to run the following queries. These queries load the sample data into Redshift and divide the data into a training set and a validation set.

1. The following query creates the `covertime_data` table.

```
CREATE TABLE public.covertime_data (  
    elevation bigint ENCODE az64,  
    aspect bigint ENCODE az64,  
    slope bigint ENCODE az64,  
    horizontal_distance_to_hydrology bigint ENCODE az64,  
    vertical_distance_to_hydrology bigint ENCODE az64,  
    horizontal_distance_to_roadways bigint ENCODE az64,  
    hillshade_9am bigint ENCODE az64,  
    hillshade_noon bigint ENCODE az64,  
    hillshade_3pm bigint ENCODE az64,  
    horizontal_distance_to_fire_points bigint ENCODE az64,  
    wilderness_area1 bigint ENCODE az64,  
    wilderness_area2 bigint ENCODE az64,  
    wilderness_area3 bigint ENCODE az64,  
    wilderness_area4 bigint ENCODE az64,  
    soil_type1 bigint ENCODE az64,  
    soil_type2 bigint ENCODE az64,  
    soil_type3 bigint ENCODE az64,  
    soil_type4 bigint ENCODE az64,  
    soil_type5 bigint ENCODE az64,  
    soil_type6 bigint ENCODE az64,  
    soil_type7 bigint ENCODE az64,  
    soil_type8 bigint ENCODE az64,  
    soil_type9 bigint ENCODE az64,  
    soil_type10 bigint ENCODE az64,  
    soil_type11 bigint ENCODE az64,  
    soil_type12 bigint ENCODE az64,  
    soil_type13 bigint ENCODE az64,  
    soil_type14 bigint ENCODE az64,  
    soil_type15 bigint ENCODE az64,  
    soil_type16 bigint ENCODE az64,  
    soil_type17 bigint ENCODE az64,
```

```
soil_type18 bigint ENCODE az64,  
soil_type19 bigint ENCODE az64,  
soil_type20 bigint ENCODE az64,  
soil_type21 bigint ENCODE az64,  
soil_type22 bigint ENCODE az64,  
soil_type23 bigint ENCODE az64,  
soil_type24 bigint ENCODE az64,  
soil_type25 bigint ENCODE az64,  
soil_type26 bigint ENCODE az64,  
soil_type27 bigint ENCODE az64,  
soil_type28 bigint ENCODE az64,  
soil_type29 bigint ENCODE az64,  
soil_type30 bigint ENCODE az64,  
soil_type31 bigint ENCODE az64,  
soil_type32 bigint ENCODE az64,  
soil_type33 bigint ENCODE az64,  
soil_type34 bigint ENCODE az64,  
soil_type35 bigint ENCODE az64,  
soil_type36 bigint ENCODE az64,  
soil_type37 bigint ENCODE az64,  
soil_type38 bigint ENCODE az64,  
soil_type39 bigint ENCODE az64,  
soil_type40 bigint ENCODE az64,  
cover_type bigint ENCODE az64  
) DISTSTYLE AUTO;
```

- The following query copies the sample data from the [Covertime dataset](#) in Amazon S3 to the `covertime_data` table you created previously in Amazon Redshift.

```
COPY public.covertime_data  
FROM  
    's3://redshift-ml-multiclass/covertime.data.gz' IAM_ROLE DEFAULT gzip DELIMITER ','  
    REGION 'us-east-1';
```

- By manually splitting the data, you will be able to verify the accuracy of the model by allocating an additional testing set. The following query splits the data into three sets. The `covertime_training` table is for training, the `covertime_validation` table is for validation, and the `covertime_test` table is for testing your model. You will use the training set to train your model and the validation set to validate the model's development. Then, you use the testing set to test the performance of the model and see if the model is overfitting or underfitting the dataset.

```
CREATE TABLE public.covertime_data_prep AS
SELECT
    a.*,
    CAST (random() * 100 AS int) AS data_group_id
FROM
    public.covertime_data a;

--training dataset
CREATE TABLE public.covertime_training as
SELECT
    *
FROM
    public.covertime_data_prep
WHERE
    data_group_id < 80;

--validation dataset
CREATE TABLE public.covertime_validation AS
SELECT
    *
FROM
    public.covertime_data_prep
WHERE
    data_group_id BETWEEN 80
    AND 89;

--test dataset
CREATE TABLE public.covertime_test AS
SELECT
    *
FROM
    public.covertime_data_prep
WHERE
    data_group_id > 89;
```

Step 2: Create the machine learning model

In this step, you use the CREATE MODEL statement to create your machine learning model with the linear learner algorithm.

The following query creates the linear learner model with the CREATE MODEL operation using your S3 bucket. Replace amzn-s3-demo-bucket with your own S3 bucket.

```
CREATE MODEL forest_cover_type_model
FROM
  (
    SELECT
      Elevation,
      Aspect,
      Slope,
      Horizontal_distance_to_hydrology,
      Vertical_distance_to_hydrology,
      Horizontal_distance_to_roadways,
      Hillshade_9am,
      Hillshade_noon,
      Hillshade_3pm,
      Horizontal_Distance_To_Fire_Points,
      Wilderness_Area1,
      Wilderness_Area2,
      Wilderness_Area3,
      Wilderness_Area4,
      soil_type1,
      Soil_Type2,
      Soil_Type3,
      Soil_Type4,
      Soil_Type5,
      Soil_Type6,
      Soil_Type7,
      Soil_Type8,
      Soil_Type9,
      Soil_Type10,
      Soil_Type11,
      Soil_Type12,
      Soil_Type13,
      Soil_Type14,
      Soil_Type15,
      Soil_Type16,
      Soil_Type17,
      Soil_Type18,
      Soil_Type19,
      Soil_Type20,
      Soil_Type21,
      Soil_Type22,
```

```
Soil_Type23,  
Soil_Type24,  
Soil_Type25,  
Soil_Type26,  
Soil_Type27,  
Soil_Type28,  
Soil_Type29,  
Soil_Type30,  
Soil_Type31,  
Soil_Type32,  
Soil_Type33,  
Soil_Type34,  
Soil_Type36,  
Soil_Type37,  
Soil_Type38,  
Soil_Type39,  
Soil_Type40,  
Cover_type  
from  
    public.covertime_training  
    ) TARGET cover_type FUNCTION predict_cover_type IAM_ROLE default MODEL_TYPE

    S3_BUCKET 'amzn-s3-demo-bucket',  
    S3_GARBAGE_COLLECT OFF,  
    MAX_RUNTIME 15000  
    );
```

Show the status of model training (optional)

You can use the SHOW MODEL command to know when your model is ready.

Use the following query to monitor the progress of the model training.

```
SHOW MODEL forest_cover_type_model;
```

When the model is ready, the output of the previous operation should look similar to the following example. Note that the output provides the `validation:multiclass_accuracy` metric, which you can view on the righthand side of the following example. Multi-class accuracy measures the percentage of data points that are classified correctly by the model. You will use multi-class accuracy to validate the accuracy of the model in the next step.

Query performance tuning

Amazon Redshift uses queries based on structured query language (SQL) to interact with data and objects in the system. Data manipulation language (DML) is the subset of SQL that you use to view, add, change, and delete data. Data definition language (DDL) is the subset of SQL that you use to add, change, and delete database objects such as tables and views.

Once your system is set up, you typically work with DML the most, especially the [SELECT](#) command for retrieving and viewing data. To write effective data retrieval queries in Amazon Redshift, become familiar with SELECT and apply the tips outlined in [Amazon Redshift best practices for designing tables](#) to maximize query efficiency.

To understand how Amazon Redshift processes queries, use the [Query processing](#) and [Query analysis and improvement](#) sections. Then you can apply this information in combination with diagnostic tools to identify and remove issues in query performance.

To identify and address some of the most common and most serious issues you are likely to encounter with Amazon Redshift queries, use the [Query troubleshooting](#) section.

Query processing

Amazon Redshift routes a submitted SQL query through the parser and optimizer to develop a query plan. The execution engine then translates the query plan into code and sends that code to the compute nodes for execution.

Topics

- [Query planning and execution workflow](#)
- [Creating and interpreting a query plan](#)
- [Reviewing query plan steps](#)
- [Factors affecting query performance](#)

Query planning and execution workflow

The following illustration provides a high-level view of the query planning and execution workflow.

The query planning and execution workflow follow these steps:

1. The leader node receives the query and parses the SQL.
2. The parser produces an initial query tree that is a logical representation of the original query. Amazon Redshift then inputs this query tree into the query optimizer.
3. The optimizer evaluates and if necessary rewrites the query to maximize its efficiency. This process sometimes results in creating multiple related queries to replace a single one.
4. The optimizer generates a query plan (or several, if the previous step resulted in multiple queries) for the execution with the best performance. The query plan specifies execution options such as join types, join order, aggregation options, and data distribution requirements.

You can use the [EXPLAIN](#) command to view the query plan. The query plan is a fundamental tool for analyzing and tuning complex queries. For more information, see [Creating and interpreting a query plan](#).

5. The execution engine translates the query plan into *steps*, *segments*, and *streams*:

Step

Each step is an individual operation needed during query execution. Steps can be combined to allow compute nodes to perform a query, join, or other database operation.

Segment

A combination of several steps that can be done by a single process, also the smallest compilation unit executable by a compute node slice. A *slice* is the unit of parallel processing in Amazon Redshift. The segments in a stream run in parallel.

Stream

A collection of segments to be parceled out over the available compute node slices.

The execution engine generates compiled code based on steps, segments, and streams. Compiled code runs faster than interpreted code and uses less compute capacity. This compiled code is then broadcast to the compute nodes.

Note

When benchmarking your queries, you should always compare the times for the second execution of a query, because the first execution time includes the overhead of compiling the code. For more information, see [Factors affecting query performance](#).

6. The compute node slices run the query segments in parallel. As part of this process, Amazon Redshift takes advantage of optimized network communication, memory, and disk management to pass intermediate results from one query plan step to the next. This also helps to speed query execution.

Steps 5 and 6 happen once for each stream. The engine creates the executable segments for one stream and sends them to the compute nodes. When the segments of that stream are complete, the engine generates the segments for the next stream. In this way, the engine can analyze what happened in the prior stream (for example, whether operations were disk-based) to influence the generation of segments in the next stream.

When the compute nodes are done, they return the query results to the leader node for final processing. The leader node merges the data into a single result set and addresses any needed sorting or aggregation. The leader node then returns the results to the client.

Note

The compute nodes might return some data to the leader node during query execution if necessary. For example, if you have a subquery with a LIMIT clause, the limit is applied on the leader node before data is redistributed across the cluster for further processing.

Creating and interpreting a query plan

You can use the query plan to get information on the individual operations required to run a query. Before you work with a query plan, we recommend that you first understand how Amazon Redshift handles processing queries and creating query plans. For more information, see [Query planning and execution workflow](#).

To create a query plan, run the [EXPLAIN](#) command followed by the actual query text. The query plan gives you the following information:

- What operations the execution engine performs, reading the results from bottom to top.
- What type of step each operation performs.
- Which tables and columns are used in each operation.
- How much data is processed in each operation, in terms of number of rows and data width in bytes.
- The relative cost of the operation. *Cost* is a measure that compares the relative execution times of the steps within a plan. Cost does not provide any precise information about actual execution times or memory consumption, nor does it provide a meaningful comparison between execution plans. It does give you an indication of which operations in a query are consuming the most resources.

The EXPLAIN command doesn't actually run the query. It only shows the plan that Amazon Redshift runs if the query is run under current operating conditions. If you change the schema or data for a table and run [ANALYZE](#) again to update the statistical metadata, the query plan might be different.

The query plan output by EXPLAIN is a simplified, high-level view of query execution. It doesn't illustrate the details of parallel query processing. To see detailed information, run the query itself, and then get query summary information from the SVL_QUERY_SUMMARY or

SVL_QUERY_REPORT view. For more information about using these views, see [Analyzing the query summary](#).

The following example shows the EXPLAIN output for a simple GROUP BY query on the EVENT table:

```
explain select eventname, count(*) from event group by eventname;
```

QUERY PLAN

```
-----  
XN HashAggregate (cost=131.97..133.41 rows=576 width=17)  
-> XN Seq Scan on event (cost=0.00..87.98 rows=8798 width=17)
```

EXPLAIN returns the following metrics for each operation:

Cost

A relative value that is useful for comparing operations within a plan. Cost consists of two decimal values separated by two periods, for example `cost=131.97..133.41`. The first value, in this case 131.97, provides the relative cost of returning the first row for this operation. The second value, in this case 133.41, provides the relative cost of completing the operation. The costs in the query plan are cumulative as you read up the plan, so the HashAggregate cost in this example (131.97..133.41) includes the cost of the Seq Scan below it (0.00..87.98).

Rows

The estimated number of rows to return. In this example, the scan is expected to return 8798 rows. The HashAggregate operator on its own is expected to return 576 rows (after duplicate event names are discarded from the result set).

Note

The rows estimate is based on the available statistics generated by the ANALYZE command. If ANALYZE has not been run recently, the estimate is less reliable.

Width

The estimated width of the average row, in bytes. In this example, the average row is expected to be 17 bytes wide.

EXPLAIN operators

This section briefly describes the operators that you see most often in the EXPLAIN output. For a complete list of operators, see [EXPLAIN](#) in the SQL Commands section.

Sequential scan operator

The sequential scan operator (Seq Scan) indicates a table scan. Seq Scan scans each column in the table sequentially from beginning to end and evaluates query constraints (in the WHERE clause) for every row.

Join operators

Amazon Redshift selects join operators based on the physical design of the tables being joined, the location of the data required for the join, and the specific requirements of the query itself.

- **Nested Loop**

The least optimal join, a nested loop is used mainly for cross-joins (Cartesian products) and some inequality joins.

- **Hash Join and Hash**

Typically faster than a nested loop join, a hash join and hash are used for inner joins and left and right outer joins. These operators are used when joining tables where the join columns are not both distribution keys *and* sort keys. The hash operator creates the hash table for the inner table in the join; the hash join operator reads the outer table, hashes the joining column, and finds matches in the inner hash table.

- **Merge Join**

Typically the fastest join, a merge join is used for inner joins and outer joins. The merge join is not used for full joins. This operator is used when joining tables where the join columns are both distribution keys *and* sort keys, and when less than 20 percent of the joining tables are unsorted. It reads two sorted tables in order and finds the matching rows. To view the percent of unsorted rows, query the [SVV_TABLE_INFO](#) system table.

- **Spatial Join**

Typically a fast join based on proximity of spatial data, used for GEOMETRY and GEOGRAPHY data types.

Aggregate operators

The query plan uses the following operators in queries that involve aggregate functions and GROUP BY operations.

- **Aggregate**

Operator for scalar aggregate functions such as AVG and SUM.

- **HashAggregate**

Operator for unsorted grouped aggregate functions.

- **GroupAggregate**

Operator for sorted grouped aggregate functions.

Sort operators

The query plan uses the following operators when queries have to sort or merge result sets.

- **Sort**

Evaluates the ORDER BY clause and other sort operations, such as sorts required by UNION queries and joins, SELECT DISTINCT queries, and window functions.

- **Merge**

Produces final sorted results according to intermediate sorted results that derive from parallel operations.

UNION, INTERSECT, and EXCEPT operators

The query plan uses the following operators for queries that involve set operations with UNION, INTERSECT, and EXCEPT.

- **Subquery**

Used to run UNION queries.

- **Hash Intersect Distinct**

Used to run INTERSECT queries.

- **SetOp Except**

Used to run EXCEPT (or MINUS) queries.

Other operators

The following operators also appear frequently in EXPLAIN output for routine queries.

- **Unique**

Removes duplicates for SELECT DISTINCT queries and UNION queries.

- **Limit**

Processes the LIMIT clause.

- **Window**

Runs window functions.

- **Result**

Runs scalar functions that do not involve any table access.

- **Subplan**

Used for certain subqueries.

- **Network**

Sends intermediate results to the leader node for further processing.

- **Materialize**

Saves rows for input to nested loop joins and some merge joins.

Joins in EXPLAIN

The query optimizer uses different join types to retrieve table data, depending on the structure of the query and the underlying tables. The EXPLAIN output references the join type, the tables used, and the way the table data is distributed across the cluster to describe how the query is processed.

Join type examples

The following examples show the different join types that the query optimizer can use. The join type used in the query plan depends on the physical design of the tables involved.

Example: Hash join two tables

The following query joins EVENT and CATEGORY on the CATID column. CATID is the distribution and sort key for CATEGORY but not for EVENT. A hash join is performed with EVENT as the outer table and CATEGORY as the inner table. Because CATEGORY is the smaller table, the planner broadcasts a copy of it to the compute nodes during query processing by using DS_BCAST_INNER. The join cost in this example accounts for most of the cumulative cost of the plan.

```
explain select * from category, event where category.catid=event.catid;
```

QUERY PLAN

```
-----
XN Hash Join DS_BCAST_INNER (cost=0.14..6600286.07 rows=8798 width=84)
  Hash Cond: ("outer".catid = "inner".catid)
    -> XN Seq Scan on event (cost=0.00..87.98 rows=8798 width=35)
    -> XN Hash (cost=0.11..0.11 rows=11 width=49)
        -> XN Seq Scan on category (cost=0.00..0.11 rows=11 width=49)
```

Note

Aligned indents for operators in the EXPLAIN output sometimes indicate that those operations do not depend on each other and can start in parallel. In the preceding example, although the scan on the EVENT table and the hash operation are aligned, the EVENT scan must wait until the hash operation has fully completed.

Example: Merge join two tables

The following query also uses SELECT *, but it joins SALES and LISTING on the LISTID column, where LISTID has been set as both the distribution and sort key for both tables. A merge join is chosen, and no redistribution of data is required for the join (DS_DIST_NONE).

```
explain select * from sales, listing where sales.listid = listing.listid;
```

QUERY PLAN

```
-----
XN Merge Join DS_DIST_NONE (cost=0.00..6285.93 rows=172456 width=97)
  Merge Cond: ("outer".listid = "inner".listid)
    -> XN Seq Scan on listing (cost=0.00..1924.97 rows=192497 width=44)
    -> XN Seq Scan on sales (cost=0.00..1724.56 rows=172456 width=53)
```

The following example demonstrates the different types of joins within the same query. As in the previous example, SALES and LISTING are merge joined, but the third table, EVENT, must be hash joined with the results of the merge join. Again, the hash join incurs a broadcast cost.

```
explain select * from sales, listing, event
where sales.listid = listing.listid and sales.eventid = event.eventid;
          QUERY PLAN
-----
XN Hash Join DS_BCAST_INNER (cost=109.98..3871130276.17 rows=172456 width=132)
  Hash Cond: ("outer".eventid = "inner".eventid)
    -> XN Merge Join DS_DIST_NONE (cost=0.00..6285.93 rows=172456 width=97)
      Merge Cond: ("outer".listid = "inner".listid)
        -> XN Seq Scan on listing (cost=0.00..1924.97 rows=192497 width=44)
        -> XN Seq Scan on sales (cost=0.00..1724.56 rows=172456 width=53)
    -> XN Hash (cost=87.98..87.98 rows=8798 width=35)
      -> XN Seq Scan on event (cost=0.00..87.98 rows=8798 width=35)
```

Example: Join, aggregate, and sort

The following query runs a hash join of the SALES and EVENT tables, followed by aggregation and sort operations to account for the grouped SUM function and the ORDER BY clause. The initial sort operator runs in parallel on the compute nodes. Then the Network operator sends the results to the leader node, where the Merge operator produces the final sorted results.

```
explain select eventname, sum(pricepaid) from sales, event
where sales.eventid=event.eventid group by eventname
order by 2 desc;
          QUERY PLAN
-----
XN Merge (cost=1002815366604.92..1002815366606.36 rows=576 width=27)
  Merge Key: sum(sales.pricepaid)
    -> XN Network (cost=1002815366604.92..1002815366606.36 rows=576 width=27)
      Send to leader
        -> XN Sort (cost=1002815366604.92..1002815366606.36 rows=576 width=27)
          Sort Key: sum(sales.pricepaid)
            -> XN HashAggregate (cost=2815366577.07..2815366578.51 rows=576
width=27)
              -> XN Hash Join DS_BCAST_INNER (cost=109.98..2815365714.80
rows=172456 width=27)
                Hash Cond: ("outer".eventid = "inner".eventid)
                  -> XN Seq Scan on sales (cost=0.00..1724.56 rows=172456
width=14)
```

```
-> XN Hash (cost=87.98..87.98 rows=8798 width=21)
      -> XN Seq Scan on event (cost=0.00..87.98 rows=8798
width=21)
```

Data redistribution

The EXPLAIN output for joins also specifies a method for how data is moved around a cluster to facilitate the join. This data movement can be either a broadcast or a redistribution. In a broadcast, the data values from one side of a join are copied from each compute node to every other compute node, so that every compute node ends up with a complete copy of the data. In a redistribution, participating data values are sent from their current slice to a new slice (possibly on a different node). Data is typically redistributed to match the distribution key of the other table participating in the join if that distribution key is one of the joining columns. If neither of the tables has distribution keys on one of the joining columns, either both tables are distributed or the inner table is broadcast to every node.

The EXPLAIN output also references inner and outer tables. The inner table is scanned first, and appears nearer the bottom of the query plan. The inner table is the table that is probed for matches. It is usually held in memory, is usually the source table for hashing, and if possible, is the smaller table of the two being joined. The outer table is the source of rows to match against the inner table. It is usually read from disk. The query optimizer chooses the inner and outer table based on database statistics from the latest run of the ANALYZE command. The order of tables in the FROM clause of a query doesn't determine which table is inner and which is outer.

Use the following attributes in query plans to identify how data is moved to facilitate a query:

- **DS_BCAST_INNER**

A copy of the entire inner table is broadcast to all compute nodes.

- **DS_DIST_ALL_NONE**

No redistribution is required, because the inner table has already been distributed to every node using DISTSTYLE ALL.

- **DS_DIST_NONE**

No tables are redistributed. Collocated joins are possible because corresponding slices are joined without moving data between nodes.

- **DS_DIST_INNER**

The inner table is redistributed.

- **DS_DIST_OUTER**

The outer table is redistributed.

- **DS_DIST_ALL_INNER**

The entire inner table is redistributed to a single slice because the outer table uses DISTSTYLE ALL.

- **DS_DIST_BOTH**

Both tables are redistributed.

Reviewing query plan steps

You can see the steps in a query plan by running the EXPLAIN command. The following example shows an SQL query and explains the output. Reading the query plan from the bottom up, you can see each of the logical operations used to perform the query. For more information, see [Creating and interpreting a query plan](#).

```
explain
select eventname, sum(pricepaid) from sales, event
where sales.eventid = event.eventid
group by eventname
order by 2 desc;
```

```
XN Merge (cost=1002815366604.92..1002815366606.36 rows=576 width=27)
  Merge Key: sum(sales.pricepaid)
    -> XN Network (cost=1002815366604.92..1002815366606.36 rows=576 width=27)
      Send to leader
        -> XN Sort (cost=1002815366604.92..1002815366606.36 rows=576 width=27)
          Sort Key: sum(sales.pricepaid)
            -> XN HashAggregate (cost=2815366577.07..2815366578.51 rows=576
width=27)
              -> XN Hash Join DS_BCAST_INNER (cost=109.98..2815365714.80
rows=172456 width=27)
                Hash Cond: ("outer".eventid = "inner".eventid)
                  -> XN Seq Scan on sales (cost=0.00..1724.56 rows=172456
width=14)
                    -> XN Hash (cost=87.98..87.98 rows=8798 width=21)
```

```
width=21)
-> XN Seq Scan on event (cost=0.00..87.98 rows=8798
```

As part of generating a query plan, the query optimizer breaks down the plan into streams, segments, and steps. The query optimizer breaks the plan down to prepare for distributing the data and query workload to the compute nodes. For more information about streams, segments, and steps, see [Query planning and execution workflow](#).

The following illustration shows the preceding query and associated query plan. It displays how the query operations involved map to steps that Amazon Redshift uses to generate compiled code for the compute node slices. Each query plan operation maps to multiple steps within the segments, and sometimes to multiple segments within the streams.

In this illustration, the query optimizer runs the query plan as follows:

1. In `Stream 0`, the query runs `Segment 0` with a sequential scan operation to scan the events table. The query continues to `Segment 1` with a hash operation to create the hash table for the inner table in the join.
2. In `Stream 1`, the query runs `Segment 2` with a sequential scan operation to scan the sales table. It continues with `Segment 2` with a hash join to join tables where the join columns are not both distribution keys and sort keys. It again continues with `Segment 2` with a hash aggregate to aggregate results. Then the query runs `Segment 3` with a hash aggregate operation to perform unsorted grouped aggregate functions, and a sort operation to evaluate the `ORDER BY` clause and other sort operations.
3. In `Stream 2`, the query runs a network operation in `Segment 4` and `Segment 5` to send intermediate results to the leader node for further processing.

The last segment of a query returns the data. If the return set is aggregated or sorted, the compute nodes each send their piece of the intermediate result to the leader node. The leader node then merges the data so the final result can be sent back to the requesting client.

For more information about `EXPLAIN` operators, see [EXPLAIN](#).

Factors affecting query performance

A number of factors can affect query performance. The following aspects of your data, cluster, and database operations all play a part in how quickly your queries process.

- **Number of nodes, processors, or slices** – A compute node is partitioned into slices. More nodes means more processors and more slices, which enables your queries to process faster by running portions of the query concurrently across the slices. However, more nodes also means greater expense, so you need to find the balance of cost and performance that is appropriate for your system. For more information on Amazon Redshift cluster architecture, see [Data warehouse system architecture](#).
- **Node types** – An Amazon Redshift cluster can use one of several node types. Each node type offers different sizes and limits to help you scale your cluster appropriately. The node size determines the storage capacity, memory, CPU, and price of each node in the cluster. For more information about node types, see [Overview of Amazon Redshift clusters](#) in the *Amazon Redshift Management Guide*.
- **Data distribution** – Amazon Redshift stores table data on the compute nodes according to a table's distribution style. When you run a query, the query optimizer redistributes the data to the

compute nodes as needed to perform any joins and aggregations. Choosing the right distribution style for a table helps minimize the impact of the redistribution step by locating the data where it needs to be before the joins are performed. For more information, see [Data distribution for query optimization](#).

- **Data sort order** – Amazon Redshift stores table data on disk in sorted order according to a table's sort keys. The query optimizer and the query processor use the information about where the data is located to reduce the number of blocks that need to be scanned and thereby improve query speed. For more information, see [Sort keys](#).
- **Dataset size** – A higher volume of data in the cluster can slow query performance for queries, because more rows need to be scanned and redistributed. You can mitigate this effect by regular vacuuming and archiving of data, and by using a predicate to restrict the query dataset.
- **Concurrent operations** – Running multiple operations at once can affect query performance. Each operation takes one or more slots in an available query queue and uses the memory associated with those slots. If other operations are running, enough query queue slots might not be available. In this case, the query has to wait for slots to open before it can begin processing. For more information about creating and configuring query queues, see [Workload management](#).
- **Query structure** – How your query is written affects its performance. As much as possible, write queries to process and return as little data as meets your needs. For more information, see [Amazon Redshift best practices for designing queries](#).
- **Code compilation** – Amazon Redshift generates and compiles code for each query execution plan.

The compiled code runs faster because it removes the overhead of using an interpreter. You generally have some overhead cost the first time code is generated and compiled. As a result, the performance of a query the first time you run it can be misleading. The overhead cost might be especially noticeable when you run one-off queries. Run the query a second time to determine its typical performance. Amazon Redshift uses a serverless compilation service to scale query compilations beyond the compute resources of an Amazon Redshift cluster. The compiled code segments are cached locally on the cluster and in a virtually unlimited cache. This cache persists after cluster reboots. Subsequent executions of the same query run faster because they can skip the compilation phase.

The cache is not compatible across Amazon Redshift versions, so the compilation cache is flushed and the code is recompiled when queries run after a version upgrade. If your queries have strict SLAs, we recommend you pre-run query segments that scan data from cluster tables. This lets Amazon Redshift cache the base table data, reducing the planning time for queries after a

version upgrade. By using a scalable compilation service, Amazon Redshift can compile code in parallel to provide consistently fast performance. The magnitude of workload speed-up depends on the complexity and concurrency of queries.

Query analysis and improvement

Retrieving information from an Amazon Redshift data warehouse involves running complex queries on extremely large amounts of data, which can take a long time to process. To make sure that queries process as quickly as possible, there are a number of tools you can use to identify potential performance issues.

Topics

- [Query analysis workflow](#)
- [Reviewing query alerts](#)
- [Analyzing the query plan](#)
- [Analyzing the query summary](#)
- [Query performance improvement](#)
- [Diagnostic queries for query tuning](#)

Query analysis workflow

If a query is taking longer than expected, use the following steps to identify and correct issues that might be negatively affecting the query's performance. If you aren't sure what queries in your system might benefit from performance tuning, start by running the diagnostic query in [Identifying queries that are top candidates for tuning](#).

1. Make sure that your tables are designed according to best practices. For more information, see [Amazon Redshift best practices for designing tables](#).
2. See if you can delete or archive any unneeded data in your tables. For example, suppose your queries always target the last 6 months' worth of data but you have the last 18 months' worth in your tables. In this case, you can delete or archive the older data to reduce the number of records that must be scanned and distributed.
3. Run the [VACUUM](#) command on the tables in the query to reclaim space and re-sort rows. Running VACUUM helps if the unsorted region is large and the query uses the sort key in a join or in the predicate.

4. Run the [ANALYZE](#) command on the tables in the query to make sure that statistics are up to date. Running ANALYZE helps if any of the tables in the query have recently changed a lot in size. If running a full ANALYZE command will take too long, run ANALYZE on a single column to reduce processing time. This approach still updates the table size statistics; table size is a significant factor in query planning.
5. Make sure that your query has been run once for each type of client (based on what type of connection protocol the client uses) so that the query is compiled and cached. This approach speeds up subsequent runs of the query. For more information, see [Factors affecting query performance](#).
6. Check the [STL_ALERT_EVENT_LOG](#) table to identify and correct possible issues with your query. For more information, see [Reviewing query alerts](#).
7. Run the [EXPLAIN](#) command to get the query plan and use it to optimize the query. For more information, see [Analyzing the query plan](#).
8. Use the [SVL_QUERY_SUMMARY](#) and [SVL_QUERY_REPORT](#) views to get summary information and use it to optimize the query. For more information, see [Analyzing the query summary](#).

Sometimes a query that should run quickly is forced to wait until another, longer-running query finishes. In that case, you might have nothing to improve in the query itself, but you can improve overall system performance by creating and using query queues for different types of queries. To get an idea of queue wait time for your queries, see [Reviewing queue wait times for queries](#). For more information about configuring query queues, see [Workload management](#).

Reviewing query alerts

To use the [STL_ALERT_EVENT_LOG](#) system table to identify and correct potential performance issues with your query, follow these steps:

1. Run the following to determine your query ID:

```
select query, elapsed, substring
from svl_qlog
order by query
desc limit 5;
```

Examine the truncated query text in the `substring` field to determine which query value to select. If you have run the query more than once, use the query value from the row with the lower `elapsed` value. That is the row for the compiled version. If you have been running many

queries, you can raise the value used by the LIMIT clause used to make sure that your query is included.

2. Select rows from STL_ALERT_EVENT_LOG for your query:

```
Select * from stl_alert_event_log where query = MyQueryID;
```

userid	query	slice	segment	step	pid	xid	event	solution	event_time

100	109829	5	1	0	8761	304543	Very selective query filter:ratio=rows(3)/r	Review the choice of sort key to enable...	2015-02-24 23:28:01
100	113910	4	1	0	8774	316848	Very selective query filter:ratio=rows(3)/r	Review the choice of sort key to enable...	2015-02-25 17:14:58

3. Evaluate the results for your query. Use the following table to locate potential solutions for any issues that you have identified.

Note

Not all queries have rows in STL_ALERT_EVENT_LOG, only those with identified issues.

Issue	Event value	Solution value	Recommended solution
Statistics for the tables in the query are missing or out of date.	Missing query planner statistics	Run the ANALYZE command	See Table statistics missing or out of date.
There is a nested loop join (the least optimal join) in the query plan.	Nested Loop Join in the query plan	Review the join predicates to avoid Cartesian products	See Nested loop.
The scan skipped a relatively large number of rows that are marked as deleted but not vacuumed, or	Scanned a large number of deleted rows	Run the VACUUM command to	See Ghost rows or uncommitted rows.

Issue	Event value	Solution value	Recommended solution
rows that have been inserted but not committed.		reclaim deleted space	
More than 1,000,000 rows were redistributed for a hash join or aggregation.	Distributed a large number of rows across the network:RowCount rows were distributed in order to process the aggregation	Review the choice of distribution key to collocate the join or aggregation	See Suboptimal data distribution .
More than 1,000,000 rows were broadcast for a hash join.	Broadcasted a large number of rows across the network	Review the choice of distribution key to collocate the join and consider using distributed tables	See Suboptimal data distribution .
A DS_DIST_ALL_INNER redistribution style was indicated in the query plan, which forces serial execution because the entire inner table was redistributed to a single node.	DS_DIST_ALL_INNER for Hash Join in the query plan	Review the choice of distribution strategy to distribute the inner, rather than outer, table	See Suboptimal data distribution .

Analyzing the query plan

Run the [EXPLAIN](#) command to get a query plan.

Before analyzing the query plan, you should be familiar with how to read it. If you are unfamiliar with reading a query plan, we recommend that you read [Creating and interpreting a query plan](#) before proceeding.

To analyze the data provided by the query plan, follow these steps:

1. Identify the steps with the highest cost. Concentrate on optimizing those when proceeding through the remaining steps.
2. Look at the join types:
 - **Nested Loop:** Such joins usually occur because a join condition was omitted. For recommended solutions, see [Nested loop](#).
 - **Hash and Hash Join:** Hash joins are used when joining tables where the join columns are not distribution keys and also not sort keys. For recommended solutions, see [Hash join](#).
 - **Merge Join:** No change is needed.
3. Notice which table is used for the inner join, and which for the outer join. The query engine generally chooses the smaller table for the inner join, and the larger table for the outer join. If such a choice doesn't occur, your statistics are likely out of date. For recommended solutions, see [Table statistics missing or out of date](#).
4. See if there are any high-cost sort operations. If there are, see [Unsorted or missorted rows](#) for recommended solutions.
5. Look for the following broadcast operators where there are high-cost operations:
 - **DS_BCAST_INNER:** Indicates that the table is broadcast to all the compute nodes. This is fine for a small table, but not ideal for a larger table.
 - **DS_DIST_ALL_INNER:** Indicates that all of the workload is on a single slice.
 - **DS_DIST_BOTH:** Indicates heavy redistribution.

For recommended solutions for these situations, see [Suboptimal data distribution](#).

Analyzing the query summary

To get execution steps and statistics in more detail than in the query plan that [EXPLAIN](#) produces, use the [SVL_QUERY_SUMMARY](#) and [SVL_QUERY_REPORT](#) system views.

`SVL_QUERY_SUMMARY` provides query statistics by stream. You can use the information it provides to identify issues with expensive steps, long-running steps, and steps that write to disk.

The `SVL_QUERY_REPORT` system view enables you to see information similar to that for `SVL_QUERY_SUMMARY`, only by compute node slice rather than by stream. You can use the slice-level information for detecting uneven data distribution across the cluster (also known as data distribution skew), which forces some nodes to do more work than others and impairs query performance.

Topics

- [Using the `SVL_QUERY_SUMMARY` view](#)
- [Using the `SVL_QUERY_REPORT` view](#)
- [Mapping the query plan to the query summary](#)

Using the `SVL_QUERY_SUMMARY` view

To analyze query summary information by stream using [`SVL_QUERY_SUMMARY`](#), do the following:

1. Run the following query to determine your query ID:

```
select query, elapsed, substring
from svl_qlog
order by query
desc limit 5;
```

Examine the truncated query text in the `substring` field to determine which query value represents your query. If you have run the query more than once, use the query value from the row with the lower `elapsed` value. That is the row for the compiled version. If you have been running many queries, you can raise the value used by the `LIMIT` clause used to make sure that your query is included.

2. Select rows from `SVL_QUERY_SUMMARY` for your query. Order the results by stream, segment, and step:

```
select * from svl_query_summary where query = MyQueryID order by stm, seg, step;
```

The following is an example result.

userid	query	stm	seg	step	maxtime	avgtime	rows	bytes	rate_row	rate_byte	label	is_diskbased	workmem	is_rscan	is_delayed_scan	rows_pre_filter
1	249059	0	0	0	58	27	4	192			scan tbl=246 name=Internal Worktable	f		0 f	f	0
1	249059	0	0	1	58	27	4	0			project	f		0 f	f	0
1	249059	0	0	2	58	27	4	64			save tbl=249	f	481296384 f	f	f	0
1	249059	1	1	0	20	20	1	48			scan tbl=250 name=Internal Worktable	f		0 f	f	0
1	249059	1	1	1	20	20	1	0			dist	f		0 f	f	0
1	249059	1	2	0	2275	1350	1	48			scan tbl=19221 name=Internal Worktable	f		0 f	f	0
1	249059	1	2	1	2275	1350	1	0			project	f		0 f	f	0
1	249059	1	2	2	2275	1350	1	16			save tbl=249	f	475004928 f	f	f	0
1	249059	2	3	0	1640	792	5	80			scan tbl=249 name=Internal Worktable	f		0 f	f	0
1	249059	2	3	1	1640	792	5	80			sort tbl=248	f	468713472 f	f	f	0
1	249059	3	4	0	26	9	5	80			scan tbl=248 name=Internal Worktable	f		0 f	f	0
1	249059	3	4	1	26	9	5	0			return	f		0 f	f	0
1	249059	3	5	0	49	49	0	0			merge	f		0 f	f	0
1	249059	3	5	1	49	49	5	0			project	f		0 f	f	0
1	249059	3	5	2	49	49	0	0			return	f		0 f	f	0

- Map the steps to the operations in the query plan using the information in [Mapping the query plan to the query summary](#). They should have approximately the same values for rows and bytes (rows * width from the query plan). If they don't, see [Table statistics missing or out of date](#) for recommended solutions.
- See if the `is_diskbased` field has a value of `t` (true) for any step. Hashes, aggregates, and sorts are the operators that are likely to write data to disk if the system doesn't have enough memory allocated for query processing.

If `is_diskbased` is true, see [Insufficient memory allocated to the query](#) for recommended solutions.
- Review the `label` field values and see if there is an AGG-DIST-AGG sequence anywhere in the steps. Its presence indicates two-step aggregation, which is expensive. To fix this, change the GROUP BY clause to use the distribution key (the first key, if there are multiple ones).
- Review the `maxtime` value for each segment (it is the same across all steps in the segment). Identify the segment with the highest `maxtime` value and review the steps in this segment for the following operators.

Note

A high `maxtime` value doesn't necessarily indicate a problem with the segment. Despite a high value, the segment might not have taken a long time to process. All segments in a stream start getting timed in unison. However, some downstream segments might not be able to run until they get data from upstream ones. This effect might make them seem to have taken a long time because their `maxtime` value includes both their waiting time and their processing time.

- BCAST or DIST:** In these cases, the high `maxtime` value might be the result of redistributing a large number of rows. For recommended solutions, see [Suboptimal data distribution](#).

- **HJOIN (hash join):** If the step in question has a very high value in the rows field compared to the rows value in the final RETURN step in the query, see [Hash join](#) for recommended solutions.
- **SCAN/SORT:** Look for a SCAN, SORT, SCAN, MERGE sequence of steps just before a join step. This pattern indicates that unsorted data is being scanned, sorted, and then merged with the sorted area of the table.

See if the rows value for the SCAN step has a very high value compared to the rows value in the final RETURN step in the query. This pattern indicates that the execution engine is scanning rows that are later discarded, which is inefficient. For recommended solutions, see [Insufficiently restrictive predicate](#).

If the maxtime value for the SCAN step is high, see [Suboptimal WHERE clause](#) for recommended solutions.

If the rows value for the SORT step is not zero, see [Unsorted or missorted rows](#) for recommended solutions.

7. Review the rows and bytes values for the 5–10 steps that precede the final RETURN step to get an idea of the amount of data that is returned to the client. This process can be a bit of an art.

For example, in the following sample query summary, the third PROJECT step provides a rows value, but not a bytes value. By looking through the preceding steps for one with the same rows value, you find the SCAN step that provides both rows and bytes information.

The following is a sample result.

userid	query	stm	seg	step	maxtime	avgtime	rows	bytes	rate_row	rate_byte	label	is_diskbased	workmem
1	187435	2	5	2	14307	12797	0	0			hash tbl=256	f	46871347
1	187435	3	6	0	531	308	387	229104			scan tbl=242 name=Internal Worktable	f	
1	187435	3	6	1	531	308	387	0			project	f	
1	187435	3	6	2	531	308	387	222912			save tbl=245	f	38063308
1	187435	4	7	0	390	390	0	0			scan tbl=238 name=Internal Worktable	f	
1	187435	4	7	1	390	390	0	0			dist	f	
1	187435	4	8	0	1218	1066	0	0			scan tbl=134954 name=Internal Worktable	f	
1	187435	4	8	1	1218	1066	0	0			project	f	
1	187435	4	8	2	1218	1066	0	0			save tbl=245	f	37434163
1	187435	5	9	0	171	83	387	222912			scan tbl=245 name=Internal Worktable	f	
1	187435	5	9	1	171	83	387	60120			dist	f	
1	187435	5	10	0	3579	3383	387	222912			scan tbl=134955 name=Internal Worktable	f	
1	187435	5	10	1	3579	3383	387	0			project	f	
1	187435	5	10	2	3579	3383	0	0			hjoin tbl=256	f	
1	187435	5	10	3	3579	3383	0	0			project	f	
1	187435	5	10	4	3579	3383	0	0			sort tbl=259	f	36805017
1	187435	6	11	0	10	7	0	0			scan tbl=259 name=Internal Worktable	f	
1	187435	6	11	1	10	7	0	0			return	f	
1	187435	6	12	0	9	9	0	0			merge	f	
1	187435	6	12	1	9	9	0	0			project	f	
1	187435	6	12	2	9	9	0	0			return	f	

If you are returning an unusually large volume of data, see [Very large result set](#) for recommended solutions.

- See if the bytes value is high relative to the rows value for any step, in comparison to other steps. This pattern can indicate that you are selecting a lot of columns. For recommended solutions, see [Large SELECT list](#).

Using the SVL_QUERY_REPORT view

To analyze query summary information by slice using [SVL_QUERY_REPORT](#), do the following:

- Run the following to determine your query ID:

```
select query, elapsed, substring
from svl_qlog
order by query
desc limit 5;
```

Examine the truncated query text in the `substring` field to determine which query value represents your query. If you have run the query more than once, use the query value from the row with the lower `elapsed` value. That is the row for the compiled version. If you have been running many queries, you can raise the value used by the `LIMIT` clause used to make sure that your query is included.

- Select rows from `SVL_QUERY_REPORT` for your query. Order the results by segment, step, `elapsed_time`, and rows:

```
select * from svl_query_report where query = MyQueryID order by segment, step,
elapsed_time, rows;
```

- For each step, check to see that all slices are processing approximately the same number of rows:

userid	query	slice	segment	step	start_time	end_time	elapsed_time	rows	bytes	label	is
100	141696	5	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	420	1100	31700	bcast	f
100	141696	1	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	437	1099	31812	bcast	f
100	141696	3	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	490	1066	30108	bcast	f
100	141696	6	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	576	1108	32316	bcast	f
100	141696	4	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	583	1128	32484	bcast	f

100	141696	7	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	2109	1150	33300	bcast	f
100	141696	2	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	2406	1068	31056	bcast	f
100	141696	2	1	0	2014-09-12 18:45:33	2014-09-12 18:45:33	3441	1797	253580	iscan tbl=95423 name=Internal Worktable	f

Also check to see that all slices are taking approximately the same amount of time:

userid	query	slice	segment	step	start_time	end_time	elapsed_time	rows	bytes	label	is
100	141696	2	0	0	2014-09-12 18:45:33	2014-09-12 18:45:33	410	1000	31800	scan tbl=95423 name=Event	f
100	141696	5	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	420	1100	31700	bcast	f
100	141696	1	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	437	1099	31812	bcast	f
100	141696	3	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	490	1066	30108	bcast	f
100	141696	6	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	576	1108	32316	bcast	f
100	141696	4	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	583	1128	32484	bcast	f
100	141696	0	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	726	1079	30804	bcast	f
100	141696	7	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	2109	1150	33300	bcast	f
100	141696	2	0	2	2014-09-12 18:45:33	2014-09-12 18:45:33	2406	1068	31056	bcast	f
100	141696	2	1	0	2014-09-12 18:45:33	2014-09-12 18:45:33	441	8798	253580	scan tbl=95423 name=Internal Worktable	f

Large discrepancies in these values can indicate data distribution skew due to a suboptimal distribution style for this particular query. For recommended solutions, see [Suboptimal data distribution](#).

Mapping the query plan to the query summary

When analyzing the query summary, you can get further details by mapping the operations from the query plan to the steps (identified by the label field values) in the query summary. The following table maps query plan operations to query summary steps.

Query plan operation	Label field value	Description
Aggregate	AGGR	Evaluates aggregate functions and GROUP BY conditions.
HashAggregate		
GroupAggregate		
DS_BCAST_INNER	BCAST (broadcast)	Broadcasts an entire table or some set of rows (such as a filtered set of rows from a table) to all nodes.
Doesn't appear in query plan	DELETE	Deletes rows from tables.
DS_DIST_NONE	DIST (distribute)	Distributes rows to nodes for parallel joining purposes or other parallel processing.
DS_DIST_ALL_NONE		
DS_DIST_INNER		

Query plan operation	Label field value	Description
DS_DIST_ALL_INNER		
DS_DIST_ALL_BOTH		
HASH	HASH	Builds hash table for use in hash joins.
Hash Join	HJOIN (hash join)	Performs a hash join of two tables or intermediate result sets.
Doesn't appear in query plan	INSERT	Inserts rows into tables.
Limit	LIMIT	Applies a LIMIT clause to result sets.
Merge	MERGE	Merges rows derived from parallel sort or join operations.
Merge Join	MJOIN (merge join)	Performs a merge join of two tables or intermediate result sets.
Nested Loop	NLOOP (nested loop)	Performs a nested loop join of two tables or intermediate result sets.
Doesn't appear in query plan	PARSE	Parses strings into binary values for loading.
Project	PROJECT	Evaluates expressions.
Network	RETURN	Returns rows to the leader or the client.
Doesn't appear in query plan	SAVE	Materializes rows for use in the next processing step.

Query plan operation	Label field value	Description
Seq Scan	SCAN	Scans tables or intermediate result sets.
Sort	SORT	Sorts rows or intermediate result sets as required by other subsequent operations (such as joins or aggregations) or to satisfy an ORDER BY clause.
Unique	UNIQUE	Applies a SELECT DISTINCT clause or removes duplicates as required by other operations.
Window	WINDOW	Computes aggregate and ranking window functions.

Query performance improvement

Following are some common issues that affect Amazon Redshift query performance, with instructions on ways to diagnose and resolve them.

Topics

- [Table statistics missing or out of date](#)
- [Nested loop](#)
- [Hash join](#)
- [Ghost rows or uncommitted rows](#)
- [Unsorted or missorted rows](#)
- [Suboptimal data distribution](#)
- [Insufficient memory allocated to the query](#)
- [Suboptimal WHERE clause](#)
- [Insufficiently restrictive predicate](#)

- [Very large result set](#)
- [Large SELECT list](#)

Table statistics missing or out of date

If table statistics are missing or out of date, you might see the following:

- A warning message in EXPLAIN command results.
- A missing statistics alert event in STL_ALERT_EVENT_LOG. For more information, see [Reviewing query alerts](#).

To fix this issue, run [ANALYZE](#).

Nested loop

If a nested loop is present, you might see a nested loop alert event in STL_ALERT_EVENT_LOG. You can also identify this type of event by running the query at [Identifying queries with nested loops](#). For more information, see [Reviewing query alerts](#).

To fix this, review your query for cross-joins and remove them if possible. Cross-joins are joins without a join condition that result in the Cartesian product of two tables. They are typically run as nested loop joins, which are the slowest of the possible join types.

Hash join

If a hash join is present, you might see the following:

- Hash and hash join operations in the query plan. For more information, see [Analyzing the query plan](#).
- An HJOIN step in the segment with the highest maxtime value in SVL_QUERY_SUMMARY. For more information, see [Using the SVL_QUERY_SUMMARY view](#).

To fix this issue, you can take a couple of approaches:

- Rewrite the query to use a merge join if possible. You can do this by specifying join columns that are both distribution keys and sort keys.
- If the HJOIN step in SVL_QUERY_SUMMARY has a very high value in the rows field compared to the rows value in the final RETURN step in the query, check whether you can rewrite the query to

join on a unique column. When a query does not join on a unique column, such as a primary key, that increases the number of rows involved in the join.

Ghost rows or uncommitted rows

If ghost rows or uncommitted rows are present, you might see an alert event in `STL_ALERT_EVENT_LOG` that indicates excessive ghost rows. For more information, see [Reviewing query alerts](#).

To fix this issue, you can take a couple of approaches:

- Check the **Loads** tab of your Amazon Redshift console for active load operations on any of the query tables. If you see active load operations, wait for those to complete before taking action.
- If there are no active load operations, run [VACUUM](#) on the query tables to remove deleted rows.

Unsorted or missorted rows

If unsorted or missorted rows are present, you might see a very selective filter alert event in `STL_ALERT_EVENT_LOG`. For more information, see [Reviewing query alerts](#).

You can also check to see if any of the tables in your query have large unsorted areas by running the query in [Identifying tables with data skew or unsorted rows](#).

To fix this issue, you can take a couple of approaches:

- Run [VACUUM](#) on the query tables to re-sort the rows.
- Review the sort keys on the query tables to see if any improvements can be made. Remember to weigh the performance of this query against the performance of other important queries and the system overall before making any changes. For more information, see [Sort keys](#).

Suboptimal data distribution

If data distribution is suboptimal, you might see the following:

- A serial execution, large broadcast, or large distribution alert event appears in `STL_ALERT_EVENT_LOG`. For more information, see [Reviewing query alerts](#).
- Slices are not processing approximately the same number of rows for a given step. For more information, see [Using the SVL_QUERY_REPORT view](#).

- Slices are not taking approximately the same amount of time for a given step. For more information, see [Using the SVL_QUERY_REPORT view](#).

If none of the preceding is true, you can also see if any of the tables in your query have data skew by running the query in [Identifying tables with data skew or unsorted rows](#).

To fix this issue, review the distribution styles for the tables in the query and see if any improvements can be made. Remember to weigh the performance of this query against the performance of other important queries and the system overall before making any changes. For more information, see [Data distribution for query optimization](#).

Insufficient memory allocated to the query

If insufficient memory is allocated to your query, you might see a step in SVL_QUERY_SUMMARY that has an `is_diskbased` value of `true`. For more information, see [Using the SVL_QUERY_SUMMARY view](#).

To fix this issue, allocate more memory to the query by temporarily increasing the number of query slots it uses. Workload Management (WLM) reserves slots in a query queue equivalent to the concurrency level set for the queue. For example, a queue with a concurrency level of 5 has 5 slots. Memory assigned to the queue is allocated equally to each slot. Assigning several slots to one query gives that query access to the memory for all of those slots. For more information on how to temporarily increase the slots for a query, see [wlm_query_slot_count](#).

Suboptimal WHERE clause

If your WHERE clause causes excessive table scans, you might see a SCAN step in the segment with the highest `maxtime` value in SVL_QUERY_SUMMARY. For more information, see [Using the SVL_QUERY_SUMMARY view](#).

To fix this issue, add a WHERE clause to the query based on the primary sort column of the largest table. This approach helps minimize scanning time. For more information, see [Amazon Redshift best practices for designing tables](#).

Insufficiently restrictive predicate

If your query has an insufficiently restrictive predicate, you might see a SCAN step in the segment with the highest `maxtime` value in SVL_QUERY_SUMMARY that has a very high `rows` value

compared to the `rows` value in the final RETURN step in the query. For more information, see [Using the SVL_QUERY_SUMMARY view](#).

To fix this issue, try adding a predicate to the query or making the existing predicate more restrictive to narrow the output.

Very large result set

If your query returns a very large result set, consider rewriting the query to use [UNLOAD](#) to write the results to Amazon S3. This approach improves the performance of the RETURN step by taking advantage of parallel processing. For more information on checking for a very large result set, see [Using the SVL_QUERY_SUMMARY view](#).

Large SELECT list

If your query has an unusually large SELECT list, you might see a bytes value that is high relative to the `rows` value for any step (in comparison to other steps) in SVL_QUERY_SUMMARY. This high bytes value can be an indicator that you are selecting a lot of columns. For more information, see [Using the SVL_QUERY_SUMMARY view](#).

To fix this issue, review the columns you are selecting and see if any can be removed.

Diagnostic queries for query tuning

Use the following queries to identify issues with queries or underlying tables that can affect query performance. We recommend using these queries with the query tuning processes discussed in [Query analysis and improvement](#).

Note

These queries are for Amazon Redshift provisioned clusters. These queries are not for use with Redshift Serverless workgroups.

Topics

- [Identifying queries that are top candidates for tuning](#)
- [Identifying tables with data skew or unsorted rows](#)
- [Identifying queries with nested loops](#)
- [Reviewing queue wait times for queries](#)

- [Reviewing query alerts by table](#)
- [Identifying tables with missing statistics](#)

Identifying queries that are top candidates for tuning

The following query identifies the top 50 most time-consuming statements that have been run in the last 7 days. You can use the results to identify queries that are taking unusually long. You can also identify queries that are run frequently (those that appear more than once in the result set). These queries are frequently good candidates for tuning to improve system performance.

This query also provides a count of the alert events associated with each query identified. These alerts provide details that you can use to improve the query's performance. For more information, see [Reviewing query alerts](#).

```
select trim(database) as db, count(query) as n_qry,
max(substring (qrytext,1,80)) as qrytext,
min(run_minutes) as "min" ,
max(run_minutes) as "max",
avg(run_minutes) as "avg", sum(run_minutes) as total,
max(query) as max_query_id,
max(starttime)::date as last_run,
sum(alerts) as alerts, aborted
from (select userid, label, stl_query.query,
trim(database) as database,
trim(querytxt) as qrytext,
md5(trim(querytxt)) as qry_md5,
starttime, endtime,
(datediff(seconds, starttime,endtime)::numeric(12,2))/60 as run_minutes,
alrt.num_events as alerts, aborted
from stl_query
left outer join
(select query, 1 as num_events from stl_alert_event_log group by query ) as alrt
on alrt.query = stl_query.query
where userid <> 1 and starttime >= dateadd(day, -7, current_date))
group by database, label, qry_md5, aborted
order by total desc limit 50;
```

Identifying tables with data skew or unsorted rows

The following query identifies tables that have uneven data distribution (data skew) or a high percentage of unsorted rows.

A low skew value indicates that table data is properly distributed. If a table has a skew value of 4.00 or higher, consider modifying its data distribution style. For more information, see [Suboptimal data distribution](#).

If a table has a `pct_unsorted` value greater than 20 percent, consider running the [VACUUM](#) command. For more information, see [Unsorted or missorted rows](#).

Also review the `mbytes` and `pct_of_total` values for each table. These columns identify the size of the table and what percentage of raw disk space the table consumes. The raw disk space includes space that is reserved by Amazon Redshift for internal use, so it is larger than the nominal disk capacity, which is the amount of disk space available to the user. Use this information to verify that you have free disk space equal to at least 2.5 times the size of your largest table. Having this space available enables the system to write intermediate results to disk when processing complex queries.

```
select trim(pgn.nspname) as schema,
trim(a.name) as table, id as tableid,
decode(pgc.reldiststyle,0, 'even',1,det.distkey ,8,'all') as distkey,
  dist_ratio.ratio::decimal(10,4) as skew,
det.head_sort as "sortkey",
det.n_sortkeys as "#sks", b.mbytes,
decode(b.mbytes,0,0,((b.mbytes/part.total::decimal)*100)::decimal(5,2)) as
  pct_of_total,
decode(det.max_enc,0,'n','y') as enc, a.rows,
decode( det.n_sortkeys, 0, null, a.unsorted_rows ) as unsorted_rows ,
decode( det.n_sortkeys, 0, null, decode( a.rows,0,0, (a.unsorted_rows::decimal(32)/
a.rows)*100) )::decimal(5,2) as pct_unsorted
from (select db_id, id, name, sum(rows) as rows,
sum(rows)-sum(sorted_rows) as unsorted_rows
from stv_tbl_perm a
group by db_id, id, name) as a
join pg_class as pgc on pgc.oid = a.id
join pg_namespace as pgn on pgn.oid = pgc.relnamespace
left outer join (select tbl, count(*) as mbytes
from stv_blocklist group by tbl) b on a.id=b.tbl
inner join (select attrelid,
min(case attisdistkey when 't' then attname else null end) as "distkey",
min(case attsortkeyord when 1 then attname else null end ) as head_sort ,
max(attsortkeyord) as n_sortkeys,
max(attencodingtype) as max_enc
from pg_attribute group by 1) as det
on det.attrelid = a.id
```

```
inner join ( select tbl, max(mbytes)::decimal(32)/min(mbytes) as ratio
from (select tbl, trim(name) as name, slice, count(*) as mbytes
from svv_diskusage group by tbl, name, slice )
group by tbl, name ) as dist_ratio on a.id = dist_ratio.tbl
join ( select sum(capacity) as total
from stv_partitions where part_begin=0 ) as part on 1=1
where mbytes is not null
order by mbytes desc;
```

Identifying queries with nested loops

The following query identifies queries that have had alert events logged for nested loops. For information on how to fix the nested loop condition, see [Nested loop](#).

```
select query, trim(querytxt) as SQL, starttime
from stl_query
where query in (
select distinct query
from stl_alert_event_log
where event like 'Nested Loop Join in the query plan%')
order by starttime desc;
```

Reviewing queue wait times for queries

The following query shows how long recent queries waited for an open slot in a query queue before running. If you see a trend of high wait times, you might want to modify your query queue configuration for better throughput. For more information, see [Implementing manual WLM](#).

```
select trim(database) as DB , w.query,
substring(q.querytxt, 1, 100) as querytxt, w.queue_start_time,
w.service_class as class, w.slot_count as slots,
w.total_queue_time/1000000 as queue_seconds,
w.total_exec_time/1000000 exec_seconds, (w.total_queue_time+w.total_Exec_time)/1000000
as total_seconds
from stl_wlm_query w
left join stl_query q on q.query = w.query and q.userid = w.userid
where w.queue_start_Time >= dateadd(day, -7, current_Date)
and w.total_queue_Time > 0 and w.userid >1
and q.starttime >= dateadd(day, -7, current_Date)
order by w.total_queue_time desc, w.queue_start_time desc limit 35;
```

Reviewing query alerts by table

The following query identifies tables that have had alert events logged for them, and also identifies what type of alerts are most frequently raised.

If the `minutes` value for a row with an identified table is high, check that table to see if it needs routine maintenance, such as having [ANALYZE](#) or [VACUUM](#) run against it.

If the count value is high for a row but the table value is null, run a query against `STL_ALERT_EVENT_LOG` for the associated event value to investigate why that alert is getting raised so often.

```
select trim(s.perm_table_name) as table,
(sum(abs(datediff(seconds, s.starttime, s.endtime)))/60)::numeric(24,0) as minutes,
trim(split_part(l.event,':',1)) as event, trim(l.solution) as solution,
max(l.query) as sample_query, count(*)
from stl_alert_event_log as l
left join stl_scan as s on s.query = l.query and s.slice = l.slice
and s.segment = l.segment and s.step = l.step
where l.event_time >= dateadd(day, -7, current_date)
group by 1,3,4
order by 2 desc,6 desc;
```

Identifying tables with missing statistics

The following query provides a count of the queries that you are running against tables that are missing statistics. If this query returns any rows, look at the `plannode` value to determine the affected table, and then run [ANALYZE](#) on it.

```
select substring(trim(plannode),1,100) as plannode, count(*)
from stl_explain
where plannode like '%missing statistics%'
group by plannode
order by 2 desc;
```

Query troubleshooting

This section provides a quick reference for identifying and addressing some of the most common and most serious issues that you are likely to encounter with Amazon Redshift queries.

Topics

- [Connection fails](#)
- [Query hangs](#)
- [Query takes too long](#)
- [Load fails](#)
- [Load takes too long](#)
- [Load data is incorrect](#)
- [Setting the JDBC fetch size parameter](#)

These suggestions give you a starting point for troubleshooting. You can also refer to the following resources for more detailed information.

- [Accessing Amazon Redshift clusters and databases](#)
- [Automatic table optimization](#)
- [Loading data in Amazon Redshift](#)
- [Tutorial: Loading data from Amazon S3](#)

Connection fails

Your query connection can fail because for the following reasons. We suggest the following troubleshooting approaches.

Client cannot connect to server

If you are using SSL or server certificates, first remove this complexity while you troubleshoot the connection issue. Then add SSL or server certificates back when you have found a solution. For more information, go to [Configure Security Options for Connections](#) in the *Amazon Redshift Management Guide*.

Connection is refused

Generally, when you receive an error message indicating that there is a failure to establish a connection, it means that there is an issue with the permission to access the cluster. For more information, go to [The connection is refused or fails](#) in the *Amazon Redshift Management Guide*.

Query hangs

Your query can hang, or stop responding, for the following reasons. We suggest the following troubleshooting approaches.

Connection to the database is dropped

Reduce the size of maximum transmission unit (MTU). The MTU size determines the maximum size, in bytes, of a packet that can be transferred in one Ethernet frame over your network connection. For more information, go to [The connection to the database is dropped](#) in the *Amazon Redshift Management Guide*.

Connection to the database times out

Your client connection to the database appears to hang or time out when running long queries, such as a COPY command. In this case, you might observe that the Amazon Redshift console displays that the query has completed, but the client tool itself still appears to be running the query. The results of the query might be missing or incomplete depending on when the connection stopped. This effect happens when idle connections are terminated by an intermediate network component. For more information, go to [Firewall Timeout Issue](#) in the *Amazon Redshift Management Guide*.

Client-side out-of-memory error occurs with ODBC

If your client application uses an ODBC connection and your query creates a result set that is too large to fit in memory, you can stream the result set to your client application by using a cursor. For more information, see [DECLARE](#) and [Performance considerations when using cursors](#).

Client-side out-of-memory error occurs with JDBC

When you attempt to retrieve large result sets over a JDBC connection, you might encounter client-side out-of-memory errors. For more information, see [Setting the JDBC fetch size parameter](#).

There is a potential deadlock

If there is a potential deadlock, try the following:

- View the [STV_LOCKS](#) and [STL_TR_CONFLICT](#) system tables to find conflicts involving updates to more than one table.
- Use the [PG_CANCEL_BACKEND](#) function to cancel one or more conflicting queries.

- Use the [PG_TERMINATE_BACKEND](#) function to terminate a session, which forces any currently running transactions in the terminated session to release all locks and roll back the transaction.
- Schedule concurrent write operations carefully. For more information, see [Managing concurrent write operations](#).

Query takes too long

Your query can take too long for the following reasons. We suggest the following troubleshooting approaches.

Tables are not optimized

Set the sort key, distribution style, and compression encoding of the tables to take full advantage of parallel processing. For more information, see [Automatic table optimization](#)

Query is writing to disk

Your queries might be writing to disk for at least part of the query execution. For more information, see [Query performance improvement](#).

Query must wait for other queries to finish

You might be able to improve overall system performance by creating query queues and assigning different types of queries to the appropriate queues. For more information, see [Workload management](#).

Queries are not optimized

Analyze the explain plan to find opportunities for rewriting queries or optimizing the database. For more information, see [Creating and interpreting a query plan](#).

Query needs more memory to run

If a specific query needs more memory, you can increase the available memory by increasing the [wlm_query_slot_count](#).

Database requires a VACUUM command to be run

Run the VACUUM command whenever you add, delete, or modify a large number of rows, unless you load your data in sort key order. The VACUUM command reorganizes your data to maintain the sort order and restore performance. For more information, see [Vacuuming tables](#).

Additional resources for troubleshooting long-running queries

The following are system-view topics and other documentation sections that are helpful for query tuning:

- The [STV_INFLIGHT](#) system view shows which queries are running on the cluster. It can be helpful to use it together with [STV_RECENTS](#) to determine which queries are currently running or recently completed.
- [SYS_QUERY_HISTORY](#) is useful for troubleshooting. It shows DDL and DML queries with relevant properties like their current status, such as `running` or `failed`, the time it took each to run, and whether a query ran on a concurrency-scaling cluster.
- [STL_QUERYTEXT](#) captures the query text for SQL commands. Additionally, [SVV_QUERY_INFLIGHT](#), which joins `STL_QUERYTEXT` to `STV_INFLIGHT`, shows more query metadata.
- A transaction-lock conflict can be a possible source of query-performance issues. For information about transactions that currently hold locks on tables, see [SVV_TRANSACTIONS](#).
- [Identifying queries that are top candidates for tuning](#) provides a troubleshooting query that helps you determine which recently-run queries were the most time consuming. This can help you focus your efforts on queries that need improvement.
- If you want to explore query management further and understand how to manage query queues, [Workload management](#) shows how to do it. Workload management is an advanced feature and we recommend automated workload management in most cases.

Load fails

Your data load can fail for the following reasons. We suggest the following troubleshooting approaches.

Data Source is in a different AWS Region

By default, the Amazon S3 bucket or Amazon DynamoDB table specified in the `COPY` command must be in the same AWS Region as the cluster. If your data and your cluster are in different Regions, you receive an error similar to the following:

```
The bucket you are attempting to access must be addressed using the specified endpoint.
```

If at all possible, make sure your cluster and your data source are in the same Region. You can specify a different Region by using the [REGION](#) option with the COPY command.

 **Note**

If your cluster and your data source are in different AWS Regions, you incur data transfer costs. You also have higher latency.

COPY command fails

Query `STL_LOAD_ERRORS` to discover the errors that occurred during specific loads. For more information, see [STL_LOAD_ERRORS](#).

Load takes too long

Your load operation can take too long for the following reasons. We suggest the following troubleshooting approaches.

COPY loads data from a single file

Split your load data into multiple files. When you load all the data from a single large file, Amazon Redshift is forced to perform a serialized load, which is much slower. The number of files should be a multiple of the number of slices in your cluster, and the files should be about equal size, between 1 MB and 1 GB after compression. For more information, see [Amazon Redshift best practices for designing queries](#).

Load operation uses multiple COPY commands

If you use multiple concurrent COPY commands to load one table from multiple files, Amazon Redshift is forced to perform a serialized load, which is much slower. In this case, use a single COPY command.

Load data is incorrect

Your COPY operation can load incorrect data in the following ways. We suggest the following troubleshooting approaches.

Wrong files are loaded

Using an object prefix to specify data files can cause unwanted files to be read. Instead, use a manifest file to specify exactly which files to load. For more information, see the [copy_from_s3_manifest_file](#) option for the COPY command and [Example: COPY from Amazon S3 using a manifest](#) in the COPY examples.

Setting the JDBC fetch size parameter

By default, the JDBC driver collects all the results for a query at one time. As a result, when you attempt to retrieve a large result set over a JDBC connection, you might encounter a client-side out-of-memory error. To enable your client to retrieve result sets in batches instead of in a single all-or-nothing fetch, set the JDBC fetch size parameter in your client application.

Note

Fetch size is not supported for ODBC.

For the best performance, set the fetch size to the highest value that does not lead to out of memory errors. A lower fetch size value results in more server trips, which prolong execution times. The server reserves resources, including the WLM query slot and associated memory, until the client retrieves the entire result set or the query is canceled. When you tune the fetch size appropriately, those resources are released more quickly, making them available to other queries.

Note

If you need to extract large datasets, we recommend using an [UNLOAD](#) statement to transfer the data to Amazon S3. When you use UNLOAD, the compute nodes work in parallel to speed up the transfer of data.

For more information about setting the JDBC fetch size parameter, go to [Getting results based on a cursor](#) in the PostgreSQL documentation.

Workload management

You can configure Amazon Redshift WLM to run with either automatic WLM or manual WLM.

With Amazon Redshift, you can manage and prioritize concurrent queries and user workloads to optimize performance and resource utilization. Workload management (WLM) allows you to define queues, user groups, and other constructs to control the resources allocated to different types of queries or users.

The following sections outline the specific workload management features in Amazon Redshift, and guide you through their configuration and monitoring.

Automatic WLM

To maximize system throughput and use resources effectively, you can enable Amazon Redshift to manage how resources are divided to run concurrent queries with automatic WLM. *Automatic WLM* manages the resources required to run queries. Amazon Redshift determines how many queries run concurrently and how much memory is allocated to each dispatched query. Use Auto WLM when you want Amazon Redshift to manage how resources are divided to run concurrent queries. For more information, see [Implementing automatic WLM](#).

Working with concurrency scaling and automatic WLM, you can support virtually unlimited concurrent users and concurrent queries, with consistently fast query performance. For more information, see [Concurrency scaling](#).

Note

In most cases we recommend that you use automatic WLM. If you're using manual WLM and you want to migrate from to automatic WLM, see [Migrating from manual WLM to automatic WLM](#).

With Auto WLM, it's possible to define query priorities for workloads in a queue. For more information about query priority, see [Query priority](#).

Manual WLM

You might have multiple sessions or users running queries at the same time. Some queries might consume cluster resources for long periods and affect the performance of others. Manual WLM can

help manage this for specialized use cases. Use Manual WLM when you want more control over concurrency.

You can manage system performance by modifying your WLM configuration to create separate queues for long-running queries and short-running queries. At runtime, you can route queries to these queues according to user groups or query groups.

You can set up rules to route queries to particular queues based on the user running the query or labels that you specify. You can also configure the amount of memory allocated to each queue, so that large queries run in queues with more memory than other queues. You can also configure a query monitoring rule (QMR) to limit long-running queries. For more information, see [Implementing manual WLM](#).

Note

We recommend configuring your manual WLM query queues with a total of 15 or fewer query slots. For more information, see [Concurrency level](#).

Note that in regards to a manual WLM configuration, the maximum slots you can allocate to a queue is 50. However, this doesn't mean that in an automatic WLM configuration, a Amazon Redshift cluster always runs 50 queries concurrently. This can change, based on the memory needs or other types of resource allocation on the cluster.

Switching WLM mode

You can enable automatic or manual WLM using the Amazon Redshift console:

1. Choose **Switch WLM mode**.
2. To set it to automatic WLM, choose **Auto WLM**. With this choice, up to eight queues are used to manage queries, and the **Memory** and **Concurrency on main** fields are both set to **Auto**. Additionally, the default priority of queries is set to **Normal**.
3. To enable manual configuration using the Amazon Redshift console, switching to **Manual WLM**. With this choice, you specify the queues used to manage queries, and the **Memory** and **Concurrency on main** field values. With a manual configuration, you can configure up to eight query queues and set the number of queries that can run in each of those queues concurrently.

Modifying the WLM configuration

The easiest way to modify the WLM configuration is by using the Amazon Redshift console. You can also use the AWS CLI or the Amazon Redshift API.

When you switch your cluster between automatic and manual WLM, your cluster is put into pending reboot state. The change doesn't take effect until the next cluster reboot.

For detailed information about modifying WLM configurations, see [Configuring Workload Management](#) in the *Amazon Redshift Management Guide*.

Migrating from manual WLM to automatic WLM

To maximize system throughput and use resources most effectively, we recommend that you set up automatic WLM for your queues. Consider taking the following approach to set up a smooth transition from manual WLM to automatic WLM.

To migrate from manual WLM to automatic WLM and use query priorities, we recommend that you create a new parameter group, and then attach that parameter group to your cluster. For more information, see [Amazon Redshift Parameter Groups](#) in the *Amazon Redshift Management Guide*.

Important

To change the parameter group or to switch from manual to automatic WLM requires a cluster reboot. For more information, see [WLM dynamic and static configuration properties](#).

Let's take an example where there are three manual WLM queues. One each for an ETL workload, an analytics workload, and a data science workload. The ETL workload runs every 6 hours, the analytics workload runs throughout the day, and the data science workload can spike at any time. With manual WLM, you specify the memory and concurrency that each workload queue gets based on your understanding of the importance of each workload to the business. Specifying the memory and concurrency is not only hard to figure out, it also results in cluster resources being statically partitioned and thereby wasted when only a subset of the workloads is running.

You can use automatic WLM with query priorities to indicate the relative priorities of the workloads, avoiding the preceding issues. For this example, follow these steps:

- Create a new parameter group and switch to **Auto WLM** mode.
- Add queues for each of the three workloads: ETL workload, analytics workload, and data science workload. Use the same user groups for each workload that was used with **Manual WLM** mode.
- Set the priority for the ETL workload to `High`, the analytics workload to `Normal`, and the data science to `Low`. These priorities reflect your business priorities for the different workloads or user groups.
- Optionally, enable concurrency scaling for the analytics or data science queue so that queries in these queues get consistent performance even when the ETL workload is running every 6 hours.

With query priorities, when only the analytics workload is running on the cluster, it gets the entire system to itself. This yields high throughput with better system utilization. However, when the ETL workload starts, it gets the right of the way since it has a higher priority. Queries running as part of the ETL workload get priority during admission, in addition to preferential resource allocation after they are admitted. As a consequence, the ETL workload performs predictably regardless of what else might be running on the system. The predictable performance for a high priority workload comes at the cost of other, lower priority workloads that run longer either because their queries are waiting behind more important queries to complete. Or, because they are getting a smaller fraction of resources when they are running concurrently with higher priority queries. The scheduling algorithms used by Amazon Redshift facilitate that the lower priority queries do not suffer from starvation, but rather continue to make progress albeit at a slower pace.

Note

- The `timeout` field is not available in automatic WLM. Instead, use the QMR rule, `query_execution_time`. For more information, see [WLM query monitoring rules](#).

- The QMR action, HOP, is not applicable to automatic WLM. Instead, use the `change priority` action. For more information, see [WLM query monitoring rules](#).
- Clusters use automatic WLM and manual WLM queues differently, which can lead to confusion with your configurations. For example, you can configure the `priority` property in automatic WLM queues but not in manual WLM queues. As such, avoid mixing automatic WLM queues and manual WLM queues within a parameter group. Instead, create a new parameter group when migrating to automatic WLM.

Implementing automatic WLM

With automatic workload management (WLM), Amazon Redshift manages query concurrency and memory allocation. You can create up to eight queues with the service class identifiers 100–107. Each queue has a priority. For more information, see [Query priority](#).

Automatic WLM determines the amount of resources that queries need and adjusts the concurrency based on the workload. When queries requiring large amounts of resources are in the system (for example, hash joins between large tables), the concurrency is lower. When lighter queries (such as inserts, deletes, scans, or simple aggregations) are submitted, concurrency is higher.

Automatic WLM is separate from short query acceleration (SQA) and it evaluates queries differently. Automatic WLM and SQA work together to allow short running and lightweight queries to complete even while long running, resource intensive queries are active. For more information about SQA, see [Short query acceleration](#).

Amazon Redshift enables automatic WLM through parameter groups:

- If your clusters use the default parameter group, Amazon Redshift enables automatic WLM for them.
- If your clusters use custom parameter groups, you can configure the clusters to enable automatic WLM. We recommend that you create a separate parameter group for your automatic WLM configuration.

To configure WLM, edit the `wlm_json_configuration` parameter in a parameter group that can be associated with one or more clusters. For more information, see [Modifying the WLM configuration](#).

You define query queues within the WLM configuration. You can add additional query queues to the default WLM configuration, up to a total of eight user queues. You can configure the following for each query queue:

- Priority
- Concurrency scaling mode
- User groups
- Query groups
- Query monitoring rules

Priority

You can define the relative importance of queries in a workload by setting a priority value. The priority is specified for a queue and inherited by all queries associated with the queue. For more information, see [Query priority](#).

Concurrency scaling mode

When concurrency scaling is enabled, Amazon Redshift automatically adds additional cluster capacity when you need it to process an increase in concurrent read and write queries. Your users see the most current data, whether the queries run on the main cluster or on a concurrency scaling cluster.

You manage which queries are sent to the concurrency scaling cluster by configuring WLM queues. When you enable concurrency scaling for a queue, eligible queries are sent to the concurrency scaling cluster instead of waiting in a queue. For more information, see [Concurrency scaling](#).

User groups

You can assign a set of user groups to a queue by specifying each user group name or by using wildcards. When a member of a listed user group runs a query, that query runs in the corresponding queue. There is no set limit on the number of user groups that can be assigned to a queue. For more information, see [Assigning queries to queues based on user groups](#).

Query groups

You can assign a set of query groups to a queue by specifying each query group name or by using wildcards. A *query group* is simply a label. At runtime, you can assign the query group label to a

series of queries. Any queries that are assigned to a listed query group run in the corresponding queue. There is no set limit to the number of query groups that can be assigned to a queue. For more information, see [Assigning a query to a query group](#).

Wildcards

If wildcards are enabled in the WLM queue configuration, you can assign user groups and query groups to a queue either individually or by using Unix shell–style wildcards. The pattern matching is case-insensitive.

For example, the '*' wildcard character matches any number of characters. Thus, if you add dba_* to the list of user groups for a queue, any user-run query that belongs to a group with a name that begins with dba_ is assigned to that queue. Examples are dba_admin or DBA_primary. The '?' wildcard character matches any single character. Thus, if the queue includes user-group dba?1, then user groups named dba11 and dba21 match, but dba12 doesn't match.

By default, wildcards aren't enabled.

Query monitoring rules

Query monitoring rules define metrics-based performance boundaries for WLM queues and specify what action to take when a query goes beyond those boundaries. For example, for a queue dedicated to short running queries, you might create a rule that cancels queries that run for more than 60 seconds. To track poorly designed queries, you might have another rule that logs queries that contain nested loops. For more information, see [WLM query monitoring rules](#).

Checking for automatic WLM

To check whether automatic WLM is enabled, run the following query. If the query returns at least one row, then automatic WLM is enabled.

```
select * from stv_wlm_service_class_config
where service_class >= 100;
```

The following query shows the number of queries that went through each query queue (service class). It also shows the average execution time, the number of queries with wait time at the 90th percentile, and the average wait time. Automatic WLM queries use service classes 100 through 107.

```
select final_state, service_class, count(*), avg(total_exec_time),
```

```
percentile_cont(0.9) within group (order by total_queue_time), avg(total_queue_time)
from stl_wlm_query where userid >= 100 group by 1,2 order by 2,1;
```

To find which queries were run by automatic WLM, and completed successfully, run the following query.

```
select a.queue_start_time, a.total_exec_time, label, trim(querytxt)
from stl_wlm_query a, stl_query b
where a.query = b.query and a.service_class >= 100 and a.final_state = 'Completed'
order by b.query desc limit 5;
```

Query priority

With Amazon Redshift, you can manage query prioritization and resource allocation across concurrent queries and workloads using Workload Management (WM). The following sections detail how to configure WM query queues, define queue properties like memory allocation and concurrency scaling, and implement priority rules tailored to your workload requirements.

Not all queries are of equal importance, and often performance of one workload or set of users might be more important. If you have enabled [automatic WLM](#), you can define the relative importance of queries in a workload by setting a priority value. The priority is specified for a queue and inherited by all queries associated with the queue. You associate queries to a queue by mapping user groups and query groups to the queue. You can set the following priorities (listed from highest to lowest priority):

1. HIGHEST
2. HIGH
3. NORMAL
4. LOW
5. LOWEST

Administrators use these priorities to show the relative importance of their workloads when there are queries with different priorities contending for the same resources. Amazon Redshift uses the priority when letting queries into the system, and to determine the amount of resources allocated to a query. By default, queries run with their priority set to NORMAL.

An additional priority, CRITICAL, which is a higher priority than HIGHEST, is available to superusers. To set this priority, you can use the functions [CHANGE_QUERY_PRIORITY](#),

[CHANGE_SESSION_PRIORITY](#), and [CHANGE_USER_PRIORITY](#). To grant a database user permission to use these functions, you can create a stored procedure and grant permission to a user. For an example, see [CHANGE_SESSION_PRIORITY](#).

Note

Only one CRITICAL query can run at a time.

Let's take an example where the priority of an extract, transform, load (ETL) workload is higher than the priority of the analytics workload. The ETL workload runs every six hours, and the analytics workload runs throughout the day. When only the analytics workload is running on the cluster, it gets the entire system to itself, yielding high throughput with optimal system utilization. However, when the ETL workload starts, it gets the right of the way because it has a higher priority. Queries running as part of the ETL workload get the right of the way during admission and also preferential resource allocation after they are admitted. As a consequence, the ETL workload performs predictably regardless of what else might be running on the system. Thus, it provides predictable performance and the ability for administrators to provide service level agreements (SLAs) for their business users.

Within a given cluster, the predictable performance for a high priority workload comes at the cost of other, lower priority workloads. Lower priority workloads might run longer either because their queries are waiting behind more important queries to complete. Or they might run longer because they're getting a smaller fraction of resources when they are running concurrently with higher priority queries. Lower priority queries don't suffer from starvation, but rather keep making progress at a slower pace.

In the preceding example, the administrator can enable [concurrency scaling](#) for the analytics workload. Doing this enables that workload to maintain its throughput, even though the ETL workload is running at high priority.

Configuring queue priority

If you have enabled automatic WLM, each queue has a priority value. Queries are routed to queues based on user groups and query groups. Start with a queue priority set to NORMAL. Set the priority higher or lower based on the workload associated with the queue's user groups and query groups.

You can change the priority of a queue on the Amazon Redshift console. On the Amazon Redshift console, the **Workload Management** page displays the queues and enables editing

of queue properties such as **Priority**. To set the priority using the CLI or API operations, use the `wlm_json_configuration` parameter. For more information, see [Configuring Workload Management](#) in the *Amazon Redshift Management Guide*.

The following `wlm_json_configuration` example defines three user groups (`ingest`, `reporting`, and `analytics`). Queries submitted from users from one of these groups run with priority `highest`, `normal`, and `low`, respectively.

```
[
  {
    "user_group": [
      "ingest"
    ],
    "priority": "highest",
    "queue_type": "auto"
  },
  {
    "user_group": [
      "reporting"
    ],
    "priority": "normal",
    "queue_type": "auto"
  },
  {
    "user_group": [
      "analytics"
    ],
    "priority": "low",
    "queue_type": "auto",
    "auto_wlm": true
  }
]
```

Changing query priority with query monitoring rules

Query monitoring rules (QMR) enable you to change the priority of a query based on its behavior while it is running. You do this by specifying the priority attribute in a QMR predicate in addition to an action. For more information, see [WLM query monitoring rules](#).

For example, you can define a rule to cancel any query classified as high priority that runs for more than 10 minutes.

```
"rules" :[
  {
    "rule_name":"rule_abort",
    "predicate":[
      {
        "metric_name":"query_cpu_time",
        "operator":">",
        "value":600
      },
      {
        "metric_name":"query_priority",
        "operator":"=",
        "value":"high"
      }
    ],
    "action":"abort"
  }
]
```

Another example is to define a rule to change the query priority to lowest for any query with current priority normal that spills more than 1 TB to disk.

```
"rules":[
  {
    "rule_name":"rule_change_priority",
    "predicate":[
      {
        "metric_name":"query_temp_blocks_to_disk",
        "operator":">",
        "value":1000000
      },
      {
        "metric_name":"query_priority",
        "operator":"=",
        "value":"normal"
      }
    ],
    "action":"change_query_priority",
    "value":"lowest"
  }
]
```

Monitoring query priority

To display priority for waiting and running queries, view the `query_priority` column in the `stv_wlm_query_state` system table.

```

query      | service_cl | wlm_start_time          | state          | queue_time |
query_priority
-----+-----+-----+-----+-----
+-----
2673299 | 102      | 2019-06-24 17:35:38.866356 | QueuedWaiting | 265116     |

2723236 |      102 | 2019-06-24 18:14:50.643636 | Highest
```

To optimize the throughput of your workload, Amazon Redshift might modify the priority of user submitted queries. Amazon Redshift uses advanced machine learning algorithms to determine when this optimization benefits your workload and automatically applies it when all the following conditions are met.

- Automatic WLM is enabled.
- Only one WLM queue is defined.
- You have not defined query monitoring rules (QMRs) which set query priority. Such rules include the QMR metric `query_priority` or the QMR action `change_query_priority`. For more information, see [WLM query monitoring rules](#).

Implementing manual WLM

With manual WLM, you can manage system performance and your users' experience by modifying the WLM configuration to create separate queues for the long-running queries and short-running queries.

When users run queries in Amazon Redshift, the queries are routed to query queues. Each query queue contains a number of query slots. Each queue is allocated a portion of the cluster's available memory. A queue's memory is divided among the queue's query slots. You can enable Amazon Redshift to manage query concurrency with automatic WLM. For more information, see [Implementing automatic WLM](#).

Or you can configure WLM properties for each query queue. You do so to specify the way that memory is allocated among slots and how queries can be routed to specific queues at runtime. You can also configure WLM properties to cancel long-running queries.

By default, Amazon Redshift configures the following query queues:

- **One superuser queue**

The superuser queue is reserved for superusers only and it can't be configured. Use this queue only when you need to run queries that affect the system or for troubleshooting purposes. For example, use this queue when you need to cancel a user's long-running query or to add users to

the database. Don't use it to perform routine queries. The queue doesn't appear in the console, but it does appear in the system tables in the database as the fifth queue. To run a query in the superuser queue, a user must be logged in as a superuser, and must run the query using the predefined `superuser` query group.

- **One default user queue**

The default queue is initially configured to run five queries concurrently. When you use manual WLM, you can change the concurrency, timeout, and memory allocation properties for the default queue, but you cannot specify user groups or query groups. The default queue must be the last queue in the WLM configuration. Any queries that are not routed to other queues run in the default queue.

Query queues are defined in the WLM configuration. The WLM configuration is an editable parameter (`wlm_json_configuration`) in a parameter group, which can be associated with one or more clusters. For more information, see [Configuring Workload Management](#) in the *Amazon Redshift Management Guide*.

You can add additional query queues to the default WLM configuration, up to a total of eight user queues. You can configure the following for each query queue:

- Concurrency scaling mode
- Concurrency level
- User groups
- Query groups
- WLM memory percent to use
- WLM timeout
- WLM query queue hopping
- Query monitoring rules

Concurrency scaling mode

When concurrency scaling is enabled, Amazon Redshift automatically adds additional cluster capacity when you need it to process an increase in concurrent read and write queries. Users see the most current data, whether the queries run on the main cluster or on a concurrency scaling cluster.

You manage which queries are sent to the concurrency scaling cluster by configuring WLM queues. When you enable concurrency scaling for a queue, eligible queries are sent to the concurrency scaling cluster instead of waiting in a queue. For more information, see [Concurrency scaling](#).

Concurrency level

Queries in a queue run concurrently until they reach the WLM query slot count, or *concurrency level*, defined for that queue. Subsequent queries then wait in the queue.

Note

WLM concurrency level is different from the number of concurrent user connections that can be made to a cluster. For more information, see [Connecting to a Cluster](#) in the *Amazon Redshift Management Guide*.

In an automatic WLM configuration, which is recommended, the concurrency level is set to **Auto**. Amazon Redshift dynamically allocates memory to queries, which subsequently determines how many to run concurrently. This is based on the resources required for both running and queued queries. Auto WLM isn't configurable. For more information, see [Implementing automatic WLM](#).

In a manual WLM configuration, Amazon Redshift statically allocates a fixed amount of memory to each queue. The queue's memory is split evenly among the query slots. To illustrate, if a queue is allocated 20% of a cluster's memory and has 10 slots, each query is allocated 2% of the cluster's memory. The memory allocation remains fixed regardless of the number of queries running concurrently. Because of this fixed memory allocation, queries that run entirely in memory when the slot count is 5 might write intermediate results to disk if the slot count is increased to 20. In this instance each query's share of the queue's memory is reduced from 1/5th to 1/20th. The additional disk I/O could degrade performance.

The maximum slot count across all user-defined queues is 50. This limits the total slots for all queues, including the default queue. The only queue that isn't subject to the limit is the reserved superuser queue.

By default, manual WLM queues have a concurrency level of 5. Your workload might benefit from a higher concurrency level in certain cases, such as the following:

- If many small queries are forced to wait for long-running queries, create a separate queue with a higher slot count and assign the smaller queries to that queue. A queue with a higher

concurrency level has less memory allocated to each query slot, but the smaller queries require less memory.

Note

If you enable short-query acceleration (SQA), WLM automatically prioritizes short queries over longer-running queries, so you don't need a separate queue for short queries for most workflows. For more information, see [Short query acceleration](#).

- If you have multiple queries that each access data on a single slice, set up a separate WLM queue to run those queries concurrently. Amazon Redshift assigns concurrent queries to separate slices, which allows multiple queries to run in parallel on multiple slices. For example, if a query is a simple aggregate with a predicate on the distribution key, the data for the query is located on a single slice.

A manual WLM example

This example is a simple, manual WLM scenario to show how slots and memory can be allocated. You implement manual WLM with three queues, which are the following:

- *data-ingestion queue* – This is set up for ingesting data. It's allocated 20% of the cluster's memory and it has 5 slots. Subsequently, 5 queries can run concurrently in the queue and each is allocated 4% of the memory.
- *data-scientist queue* – This is designed for memory-intensive queries. It's allocated 40% of the cluster's memory and it has 5 slots. Subsequently, 5 queries can run concurrently and each is allocated 8% of the memory.
- *default queue* – This is designed for the majority of the users in the organization. This includes sales and accounting groups that typically have short or medium running queries that aren't complicated. It's allocated 40% of the cluster's memory and it has 40 slots. 40 queries can run concurrently in this queue, with each query allocated 1% of the memory. This is the maximum number of slots that can be allocated for this queue because between all queues the limit is 50.

If you're running automatic WLM and your workload requires more than 15 queries to run in parallel, we recommend turning on concurrency scaling. This is because increasing the query slot count above 15 might create contention for system resources and limit the overall throughput of a single cluster. With concurrency scaling, you can run hundreds of queries in parallel, up to a configured number of concurrency scaling clusters. The number of concurrency scaling clusters is

controlled by [max_concurrency_scaling_clusters](#). For more information about concurrency scaling, see [Concurrency scaling](#).

For more information, see [Query performance improvement](#).

User groups

You can assign a set of user groups to a queue by specifying each user group name or by using wildcards. When a member of a listed user group runs a query, that query runs in the corresponding queue. There is no set limit on the number of user groups that can be assigned to a queue. For more information, see [Assigning queries to queues based on user groups](#).

Query groups

You can assign a set of query groups to a queue by specifying each query group name or by using wildcards. A query group is simply a label. At runtime, you can assign the query group label to a series of queries. Any queries that are assigned to a listed query group run in the corresponding queue. There is no set limit to the number of query groups that can be assigned to a queue. For more information, see [Assigning a query to a query group](#).

Wildcards

If wildcards are enabled in the WLM queue configuration, you can assign user groups and query groups to a queue either individually or by using Unix shell-style wildcards. The pattern matching is case-insensitive.

For example, the '*' wildcard character matches any number of characters. Thus, if you add dba_* to the list of user groups for a queue, any user-run query that belongs to a group with a name that begins with dba_ is assigned to that queue. Examples are dba_admin or DBA_primary, . The '?' wildcard character matches any single character. Thus, if the queue includes user-group dba?1, then user groups named dba11 and dba21 match, but dba12 doesn't match.

Wildcards are turned off by default.

WLM memory percent to use

In an automatic WLM configuration, memory percent is set to **auto**. For more information, see [Implementing automatic WLM](#).

In a manual WLM configuration, to specify the amount of available memory that is allocated to a query, you can set the `WLM Memory Percent to Use` parameter. By default, each user-defined queue is allocated an equal portion of the memory that is available for user-defined queries. For example, if you have four user-defined queues, each queue is allocated 25 percent of the available memory. The superuser queue has its own allocated memory and cannot be modified. To change the allocation, you assign an integer percentage of memory to each queue, up to a total of 100 percent. Any unallocated memory is managed by Amazon Redshift and can be temporarily given to a queue if the queue requests additional memory for processing.

For example, if you configure four queues, you can allocate memory as follows: 20 percent, 30 percent, 15 percent, 15 percent. The remaining 20 percent is unallocated and managed by the service.

WLM timeout

WLM timeout (`max_execution_time`) is deprecated. Instead, create a query monitoring rule (QMR) using `query_execution_time` to limit the elapsed execution time for a query. For more information, see [WLM query monitoring rules](#).

To limit the amount of time that queries in a given WLM queue are permitted to use, you can set the WLM timeout value for each queue. The timeout parameter specifies the amount of time, in milliseconds, that Amazon Redshift waits for a query to run before either canceling or hopping the query. The timeout is based on query execution time and doesn't include time spent waiting in a queue.

WLM attempts to hop [CREATE TABLE AS](#) (CTAS) statements and read-only queries, such as SELECT statements. Queries that can't be hopped are canceled. For more information, see [WLM query queue hopping](#).

WLM timeout doesn't apply to a query that has reached the returning state. To view the state of a query, see the [STV_WLM_QUERY_STATE](#) system table. COPY statements and maintenance operations, such as ANALYZE and VACUUM, are not subject to WLM timeout.

The function of WLM timeout is similar to the [statement_timeout](#) configuration parameter. The difference is that, where the `statement_timeout` configuration parameter applies to the entire cluster, WLM timeout is specific to a single queue in the WLM configuration.

If [statement_timeout](#) is also specified, the lower of `statement_timeout` and WLM timeout (`max_execution_time`) is used.

Query monitoring rules

Query monitoring rules define metrics-based performance boundaries for WLM queues and specify what action to take when a query goes beyond those boundaries. For example, for a queue dedicated to short running queries, you might create a rule that cancels queries that run for more than 60 seconds. To track poorly designed queries, you might have another rule that logs queries that contain nested loops. For more information, see [WLM query monitoring rules](#).

WLM query queue hopping

With Amazon Redshift, you can manage workload concurrency and resource allocation by enabling WLM (Workload Management) query queue hopping. This feature allows queries to temporarily "hop" from an assigned queue to a higher priority queue when resources are available, improving overall query performance and system utilization. The following sections provide detailed guidance on configuring and utilizing WLM query queue hopping in Amazon Redshift.

A query can be hopped due to a [WLM timeout](#) or a [query monitoring rule \(QMR\) hop action](#). You can only hop queries in a manual WLM configuration.

When a query is hopped, WLM attempts to route the query to the next matching queue based on the [WLM queue assignment rules](#). If the query doesn't match any other queue definition, the query is canceled. It's not assigned to the default queue.

WLM timeout actions

The following table summarizes the behavior of different types of queries with a WLM timeout.

Query type	Action
INSERT, UPDATE, and DELETE	Cancel
User-defined functions (UDFs)	Cancel
UNLOAD	Cancel
COPY	Continue execution
Maintenance operations	Continue execution
Read-only queries in a returning state	Continue execution

Query type	Action
Read-only queries in a running state	Reassign or restart
CREATE TABLE AS (CTAS), SELECT INTO	Reassign or restart

WLM timeout queue hopping

WLM hops the following types of queries when they time out:

- Read-only queries, such as SELECT statements, that are in a WLM state of running. To find the WLM state of a query, view the STATE column on the [STV_WLM_QUERY_STATE](#) system table.
- CREATE TABLE AS (CTAS) statements. WLM queue hopping supports both user-defined and system-generated CTAS statements.
- SELECT INTO statements.

Queries that aren't subject to WLM timeout continue running in the original queue until completion. The following types of queries aren't subject to WLM timeout:

- COPY statements
- Maintenance operations, such as ANALYZE and VACUUM
- Read-only queries, such as SELECT statements, that have reached a WLM state of returning. To find the WLM state of a query, view the STATE column on the [STV_WLM_QUERY_STATE](#) system table.

Queries that aren't eligible for hopping by WLM timeout are canceled when they time out. The following types of queries are not eligible for hopping by a WLM timeout:

- INSERT, UPDATE, and DELETE statements
- UNLOAD statements
- User-defined functions (UDFs)

WLM timeout reassigned and restarted queries

When a query is hopped and no matching queue is found, the query is canceled.

When a query is hopped and a matching queue is found, WLM attempts to reassign the query to the new queue. If a query can't be reassigned, it's restarted in the new queue, as described following.

A query is reassigned only if all of the following are true:

- A matching queue is found.
- The new queue has enough free slots to run the query. A query might require multiple slots if the [wlm_query_slot_count](#) parameter was set to a value greater than 1.
- The new queue has at least as much memory available as the query currently uses.

If the query is reassigned, the query continues executing in the new queue. Intermediate results are preserved, so there is minimal effect on total execution time.

If the query can't be reassigned, the query is canceled and restarted in the new queue. Intermediate results are deleted. The query waits in the queue, then begins running when enough slots are available.

QMR hop actions

The following table summarizes the behavior of different types of queries with a QMR hop action.

Query type	Action
COPY	Continue execution
Maintenance operations	Continue execution
User-defined functions (UDFs)	Continue execution
UNLOAD	Reassign or continue execution
INSERT, UPDATE, and DELETE	Reassign or continue execution
Read-only queries in a returning state	Reassign or continue execution
Read-only queries in a running state	Reassign or restart
CREATE TABLE AS (CTAS), SELECT INTO	Reassign or restart

To find whether a query that was hopped by QMR was reassigned, restarted, or canceled, query the [STL_WLM_RULE_ACTION](#) system log table.

QMR hop action reassigned and restarted queries

When a query is hopped and no matching queue is found, the query is canceled.

When a query is hopped and a matching queue is found, WLM attempts to reassign the query to the new queue. If a query can't be reassigned, it's restarted in the new queue or continues execution in the original queue, as described following.

A query is reassigned only if all of the following are true:

- A matching queue is found.
- The new queue has enough free slots to run the query. A query might require multiple slots if the [wlm_query_slot_count](#) parameter was set to a value greater than 1.
- The new queue has at least as much memory available as the query currently uses.

If the query is reassigned, the query continues executing in the new queue. Intermediate results are preserved, so there is minimal effect on total execution time.

If a query can't be reassigned, the query is either restarted or continues execution in the original queue. If the query is restarted, the query is canceled and restarted in the new queue. Intermediate results are deleted. The query waits in the queue, then begins execution when enough slots are available.

Tutorial: Configuring manual workload management (WLM) queues

With Amazon Redshift, you can configure manual workload management (WLM) queues to prioritize and allocate resources for different types of queries and users. Manual WLM queues allow you to control the memory and concurrency settings for specific queues, ensuring that critical workloads receive the necessary resources while preventing low-priority queries from monopolizing the system. The following sections guide you through the process of creating and configuring manual WLM queues in Amazon Redshift to meet your workload management requirements.

Overview

We recommend configuring automatic workload management (WLM) in Amazon Redshift. For more information about automatic WLM, see [Workload management](#). However, if you need

multiple WLM queues, this tutorial walks you through the process of configuring manual workload management (WLM) in Amazon Redshift. By configuring manual WLM, you can improve query performance and resource allocation in your cluster.

Amazon Redshift routes user queries to queues for processing. WLM defines how those queries are routed to the queues. By default, Amazon Redshift has two queues available for queries: one for superusers, and one for users. The superuser queue cannot be configured and can only process one query at a time. You should reserve this queue for troubleshooting purposes only. The user queue can process up to five queries at a time, but you can configure this by changing the concurrency level of the queue if needed.

When you have several users running queries against the database, you might find another configuration to be more efficient. For example, if some users run resource-intensive operations, such as VACUUM, these might have a negative impact on less-intensive queries, such as reports. You might consider adding additional queues and configuring them for different workloads.

Estimated time: 75 minutes

Estimated cost: 50 cents

Prerequisites

You need an Amazon Redshift cluster, the sample TICKIT database, and the Amazon Redshift RSQL client tool. If you do not already have these set up, go to [Amazon Redshift Getting Started Guide](#) and [Amazon Redshift RSQL](#).

Sections

- [Section 1: Understanding the default queue processing behavior](#)
- [Section 2: Modifying the WLM query queue configuration](#)
- [Section 3: Routing queries to queues based on user groups and query groups](#)
- [Section 4: Using wlm_query_slot_count to temporarily override the concurrency level in a queue](#)
- [Section 5: Cleaning up your resources](#)

Section 1: Understanding the default queue processing behavior

Before you start to configure manual WLM, it's useful to understand the default behavior of queue processing in Amazon Redshift. In this section, you create two database views that return information from several system tables. Then you run some test queries to see how queries

are routed by default. For more information about system tables, see [System tables and views reference](#).

Step 1: Create the WLM_QUEUE_STATE_VW view

In this step, you create a view called WLM_QUEUE_STATE_VW. This view returns information from the following system tables.

- [STV_WLM_CLASSIFICATION_CONFIG](#)
- [STV_WLM_SERVICE_CLASS_CONFIG](#)
- [STV_WLM_SERVICE_CLASS_STATE](#)

You use this view throughout the tutorial to monitor what happens to queues after you change the WLM configuration. The following table describes the data that the WLM_QUEUE_STATE_VW view returns.

Column	Description
queue	The number associated with the row that represents a queue. Queue number determines the order of the queues in the database.
description	A value that describes whether the queue is available only to certain user groups, to certain query groups, or all types of queries.
slots	The number of slots allocated to the queue.
mem	The amount of memory, in MB per slot, allocated to the queue.
max_execution_time	The amount of time a query is allowed to run before it is terminated.
user_*	A value that indicates whether wildcard characters are allowed in the WLM configuration to match user groups.
query_*	A value that indicates whether wildcard characters are allowed in the WLM configuration to match query groups.
queued	The number of queries that are waiting in the queue to be processed.
executing	The number of queries that are currently running.

Column	Description
executed	The number of queries that have been run.

To create the WLM_QUEUE_STATE_VW view

1. Open [Amazon Redshift RSQL](#) and connect to your TICKIT sample database. If you do not have this database, see [Prerequisites](#).
2. Run the following query to create the WLM_QUEUE_STATE_VW view.

```
create view WLM_QUEUE_STATE_VW as
select (config.service_class-5) as queue
, trim (class.condition) as description
, config.num_query_tasks as slots
, config.query_working_mem as mem
, config.max_execution_time as max_time
, config.user_group_wild_card as "user_*"
, config.query_group_wild_card as "query_*"
, state.num_queued_queries queued
, state.num_executing_queries executing
, state.num_executed_queries executed
from
STV_WLM_CLASSIFICATION_CONFIG class,
STV_WLM_SERVICE_CLASS_CONFIG config,
STV_WLM_SERVICE_CLASS_STATE state
where
class.action_service_class = config.service_class
and class.action_service_class = state.service_class
and config.service_class > 4
order by config.service_class;
```

3. Run the following query to see the information that the view contains.

```
select * from wlm_queue_state_vw;
```

The following is an example result.

```
query | description | slots | mem | max_time | user_* |
query_* | queued | executing | executed
```

```

-----+-----+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----+-----+-----
  0 | (super user) and (query group: superuser) |      1 | 357 |      0 | false |
false |      0 |      0 |      0
  1 | (querytype:any) |      5 | 836 |      0 | false |
false |      0 |      1 |     160

```

Step 2: Create the WLM_QUERY_STATE_VW view

In this step, you create a view called `WLM_QUERY_STATE_VW`. This view returns information from the [STV_WLM_QUERY_STATE](#) system table.

You use this view throughout the tutorial to monitor the queries that are running. The following table describes the data that the `WLM_QUERY_STATE_VW` view returns.

Column	Description
query	The query ID.
queue	The queue number.
slot_count	The number of slots allocated to the query.
start_time	The time that the query started.
state	The state of the query, such as executing.
queue_time	The number of microseconds that the query has spent in the queue.
exec_time	The number of microseconds that the query has been running.

To create the WLM_QUERY_STATE_VW view

1. In RSQL, run the following query to create the `WLM_QUERY_STATE_VW` view.

```

create view WLM_QUERY_STATE_VW as
select query, (service_class-5) as queue, slot_count, trim(wlm_start_time) as
start_time, trim(state) as state, trim(queue_time) as queue_time, trim(exec_time) as
exec_time
from stv_wlm_query_state;

```

2. Run the following query to see the information that the view contains.

```
select * from wlm_query_state_vw;
```

The following is an example result.

```
query | queue | slot_count | start_time          | state      | queue_time | exec_time
-----+-----+-----+-----+-----+-----+-----
+-----+
1249 | 1 | 1 | 2014-09-24 22:19:16 | Executing | 0          | 516
```

Step 3: Run test queries

In this step, you run queries from multiple connections in RSQL and review the system tables to determine how the queries were routed for processing.

For this step, you need two RSQL windows open:

- In RSQL window 1, you run queries that monitor the state of the queues and queries using the views you already created in this tutorial.
- In RSQL window 2, you run long-running queries to change the results you find in RSQL window 1.

To run the test queries

1. Open two RSQL windows. If you already have one window open, you only need to open a second window. You can use the same user account for both of these connections.
2. In RSQL window 1, run the following query.

```
select * from wlm_query_state_vw;
```

The following is an example result.

```
query | queue | slot_count | start_time          | state      | queue_time | exec_time
-----+-----+-----+-----+-----+-----+-----
+-----+
1258 | 1 | 1 | 2014-09-24 22:21:03 | Executing | 0          | 549
```

This query returns a self-referential result. The query that is currently running is the SELECT statement from this view. A query on this view always returns at least one result. Compare this result with the result that occurs after starting the long-running query in the next step.

- In RSQL window 2, run a query from the TICKIT sample database. This query should run for approximately a minute so that you have time to explore the results of the WLM_QUEUE_STATE_VW view and the WLM_QUERY_STATE_VW view that you created earlier. In some cases, you might find that the query doesn't run long enough for you to query both views. In these cases, you can increase the value of the filter on `l.listid` to make it run longer.

Note

To reduce query execution time and improve system performance, Amazon Redshift caches the results of certain types of queries in memory on the leader node. When result caching is enabled, subsequent queries run much faster. To prevent the query from running too quickly, disable result caching for the current session.

To turn off result caching for the current session, set the [enable_result_cache_for_session](#) parameter to `off`, as shown following.

```
set enable_result_cache_for_session to off;
```

In RSQL window 2, run the following query.

```
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <
100000;
```

- In RSQL window 1, query WLM_QUEUE_STATE_VW and WLM_QUERY_STATE_VW and compare the results to your earlier results.

```
select * from wlm_queue_state_vw;
select * from wlm_query_state_vw;
```

The following are example results.

```
query | description | slots | mem | max_time | user_* |
query_* | queued | executing | executed
```

```

-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+-----+
+-----+-----+-----+-----+-----+
  0 | (super user) and (query group: superuser) |    1 | 357 |    0 | false |
false |    0 |    0 |    0
  1 | (querytype:any) |    5 | 836 |    0 | false |
false |    0 |    2 |   163

query | queue | slot_count | start_time          | state      | queue_time | exec_time
-----+-----+-----+-----+-----+-----+-----+
+-----+-----+
1267 |    1 |          1 | 2014-09-24 22:22:30 | Executing | 0           | 684
1265 |    1 |          1 | 2014-09-24 22:22:36 | Executing | 0           | 4080859

```

Note the following differences between your previous queries and the results in this step:

- There are two rows now in `WLM_QUERY_STATE_VW`. One result is the self-referential query for running a `SELECT` operation on this view. The second result is the long-running query from the previous step.
- The `executing` column in `WLM_QUEUE_STATE_VW` has increased from 1 to 2. This column entry means that there are two queries running in the queue.
- The `executed` column is incremented each time you run a query in the queue.

The `WLM_QUEUE_STATE_VW` view is useful for getting an overall view of the queues and how many queries are being processed in each queue. The `WLM_QUERY_STATE_VW` view is useful for getting a more detailed view of the individual queries that are currently running.

Section 2: Modifying the WLM query queue configuration

Now that you understand how queues work by default, you can learn how to configure query queues using manual WLM. In this section, you create and configure a new parameter group for your cluster. You create two additional user queues and configure them to accept queries based on the queries' user group or query group labels. Any queries that don't get routed to one of these two queues are routed to the default queue at runtime.

To create a manual WLM configuration in a parameter group

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.

2. On the navigation menu, choose **Configurations**, then choose **Workload management** to display the **Workload management** page.
3. Choose **Create** to display the **Create parameter group** window.
4. Enter **WLMTutorial1** for both **Parameter group name** and **Description**, and then choose **Create** to create the parameter group.

 **Note**

The **Parameter group name** is converted to all lower case format when created.

5. On the **Workload management** page, choose the parameter group **wlmtutorial1** to display the details page with tabs for **Parameters** and **Workload management**.
6. Confirm that you're on the **Workload management** tab, then choose **Switch WLM mode** to display the **Concurrency settings** window.
7. Choose **Manual WLM**, then choose **Save** to switch to manual WLM.
8. Choose **Edit workload queues**.
9. Choose **Add queue** twice to add two queues. Now there are three queues: **Queue 1**, **Queue 2**, and **Default queue**.
10. Enter information for each queue as follows:
 - For **Queue 1**, enter **30** for **Memory (%)**, **2** for **Concurrency on main**, and **test** for **Query groups**. Leave the other settings with their default values.
 - For **Queue 2**, enter **40** for **Memory (%)**, **3** for **Concurrency on main**, and **admin** for **User groups**. Leave the other settings with their default values.
 - Don't make any changes to the **Default queue**. WLM assigns unallocated memory to the default queue.
11. Choose **Save** to save your settings.

Next, associate the parameter group that has the manual WLM configuration with a cluster.

To associate a parameter group with a manual WLM configuration with a cluster

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.

2. On the navigation menu, choose **Clusters**, then choose **Clusters** to display a list of your clusters.
3. Choose your cluster, such as `examplecluster` to display the details of the cluster. Then choose the **Properties** tab to display the properties of that cluster.
4. In the **Database configurations** section, choose **Edit, Edit parameter group** to display the parameter groups window.
5. For **Parameter groups** choose the `wlmtutorial` parameter group that you previously created.
6. Choose **Save changes** to associate the parameter group.

The cluster is modified with the changed parameter group. However, you need to reboot the cluster for the changes to also be applied to the database.

7. Choose your cluster, and then choose **Reboot** for **Actions**.

After the cluster is rebooted, its status returns to **Available**.

Section 3: Routing queries to queues based on user groups and query groups

Now you have your cluster associated with a new parameter group and you've configured WLM. Next, run some queries to see how Amazon Redshift routes queries into queues for processing.

Step 1: View query queue configuration in the database

First, verify that the database has the WLM configuration that you expect.

To view the query queue configuration

1. Open RSQL and run the following query. The query uses the `WLM_QUEUE_STATE_VW` view you created in [Step 1: Create the WLM_QUEUE_STATE_VW view](#). If you already had a session connected to the database prior to the cluster reboot, you need to reconnect.

```
select * from wlm_queue_state_vw;
```

The following is an example result.

```
query | description | slots | mem | max_time | user_* |
query_* | queued | executing | executed
-----+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----+-----
```

```

0 | (super user) and (query group: superuser) | 1 | 357 | 0 | false |
false | 0 | 0 | 0
1 | (query group: test) | 2 | 627 | 0 | false |
false | 0 | 0 | 0
2 | (suser group: admin) | 3 | 557 | 0 | false |
false | 0 | 0 | 0
3 | (querytype:any) | 5 | 250 | 0 | false |
false | 0 | 1 | 0

```

Compare these results to the results you received in [Step 1: Create the WLM_QUEUE_STATE_VW view](#). Notice that there are now two additional queues. Queue 1 is now the queue for the test query group, and queue 2 is the queue for the admin user group.

Queue 3 is now the default queue. The last queue in the list is always the default queue. That's the queue to which queries are routed by default if no user group or query group is specified in a query.

2. Run the following query to confirm that your query now runs in queue 3.

```
select * from wlm_query_state_vw;
```

The following is an example result.

```

query | queue | slot_count | start_time          | state      | queue_time | exec_time
-----+-----+-----+-----+-----+-----+-----
+-----+
2144 | 3 | 1 | 2014-09-24 23:49:59 | Executing | 0 | 550430

```

Step 2: Run a query using the query group queue

To run a query using the query group queue

1. Run the following query to route it to the test query group.

```
set query_group to test;
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <40000;
```

2. From the other RSQL window, run the following query.

```
select * from wlm_query_state_vw;
```

The following is an example result.

```

query | queue | slot_count | start_time          | state      | queue_time | exec_time
-----+-----+-----+-----+-----+-----+-----
+-----+
2168 | 1 | 1 | 2014-09-24 23:54:18 | Executing | 0          | 6343309
2170 | 3 | 1 | 2014-09-24 23:54:24 | Executing | 0          | 847

```

The query was routed to the test query group, which is queue 1 now.

3. Select all from the queue state view.

```
select * from wlm_queue_state_vw;
```

You see a result similar to the following.

```

query | description                                     | slots | mem | max_time | user_* |
query_* | queued | executing | executed
-----+-----+-----+-----+-----+-----+-----
+-----+
0 | (super user) and (query group: superuser) | 1 | 357 | 0 | false |
false | 0 | 0 | 0
1 | (query group: test) | 2 | 627 | 0 | false |
false | 0 | 1 | 0
2 | (suser group: admin) | 3 | 557 | 0 | false |
false | 0 | 0 | 0
3 | (querytype:any) | 5 | 250 | 0 | false |
false | 0 | 1 | 0

```

4. Now, reset the query group and run the long query again:

```

reset query_group;
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <40000;

```

5. Run the queries against the views to see the results.

```

select * from wlm_queue_state_vw;
select * from wlm_query_state_vw;

```

The following are example results.

```

query | description | slots | mem | max_time | user_* |
query_* | queued | executing | executed
-----+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----+-----
    0 | (super user) and (query group: superuser) | 1 | 357 | 0 | false |
false | 0 | 0 | 0
    1 | (query group: test) | 2 | 627 | 0 | false |
false | 0 | 0 | 1
    2 | (suser group: admin) | 3 | 557 | 0 | false |
false | 0 | 0 | 0
    3 | (querytype:any) | 5 | 250 | 0 | false |
false | 0 | 2 | 5

query | queue | slot_count | start_time | state | queue_time | exec_time
-----+-----+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----+-----
2186 | 3 | 1 | 2014-09-24 23:57:52 | Executing | 0 | 649
2184 | 3 | 1 | 2014-09-24 23:57:48 | Executing | 0 | 4137349

```

The result should be that the query is now running in queue 3 again.

Step 3: Create a database user and group

Before you can run any queries in this queue, you need to create the user group in the database and add a user to the group. Then you log in with RSQL using the new user's credentials and run queries. You need to run queries as a superuser, such as the admin user, to create database users.

To create a new database user and user group

1. In the database, create a new database user named `adminwlm` by running the following command in an RSQL window.

```
create user adminwlm createuser password '123Admin';
```

2. Then, run the following commands to create the new user group and add your new `adminwlm` user to it.

```
create group admin;
alter group admin add user adminwlm;
```

Step 4: Run a query using the user group queue

Next you run a query and route it to the user group queue. You do this when you want to route your query to a queue that is configured to handle the type of query you want to run.

To run a query using the user group queue

1. In RSQL window 2, run the following queries to switch to the adminwlm account and run a query as that user.

```
set session authorization 'adminwlm';
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <40000;
```

2. In RSQL window 1, run the following query to see the query queue that the queries are routed to.

```
select * from wlm_query_state_vw;
select * from wlm_queue_state_vw;
```

The following are example results.

query	description	slots	mem	max_time	user_*
0	(super user) and (query group: superuser)	1	357	0	false
1	(query group: test)	2	627	0	false
2	(suser group: admin)	3	557	0	false
3	(querytype:any)	5	250	0	false

query	queue	slot_count	start_time	state	queue_time	exec_time
2202	2	1	2014-09-25 00:01:38	Executing	0	4885796
2204	3	1	2014-09-25 00:01:43	Executing	0	650

The queue that this query ran in is queue 2, the admin user queue. Anytime you run queries logged in as this user, they run in queue 2 unless you specify a different query group to use. The chosen queue depends on the queue assignment rules. For more information, see [WLM queue assignment rules](#).

3. Now run the following query from RSQL window 2.

```
set query_group to test;
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <40000;
```

4. In RSQL window 1, run the following query to see the query queue that the queries are routed to.

```
select * from wlm_queue_state_vw;
select * from wlm_query_state_vw;
```

The following are example results.

query	description	slots	mem	max_time	user_*
query_*	queued	executing	executed		
0	(super user) and (query group: superuser)	1	357	0	false
false	0	0	0		
1	(query group: test)	2	627	0	false
false	0	1	1		
2	(suser group: admin)	3	557	0	false
false	0	0	1		
3	(querytype:any)	5	250	0	false
false	0	1	10		

query	queue	slot_count	start_time	state	queue_time	exec_time
2218	1	1	2014-09-25 00:04:30	Executing	0	4819666
2220	3	1	2014-09-25 00:04:35	Executing	0	685

5. When you're done, reset the query group.

```
reset query_group;
```

Section 4: Using `wlm_query_slot_count` to temporarily override the concurrency level in a queue

Sometimes, users might temporarily need more resources for a particular query. If so, they can use the `wlm_query_slot_count` configuration setting to temporarily override the way slots are allocated in a query queue. *Slots* are units of memory and CPU that are used to process queries. You might override the slot count when you have occasional queries that take a lot of resources in the cluster, such as when you perform a `VACUUM` operation in the database.

You might find that users often need to set `wlm_query_slot_count` for certain types of queries. If so, consider adjusting the WLM configuration and giving users a queue that better suits the needs of their queries. For more information about temporarily overriding the concurrency level by using slot count, see [wlm_query_slot_count](#).

Step 1: Override the concurrency level using `wlm_query_slot_count`

For the purposes of this tutorial, we run the same long-running `SELECT` query. We run it as the `adminwlm` user using `wlm_query_slot_count` to increase the number of slots available for the query.

To override the concurrency level using `wlm_query_slot_count`

1. Increase the limit on the query to make sure that you have enough time to query the `WLM_QUERY_STATE_VW` view and see a result.

```
set wlm_query_slot_count to 3;
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <40000;
```

2. Now, query `WLM_QUERY_STATE_VW` with the admin user to see how the query is running.

```
select * from wlm_query_state_vw;
```

The following is an example result.

query	queue	slot_count	start_time	state	queue_time	exec_time
2240	2	1	2014-09-25 00:08:45	Executing	0	3731414
2242	3	1	2014-09-25 00:08:49	Executing	0	596

Notice that the slot count for the query is 3. This count means that the query is using all three slots to process the query, allocating all of the resources in the queue to that query.

3. Now, run the following query.

```
select * from WLM_QUEUE_STATE_VW;
```

The following is an example result.

query query_*	description description	slots	mem	max_time	user_*
0	(super user) and (query group: superuser)	1	357	0	false
1	(query group: test)	2	627	0	false
2	(suser group: admin)	3	557	0	false
3	(querytype:any)	5	250	0	false

The `wlm_query_slot_count` configuration setting is valid for the current session only. If that session expires, or another user runs a query, the WLM configuration is used.

4. Reset the slot count and rerun the test.

```
reset wlm_query_slot_count;
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <40000;
```

The following are example results.

query query_*	description description	slots	mem	max_time	user_*
0	(super user) and (query group: superuser)	1	357	0	false
1	(query group: test)	2	627	0	false

```

  2 | (suser group: admin) | 3 | 557 | 0 | false |
false | 0 | 1 | 2
  3 | (querytype:any) | 5 | 250 | 0 | false |
false | 0 | 1 | 14

query | queue | slot_count | start_time | state | queue_time | exec_time
-----+-----+-----+-----+-----+-----+-----
+-----+
2260 | 2 | 1 | 2014-09-25 00:12:11 | Executing | 0 | 4042618
2262 | 3 | 1 | 2014-09-25 00:12:15 | Executing | 0 | 680

```

Step 2: Run queries from different sessions

Next, run queries from different sessions.

To run queries from different sessions

1. In RSQL window 1 and 2, run the following to use the test query group.

```
set query_group to test;
```

2. In RSQL window 1, run the following long-running query.

```
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <40000;
```

3. As the long-running query is still going in RSQL window 1, run the following. These commands increase the slot count to use all the slots for the queue and then start running the long-running query.

```
set wlm_query_slot_count to 2;
select avg(l.priceperticket*s.qtysold) from listing l, sales s where l.listid <40000;
```

4. Open a third RSQL window and query the views to see the results.

```
select * from wlm_queue_state_vw;
select * from wlm_query_state_vw;
```

The following are example results.

```

query | description | slots | mem | max_time | user_* |
query_* | queued | executing | executed

```

```

-----+-----+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----+-----+-----
  0 | (super user) and (query group: superuser) | 1 | 357 | 0 | false |
false | 0 | 0 | 0
  1 | (query group: test) | 2 | 627 | 0 | false |
false | 1 | 1 | 2
  2 | (suser group: admin) | 3 | 557 | 0 | false |
false | 0 | 0 | 3
  3 | (querytype:any) | 5 | 250 | 0 | false |
false | 0 | 1 | 18

query | queue | slot_count | start_time          | state          | queue_time |
exec_time
-----+-----+-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----+-----+-----
2286 | 1 | 2 | 2014-09-25 00:16:48 | QueuedWaiting | 3758950 | 0
2282 | 1 | 1 | 2014-09-25 00:16:33 | Executing    | 0       |
19335850
2288 | 3 | 1 | 2014-09-25 00:16:52 | Executing    | 0       | 666

```

Notice that the first query is using one of the slots allocated to queue 1 to run the query. In addition, notice that there is one query that is waiting in the queue (where queued is 1 and state is QueuedWaiting). After the first query completes, the second one begins running. This execution happens because both queries are routed to the test query group, and the second query must wait for enough slots to begin processing.

Section 5: Cleaning up your resources

Your cluster continues to accrue charges as long as it is running. When you have completed this tutorial, return your environment to the previous state by following the steps in [Find Additional Resources and Reset Your Environment](#) in *Amazon Redshift Getting Started Guide*.

For more information about WLM, see [Workload management](#).

Concurrency scaling

With the Concurrency Scaling feature, you can support thousands of concurrent users and concurrent queries, with consistently fast query performance. When you turn on concurrency scaling, Amazon Redshift automatically adds additional cluster capacity to process an increase in

both read and write queries. Users see the most current data, whether the queries run on the main cluster or a concurrency-scaling cluster.

You can manage which queries are sent to the concurrency-scaling cluster by configuring WLM queues. When you turn on concurrency scaling, eligible queries are sent to the concurrency-scaling cluster instead of waiting in a queue.

You're charged for concurrency-scaling clusters only for the time they're actively running queries. For more information about pricing, including how charges accrue and minimum charges, see [Concurrency Scaling pricing](#).

Topics

- [Limitations for concurrency scaling](#)
- [AWS Regions for concurrency scaling](#)
- [Concurrency scaling candidates](#)
- [Configuring concurrency scaling queues](#)
- [Monitoring concurrency scaling](#)
- [Concurrency scaling system views](#)

Concurrency scaling capabilities

When you turn on concurrency scaling for a WLM queue, it works for read operations, such as dashboard queries. It also works for commonly used write operations, such as statements for data ingestion and processing.

Concurrency scaling capabilities for write operations

Concurrency scaling supports frequently used write operations, such as extract, transform, and load (ETL) statements. Concurrency scaling for write operations is especially useful when you want to maintain consistent response times when your cluster receives a large number of requests. It improves throughput for write operations contending for resources on the main cluster.

Concurrency scaling supports COPY, INSERT, DELETE, UPDATE, and CREATE TABLE AS (CTAS) statements. Additionally, concurrency scaling supports materialized-view refresh for MVs that do not use aggregations. Other data-manipulation language (DML) statements and data-definition language (DDL) statements aren't supported. When non-supported write statements, such as

CREATE without TABLE AS, are included in an explicit transaction before the supported write statements, none of the write statements will run on concurrency-scaling clusters.

When you accrue credit for concurrency scaling, this credit accrual applies to both read and write operations.

Limitations for concurrency scaling

The following are limitations for using Amazon Redshift concurrency scaling:

- It doesn't support queries on tables that use interleaved sort keys.
- It doesn't support queries on temporary tables.
- It doesn't support queries that access external resources that are protected by restrictive network or virtual private cloud (VPC) configurations.
- It doesn't support queries that contain Python user-defined functions (UDFs) and Lambda UDFs.
- It doesn't support queries that access system tables, PostgreSQL catalog tables, or no-backup tables.
- It doesn't support COPY or UNLOAD queries that access an external resource when restrictive IAM policy permissions are in place. This includes permissions applied either to the resource, like an Amazon S3 bucket or DynamoDB table, or to the source. IAM sources can include the following:
 - `aws:sourceVpc` – A source VPC.
 - `aws:sourceVpce` – A source VPC endpoint.
 - `aws:sourceIp` – A source IP address.

In some cases, you might need to remove permissions that restrict either the resource or the source, so that COPY and UNLOAD queries accessing the resource are sent to the concurrency-scaling cluster.

For more information about resource policies, see [Policy types](#) in the AWS Identity and Access Management user guide and [Controlling access from VPC endpoints with bucket policies](#).

- Amazon Redshift concurrency scaling for write operations is not supported for DDL operations, such as CREATE TABLE or ALTER TABLE.
- It doesn't support ANALYZE for the COPY command.
- It doesn't support write operations on a target table where DISTSTYLE is set to ALL.
- It doesn't support COPY from the following file formats:

- Parquet
- ORC
- It doesn't support write operations on tables with identity columns.
- Amazon Redshift supports concurrency scaling for write operations on only Amazon Redshift RA3 nodes, specifically ra3.16xlarge, ra3.4xlarge, and ra3.xlplus. Concurrency scaling for write operations isn't supported on other node types.

AWS Regions for concurrency scaling

With Amazon Redshift, you can use concurrency scaling to manage concurrent workload demands across Redshift clusters. This topic details in which regions you can use concurrency scaling with Amazon Redshift.

Concurrency scaling is available in these AWS Regions:

- US East (N. Virginia) Region (us-east-1)
- US East (Ohio) Region (us-east-2)
- US West (N. California) Region (us-west-1)
- US West (Oregon) Region (us-west-2)
- Asia Pacific (Mumbai) Region (ap-south-1)
- Asia Pacific (Seoul) Region (ap-northeast-2)
- Asia Pacific (Singapore) Region (ap-southeast-1)
- Asia Pacific (Sydney) Region (ap-southeast-2)
- Asia Pacific (Tokyo) Region (ap-northeast-1)
- Canada (Central) Region (ca-central-1)
- China (Beijing) Region (cn-north-1)
- China (Ningxia) Region (cn-northwest-1)
- Europe (Frankfurt) Region (eu-central-1)
- Europe (Ireland) Region (eu-west-1)
- Europe (London) Region (eu-west-2)
- Europe (Paris) Region (eu-west-3)
- Europe (Stockholm) Region (eu-north-1)
- Europe (Zurich) Region (eu-central-2)

- Europe (Spain) Region (eu-south-2)
- South America (São Paulo) Region (sa-east-1)
- AWS GovCloud (US-East)

Concurrency scaling candidates

With Amazon Redshift, you can scale out query processing to accelerate execution of concurrent queries. The following topic describes the criteria that Amazon Redshift uses to determine what queries to route to concurrency scaling.

Queries are routed to the concurrency scaling cluster only when the main cluster meets the following requirements:

- EC2-VPC platform.
- Node type must be dc2.8xlarge, dc2.large, ra3.xlplus, ra3.4xlarge, or ra3.16xlarge. Concurrency scaling for write operations is supported on only the following Amazon Redshift RA3 nodes: ra3.16xlarge, ra3.4xlarge, and ra3.xlplus.
- Maximum of 32 compute nodes for clusters with ra3.xlplus, ra3.4xlarge, or ra3.16xlarge node types. In addition, the number of nodes of the main cluster can't be larger than 32 nodes when the cluster was originally created. For example, even if a cluster currently has 20 nodes, but was originally created with 40, it does not meet the requirements for concurrency scaling. Conversely, if a DC2 cluster currently has 40 nodes, but was originally created with 20, it does meet the requirements for concurrency scaling.
- Not a single-node cluster.

Configuring concurrency scaling queues

With Amazon Redshift, you can manage concurrency and system resources by configuring concurrency scaling. Concurrency scaling queues allow you to set limits on the number of queries or user sessions that can be executed concurrently. The following section provides instructions on how to enable concurrency scaling queues in Amazon Redshift, enabling you to effectively handle concurrent queries and user sessions.

You route queries to concurrency scaling clusters by enabling concurrency scaling in a workload manager (WLM) queue. To turn on concurrency scaling for a queue, set the **Concurrency Scaling mode** value to **auto**.

When the number of queries routed to a queue with concurrency scaling enabled exceeds the queue's concurrency capacity, whether the capacity is configured manually or determined automatically, eligible queries are sent to the concurrency scaling cluster. When queue slots become available on the main cluster, queries are routed to and run on the main cluster. As with any WLM queue, you route queries to a concurrency scaling queue based on user groups, or by labeling queries with query group labels, or according to matching conditions defined in [Assigning queries to queues](#). You can also route queries by defining [WLM query monitoring rules](#). For example, you might route all queries that take longer than 5 seconds to a concurrency scaling queue. Keep in mind that queuing behavior can vary, depending on whether you're using automatic WLM or manual WLM. For more information, see [Implementing automatic WLM](#) or [Implementing manual WLM](#).

The default number of concurrency scaling clusters is one. The number of concurrency scaling clusters that can be used is controlled by [max_concurrency_scaling_clusters](#).

Monitoring concurrency scaling

With Amazon Redshift, you can monitor and manage concurrency scaling to optimize performance and cost efficiency for your data warehousing workloads. Concurrency scaling allows Amazon Redshift to automatically add additional cluster capacity when workload demands increase, and remove that capacity when demands decrease. The following section provides guidance on monitoring concurrency scaling for your Amazon Redshift clusters.

You can see whether a query is running on the main cluster or a concurrency scaling cluster by navigating to **Cluster** in the Amazon Redshift console and choosing a cluster. Then choose the **Query monitoring** tab and **Workload concurrency** to view information about running queries and queued queries.

To find execution times, query the STL_QUERY table and filter on the concurrency_scaling_status column. The following query compares the queue time and execution time for queries run on the concurrency scaling cluster and queries run on the main cluster.

```
SELECT w.service_class AS queue
, CASE WHEN q.concurrency_scaling_status = 1 THEN 'concurrency scaling cluster' ELSE
'main cluster' END as concurrency_scaling_status
, COUNT( * ) AS queries
, SUM( q.aborted ) AS aborted
, SUM( ROUND( total_queue_time::NUMERIC / 1000000,2) ) AS queue_secs
```

```
, SUM( ROUND( total_exec_time::NUMERIC / 1000000,2) ) AS exec_secs
FROM stl_query q
JOIN stl_wlm_query w
USING (userid,query)
WHERE q.userid > 1
AND q.starttime > '2019-01-04 16:38:00'
AND q.endtime < '2019-01-04 17:40:00'
GROUP BY 1,2
ORDER BY 1,2;
```

Adjust the `starttime` and `endtime` values according to your requirements.

Concurrency scaling system views

With Amazon Redshift, you can use Concurrency scaling system views to monitor and manage concurrency scaling activity in your cluster. The following section describes querying these system views and interpreting the results to effectively leverage concurrency scaling in your Amazon Redshift environment.

A set of system views with the prefix `SVCS` provides details from the system log tables about queries on both the main and concurrency scaling clusters.

The following views have similar information as the corresponding `STL` views or `SVL` views:

- [SVCS_ALERT_EVENT_LOG](#)
- [SVCS_COMPILE](#)
- [SVCS_EXPLAIN](#)
- [SVCS_PLAN_INFO](#)
- [SVCS_QUERY_SUMMARY](#)
- [SVCS_STREAM_SEGS](#)

The following views are specific to concurrency scaling.

- [SVCS_CONCURRENCY_SCALING_USAGE](#)

For more information about concurrency scaling, see the following topics in the *Amazon Redshift Management Guide*.

- [Viewing Concurrency Scaling Data](#)
- [Viewing Cluster Performance During Query Execution](#)
- [Viewing Query Details](#)

Short query acceleration

Short query acceleration (SQA) prioritizes selected short-running queries ahead of longer-running queries. SQA runs short-running queries in a dedicated space, so that SQA queries aren't forced to wait in queues behind longer queries. SQA only prioritizes queries that are short-running and are in a user-defined queue. With SQA, short-running queries begin running more quickly and users see results sooner.

If you enable SQA, you can reduce workload management (WLM) queues that are dedicated to running short queries. In addition, long-running queries don't need to contend with short queries for slots in a queue, so you can configure your WLM queues to use fewer query slots. When you use lower concurrency, query throughput is increased and overall system performance is improved for most workloads.

[CREATE TABLE AS](#) (CTAS) statements and read-only queries, such as [SELECT](#) statements, are eligible for SQA.

Amazon Redshift uses a machine learning algorithm to analyze each eligible query and predict the query's execution time. By default, WLM dynamically assigns a value for the SQA maximum runtime based on analysis of your cluster's workload. Alternatively, you can specify a fixed value of 1–20 seconds. If the query's predicted run time is less than the defined or dynamically assigned SQA maximum runtime and the query is waiting in a WLM queue, SQA separates the query from the WLM queues and schedules it for priority execution. If a query runs longer than the SQA maximum runtime, WLM moves the query to the first matching WLM queue based on the [WLM queue assignment rules](#). Over time, predictions improve as SQA learns from your query patterns.

SQA is enabled by default in the default parameter group and for all new parameter groups. To disable SQA in the Amazon Redshift console, edit the WLM configuration for a parameter group and deselect **Enable short query acceleration**. As a best practice, we recommend using a WLM query slot count of 15 or fewer to maintain optimum overall system performance. For information about modifying WLM configurations, see [Configuring Workload Management](#) in the *Amazon Redshift Management Guide*.

Maximum runtime for short queries

When you enable SQA, WLM sets the maximum runtime for short queries to dynamic by default. We recommend keeping the dynamic setting for SQA maximum runtime. You can override the default setting by specifying a fixed value of 1–20 seconds.

In some cases, you might consider using different values for the SQA maximum runtime values to improve your system performance. In such cases, analyze your workload to find the maximum execution time for most of your short-running queries. The following query returns the maximum runtime for queries at about the 70th percentile.

```
select least(greatest(percentile_cont(0.7)
within group (order by total_exec_time / 1000000) + 2, 2), 20)
from stl_wlm_query
where userid >= 100
and final_state = 'Completed';
```

After you identify a maximum runtime value that works well for your workload, you don't need to change it unless your workload changes significantly.

Monitoring SQA

To check whether SQA is enabled, run the following query. If the query returns a row, then SQA is enabled.

```
select * from stv_wlm_service_class_config
where service_class = 14;
```

The following query shows the number of queries that went through each query queue (service class). It also shows the average execution time, the number of queries with wait time at the 90th percentile, and the average wait time. SQA queries use in service class 14.

```
select final_state, service_class, count(*), avg(total_exec_time),
percentile_cont(0.9) within group (order by total_queue_time), avg(total_queue_time)
from stl_wlm_query where userid >= 100 group by 1,2 order by 2,1;
```

To find which queries were picked up by SQA and completed successfully, run the following query.

```
select a.queue_start_time, a.total_exec_time, label, trim(querytxt)
```

```
from stl_wlm_query a, stl_query b
where a.query = b.query and a.service_class = 14 and a.final_state = 'Completed'
order by b.query desc limit 5;
```

To find queries that SQA picked up but that timed out, run the following query.

```
select a.queue_start_time, a.total_exec_time, label, trim(querytxt)
from stl_wlm_query a, stl_query b
where a.query = b.query and a.service_class = 14 and a.final_state = 'Evicted'
order by b.query desc limit 5;
```

For more information about evicted queries and, more generally, rule-based actions that can be taken on queries, see [WLM query monitoring rules](#).

WLM queue assignment rules

With Amazon Redshift, you can control the allocation of memory and CPU resources to user queries by defining queue assignment rules in a workload management (WLM) configuration. The following section describes creating and managing WLM queue assignment rules to achieve efficient resource allocation and meet service-level agreements for diverse workloads in Amazon Redshift.

When a user runs a query, WLM assigns the query to the first matching queue, based on the WLM queue assignment rules:

1. If a user is logged in as a superuser and runs a query in the query group labeled superuser, the query is assigned to the superuser queue.
2. If a user is part of a role, belongs to a listed user group, or runs a query within a listed query group, the query is assigned to the first matching queue.
3. If a query doesn't meet any criteria, the query is assigned to the default queue, which is the last queue defined in the WLM configuration.

The following diagram illustrates how these rules work.

Queue assignments example

The following table shows a WLM configuration with the superuser queue and four user-defined queues.

Queue	Concurrency	User Roles	User Groups	Query Groups
Superuser	1			superuser
1	5	test_db_rw	UG_1	
2	5			QG_B
3	5		UG_2	QG_C
Default	5			

The following illustration shows how queries are assigned to the queues in the previous table according to user groups and query groups. For information about how to assign queries to user groups and query groups at runtime, see [Assigning queries to queues](#) later in this section.

In this example, WLM makes the following assignments:

1. The first set of statements shows three ways to assign users to user groups. The statements are run by the user `adminuser1`, which is not a member of a user group listed in any WLM queue. No query group is set, so the statements are routed to the default queue.
2. The user `adminuser1` is a superuser and the query group is set to `'superuser'`, so the query is assigned to the superuser queue.
3. The user `test_user1` is assigned the role `test_db_rw` listed in queue 1, so the query is assigned to queue 1.
4. The user `admin1` is a member of the user group listed in queue 1, so the query is assigned to queue 1.
5. The user `vp1` is not a member of any listed user group. The query group is set to `'QG_B'`, so the query is assigned to queue 2.
6. The user `analyst1` is a member of the user group listed in queue 3, but `'QG_B'` matches queue 2, so the query is assigned to queue 2.
7. The user `ralph` is not a member of any listed user group and the query group was reset, so there is no matching queue. The query is assigned to the default queue.

Assigning queries to queues

With Amazon Redshift, you can manage workload concurrency and prioritize queries by assigning them to queues. Queues allow you to allocate resources like memory and CPU for different types of queries or users, ensuring critical queries get prioritized over less important ones. The following sections describe how to create queues, configure their properties, and assign incoming queries based on criteria you define.

The following examples assign queries to queues according to user roles, user groups, and query groups.

Assigning queries to queues based on user roles

If a user is assigned to a role and that role is attached to a queue, then queries run by that user are assigned to that queue. The following example creates a user role named `sales_rw` and assigns the user `test_user1` to that role.

```
create role sales_rw;  
grant role sales_rw to test_user1;
```

You can also combine permissions of two roles by explicitly granting one role to another role. Assigning a nested role to a user grants permissions of both roles to the user.

```
create role sales_rw;  
create role sales_ro;  
grant role sales_ro to role sales_rw;  
grant role sales_rw to test_user;
```

To see the list of users that have been granted roles in the cluster, query the `SVV_USER_GRANTS` table. To see the list of roles that have been granted roles in the cluster, query the `SVV_ROLE_GRANTS` table.

```
select * from svv_user_grants;  
select * from svv_role_grants;
```

Assigning queries to queues based on user groups

If a user group name is listed in a queue definition, queries run by members of that user group are assigned to the corresponding queue. The following example creates user groups and adds users to groups by using the SQL commands [CREATE USER](#), [CREATE GROUP](#), and [ALTER GROUP](#).

```
create group admin_group with user admin246, admin135, sec555;  
create user vp1234 in group ad_hoc_group password 'vpPass1234';  
alter group admin_group add user analyst44, analyst45, analyst46;
```

Assigning a query to a query group

You can assign a query to a queue at runtime by assigning your query to the appropriate query group. Use the `SET` command to begin a query group.

```
SET query_group TO group_label
```

Here, *group_label* is a query group label that is listed in the WLM configuration.

All queries that you run after the `SET query_group` command run as members of the specified query group until you either reset the query group or end your current login session. For information about setting and resetting Amazon Redshift objects, see [SET](#) and [RESET](#) in the SQL Command Reference.

The query group labels that you specify must be included in the current WLM configuration; otherwise, the `SET query_group` command has no effect on query queues.

The label defined in the TO clause is captured in the query logs so that you can use the label for troubleshooting. For information about the `query_group` configuration parameter, see [query_group](#) in the Configuration Reference.

The following example runs two queries as part of the query group 'priority' and then resets the query group.

```
set query_group to 'priority';
select count(*)from stv_blocklist;
select query, elapsed, substring from svl_qlog order by query desc limit 5;
reset query_group;
```

Assigning queries to the superuser queue

To assign a query to the superuser queue, log on to Amazon Redshift as a superuser and then run the query in the superuser group. When you are done, reset the query group so that subsequent queries do not run in the superuser queue.

The following example assigns two commands to run in the superuser queue.

```
set query_group to 'superuser';

analyze;
vacuum;
reset query_group;
```

To view a list of superusers, query the `PG_USER` system catalog table.

```
select * from pg_user where usesuper = 'true';
```

WLM dynamic and static configuration properties

The WLM configuration properties are either dynamic or static. You can apply dynamic properties to the database without a cluster reboot, but static properties require a cluster reboot for changes to take effect. However, if you change dynamic and static properties at the same time, then you must reboot the cluster for all the property changes to take effect. This is true whether the changed properties are dynamic or static.

While dynamic properties are being applied, your cluster status is `modifying`. Switching between automatic WLM and manual WLM is a static change and requires a cluster reboot to take effect.

The following table indicates which WLM properties are dynamic or static when using automatic WLM or manual WLM.

WLM Property	Automatic WLM	Manual WLM
Query groups	Dynamic	Static
Query group wildcard	Dynamic	Static
User groups	Dynamic	Static
User group wildcard	Dynamic	Static
User roles	Dynamic	Static
User role wildcard	Dynamic	Static
Concurrency on main	Not applicable	Dynamic
Concurrency Scaling mode	Dynamic	Dynamic
Enable short query acceleration	Not applicable	Dynamic
Maximum runtime for short queries	Dynamic	Dynamic
Percent of memory to use	Not applicable	Dynamic
Timeout	Not applicable	Dynamic
Priority	Dynamic	Not applicable
Adding or removing queues	Dynamic	Static

If you modify a query monitoring rule (QMR), the change happens automatically without the need to modify the cluster.

Note

When using manual WLM, if the timeout value is changed, the new value is applied to any query that begins running after the value is changed. If the concurrency or percent of memory to use are changed, Amazon Redshift changes to the new configuration dynamically. Thus, currently running queries aren't affected by the change. For more information, see [WLM Dynamic Memory Allocation](#).

Topics

- [WLM dynamic memory allocation](#)
- [Dynamic WLM example](#)

WLM dynamic memory allocation

In each queue, WLM creates a number of query slots equal to the queue's concurrency level. The amount of memory allocated to a query slot equals the percentage of memory allocated to the queue divided by the slot count. If you change the memory allocation or concurrency, Amazon Redshift dynamically manages the transition to the new WLM configuration. Thus, active queries can run to completion using the currently allocated amount of memory. At the same time, Amazon Redshift ensures that total memory usage never exceeds 100 percent of available memory.

The workload manager uses the following process to manage the transition:

1. WLM recalculates the memory allocation for each new query slot.
2. If a query slot is not actively being used by a running query, WLM removes the slot, which makes that memory available for new slots.
3. If a query slot is actively in use, WLM waits for the query to finish.
4. As active queries complete, the empty slots are removed and the associated memory is freed.
5. As enough memory becomes available to add one or more slots, new slots are added.
6. When all queries that were running at the time of the change finish, the slot count equals the new concurrency level, and the transition to the new WLM configuration is complete.

In effect, queries that are running when the change takes place continue to use the original memory allocation. Queries that are queued when the change takes place are routed to new slots as they become available.

If the WLM dynamic properties are changed during the transition process, WLM immediately begins to transition to the new configuration, starting from the current state. To view the status of the transition, query the [STV_WLM_SERVICE_CLASS_CONFIG](#) system table.

Dynamic WLM example

With Amazon Redshift, you can automatically manage workload distribution and resource allocation across your Amazon Redshift clusters using Dynamic WLM (Workload Management). Dynamic WLM is an example of a Workload Management (WLM) configuration that dynamically adjusts memory allocations based on workload demands, allowing for optimal concurrency and performance. The following section provides details on implementing and configuring Dynamic WLM for your Amazon Redshift clusters.

Suppose that your cluster WLM is configured with two queues, using the following dynamic properties.

Queue	Concurrency	% Memory to Use
1	4	50%
2	4	50%

Now suppose that your cluster has 200 GB of memory available for query processing. (This number is arbitrary and used for illustration only.) As the following equation shows, each slot is allocated 25 GB.

$$(200 \text{ GB} * 50\%) / 4 \text{ slots} = 25 \text{ GB}$$

Next, you change your WLM to use the following dynamic properties.

Queue	Concurrency	% Memory to Use
1	3	75%

Queue	Concurrency	% Memory to Use
2	4	25%

As the following equation shows, the new memory allocation for each slot in queue 1 is 50 GB.

$$(200 \text{ GB} * 75\%) / 3 \text{ slots} = 50 \text{ GB}$$

Suppose that queries A1, A2, A3, and A4 are running when the new configuration is applied, and queries B1, B2, B3, and B4 are queued. WLM dynamically reconfigures the query slots as follows.

Step	Queries Running	Current Slot Count	Target Slot Count	Allocated Memory	Available Memory
1	A1, A2, A3, A4	4	0	100 GB	50 GB
2	A2, A3, A4	3	0	75 GB	75 GB
3	A3, A4	2	0	50 GB	100 GB
4	A3, A4, B1	2	1	100 GB	50 GB
5	A4, B1	1	1	75 GB	75 GB
6	A4, B1, B2	1	2	125 GB	25 GB
7	B1, B2	0	2	100 GB	50 GB
8	B1, B2, B3	0	3	150 GB	0 GB

1. WLM recalculates the memory allocation for each query slot. Originally, queue 1 was allocated 100 GB. The new queue has a total allocation of 150 GB, so the new queue immediately has 50 GB available. Queue 1 is now using four slots, and the new concurrency level is three slots, so no new slots are added.

2. When one query finishes, the slot is removed and 25 GB is freed. Queue 1 now has three slots and 75 GB of available memory. The new configuration needs 50 GB for each new slot, but the new concurrency level is three slots, so no new slots are added.
3. When a second query finishes, the slot is removed, and 25 GB is freed. Queue 1 now has two slots and 100 GB of free memory.
4. A new slot is added using 50 GB of the free memory. Queue 1 now has three slots, and 50 GB free memory. Queued queries can now be routed to the new slot.
5. When a third query finishes, the slot is removed, and 25 GB is freed. Queue 1 now has two slots, and 75 GB of free memory.
6. A new slot is added using 50 GB of the free memory. Queue 1 now has three slots, and 25 GB free memory. Queued queries can now be routed to the new slot.
7. When the fourth query finishes, the slot is removed, and 25 GB is freed. Queue 1 now has two slots and 50 GB of free memory.
8. A new slot is added using the 50 GB of free memory. Queue 1 now has three slots with 50 GB each and all available memory has been allocated.

The transition is complete and all query slots are available to queued queries.

WLM query monitoring rules

In Amazon Redshift workload management (WLM), query monitoring rules define metrics-based performance boundaries for WLM queues and specify what action to take when a query goes beyond those boundaries. For example, for a queue dedicated to short running queries, you might create a rule that cancels queries that run for more than 60 seconds. To track poorly designed queries, you might have another rule that logs queries that contain nested loops.

You define query monitoring rules as part of your workload management (WLM) configuration. You can define up to 25 rules for each queue, with a limit of 25 rules for all queues. Each rule includes up to three conditions, or predicates, and one action. A *predicate* consists of a metric, a comparison condition ($=$, $<$, or $>$), and a value. If all of the predicates for any rule are met, that rule's action is triggered. Possible rule actions are log, hop, and abort, as discussed following.

The rules in a given queue apply only to queries running in that queue. A rule is independent of other rules.

WLM evaluates metrics every 10 seconds. If more than one rule is triggered during the same period, WLM chooses the rule with the most severe action. If the action for two rules has the

same severity, WLM runs the rules in alphabetical order, based on the rule name. If the action is hop or abort, the action is logged and the query is evicted from the queue. If the action is log, the query continues to run in the queue. WLM initiates only one log action per query per rule. If the queue contains other rules, those rules remain in effect. If the action is hop and the query is routed to another queue, the rules for the new queue apply. For more information about query monitoring and tracking actions taken on specific queries, see the collection of samples at [Short query acceleration](#).

When all of a rule's predicates are met, WLM writes a row to the [STL_WLM_RULE_ACTION](#) system table. In addition, Amazon Redshift records query metrics for currently running queries to [STV_QUERY_METRICS](#). Metrics for completed queries are stored in [STL_QUERY_METRICS](#).

Defining a query monitoring rule

You create query monitoring rules as part of your WLM configuration, which you define as part of your cluster's parameter group definition.

You can create rules using the AWS Management Console or programmatically using JSON.

Note

If you choose to create rules programmatically, we strongly recommend using the console to generate the JSON that you include in the parameter group definition. For more information, see [Creating or modifying a query monitoring rule using the console](#) and [Configuring Parameter Values Using the AWS CLI](#) in the *Amazon Redshift Management Guide*.

To define a query monitoring rule, you specify the following elements:

- A rule name – Rule names must be unique within the WLM configuration. Rule names can be up to 32 alphanumeric characters or underscores, and can't contain spaces or quotation marks. You can have up to 25 rules per queue, and the total limit for all queues is 25 rules.
- One or more predicates – You can have up to three predicates per rule. If all the predicates for any rule are met, the associated action is triggered. A predicate is defined by a metric name, an operator (=, <, or >), and a value. An example is `query_cpu_time > 100000`. For a list of metrics and examples of values for different metrics, see [Query monitoring metrics for Amazon Redshift provisioned](#) following in this section.

- An action – If more than one rule is triggered, WLM chooses the rule with the most severe action. Possible actions, in ascending order of severity, are:
 - Log – Record information about the query in the `STL_WLM_RULE_ACTION` system table. Use the Log action when you want to only write a log record. WLM creates at most one log per query, per rule. Following a log action, other rules remain in force and WLM continues to monitor the query.
 - Hop (only available with manual WLM) – Log the action and hop the query to the next matching queue. If there isn't another matching queue, the query is canceled. QMR hops only [CREATE TABLE AS](#) (CTAS) statements and read-only queries, such as SELECT statements. For more information, see [WLM query queue hopping](#).
 - Abort – Log the action and cancel the query. QMR doesn't stop COPY statements and maintenance operations, such as ANALYZE and VACUUM.
 - Change priority (only available with automatic WLM) – Change the priority of a query.

To limit the runtime of queries, we recommend creating a query monitoring rule instead of using WLM timeout. For example, you can set `max_execution_time` to 50,000 milliseconds as shown in the following JSON snippet.

```
"max_execution_time": 50000
```

But we recommend instead that you define an equivalent query monitoring rule that sets `query_execution_time` to 50 seconds as shown in the following JSON snippet.

```
"rules":  
[  
  {  
    "rule_name": "rule_query_execution",  
    "predicate": [  
      {  
        "metric_name": "query_execution_time",  
        "operator": ">",  
        "value": 50  
      }  
    ],  
    "action": "abort"  
  }  
]
```

For steps to create or modify a query monitoring rule, see [Creating or modifying a query monitoring rule using the console](#) and [Properties in the wlm_json_configuration Parameter](#) in the *Amazon Redshift Management Guide*.

You can find more information about query monitoring rules in the following topics:

- [Query monitoring metrics for Amazon Redshift provisioned](#)
- [Query monitoring rules templates](#)
- [Creating a Rule Using the Console](#)
- [Configuring Workload Management](#)
- [System tables and views for query monitoring rules](#)

Query monitoring metrics for Amazon Redshift provisioned

The following table describes the metrics used in query monitoring rules. (These metrics are distinct from the metrics stored in the [STV_QUERY_METRICS](#) and [STL_QUERY_METRICS](#) system tables.)

For a given metric, the performance threshold is tracked either at the query level or the segment level. For more information about segments and steps, see [Query planning and execution workflow](#).

Note

The [WLM timeout](#) parameter is distinct from query monitoring rules.

Metric	Name	Description
Query CPU time	query_cpu_time	CPU time used by the query, in seconds. CPU time is distinct from Query execution time. Valid values are 0–999,999.
Blocks read	query_blocks_read	Number of 1 MB data blocks read by the query.

Metric	Name	Description
		Valid values are 0–1,048,575.
Scan row count	scan_row_count	<p>The number of rows in a scan step. The row count is the total number of rows emitted before filtering rows marked for deletion (ghost rows) and before applying user-defined query filters.</p> <p>Valid values are 0–999,999,999,999.</p>
Query execution time	query_execution_time	<p>Elapsed execution time for a query, in seconds. Execution time doesn't include time spent waiting in a queue.</p> <p>Valid values are 0–86,399.</p>
Query queue time	query_queue_time	<p>Time spent waiting in a queue, in seconds.</p> <p>Valid values are 0–86,399.</p>
CPU usage	query_cpu_usage_percent	<p>Percent of CPU capacity used by the query.</p> <p>Valid values are 0–6,399.</p>
Memory to disk	query_temp_blocks_to_disk	<p>Temporary disk space used to write intermediate results, in 1 MB blocks.</p> <p>Valid values are 0–319,815,679.</p>
CPU skew	cpu_skew	<p>The ratio of maximum CPU usage for any slice to average CPU usage for all slices. This metric is defined at the segment level.</p> <p>Valid values are 0–99.</p>

Metric	Name	Description
I/O skew	<code>io_skew</code>	The ratio of maximum blocks read (I/O) for any slice to average blocks read for all slices. This metric is defined at the segment level. Valid values are 0–99.
Rows joined	<code>join_row_count</code>	The number of rows processed in a join step. Valid values are 0–999,999,999,999,999.
Nested loop join row count	<code>nested_loop_join_row_count</code>	The number of rows in a nested loop join. Valid values are 0–999,999,999,999,999.
Return row count	<code>return_row_count</code>	The number of rows returned by the query. Valid values are 0–999,999,999,999,999.
Segment execution time	<code>segment_execution_time</code>	Elapsed execution time for a single segment, in seconds. To avoid or reduce sampling errors, include <code>segment_execution_time > 10</code> in your rules. Valid values are 0–86,388.
Spectrum scan row count	<code>spectrum_scan_row_count</code>	The number of rows of data in Amazon S3 scanned by an Amazon Redshift Spectrum query. Valid values are 0–999,999,999,999,999.
Spectrum scan size	<code>spectrum_scan_size_mb</code>	The size of data in Amazon S3, in MB, scanned by an Amazon Redshift Spectrum query. Valid values are 0–999,999,999,999,999.

Metric	Name	Description
Query priority	query_priority	The priority of the query. Valid values are HIGHEST, HIGH, NORMAL, LOW, and LOWEST. When comparing query_priority using greater than (>) and less than (<) operators, HIGHEST is greater than HIGH, HIGH is greater than NORMAL, and so on.

Note

- The hop action is not supported with the query_queue_time predicate. That is, rules defined to hop when a query_queue_time predicate is met are ignored.
- Short segment execution times can result in sampling errors with some metrics, such as io_skew and query_cpu_usage_percent. To avoid or reduce sampling errors, include segment execution time in your rules. A good starting point is segment_execution_time > 10.

The [SVL_QUERY_METRICS](#) view shows the metrics for completed queries. The [SVL_QUERY_METRICS_SUMMARY](#) view shows the maximum values of metrics for completed queries. Use the values in these views as an aid to determine threshold values for defining query monitoring rules.

Query monitoring metrics for Amazon Redshift Serverless

The following table describes the metrics used in query monitoring rules for Amazon Redshift Serverless.

Metric	Name	Description
Query CPU time	max_query_cpu_time	CPU time used by the query, in seconds. CPU time is distinct from Query execution time.

Metric	Name	Description
		Valid values are 0–999,999.
Blocks read	max_query_blocks_read	Number of 1 MB data blocks read by the query. Valid values are 0–1,048,575.
Scan row count	max_scan_row_count	The number of rows in a scan step. The row count is the total number of rows emitted before filtering rows marked for deletion (ghost rows) and before applying user-defined query filters. Valid values are 0–999,999,999,999,999.
Query execution time	max_query_execution_time	Elapsed execution time for a query, in seconds. Execution time doesn't include time spent waiting in a queue. If a query exceeds the set execution time, Amazon Redshift Serverless stops the query. Valid values are 0–86,399.
Query queue time	max_query_queue_time	Time spent waiting in a queue, in seconds. Valid values are 0–86,399.
CPU usage	max_query_cpu_usage_percent	Percent of CPU capacity used by the query. Valid values are 0–6,399.
Memory to disk	max_query_temp_blocks_to_disk	Temporary disk space used to write intermediate results, in 1 MB blocks. Valid values are 0–319,815,679.
Rows joined	max_join_row_count	The number of rows processed in a join step. Valid values are 0–999,999,999,999,999.

Metric	Name	Description
Nested loop join row count	max_nested_loop_join_row_count	The number of rows in a nested loop join. Valid values are 0–999,999,999,999.

Note

- The hop action is not supported with the `max_query_queue_time` predicate. That is, rules defined to hop when a `max_query_queue_time` predicate is met are ignored.
- Short segment execution times can result in sampling errors with some metrics, such as `max_io_skew` and `max_query_cpu_usage_percent`.

Query monitoring rules templates

When you add a rule using the Amazon Redshift console, you can choose to create a rule from a predefined template. Amazon Redshift creates a new rule with a set of predicates and populates the predicates with default values. The default action is log. You can modify the predicates and action to meet your use case.

The following table lists available templates.

Template Name	Predicates	Description
Nested loop join	<code>nested_loop_join_row_count > 100</code>	A nested loop join might indicate an incomplete join predicate, which often results in a very large return set (a Cartesian product). Use a low row count to find a potentially runaway query early.
Query returns a high number of rows	<code>return_row_count > 1000000</code>	If you dedicate a queue to simple, short running queries, you might include a rule that finds queries returning a high row count. The template uses a default of 1 million rows. For some systems, you might consider one million

Template Name	Predicates	Description
		rows to be high, or in a larger system, a billion or more rows might be high.
Join with a high number of rows	<code>join_row_count > 1000000000</code>	A join step that involves an unusually high number of rows might indicate a need for more restrictive filters. The template uses a default of 1 billion rows. For an ad hoc (one-time) query that's intended for quick, simple queries, you might use a lower number.
High disk usage when writing intermediate results	<code>query_temp_blocks_to_disk > 100000</code>	When currently executing queries use more than the available system RAM, the query execution engine writes intermediate results to disk (spilled memory). Typically, this condition is the result of a rogue query, which usually is also the query that uses the most disk space. The acceptable threshold for disk usage varies based on the cluster node type and number of nodes. The template uses a default of 100,000 blocks, or 100 GB. For a small cluster, you might use a lower number.
Long running query with high I/O skew	<code>segment_execution_time > 120</code> and <code>io_skew > 1.30</code>	I/O skew occurs when one node slice has a much higher I/O rate than the other slices. As a starting point, a skew of 1.30 (1.3 times average) is considered high. High I/O skew is not always a problem, but when combined with a long running query time, it might indicate a problem with the distribution style or sort key.

System tables and views for query monitoring rules

When all of a rule's predicates are met, WLM writes a row to the [STL_WLM_RULE_ACTION](#) system table. This row contains details for the query that triggered the rule and the resulting action.

In addition, Amazon Redshift records query metrics the following system tables and views.

- The [STV_QUERY_METRICS](#) table displays the metrics for currently running queries.
- The [STL_QUERY_METRICS](#) table records the metrics for completed queries.
- The [SVL_QUERY_METRICS](#) view shows the metrics for completed queries.
- The [SVL_QUERY_METRICS_SUMMARY](#) view shows the maximum values of metrics for completed queries.

WLM system tables and views

WLM configures query queues according to WLM service classes, which are internally defined. Amazon Redshift creates several internal queues according to these service classes along with the queues defined in the WLM configuration. The terms *queue* and *service class* are often used interchangeably in the system tables. The superuser queue uses service class 5. User-defined queues use service class 6 and greater.

You can view the status of queries, queues, and service classes by using WLM-specific system tables. Query the following system tables to do the following:

- View which queries are being tracked and what resources are allocated by the workload manager.
- See which queue a query has been assigned to.
- View the status of a query that is currently being tracked by the workload manager.

Table Name	Description
STL_WLM_ERROR	Contains a log of WLM-related error events.
STL_WLM_QUERY	Lists queries that are being tracked by WLM.
STV_WLM_CLASSIFICATION_CONFIG	Shows the current classification rules for WLM.
STV_WLM_QUERY_QUEUE_STATE	Records the current state of the query queues.

Table Name	Description
<u>STV_WLM_QUERY_STATE</u>	Provides a snapshot of the current state of queries that are being tracked by WLM.
<u>STV_WLM_QUERY_TASK_STATE</u>	Contains the current state of query tasks.
<u>STV_WLM_SERVICE_CL</u> <u>ASS_CONFIG</u>	Records the service class configurations for WLM.
<u>STV_WLM_SERVICE_CL</u> <u>ASS_STATE</u>	Contains the current state of the service classes.
<u>STL_WLM_RULE_ACTION</u>	Records details about actions resulting from WLM query monitoring rules associated with user-defined queues.
<u>STV_WLM_QMR_CONFIG</u>	Records the configuration for WLM query monitoring rules (QMR).

You use the task ID to track a query in the system tables. The following example shows how to obtain the task ID of the most recently submitted user query:

```
select task from stl_wlm_query where exec_start_time =(select max(exec_start_time) from
stl_wlm_query);
```

```
task
-----
137
(1 row)
```

The following example displays queries that are currently executing or waiting in various service classes (queues). This query is useful in tracking the overall concurrent workload for Amazon Redshift:

```
select * from stv_wlm_query_state order by query;
```

```
xid |task|query|service_| wlm_start_ | state |queue_ | exec_
    |   |     |class   | time       |      |time   | time
```

```

-----+-----+-----+-----+-----+-----+-----+-----+
2645| 84 | 98 | 3      | 2010-10-... |Returning| 0 | 3438369
2650| 85 | 100 | 3     | 2010-10-... |Waiting  | 0 | 1645879
2660| 87 | 101 | 2     | 2010-10-... |Executing| 0 | 916046
2661| 88 | 102 | 1     | 2010-10-... |Executing| 0 | 13291
(4 rows)

```

WLM service class IDs

The following table lists the IDs assigned to service classes.

ID	Service class
1–4	Reserved for system use.
5	Used by the superuser queue.
6–13	Used by manual WLM queues that are defined in the WLM configuration.
14	Used by short query acceleration.
15	Reserved for maintenance activities run by Amazon Redshift.
100–107	Used by automatic WLM queue when auto_wlm is true.

Database security

Topics

- [Amazon Redshift security overview](#)
- [Default database user permissions](#)
- [Superusers](#)
- [Users](#)
- [Groups](#)
- [Schemas](#)
- [Role-based access control \(RBAC\)](#)
- [Row-level security](#)
- [Metadata security](#)
- [Dynamic data masking](#)
- [Scoped permissions](#)

You manage database security by controlling which users have access to which database objects.

Access to database objects depends on the permissions that you grant to users or groups. The following guidelines summarize how database security works:

- By default, permissions are granted only to the object owner.
- Amazon Redshift database users are named users that can connect to a database. A user is granted permissions in two ways: explicitly, by having those permissions assigned directly to the account, or implicitly, by being a member of a group that is granted permissions.
- Groups are collections of users that can be collectively assigned permissions for streamlined security maintenance.
- Schemas are collections of database tables and other database objects. Schemas are similar to file system directories, except that schemas cannot be nested. Users can be granted access to a single schema or to multiple schemas.

Additionally, Amazon Redshift employs the following features to give you finer control over which users have access to which database objects:

- **Role-based access control (RBAC)** lets you assign permissions to roles which you can then apply to users, letting you control permissions for large groups of users. Unlike groups, roles can inherit permissions from other roles.

Row-level security (RLS) lets you define policies that restrict access to rows of your choosing, then apply those policies to users or groups.

Dynamic data masking (DDM) further protects your data by transforming it at query runtime so that you can allow users access to data without exposing sensitive details.

For examples of security implementation, see [Example for controlling user and group access](#).

For more information about protecting your data, see [Security in Amazon Redshift](#) in the *Amazon Redshift Management Guide*.

Amazon Redshift security overview

Amazon Redshift database security is distinct from other types of Amazon Redshift security. In addition to database security, which is described in this section, Amazon Redshift provides these features to manage security:

- **Sign-in credentials** — Access to your Amazon Redshift AWS Management Console is controlled by your AWS account permissions. For more information, see [Sign-in credentials](#).
- **Access management** — To control access to specific Amazon Redshift resources, you define AWS Identity and Access Management (IAM) accounts. For more information, see [Controlling access to Amazon Redshift resources](#).
- **Cluster security groups** — To grant other users inbound access to an Amazon Redshift cluster, you define a cluster security group and associate it with a cluster. For more information, see [Amazon Redshift cluster security groups](#).
- **VPC** — To protect access to your cluster by using a virtual networking environment, you can launch your cluster in an Amazon Virtual Private Cloud (VPC). For more information, see [Managing clusters in Virtual Private Cloud \(VPC\)](#).
- **Cluster encryption** — To encrypt the data in all your user-created tables, you can turn on cluster encryption when you launch the cluster. For more information, see [Amazon Redshift clusters](#).

- **SSL connections** — To encrypt the connection between your SQL client and your cluster, you can use secure sockets layer (SSL) encryption. For more information, see [Connect to your cluster using SSL](#).
- **Load data encryption** — To encrypt your table load data files when you upload them to Amazon S3, you can use either server-side encryption or client-side encryption. When you load from server-side encrypted data, Amazon S3 handles decryption transparently. When you load from client-side encrypted data, the Amazon Redshift COPY command decrypts the data as it loads the table. For more information, see [Uploading encrypted data to Amazon S3](#).
- **Data in transit** — To protect your data in transit within the AWS Cloud, Amazon Redshift uses hardware accelerated SSL to communicate with Amazon S3 or Amazon DynamoDB for COPY, UNLOAD, backup, and restore operations.
- **Column-level access control** — To have column-level access control for data in Amazon Redshift, use column-level grant and revoke statements without having to implement views-based access control or use another system.
- **Row-level security control** — To have row-level security control for data in Amazon Redshift, create and attach policies to roles or users that restrict access to rows defined in the policy.

Default database user permissions

When you create a database object, you are its owner. By default, only a superuser or the owner of an object can query, modify, or grant permissions on the object. For users to use an object, you must grant the necessary permissions to the user or the group that contains the user. Database superusers have the same permissions as database owners.

Amazon Redshift supports the following permissions: SELECT, INSERT, UPDATE, DELETE, REFERENCES, CREATE, TEMPORARY, and USAGE. Different permissions are associated with different object types. For information about database object permissions supported by Amazon Redshift, see the [GRANT](#) command.

Only the owner has the permission to modify or destroy an object.

By default, all users have CREATE and USAGE permissions on the PUBLIC schema of a database. To disallow users from creating objects in the PUBLIC schema of a database, use the REVOKE command to remove that permission.

To revoke a permission that was previously granted, use the [REVOKE](#) command. The permissions of the object owner, such as DROP, GRANT, and REVOKE permissions, are implicit and cannot be

granted or revoked. Object owners can revoke their own ordinary permissions, for example, to make a table read-only for themselves and others. Superusers retain all permissions regardless of GRANT and REVOKE commands.

Superusers

Database superusers have the same permissions as database owners for all databases.

The *admin* user, which is the user you created when you launched the cluster, is a superuser.

You must be a superuser to create a superuser.

Amazon Redshift system tables and system views are either visible only to superusers or visible to all users. Only superusers can query system tables and system views that are designated "visible to superusers." For information, see [System tables and views](#).

Superusers can view all catalog tables. For information, see [System catalog tables](#).

A database superuser bypasses all permission checks. Superusers retain all permissions regardless of GRANT and REVOKE commands. Be careful when using a superuser role. We recommend that you do most of your work as a role that is not a superuser. You can create an administrator role with more restrictive permissions. For more information about creating roles, see [Role-based access control \(RBAC\)](#)

To create a new database superuser, log on to the database as a superuser and issue a CREATE USER command or an ALTER USER command with the CREATEUSER permission.

```
CREATE USER adminuser CREATEUSER PASSWORD '1234Admin';  
ALTER USER adminuser CREATEUSER;
```

To create, alter, or drop a superuser, use the same commands to manage users. For more information, see [Creating, altering, and deleting users](#).

Users

You can create and manage database users using the Amazon Redshift SQL commands CREATE USER and ALTER USER. Or you can configure your SQL client with custom Amazon Redshift JDBC or ODBC drivers. These manage the process of creating database users and temporary passwords as part of the database logon process.

The drivers authenticate database users based on AWS Identity and Access Management (IAM) authentication. If you already manage user identities outside of AWS, you can use a SAML 2.0-compliant identity provider (IdP) to manage access to Amazon Redshift resources. You use an IAM role to configure your IdP and AWS to permit your federated users to generate temporary database credentials and log on to Amazon Redshift databases. For more information, see [Using IAM authentication to generate database user credentials](#).

Amazon Redshift users can only be created and dropped by a database superuser. Users are authenticated when they log on to Amazon Redshift. They can own databases and database objects (for example, tables). They can also grant permissions on those objects to users, groups, and schemas to control who has access to which object. Users with CREATE DATABASE rights can create databases and grant permissions to those databases. Superusers have database ownership permissions for all databases.

Creating, altering, and deleting users

Database users are global across a data warehouse cluster (and not for each individual database).

- To create a user, use the [CREATE USER](#) command.
- To create a superuser, use the [CREATE USER](#) command with the CREATEUSER option.
- To remove an existing user, use the [DROP USER](#) command.
- To change a user, for example changing a password, use the [ALTER USER](#) command.
- To view a list of users, query the PG_USER catalog table.

```
select * from pg_user;
```

username	usesysid	usecreatedb	usesuper	usecatupd	passwd	valuntil	useconfig
rdsdb	1	t	t	t	*****		
masteruser	100	t	t	f	*****		
dwuser	101	f	f	f	*****		
simpleuser	102	f	f	f	*****		
poweruser	103	f	t	f	*****		
dbuser	104	t	f	f	*****		

(6 rows)

Groups

Groups are collections of users who are all granted whatever permissions are associated with the group. You can use groups to assign permissions. For example, you can create different groups for sales, administration, and support and give the users in each group the appropriate access to the data they need for their work. You can grant or revoke permissions at the group level, and those changes will apply to all members of the group, except for superusers.

To view all user groups, query the PG_GROUP system catalog table:

```
select * from pg_group;
```

For example, to list all database users by group, run the following SQL.

```
SELECT u.usesysid
, g.groname
, u.username
FROM pg_user u
LEFT JOIN pg_group g ON u.usesysid = ANY (g.grolist)
```

Creating, altering, and deleting groups

Only a superuser can create, alter, or drop groups.

You can perform the following actions:

- To create a group, use the [CREATE GROUP](#) command.
- To add users to or remove users from an existing group, use the [ALTER GROUP](#) command.
- To delete a group, use the [DROP GROUP](#) command. This command only drops the group, not its member users.

Example for controlling user and group access

This example creates user groups and users and then grants them various permissions for an Amazon Redshift database that connects to a web application client. This example assumes three groups of users: regular users of a web application, power users of a web application, and web developers.

1. Create the groups where the users will be assigned. The following set of commands creates three different user groups:

```
create group webappusers;  
  
create group webpowerusers;  
  
create group webdevusers;
```

2. Create several database users with different permissions and add them to the groups.

- a. Create two users and add them to the WEBAPPUSERS group:

```
create user webappuser1 password 'webAppuser1pass'  
in group webappusers;  
  
create user webappuser2 password 'webAppuser2pass'  
in group webappusers;
```

- b. Create a web developer user and add it to the WEBDEVUSERS group:

```
create user webdevuser1 password 'webDevuser2pass'  
in group webdevusers;
```

- c. Create a superuser. This user will have administrative rights to create other users:

```
create user webappadmin password 'webAppadminpass1'  
createuser;
```

3. Create a schema to be associated with the database tables used by the web application, and grant the various user groups access to this schema:

- a. Create the WEBAPP schema:

```
create schema webapp;
```

- b. Grant USAGE permissions to the WEBAPPUSERS group:

```
grant usage on schema webapp to group webappusers;
```

- c. Grant USAGE permissions to the WEBPOWERUSERS group:

```
grant usage on schema webapp to group webpowerusers;
```

d. Grant ALL permissions to the WEBDEVUSERS group:

```
grant all on schema webapp to group webdevusers;
```

The basic users and groups are now set up. You can now alter the users and groups.

4. For example, the following command alters the `search_path` parameter for the `WEBAPPUSER1`.

```
alter user webappuser1 set search_path to webapp, public;
```

The `SEARCH_PATH` specifies the schema search order for database objects, such as tables and functions, when the object is referenced by a simple name with no schema specified.

5. You can also add users to a group after creating the group, such as adding `WEBAPPUSER2` to the `WEBPOWERUSERS` group:

```
alter group webpowerusers add user webappuser2;
```

Schemas

A database contains one or more named schemas. Each schema in a database contains tables and other kinds of named objects. By default, a database has a single schema, which is named `PUBLIC`. You can use schemas to group database objects under a common name. Schemas are similar to file system directories, except that schemas cannot be nested.

Identical database object names can be used in different schemas in the same database without conflict. For example, both `MY_SCHEMA` and `YOUR_SCHEMA` can contain a table named `MYTABLE`. Users with the necessary permissions can access objects across multiple schemas in a database.

By default, an object is created within the first schema in the search path of the database. For information, see [Search path](#) later in this section.

Schemas can help with organization and concurrency issues in a multiuser environment in the following ways:

- To let many developers work in the same database without interfering with each other.

- To organize database objects into logical groups to make them more manageable.
- To give applications the ability to put their objects into separate schemas so that their names will not collide with the names of objects used by other applications.

Search path

The search path is defined in the `search_path` parameter with a comma-separated list of schema names. The search path specifies the order in which schemas are searched when an object, such as a table or function, is referenced by a simple name that does not include a schema qualifier.

If an object is created without specifying a target schema, the object is added to the first schema that is listed in search path. When objects with identical names exist in different schemas, an object name that does not specify a schema will refer to the first schema in the search path that contains an object with that name.

To change the default schema for the current session, use the [SET](#) command.

For more information, see the [search_path](#) description in the Configuration Reference.

Creating, altering, and deleting schemas

Any user can create schemas and alter or drop schemas they own.

You can perform the following actions:

- To create a schema, use the [CREATE SCHEMA](#) command.
- To change the owner of a schema, use the [ALTER SCHEMA](#) command.
- To delete a schema and its objects, use the [DROP SCHEMA](#) command.
- To create a table within a schema, create the table with the format *schema_name.table_name*.

To view a list of all schemas, query the `PG_NAMESPACE` system catalog table:

```
select * from pg_namespace;
```

To view a list of tables that belong to a schema, query the `PG_TABLE_DEF` system catalog table. For example, the following query returns a list of tables in the `PG_CATALOG` schema.

```
select distinct(tablename) from pg_table_def
```

```
where schemaname = 'pg_catalog';
```

Schema-based permissions

Schema-based permissions are determined by the owner of the schema:

- By default, all users have CREATE and USAGE permissions on the PUBLIC schema of a database. To disallow users from creating objects in the PUBLIC schema of a database, use the [REVOKE](#) command to remove that permission.
- Unless they are granted the USAGE permission by the object owner, users cannot access any objects in schemas they do not own.
- If users have been granted the CREATE permission to a schema that was created by another user, those users can create objects in that schema.

Role-based access control (RBAC)

By using role-based access control (RBAC) to manage database permissions in Amazon Redshift, you can simplify the management of security permissions in Amazon Redshift. You can secure the access to sensitive data by controlling what users can do both at a broad or fine level. You can also control user access to tasks that are normally restricted to superusers. By assigning different permissions to different roles and assigning them to different users, you can have more granular control of user access.

Users with an assigned role can perform only the tasks that are specified by the assigned role that they are authorized with. For example, a user with the assigned role that has the CREATE TABLE and DROP TABLE permissions is only authorized to perform those tasks. You can control user access by granting different levels of security permissions to different users to access the data they require for their work.

RBAC applies the principle of least permissions to users based on their role requirements, regardless of the types of objects that are involved. Granting and revoking of permissions is performed at the role level, without the need to update permissions on individual database objects.

With RBAC, you can create roles with permissions to run commands that used to require superuser permissions. Users can run these commands, as long as they are authorized with a role that includes these permissions. Similarly, you can also create roles to limit the access to certain

commands, and assign the role to either superusers or users that have been authorized with the role.

To learn how Amazon Redshift RBAC works, watch the following video: [Introducing Role-based access control \(RBAC\) in Amazon Redshift](#).

Role hierarchy

Roles are collections of permissions that you can assign to a user or another role. You can assign system or database permissions to a role. A user inherits permissions from an assigned role.

In RBAC, users can have nested roles. You can grant roles to both users and roles. When granting a role to a user, you authorize the user with all the permissions that this role includes. When granting a role *r1* to a user, you authorize the user with permissions from *r1*. The user now has permissions from *r1* and also any existing permissions they already have.

When granting a role (*r1*) to another role (*r2*), you authorize *r2* with all the permissions from *r1*. Also, when granting *r2* to another role (*r3*), the permissions of *r3* are the combination of the permissions from *r1* and *r2*. Role hierarchy has *r2* inherit permissions from *r1*. Amazon Redshift propagates permissions with each role authorization. Granting *r1* to *r2* and then *r2* to *r3* authorizes *r3* with all the permissions from the three roles. Thus, by granting *r3* to a user, the user has all the permissions from the three roles.

Amazon Redshift doesn't allow the creation of a role authorization cycle. A role authorization cycle happens when a nested role is assigned back to a role earlier in the role hierarchy, such as *r3* being assigned back to *r1*. For more information about how to create roles and manage role assignments, see [Managing roles in RBAC](#).

Role assignment

Superusers and regular users with the CREATE ROLE permissions can use the CREATE ROLE statement to create roles. Superusers and role administrators can use the GRANT ROLE statement to grant a role to others. They can use the REVOKE ROLE statement to revoke a role from others, and the DROP ROLE statement to drop roles. Role administrators include role owners and users who have been granted the role with the ADMIN OPTION permission.

Only superusers or role administrators can grant and revoke roles. You can grant or revoke one or more roles to or from one or more roles or users. Use the WITH ADMIN OPTION option in the GRANT ROLE statement to provide the administration options for all the granted roles to all the grantees.

Amazon Redshift supports different combinations of role assignments, such as granting multiple roles or having multiple grantees. The `WITH ADMIN OPTION` only applies to users and not to roles. Similarly, use the `WITH ADMIN OPTION` option in the `REVOKE ROLE` statement to remove the role and the administrative authorization from the grantee. When used with the `ADMIN OPTION`, only the administrative authorization is revoked from the role.

The following example revokes the administrative authorization of the `sample_role2` role from `user2`.

```
REVOKE ADMIN OPTION FOR sample_role2 FROM user2;
```

For more information about how to create roles and manage role assignments, see [Managing roles in RBAC](#).

Amazon Redshift system-defined roles

Amazon Redshift provides a few system-defined roles that are defined with specific permissions. System-specific roles start with a `sys :` prefix. Only users with appropriate access can alter system-defined roles or create custom system-defined roles. You can't use the `sys :` prefix for a custom system-defined role.

The following table summarizes the roles and their permissions.

Role name	Description		
<code>sys:monitor</code>	This role has the permission to access catalog or system tables.		
<code>sys:operator</code>	This role has the permissions to access catalog or system tables, analyze, vacuum, or cancel queries.		
<code>sys:dba</code>	This role has the permissions to create schemas, create tables, drop schemas, drop tables, and truncate tables. It has the permissions to create or		

Role name	Description		
	<p>replace stored procedures, drop procedures, create or replace functions, create or replace external functions, create views, and drop views. Also, this role inherits all the permissions from the <code>sys:operator</code> role.</p>		
<code>sys:superuser</code>	<p>This role has all the supported system permissions defined in System permissions for RBAC.</p>		
<code>sys:secadmin</code>	<ul style="list-style-type: none"> • This role has the permissions to create users, alter users, drop users, create roles, drop roles, and grant roles. • This role has permissions to turn RLS ON or OFF on a relation and permissions to manage RLS and DDM policies (CREATE, DROP, ATTACH, DETACH, and ALTER). Also, note that EXPLAIN RLS, IGNORE RLS, and EXPLAIN MASKING permissions are granted to this role by default. • This role can have access to user tables only when the permission is explicitly granted to the role. 		

System-defined roles and users for data sharing

Amazon Redshift creates roles and users for internal use that correspond to datashares and datashare consumers. Each internal role name and user name has the reserved namespace prefix `ds :`. They have the following format:

Name	Description		
<code>ds : <i>share</i></code>	A system role that corresponds with a datashare.		
<code>ds : <i>share</i> _consume:</code>	A system user that corresponds with a datashare consumer.		

A data sharing role is created for each datashare. It holds all permissions currently granted to the datashare. A data sharing user is created for each consumer of a datashare. It is granted permission to a single data sharing role. A consumer added to multiple datashares will have a data sharing user created for each datashare.

These users and roles are required for data sharing to work properly. They cannot be modified or dropped and they cannot be accessed or used for any tasks run by customers. You can safely ignore them. For more information about data sharing, see [Sharing data across clusters in Amazon Redshift](#).

Note

You can't use the `ds :` prefix to create user-defined roles or users.

System permissions for RBAC

Following is a list of system permissions that you can grant to or revoke from a role.

Command	You must have permission by one of the following ways to run the command		
CREATE ROLE	<ul style="list-style-type: none"> • Superuser. • Users with the CREATE ROLE permission. 		
DROP ROLE	<ul style="list-style-type: none"> • Superuser. • Role owner who is either the user that created the role or a user that has been granted the role with the WITH ADMIN OPTION permission. 		
CREATE USER	<ul style="list-style-type: none"> • Superuser. • Users with the CREATE USER permission. These users can't create superusers. 		
DROP USER	<ul style="list-style-type: none"> • Superuser. • Users with the DROP USER permission. 		
ALTER USER	<ul style="list-style-type: none"> • Superuser. • Users with the ALTER USER permission. These users can't change users to superusers or change superusers to users. • Current user who wants to change their own password. 		
CREATE SCHEMA	<ul style="list-style-type: none"> • Superuser. • Users with the CREATE SCHEMA permission. 		
DROP SCHEMA	<ul style="list-style-type: none"> • Superuser. • Users with the DROP SCHEMA permission. • Schema owner. 		
ALTER DEFAULT PRIVILEGES	<ul style="list-style-type: none"> • Superuser. • Users with the ALTER DEFAULT PRIVILEGES permission. • Users changing their own default access permissions. • Users setting permissions for schemas that they have access permissions to. 		

Command	You must have permission by one of the following ways to run the command		
CREATE TABLE	<ul style="list-style-type: none"> • Superuser. • Users with the CREATE TABLE permission. • Users with the CREATE permission on schemas. 		
DROP TABLE	<ul style="list-style-type: none"> • Superuser. • Users with the DROP TABLE permission. • Table owner with the USAGE permission on the schema. 		
ALTER TABLE	<ul style="list-style-type: none"> • Superuser. • Users with the ALTER TABLE permission. • Table owner with the USAGE permission on the schema. 		
CREATE OR REPLACE FUNCTION	<ul style="list-style-type: none"> • For CREATE FUNCTION: <ul style="list-style-type: none"> • Superuser. • Users with the CREATE OR REPLACE FUNCTION permission. • Users with the USAGE permission on language. • For REPLACE FUNCTION: <ul style="list-style-type: none"> • Superuser. • Users with the CREATE OR REPLACE FUNCTION permission. • Function owner. 		
CREATE OR REPLACE EXTERNAL FUNCTION	<ul style="list-style-type: none"> • Superuser. • Users with the CREATE OR REPLACE EXTERNAL FUNCTION permission. 		
DROP FUNCTION	<ul style="list-style-type: none"> • Superuser. • Users with the DROP FUNCTION permission. • Function owner. 		

Command	You must have permission by one of the following ways to run the command		
CREATE OR REPLACE PROCEDURE	<ul style="list-style-type: none"> • For CREATE PROCEDURE: <ul style="list-style-type: none"> • Superuser. • Users with the CREATE OR REPLACE PROCEDURE permission. • Users with the USAGE permission on language. • For REPLACE PROCEDURE: <ul style="list-style-type: none"> • Superuser. • Users with the CREATE OR REPLACE PROCEDURE permission. • Procedure owner. 		
DROP PROCEDURE	<ul style="list-style-type: none"> • Superuser. • Users with the DROP PROCEDURE permission. • Procedure owner. 		
CREATE OR REPLACE VIEW	<ul style="list-style-type: none"> • For CREATE VIEW: <ul style="list-style-type: none"> • Superuser. • Users with the CREATE OR REPLACE VIEW permission. • Users with the CREATE permission on schemas. • For REPLACE VIEW: <ul style="list-style-type: none"> • Superuser. • Users with the CREATE OR REPLACE VIEW permission. • View owner. 		
DROP VIEW	<ul style="list-style-type: none"> • Superuser. • Users with the DROP VIEW permission. • View owner. 		

Command	You must have permission by one of the following ways to run the command		
CREATE MODEL	<ul style="list-style-type: none"> • Superuser. • Users with the CREATE MODEL system permission, who should be able to read the relation of the CREATE MODEL. • Users with the CREATE MODEL permission. 		
DROP MODEL	<ul style="list-style-type: none"> • Superuser. • Users with the DROP MODEL permission. • Model owner. • Schema owner. 		
CREATE DATASHARE	<ul style="list-style-type: none"> • Superuser. • Users with the CREATE DATASHARE permission. • Database owner. 		
ALTER DATASHARE	<ul style="list-style-type: none"> • Superuser. • User with the ALTER DATASHARE permission. • Users who have the ALTER or ALL permission on the datashare. • To add specific objects to a datashare, these users must have the permission on the objects. Users should be the owners of objects or have SELECT, USAGE, or ALL permissions on the objects. 		
DROP DATASHARE	<ul style="list-style-type: none"> • Superuser. • Users with the DROP DATASHARE permission. • Database owner. 		
CREATE LIBRARY	<ul style="list-style-type: none"> • Superuser. • Users with the CREATE LIBRARY permission or with the permission of the specified language. 		

Command	You must have permission by one of the following ways to run the command		
DROP LIBRARY	<ul style="list-style-type: none"> • Superuser. • Users with the DROP LIBRARY permission. • Library owner. 		
ANALYZE	<ul style="list-style-type: none"> • Superuser. • Users with the ANALYZE permission. • Owner of the relation. • Database owner whom the table is shared to. 		
CANCEL	<ul style="list-style-type: none"> • Superuser canceling their own query. • Superuser canceling a user's query. • Users with the CANCEL permission canceling a user's query. • User canceling their own query. 		
TRUNCATE TABLE	<ul style="list-style-type: none"> • Superuser. • Users with the TRUNCATE TABLE permission. • Table owner. 		
VACUUM	<ul style="list-style-type: none"> • Superuser. • Users with the VACUUM permission. • Table owner. • Database owner whom the table is shared to. 		
IGNORE RLS	<ul style="list-style-type: none"> • Superuser. • Users within the <code>sys:secadmin</code> role. 		
EXPLAIN RLS	<ul style="list-style-type: none"> • Superuser. • Users within the <code>sys:secadmin</code> role. 		
EXPLAIN MASKING	<ul style="list-style-type: none"> • Superuser. • Users within the <code>sys:secadmin</code> role. 		

Database object permissions

Apart from system permissions, Amazon Redshift includes database object permissions that define access options. These include such options as the ability to read data in tables and views, write data, create tables, and drop tables. For more information, see [GRANT](#).

By using RBAC, you can assign database object permissions to roles, similarly to how you can with system permissions. Then you can assign roles to users, authorize users with system permissions, and authorize users with database permissions.

ALTER DEFAULT PRIVILEGES for RBAC

Use the ALTER DEFAULT PRIVILEGES statement to define the default set of access permissions to be applied to objects that are created in the future by the specified user. By default, users can change only their own default access permissions. With RBAC, you can set the default access permissions for roles. For more information, see the [ALTER DEFAULT PRIVILEGES](#) command.

RBAC enables you to assign database object permissions to roles, similarly to system permissions. Then you can assign roles to users, authorize users with system and/or database permissions.

Considerations for role usage in RBAC

When working with RBAC roles, consider the following:

- Amazon Redshift doesn't allow cycles of role authorizations. You can't grant r1 to r2 and then grant r2 to r1.
- RBAC works for both native Amazon Redshift objects and Amazon Redshift Spectrum tables.
- As an Amazon Redshift administrator, you can turn on RBAC by upgrading your cluster to the latest maintenance patch to get started.
- Only superusers and users with the CREATE ROLE system permission can create roles.
- Only superusers and role administrators can modify or drop roles.
- A role name can't be the same as a user name.
- A role name can't contain invalid characters, such as “:\n.”
- A role name can't be a reserved word, such as PUBLIC.
- The role name can't start with the reserved prefix for default roles, sys :.

- You can't drop a role that has the `RESTRICT` parameter when it is granted to another role. The default setting is `RESTRICT`. Amazon Redshift throws an error when you try to drop a role that has inherited another role.
- Users that don't have admin permissions on a role can't grant or revoke a role.

Managing roles in RBAC

To perform the following actions, use the following commands:

- To create a role, use the [CREATE ROLE](#) command.
- To rename a role or change the owner of the role, use the [ALTER ROLE](#) command.
- To delete a role, use the [DROP ROLE](#) command.
- To grant a role to a user, use the [GRANT](#) command.
- To revoke a role from a user, use the [REVOKE](#) command.
- To grant system permissions to a role, use the [GRANT](#) command.
- To revoke system permissions from a role, use the [REVOKE](#) command.

To view a list of roles in your cluster or workgroup, see [SVV_ROLES](#).

Tutorial: Creating roles and querying with RBAC

With RBAC, you can create roles with permissions to run commands that used to require superuser permissions. Users can run these commands, as long as they are authorized with a role that includes these permissions.

In this tutorial, you use role-based access control (RBAC) to manage permissions in a database you create. You then connect to the database and query the database from two different roles to test the functionality of RBAC.

The two roles that you create and use to query the database are the `sales_ro` and `sales_rw`. You create the `sales_ro` role and query data as a user with the `sales_ro` role. The `sales_ro` user can only use the `SELECT` command but cannot use the `UPDATE` command. Then, you create the `sales_rw` role and query data as a user with the `sales_rw` role. The `sales_rw` user can use the `SELECT` command and the `UPDATE` command.

Additionally, you can create roles to limit the access to certain commands, and assign the role to either superusers or users.

Tasks

- [Prerequisites](#)
- [Step 1: Create an administrator user](#)
- [Step 2: Set up schemas](#)
- [Step 3: Create a read-only user](#)
- [Step 4: Query the data as the read-only user](#)
- [Step 5: Create a read-write user](#)
- [Step 6: Query the data as the user with the inherited read-only role](#)
- [Step 7: Grant update and insert permissions to the read-write role](#)
- [Step 8: Query the data as the read-write user](#)
- [Step 9: Analyze and vacuum tables in a database as the administrator user](#)
- [Step 10: Truncate tables as the read-write user](#)
- [System functions for RBAC \(optional\)](#)
- [System views for RBAC \(optional\)](#)
- [Use row-level security with RBAC \(optional\)](#)

Prerequisites

- Create an Amazon Redshift cluster or serverless workgroup that is loaded with the TICKIT sample database. To create a serverless workgroup, see [Get started with Redshift Serverless data warehouses](#). To create a cluster, see [Create a sample Amazon Redshift cluster](#). For more information about the TICKIT sample database, see [Sample database](#).
- Have access to a user with superuser or role administrator permissions. Only superusers or role administrators can grant or revoke roles. For more information about permissions required for RBAC, see [System permissions for RBAC](#).
- Review the [Considerations for role usage in RBAC](#).

Step 1: Create an administrator user

To set up for this tutorial, you create a database admin role and attach it to a database administrator user in this step. You must create the database administrator as a superuser or role administrator.

Run all queries in the Amazon Redshift [query editor v2](#).

1. To create the administrator role db_admin, use the following example.

```
CREATE ROLE db_admin;
```

2. To create a database user named dbadmin, use the following example.

```
CREATE USER dbadmin PASSWORD 'Test12345';
```

3. To grant the system defined role named sys:dba to the db_admin role, use the following example. When granted the sys:dba role, the dbadmin user can create schemas and tables. For more information, see [Amazon Redshift system-defined roles](#).

Step 2: Set up schemas

In this step, you connect to your database as the database administrator. Then, you create two schemas and add data to them.

1. Connect to the dev database as the dbadmin user using query editor v2. For more information about connecting to a database, see [Working with query editor v2](#).
2. To create the sales and marketing database schemas, use the following example.

```
CREATE SCHEMA sales;  
CREATE SCHEMA marketing;
```

3. To create and insert values into tables in the sales schema, use the following example.

```
CREATE TABLE sales.cat(  
  catid smallint,  
  catgroup varchar(10),  
  catname varchar(10),  
  catdesc varchar(50)  
);  
INSERT INTO sales.cat(SELECT * FROM category);  
  
CREATE TABLE sales.dates(  
  dateid smallint,  
  caldate date,  
  day char(3),  
  week smallint,
```

```
month char(5),
qtr char(5),
year smallint,
holiday boolean
);
INSERT INTO sales.dates(SELECT * FROM date);

CREATE TABLE sales.events(
eventid integer,
venueid smallint,
catid smallint,
dateid smallint,
eventname varchar(200),
starttime timestamp
);
INSERT INTO sales.events(SELECT * FROM event);

CREATE TABLE sales.sale(
salesid integer,
listid integer,
sellerid integer,
buyerid integer,
eventid integer,
dateid smallint,
qtysold smallint,
pricepaid decimal(8,2),
commission decimal(8,2),
saletime timestamp
);
INSERT INTO sales.sale(SELECT * FROM sales);
```

4. To create and insert values into tables in the marketing schema, use the following example.

```
CREATE TABLE marketing.cat(
catid smallint,
catgroup varchar(10),
catname varchar(10),
catdesc varchar(50)
);
INSERT INTO marketing.cat(SELECT * FROM category);

CREATE TABLE marketing.dates(
dateid smallint,
caldate date,
```

```
day char(3),
week smallint,
month char(5),
qtr char(5),
year smallint,
holiday boolean
);
INSERT INTO marketing.dates(SELECT * FROM date);

CREATE TABLE marketing.events(
eventid integer,
venueid smallint,
catid smallint,
dateid smallint,
eventname varchar(200),
starttime timestamp
);
INSERT INTO marketing.events(SELECT * FROM event);

CREATE TABLE marketing.sale(
marketingid integer,
listid integer,
sellerid integer,
buyerid integer,
eventid integer,
dateid smallint,
qtysold smallint,
pricepaid decimal(8,2),
commission decimal(8,2),
saletime timestamp
);
INSERT INTO marketing.sale(SELECT * FROM marketing);
```

Step 3: Create a read-only user

In this step, you create a read-only role and a salesanalyst user for the read-only role. The sales analyst only needs read-only access to the tables in the sales schema to accomplish their assigned task of finding the events that resulted in the largest commissions.

1. Connect to the database as the dbadmin user.
2. To create the sales_ro role, use the following example.

```
CREATE ROLE sales_ro;
```

- To create the salesanalyst user, use the following example.

```
CREATE USER salesanalyst PASSWORD 'Test12345';
```

- To grant the sales_ro role usage and select access to objects of the sales schema, use the following example.

```
GRANT USAGE ON SCHEMA sales TO ROLE sales_ro;
GRANT SELECT ON ALL TABLES IN SCHEMA sales TO ROLE sales_ro;
```

- To grant the salesanalyst user the sales_ro role, use the following example.

```
GRANT ROLE sales_ro TO salesanalyst;
```

Step 4: Query the data as the read-only user

In this step, the salesanalyst user queries data from the sales schema. Then, the salesanalyst user attempts to update a table and read tables in the marketing schema.

- Connect to the database as the salesanalyst user.
- To find the 10 sales with the highest commissions, use the following example.

```
SET SEARCH_PATH TO sales;
SELECT DISTINCT events.dateid, sale.commission, cat.catname
FROM sale, events, dates, cat
WHERE events.dateid=dates.dateid AND events.dateid=sale.dateid AND events.catid =
      cat.catid
ORDER BY 2 DESC LIMIT 10;
```

```
+-----+-----+-----+
| dateid | commission | catname |
+-----+-----+-----+
| 1880 | 1893.6 | Pop |
| 1880 | 1893.6 | Opera |
| 1880 | 1893.6 | Plays |
| 1880 | 1893.6 | Musicals |
| 1861 | 1500 | Plays |
| 2003 | 1500 | Pop |
```

```

| 1861 | 1500 | Opera |
| 2003 | 1500 | Plays |
| 1861 | 1500 | Musicals |
| 1861 | 1500 | Pop |
+-----+-----+-----+

```

3. To select 10 events from the events table in the sales schema, use the following example.

```
SELECT * FROM sales.events LIMIT 10;
```

```

+-----+-----+-----+-----+-----+-----+-----+
| eventid | venueid | catid | dateid | eventname | starttime |
+-----+-----+-----+-----+-----+-----+-----+
| 4836 | 73 | 9 | 1871 | Soulfest | 2008-02-14 19:30:00 |
| 5739 | 41 | 9 | 1871 | Fab Faux | 2008-02-14 19:30:00 |
| 627 | 229 | 6 | 1872 | High Society | 2008-02-15 14:00:00 |
| 2563 | 246 | 7 | 1872 | Hamlet | 2008-02-15 20:00:00 |
| 7703 | 78 | 9 | 1872 | Feist | 2008-02-15 14:00:00 |
| 7903 | 90 | 9 | 1872 | Little Big Town | 2008-02-15 19:30:00 |
| 7925 | 101 | 9 | 1872 | Spoon | 2008-02-15 19:00:00 |
| 8113 | 17 | 9 | 1872 | Santana | 2008-02-15 15:00:00 |
| 463 | 303 | 8 | 1873 | Tristan und Isolde | 2008-02-16 19:00:00 |
| 613 | 236 | 6 | 1873 | Pal Joey | 2008-02-16 15:00:00 |
+-----+-----+-----+-----+-----+-----+-----+

```

4. To attempt to update the eventname for eventid 1, run the following example. This example will result in a permission denied error because the salesanalyst user only has SELECT permissions on the events table in the sales schema. To update the events table, you must grant the sales_role permissions to UPDATE. For more information about granting permissions to update a table, see the UPDATE parameter for [GRANT](#). For more information about the UPDATE command, see [UPDATE](#).

```
UPDATE sales.events
SET eventname = 'Comment event'
WHERE eventid = 1;
```

```
ERROR: permission denied for relation events
```

5. To attempt to select all from the events table in the marketing schema, use the following example. This example will result in a permission denied error because the salesanalyst user only has SELECT permissions for the events table in the sales schema. To select data from the

events table in the marketing schema, you must grant the sales_ro role SELECT permissions on the events table in the marketing schema.

```
SELECT * FROM marketing.events;
```

```
ERROR: permission denied for schema marketing
```

Step 5: Create a read-write user

In this step, the sales engineer who is responsible for building the extract, transform, and load (ETL) pipeline for data processing in the sales schema will be given read-only access, but will later be given read and write access to perform their tasks.

1. Connect to the database as the dbadmin user.
2. To create the sales_rw role in the sales schema, use the following example.

```
CREATE ROLE sales_rw;
```

3. To create the salesengineer user, use the following example.

```
CREATE USER salesengineer PASSWORD 'Test12345';
```

4. To grant the sales_rw role usage and select access to objects of the sales schema by assigning the sales_ro role to it, use the following example. For more information on how roles inherit permissions in Amazon Redshift, see [Role hierarchy](#).

```
GRANT ROLE sales_ro TO ROLE sales_rw;
```

5. To assign the sales_rw role to the salesengineer user, use the following example.

```
GRANT ROLE sales_rw TO salesengineer;
```

Step 6: Query the data as the user with the inherited read-only role

In this step, the salesengineer user attempts to update the events table before they are granted read permissions.

1. Connect to the database as the salesengineer user.

2. The salesengineer user can successfully read data from the events table of the sales schema. To select the event with eventid 1 from the events table in the sales schema, use the following example.

```
SELECT * FROM sales.events where eventid=1;
```

```
+-----+-----+-----+-----+-----+-----+
| eventid | venueid | catid | dateid | eventname | starttime |
+-----+-----+-----+-----+-----+-----+
|      1 |      305 |      8 |    1851 | Gotterdammerung | 2008-01-25 14:30:00 |
+-----+-----+-----+-----+-----+-----+
```

3. To attempt to select all from the events table in the marketing schema, use the following example. The salesengineer user doesn't have permissions for tables in the marketing schema, so this query will result in a permission denied error. To select data from the events table in the marketing schema, you must grant the sales_rw role SELECT permissions on the events table in the marketing schema.

```
SELECT * FROM marketing.events;
```

```
ERROR: permission denied for schema marketing
```

4. To attempt to update the eventname for eventid 1, run the following example. This example will result in a permission denied error because the salesengineer user only has select permissions on the events table in the sales schema. To update the events table, you must grant the sales_rw role permissions to UPDATE.

```
UPDATE sales.events
SET eventname = 'Comment event'
WHERE eventid = 1;
```

```
ERROR: permission denied for relation events
```

Step 7: Grant update and insert permissions to the read-write role

In this step, you grant update and insert permissions to the sales_rw role.

1. Connect to the database as the dbadmin user.

- To grant UPDATE, INSERT, and DELETE permissions to the sales_rw role, use the following example.

```
GRANT UPDATE, INSERT, ON ALL TABLES IN SCHEMA sales TO role sales_rw;
```

Step 8: Query the data as the read-write user

In this step, the salesengineer successfully updates the table after their role is granted insert and update permissions. Next, the salesengineer attempts to analyze and vacuum the events table but fails to do so.

- Connect to the database as the salesengineer user.
- To update the eventname for eventid 1, run the following example.

```
UPDATE sales.events
SET eventname = 'Comment event'
WHERE eventid = 1;
```

- To view the change made in the previous query, use the following example to select the event with eventid 1 from the events table in the sales schema.

```
SELECT * FROM sales.events WHERE eventid=1;
```

```
+-----+-----+-----+-----+-----+-----+
| eventid | venueid | catid | dateid | eventname | starttime |
+-----+-----+-----+-----+-----+-----+
|      1 |      305 |      8 |   1851 | Comment event | 2008-01-25 14:30:00 |
+-----+-----+-----+-----+-----+-----+
```

- To analyze the updated events table in the sales schema, use the following example. This example will result in a permission denied error because the salesengineer user does not have the necessary permissions and isn't the owner of the events table in the sales schema. To analyze the events table, you must grant the sales_rw role permissions to ANALYZE using the GRANT command. For more information about the ANALYZE command, see [ANALYZE](#).

```
ANALYZE sales.events;
```

```
ERROR: skipping "events" --- only table or database owner can analyze
```

5. To vacuum the updated events table, use the following example. This example will result in a permission denied error because the salesengineer user does not have the necessary permissions and isn't the owner of the events table in the sales schema. To vacuum the events table, you must grant the sales_rw role permissions to VACUUM using the GRANT command. For more information about the VACUUM command, see [VACUUM](#).

```
VACUUM sales.events;
```

```
ERROR: skipping "events" --- only table or database owner can vacuum it
```

Step 9: Analyze and vacuum tables in a database as the administrator user

In this step, the dbadmin user analyzes and vacuums all of the tables. The user has administrator permissions on this database, so they are able to run these commands.

1. Connect to the database as the dbadmin user.
2. To analyze the events table in the sales schema, use the following example.

```
ANALYZE sales.events;
```

3. To vacuum the events table in the sales schema, use the following example.

```
VACUUM sales.events;
```

4. To analyze the events table in the marketing schema, use the following example.

```
ANALYZE marketing.events;
```

5. To vacuum the events table in the marketing schema, use the following example.

```
VACUUM marketing.events;
```

Step 10: Truncate tables as the read-write user

In this step, the salesengineer user attempts to truncate the events table in the sales schema, but only succeeds when granted truncate permissions by the dbadmin user.

1. Connect to the database as the salesengineer user.

- To try to delete all of the rows from the events table in the sales schema, use the following example. This example will result in an error because the salesengineer user does not have the necessary permissions and isn't the owner of the events table in the sales schema. To truncate the events table, you must grant the sales_rw role permissions to TRUNCATE using the GRANT command. For more information about the TRUNCATE command, see [TRUNCATE](#).

```
TRUNCATE sales.events;
```

```
ERROR: must be owner of relation events
```

- Connect to the database as the dbadmin user.
- To grant truncate table privileges to the sales_rw role, use the following example.

```
GRANT TRUNCATE TABLE TO role sales_rw;
```

- Connect to the database as the salesengineer user using query editor v2.
- To read the first 10 events from the events table in the sales schema, use the following example.

```
SELECT * FROM sales.events ORDER BY eventid LIMIT 10;
```

```
+-----+-----+-----+-----+-----+
+-----+
| eventid | venueid | catid | dateid |          eventname          |      starttime      |
|         |         |      |        |                              |                     |
+-----+-----+-----+-----+-----+
+-----+
|         1 |      305 |      8 |   1851 | Comment event              | 2008-01-25
14:30:00 |
|         2 |      306 |      8 |   2114 | Boris Godunov              | 2008-10-15
20:00:00 |
|         3 |      302 |      8 |   1935 | Salome                      | 2008-04-19
14:30:00 |
|         4 |      309 |      8 |   2090 | La Cenerentola (Cinderella) | 2008-09-21
14:30:00 |
|         5 |      302 |      8 |   1982 | Il Trovatore                | 2008-06-05
19:00:00 |
|         6 |      308 |      8 |   2109 | L Elisir d Amore            | 2008-10-10
19:30:00 |
|         7 |      309 |      8 |   1891 | Doctor Atomic               | 2008-03-06
14:00:00 |
```

```

|      8 |      302 |      8 |    1832 | The Magic Flute | 2008-01-06
20:00:00 |
|      9 |      308 |      8 |    2087 | The Fly         | 2008-09-18
19:30:00 |
|     10 |      305 |      8 |    2079 | Rigoletto      | 2008-09-10
15:00:00 |
+-----+-----+-----+-----+-----+
+-----+

```

7. To truncate the events table in the sales schema, use the following example.

```
TRUNCATE sales.events;
```

8. To read the data from the updated events table in the sales schema, use the following example.

```
SELECT * FROM sales.events ORDER BY eventid LIMIT 10;
```

```

+-----+-----+-----+-----+-----+
+-----+
| eventid | venueid | catid | dateid |          eventname          |          starttime
|
+-----+-----+-----+-----+-----+
+-----+

```

Create read-only and read-write roles for the marketing schema (optional)

In this step, you create read-only and read-write roles for the marketing schema.

1. Connect to the database as the dbadmin user.
2. To create read-only and read-write roles for the marketing schema, use the following example.

```

CREATE ROLE marketing_ro;

CREATE ROLE marketing_rw;

GRANT USAGE ON SCHEMA marketing TO ROLE marketing_ro, ROLE marketing_rw;

GRANT SELECT ON ALL TABLES IN SCHEMA marketing TO ROLE marketing_ro;

GRANT ROLE marketing_ro TO ROLE marketing_rw;

GRANT INSERT, UPDATE, DELETE ON ALL TABLES IN SCHEMA marketing TO ROLE marketing_rw;

```

```
CREATE USER marketinganalyst PASSWORD 'Test12345';

CREATE USER marketingengineer PASSWORD 'Test12345';

GRANT ROLE marketing_ro TO marketinganalyst;

GRANT ROLE marketing_rw TO marketingengineer;
```

System functions for RBAC (optional)

Amazon Redshift has two functions to provide system information about user membership and role membership in additional groups or roles: `role_is_member_of` and `user_is_member_of`. These functions are available to superusers and regular users. Superusers can check all role memberships. Regular users can only check membership for roles that they have been granted access to.

To use the `role_is_member_of` function

1. Connect to the database as the `salesengineer` user.
2. To check if the `sales_rw` role is a member of the `sales_ro` role, use the following example.

```
SELECT role_is_member_of('sales_rw', 'sales_ro');
```

role_is_member_of
true

3. To check if the `sales_ro` role is a member of the `sales_rw` role, use the following example.

```
SELECT role_is_member_of('sales_ro', 'sales_rw');
```

role_is_member_of
false

To use the `user_is_member_of` function

1. Connect to the database as the salesengineer user.
2. The following example attempts to check the user membership for the salesanalyst user. This query results in an error because salesengineer does not have access to salesanalyst. To run this command successfully, connect to the database as the salesanalyst user and use the example.

```
SELECT user_is_member_of('salesanalyst', 'sales_ro');
```

```
ERROR
```

3. Connect to the database as a superuser.
4. To check the membership of the salesanalyst user when connected as a superuser, use the following example.

```
SELECT user_is_member_of('salesanalyst', 'sales_ro');
```

```
+-----+
| user_is_member_of |
+-----+
| true              |
+-----+
```

5. Connect to the database as the dbadmin user.
6. To check the membership of the salesengineer user, use the following example.

```
SELECT user_is_member_of('salesengineer', 'sales_ro');
```

```
+-----+
| user_is_member_of |
+-----+
| true              |
+-----+
```

```
SELECT user_is_member_of('salesengineer', 'marketing_ro');
```

```
+-----+
| user_is_member_of |
+-----+
| false             |
+-----+
```

```
SELECT user_is_member_of('marketinganalyst', 'sales_ro');
```

```
+-----+
| user_is_member_of |
+-----+
| false             |
+-----+
```

System views for RBAC (optional)

To view the roles, the assignment of roles to users, the role hierarchy, and the privileges for database objects via roles, use the system views for Amazon Redshift. These views are available to superusers and regular users. Superusers can check all role details. Regular users can only check details for roles that they have been granted access to.

1. To view a list of users that are explicitly granted roles in the cluster, use the following example.

```
SELECT * FROM svv_user_grants;
```

2. To view a list of roles that are explicitly granted roles in the cluster, use the following example.

```
SELECT * FROM svv_role_grants;
```

For the full list of system views, refer to [SVV metadata views](#).

Use row-level security with RBAC (optional)

To have granular access control over your sensitive data, use row-level security (RLS). For more information about RLS, see [Row-level security](#).

In this section, you create a RLS policy that gives the `salesengineer` user permissions to only view rows in the `cat` table that have the `catdesc` value of Major League Baseball. You then query the database as the `salesengineer` user.

1. Connect to the database as the `salesengineer` user.
2. To view the first 5 entries in the `cat` table, use the following example.

```
SELECT *
```

```

FROM sales.cat
ORDER BY catid ASC
LIMIT 5;

```

```

+-----+-----+-----+-----+
| catid | catgroup | catname |          catdesc          |
+-----+-----+-----+-----+
|     1 | Sports   | MLB     | Major League Baseball    |
|     2 | Sports   | NHL     | National Hockey League    |
|     3 | Sports   | NFL     | National Football League  |
|     4 | Sports   | NBA     | National Basketball Association |
|     5 | Sports   | MLS     | Major League Soccer       |
+-----+-----+-----+-----+

```

3. Connect to the database as the `dbadmin` user.
4. To create a RLS policy for the `catdesc` column in the `cat` table, use the following example.

```

CREATE RLS POLICY policy_mlb_engineer
WITH (catdesc VARCHAR(50))
USING (catdesc = 'Major League Baseball');

```

5. To attach the RLS policy to the `sales_rw` role, use the following example.

```

ATTACH RLS POLICY policy_mlb_engineer ON sales.cat TO ROLE sales_rw;

```

6. To alter the table to turn on RLS, use the following example.

```

ALTER TABLE sales.cat ROW LEVEL SECURITY ON;

```

7. Connect to the database as the `salesengineer` user.
8. To attempt to view the first 5 entries in the `cat` table, use the following example. Note that only entries only appear when the `catdesc` column is `Major League Baseball`.

```

SELECT *
FROM sales.cat
ORDER BY catid ASC
LIMIT 5;

```

```

+-----+-----+-----+-----+
| catid | catgroup | catname |          catdesc          |
+-----+-----+-----+-----+
|     1 | Sports   | MLB     | Major League Baseball    |

```

```
+-----+-----+-----+-----+
```

9. Connect to the database as the `salesanalyst` user.

10. To attempt to view the first 5 entries in the `cat` table, use the following example. Note that no entries appear because the default deny all policy is applied.

```
SELECT *
FROM sales.cat
ORDER BY catid ASC
LIMIT 5;
```

```
+-----+-----+-----+-----+
| catid | catgroup | catname |          catdesc          |
+-----+-----+-----+-----+
```

11. Connect to the database as the `dbadmin` user.

12. To grant the IGNORE RLS permission to the `sales_ro` role, use the following example. This grants the `salesanalyst` user the permissions to ignore RLS policies since they are a member of the `sales_ro` role.

```
GRANT IGNORE RLS TO ROLE sales_ro;
```

13. Connect to the database as the `salesanalyst` user.

14. To view the first 5 entries in the `cat` table, use the following example.

```
SELECT *
FROM sales.cat
ORDER BY catid ASC
LIMIT 5;
```

```
+-----+-----+-----+-----+
| catid | catgroup | catname |          catdesc          |
+-----+-----+-----+-----+
|     1 | Sports   | MLB     | Major League Baseball   |
|     2 | Sports   | NHL     | National Hockey League   |
|     3 | Sports   | NFL     | National Football League |
|     4 | Sports   | NBA     | National Basketball Association |
|     5 | Sports   | MLS     | Major League Soccer     |
+-----+-----+-----+-----+
```

15. Connect to the database as the `dbadmin` user.

16.To revoke the IGNORE RLS permission from the `sales_ro` role, use the following example.

```
REVOKE IGNORE RLS FROM ROLE sales_ro;
```

17.Connect to the database as the `salesanalyst` user.

18.To attempt to view the first 5 entries in the `cat` table, use the following example. Note that no entries appear because the default deny all policy is applied.

```
SELECT *
FROM sales.cat
ORDER BY catid ASC
LIMIT 5;
```

```
+-----+-----+-----+-----+
| catid | catgroup | catname |          catdesc          |
+-----+-----+-----+-----+
```

19.Connect to the database as the `dbadmin` user.

20.To detach the RLS policy from the `cat` table, use the following example.

```
DETACH RLS POLICY policy_mlb_engineer ON cat FROM ROLE sales_rw;
```

21.Connect to the database as the `salesanalyst` user.

22.To attempt to view the first 5 entries in the `cat` table, use the following example. Note that no entries appear because the default deny all policy is applied.

```
SELECT *
FROM sales.cat
ORDER BY catid ASC
LIMIT 5;
```

```
+-----+-----+-----+-----+
| catid | catgroup | catname |          catdesc          |
+-----+-----+-----+-----+
|    1  | Sports   | MLB     | Major League Baseball    |
|    2  | Sports   | NHL     | National Hockey League    |
|    3  | Sports   | NFL     | National Football League  |
|    4  | Sports   | NBA     | National Basketball Association |
|    5  | Sports   | MLS     | Major League Soccer       |
+-----+-----+-----+-----+
```

23. Connect to the database as the `dbadmin` user.

24. To drop the RLS policy, use the following example.

```
DROP RLS POLICY policy_mlb_engineer;
```

25. To remove RLS, use the following example.

```
ALTER TABLE cat ROW LEVEL SECURITY OFF;
```

Row-level security

Using row-level security (RLS) in Amazon Redshift, you can have granular access control over your sensitive data. You can decide which users or roles can access specific records of data within schemas or tables, based on security policies that are defined at the database objects level. In addition to column-level security, where you can grant users permissions to a subset of columns, use RLS policies to further restrict access to particular rows of the visible columns. For more information about column-level security, see [Usage notes for column-level access control](#).

When you enforce RLS policies on tables, you can restrict returned result sets when users run queries.

When creating RLS policies, you can specify expressions that dictate whether Amazon Redshift returns any existing rows in a table in a query. By creating RLS policies to limit access, you don't have to add or externalize additional conditions in your queries.

When creating RLS policies, we recommend that you create simple policies and avoid complex statements in policies. When defining RLS policies, don't use excessive table joins in the policy definition that are based on policies.

When a policy refers to a lookup table, Amazon Redshift scans the additional table, in addition to the table on which the policy exists. There will be performance differences between the same query for a user with an RLS policy attached, and a user without any policy attached.

Using RLS policies in SQL statements

When using RLS policies in SQL statements, Amazon Redshift applies the following rules:

- Amazon Redshift applies RLS policies to the SELECT, UPDATE, and DELETE statements by default.
- For SELECT and UNLOAD, Amazon Redshift filters rows according to your defined policy.
- For UPDATE, Amazon Redshift updates only the rows that are visible to you. If a policy restricts a subset of the rows in a table, then you can't update them.
- For DELETE, you can delete only the rows that are visible to you. If a policy restricts a subset of the rows in a table, then you can't delete them. For TRUNCATE, you can still truncate the table.
- For CREATE TABLE LIKE, tables created with the LIKE options won't inherit permission settings from the source table. Similarly, the target table won't inherit the RLS policies from source table.

Combining multiple policies per user

RLS in Amazon Redshift supports attaching multiple policies per user and object. When there are multiple policies defined for a user, Amazon Redshift applies all the policies with either AND or OR syntax depending on the RLS CONJUNCTION TYPE setting for the table. For more information about conjunction type, see [ALTER TABLE](#).

Multiple policies on a table can be associated with you. Either multiple policies are directly attached to you, or you belong to multiple roles, and the roles have different policies attached to them.

When the multiple policies should restrict rows access in a given relation, you can set RLS CONJUNCTION TYPE of the relation to AND. Consider the following example. Alice can only see Sports event that has a "catname" of NBA as the policy specified.

```
-- Create an analyst role and grant it to a user named Alice.
CREATE ROLE analyst;
CREATE USER alice WITH PASSWORD 'Name_is_alice_1';
GRANT ROLE analyst TO alice;

-- Create an RLS policy that only lets the user see sports.
```

```

CREATE RLS POLICY policy_sports
WITH (catgroup VARCHAR(10))
USING (catgroup = 'Sports');

-- Create an RLS policy that only lets the user see NBA.
CREATE RLS POLICY policy_nba
WITH (catname VARCHAR(10))
USING (catname = 'NBA');

-- Attach both to the analyst role.
ATTACH RLS POLICY policy_sports ON category TO ROLE analyst;
ATTACH RLS POLICY policy_nba ON category TO ROLE analyst;

-- Activate RLS on the category table with AND CONJUNCTION TYPE.
ALTER TABLE category ROW LEVEL SECURITY ON CONJUNCTION TYPE AND;

-- Change session to Alice.
SET SESSION AUTHORIZATION alice;

-- Select all from the category table.
SELECT catgroup, catname
FROM category;

  catgroup | catname
-----+-----
  Sports   | NBA
(1 row)

```

When the multiple policies should permit the users to see more rows in a given relation, user can set RLS CONJUNCTION TYPE of the relation to OR. Consider the following example. Alice can only see "Concerts" and "Sports" as the policy specified.

```

-- Create an analyst role and grant it to a user named Alice.
CREATE ROLE analyst;
CREATE USER alice WITH PASSWORD 'Name_is_alice_1';
GRANT ROLE analyst TO alice;

-- Create an RLS policy that only lets the user see concerts.
CREATE RLS POLICY policy_concerts
WITH (catgroup VARCHAR(10))
USING (catgroup = 'Concerts');

-- Create an RLS policy that only lets the user see sports.

```

```

CREATE RLS POLICY policy_sports
WITH (catgroup VARCHAR(10))
USING (catgroup = 'Sports');

-- Attach both to the analyst role.
ATTACH RLS POLICY policy_concerts ON category TO ROLE analyst;
ATTACH RLS POLICY policy_sports ON category TO ROLE analyst;

-- Activate RLS on the category table with OR CONJUNCTION TYPE.
ALTER TABLE category ROW LEVEL SECURITY ON CONJUNCTION TYPE OR;

-- Change session to Alice.
SET SESSION AUTHORIZATION alice;

-- Select all from the category table.
SELECT catgroup, count(*)
FROM category
GROUP BY catgroup ORDER BY catgroup;

  catgroup | count
-----+-----
  Concerts |    3
   Sports  |    5
(2 rows)

```

RLS policy ownership and management

As a superuser, security administrator, or user that has the `sys:secadmin` role, you can create, modify, or manage all RLS policies for tables. At the object level, you can turn row-level security on or off without modifying the schema definition for tables.

To get started with row-level security, following are SQL statements that you can use:

- Use the `ALTER TABLE` statement to turn on or off RLS on a table. For more information, see [ALTER TABLE](#).
- Use the `CREATE RLS POLICY` statement to create a security policy for one or more tables, and specify one or more users or roles in the policy.

For more information, see [CREATE RLS POLICY](#).

- Use the `ALTER RLS POLICY` statement to alter the policy, such as changing the policy definition. You can use the same policy for multiple tables or views.

For more information, see [ALTER RLS POLICY](#).

- Use the ATTACH RLS POLICY statement to attach a policy to one or more relations, to one or more users, or to roles.

For more information, see [ATTACH RLS POLICY](#).

- Use the DETACH RLS POLICY statement to detach a policy from one or more relations, from one or more users, or from roles.

For more information, see [DETACH RLS POLICY](#).

- Use the DROP RLS POLICY statement to drop a policy.

For more information, see [DROP RLS POLICY](#).

- Use the GRANT and REVOKE statements to explicitly grant and revoke SELECT permissions to RLS policies that reference lookup tables. For more information, see [GRANT](#) and [REVOKE](#).

To monitor the policies created, sys:secadmin can view the [SVV_RLS_POLICY](#) and [SVV_RLS_ATTACHED_POLICY](#).

To list RLS-protected relations, sys:secadmin can view SVV_RLS_RELATION.

To trace the application of RLS policies on queries that reference RLS-protected relations, a superuser, sys:operator, or any user with the system permission ACCESS SYSTEM TABLE can view [SVV_RLS_APPLIED_POLICY](#). Note that sys:secadmin is not granted these permissions by default.

To query tables with attached RLS policies, but not see them, you can grant the permission IGNORE RLS to any user. Users that are superusers or sys:secadmin are automatically granted the permission IGNORE RLS. For more information, see [GRANT](#).

To explain the RLS policy filters of a query in the EXPLAIN plan to troubleshoot RLS-related queries, you can grant the permission EXPLAIN RLS to any user. For more information, see [GRANT](#) and [EXPLAIN](#).

Policy-dependent objects and principles

To provide security for applications and to prevent policy objects from becoming stale or invalid, Amazon Redshift doesn't permit dropping or altering objects referenced by RLS policies.

Following lists schema object dependencies that Amazon Redshift tracks for RLS policies.

- When tracking schema object dependency for the target table, Amazon Redshift follows these rules:
 - Amazon Redshift detaches the policy from a relation, user, role, or public when you drop a target table.
 - When you rename a target table name, there is no impact to the attached policies.
 - You can only drop the columns of the target table referenced inside the policy definition if you drop or detach the policy first. This also applies when the CASCADE option is specified. You can drop other columns in the target table.
 - You can't rename the referred columns of the target table. To rename referred columns, detach the policy first. This also applies when the CASCADE option is specified.
 - You can't change the type of the referred column, even when you specify the CASCADE option.
- When tracking schema object dependency for the lookup table, Amazon Redshift follows these rules:
 - You can't drop a lookup table. To drop a lookup table, first drop the policy in which the lookup table is referred.
 - You can't rename a lookup table. To rename a lookup table, first drop the policy in which the lookup table is referred. This also applies when the CASCADE option is specified.
 - You can't drop the lookup table columns used in the policy definition. To drop the lookup table columns used in the policy definition, first drop the policy in which the lookup table is referred. This also applies when the CASCADE option is specified in the ALTER TABLE DROP COLUMN statement. You can drop other columns in the lookup table.
 - You can't rename the referred columns of the lookup table. To rename referred columns, first drop the policy in which the lookup table is referred. This also applies when the CASCADE option is specified.
 - You can't change the type of the referred column.
- When a user or role is dropped, Amazon Redshift detaches all policies attached to the user or role automatically.
- When you use the CASCADE option in the DROP SCHEMA statement, Amazon Redshift also drops the relations in the schema. It also drops the relations in any other schemas that are dependent on relations in the dropped schema. For a relation that is a lookup table in a policy, Amazon Redshift fails the DROP SCHEMA DDL. For any relations dropped by the DROP SCHEMA statement, Amazon Redshift detaches all policies that are attached to those relations.
- You can only drop a lookup function (a function that is referred inside a policy definition) when you also drop the policy. This also applies when the CASCADE option is specified.

- When a policy is attached to a table, Amazon Redshift checks if this table is a lookup table in a different policy. If this is the case, Amazon Redshift won't allow attaching a policy to this table.
- While creating an RLS policy, Amazon Redshift checks if this table is a target table for any other RLS policy. If this is the case, Amazon Redshift won't allow creating a policy on this table.

Example

The following example illustrates how schema dependency is tracked.

```
-- The CREATE and ATTACH policy statements for `policy_events` references some
-- target and lookup tables.
-- Target tables are tickit_event_redshift and target_schema.target_event_table.
-- Lookup table is tickit_sales_redshift.
-- Policy `policy_events` has following dependencies:
-- table tickit_sales_redshift column eventid, qtysold
-- table tickit_event_redshift column eventid
-- table target_event_table column eventid
-- schema public and target_schema
CREATE RLS POLICY policy_events
WITH (eventid INTEGER)
USING (
    eventid IN (SELECT eventid FROM tickit_sales_redshift WHERE qtysold <3)
);

ATTACH RLS POLICY policy_events ON tickit_event_redshift TO ROLE analyst;

ATTACH RLS POLICY policy_events ON target_schema.target_event_table TO ROLE consumer;
```

Considerations and limitations using RLS policies

Considerations

Following are considerations for working with RLS policies:

- Amazon Redshift applies RLS policies to SELECT, UPDATE, or DELETE statements.
- Amazon Redshift doesn't apply RLS policies to INSERT, COPY, ALTER TABLE APPEND statements.
- Row-level security works with column-level security to protect your data.
- When your Amazon Redshift cluster was on the latest generally available version that supports RLS, but is downgraded to an earlier version, Amazon Redshift returns an error when you run a

query on base tables with RLS policies attached. The sys:secadmin can revoke access from users that were granted restricted policies, turn off RLS on tables, and drop the policies.

- When RLS is turned on for the source relation, Amazon Redshift supports the ALTER TABLE APPEND statement for superusers, users that have been explicitly granted the system permission IGNORE RLS, or the sys:secadmin role. In this case, you can run the ALTER TABLE APPEND statement to append rows to a target table by moving data from an existing source table. Amazon Redshift moves all tuples from the source relation into the target relation. The RLS status of the target relation doesn't affect the ALTER TABLE APPEND statement.
- To facilitate migration from other data warehouse systems, you can set and retrieve customized session context variables for a connection by specifying the variable name and value.

The following example sets session context variables for a row-level security (RLS) policy.

```
-- Set a customized context variable.
SELECT set_config('app.category', 'Concerts', FALSE);

-- Create a RLS policy using current_setting() to get the value of a customized
  context variable.
CREATE RLS POLICY policy_categories
WITH (catgroup VARCHAR(10))
USING (catgroup = current_setting('app.category', FALSE));

-- Set correct roles and attach the policy on the target table to one or more roles.
ATTACH RLS POLICY policy_categories ON tickit_category_redshift TO ROLE analyst, ROLE
dbadmin;
```

For details on how to set and retrieve customized session context variables, go to [SET](#), [SET_CONFIG](#), [SHOW](#), [CURRENT_SETTING](#), and [RESET](#). For more information on modifying the server configuration in general, go to [Modifying the server configuration](#).

Important

When using session context variables within RLS policies, the security policy is reliant on the user or role that invokes the policy. Be careful to avoid security vulnerabilities when using session context variables in RLS policies.

- Changing session user using SET SESSION AUTHORIZATION between DECLARE and FETCH or between subsequent FETCH statements won't refresh the already prepared plan based on the

user policies at DECLARE time. Avoid changing session user when cursors are used with RLS-protected tables.

- When the base objects inside a view object are RLS-protected, policies attached to the user running the query are applied on the respective base objects. This is different from object-level permission checks, where the view owner's permissions are checked against the view base objects. You can view the RLS-protected relations of a query in its EXPLAIN plan output.
- When a user-defined function (UDF) is referenced in a RLS policy of a relation attached to a user, the user must have the EXECUTE permission over the UDF to query the relation.
- Row-level security might limit query optimization. We recommend carefully evaluating query performance before deploying RLS-protected views on large datasets.
- Row-level security policies applied to late-binding views might be pushed into federated tables. These RLS policies might be visible in external processing engine logs.

Limitations

Following are the limitations when working with RLS policies:

- Amazon Redshift supports SELECT statements for certain RLS policies with lookups that have complex joins, but doesn't support UPDATE or DELETE statements. In cases with UPDATE or DELETE statements, Amazon Redshift returns the following error:

```
ERROR: One of the RLS policies on target relation is not supported in UPDATE/DELETE.
```

- Whenever a user-defined function (UDF) is referenced in a RLS policy of a relation attached to a user, the user must have the EXECUTE permission over the UDF to query the relation.
- Correlated subqueries aren't supported. Amazon Redshift returns the following error:

```
ERROR: RLS policy could not be rewritten.
```

- RLS policies can't be attached to external tables.
- Amazon Redshift doesn't support datasharing with RLS. If a relation doesn't have RLS turned off for datashares, the query fails on the consumer cluster with the following error:

```
RLS-protected relation "rls_protected_table" cannot be accessed via datasharing query.
```

You can turn off RLS for datashares using the ALTER TABLE command with the parameter ROW LEVEL SECURITY OFF FOR DATASHARES. For more information about using ALTER TABLE to enable or disable RLS, go to [ALTER TABLE](#).

- In cross-database queries, Amazon Redshift blocks reads to RLS-protected relations. Users with the IGNORE RLS permission can access the protected relation using cross-database queries. When a user without the IGNORE RLS permission accesses RLS-protected relation through a cross-database query, the following error appears:

```
RLS-protected relation "rls_protected_table" cannot be accessed via cross-database query.
```

- ALTER RLS POLICY only supports modifying a RLS policy using the USING (using_predicate_exp) clause. You can't modify a RLS policy with a WITH clause when running ALTER RLS POLICY.
- You can't query relations that have row-level security turned on if the values for any of the following configuration options don't match the default value of the session:
 - enable_case_sensitive_super_attribute
 - enable_case_sensitive_identifier
 - downcase_delimited_identifier

Consider resetting your session's configuration options if you attempt to query a relation with row-level security on and see the message "RLS protected relation does not support session level config on case sensitivity being different from its default value."

- When your provisioned cluster or serverless namespace has any row-level security policies, the following commands are blocked for regular users:

```
ALTER <current_user> SET enable_case_sensitive_super_attribute/  
enable_case_sensitive_identifier/downcase_delimited_identifier
```

When you create RLS policies, we recommend that you change the default configuration option settings for regular users to match the session's configuration option settings at the time the policy was created. Superusers and users with the ALTER USER privilege can do this by using parameter group settings or the ALTER USER command. For information about parameter groups, see [Amazon Redshift parameter groups](#) in the *Amazon Redshift Management Guide*. For information about the ALTER USER command, see [ALTER USER](#).

- Views and late-binding views with row-level security policies can't be replaced by regular users using the [CREATE VIEW](#) command. To replace views or LBVs with RLS policies, first detach any

RLS policies attached to them, replace the views or LBVs, and reattach the policies. Superusers and users with the `sys:secadmin` permission can use `CREATE VIEW` on views or LBVs with RLS policies without detaching the policies.

- Views with row-level security policies can't reference system tables and system views.
- A late-binding view that's referenced by a regular view can't be RLS protected.
- RLS-protected relations and nested data from data lakes can't be accessed in the same query.

Best practices for RLS performance

Following are best practices to ensure better performance from Amazon Redshift on tables protected by RLS.

Safety of operators and functions

When querying RLS-protected tables, the usage of certain operators or functions may lead to performance degradation. Amazon Redshift classifies operators and functions either as safe or unsafe for querying RLS-protected tables. A function or operator is classified as RLS-safe when it doesn't have any observable side-effects depending on the inputs. In particular, a RLS-safe function or operator can't be one of the following:

- Outputs an input value, or any value that is dependent on the input value, with or without an error message.
- Fails or returns errors that are dependent on the input value.

RLS-unsafe operators include:

- Arithmetic operators — `+`, `-`, `/`, `*`, `%`.
- Text operators — `LIKE` and `SIMILAR TO`.
- Cast operators.
- UDFs.

Use the following `SELECT` statement to check the safety of operators and functions.

```
SELECT proname, proc_is_qls_safe(oid) FROM pg_proc;
```

Amazon Redshift imposes restrictions on the order of evaluation of user predicates containing RLS-unsafe operators and functions when planning queries on RLS-protected tables. Queries referencing RLS-unsafe operators or functions might cause performance degradation when querying RLS-protected tables. Performance can degrade significantly when Amazon Redshift can't push RLS-unsafe predicates down to base table scans to take advantage of sort keys. For better performance, avoid queries using RLS-unsafe predicates that take advantage of a sort key. To verify that Amazon Redshift is able to push down operators and functions, you can use EXPLAIN statements in combination with the system permission EXPLAIN RLS.

Result caching

To reduce query runtime and improve system performance, Amazon Redshift caches the results of certain types of queries in the memory on the leader node.

Amazon Redshift uses cached results for a new query scanning RLS-protected tables when all the conditions for unprotected tables are true and when all of the following are true:

- The tables or views in the policy haven't been modified.
- The policy doesn't use a function that must be evaluated each time it's run, such as GETDATE or CURRENT_USER.

For better performance, avoid using policy predicates that don't satisfy the preceding conditions.

For more information about result caching in Amazon Redshift, see [Result caching](#).

Complex policies

For better performance, avoid using complex policies with subqueries that join multiple tables.

Row-level security end-to-end example

The following is an end-to-end example to illustrate how a superuser creates some users and roles. Then, a user with the secadmin role creates, attaches, detaches, and drops RLS policies. This example uses the tickit sample database. For more information, see [Load data from Amazon S3 to Amazon Redshift](#) in the *Amazon Redshift Getting Started Guide*.

```
-- Create users and roles referenced in the policy statements.  
CREATE ROLE analyst;  
CREATE ROLE consumer;  
CREATE ROLE dbadmin;
```

```
CREATE ROLE auditor;

Metadata security

Like Amazon Redshift's row-level security, metadata security gives you more granular control over your metadata. If metadata security is enabled for your provisioned cluster or serverless workgroup, users can see metadata for the objects for which they have viewing access. Metadata security lets you separate visibility based on your needs. For example, you can use a single data warehouse to centralize all of your data storage. However, if you store data for multiple sectors, managing security can become troublesome. With metadata security enabled, you can configure your visibility. Users of one sector can have more visibility over their objects, while you restrict viewing access to users of another sector. Metadata security supports all object types, such as schemas, tables, views, materialized views, stored procedures, user-defined functions, and machine learning models.

Users can see metadata of objects under the following circumstances:

- If object access is granted to the user.
- If object access is granted to a group or a role that the user is a part of.
- The object is public.
- The user is the owner of the database object.

To enable metadata security, use the [ALTER SYSTEM](#) command. The following is the syntax of how to use the ALTER SYSTEM command with metadata security.

```
ALTER SYSTEM SET metadata_security=[true|t|on|false|f|off];
```

When you enable metadata security, all users who have the necessary permissions can see the relevant metadata of objects that they have access to. If you want only certain users to be able to see metadata security, grant the ACCESS CATALOG permission to a role, and then assign the role to the user. For more information about using roles to better control security, see [Role-based access control](#).

The following example demonstrates how to grant the ACCESS CATALOG permission to a role, and then assigns the role to a user. For more information about granting permissions, see the [GRANT](#) command.

```
CREATE ROLE sample_metadata_viewer;  
  
GRANT ACCESS CATALOG TO ROLE sample_metadata_viewer;  
  
GRANT ROLE sample_metadata_viewer to salesadmin;
```

If you prefer to use already defined roles, the [system-defined roles](#) operator, secadmin, dba, and superuser all have the necessary permissions to view object metadata. By default, superusers can see the complete catalog.

```
GRANT ROLE operator to sample_user;
```

If you're using roles to control metadata security, you have access to all of the system views and functions that come with role-based access control. For example, you can query the [SVV_ROLES](#) view to see all roles. To see if a user is a member of a role or group, use the [USER_IS_MEMBER_OF](#) function. For a full list of SVV views, see [SVV metadata views](#). For a list of system information functions, see [System information functions](#).

Dynamic data masking

Overview

Using dynamic data masking (DDM) in Amazon Redshift, you can protect sensitive data in your data warehouse. You can manipulate how Amazon Redshift shows sensitive data to the user at query time, without transforming it in the database. You control access to data through masking policies that apply custom obfuscation rules to a given user or role. In that way, you can respond to changing privacy requirements without altering underlying data or editing SQL queries.

Dynamic data masking policies hide, obfuscate, or pseudonymize data that matches a given format. When attached to a table, the masking expression is applied to one or more of its columns. You can further modify masking policies to only apply them to certain users, or to user-defined roles that you can create with [Role-based access control \(RBAC\)](#). Additionally, you can apply DDM on the cell level by using conditional columns when creating your masking policy. For more information about conditional masking, see [Conditional dynamic data masking](#).

You can apply multiple masking policies with varying levels of obfuscation to the same column in a table and assign them to different roles. To avoid conflicts when you have different roles

with different policies applying to one column, you can set priorities for each application. In that way, you can control what data a given user or role can access. DDM policies can partially or completely redact data, or hash it by using user-defined functions written in SQL, Python, or with AWS Lambda. By masking data using hashes, you can apply joins on this data without access to potentially sensitive information.

SQL commands for managing dynamic data masking policies

You can perform the following actions to create, attach, detach, and delete dynamic data masking policies:

- To create a DDM policy, use the [CREATE MASKING POLICY](#) command.

The following is an example of creating a masking policy using a SHA-2 hash function.

```
CREATE MASKING POLICY hash_credit
WITH (credit_card varchar(256))
USING (sha2(credit_card + 'testSalt', 256));
```

- To alter an existing DDM policy, use the [ALTER MASKING POLICY](#) command.

The following is an example of altering an existing masking policy.

```
ALTER MASKING POLICY hash_credit
USING (sha2(credit_card + 'otherTestSalt', 256));
```

- To attach a DDM policy on a table to one or more users or roles, use the [ATTACH MASKING POLICY](#) command.

The following is an example of attaching a masking policy to a column/role pair.

```
ATTACH MASKING POLICY hash_credit
ON credit_cards (credit_card)
TO ROLE science_role
PRIORITY 30;
```

The `PRIORITY` clause determines which masking policy applies to a user session when multiple policies are attached to the same column. For example, if the user in the preceding example has another masking policy attached to the same credit card column with a priority of 20, `science_role`'s policy is the one that applies, as it has the higher priority of 30.

- To detach a DDM policy on a table from one or more users or roles, use the [DETACH MASKING POLICY](#) command.

The following is an example of detaching a masking policy from a column/role pair.

```
DETACH MASKING POLICY hash_credit
ON credit_cards(credit_card)
FROM ROLE science_role;
```

- To drop a DDM policy from all databases, use the [DROP MASKING POLICY](#) command.

The following is an example of dropping a masking policy from all databases.

```
DROP MASKING POLICY hash_credit;
```

Dynamic data masking policy hierarchy

When attaching multiple masking policies, consider the following:

- You can attach multiple masking policies to a single column.
- When multiple masking policies are applicable to a query, the highest priority policy attached to each respective column applies. Consider the following example.

```
ATTACH MASKING POLICY partial_hash
ON credit_cards(address, credit_card)
TO ROLE analytics_role
PRIORITY 20;
```

```
ATTACH MASKING POLICY full_hash
ON credit_cards(credit_card, ssn)
TO ROLE auditor_role
PRIORITY 30;
```

```
SELECT address, credit_card, ssn
FROM credit_cards;
```

When running the `SELECT` statement, a user with both the `analytics` and `auditor` roles sees the `address` column with the `partial_hash` masking policy applied. They see the credit card and

SSN columns with the `full_hash` masking policy applied because the `full_hash` policy has the higher priority on the credit card column.

- If you don't specify a priority when attaching a masking policy, the default priority is 0.
- You can't attach two policies to the same column with equal priority.
- You can't attach two policies to the same combination of user and column or role and column.
- When multiple masking policies are applicable along the same SUPER path while attached to the same user or role, only the highest priority attachment takes effect. Consider the following examples.

The first example shows two masking policies attached on the same path, with the higher priority policy taking effect.

```
ATTACH MASKING POLICY hide_name
ON employees(col_person.name)
TO PUBLIC
PRIORITY 20;

ATTACH MASKING POLICY hide_last_name
ON employees(col_person.name.last)
TO PUBLIC
PRIORITY 30;

--Only the hide_last_name policy takes effect.
SELECT employees.col_person.name FROM employees;
```

The second example shows two masking policies attached to different paths in the same SUPER object, with no conflict between the policies. Both attachments will apply at the same time.

```
ATTACH MASKING POLICY hide_first_name
ON employees(col_person.name.first)
TO PUBLIC
PRIORITY 20;

ATTACH MASKING POLICY hide_last_name
ON employees(col_person.name.last)
TO PUBLIC
PRIORITY 20;

--Both col_person.name.first and col_person.name.last are masked.
```

```
SELECT employees.col_person.name FROM employees;
```

To confirm which masking policy applies to a given user and column or role and column combination, users with the [sys:secadmin](#) role can look up the column/role or column/user pair in the [SVV_ATTACHED_MASKING_POLICY](#) system view. For more information, see [Dynamic data masking system views](#).

Using dynamic data masking with SUPER data type paths

Amazon Redshift supports attaching dynamic data masking policies to paths of SUPER type columns. For more information about the SUPER data type, see [Semistructured data in Amazon Redshift](#).

When attaching masking policies to paths of SUPER type columns, consider the following.

- When attaching a masking policy to a path on a column, that column must be defined as the SUPER data type. You can only apply masking policies to *scalar* values on the SUPER path. You can't apply masking policies to complex structures or arrays.
- You can apply different masking policies to multiple scalar values on a single SUPER column, as long as the SUPER paths don't conflict. For example, the SUPER paths `a.b` and `a.b.c` conflict because they are on the same path, with `a.b` being the parent of `a.b.c`. The SUPER paths `a.b.c` and `a.b.d` don't conflict.
- Amazon Redshift can't check that the paths that a masking policy attaches to exist in the data and are of the expected type until the policy is applied at user query runtime. For example, when you attach a masking policy that masks TEXT values to a SUPER path that contains an INT value, Amazon Redshift will attempt to cast the type of the value at the path.

In such situations, the behavior of Amazon Redshift at runtime depends on your configuration settings for querying SUPER objects. By default, Amazon Redshift is in lax mode, and will resolve missing paths and invalid casts as NULL for the given SUPER path. For more information about SUPER-related configuration settings, see [SUPER configurations](#).

- SUPER is a schemaless type, which means that Amazon Redshift can't confirm the existence of the value at a given SUPER path. If you attach a masking policy to a SUPER path that doesn't exist and Amazon Redshift is in lax mode, Amazon Redshift will resolve the path to a NULL value. We recommend that you consider the expected format of SUPER objects and the likelihood of them having unexpected attributes when attaching masking policies to paths of SUPER columns. If you think there might be an unexpected schema in your SUPER column, consider attaching

your masking policies directly to the SUPER column. You can use SUPER type information functions to check attributes and types, and using `OBJECT_TRANSFORM` to mask the values. For more information about SUPER type information functions, see [SUPER type information functions](#).

Examples

Attaching masking policies to SUPER paths

The following example attaches multiple masking policies onto multiple SUPER type paths in one column.

```
CREATE TABLE employees (  
    col_person SUPER  
);  
  
INSERT INTO employees  
VALUES  
    (  
        json_parse('  
            {  
                "name": {  
                    "first": "John",  
                    "last": "Doe"  
                },  
                "age": 25,  
                "ssn": "111-22-3333",  
                "company": "Company Inc."  
            }  
        ')  
    ),  
    (  
        json_parse('  
            {  
                "name": {  
                    "first": "Jane",  
                    "last": "Appleseed"  
                },  
                "age": 34,  
                "ssn": "444-55-7777",  
                "company": "Organization Org."  
            }  
        ')  
    )  
);
```

```
        ')
    )
;
GRANT ALL ON ALL TABLES IN SCHEMA "public" TO PUBLIC;

-- Create the masking policies.

-- This policy converts the given name to all uppercase letters.
CREATE MASKING POLICY mask_first_name
WITH(first_name TEXT)
USING ( UPPER(first_name) );

-- This policy replaces the given name with the fixed string 'XXXX'.
CREATE MASKING POLICY mask_last_name
WITH(last_name TEXT)
USING ( 'XXXX'::TEXT );

-- This policy rounds down the given age to the nearest 10.
CREATE MASKING POLICY mask_age
WITH(age INT)
USING ( (FLOOR(age::FLOAT / 10) * 10)::INT );

-- This policy converts the first five digits of the given SSN to 'XXX-XX'.
CREATE MASKING POLICY mask_ssn
WITH(ssn TEXT)
USING ( 'XXX-XX-'::TEXT || SUBSTRING(ssn::TEXT FROM 8 FOR 4) );

-- Attach the masking policies to the employees table.
ATTACH MASKING POLICY mask_first_name
ON employees(col_person.name.first)
TO PUBLIC;

ATTACH MASKING POLICY mask_last_name
ON employees(col_person.name.last)
TO PUBLIC;

ATTACH MASKING POLICY mask_age
ON employees(col_person.age)
TO PUBLIC;

ATTACH MASKING POLICY mask_ssn
ON employees(col_person.ssn)
TO PUBLIC;
```

```
-- Verify that your masking policies are attached.
SELECT
    policy_name,
    TABLE_NAME,
    priority,
    input_columns,
    output_columns
FROM
    svv_attached_masking_policy;

    policy_name | table_name | priority |          input_columns          |
    output_columns
-----+-----+-----+-----+-----
+-----+-----+-----+-----+-----
mask_age      | employees |         0 | ["col_person.\"age\""]          |
["col_person.\"age\""]
mask_first_name | employees |         0 | ["col_person.\"name\".\"first\""] |
["col_person.\"name\".\"first\""]
mask_last_name | employees |         0 | ["col_person.\"name\".\"last\""]  |
["col_person.\"name\".\"last\""]
mask_ssn      | employees |         0 | ["col_person.\"ssn\""]          |
["col_person.\"ssn\""]
(4 rows)

-- Observe the masking policies taking effect.
SELECT col_person FROM employees ORDER BY col_person.age;

-- This result is formatted for ease of reading.
    col_person
-----
{
    "name": {
        "first": "JOHN",
        "last": "XXXX"
    },
    "age": 20,
    "ssn": "XXX-XX-3333",
    "company": "Company Inc."
}
{
    "name": {
        "first": "JANE",
        "last": "XXXX"
    },

```

```

    "age": 30,
    "ssn": "XXX-XX-7777",
    "company": "Organization Org."
}

```

Following are some examples of invalid masking policy attachments to SUPER paths.

```

-- This attachment fails because there is already a policy
-- with equal priority attached to employees.name.last, which is
-- on the same SUPER path as employees.name.
ATTACH MASKING POLICY mask_ssn
ON employees(col_person.name)
TO PUBLIC;
ERROR: DDM policy "mask_last_name" is already attached on relation "employees" column
"col_person."name"."last"" with same priority

-- Create a masking policy that masks DATETIME objects.
CREATE MASKING POLICY mask_date
WITH(INPUT DATETIME)
USING ( INPUT );

-- This attachment fails because SUPER type columns can't contain DATETIME objects.
ATTACH MASKING POLICY mask_date
ON employees(col_person.company)
TO PUBLIC;
ERROR: cannot attach masking policy for output of type "timestamp without time zone"
to column "col_person."company"" of type "super

```

Following is an example of attaching a masking policy to a SUPER path that doesn't exist. By default, Amazon Redshift will resolve the path to NULL.

```

ATTACH MASKING POLICY mask_first_name
ON employees(col_person.not_exists)
TO PUBLIC;

SELECT col_person FROM employees LIMIT 1;

-- This result is formatted for ease of reading.
    col_person
-----
{
  "name": {
    "first": "JOHN",

```

```
    "last": "XXXX"
  },
  "age": 20,
  "ssn": "XXX-XX-3333",
  "company": "Company Inc.",
  "not_exists": null
}
```

Conditional dynamic data masking

You can mask data at the cell level by creating masking policies with conditional expressions in the masking expression. For example, you can create a masking policy that applies different masks to a value, depending on another column's value in that row.

The following is an example of using conditional data masking to create and attach a masking policy that partially redacts credit card numbers involved in fraud, while completely hiding all other credit card numbers. You must be a superuser or have the [sys:secadmin](#) role to run this example.

```
--Create an analyst role.
CREATE ROLE analyst;

--Create a credit card table. The table contains an is_fraud boolean column,
--which is TRUE if the credit card number in that row was involved in a fraudulent
transaction.
CREATE TABLE credit_cards (id INT, is_fraud BOOLEAN, credit_card_number VARCHAR(16));

--Create a function that partially redacts credit card numbers.
CREATE FUNCTION REDACT_CREDIT_CARD (credit_card VARCHAR(16))
RETURNS VARCHAR(16) IMMUTABLE
AS $$
    import re
    regexp = re.compile("^[0-9]{6})[0-9]{5,6}([0-9]{4})")

    match = regexp.search(credit_card)
    if match != None:
        first = match.group(1)
        last = match.group(2)
    else:
        first = "000000"
        last = "0000"
```

```

    return "{}XXXXX{}".format(first, last)
$$ LANGUAGE plpythonu;

--Create a masking policy that partially redacts credit card numbers if the is_fraud
value for that row is TRUE,
--and otherwise blanks out the credit card number completely.
CREATE MASKING POLICY card_number_conditional_mask
    WITH (fraudulent BOOLEAN, pan varchar(16))
    USING (CASE WHEN fraudulent THEN REDACT_CREDIT_CARD(pan)
            ELSE Null
            END);

--Attach the masking policy to the credit_cards/analyst table/role pair.
ATTACH MASKING POLICY card_number_conditional_mask ON credit_cards (credit_card_number)
    USING (is_fraud, credit_card_number)
    TO ROLE analyst PRIORITY 100;

```

Dynamic data masking system views

Superusers, users with the `sys:operator` role, and users with the `ACCESS SYSTEM TABLE` permission can access the following DDM-related system views.

- [SVV_MASKING_POLICY](#)

Use `SVV_MASKING_POLICY` to view all masking policies created on the cluster or workgroup.

- [SVV_ATTACHED_MASKING_POLICY](#)

Use `SVV_ATTACHED_MASKING_POLICY` to view all the relations and users or roles with policies attached on the currently connected database.

- [SYS_APPLIED_MASKING_POLICY_LOG](#)

Use `SYS_APPLIED_MASKING_POLICY_LOG` to trace the application of masking policies on queries that reference DDM-protected relations.

Following are some examples of the information that you can find using system views.

```

--Select all policies associated with specific users, as opposed to roles
SELECT policy_name,
       schema_name,
       table_name,
       grantee

```

```
FROM svv_attached_masking_policy
WHERE grantee_type = 'user';

--Select all policies attached to a specific user
SELECT policy_name,
       schema_name,
       table_name,
       grantee
FROM svv_attached_masking_policy
WHERE grantee = 'target_grantee_name';

--Select all policies attached to a given table
SELECT policy_name,
       schema_name,
       table_name,
       grantee
FROM svv_attached_masking_policy
WHERE table_name = 'target_table_name'
      AND schema_name = 'target_schema_name';

--Select the highest priority policy attachment for a given role
SELECT samp.policy_name,
       samp.priority,
       samp.grantee,
       smp.policy_expression
FROM svv_masking_policy AS smp
JOIN svv_attached_masking_policy AS samp
      ON samp.policy_name = smp.policy_name
WHERE
      samp.grantee_type = 'role' AND
      samp.policy_name = mask_get_policy_for_role_on_column(
        'target_schema_name',
        'target_table_name',
        'target_column_name',
        'target_role_name')
ORDER BY samp.priority desc
LIMIT 1;

--See which policy a specific user will see on a specific column in a given relation
SELECT samp.policy_name,
       samp.priority,
       samp.grantee,
       smp.policy_expression
FROM svv_masking_policy AS smp
```

```
JOIN svv_attached_masking_policy AS samp
  ON samp.policy_name = smp.policy_name
WHERE
  samp.grantee_type = 'role' AND
  samp.policy_name = mask_get_policy_for_user_on_column(
    'target_schema_name',
    'target_table_name',
    'target_column_name',
    'target_user_name')
ORDER BY samp.priority desc;

--Select all policies attached to a given relation.
SELECT policy_name,
schema_name,
relation_name,
database_name
FROM sys_applied_masking_policy_log
WHERE relation_name = 'relation_name'
AND schema_name = 'schema_name';
```

Considerations when using dynamic data masking

When using dynamic data masking, consider the following:

- When querying objects created from tables, such as views, users will see results based on their own masking policies, not the policies of the user who created the objects. For example, a user with the analyst role querying a view created by a secadmin would see results with masking policies attached to the analyst role.
- To prevent the EXPLAIN command from potentially exposing sensitive masking policy filters, only users with the SYS_EXPLAIN_DDM permission can see masking policies applied in EXPLAIN outputs. Users don't have the SYS_EXPLAIN_DDM permission by default.

The following is the syntax for granting the permission to a role.

```
GRANT EXPLAIN MASKING TO ROLE rolename
```

For more information about the EXPLAIN command, see [EXPLAIN](#).

- Users with different roles can see differing results based on the filter conditions or join conditions used. For example, running a SELECT command on a table using a specific column

value will fail if the user running the command has a masking policy applied that obfuscates that column.

- DDM policies must be applied ahead of any predicate operations, or projections. Masking policies can include the following:
 - Low cost constant operations such as converting a value to null
 - Moderate cost operations such as HMAC hashing
 - High cost operations such as calls to external Lambda user defined functions

As such, we recommend that you use simple masking expressions when possible.

- You can use DDM policies for roles with row-level security policies, but note that RLS policies are applied before DDM. A dynamic data masking expression won't be able to read a row that was protected by RLS. For more information about RLS, see [Row-level security](#).
- When using the [COPY](#) command to copy from parquet to protected target tables, you should explicitly specify columns in the COPY statement. For more information about mapping columns with COPY, see [Column mapping options](#).
- DDM policies can't attach to the following relations:
 - System tables and catalogs
 - External tables
 - Datasharing tables
 - Materialized views
 - Cross-DB relations
 - Temporary tables
 - Correlated queries
- DDM policies can contain lookup tables. Lookup tables can be present in the USING clause. The following relation types can't be used as lookup tables:
 - System tables and catalogs
 - External tables
 - Datasharing tables
 - Views, materialized views, and late-binding views
 - Cross-DB relations
 - Temporary tables
 - [Correlated queries](#)

Following is an example of attaching a masking policy to a lookup table.

```
--Create a masking policy referencing a lookup table
CREATE MASKING POLICY lookup_mask_credit_card WITH (credit_card TEXT) USING (
  CASE
    WHEN
      credit_card IN (SELECT credit_card_lookup FROM credit_cards_lookup)
    THEN '000000XXXX0000'
    ELSE REDACT_CREDIT_CARD(credit_card)
  END
);

--Provides access to the lookup table via a policy attached to a role
GRANT SELECT ON TABLE credit_cards_lookup TO MASKING POLICY lookup_mask_credit_card;
```

- You can't attach a masking policy that would produce an output incompatible with the target column's type and size. For example, you can't attach a masking policy that outputs a 12 character long string to a VARCHAR(10) column. Amazon Redshift supports the following exceptions:
 - A masking policy with the input type INTN can be attached to a policy with size INTM as long as $M < N$. For example, a BIGINT (INT8) input policy can be attached to a smallint (INT4) column.
 - A masking policy with the input type NUMERIC or DECIMAL can always be attached to a FLOAT column.
- DDM policies can't be used with data sharing. If the datashare's data producer attaches a DDM policy to a table in the datashare, the table becomes inaccessible to users from the data consumer who are trying to query the table. Tables with DDM policies attached can't be added to a datashare.
- You can't query relations that have attached DDM policies if your values for any of the following configuration options don't match the default value of the session:
 - `enable_case_sensitive_super_attribute`
 - `enable_case_sensitive_identifier`
 - `downcase_delimited_identifier`

Consider resetting your session's configuration options if you attempt to query a relation with a DDM policy attached and see the message "DDM protected relation does not support session level config on case sensitivity being different from its default value."

- When your provisioned cluster or serverless namespace has any dynamic data masking policies, the following commands are blocked for regular users:

```
ALTER <current_user> SET enable_case_sensitive_super_attribute/  
enable_case_sensitive_identifier/downcase_delimited_identifier
```

When you create DDM policies, we recommend that you change the default configuration option settings for regular users to match the session's configuration option settings at the time the policy was created. Superusers and users with the ALTER USER privilege can do this by using parameter group settings or the ALTER USER command. For information about parameter groups, see [Amazon Redshift parameter groups](#) in the *Amazon Redshift Management Guide*. For information about the ALTER USER command, see [ALTER USER](#).

- Views and late-binding views with attached DDM policies can't be replaced by regular users using the [CREATE VIEW](#) command. To replace views or LBVs with DDM policies, first detach any DDM policies attached to them, replace the views or LBVs, and reattach the policies. Superusers and users with the sys:secadmin permission can use CREATE VIEW on views or LBVs with DDM policies without detaching the policies.
- Views with attached DDM policies can't reference system tables and views. Late-binding views can reference system tables and views.
- Late-binding views with attached DDM policies can't reference nested data in data lakes, such as JSON documents.
- Late-binding views can't have DDM policies attached if that late-binding view is referenced by any view.
- DDM policies attached to late-binding views are attached by column name. At query time, Amazon Redshift validates that all masking policies attached to the late-binding view have been applied successfully, and that the late-binding view's output column type matches the types in the attached masking policies. If the validation fails, Amazon Redshift returns an error for the query.
- You can use customized session context variables when creating DDM policies. The following example sets session context variables for a DDM policy.

```
-- Set a customized context variable.  
SELECT set_config('app.city', 'XXXX', FALSE);  
  
-- Create a MASKING policy using current_setting() to get the value of a customized  
context variable.
```

```
CREATE MASKING POLICY city_mask
WITH (city VARCHAR(30))
USING (current_setting('app.city')::VARCHAR(30));

-- Attach the policy on the target table to one or more roles.
ATTACH MASKING POLICY city_mask
ON tickit_users_redshift(city)
TO ROLE analyst, ROLE dbadmin;
```

For details on how to set and retrieve customized session context variables, go to [SET](#), [SET_CONFIG](#), [SHOW](#), [CURRENT_SETTING](#), and [RESET](#). For more information on modifying the server configuration in general, go to [Modifying the server configuration](#).

Important

When using session context variables within DDM policies, the security policy is reliant on the user or role that invokes the policy. Be careful to avoid security vulnerabilities when using session context variables in DDM policies.

Dynamic data masking end-to-end example

The following is an end-to-end example showing how you can create and attach masking policies to a column. These policies let users access a column and see different values, depending on the degree of obfuscation in the policies attached to their roles. You must be a superuser or have the [sys:secadmin](#) role to run this example.

Creating a masking policy

First, create a table and populate it with credit card values.

```
--create the table
CREATE TABLE credit_cards (
  customer_id INT,
  credit_card TEXT
);

--populate the table with sample values
INSERT INTO credit_cards
VALUES
  (100, '4532993817514842'),
```

```
(100, '4716002041425888'),
(102, '5243112427642649'),
(102, '6011720771834675'),
(102, '6011378662059710'),
(103, '373611968625635')
;

--run GRANT to grant permission to use the SELECT statement on the table
GRANT SELECT ON credit_cards TO PUBLIC;

--create two users
CREATE USER regular_user WITH PASSWORD '1234Test!';

CREATE USER analytics_user WITH PASSWORD '1234Test!';

--create the analytics_role role and grant it to analytics_user
--regular_user does not have a role
CREATE ROLE analytics_role;

GRANT ROLE analytics_role TO analytics_user;
```

Next, create a masking policy to apply to the analytics role.

```
--create a masking policy that fully masks the credit card number
CREATE MASKING POLICY mask_credit_card_full
WITH (credit_card VARCHAR(256))
USING ('000000XXXX0000'::TEXT);

--create a user-defined function that partially obfuscates credit card data
CREATE FUNCTION REDACT_CREDIT_CARD (credit_card TEXT)
RETURNS TEXT IMMUTABLE
AS $$
    import re
    regexp = re.compile("^[0-9]{6}[0-9]{5,6}([0-9]{4})")

    match = regexp.search(credit_card)
    if match != None:
        first = match.group(1)
        last = match.group(2)
    else:
        first = "000000"
        last = "0000"
```

```
    return "{}XXXXX{}".format(first, last)
$$ LANGUAGE plpythonu;

--create a masking policy that applies the REDACT_CREDIT_CARD function
CREATE MASKING POLICY mask_credit_card_partial
WITH (credit_card VARCHAR(256))
USING (REDACT_CREDIT_CARD(credit_card));

--confirm the masking policies using the associated system views
SELECT * FROM svv_masking_policy;

SELECT * FROM svv_attached_masking_policy;
```

Attaching a masking policy

Attach the masking policies to the credit card table.

```
--attach mask_credit_card_full to the credit card table as the default policy
--all users will see this masking policy unless a higher priority masking policy is
  attached to them or their role
ATTACH MASKING POLICY mask_credit_card_full
ON credit_cards(credit_card)
TO PUBLIC;

--attach mask_credit_card_partial to the analytics role
--users with the analytics role can see partial credit card information
ATTACH MASKING POLICY mask_credit_card_partial
ON credit_cards(credit_card)
TO ROLE analytics_role
PRIORITY 10;

--confirm the masking policies are applied to the table and role in the associated
  system view
SELECT * FROM svv_attached_masking_policy;

--confirm the full masking policy is in place for normal users by selecting from the
  credit card table as regular_user
SET SESSION AUTHORIZATION regular_user;

SELECT * FROM credit_cards;

--confirm the partial masking policy is in place for users with the analytics role by
  selecting from the credit card table as analytics_user
```

```
SET SESSION AUTHORIZATION analytics_user;

SELECT * FROM credit_cards;
```

Altering a masking policy

The following section shows how to alter a dynamic data masking policy.

```
--reset session authorization to the default
RESET SESSION AUTHORIZATION;

--alter the mask_credit_card_full policy
ALTER MASKING POLICY mask_credit_card_full
USING ('00000000000000'::TEXT);

--confirm the full masking policy is in place after altering the policy, and that
  results are altered from '000000XXXX0000' to '0000000000000000'
SELECT * FROM credit_cards;
```

Detaching and dropping a masking policy

The following section shows how to detach and drop masking policies by removing all dynamic data masking policies from the table.

```
--reset session authorization to the default
RESET SESSION AUTHORIZATION;

--detach both masking policies from the credit_cards table
DETACH MASKING POLICY mask_credit_card_full
ON credit_cards(credit_card)
FROM PUBLIC;

DETACH MASKING POLICY mask_credit_card_partial
ON credit_cards(credit_card)
FROM ROLE analytics_role;

--drop both masking policies
DROP MASKING POLICY mask_credit_card_full;

DROP MASKING POLICY mask_credit_card_partial;
```

Scoped permissions

Scoped permissions let you grant permissions to a user or role on all objects of a type within a database or schema. Users and roles with scoped permissions have the specified permissions on all current and future objects within the database or schema.

You can view the scope of database-level scoped permissions in [SVV_DATABASE_PRIVILEGES](#). You can view the scope of schema-level scoped permissions in [SVV_SCHEMA_PRIVILEGES](#).

For more information on applying scoped permissions, see [GRANT](#) and [REVOKE](#).

Considerations for using scoped permissions

When using scoped permissions, consider the following:

- You can use scoped permissions to grant or revoke permissions on a database or schema scope to or from a specified user or role.
- You can't grant scoped permissions to user groups.
- Granting or revoking scoped permissions changes permissions for all current and future objects in the scope.
- Scoped permissions and object-level permissions operate independently of each other. For example, a user will maintain permissions on a table in both of the following cases.
 - The user is granted SELECT on the table schema1.table1 and SELECT scoped permission on schema1. The user then has SELECT revoked for all tables in schema schema1. The user retains SELECT on schema1.table1.
 - The user is granted SELECT on the table schema1.table1 and SELECT scoped permission on schema1. The user then has SELECT revoked for schema1.table1. The user retains SELECT on schema1.table1.
- To grant or revoke scoped permissions, you must meet one of the following criteria:
 - Superusers.
 - Users with the grant option for that permission. For more information on grant options, go to the WITH GRANT OPTION parameter in [GRANT](#).
- Scoped permissions can only be granted to or revoked from objects for the connected database, or from databases imported from a datashare.
- You can use scoped permissions to set the default permissions on a database created from a datashare. A consumer-side datashare user who is granted scoped permissions on a shared

database will automatically gain those permissions for any new object added to the datashare on the producer side.

- Producers can grant scoped permissions on objects within a schema to a datashare. (preview)

SQL reference

Topics

- [Amazon Redshift SQL](#)
- [Using SQL](#)
- [SQL commands](#)
- [SQL functions reference](#)
- [Reserved words](#)

Amazon Redshift SQL

Topics

- [SQL functions supported on the leader node](#)
- [Amazon Redshift and PostgreSQL](#)

Amazon Redshift is built around industry-standard SQL, with added functionality to manage very large datasets and support high-performance analysis and reporting of those data.

Note

The maximum size for a single Amazon Redshift SQL statement is 16 MB.

SQL functions supported on the leader node

Some Amazon Redshift queries are distributed and run on the compute nodes, and other queries run exclusively on the leader node.

The leader node distributes SQL to the compute nodes whenever a query references user-created tables or system tables (tables with an STL or STV prefix and system views with an SVL or SVV prefix). A query that references only catalog tables (tables with a PG prefix, such as PG_TABLE_DEF, which reside on the leader node) or that does not reference any tables, runs exclusively on the leader node.

Some Amazon Redshift SQL functions are supported only on the leader node and are not supported on the compute nodes. A query that uses a leader-node function must run exclusively on the leader node, not on the compute nodes, or it will return an error.

The documentation for each function that must run exclusively on the leader node includes a note stating that the function will return an error if it references user-defined tables or Amazon Redshift system tables. See [Leader node-only functions](#) for a list of functions that run exclusively on the leader node.

Examples

The following examples use the sample TICKIT database. For more information on the sample database, go to [Sample database](#).

CURRENT_SCHEMA

The CURRENT_SCHEMA function is a leader-node only function. In this example, the query does not reference a table, so it runs exclusively on the leader node.

```
select current_schema();
```

```
current_schema
-----
public
```

In the next example, the query references a system catalog table, so it runs exclusively on the leader node.

```
select * from pg_table_def
where schemaname = current_schema() limit 1;
```

```
 schemaname | tablename | column | type | encoding | distkey | sortkey | notnull
-----+-----+-----+-----+-----+-----+-----+-----
 public    | category | catid  | smallint | none      | t       | 1       | t
```

In the next example, the query references an Amazon Redshift system table that resides on the compute nodes, so it returns an error.

```
select current_schema(), userid from users;
```

```
INFO: Function "current_schema()" not supported.
```

```
ERROR: Specified types or functions (one per INFO message) not supported on Amazon
Redshift tables.
```

SUBSTR

SUBSTR is also a leader-node only function. In the following example, the query runs exclusive on the leader node because it does not reference a table.

```
SELECT SUBSTR('amazon', 5);
```

```
+-----+
| substr |
+-----+
| on     |
+-----+
```

In the following example, the query references a table that resides on the compute nodes. This results in an error.

```
SELECT SUBSTR(catdesc, 1) FROM category LIMIT 1;
```

```
ERROR: SUBSTR() function is not supported (Hint: use SUBSTRING instead)
```

To successfully run the previous query, use [SUBSTRING](#).

```
SELECT SUBSTRING(catdesc, 1) FROM category LIMIT 1;
```

```
+-----+
|          substring          |
+-----+
| National Basketball Association |
+-----+
```

FACTORIAL()

FACTORIAL() is a leader-node only function. In the following example, the query runs exclusive on the leader node because it does not reference a table.

```
SELECT FACTORIAL(5);
```

```
factorial
-----
```

In the following example, the query references a table that resides on the compute nodes. This results in an error when run using query editor v2.

```
create table t(a int);
insert into t values (5);
select factorial(a) from t;
```

```
ERROR: Specified types or functions (one per INFO message) not supported on Redshift tables.
```

```
Info: Function "factorial(bigint)" not supported.
```

Amazon Redshift and PostgreSQL

Topics

- [Amazon Redshift and PostgreSQL JDBC and ODBC](#)
- [Features that are implemented differently](#)
- [Unsupported PostgreSQL features](#)
- [Unsupported PostgreSQL data types](#)
- [Unsupported PostgreSQL functions](#)

Amazon Redshift is based on PostgreSQL. Amazon Redshift and PostgreSQL have a number of very important differences that you must be aware of as you design and develop your data warehouse applications.

Amazon Redshift is specifically designed for online analytic processing (OLAP) and business intelligence (BI) applications, which require complex queries against large datasets. Because it addresses very different requirements, the specialized data storage schema and query execution engine that Amazon Redshift uses are completely different from the PostgreSQL implementation. For example, where online transaction processing (OLTP) applications typically store data in rows, Amazon Redshift stores data in columns, using specialized data compression encodings for optimum memory usage and disk I/O. Some PostgreSQL features that are suited to smaller-scale OLTP processing, such as secondary indexes and efficient single-row data manipulation operations, have been omitted to improve performance.

See [Amazon Redshift architecture](#) for a detailed explanation of the Amazon Redshift data warehouse system architecture.

PostgreSQL 9.x includes some features that are not supported in Amazon Redshift. In addition, there are important differences between Amazon Redshift SQL and PostgreSQL that you must be aware of. This section highlights the differences between Amazon Redshift and PostgreSQL and provides guidance for developing a data warehouse that takes full advantage of the Amazon Redshift SQL implementation.

Amazon Redshift and PostgreSQL JDBC and ODBC

Because Amazon Redshift is based on PostgreSQL, we previously recommended using JDBC4 Postgresql driver version 8.4.703 and psqLODBC version 9.x drivers. If you are currently using those drivers, we recommend moving to the new Amazon Redshift-specific drivers going forward. For more information about drivers and configuring connections, see [JDBC and ODBC Drivers for Amazon Redshift](#) in the *Amazon Redshift Management Guide*.

To avoid client-side out-of-memory errors when retrieving large data sets using JDBC, you can enable your client to fetch data in batches by setting the JDBC fetch size parameter. For more information, see [Setting the JDBC fetch size parameter](#).

Amazon Redshift does not recognize the JDBC maxRows parameter. Instead, specify a [LIMIT](#) clause to restrict the result set. You can also use an [OFFSET](#) clause to skip to a specific starting point in the result set.

Features that are implemented differently

Many Amazon Redshift SQL language elements have different performance characteristics and use syntax and semantics and that are quite different from the equivalent PostgreSQL implementation.

Important

Do not assume that the semantics of elements that Amazon Redshift and PostgreSQL have in common are identical. Make sure to consult the *Amazon Redshift Developer Guide* [SQL commands](#) to understand the often subtle differences.

One example in particular is the [VACUUM](#) command, which is used to clean up and reorganize tables. VACUUM functions differently and uses a different set of parameters than the PostgreSQL version. See [Vacuuming tables](#) for more about information about using VACUUM in Amazon Redshift.

Often, database management and administration features and tools are different as well. For example, Amazon Redshift maintains a set of system tables and views that provide information about how the system is functioning. See [System tables and views](#) for more information.

The following list includes some examples of SQL features that are implemented differently in Amazon Redshift.

- [CREATE TABLE](#)

Amazon Redshift does not support tablespaces, table partitioning, inheritance, and certain constraints. The Amazon Redshift implementation of CREATE TABLE enables you to define the sort and distribution algorithms for tables to optimize parallel processing.

Amazon Redshift Spectrum supports table partitioning using the [CREATE EXTERNAL TABLE](#) command.

- [ALTER TABLE](#)

Only a subset of ALTER COLUMN actions are supported.

ADD COLUMN supports adding only one column in each ALTER TABLE statement.

- [COPY](#)

The Amazon Redshift COPY command is highly specialized to enable the loading of data from Amazon S3 buckets and Amazon DynamoDB tables and to facilitate automatic compression. See the [Loading data in Amazon Redshift](#) section and the COPY command reference for details.

- [VACUUM](#)

The parameters for VACUUM are entirely different. For example, the default VACUUM operation in PostgreSQL simply reclaims space and makes it available for re-use; however, the default VACUUM operation in Amazon Redshift is VACUUM FULL, which reclaims disk space and resorts all rows.

- Trailing spaces in VARCHAR values are ignored when string values are compared. For more information, see [Significance of trailing blanks](#).

Unsupported PostgreSQL features

These PostgreSQL features are not supported in Amazon Redshift.

⚠ Important

Do not assume that the semantics of elements that Amazon Redshift and PostgreSQL have in common are identical. Make sure to consult the *Amazon Redshift Developer Guide* [SQL commands](#) to understand the often subtle differences.

- The query tool *psql* is unsupported. The [Amazon Redshift RSQL](#) client is supported.
- Table partitioning (range and list partitioning)
- Tablespaces
- Constraints
 - Unique
 - Foreign key
 - Primary key
 - Check constraints
 - Exclusion constraints

Unique, primary key, and foreign key constraints are permitted, but they are informational only. They are not enforced by the system, but they are used by the query planner.

- Database roles
- Inheritance
- PostgreSQL system columns

Amazon Redshift SQL does not implicitly define system columns. However, the following PostgreSQL system column names cannot be used as names of user-defined columns: `oid`, `tableoid`, `xmin`, `cmin`, `xmax`, `cmax`, and `ctid`. For more information, see <https://www.postgresql.org/docs/8.0/static/ddl-system-columns.html>.

- Indexes
- NULLS clause in Window functions
- Collations

Amazon Redshift does not support locale-specific or user-defined collation sequences. See [Collation sequences](#).

- Value expressions

- Subscripted expressions
- Array constructors
- Row constructors
- Triggers
- Management of External Data (SQL/MED)
- Table functions
- VALUES list used as constant tables
- Sequences
- Full text search
- The RULE and TRIGGER permissions.

Amazon Redshift grants or revokes these permissions when you run GRANT ALL or REVOKE ALL, but the presence or absence of the RULE and TRIGGER permissions doesn't affect the grantee's access permissions in any way.

Unsupported PostgreSQL data types

Generally, if a query attempts to use an unsupported data type, including explicit or implicit casts, it will return an error. However, some queries that use unsupported data types will run on the leader node but not on the compute nodes. See [SQL functions supported on the leader node](#).

For a list of the supported data types, see [Data types](#).

These PostgreSQL data types are not supported in Amazon Redshift.

- Arrays
- BIT, BIT VARYING
- BYTEA
- Composite Types
- Date/Time Types
- Enumerated Types
- Geometric Types
- HSTORE
- JSON

- Network Address Types
- Numeric Types
 - SERIAL, BIGSERIAL, SMALLSERIAL
 - MONEY
- Object Identifier Types
- Pseudo-Types
- Range Types
- Special Character Types
 - "char" – A single-byte internal type (where the data type named char is enclosed in quotation marks).
 - name – An internal type for object names.

For more information about these types, see [Special Character Types](#) in the PostgreSQL documentation.

- Text Search Types
- TXID_SNAPSHOT
- UUID
- XML

Unsupported PostgreSQL functions

Many functions that are not excluded have different semantics or usage. For example, some supported functions will run only on the leader node. Also, some unsupported functions will not return an error when run on the leader node. The fact that these functions do not return an error in some cases should not be taken to indicate that the function is supported by Amazon Redshift.

Important

Do not assume that the semantics of elements that Amazon Redshift and PostgreSQL have in common are identical. Make sure to consult the *Amazon Redshift Database Developer Guide* [SQL commands](#) to understand the often subtle differences.

For more information, see [SQL functions supported on the leader node](#).

These PostgreSQL functions are not supported in Amazon Redshift.

- Access privilege inquiry functions

Using SQL

Topics

- [SQL reference conventions](#)
- [Basic elements](#)
- [Expressions](#)
- [Conditions](#)

The SQL language consists of commands and functions that you use to work with databases and database objects. The language also enforces rules regarding the use of data types, expressions, and literals.

SQL reference conventions

This section explains the conventions that are used to write the syntax for the SQL expressions, commands, and functions described in the SQL reference section.

Character	Description
CAPS	Words in capital letters are key words.
[]	Brackets denote optional arguments. Multiple arguments in brackets indicate that you can choose any number of the arguments. In addition, arguments in brackets on separate lines indicate that the Amazon Redshift parser expects the arguments to be in the order that they are listed in the syntax. For an example, see SELECT .
{ }	Braces indicate that you are required to choose one of the arguments inside the braces.
	Pipes indicate that you can choose between the arguments.
<i>italics</i>	Words in italics indicate placeholders. You must insert the appropriate value in place of the word in italics.
...	An ellipsis indicates that you can repeat the preceding element.
'	Words in single quotation marks indicate that you must type the quotes.

Basic elements

Topics

- [Names and identifiers](#)
- [Literals](#)
- [Nulls](#)
- [Data types](#)
- [Collation sequences](#)

This section covers the rules for working with database object names, literals, nulls, and data types.

Names and identifiers

Names identify database objects, including tables and columns, as well as users and passwords. The terms *name* and *identifier* can be used interchangeably. There are two types of identifiers,

standard identifiers and quoted or delimited identifiers. Identifiers must consist of only UTF-8 printable characters. ASCII letters in standard and delimited identifiers are case-insensitive and are folded to lowercase in the database. In query results, column names are returned as lowercase by default. To return column names in uppercase, set the [describe_field_name_in_uppercase](#) configuration parameter to **true**.

Standard identifiers

Standard SQL identifiers adhere to a set of rules and must:

- Begin with an ASCII single-byte alphabetic character or underscore character, or a UTF-8 multibyte character two to four bytes long.
- Subsequent characters can be ASCII single-byte alphanumeric characters, underscores, or dollar signs, or UTF-8 multibyte characters two to four bytes long.
- Be between 1 and 127 bytes in length, not including quotation marks for delimited identifiers.
- Contain no quotation marks and no spaces.
- Not be a reserved SQL key word.

Delimited identifiers

Delimited identifiers (also known as quoted identifiers) begin and end with double quotation marks ("). If you use a delimited identifier, you must use the double quotation marks for every reference to that object. The identifier can contain any standard UTF-8 printable characters other than the double quotation mark itself. Therefore, you can create column or table names that include otherwise illegal characters, such as spaces or the percent symbol.

ASCII letters in delimited identifiers are case-insensitive and are folded to lowercase. To use a double quotation mark in a string, you must precede it with another double quotation mark character.

Case-sensitive identifiers

Case-sensitive identifiers (also known as mixed-case identifiers) can contain both uppercase and lowercase letters. To use case-sensitive identifiers, you can set the configuration `enable_case_sensitive_identifier` to `true`. You can set this configuration for the cluster or for a session. For more information, see [Default parameter values](#) in the *Amazon Redshift Management Guide* and [enable_case_sensitive_identifier](#).

System column names

The following PostgreSQL system column names can't be used as column names in user-defined columns. For more information, see <https://www.postgresql.org/docs/8.0/static/dml-system-columns.html>.

- oid
- tableoid
- xmin
- cmin
- xmax
- cmax
- ctid

Examples

This table shows examples of delimited identifiers, the resulting output, and a discussion:

Syntax	Result	Discussion
"group"	group	GROUP is a reserved word, so usage of it within an identifier requires double quotation marks.
""WHERE""	"where"	WHERE is also a reserved word. To include quotation marks in the string, escape each double quotation mark character with additional double quotation mark characters.
"This name"	this name	Double quotation marks are required to preserve the space.
"This ""IS IT""	this "is it"	The quotation marks surrounding IS IT must each be preceded by an extra quotation mark in order to become part of the name.

To create a table named group with a column named this "is it":

```
create table "group" (
  "This ""IS IT"" char(10));
```

The following queries return the same result:

```
select "This ""IS IT""
from "group";

this "is it"
-----
(0 rows)
```

```
select "this ""is it""
from "group";

this "is it"
-----
(0 rows)
```

The following fully qualified table.column syntax also returns the same result:

```
select "group"."this ""is it""
from "group";

this "is it"
-----
(0 rows)
```

The following CREATE TABLE command creates a table with a slash in a column name:

```
create table if not exists city_slash_id(
  "city/id" integer not null,
  state char(2) not null);
```

Literals

A literal or constant is a fixed data value, composed of a sequence of characters or a numeric constant. Amazon Redshift supports several types of literals, including:

- Numeric literals for integer, decimal, and floating-point numbers. For more information, see [Integer and floating-point literals](#).
- Character literals, also referred to as strings, character strings, or character constants
- Datetime and interval literals, used with datetime data types. For more information, see [Date, time, and timestamp literals](#) and [Interval data types and literals](#).

Nulls

If a column in a row is missing, unknown, or not applicable, it is a null value or is said to contain null. Nulls can appear in fields of any data type that are not restricted by primary key or NOT NULL constraints. A null is not equivalent to the value zero or to an empty string.

Any arithmetic expression containing a null always evaluates to a null. All operators except concatenation return a null when given a null argument or operand.

To test for nulls, use the comparison conditions IS NULL and IS NOT NULL. Because null represents a lack of data, a null is not equal or unequal to any value or to another null.

Data types

Topics

- [Multibyte characters](#)
- [Numeric types](#)
- [Character types](#)
- [Datetime types](#)
- [Boolean type](#)
- [HLLSKETCH type](#)
- [SUPER type](#)
- [VARBYTE type](#)
- [Type compatibility and conversion](#)

Each value that Amazon Redshift stores or retrieves has a data type with a fixed set of associated properties. Data types are declared when tables are created. A data type constrains the set of values that a column or argument can contain.

The following table lists the data types that you can use in Amazon Redshift tables.

Data type	Aliases	Description
SMALLINT	INT2	Signed two-byte integer
INTEGER	INT, INT4	Signed four-byte integer
BIGINT	INT8	Signed eight-byte integer
DECIMAL	NUMERIC	Exact numeric of selectable precision
REAL	FLOAT4	Single precision floating-point number
DOUBLE PRECISION	FLOAT8, FLOAT	Double precision floating-point number
CHAR	CHARACTER, NCHAR, BPCHAR	Fixed-length character string
VARCHAR	CHARACTER VARYING, NVARCHAR, TEXT	Variable-length character string with a user-defined limit
DATE		Calendar date (year, month, day)
TIME	TIME WITHOUT TIME ZONE	Time of day
TIMETZ	TIME WITH TIME ZONE	Time of day with time zone
TIMESTAMP	TIMESTAMP WITHOUT TIME ZONE	Date and time (without time zone)
TIMESTAMPTZ	TIMESTAMP WITH TIME ZONE	Date and time (with time zone)
INTERVAL YEAR TO MONTH		Time duration in year to month order

Data type	Aliases	Description
INTERVAL DAY TO SECOND		Time duration in day to second order
BOOLEAN	BOOL	Logical Boolean (true/false)
HLLSKETCH		Type used with HyperLogLog sketches.
SUPER		A superset data type that encompasses all scalar types of Amazon Redshift including complex types such as ARRAY and STRUCTS.
VARBYTE	VARBINARY, BINARY VARYING	Variable-length binary value
GEOMETRY		Spatial data
GEOGRAPHY		Spatial data

Note

For information about unsupported data types, such as "char" (notice that char is enclosed in quotation marks), see [Unsupported PostgreSQL data types](#).

Multibyte characters

The VARCHAR data type supports UTF-8 multibyte characters up to a maximum of four bytes. Five-byte or longer characters are not supported. To calculate the size of a VARCHAR column that contains multibyte characters, multiply the number of characters by the number of bytes per character. For example, if a string has four Chinese characters, and each character is three bytes long, then you will need a VARCHAR(12) column to store the string.

The VARCHAR data type doesn't support the following invalid UTF-8 codepoints:

0xD800 – 0xDFFF (Byte sequences: ED A0 80 – ED BF BF)

The CHAR data type doesn't support multibyte characters.

Numeric types

Topics

- [Integer types](#)
- [DECIMAL or NUMERIC type](#)
- [Notes about using 128-bit DECIMAL or NUMERIC columns](#)
- [Floating-Point types](#)
- [Computations with numeric values](#)
- [Integer and floating-point literals](#)
- [Examples with numeric types](#)

Numeric data types include integers, decimals, and floating-point numbers.

Integer types

Use the SMALLINT, INTEGER, and BIGINT data types to store whole numbers of various ranges. You cannot store values outside of the allowed range for each type.

Name	Storage	Range
SMALLINT or INT2	2 bytes	-32768 to +32767
INTEGER, INT, or INT4	4 bytes	-2147483648 to +2147483647
BIGINT or INT8	8 bytes	-9223372036854775808 to 9223372036854775807

DECIMAL or NUMERIC type

Use the DECIMAL or NUMERIC data type to store values with a *user-defined precision*. The DECIMAL and NUMERIC keywords are interchangeable. In this document, *decimal* is the preferred term for

this data type. The term *numeric* is used generically to refer to integer, decimal, and floating-point data types.

Storage	Range
Variable, up to 128 bits for uncompressed DECIMAL types.	128-bit signed integers with up to 38 digits of precision.

Define a DECIMAL column in a table by specifying a *precision* and *scale*:

```
decimal(precision, scale)
```

precision

The total number of significant digits in the whole value: the number of digits on both sides of the decimal point. For example, the number 48.2891 has a precision of 6 and a scale of 4. The default precision, if not specified, is 18. The maximum precision is 38.

If the number of digits to the left of the decimal point in an input value exceeds the precision of the column minus its scale, the value cannot be copied into the column (or inserted or updated). This rule applies to any value that falls outside the range of the column definition. For example, the allowed range of values for a `numeric(5, 2)` column is -999.99 to 999.99.

scale

The number of decimal digits in the fractional part of the value, to the right of the decimal point. Integers have a scale of zero. In a column specification, the scale value must be less than or equal to the precision value. The default scale, if not specified, is 0. The maximum scale is 37.

If the scale of an input value that is loaded into a table is greater than the scale of the column, the value is rounded to the specified scale. For example, the PRICEPAID column in the SALES table is a DECIMAL(8,2) column. If a DECIMAL(8,4) value is inserted into the PRICEPAID column, the value is rounded to a scale of 2.

```
insert into sales
values (0, 8, 1, 1, 2000, 14, 5, 4323.8951, 11.00, null);

select pricepaid, salesid from sales where salesid=0;
```

```

pricepaid | salesid
-----+-----
4323.90 |      0
(1 row)

```

However, results of explicit casts of values selected from tables are not rounded.

Note

The maximum positive value that you can insert into a DECIMAL(19,0) column is 9223372036854775807 ($2^{63} - 1$). The maximum negative value is -9223372036854775808. For example, an attempt to insert the value 9999999999999999999 (19 nines) will cause an overflow error. Regardless of the placement of the decimal point, the largest string that Amazon Redshift can represent as a DECIMAL number is 9223372036854775807. For example, the largest value that you can load into a DECIMAL(19,18) column is 9.223372036854775807.

These rules are because DECIMAL values with 19 or fewer significant digits of precision are stored internally as 8-byte integers, while DECIMAL values with 20 to 38 significant digits of precision are stored as 16-byte integers.

Notes about using 128-bit DECIMAL or NUMERIC columns

Do not arbitrarily assign maximum precision to DECIMAL columns unless you are certain that your application requires that precision. 128-bit values use twice as much disk space as 64-bit values and can slow down query execution time.

Floating-Point types

Use the REAL and DOUBLE PRECISION data types to store numeric values with *variable precision*. These types are *inexact* types, meaning that some values are stored as approximations, such that storing and returning a specific value may result in slight discrepancies. If you require exact storage and calculations (such as for monetary amounts), use the DECIMAL data type.

REAL represents the single-precision floating point format, according to the IEEE Standard 754 for Binary Floating-Point Arithmetic. It has a precision of about 6 digits, and a range of around 1E-37 to 1E+37. You can also specify this data type as FLOAT4.

DOUBLE PRECISION represents the double-precision floating point format, according to the IEEE Standard 754 for Binary Floating-Point Arithmetic. It has a precision of about 15 digits, and a range of around 1E-307 to 1E+308. You can also specify this data type as FLOAT or FLOAT8.

In addition to ordinary numeric values, the floating-point types have several special values. Use single quotation marks around these values when using them in SQL:

- NaN – not-a-number
- Infinity – infinity
- -Infinity – negative infinity

For example, to insert not-a-number in column `day_charge` of table `customer_activity` run the following SQL:

```
insert into customer_activity(day_charge) values('NaN');
```

Computations with numeric values

In this context, *computation* refers to binary mathematical operations: addition, subtraction, multiplication, and division. This section describes the expected return types for these operations, as well as the specific formula that is applied to determine precision and scale when DECIMAL data types are involved.

When numeric values are computed during query processing, you might encounter cases where the computation is impossible and the query returns a numeric overflow error. You might also encounter cases where the scale of computed values varies or is unexpected. For some operations, you can use explicit casting (type promotion) or Amazon Redshift configuration parameters to work around these problems.

For information about the results of similar computations with SQL functions, see [Aggregate functions](#).

Return types for computations

Given the set of numeric data types supported in Amazon Redshift, the following table shows the expected return types for addition, subtraction, multiplication, and division operations. The first column on the left side of the table represents the first operand in the calculation, and the top row represents the second operand.

Operand 1	Operand 2	Return type
INT2	INT2	INT2
INT2	INT4	INT4
INT2	INT8	INT8
INT2	DECIMAL	DECIMAL
INT2	FLOAT4	FLOAT8
INT2	FLOAT8	FLOAT8
INT4	INT4	INT4
INT4	INT8	INT8
INT4	DECIMAL	DECIMAL
INT4	FLOAT4	FLOAT8
INT4	FLOAT8	FLOAT8
INT8	INT8	INT8
INT8	DECIMAL	DECIMAL
INT8	FLOAT4	FLOAT8
INT8	FLOAT8	FLOAT8
DECIMAL	DECIMAL	DECIMAL
DECIMAL	FLOAT4	FLOAT8
DECIMAL	FLOAT8	FLOAT8
FLOAT4	FLOAT8	FLOAT8
FLOAT8	FLOAT8	FLOAT8

Precision and scale of computed DECIMAL results

The following table summarizes the rules for computing resulting precision and scale when mathematical operations return DECIMAL results. In this table, p1 and s1 represent the precision and scale of the first operand in a calculation and p2 and s2 represent the precision and scale of the second operand. (Regardless of these calculations, the maximum result precision is 38, and the maximum result scale is 38.)

Operation	Result precision and scale
+ or -	Scale = $\max(s1, s2)$ Precision = $\max(p1-s1, p2-s2)+1+scale$
*	Scale = $s1+s2$ Precision = $p1+p2+1$
/	Scale = $\max(4, s1+p2-s2+1)$ Precision = $p1-s1+ s2+scale$

For example, the PRICEPAID and COMMISSION columns in the SALES table are both DECIMAL(8,2) columns. If you divide PRICEPAID by COMMISSION (or vice versa), the formula is applied as follows:

```
Precision = 8-2 + 2 + max(4, 2+8-2+1)
= 6 + 2 + 9 = 17
```

```
Scale = max(4, 2+8-2+1) = 9
```

```
Result = DECIMAL(17,9)
```

The following calculation is the general rule for computing the resulting precision and scale for operations performed on DECIMAL values with set operators such as UNION, INTERSECT, and EXCEPT or functions such as COALESCE and DECODE:

```
Scale = max(s1, s2)
Precision = min(max(p1-s1, p2-s2)+scale, 19)
```

For example, a DEC1 table with one DECIMAL(7,2) column is joined with a DEC2 table with one DECIMAL(15,3) column to create a DEC3 table. The schema of DEC3 shows that the column becomes a NUMERIC(15,3) column.

```
create table dec3 as select * from dec1 union select * from dec2;
```

Result

```
select "column", type, encoding, distkey, sortkey
from pg_table_def where tablename = 'dec3';
```

column	type	encoding	distkey	sortkey
c1	numeric(15,3)	none	f	0

In the above example, the formula is applied as follows:

```
Precision = min(max(7-2,15-3) + max(2,3), 19)
= 12 + 3 = 15
```

```
Scale = max(2,3) = 3
```

```
Result = DECIMAL(15,3)
```

Notes on division operations

For division operations, divide-by-zero conditions return errors.

The scale limit of 100 is applied after the precision and scale are calculated. If the calculated result scale is greater than 100, division results are scaled as follows:

- Precision = precision - (scale - max_scale)
- Scale = max_scale

If the calculated precision is greater than the maximum precision (38), the precision is reduced to 38, and the scale becomes the result of: $\max((38 + \text{scale} - \text{precision}), \min(4, 100))$

Overflow conditions

Overflow is checked for all numeric computations. DECIMAL data with a precision of 19 or less is stored as 64-bit integers. DECIMAL data with a precision that is greater than 19 is stored as 128-bit integers. The maximum precision for all DECIMAL values is 38, and the maximum scale is 37. Overflow errors occur when a value exceeds these limits, which apply to both intermediate and final result sets:

- Explicit casting results in runtime overflow errors when specific data values do not fit the requested precision or scale specified by the cast function. For example, you cannot cast all values from the PRICEPAID column in the SALES table (a DECIMAL(8,2) column) and return a DECIMAL(7,3) result:

```
select pricepaid::decimal(7,3) from sales;
ERROR: Numeric data overflow (result precision)
```

This error occurs because *some* of the larger values in the PRICEPAID column cannot be cast.

- Multiplication operations produce results in which the result scale is the sum of the scale of each operand. If both operands have a scale of 4, for example, the result scale is 8, leaving only 10 digits for the left side of the decimal point. Therefore, it is relatively easy to run into overflow conditions when multiplying two large numbers that both have significant scale.

The following example results in an overflow error.

```
SELECT CAST(1 AS DECIMAL(38, 20)) * CAST(10 AS DECIMAL(38, 20));
ERROR: 128 bit numeric data overflow (multiplication)
```

You can work around the overflow error by using division instead of multiplication. Use the following example to divide by 1 divided by the original divisor.

```
SELECT CAST(1 AS DECIMAL(38, 20)) / (1 / CAST(10 AS DECIMAL(38, 20)));
+-----+
| ?column? |
+-----+
| 10      |
+-----+
```

Numeric calculations with INTEGER and DECIMAL types

When one of the operands in a calculation has an INTEGER data type and the other operand is DECIMAL, the INTEGER operand is implicitly cast as a DECIMAL:

- INT2 (SMALLINT) is cast as DECIMAL(5,0)
- INT4 (INTEGER) is cast as DECIMAL(10,0)
- INT8 (BIGINT) is cast as DECIMAL(19,0)

For example, if you multiply SALES.COMMISSION, a DECIMAL(8,2) column, and SALES.QTYSOLD, a SMALLINT column, this calculation is cast as:

```
DECIMAL(8,2) * DECIMAL(5,0)
```

Integer and floating-point literals

Literals or constants that represent numbers can be integer or floating-point.

Integer literals

An integer constant is a sequence of the digits 0-9, with an optional positive (+) or negative (-) sign preceding the digits.

Syntax

```
[ + | - ] digit ...
```

Examples

Valid integers include the following:

```
23  
-555  
+17
```

Floating-point literals

Floating-point literals (also referred to as decimal, numeric, or fractional literals) are sequences of digits that can include a decimal point, and optionally the exponent marker (e).

Syntax

```
[ + | - ] digit ... [ . ] [ digit ... ]  
[ e | E [ + | - ] digit ... ]
```

Arguments

e | E

e or E indicates that the number is specified in scientific notation.

Examples

Valid floating-point literals include the following:

```
3.14159  
-37.  
2.0e19  
-2E-19
```

Examples with numeric types

CREATE TABLE statement

The following CREATE TABLE statement demonstrates the declaration of different numeric data types:

```
create table film (  
  film_id integer,  
  language_id smallint,  
  original_language_id smallint,  
  rental_duration smallint default 3,  
  rental_rate numeric(4,2) default 4.99,  
  length smallint,  
  replacement_cost real default 25.00);
```

Attempt to insert an integer that is out of range

The following example attempts to insert the value 33000 into a SMALLINT column.

```
insert into film(language_id) values(33000);
```

The range for SMALLINT is -32768 to +32767, so Amazon Redshift returns an error.

```
An error occurred when executing the SQL command:  
insert into film(language_id) values(33000)  
  
ERROR: smallint out of range [SQL State=22003]
```

Insert a decimal value into an integer column

The following example inserts the a decimal value into an INT column.

```
insert into film(language_id) values(1.5);
```

This value is inserted but rounded up to the integer value 2.

Insert a decimal that succeeds because its scale is rounded

The following example inserts a decimal value that has higher precision than the column.

```
insert into film(rental_rate) values(35.512);
```

In this case, the value 35.51 is inserted into the column.

Attempt to insert a decimal value that is out of range

In this case, the value 350.10 is out of range. The number of digits for values in DECIMAL columns is equal to the column's precision minus its scale (4 minus 2 for the RENTAL_RATE column). In other words, the allowed range for a DECIMAL(4, 2) column is -99.99 through 99.99.

```
insert into film(rental_rate) values (350.10);  
ERROR: numeric field overflow  
DETAIL: The absolute value is greater than or equal to 10^2 for field with precision  
4, scale 2.
```

Insert variable-precision values into a REAL column

The following example inserts variable-precision values into a REAL column.

```
insert into film(replacement_cost) values(1999999.99);  
  
insert into film(replacement_cost) values(1999.99);
```

```
select replacement_cost from film;
```

```
+-----+
| replacement_cost |
+-----+
| 2000000          |
| 1999.99          |
+-----+
```

The value 1999999.99 is converted to 2000000 to meet the precision requirement for the REAL column. The value 1999.99 is loaded as is.

Character types

Topics

- [Storage and ranges](#)
- [CHAR or CHARACTER](#)
- [VARCHAR or CHARACTER VARYING](#)
- [NCHAR and NVARCHAR types](#)
- [TEXT and BPCHAR types](#)
- [Significance of trailing blanks](#)
- [Examples with character types](#)

Character data types include CHAR (character) and VARCHAR (character varying).

Storage and ranges

CHAR and VARCHAR data types are defined in terms of bytes, not characters. A CHAR column can only contain single-byte characters, so a CHAR(10) column can contain a string with a maximum length of 10 bytes. A VARCHAR can contain multibyte characters, up to a maximum of four bytes per character. For example, a VARCHAR(12) column can contain 12 single-byte characters, 6 two-byte characters, 4 three-byte characters, or 3 four-byte characters.

Name	Storage	Range (width of column)
CHAR, CHARACTER or NCHAR	Length of string, including trailing blanks (if any)	4096 bytes

Name	Storage	Range (width of column)
VARCHAR, CHARACTER VARYING, or NVARCHAR	4 bytes + total bytes for characters, where each character can be 1 to 4 bytes.	65535 bytes (64K -1)
BPCHAR	Converted to fixed-length CHAR(256).	256 bytes
TEXT	Converted to VARCHAR(256).	260 bytes

Note

The CREATE TABLE syntax supports the MAX keyword for character data types. For example:

```
create table test(col1 varchar(max));
```

The MAX setting defines the width of the column as 4096 bytes for CHAR or 65535 bytes for VARCHAR.

CHAR or CHARACTER

Use a CHAR or CHARACTER column to store fixed-length strings. These strings are padded with blanks, so a CHAR(10) column always occupies 10 bytes of storage.

```
char(10)
```

A CHAR column without a length specification results in a CHAR(1) column.

VARCHAR or CHARACTER VARYING

Use a VARCHAR or CHARACTER VARYING column to store variable-length strings with a fixed limit. These strings are not padded with blanks, so a VARCHAR(120) column consists of a maximum of 120 single-byte characters, 60 two-byte characters, 40 three-byte characters, or 30 four-byte characters.

```
varchar(120)
```

If you use the VARCHAR data type without a length specifier in a CREATE TABLE statement, the default length is 256. If used in an expression, the size of the output is determined using the input expression (up to 65535).

NCHAR and NVARCHAR types

You can create columns with the NCHAR and NVARCHAR types (also known as NATIONAL CHARACTER and NATIONAL CHARACTER VARYING types). These types are converted to CHAR and VARCHAR types, respectively, and are stored in the specified number of bytes.

An NCHAR column without a length specification is converted to a CHAR(1) column.

An NVARCHAR column without a length specification is converted to a VARCHAR(256) column.

TEXT and BPCHAR types

You can create an Amazon Redshift table with a TEXT column, but it is converted to a VARCHAR(256) column that accepts variable-length values with a maximum of 256 characters.

You can create an Amazon Redshift column with a BPCHAR (blank-padded character) type, which Amazon Redshift converts to a fixed-length CHAR(256) column.

Significance of trailing blanks

Both CHAR and VARCHAR data types store strings up to n bytes in length. An attempt to store a longer string into a column of these types results in an error, unless the extra characters are all spaces (blanks), in which case the string is truncated to the maximum length. If the string is shorter than the maximum length, CHAR values are padded with blanks, but VARCHAR values store the string without blanks.

Trailing blanks in CHAR values are always semantically insignificant. They are disregarded when you compare two CHAR values, not included in LENGTH calculations, and removed when you convert a CHAR value to another string type.

Trailing spaces in VARCHAR and CHAR values are treated as semantically insignificant when values are compared.

Length calculations return the length of VARCHAR character strings with trailing spaces included in the length. Trailing blanks are not counted in the length for fixed-length character strings.

Examples with character types

CREATE TABLE statement

The following CREATE TABLE statement demonstrates the use of VARCHAR and CHAR data types:

```
create table address(  
  address_id integer,  
  address1 varchar(100),  
  address2 varchar(50),  
  district varchar(20),  
  city_name char(20),  
  state char(2),  
  postal_code char(5)  
);
```

The following examples use this table.

Trailing blanks in variable-length character strings

Because ADDRESS1 is a VARCHAR column, the trailing blanks in the second inserted address are semantically insignificant. In other words, these two inserted addresses *match*.

```
insert into address(address1) values('9516 Magnolia Boulevard');  
  
insert into address(address1) values('9516 Magnolia Boulevard ');
```

```
select count(*) from address  
where address1='9516 Magnolia Boulevard';
```

```
count  
-----  
2  
(1 row)
```

If the ADDRESS1 column were a CHAR column and the same values were inserted, the COUNT(*) query would recognize the character strings as the same and return 2.

Results of the LENGTH function

The LENGTH function recognizes trailing blanks in VARCHAR columns:

```
select length(address1) from address;
```

```
length
-----
23
25
(2 rows)
```

A value of Augusta in the CITY_NAME column, which is a CHAR column, would always return a length of 7 characters, regardless of any trailing blanks in the input string.

Values that exceed the length of the column

Character strings are not truncated to fit the declared width of the column:

```
insert into address(city_name) values('City of South San Francisco');
ERROR: value too long for type character(20)
```

A workaround for this problem is to cast the value to the size of the column:

```
insert into address(city_name)
values('City of South San Francisco'::char(20));
```

In this case, the first 20 characters of the string (City of South San Fr) would be loaded into the column.

Datetime types

Topics

- [Storage and ranges](#)
- [DATE](#)
- [TIME](#)

- [TIMETZ](#)
- [TIMESTAMP](#)
- [TIMESTAMPTZ](#)
- [Examples with datetime types](#)
- [Date, time, and timestamp literals](#)
- [Interval data types and literals](#)

Datetime data types include DATE, TIME, TIMETZ, TIMESTAMP, and TIMESTAMPTZ.

Storage and ranges

Name	Storage	Range	Resolution
DATE	4 bytes	4713 BC to 294276 AD	1 day
TIME	8 bytes	00:00:00 to 24:00:00	1 microsecond
TIMETZ	8 bytes	00:00:00+1459 to 00:00:00+1459	1 microsecond
TIMESTAMP	8 bytes	4713 BC to 294276 AD	1 microsecond
TIMESTAMP TZ	8 bytes	4713 BC to 294276 AD	1 microsecond

DATE

Use the DATE data type to store simple calendar dates without timestamps.

TIME

TIME is an alias of TIME WITHOUT TIME ZONE.

Use the TIME data type to store the time of day.

TIME columns store values with up to a maximum of six digits of precision for fractional seconds.

By default, TIME values are Coordinated Universal Time (UTC) in both user tables and Amazon Redshift system tables.

TIMETZ

TIMETZ is an alias of TIME WITH TIME ZONE.

Use the TIMETZ data type to store the time of day with a time zone.

TIMETZ columns store values with up to a maximum of six digits of precision for fractional seconds.

By default, TIMETZ values are UTC in both user tables and Amazon Redshift system tables.

TIMESTAMP

TIMESTAMP is an alias of TIMESTAMP WITHOUT TIME ZONE.

Use the TIMESTAMP data type to store complete timestamp values that include the date and the time of day.

TIMESTAMP columns store values with up to a maximum of six digits of precision for fractional seconds.

If you insert a date into a TIMESTAMP column, or a date with a partial timestamp value, the value is implicitly converted into a full timestamp value. This full timestamp value has default values (00) for missing hours, minutes, and seconds. Time zone values in input strings are ignored.

By default, TIMESTAMP values are UTC in both user tables and Amazon Redshift system tables.

TIMESTAMPTZ

TIMESTAMPTZ is an alias of TIMESTAMP WITH TIME ZONE.

Use the TIMESTAMPTZ data type to input complete timestamp values that include the date, the time of day, and a time zone. When an input value includes a time zone, Amazon Redshift uses the time zone to convert the value to UTC and stores the UTC value.

To view a list of supported time zone names, run the following command.

```
select pg_timezone_names();
```

To view a list of supported time zone abbreviations, run the following command.

```
select pg_timezone_abbrevs();
```

You can also find current information about time zones in the [IANA Time Zone Database](#).

The following table has examples of time zone formats.

Format	Example
dd mon hh:mi:ss yyyy tz	17 Dec 07:37:16 1997 PST
mm/dd/yyyy hh:mi:ss.ss tz	12/17/1997 07:37:16.00 PST
mm/dd/yyyy hh:mi:ss.ss tz	12/17/1997 07:37:16.00 US/Pacific
yyyy-mm-dd hh:mi:ss+/-tz	1997-12-17 07:37:16-08
dd.mm.yyyy hh:mi:ss tz	17.12.1997 07:37:16.00 PST

TIMESTAMPTZ columns store values with up to a maximum of six digits of precision for fractional seconds.

If you insert a date into a TIMESTAMPTZ column, or a date with a partial timestamp, the value is implicitly converted into a full timestamp value. This full timestamp value has default values (00) for missing hours, minutes, and seconds.

TIMESTAMPTZ values are UTC in user tables.

Examples with datetime types

Following, you can find examples for working with datetime types supported by Amazon Redshift.

Date examples

The following examples insert dates that have different formats and display the output.

```
create table datetable (start_date date, end_date date);
```

```
insert into datetable values ('2008-06-01','2008-12-31');
```

```
insert into datetable values ('Jun 1,2008','20081231');
```

```
select * from datetable order by 1;
```

```
start_date | end_date
```

```
-----
2008-06-01 | 2008-12-31
2008-06-01 | 2008-12-31
```

If you insert a timestamp value into a DATE column, the time portion is ignored and only the date is loaded.

Time examples

The following examples insert TIME and TIMETZ values that have different formats and display the output.

```
create table timetable (start_time time, end_time timetz);
```

```
insert into timetable values ('19:11:19', '20:41:19 UTC');
insert into timetable values ('191119', '204119 UTC');
```

```
select * from timetable order by 1;
start_time | end_time
-----
19:11:19 | 20:41:19+00
19:11:19 | 20:41:19+00
```

Time stamp examples

If you insert a date into a TIMESTAMP or TIMESTAMPTZ column, the time defaults to midnight. For example, if you insert the literal 20081231, the stored value is 2008-12-31 00:00:00.

To change the time zone for the current session, use the [SET](#) command to set the [timezone](#) configuration parameter.

The following example inserts timestamps that have different formats and display the resulting table.

```
create table tstamp(timeofday timestamp, timeofdaytz timestamptz);

insert into tstamp values('Jun 1,2008 09:59:59', 'Jun 1,2008 09:59:59 EST' );
insert into tstamp values('Dec 31,2008 18:20', 'Dec 31,2008 18:20');
insert into tstamp values('Jun 1,2008 09:59:59 EST', 'Jun 1,2008 09:59:59');

SELECT * FROM tstamp;
```

```

+-----+-----+
|     timeofday      |     timeofdaytz      |
+-----+-----+
| 2008-06-01 09:59:59 | 2008-06-01 14:59:59+00 |
| 2008-12-31 18:20:00 | 2008-12-31 18:20:00+00 |
| 2008-06-01 09:59:59 | 2008-06-01 09:59:59+00 |
+-----+-----+

```

Date, time, and timestamp literals

Following are rules for working with date, time, and timestamp literals supported by Amazon Redshift.

Dates

The following input dates are all valid examples of literal date values for the DATE data type that you can load into Amazon Redshift tables. The default MDY `DateStyle` mode is assumed to be in effect. This mode means that the month value precedes the day value in strings such as 1999-01-08 and 01/02/00.

Note

A date or timestamp literal must be enclosed in quotation marks when you load it into a table.

Input date	Full date
January 8, 1999	January 8, 1999
1999-01-08	January 8, 1999
1/8/1999	January 8, 1999
01/02/00	January 2, 2000
2000-Jan-31	January 31, 2000
Jan-31-2000	January 31, 2000

Input date	Full date
31-Jan-2000	January 31, 2000
20080215	February 15, 2008
080215	February 15, 2008
2008.366	December 31, 2008 (the three-digit part of date must be between 001 and 366)

Times

The following input times are all valid examples of literal time values for the TIME and TIMETZ data types that you can load into Amazon Redshift tables.

Input times	Description (of time part)
04:05:06.789	4:05 AM and 6.789 seconds
04:05:06	4:05 AM and 6 seconds
04:05	4:05 AM exactly
040506	4:05 AM and 6 seconds
04:05 AM	4:05 AM exactly; AM is optional
04:05 PM	4:05 PM exactly; the hour value must be less than 12
16:05	4:05 PM exactly

Timestamps

The following input timestamps are all valid examples of literal time values for the TIMESTAMP and TIMESTAMPTZ data types that you can load into Amazon Redshift tables. All of the valid date literals can be combined with the following time literals.

Input timestamps (concatenated dates and times)	Description (of time part)
20080215 04:05:06.789	4:05 AM and 6.789 seconds
20080215 04:05:06	4:05 AM and 6 seconds
20080215 04:05	4:05 AM exactly
20080215 040506	4:05 AM and 6 seconds
20080215 04:05 AM	4:05 AM exactly; AM is optional
20080215 04:05 PM	4:05 PM exactly; the hour value must be less than 12
20080215 16:05	4:05 PM exactly
20080215	Midnight (by default)

Special datetime values

The following special values can be used as datetime literals and as arguments to date functions. They require single quotation marks and are converted to regular timestamp values during query processing.

Special value	Description
<code>now</code>	Evaluates to the start time of the current transaction and returns a timestamp with microsecond precision.
<code>today</code>	Evaluates to the appropriate date and returns a timestamp with zeroes for the time parts.
<code>tomorrow</code>	Evaluates to the appropriate date and returns a timestamp with zeroes for the time parts.

Special value	Description
yesterday	Evaluates to the appropriate date and returns a timestamp with zeroes for the time parts.

The following examples show how `now` and `today` work with the `DATEADD` function.

```
select dateadd(day,1,'today');
```

```
date_add
-----
2009-11-17 00:00:00
(1 row)
```

```
select dateadd(day,1,'now');
```

```
date_add
-----
2009-11-17 10:45:32.021394
(1 row)
```

Interval data types and literals

You can use an interval data type to store durations of time in units such as, seconds, minutes, hours, days, months, and years. Interval data types and literals can be used in datetime calculations, such as, adding intervals to dates and timestamps, summing intervals, and subtracting an interval from a date or timestamp. Interval literals can be used as input values to interval data type columns in a table.

Syntax of interval data type

To specify an interval data type to store a duration of time in years and months:

```
INTERVAL year_to_month_qualifier
```

To specify an interval data type to store a duration in days, hours, minutes, and seconds:

```
INTERVAL day_to_second_qualifier [ (fractional_precision) ]
```

Syntax of interval literal

To specify an interval literal to define a duration of time in years and months:

```
INTERVAL quoted-string year_to_month_qualifier
```

To specify an interval literal to define a duration in days, hours, minutes, and seconds:

```
INTERVAL quoted-string day_to_second_qualifier [ (fractional_precision) ]
```

Arguments

quoted-string

Specifies a positive or negative numeric value specifying a quantity and the datetime unit as an input string. If the *quoted-string* contains only a numeric, then Amazon Redshift determines the units from the *year_to_month_qualifier* or *day_to_second_qualifier*. For example, '23' MONTH represents 1 year 11 months, '-2' DAY represents -2 days 0 hours 0 minutes 0.0 seconds, '1-2' MONTH represents 1 year 2 months, and '13 day 1 hour 1 minute 1.123 seconds' SECOND represents 13 days 1 hour 1 minute 1.123 seconds. For more information about output formats of an interval, see [Interval styles](#).

year_to_month_qualifier

Specifies the range of the interval. If you use a qualifier and create an interval with time units smaller than the qualifier, Amazon Redshift truncates and discards the smaller parts of the interval. Valid values for *year_to_month_qualifier* are:

- YEAR
- MONTH
- YEAR TO MONTH

day_to_second_qualifier

Specifies the range of the interval. If you use a qualifier and create an interval with time units smaller than the qualifier, Amazon Redshift truncates and discards the smaller parts of the interval. Valid values for *day_to_second_qualifier* are:

- DAY
- HOUR
- MINUTE

- SECOND
- DAY TO HOUR
- DAY TO MINUTE
- DAY TO SECOND
- HOUR TO MINUTE
- HOUR TO SECOND
- MINUTE TO SECOND

The output of the INTERVAL literal is truncated to the smallest INTERVAL component specified. For example, when using a MINUTE qualifier, Amazon Redshift discards the time units smaller than MINUTE.

```
select INTERVAL '1 day 1 hour 1 minute 1.123 seconds' MINUTE
```

The resulting value is truncated to '1 day 01:01:00'.

fractional_precision

Optional parameter that specifies the number of fractional digits allowed in the interval. The *fractional_precision* argument should only be specified if your interval contains SECOND. For example, SECOND(3) creates an interval that allows only three fractional digits, such as 1.234 seconds. The maximum number of fractional digits is six.

The session configuration `interval_forbid_composite_literals` determines whether an error is returned when an interval is specified with both YEAR TO MONTH and DAY TO SECOND parts. For more information, see [interval_forbid_composite_literals](#).

Interval arithmetic

You can use interval values with other datetime values to perform arithmetic operations. The following tables describe the available operations and what data type results from each operation.

Note

Operations that can produce both date and timestamp results do so based on the smallest unit of time involved in the equation. For example, when you add an interval to a date the result is a date if it is a YEAR TO MONTH interval, and a timestamp if it is a DAY TO SECOND interval.

Operations where the first operand is an `interval` produce the following results for the given second operand:

Operator	Date	Timestamp	Interval	Numeric
-	N/A	N/A	Interval	N/A
+	Date	Date/Timestamp	Interval	N/A
*	N/A	N/A	N/A	Interval
/	N/A	N/A	N/A	Interval

Operations where the first operand is a date produce the following results for the given second operand:

Operator	Date	Timestamp	Interval	Numeric
-	Numeric	Interval	Date/Timestamp	Date
+	N/A	N/A	N/A	N/A

Operations where the first operand is a timestamp produce the following results for the given second operand:

Operator	Date	Timestamp	Interval	Numeric
-	Numeric	Interval	Timestamp	Timestamp
+	N/A	N/A	N/A	N/A

Interval styles

You can use the SQL [the section called "SET"](#) command to change the output display format of your interval values. When you use the interval data type in SQL, cast it to text to see the expected interval style, for example, `YEAR TO MONTH::text`. Available values to SET the `IntervalStyle` value are:

- `postgres` – follows PostgreSQL style. This is the default.
- `postgres_verbose` – follows PostgreSQL verbose style.
- `sql_standard` – follows the SQL standard interval literals style.

The following command sets the interval style to `sql_standard`.

```
SET IntervalStyle to 'sql_standard';
```

postgres output format

The following is the output format for `postgres` interval style. Each numeric value can be negative.

```
'<numeric> <unit> [, <numeric> <unit> ...]'
```

```
select INTERVAL '1-2' YEAR TO MONTH::text
```

```
varchar
```

```
-----
```

```
1 year 2 mons
```

```
select INTERVAL '1 2:3:4.5678' DAY TO SECOND::text
```

```
varchar
```

```
-----
```

```
1 day 02:03:04.5678
```

postgres_verbose output format

`postgres_verbose` syntax is similar to `postgres`, but `postgres_verbose` outputs also contain the unit of time.

```
'[@] <numeric> <unit> [, <numeric> <unit> ...] [direction]'
```

```
select INTERVAL '1-2' YEAR TO MONTH::text
```

```
varchar
```

```
-----
```

```
@ 1 year 2 mons
```

```
select INTERVAL '1 2:3:4.5678' DAY TO SECOND::text
```

```
varchar
```

```
-----  
@ 1 day 2 hours 3 mins 4.56 secs
```

sql_standard output format

Interval year to month values are formatted as the following. Specifying a negative sign before the interval indicates the interval is a negative value and applies to the entire interval.

```
'[-]yy-mm'
```

Interval day to second values are formatted as the following.

```
'[-]dd hh:mm:ss.ffffff'
```

```
SELECT INTERVAL '1-2' YEAR TO MONTH::text
```

```
varchar
```

```
-----  
1-2
```

```
select INTERVAL '1 2:3:4.5678' DAY TO SECOND::text
```

```
varchar
```

```
-----  
1 2:03:04.5678
```

Examples of interval data type

The following examples demonstrate how to use INTERVAL data types with tables.

```
create table sample_intervals (y2m interval month, h2m interval hour to minute);
insert into sample_intervals values (interval '20' month, interval '2 days
1:1:1.123456' day to second);
select y2m::text, h2m::text from sample_intervals;
```

```

      y2m      |      h2m
-----+-----
1 year 8 mons | 2 days 01:01:00

```

```

update sample_intervals set y2m = interval '2' year where y2m = interval '1-8' year to
month;
select * from sample_intervals;

```

```

      y2m      |      h2m
-----+-----
2 years      | 2 days 01:01:00

```

```

delete from sample_intervals where h2m = interval '2 1:1:0' day to second;
select * from sample_intervals;

```

```

      y2m | h2m
-----+-----

```

Examples of interval literals

The following examples are run with interval style set to postgres.

The following example demonstrates how to create an INTERVAL literal of 1 year.

```

select INTERVAL '1' YEAR

intervaly2m
-----
1 years 0 mons

```

If you specify a *quoted-string* that exceeds the qualifier, the remaining units of time are truncated from the interval. In the following example, an interval of 13 months becomes 1 year and 1 month, but the remaining 1 month is left out because of the YEAR qualifier.

```

select INTERVAL '13 months' YEAR

intervaly2m
-----
1 years 0 mons

```

If you use a qualifier lower than your interval string, leftover units are included.

```
select INTERVAL '13 months' MONTH
```

```
intervaly2m
-----
1 years 1 mons
```

Specifying a precision in your interval truncates the number of fractional digits to the specified precision.

```
select INTERVAL '1.234567' SECOND (3)
```

```
intervald2s
-----
0 days 0 hours 0 mins 1.235 secs
```

If you don't specify a precision, Amazon Redshift uses the maximum precision of 6.

```
select INTERVAL '1.23456789' SECOND
```

```
intervald2s
-----
0 days 0 hours 0 mins 1.234567 secs
```

The following example demonstrates how to create a ranged interval.

```
select INTERVAL '2:2' MINUTE TO SECOND
```

```
intervald2s
-----
0 days 0 hours 2 mins 2.0 secs
```

Qualifiers dictate the units that you're specifying. For example, even though the following example uses the same *quoted-string* of '2:2' as the previous example, Amazon Redshift recognizes that it uses different units of time because of the qualifier.

```
select INTERVAL '2:2' HOUR TO MINUTE
```

```
intervald2s
```

```
-----
0 days 2 hours 2 mins 0.0 secs
```

Abbreviations and plurals of each unit are also supported. For example, 5s, 5 second, and 5 seconds are equivalent intervals. Supported units are years, months, hours, minutes, and seconds.

```
select INTERVAL '5s' SECOND
```

```
intervald2s
```

```
-----
0 days 0 hours 0 mins 5.0 secs
```

```
select INTERVAL '5 HOURS' HOUR
```

```
intervald2s
```

```
-----
0 days 5 hours 0 mins 0.0 secs
```

```
select INTERVAL '5 h' HOUR
```

```
intervald2s
```

```
-----
0 days 5 hours 0 mins 0.0 secs
```

Examples of interval literals without qualifier syntax

Note

The following examples demonstrate using an interval literal without a YEAR TO MONTH or DAY TO SECOND qualifier. For information about using the recommended interval literal with a qualifier, see [Interval data types and literals](#).

Use an interval literal to identify specific periods of time, such as 12 hours or 6 months. You can use these interval literals in conditions and calculations that involve datetime expressions.

An interval literal is expressed as a combination of the INTERVAL keyword with a numeric quantity and a supported date part, for example INTERVAL '7 days' or INTERVAL '59 minutes'. You can connect several quantities and units to form a more precise interval, for example: INTERVAL

'7 days, 3 hours, 59 minutes'. Abbreviations and plurals of each unit are also supported; for example: 5 s, 5 second, and 5 seconds are equivalent intervals.

If you don't specify a date part, the interval value represents seconds. You can specify the quantity value as a fraction (for example: 0.5 days).

The following examples show a series of calculations with different interval values.

The following adds 1 second to the specified date.

```
select caldate + interval '1 second' as dateplus from date
where caldate='12-31-2008';
dateplus
-----
2008-12-31 00:00:01
(1 row)
```

The following adds 1 minute to the specified date.

```
select caldate + interval '1 minute' as dateplus from date
where caldate='12-31-2008';
dateplus
-----
2008-12-31 00:01:00
(1 row)
```

The following adds 3 hours and 35 minutes to the specified date.

```
select caldate + interval '3 hours, 35 minutes' as dateplus from date
where caldate='12-31-2008';
dateplus
-----
2008-12-31 03:35:00
(1 row)
```

The following adds 52 weeks to the specified date.

```
select caldate + interval '52 weeks' as dateplus from date
where caldate='12-31-2008';
dateplus
-----
2009-12-30 00:00:00
```

```
(1 row)
```

The following adds 1 week, 1 hour, 1 minute, and 1 second to the specified date.

```
select caldate + interval '1w, 1h, 1m, 1s' as dateplus from date
where caldate='12-31-2008';
dateplus
-----
2009-01-07 01:01:01
(1 row)
```

The following adds 12 hours (half a day) to the specified date.

```
select caldate + interval '0.5 days' as dateplus from date
where caldate='12-31-2008';
dateplus
-----
2008-12-31 12:00:00
(1 row)
```

The following subtracts 4 months from February 15, 2023 and the result is October 15, 2022.

```
select date '2023-02-15' - interval '4 months';

?column?
-----
2022-10-15 00:00:00
```

The following subtracts 4 months from March 31, 2023 and the result is November 30, 2022. The calculation considers the number of days in a month.

```
select date '2023-03-31' - interval '4 months';

?column?
-----
2022-11-30 00:00:00
```

Boolean type

Use the BOOLEAN data type to store true and false values in a single-byte column. The following table describes the three possible states for a Boolean value and the literal values that result in

that state. Regardless of the input string, a Boolean column stores and outputs "t" for true and "f" for false.

State	Valid literal values	Storage
True	TRUE 't' 'true' 'y' 'yes' '1'	1 byte
False	FALSE 'f' 'false' 'n' 'no' '0'	1 byte
Unknown	NULL	1 byte

You can use an IS comparison to check a Boolean value only as a predicate in the WHERE clause. You can't use the IS comparison with a Boolean value in the SELECT list.

Examples

You could use a BOOLEAN column to store an "Active/Inactive" state for each customer in a CUSTOMER table.

```
create table customer(
  custid int,
  active_flag boolean default true);
```

```
insert into customer values(100, default);
```

```
select * from customer;
custid | active_flag
-----+-----
  100 | t
```

If no default value (true or false) is specified in the CREATE TABLE statement, inserting a default value means inserting a null.

In this example, the query selects users from the `USERS` table who like sports but do not like theatre:

```
select firstname, lastname, likesports, liketheatre
from users
where likesports is true and liketheatre is false
order by userid limit 10;
```

firstname	lastname	likesports	liketheatre
Lars	Ratliff	t	f
Mufutau	Watkins	t	f
Scarlett	Mayer	t	f
Shafira	Glenn	t	f
Winifred	Cherry	t	f
Chase	Lamb	t	f
Liberty	Ellison	t	f
Aladdin	Haney	t	f
Tashya	Michael	t	f
Lucian	Montgomery	t	f

(10 rows)

The following example selects users from the `USERS` table for whom it is unknown whether they like rock music.

```
select firstname, lastname, likerock
from users
where likerock is unknown
order by userid limit 10;
```

firstname	lastname	likerock
Rafael	Taylor	
Vladimir	Humphrey	
Barry	Roy	
Tamekah	Juarez	
Mufutau	Watkins	
Naida	Calderon	
Anika	Huff	
Bruce	Beck	
Mallory	Farrell	
Scarlett	Mayer	

(10 rows)

The following example returns an error because it uses an IS comparison in the SELECT list.

```
select firstname, lastname, likerock is true as "check"
from users
order by userid limit 10;
```

```
[Amazon](500310) Invalid operation: Not implemented
```

The following example succeeds because it uses an equal comparison (=) in the SELECT list instead of the IS comparison.

```
select firstname, lastname, likerock = true as "check"
from users
order by userid limit 10;
```

firstname	lastname	check
Rafael	Taylor	
Vladimir	Humphrey	
Lars	Ratliff	true
Barry	Roy	
Reagan	Hodge	true
Victor	Hernandez	true
Tamekah	Juarez	
Colton	Roy	false
Mufutau	Watkins	
Naida	Calderon	

HLLSKETCH type

Use the HLLSKETCH data type for HyperLogLog sketches. Amazon Redshift supports HyperLogLog sketch representations that are either sparse or dense. Sketches begin as sparse and switch to dense when the dense format is more efficient to minimize the memory footprint that is used.

Amazon Redshift automatically transitions a sparse HyperLogLog sketch when importing, exporting, or printing sketches in the following JSON format.

```
{"logm":15,"sparse":{"indices":[4878,9559,14523],"values":[1,2,1]}}
```

Amazon Redshift uses a string representation in a Base64 format to represent a dense HyperLogLog sketch.

Amazon Redshift uses the following string representation in a Base64 format to represent a dense HyperLogLog sketch.

```
"ABAABA . . ."
```

The maximum size of a HLLSKETCH object is 24,580 bytes when used in raw compression.

SUPER type

Use the SUPER data type to store semistructured data or documents as values.

Semistructured data doesn't conform to the rigid and tabular structure of the relational data model used in SQL databases. It contains tags that reference distinct entities within the data. They can contain complex values such as arrays, nested structures, and other complex structures that are associated with serialization formats, such as JSON. The SUPER data type is a set of schemaless array and structure values that encompass all other scalar types of Amazon Redshift.

The SUPER data type supports up to 16 MB of data for an individual SUPER object. For more information on the SUPER data type, including examples of implementing it in a table, see [Semistructured data in Amazon Redshift](#).

SUPER objects larger than 1MB can only be ingested from the following file formats:

- Parquet
- JSON
- TEXT
- CSV

The SUPER data type has the following properties:

- An Amazon Redshift scalar value:
 - A null
 - A boolean
 - A number, such as smallint, integer, bigint, decimal, or floating point (such as float4 or float8)

- A string value, such as varchar or char
- A complex value:
 - An array of values, including scalar or complex
 - A structure, also known as tuple or object, that is a map of attribute names and values (scalar or complex)

Any of the two types of complex values contain their own scalars or complex values without having any restrictions for regularity.

The SUPER data type supports the persistence of semistructured data in a schemaless form. Although hierarchical data model can change, the old versions of data can coexist in the same SUPER column.

Amazon Redshift uses PartiQL to enable navigation into arrays and structures. Amazon Redshift also uses the PartiQL syntax to iterate over SUPER arrays. For more information, see [Navigation](#) and [Unnesting queries](#).

Amazon Redshift uses dynamic typing to process schemaless SUPER data without needing to declare the data types before you use them in your query. For more information, see [Dynamic typing](#).

You can apply dynamic data masking policies to scalar values on the paths of SUPER type columns. For more information about dynamic data masking, see [Dynamic data masking](#). For information about using dynamic data masking with the SUPER data type, see [Using dynamic data masking with SUPER data type paths](#).

VARBYTE type

Use a VARBYTE, VARBINARY, or BINARY VARYING column to store variable-length binary value with a fixed limit.

```
varbyte [ (n) ]
```

The maximum number of bytes (*n*) can range from 1 – 16,777,216. The default is 64,000.

Some examples where you might want to use a VARBYTE data type are as follows:

- Joining tables on VARBYTE columns.

- Creating materialized views that contain VARBYTE columns. Incremental refresh of materialized views that contain VARBYTE columns is supported. However, aggregate functions other than COUNT, MIN, and MAX and GROUP BY on VARBYTE columns don't support incremental refresh.

To ensure that all bytes are printable characters, Amazon Redshift uses the hex format to print VARBYTE values. For example, the following SQL converts the hexadecimal string 6162 into a binary value. Even though the returned value is a binary value, the results are printed as hexadecimal 6162.

```
select from_hex('6162');

 from_hex
-----
 6162
```

Amazon Redshift supports casting between VARBYTE and the following data types:

- CHAR
- VARCHAR
- SMALLINT
- INTEGER
- BIGINT

When casting with CHAR and VARCHAR the UTF-8 format is used. For more information about the UTF-8 format, see [TO_VARBYTE](#). When casting from SMALLINT, INTEGER, and BIGINT the number of bytes of the original data type is maintained. That is two bytes for SMALLINT, four bytes for INTEGER, and eight bytes for BIGINT.

The following SQL statement casts a VARCHAR string to a VARBYTE. Even though the returned value is a binary value, the results are printed as hexadecimal 616263.

```
select 'abc'::varbyte;

 varbyte
-----
 616263
```

The following SQL statement casts a CHAR value in a column to a VARBYTE. This example creates a table with a CHAR(10) column (c), inserts character values that are shorter than the length of 10. The resulting cast pads the result with a space characters (hex'20') to the defined column size. Even though the returned value is a binary value, the results are printed as hexadecimal.

```
create table t (c char(10));
insert into t values ('aa'), ('abc');
select c::varbyte from t;
      c
-----
61612020202020202020
61626320202020202020
```

The following SQL statement casts a SMALLINT string to a VARBYTE. Even though the returned value is a binary value, the results are printed as hexadecimal 0005, which is two bytes or four hexadecimal characters.

```
select 5::smallint::varbyte;

varbyte
-----
0005
```

The following SQL statement casts an INTEGER to a VARBYTE. Even though the returned value is a binary value, the results are printed as hexadecimal 00000005, which is four bytes or eight hexadecimal characters.

```
select 5::int::varbyte;

varbyte
-----
00000005
```

The following SQL statement casts a BIGINT to a VARBYTE. Even though the returned value is a binary value, the results are printed as hexadecimal 0000000000000005, which is eight bytes or 16 hexadecimal characters.

```
select 5::bigint::varbyte;
```

```
varbyte
```

```
-----  
000000000000000005
```

Amazon Redshift features that support the VARBYTE data type include:

- [VARBYTE operators](#)
- [CONCAT](#)
- [LEN](#)
- [LENGTH function](#)
- [OCTET_LENGTH](#)
- [SUBSTRING function](#)
- [FROM_HEX](#)
- [TO_HEX](#)
- [FROM_VARBYTE](#)
- [TO_VARBYTE](#)
- [GETBIT](#)
- [Loading a column of the VARBYTE data type](#)
- [Unloading a column of the VARBYTE data type](#)

Limitations when using the VARBYTE data type with Amazon Redshift

The following are limitations when using the VARBYTE data type with Amazon Redshift:

- Amazon Redshift Spectrum supports the VARBYTE data type only for Parquet and ORC files.
- Amazon Redshift query editor and Amazon Redshift query editor v2 don't yet fully support VARBYTE data type. Therefore, use a different SQL client when working with VARBYTE expressions.

As a workaround to use the query editor, if the length of your data is below 64 KB and the content is valid UTF-8, you can cast the VARBYTE values to VARCHAR, for example:

```
select to_varbyte('6162', 'hex')::varchar;
```

- You can't use VARBYTE data types with Python or Lambda user-defined functions (UDFs).

- You can't create a HLLSKETCH column from a VARBYTE column or use APPROXIMATE COUNT DISTINCT on a VARBYTE column.
- VARBYTE values larger than 1 MB can only be ingested from the following file formats:
 - Parquet
 - Text
 - Comma-separated values (CSV)

Type compatibility and conversion

Following, you can find a discussion about how type conversion rules and data type compatibility work in Amazon Redshift.

Compatibility

Data type matching and matching of literal values and constants to data types occurs during various database operations, including the following:

- Data manipulation language (DML) operations on tables
- UNION, INTERSECT, and EXCEPT queries
- CASE expressions
- Evaluation of predicates, such as LIKE and IN
- Evaluation of SQL functions that do comparisons or extractions of data
- Comparisons with mathematical operators

The results of these operations depend on type conversion rules and data type compatibility. *Compatibility* implies that a one-to-one matching of a certain value and a certain data type is not always required. Because some data types are *compatible*, an implicit conversion, or *coercion*, is possible (for more information, see [Implicit conversion types](#)). When data types are incompatible, you can sometimes convert a value from one data type to another by using an explicit conversion function.

General compatibility and conversion rules

Note the following compatibility and conversion rules:

- In general, data types that fall into the same type category (such as different numeric data types) are compatible and can be implicitly converted.

For example, with implicit conversion you can insert a decimal value into an integer column. The decimal is rounded to produce a whole number. Or you can extract a numeric value, such as 2008, from a date and insert that value into an integer column.

- Numeric data types enforce overflow conditions that occur when you attempt to insert out-of-range values. For example, a decimal value with a precision of 5 does not fit into a decimal column that was defined with a precision of 4. An integer or the whole part of a decimal is never truncated; however, the fractional part of a decimal can be rounded up or down, as appropriate. However, results of explicit casts of values selected from tables are not rounded.
- Different types of character strings are compatible; VARCHAR column strings containing single-byte data and CHAR column strings are comparable and implicitly convertible. VARCHAR strings that contain multibyte data are not comparable. Also, you can convert a character string to a date, time, timestamp, or numeric value if the string is an appropriate literal value; any leading or trailing spaces are ignored. Conversely, you can convert a date, time, timestamp, or numeric value to a fixed-length or variable-length character string.

 **Note**

A character string that you want to cast to a numeric type must contain a character representation of a number. For example, you can cast the strings '1.0' or '5.9' to decimal values, but you cannot cast the string 'ABC' to any numeric type.

- If you compare DECIMAL values with character strings, Amazon Redshift attempts to convert the character string to a DECIMAL value. When comparing all other numeric values with character strings, the numeric values are converted to character strings. To enforce the opposite conversion (for example, converting character strings to integers, or converting DECIMAL values to character strings), use an explicit function, such as [CAST](#).
- To convert 64-bit DECIMAL or NUMERIC values to a higher precision, you must use an explicit conversion function such as the CAST or CONVERT functions.
- When converting DATE or TIMESTAMP to TIMESTAMPTZ, or converting TIME to TIMETZ, the time zone is set to the current session time zone. The session time zone is UTC by default. For more information about setting the session time zone, see [timezone](#).
- Similarly, TIMESTAMPTZ is converted to DATE, TIME, or TIMESTAMP based on the current session time zone. The session time zone is UTC by default. After the conversion, time zone information is dropped.

- Character strings that represent a timestamp with time zone specified are converted to TIMESTAMPTZ using the current session time zone, which is UTC by default. Likewise, character strings that represent a time with time zone specified are converted to TIMETZ using the current session time zone, which is UTC by default.

Implicit conversion types

There are two types of implicit conversions:

- Implicit conversions in assignments, such as setting values in INSERT or UPDATE commands.
- Implicit conversions in expressions, such as performing comparisons in the WHERE clause.

The table following lists the data types that can be converted implicitly in assignments or expressions. You can also use an explicit conversion function to perform these conversions.

From type	To type
BIGINT (INT8)	BOOLEAN
	CHAR
	DECIMAL (NUMERIC)
	DOUBLE PRECISION (FLOAT8)
	INTEGER (INT, INT4)
	REAL (FLOAT4)
	SMALLINT (INT2)
	VARCHAR
CHAR	VARCHAR
DATE	CHAR
	VARCHAR
	TIMESTAMP

From type	To type
	TIMESTAMPTZ
DECIMAL (NUMERIC)	BIGINT (INT8)
	CHAR
	DOUBLE PRECISION (FLOAT8)
	INTEGER (INT, INT4)
	REAL (FLOAT4)
	SMALLINT (INT2)
	VARCHAR
DOUBLE PRECISION (FLOAT8)	BIGINT (INT8)
	CHAR
	DECIMAL (NUMERIC)
	INTEGER (INT, INT4)
	REAL (FLOAT4)
	SMALLINT (INT2)
	VARCHAR
INTEGER (INT, INT4)	BIGINT (INT8)
	BOOLEAN
	CHAR
	DECIMAL (NUMERIC)
	DOUBLE PRECISION (FLOAT8)

From type	To type
	REAL (FLOAT4)
	SMALLINT (INT2)
	VARCHAR
REAL (FLOAT4)	BIGINT (INT8)
	CHAR
	DECIMAL (NUMERIC)
	INTEGER (INT, INT4)
	SMALLINT (INT2)
	VARCHAR
SMALLINT (INT2)	BIGINT (INT8)
	BOOLEAN
	CHAR
	DECIMAL (NUMERIC)
	DOUBLE PRECISION (FLOAT8)
	INTEGER (INT, INT4)
	REAL (FLOAT4)
	VARCHAR
TIMESTAMP	CHAR
	DATE
	VARCHAR

From type	To type
	TIMESTAMPTZ
	TIME
TIMESTAMPTZ	CHAR
	DATE
	VARCHAR
	TIMESTAMP
	TIMETZ
TIME	VARCHAR
	TIMETZ
	INTERVAL DAY TO SECOND
TIMETZ	VARCHAR
	TIME
GEOMETRY	GEOGRAPHY
GEOGRAPHY	GEOMETRY

 **Note**

Implicit conversions between TIMESTAMPTZ, TIMESTAMP, DATE, TIME, TIMETZ, or character strings use the current session time zone. For information about setting the current time zone, see [timezone](#).

The GEOMETRY and GEOGRAPHY data types can't be implicitly converted to any other data type, except each other. For more information, see [CAST function](#).

The VARBYTE data type can't be implicitly converted to any other data type. For more information, see [CAST function](#).

Using dynamic typing for the SUPER data type

Amazon Redshift uses dynamic typing to process schemaless SUPER data without the need to declare the data types before you use them in your query. Dynamic typing uses the results of navigating into SUPER data columns without having to explicitly cast them into Amazon Redshift types. For more information about using dynamic typing for SUPER data type, see [Dynamic typing](#).

You can cast SUPER values to and from other data types with some exceptions. For more information, see [Limitations](#).

Collation sequences

Amazon Redshift doesn't support locale-specific or user-defined collation sequences. In general, the results of any predicate in any context could be affected by the lack of locale-specific rules for sorting and comparing data values. For example, ORDER BY expressions and functions such as MIN, MAX, and RANK return results based on binary UTF8 ordering of the data that does not take locale-specific characters into account.

Expressions

Topics

- [Simple expressions](#)
- [Compound expressions](#)
- [Expression lists](#)
- [Scalar subqueries](#)
- [Function expressions](#)

An expression is a combination of one or more values, operators, or functions that evaluate to a value. The data type of an expression is generally that of its components.

Simple expressions

A simple expression is one of the following:

- A constant or literal value
- A column name or column reference
- A scalar function

- An aggregate (set) function
- A window function
- A scalar subquery

Examples of simple expressions include:

```
5+12
dateid
sales.qtysold * 100
sqrt (4)
max (qtysold)
(select max (qtysold) from sales)
```

Compound expressions

A compound expression is a series of simple expressions joined by arithmetic operators. A simple expression used in a compound expression must return a numeric value.

Syntax

```
expression
operator
expression | (compound_expression)
```

Arguments

expression

A simple expression that evaluates to a value.

operator

A compound arithmetic expression can be constructed using the following operators, in this order of precedence:

- () : parentheses to control the order of evaluation
- + , - : positive and negative sign/operator
- ^ , |/ , ||/ : exponentiation, square root, cube root
- * , / , % : multiplication, division, and modulo operators
- @ : absolute value

- + , - : addition and subtraction
- & , |, #, ~, <<, >> : AND, OR, NOT, shift left, shift right bitwise operators
- ||: concatenation

(compound_expression)

Compound expressions can be nested using parentheses.

Examples

Examples of compound expressions include the following.

```
('SMITH' || 'JONES')
sum(x) / y
sqrt(256) * avg(column)
rank() over (order by qtysold) / 100
(select (pricepaid - commission) from sales where dateid = 1882) * (qtysold)
```

Some functions can also be nested within other functions. For example, any scalar function can nest within another scalar function. The following example returns the sum of the absolute values of a set of numbers:

```
sum(abs(qtysold))
```

Window functions cannot be used as arguments for aggregate functions or other window functions. The following expression would return an error:

```
avg(rank() over (order by qtysold))
```

Window functions can have a nested aggregate function. The following expression sums sets of values and then ranks them:

```
rank() over (order by sum(qtysold))
```

Expression lists

An expression list is a combination of expressions, and can appear in membership and comparison conditions (WHERE clauses) and in GROUP BY clauses.

Syntax

```
expression , expression , ... | (expression, expression, ...)
```

Arguments

expression

A simple expression that evaluates to a value. An expression list can contain one or more comma-separated expressions or one or more sets of comma-separated expressions. When there are multiple sets of expressions, each set must contain the same number of expressions, and be separated by parentheses. The number of expressions in each set must match the number of expressions before the operator in the condition.

Examples

The following are examples of expression lists in conditions:

```
(1, 5, 10)
('THESE', 'ARE', 'STRINGS')
(('one', 'two', 'three'), ('blue', 'yellow', 'green'))
```

The number of expressions in each set must match the number in the first part of the statement:

```
select * from venue
where (venuecity, venuestate) in (('Miami', 'FL'), ('Tampa', 'FL'))
order by venueid;
```

venueid	venuename	venuecity	venuestate	venueseats
28	American Airlines Arena	Miami	FL	0
54	St. Pete Times Forum	Tampa	FL	0
91	Raymond James Stadium	Tampa	FL	65647

(3 rows)

Scalar subqueries

A scalar subquery is a regular SELECT query in parentheses that returns exactly one value: one row with one column. The query is run and the returned value is used in the outer query. If the

subquery returns zero rows, the value of the subquery expression is null. If it returns more than one row, Amazon Redshift returns an error. The subquery can refer to variables from the parent query, which will act as constants during any one invocation of the subquery.

You can use scalar subqueries in most statements that call for an expression. Scalar subqueries are not valid expressions in the following cases:

- As default values for expressions
- In GROUP BY and HAVING clauses

Example

The following subquery computes the average price paid per sale across the entire year of 2008, then the outer query uses that value in the output to compare against the average price per sale per quarter:

```
select qtr, avg(pricepaid) as avg_saleprice_per_qtr,
(select avg(pricepaid)
from sales join date on sales.dateid=date.dateid
where year = 2008) as avg_saleprice_yearly
from sales join date on sales.dateid=date.dateid
where year = 2008
group by qtr
order by qtr;
```

qtr	avg_saleprice_per_qtr	avg_saleprice_yearly
1	647.64	642.28
2	646.86	642.28
3	636.79	642.28
4	638.26	642.28

(4 rows)

Function expressions

Syntax

Any built-in can be used as an expression. The syntax for a function call is the name of a function followed by its argument list in parentheses.

```
function ( [expression [, expression...]] )
```

Arguments

function

Any built-in function. For some example functions, see [SQL functions reference](#).

expression

Any expression(s) matching the data type and parameter count expected by the function.

Examples

```
abs (variable)
select avg (qtysold + 3) from sales;
select dateadd (day,30,caldate) as plus30days from date;
```

Conditions

Topics

- [Syntax](#)
- [Comparison condition](#)
- [Logical conditions](#)
- [Pattern-matching conditions](#)
- [BETWEEN range condition](#)
- [Null condition](#)
- [EXISTS condition](#)
- [IN condition](#)

A condition is a statement of one or more expressions and logical operators that evaluates to true, false, or unknown. Conditions are also sometimes referred to as predicates.

Note

All string comparisons and LIKE pattern matches are case-sensitive. For example, 'A' and 'a' do not match. However, you can do a case-insensitive pattern match by using the ILIKE predicate.

Syntax

```
comparison_condition
| logical_condition
| range_condition
| pattern_matching_condition
| null_condition
| EXISTS_condition
| IN_condition
```

Comparison condition

Comparison conditions state logical relationships between two values. All comparison conditions are binary operators with a Boolean return type. Amazon Redshift supports the comparison operators described in the following table:

Operator	Syntax	Description
<	a < b	Value a is less than value b.
>	a > b	Value a is greater than value b.
<=	a <= b	Value a is less than or equal to value b.
>=	a >= b	Value a is greater than or equal to value b.
=	a = b	Value a is equal to value b.
<> or !=	a <> b or a != b	Value a is not equal to value b.
ANY SOME	a = ANY(subquery)	Value a is equal to any value returned by the subquery.
ALL	a <> ALL or != ALL (subquery))	Value a is not equal to any value returned by the subquery.
IS TRUE FALSE UNKNOWN	a IS TRUE	Value a is Boolean TRUE.

Usage notes

= ANY | SOME

The ANY and SOME keywords are synonymous with the *IN* condition, and return true if the comparison is true for at least one value returned by a subquery that returns one or more values. Amazon Redshift supports only the = (equals) condition for ANY and SOME. Inequality conditions are not supported.

Note

The ALL predicate is not supported.

<> ALL

The ALL keyword is synonymous with NOT IN (see [IN condition](#) condition) and returns true if the expression is not included in the results of the subquery. Amazon Redshift supports only the <> or != (not equals) condition for ALL. Other comparison conditions are not supported.

IS TRUE/FALSE/UNKNOWN

Non-zero values equate to TRUE, 0 equates to FALSE, and null equates to UNKNOWN. See the [Boolean type](#) data type.

Examples

Here are some simple examples of comparison conditions:

```
a = 5
a < b
min(x) >= 5
qtysold = any (select qtysold from sales where dateid = 1882
```

The following query returns venues with more than 10000 seats from the VENUE table:

```
select venueid, venuename, venueseats from venue
where venueseats > 10000
order by venueseats desc;
```

```
venueid |          venuename          | venueseats
-----+-----+-----
```

```

83 | FedExField | 91704
 6 | New York Giants Stadium | 80242
79 | Arrowhead Stadium | 79451
78 | INVESCO Field | 76125
69 | Dolphin Stadium | 74916
67 | Ralph Wilson Stadium | 73967
76 | Jacksonville Municipal Stadium | 73800
89 | Bank of America Stadium | 73298
72 | Cleveland Browns Stadium | 73200
86 | Lambeau Field | 72922
...
(57 rows)

```

This example selects the users (USERID) from the USERS table who like rock music:

```

select userid from users where likerock = 't' order by 1 limit 5;

userid
-----
3
5
6
13
16
(5 rows)

```

This example selects the users (USERID) from the USERS table where it is unknown whether they like rock music:

```

select firstname, lastname, likerock
from users
where likerock is unknown
order by userid limit 10;

firstname | lastname | likerock
-----+-----+-----
Rafael    | Taylor   |
Vladimir | Humphrey |
Barry     | Roy      |
Tamekah   | Juarez   |
Mufutau   | Watkins  |
Naida     | Calderon |
Anika     | Huff     |

```

```
Bruce      | Beck      |
Mallory    | Farrell   |
Scarlett   | Mayer     |
(10 rows)
```

Examples with a TIME column

The following example table TIME_TEST has a column TIME_VAL (type TIME) with three values inserted.

```
select time_val from time_test;
```

```
time_val
-----
20:00:00
00:00:00.5550
00:58:00
```

The following example extracts the hours from each timetz_val.

```
select time_val from time_test where time_val < '3:00';
```

```
time_val
-----
00:00:00.5550
00:58:00
```

The following example compares two time literals.

```
select time '18:25:33.123456' = time '18:25:33.123456';
```

```
?column?
-----
t
```

Examples with a TIMETZ column

The following example table TIMETZ_TEST has a column TIMETZ_VAL (type TIMETZ) with three values inserted.

```
select timetz_val from timetz_test;
```

```
timetz_val
-----
```

```
04:00:00+00
00:00:00.5550+00
05:58:00+00
```

The following example selects only the TIMETZ values less than 3:00:00 UTC. The comparison is made after converting the value to UTC.

```
select timetz_val from timetz_test where timetz_val < '3:00:00 UTC';

   timetz_val
-----
00:00:00.5550+00
```

The following example compares two TIMETZ literals. The time zone is ignored for the comparison.

```
select time '18:25:33.123456 PST' < time '19:25:33.123456 EST';

?column?
-----
t
```

Logical conditions

Logical conditions combine the result of two conditions to produce a single result. All logical conditions are binary operators with a Boolean return type.

Syntax

```
expression
{ AND | OR }
expression
NOT expression
```

Logical conditions use a three-valued Boolean logic where the null value represents an unknown relationship. The following table describes the results for logical conditions, where E1 and E2 represent expressions:

E1	E2	E1 AND E2	E1 OR E2	NOT E2
TRUE	TRUE	TRUE	TRUE	FALSE

E1	E2	E1 AND E2	E1 OR E2	NOT E2
TRUE	FALSE	FALSE	TRUE	TRUE
TRUE	UNKNOWN	UNKNOWN	TRUE	UNKNOWN
FALSE	TRUE	FALSE	TRUE	
FALSE	FALSE	FALSE	FALSE	
FALSE	UNKNOWN	FALSE	UNKNOWN	
UNKNOWN	TRUE	UNKNOWN	TRUE	
UNKNOWN	FALSE	FALSE	UNKNOWN	
UNKNOWN	UNKNOWN	UNKNOWN	UNKNOWN	

The NOT operator is evaluated before AND, and the AND operator is evaluated before the OR operator. Any parentheses used may override this default order of evaluation.

Examples

The following example returns USERID and USERNAME from the USERS table where the user likes both Las Vegas and sports:

```
select userid, username from users
where likevegas = 1 and likesports = 1
order by userid;
```

```
userid | username
-----+-----
1 | JSG99FHE
67 | TWU10MZT
87 | DUF19VXU
92 | HYP36WEQ
109 | FPL38HZK
120 | DMJ24GUZ
123 | QZR22XGQ
130 | ZQC82ALK
133 | LBN45WCH
144 | UCX04JKN
```

```

165 | TEY680EB
169 | AYQ83HGO
184 | TVX65AZX
...
(2128 rows)

```

The next example returns the USERID and USERNAME from the USERS table where the user likes Las Vegas, or sports, or both. This query returns all of the output from the previous example plus the users who like only Las Vegas or sports.

```

select userid, username from users
where likevegas = 1 or likesports = 1
order by userid;

```

```

userid | username
-----+-----
 1 | JSG99FHE
 2 | PGL08LJI
 3 | IFT66TXU
 5 | AEB55QTM
 6 | NDQ15VBM
 9 | MSD36KVR
10 | WKW41AIW
13 | QTF33MCG
15 | OWU78MTR
16 | ZMG93CDD
22 | RHT62AGI
27 | KOY02CVE
29 | HUH27PKK
...
(18968 rows)

```

The following query uses parentheses around the OR condition to find venues in New York or California where Macbeth was performed:

```

select distinct venuename, venuecity
from venue join event on venue.venueid=event.venueid
where (venuestate = 'NY' or venuestate = 'CA') and eventname='Macbeth'
order by 2,1;

```

```

venuename          | venuecity
-----+-----

```

Geffen Playhouse		Los Angeles
Greek Theatre		Los Angeles
Royce Hall		Los Angeles
American Airlines Theatre		New York City
August Wilson Theatre		New York City
Belasco Theatre		New York City
Bernard B. Jacobs Theatre		New York City
...		

Removing the parentheses in this example changes the logic and results of the query.

The following example uses the NOT operator:

```
select * from category
where not catid=1
order by 1;
```

catid	catgroup	catname	catdesc
2	Sports	NHL	National Hockey League
3	Sports	NFL	National Football League
4	Sports	NBA	National Basketball Association
5	Sports	MLS	Major League Soccer
...			

The following example uses a NOT condition followed by an AND condition:

```
select * from category
where (not catid=1) and catgroup='Sports'
order by catid;
```

catid	catgroup	catname	catdesc
2	Sports	NHL	National Hockey League
3	Sports	NFL	National Football League
4	Sports	NBA	National Basketball Association
5	Sports	MLS	Major League Soccer

(4 rows)

Pattern-matching conditions

Topics

- [LIKE](#)
- [SIMILAR TO](#)
- [POSIX operators](#)

A pattern-matching operator searches a string for a pattern specified in the conditional expression and returns true or false depend on whether it finds a match. Amazon Redshift uses three methods for pattern matching:

- LIKE expressions

The LIKE operator compares a string expression, such as a column name, with a pattern that uses the wildcard characters % (percent) and _ (underscore). LIKE pattern matching always covers the entire string. LIKE performs a case-sensitive match and ILIKE performs a case-insensitive match.

- SIMILAR TO regular expressions

The SIMILAR TO operator matches a string expression with a SQL standard regular expression pattern, which can include a set of pattern-matching metacharacters that includes the two supported by the LIKE operator. SIMILAR TO matches the entire string and performs a case-sensitive match.

- POSIX-style regular expressions

POSIX regular expressions provide a more powerful means for pattern matching than the LIKE and SIMILAR TO operators. POSIX regular expression patterns can match any portion of the string and performs a case-sensitive match.

Regular expression matching, using SIMILAR TO or POSIX operators, is computationally expensive. We recommend using LIKE whenever possible, especially when processing a very large number of rows. For example, the following queries are functionally identical, but the query that uses LIKE runs several times faster than the query that uses a regular expression:

```
select count(*) from event where eventname SIMILAR TO '%(Ring|Die)%';
select count(*) from event where eventname LIKE '%Ring%' OR eventname LIKE '%Die%';
```

LIKE

The LIKE operator compares a string expression, such as a column name, with a pattern that uses the wildcard characters % (percent) and _ (underscore). LIKE pattern matching always covers the

entire string. To match a sequence anywhere within a string, the pattern must start and end with a percent sign.

LIKE is case-sensitive; ILIKE is case-insensitive.

Syntax

```
expression [ NOT ] LIKE | ILIKE pattern [ ESCAPE 'escape_char' ]
```

Arguments

expression

A valid UTF-8 character expression, such as a column name.

LIKE | ILIKE

LIKE performs a case-sensitive pattern match. ILIKE performs a case-insensitive pattern match for single-byte UTF-8 (ASCII) characters. To perform a case-insensitive pattern match for multibyte characters, use the [LOWER](#) function on *expression* and *pattern* with a LIKE condition.

In contrast to comparison predicates, such as = and <>, LIKE and ILIKE predicates do not implicitly ignore trailing spaces. To ignore trailing spaces, use RTRIM or explicitly cast a CHAR column to VARCHAR.

The ~~ operator is equivalent to LIKE, and ~~* is equivalent to ILIKE. Also the !~~ and !~~* operators are equivalent to NOT LIKE and NOT ILIKE.

pattern

A valid UTF-8 character expression with the pattern to be matched.

escape_char

A character expression that will escape metacharacters characters in the pattern. The default is two backslashes ('\').

If *pattern* does not contain metacharacters, then the pattern only represents the string itself; in that case LIKE acts the same as the equals operator.

Either of the character expressions can be CHAR or VARCHAR data types. If they differ, Amazon Redshift converts *pattern* to the data type of *expression*.

LIKE supports the following pattern-matching metacharacters:

Operator	Description
%	Matches any sequence of zero or more characters.
_	Matches any single character.

Examples

The following table shows examples of pattern matching using LIKE:

Expression	Returns
'abc' LIKE 'abc'	True
'abc' LIKE 'a%'	True
'abc' LIKE '_B_'	False
'abc' ILIKE '_B_'	True
'abc' LIKE 'c%'	False

The following example finds all cities whose names start with "E":

```
select distinct city from users
where city like 'E%' order by city;
city
-----
East Hartford
East Lansing
East Rutherford
East St. Louis
Easthampton
Easton
Eatontown
Eau Claire
...
```

The following example finds users whose last name contains "ten" :

```
select distinct lastname from users
where lastname like '%ten%' order by lastname;
lastname
-----
Christensen
Wooten
...
```

The following example demonstrates how to match multiple patterns.

```
select distinct lastname from tickit.users
where lastname like 'Chris%' or lastname like '%Wooten' order by lastname;
lastname
-----
Christensen
Christian
Wooten
...
```

The following example finds cities whose third and fourth characters are "ea". The command uses ILIKE to demonstrate case insensitivity:

```
select distinct city from users where city ilike '__EA%' order by city;
city
-----
Brea
Clearwater
Great Falls
Ocean City
Olean
Wheaton
(6 rows)
```

The following example uses the default escape string (\\) to search for strings that include "start_" (the text start followed by an underscore _):

```
select tablename, "column" from pg_table_def
where "column" like '%start\\_%'
limit 5;
```

tablename	column
stl_s3client	start_time
stl_tr_conflict	xact_start_ts
stl_undone	undo_start_ts
stl_unload_log	start_time
stl_vacuum_detail	start_row

(5 rows)

The following example specifies '^' as the escape character, then uses the escape character to search for strings that include "start_" (the text start followed by an underscore _):

```
select tablename, "column" from pg_table_def
where "column" like '%start^_%' escape '^'
limit 5;
```

tablename	column
stl_s3client	start_time
stl_tr_conflict	xact_start_ts
stl_undone	undo_start_ts
stl_unload_log	start_time
stl_vacuum_detail	start_row

(5 rows)

The following example uses the ~* operator to do a case-insensitive (ILIKE) search for cities that start with "Ag".

```
select distinct city from users where city ~* 'Ag%' order by city;
```

```
city
-----
Agat
Agawam
Agoura Hills
Aguadilla
```

SIMILAR TO

The SIMILAR TO operator matches a string expression, such as a column name, with a SQL standard regular expression pattern. A SQL regular expression pattern can include a set of pattern-matching metacharacters, including the two supported by the [LIKE](#) operator.

The SIMILAR TO operator returns true only if its pattern matches the entire string, unlike POSIX regular expression behavior, where the pattern can match any portion of the string.

SIMILAR TO performs a case-sensitive match.

Note

Regular expression matching using SIMILAR TO is computationally expensive. We recommend using LIKE whenever possible, especially when processing a very large number of rows. For example, the following queries are functionally identical, but the query that uses LIKE runs several times faster than the query that uses a regular expression:

```
select count(*) from event where eventname SIMILAR TO '%(Ring|Die)%';
select count(*) from event where eventname LIKE '%Ring%' OR eventname LIKE '%Die%';
```

Syntax

```
expression [ NOT ] SIMILAR TO pattern [ ESCAPE 'escape_char' ]
```

Arguments

expression

A valid UTF-8 character expression, such as a column name.

SIMILAR TO

SIMILAR TO performs a case-sensitive pattern match for the entire string in *expression*.

pattern

A valid UTF-8 character expression representing a SQL standard regular expression pattern.

escape_char

A character expression that will escape metacharacters in the pattern. The default is two backslashes ('\\').

If *pattern* does not contain metacharacters, then the pattern only represents the string itself.

Either of the character expressions can be CHAR or VARCHAR data types. If they differ, Amazon Redshift converts *pattern* to the data type of *expression*.

SIMILAR TO supports the following pattern-matching metacharacters:

Operator	Description
%	Matches any sequence of zero or more characters.
_	Matches any single character.
	Denotes alternation (either of two alternatives).
*	Repeat the previous item zero or more times.
+	Repeat the previous item one or more times.
?	Repeat the previous item zero or one time.
{m}	Repeat the previous item exactly <i>m</i> times.
{m, }	Repeat the previous item <i>m</i> or more times.
{m, n}	Repeat the previous item at least <i>m</i> and not more than <i>n</i> times.
()	Parentheses group items into a single logical item.
[...]	A bracket expression specifies a character class, just as in POSIX regular expressions.

Examples

The following table shows examples of pattern matching using SIMILAR TO:

Expression	Returns
'abc' SIMILAR TO 'abc'	True
'abc' SIMILAR TO '_b_'	True

Expression	Returns
'abc' SIMILAR TO '_A_'	False
'abc' SIMILAR TO '%(b d)%'	True
'abc' SIMILAR TO '(b c)%'	False
'AbcAbcdefgfg12efgfg12' SIMILAR TO '((Ab)?c)+d((efg)+(12))+'	True
'aaaaaab11111xy' SIMILAR TO 'a{6}_ [0-9]{5}(x y){2}'	True
'\$0.87' SIMILAR TO '\$[0-9]+(.[0-9][0-9])?'	True

The following example finds cities whose names contain "E" or "H":

```
SELECT DISTINCT city FROM users
WHERE city SIMILAR TO '%E|%H%' ORDER BY city LIMIT 5;
```

```

      city
-----
Agoura Hills
Auburn Hills
Benton Harbor
Beverly Hills
Chicago Heights
```

The following example uses the default escape string ('\\') to search for strings that include "_":

```
SELECT tablename, "column" FROM pg_table_def
WHERE "column" SIMILAR TO '%start\\_%'
ORDER BY tablename, "column" LIMIT 5;
```

```

      tablename          |      column
-----+-----
stcs_abort_idle         | idle_start_time
stcs_abort_idle         | txn_start_time
stcs_analyze_compression | start_time
```

```
stcs_auto_worker_levels | start_level
stcs_auto_worker_levels | start_wlm_occupancy
```

The following example specifies '^' as the escape string, then uses the escape string to search for strings that include "_":

```
SELECT tablename, "column" FROM pg_table_def
WHERE "column" SIMILAR TO '%start^_%' ESCAPE '^'
ORDER BY tablename, "column" LIMIT 5;
```

tablename	column
stcs_abort_idle	idle_start_time
stcs_abort_idle	txn_start_time
stcs_analyze_compression	start_time
stcs_auto_worker_levels	start_level
stcs_auto_worker_levels	start_wlm_occupancy

POSIX operators

A POSIX regular expression is a sequence of characters that specifies a match pattern. A string matches a regular expression if it is a member of the regular set described by the regular expression.

POSIX regular expressions provide a more powerful means for pattern matching than the [LIKE](#) and [SIMILAR TO](#) operators. POSIX regular expression patterns can match any portion of a string, unlike the SIMILAR TO operator, which returns true only if its pattern matches the entire string.

Note

Regular expression matching using POSIX operators is computationally expensive. We recommend using LIKE whenever possible, especially when processing a very large number of rows. For example, the following queries are functionally identical, but the query that uses LIKE runs several times faster than the query that uses a regular expression:

```
select count(*) from event where eventname ~ '.*(Ring|Die).*';
select count(*) from event where eventname LIKE '%Ring%' OR eventname LIKE '%Die%';
```

Syntax

```
expression [ ! ] ~ pattern
```

Arguments

expression

A valid UTF-8 character expression, such as a column name.

!

Negation operator. Does not match the regular expression.

~

Perform a case-sensitive match for any substring of *expression*.

Note

A ~~ is a synonym for [LIKE](#).

pattern

A string literal that represents a regular expression pattern.

If *pattern* does not contain wildcard characters, then the pattern only represents the string itself.

To search for strings that include metacharacters, such as `' . * | ? '`, and so on, escape the character using two backslashes (`' \\'`). Unlike `SIMILAR TO` and `LIKE`, POSIX regular expression syntax does not support a user-defined escape character.

Either of the character expressions can be `CHAR` or `VARCHAR` data types. If they differ, Amazon Redshift converts *pattern* to the data type of *expression*.

All of the character expressions can be `CHAR` or `VARCHAR` data types. If the expressions differ in data type, Amazon Redshift converts them to the data type of *expression*.

POSIX pattern matching supports the following metacharacters:

POSIX	Description
.	Matches any single character.
*	Matches zero or more occurrences.
+	Matches one or more occurrences.
?	Matches zero or one occurrence.
	Specifies alternative matches; for example, E H means E or H.
^	Matches the beginning-of-line character.
\$	Matches the end-of-line character.
\$	Matches the end of the string.
[]	Brackets specify a matching list, that should match one expression in the list. A caret (^) precedes a nonmatching list, which matches any character except for the expressions represented in the list.
()	Parentheses group items into a single logical item.
{m}	Repeat the previous item exactly <i>m</i> times.
{m, }	Repeat the previous item <i>m</i> or more times.
{m, n}	Repeat the previous item at least <i>m</i> and not more than <i>n</i> times.
[: :]	Matches any character within a POSIX character class. In the following character classes, Amazon Redshift supports only ASCII characters: [:alnum:] , [:alpha:] , [:lower:] , [:upper:]

Amazon Redshift supports the following POSIX character classes.

Character Class	Description
[[:alnum:]]	All ASCII alphanumeric characters

Character Class	Description
<code>[[:alpha:]]</code>	All ASCII alphabetic characters
<code>[[:blank:]]</code>	All blank space characters
<code>[[:cntrl:]]</code>	All control characters (nonprinting)
<code>[[:digit:]]</code>	All numeric digits
<code>[[:lower:]]</code>	All lowercase ASCII alphabetic characters
<code>[[:punct:]]</code>	All punctuation characters
<code>[[:space:]]</code>	All space characters (nonprinting)
<code>[[:upper:]]</code>	All uppercase ASCII alphabetic characters
<code>[[:xdigit:]]</code>	All valid hexadecimal characters

Amazon Redshift supports the following Perl-influenced operators in regular expressions. Escape the operator using two backslashes (`'\\'`).

Operator	Description	Equivalent character class expression
<code>\\d</code>	A digit character	<code>[[:digit:]]</code>
<code>\\D</code>	A nondigit character	<code>[^[:digit:]]</code>
<code>\\w</code>	A word character	<code>[[:word:]]</code>
<code>\\W</code>	A nonword character	<code>[^[:word:]]</code>
<code>\\s</code>	A white space character	<code>[[:space:]]</code>
<code>\\S</code>	A non-white space character	<code>[^[:space:]]</code>
<code>\\b</code>	A boundary word	

Examples

The following table shows examples of pattern matching using POSIX operators:

Expression	Returns
'abc' ~ 'abc'	True
'abc' ~ 'a'	True
'abc' ~ 'A'	False
'abc' ~ '.*(b d).*'	True
'abc' ~ '(b c).*'	True
'AbcAbcdefgfe12efgfe12' ~ '((Ab)?c)+d((efg)+(12))+'	True
'aaaaaab11111xy' ~ 'a{6}.[1]{5} (x y){2}'	True
'\$0.87' ~ '\\\$[0-9]+(\\.[0-9] [0-9])?'	True
'ab c' ~ '[[[:space:]]'	True
'ab c' ~ '\\s'	True
' ' ~ '\\S'	False

The following example finds cities whose names contain E or H:

```
SELECT DISTINCT city FROM users
WHERE city ~ '.*E.*|.H.*' ORDER BY city LIMIT 5;
```

```
city
```

```
-----
```

```
Agoura Hills
```

```
Auburn Hills
```

```
Benton Harbor
```

```
Beverly Hills
Chicago Heights
```

The following example finds cities whose names don't contain E or H:

```
SELECT DISTINCT city FROM users WHERE city !~ '.*E.*|.H.*' ORDER BY city LIMIT 5;
```

```
      city
-----
Aberdeen
Abilene
Ada
Agat
Agawam
```

The following example uses the escape string ('\\') to search for strings that include a period.

```
SELECT venueid FROM venue
WHERE venueid ~ '.*\\..*'
ORDER BY venueid;
```

```
      venueid
-----
St. Pete Times Forum
Jobing.com Arena
Hubert H. Humphrey Metrodome
U.S. Cellular Field
Superpages.com Center
E.J. Nutter Center
Bernard B. Jacobs Theatre
St. James Theatre
```

BETWEEN range condition

A BETWEEN condition tests expressions for inclusion in a range of values, using the keywords BETWEEN and AND.

Syntax

```
expression [ NOT ] BETWEEN expression AND expression
```

Expressions can be numeric, character, or datetime data types, but they must be compatible. The range is inclusive.

Examples

The first example counts how many transactions registered sales of either 2, 3, or 4 tickets:

```
select count(*) from sales
where qtysold between 2 and 4;

count
-----
104021
(1 row)
```

The range condition includes the begin and end values.

```
select min(dateid), max(dateid) from sales
where dateid between 1900 and 1910;

min | max
-----+-----
1900 | 1910
```

The first expression in a range condition must be the lesser value and the second expression the greater value. The following example will always return zero rows due to the values of the expressions:

```
select count(*) from sales
where qtysold between 4 and 2;

count
-----
0
(1 row)
```

However, applying the NOT modifier will invert the logic and produce a count of all rows:

```
select count(*) from sales
where qtysold not between 4 and 2;
```

```
count
-----
172456
(1 row)
```

The following query returns a list of venues with 20000 to 50000 seats:

```
select venueid, venuename, venueseats from venue
where venueseats between 20000 and 50000
order by venueseats desc;
```

```
venueid |          venuename          | venueseats
-----+-----+-----
116 | Busch Stadium                |    49660
106 | Rangers BallPark in Arlington |    49115
96  | Oriole Park at Camden Yards  |    48876
...
(22 rows)
```

The following example demonstrates using BETWEEN for date values:

```
select salesid, qty sold, pricepaid, commission, saletime
from sales
where eventid between 1000 and 2000
   and saletime between '2008-01-01' and '2008-01-03'
order by saletime asc;
```

```
salesid | qty sold | pricepaid | commission | saletime
-----+-----+-----+-----+-----
65082 | 4 | 472 | 70.8 | 1/1/2008 06:06
110917 | 1 | 337 | 50.55 | 1/1/2008 07:05
112103 | 1 | 241 | 36.15 | 1/2/2008 03:15
137882 | 3 | 1473 | 220.95 | 1/2/2008 05:18
40331 | 2 | 58 | 8.7 | 1/2/2008 05:57
110918 | 3 | 1011 | 151.65 | 1/2/2008 07:17
96274 | 1 | 104 | 15.6 | 1/2/2008 07:18
150499 | 3 | 135 | 20.25 | 1/2/2008 07:20
68413 | 2 | 158 | 23.7 | 1/2/2008 08:12
```

Note that although BETWEEN's range is inclusive, dates default to having a time value of 00:00:00. The only valid January 3 row for the sample query would be a row with a saletime of 1/3/2008 00:00:00.

Null condition

The null condition tests for nulls, when a value is missing or unknown.

Syntax

```
expression IS [ NOT ] NULL
```

Arguments

expression

Any expression such as a column.

IS NULL

Is true when the expression's value is null and false when it has a value.

IS NOT NULL

Is false when the expression's value is null and true when it has a value.

Example

This example indicates how many times the SALES table contains null in the QTYSOLD field:

```
select count(*) from sales
where qtysold is null;
count
-----
0
(1 row)
```

EXISTS condition

EXISTS conditions test for the existence of rows in a subquery, and return true if a subquery returns at least one row. If NOT is specified, the condition returns true if a subquery returns no rows.

Syntax

```
[ NOT ] EXISTS (table_subquery)
```

Arguments

EXISTS

Is true when the *table_subquery* returns at least one row.

NOT EXISTS

Is true when the *table_subquery* returns no rows.

table_subquery

A subquery that evaluates to a table with one or more columns and one or more rows.

Example

This example returns all date identifiers, one time each, for each date that had a sale of any kind:

```
select dateid from date
where exists (
select 1 from sales
where date.dateid = sales.dateid
)
order by dateid;

dateid
-----
1827
1828
1829
...
```

IN condition

An IN condition tests a value for membership in a set of values or in a subquery.

Syntax

```
expression [ NOT ] IN (expr_list | table_subquery)
```

Arguments

expression

A numeric, character, or datetime expression that is evaluated against the *expr_list* or *table_subquery* and must be compatible with the data type of that list or subquery.

expr_list

One or more comma-delimited expressions, or one or more sets of comma-delimited expressions bounded by parentheses.

table_subquery

A subquery that evaluates to a table with one or more rows, but is limited to only one column in its select list.

IN | NOT IN

IN returns true if the expression is a member of the expression list or query. NOT IN returns true if the expression is not a member. IN and NOT IN return NULL and no rows are returned in the following cases: If *expression* yields null; or if there are no matching *expr_list* or *table_subquery* values and at least one of these comparison rows yields null.

Examples

The following conditions are true only for those values listed:

```
qty sold in (2, 4, 5)
date.day in ('Mon', 'Tues')
date.month not in ('Oct', 'Nov', 'Dec')
```

Optimization for Large IN Lists

To optimize query performance, an IN list that includes more than 10 values is internally evaluated as a scalar array. IN lists with fewer than 10 values are evaluated as a series of OR predicates. This optimization is supported for SMALLINT, INTEGER, BIGINT, REAL, DOUBLE PRECISION, BOOLEAN, CHAR, VARCHAR, DATE, TIMESTAMP, and TIMESTAMPTZ data types.

Look at the EXPLAIN output for the query to see the effect of this optimization. For example:

```
explain select * from sales
```

QUERY PLAN

```
-----  
XN Seq Scan on sales (cost=0.00..6035.96 rows=86228 width=53)  
Filter: (salesid = ANY ('{1,2,3,4,5,6,7,8,9,10,11}'::integer[]))  
(2 rows)
```

SQL commands

The SQL language consists of commands that you use to create and manipulate database objects, run queries, load tables, and modify the data in tables.

Amazon Redshift is based on PostgreSQL. Amazon Redshift and PostgreSQL have a number of important differences that you must be aware of as you design and develop your data warehouse applications. For more information about how Amazon Redshift SQL differs from PostgreSQL, see [Amazon Redshift and PostgreSQL](#).

Note

The maximum size for a single SQL statement is 16 MB.

ABORT

Stops the currently running transaction and discards all updates made by that transaction. ABORT has no effect on already completed transactions.

This command performs the same function as the ROLLBACK command. For information, see [ROLLBACK](#).

Syntax

```
ABORT [ WORK | TRANSACTION ]
```

Parameters

WORK

Optional keyword.

TRANSACTION

Optional keyword; WORK and TRANSACTION are synonyms.

Example

The following example creates a table then starts a transaction where data is inserted into the table. The ABORT command then rolls back the data insertion to leave the table empty.

The following command creates an example table called MOVIE_GROSS:

```
create table movie_gross( name varchar(30), gross bigint );
```

The next set of commands starts a transaction that inserts two data rows into the table:

```
begin;  
  
insert into movie_gross values ( 'Raiders of the Lost Ark', 23400000);  
  
insert into movie_gross values ( 'Star Wars', 10000000 );
```

Next, the following command selects the data from the table to show that it was successfully inserted:

```
select * from movie_gross;
```

The command output shows that both rows are successfully inserted:

```
      name          | gross  
-----+-----  
Raiders of the Lost Ark | 23400000  
Star Wars           | 10000000  
(2 rows)
```

This command now rolls back the data changes to where the transaction began:

```
abort;
```

Selecting data from the table now shows an empty table:

```
select * from movie_gross;  
  
 name | gross  
-----+-----  
(0 rows)
```

ALTER DATABASE

Changes the attributes of a database.

Required privileges

To use ALTER DATABASE, one of the following privileges is required..

- Superuser
- Users with the ALTER DATABASE privilege
- Database owner

Syntax

```
ALTER DATABASE database_name
{ RENAME TO new_name
| OWNER TO new_owner
| CONNECTION LIMIT { limit | UNLIMITED }
| COLLATE { CASE_SENSITIVE | CASE_INSENSITIVE }
| ISOLATION LEVEL { SERIALIZABLE | SNAPSHOT }
| INTEGRATION REFRESH {{ ALL | INERROR } TABLES [IN SCHEMA schema [, ...]] |
  TABLE schema.table [, ...]}
}
```

Parameters

database_name

Name of the database to alter. Typically, you alter a database that you are not currently connected to; in any case, the changes take effect only in subsequent sessions. You can change the owner of the current database, but you can't rename it:

```
alter database tickit rename to newticket;
ERROR:  current database may not be renamed
```

RENAME TO

Renames the specified database. For more information about valid names, see [Names and identifiers](#). You can't rename the dev, padb_harvest, template0, template1, or sys:internal databases, and you can't rename the current database. Only the database owner or a [superuser \(p. 872\)](#) can rename a database; non-superuser owners must also have the CREATEDB privilege.

new_name

New database name.

OWNER TO

Changes the owner of the specified database. You can change the owner of the current database or some other database. Only a superuser can change the owner.

new_owner

New database owner. The new owner must be an existing database user with write privileges. For more information about user privileges, see [GRANT](#).

CONNECTION LIMIT { *limit* | UNLIMITED }

The maximum number of database connections users are permitted to have open concurrently. The limit is not enforced for superusers. Use the UNLIMITED keyword to permit the maximum number of concurrent connections. A limit on the number of connections for each user might also apply. For more information, see [CREATE USER](#). The default is UNLIMITED. To view current connections, query the [STV_SESSIONS](#) system view.

 **Note**

If both user and database connection limits apply, an unused connection slot must be available that is within both limits when a user attempts to connect.

COLLATE { CASE_SENSITIVE | CASE_INSENSITIVE }

A clause that specifies whether string search or comparison is case-sensitive or case-insensitive.

You can change the case sensitivity of the current database which is empty.

You must have the privilege to the current database to change case sensitivity. Superusers or database owners with the CREATE DATABASE privilege can also change database case sensitivity.

ISOLATION LEVEL { SERIALIZABLE | SNAPSHOT }

A clause that specifies the isolation level used when queries run against a database.

- SERIALIZABLE isolation – provides full serializability for concurrent transactions. For more information, see [Serializable isolation](#).

- SNAPSHOT isolation – provides an isolation level with protection against update and delete conflicts.

For more information about isolation levels, see [CREATE DATABASE](#).

Consider the following items when altering the isolation level of a database:

- You must have the superuser or CREATE DATABASE privilege to the current database to change the database isolation level.
- You can't alter the isolation level of the dev database.
- You can't alter the isolation level within a transaction block.
- The alter isolation level command fails if other users are connected to the database.
- The alter isolation level command can alter the isolation level settings of the current session.

```
INTEGRATION REFRESH {{ ALL | INERROR } TABLES [IN SCHEMA schema [, ...]] | TABLE schema.table [, ...]}
```

A clause that specifies whether Amazon Redshift will refresh all tables or tables with errors in the specified schema or table. The refresh will trigger the tables in the specified schema or table to be fully replicated from the source database.

For more information, see [Working with zero-ETL integrations](#) in the *Amazon Redshift Management Guide*. For more information about integration states, see [SVV_INTEGRATION_TABLE_STATE](#) and [SVV_INTEGRATION](#).

Usage notes

ALTER DATABASE commands apply to subsequent sessions not current sessions. You must reconnect to the altered database to see the effect of the change.

Examples

The following example renames a database named TICKIT_SANDBOX to TICKIT_TEST:

```
alter database tickit_sandbox rename to tickit_test;
```

The following example changes the owner of the TICKIT database (the current database) to DWUSER:

```
alter database tickit owner to dwuser;
```

The following example changes the database case sensitivity of the `sampledb` database:

```
ALTER DATABASE sampledb COLLATE CASE_INSENSITIVE;
```

The following example alters a database named `sampledb` with `SNAPSHOT` isolation level.

```
ALTER DATABASE sampledb ISOLATION LEVEL SNAPSHOT;
```

The following example refreshes the tables `sample_table1` and `sample_table2` in the database `sample_integration_db` in your zero-ETL integration.

```
ALTER DATABASE sample_integration_db INTEGRATION REFRESH TABLES sample_table1,  
sample_table2;
```

The following example refreshes all synced and failed tables within your zero-ETL integration.

```
ALTER DATABASE sample_integration_db INTEGRATION REFRESH ALL tables;
```

The following example refresh all tables that are in the `ErrorState` in the schema `sample_schema`.

```
ALTER DATABASE sample_integration_db INTEGRATION REFRESH INERROR TABLES in SCHEMA  
sample_schema;
```

ALTER DATASHARE

Changes the definition of a datashare. You can add objects or remove objects using `ALTER DATASHARE`. You can only change a datashare in the current database. Add or remove objects from the associated database to a datashare. The owner of the datashare with the required permissions on the datashare objects to be added or removed can alter the datashare.

Required privileges

Following are required privileges for `ALTER DATASHARE`:

- Superuser.
- User with the `ALTER DATASHARE` privilege.

- Users who have the ALTER or ALL privilege on the datashare.
- To add specific objects to a datashare, users must have the privilege on the objects. For this case, users should be the owners of objects or have SELECT, USAGE, or ALL privileges on the objects.

Syntax

The following syntax illustrates how to add or remove objects to the datashare.

```
ALTER DATASHARE datashare_name { ADD | REMOVE } {
TABLE schema.table [, ...]
| SCHEMA schema [, ...]
| FUNCTION schema.sql_udf (argtype,...) [, ...]
| ALL TABLES IN SCHEMA schema [, ...]
| ALL FUNCTIONS IN SCHEMA schema [, ...] }
```

The following syntax illustrates how to configure the properties of the datashare.

```
ALTER DATASHARE datashare_name {
[ SET PUBLICACCESSIBLE [=] TRUE | FALSE ]
[ SET INCLUDENEW [=] TRUE | FALSE FOR SCHEMA schema ] }
```

Parameters

datashare_name

The name of the datashare to be altered.

ADD | REMOVE

A clause that specifies whether to add objects to or remove objects from the datashare.

TABLE *schema.table* [, ...]

The name of the table or view in the specified schema to add to the datashare.

SCHEMA *schema* [, ...]

The name of the schema to add to the datashare.

FUNCTION *schema.sql_udf* (argtype,...) [, ...]

The name of the user-defined SQL function with argument types to add to the datashare.

ALL TABLES IN SCHEMA *schema* [, ...]

A clause that specifies whether to add all tables and views in the specified schema to the datashare.

ALL FUNCTIONS IN SCHEMA *schema* [, ...] }

A clause that specifies adding all functions in the specified schema to the datashare.

[SET PUBLICACCESSIBLE [=] TRUE | FALSE]

A clause that specifies whether a datashare can be shared to clusters that are publicly accessible.

[SET INCLUDENEW [=] TRUE | FALSE FOR SCHEMA *schema*]

A clause that specifies whether to add any future tables, views, or SQL user-defined functions (UDFs) created in the specified schema to the datashare. Current tables, views, or SQL UDFs in the specified schema aren't added to the datashare. Only superusers can change this property for each datashare-schema pair. By default, the INCLUDENEW clause is false.

ALTER DATASHARE usage notes

- The following users can alter a datashare:
 - A superuser
 - The owner of the datashare
 - Users that have ALTER or ALL privilege on the datashare
- To add specific objects to a datashare, users must have the correct privileges on the objects. Users should be the owners of objects or have SELECT, USAGE, or ALL privileges on the objects.
- You can share schemas, tables, regular views, late-binding views, materialized views, and SQL user-defined functions (UDFs). Add a schema to a datashare first before adding objects in the schema.

When you add a schema, Amazon Redshift doesn't add all the objects under it. You must add them explicitly.

- We recommend that you create AWS Data Exchange datashares with the publicly accessible setting turned on.
- In general, we recommend that you don't alter an AWS Data Exchange datashare to turn off public accessibility using the ALTER DATASHARE statement. If you do, the AWS accounts that

have access to the datashare lose access if their clusters are publicly accessible. Performing this type of alteration can breach data product terms in AWS Data Exchange. For an exception to this recommendation, see following.

The following example shows an error when an AWS Data Exchange datashare is created with the setting turned off.

```
ALTER DATASHARE salesshare SET PUBLICACCESSIBLE FALSE;
ERROR: Alter of ADX-managed datashare salesshare requires session variable
datashare_break_glass_session_var to be set to value 'c670ba4db22f4b'
```

To allow altering an AWS Data Exchange datashare to turn off the publicly accessible setting, set the following variable and run the ALTER DATASHARE statement again.

```
SET datashare_break_glass_session_var to 'c670ba4db22f4b';
```

```
ALTER DATASHARE salesshare SET PUBLICACCESSIBLE FALSE;
```

In this case, Amazon Redshift generates a random one-time value to set the session variable to allow ALTER DATASHARE SET PUBLICACCESSIBLE FALSE for an AWS Data Exchange datashare.

Examples

The following example adds the public schema to the datashare salesshare.

```
ALTER DATASHARE salesshare ADD SCHEMA public;
```

The following example adds the public.tickit_sales_redshift table to the datashare salesshare.

```
ALTER DATASHARE salesshare ADD TABLE public.tickit_sales_redshift;
```

The following example adds all tables to the datashare salesshare.

```
ALTER DATASHARE salesshare ADD ALL TABLES IN SCHEMA PUBLIC;
```

The following example removes the public.tickit_sales_redshift table from the datashare salesshare.

```
ALTER DATASHARE salesshare REMOVE TABLE public.tickit_sales_redshift;
```

ALTER DEFAULT PRIVILEGES

Defines the default set of access permissions to be applied to objects that are created in the future by the specified user. By default, users can change only their own default access permissions. Only a superuser can specify default permissions for other users.

You can apply default privileges to roles, users, or user groups. You can set default permissions globally for all objects created in the current database, or for objects created only in the specified schemas.

Default permissions apply only to new objects. Running ALTER DEFAULT PRIVILEGES doesn't change permissions on existing objects. To grant permissions on all current and future objects created by any user within a database or schema, see [Scoped permissions](#).

To view information about the default privileges for database users, query the [PG_DEFAULT_ACL](#) system catalog table.

For more information about privileges, see [GRANT](#).

Required privileges

Following are required privileges for ALTER DEFAULT PRIVILEGES:

- Superuser
- Users with the ALTER DEFAULT PRIVILEGES privilege
- Users changing their own default access privileges
- Users setting privileges for schemas that they have access privileges to

Syntax

```
ALTER DEFAULT PRIVILEGES
  [ FOR USER target_user [, ...] ]
  [ IN SCHEMA schema_name [, ...] ]
  grant_or_revoke_clause
```

where *grant_or_revoke_clause* is one of:

```
GRANT { { SELECT | INSERT | UPDATE | DELETE | DROP | REFERENCES | TRUNCATE } [,...] |
ALL [ PRIVILEGES ] }
ON TABLES
TO { user_name [ WITH GRANT OPTION ] | ROLE role_name | GROUP group_name | PUBLIC }
[, ...]

GRANT { EXECUTE | ALL [ PRIVILEGES ] }
ON FUNCTIONS
TO { user_name [ WITH GRANT OPTION ] | ROLE role_name | GROUP group_name | PUBLIC }
[, ...]

GRANT { EXECUTE | ALL [ PRIVILEGES ] }
ON PROCEDURES
TO { user_name [ WITH GRANT OPTION ] | ROLE role_name | GROUP group_name | PUBLIC }
[, ...]

REVOKE [ GRANT OPTION FOR ] { { SELECT | INSERT | UPDATE | DELETE | REFERENCES |
TRUNCATE } [,...] | ALL [ PRIVILEGES ] }
ON TABLES
FROM user_name [, ...] [ RESTRICT ]

REVOKE { { SELECT | INSERT | UPDATE | DELETE | REFERENCES | TRUNCATE } [,...] | ALL
[ PRIVILEGES ] }
ON TABLES
FROM { ROLE role_name | GROUP group_name | PUBLIC } [, ...] [ RESTRICT ]

REVOKE [ GRANT OPTION FOR ] { EXECUTE | ALL [ PRIVILEGES ] }
ON FUNCTIONS
FROM user_name [, ...] [ RESTRICT ]

REVOKE { EXECUTE | ALL [ PRIVILEGES ] }
ON FUNCTIONS
FROM { ROLE role_name | GROUP group_name | PUBLIC } [, ...] [ RESTRICT ]

REVOKE [ GRANT OPTION FOR ] { EXECUTE | ALL [ PRIVILEGES ] }
ON PROCEDURES
FROM user_name [, ...] [ RESTRICT ]

REVOKE { EXECUTE | ALL [ PRIVILEGES ] }
ON PROCEDURES
FROM { ROLE role_name | GROUP group_name | PUBLIC } [, ...] [ RESTRICT ]
```

Parameters

FOR USER *target_user*

Optional. The name of the user for which default privileges are defined. Only a superuser can specify default privileges for other users. The default value is the current user.

IN SCHEMA *schema_name*

Optional. If an IN SCHEMA clause appears, the specified default privileges are applied to new objects created in the specified *schema_name*. In this case, the user or user group that is the target of ALTER DEFAULT PRIVILEGES must have CREATE privilege for the specified schema. Default privileges that are specific to a schema are added to existing global default privileges. By default, default privileges are applied globally to the entire database.

GRANT

The set of privileges to grant to the specified users or groups for all new tables and views, functions, or stored procedures created by the specified user. You can set the same privileges and options with the GRANT clause that you can with the [GRANT](#) command.

WITH GRANT OPTION

A clause that indicates that the user receiving the privileges can in turn grant the same privileges to others. You can't grant WITH GRANT OPTION to a group or to PUBLIC.

TO *user_name* | ROLE *role_name* | GROUP *group_name*

The name of the user, role, or user group to which the specified default privileges are applied.

REVOKE

The set of privileges to revoke from the specified users or groups for all new tables, functions, or stored procedures created by the specified user. You can set the same privileges and options with the REVOKE clause that you can with the [REVOKE](#) command.

GRANT OPTION FOR

A clause that revokes only the option to grant a specified privilege to other users and doesn't revoke the privilege itself. You can't revoke GRANT OPTION from a group or from PUBLIC.

FROM *user_name* | ROLE *role_name* | GROUP *group_name*

The name of the user, role, or user group from which the specified privileges are revoked by default.

RESTRICT

The RESTRICT option revokes only those privileges that the user directly granted. This is the default.

Examples

Suppose that you want to allow any user in the user group `report_readers` to view all tables and views created by the user `report_admin`. In this case, run the following command as a superuser.

```
alter default privileges for user report_admin grant select on tables to group
report_readers;
```

In the following example, the first command grants SELECT privileges on all new tables and views you create.

```
alter default privileges grant select on tables to public;
```

The following example grants INSERT privilege to the `sales_admin` user group for all new tables and views that you create in the `sales` schema.

```
alter default privileges in schema sales grant insert on tables to group sales_admin;
```

The following example reverses the ALTER DEFAULT PRIVILEGES command in the preceding example.

```
alter default privileges in schema sales revoke insert on tables from group
sales_admin;
```

By default, the PUBLIC user group has execute permission for all new user-defined functions. To revoke public execute permissions for your new functions and then grant execute permission only to the `dev_test` user group, run the following commands.

```
alter default privileges revoke execute on functions from public;
alter default privileges grant execute on functions to group dev_test;
```

ALTER EXTERNAL VIEW (preview)

This is prerelease documentation views in Data Catalog for Amazon Redshift, which is in preview release. The documentation and the feature are both subject to change. We recommend that you use this feature only with test clusters, and not in production environments. For preview terms and conditions, see Beta and Previews in [AWS Service Terms](#).

You can create an Amazon Redshift cluster in **Preview** to test new features of Amazon Redshift. You can't use those features in production or move your **Preview** cluster to a production cluster or a cluster on another track. For preview terms and conditions, see *Beta and Previews* in [AWS Service Terms](#).

To create a cluster in Preview

1. Sign in to the AWS Management Console and open the Amazon Redshift console at <https://console.aws.amazon.com/redshiftv2/>.
2. On the navigation menu, choose **Provisioned clusters dashboard**, and choose **Clusters**. The clusters for your account in the current AWS Region are listed. A subset of properties of each cluster is displayed in columns in the list.
3. A banner displays on the **Clusters** list page that introduces preview. Choose the button **Create preview cluster** to open the create cluster page.
4. Enter properties for your cluster. Choose the **Preview track** that contains the features you want to test. We recommend entering a name for the cluster that indicates that it is on a preview track. Choose options for your cluster, including options labeled as **-preview**, for the features you want to test. For general information about creating clusters, see [Creating a cluster](#) in the *Amazon Redshift Management Guide*.
5. Choose **Create cluster** to create a cluster in preview.

Note

The `preview_2023` track is the most recent preview track available. This track supports creating clusters with RA3 node types only. Node type DC2 and any older node type is not supported.

6. When your preview cluster is available, use your SQL client to load and query data.

The Data Catalog views preview feature is available only in the following Regions.

- US East (Ohio) (us-east-2)
- US East (N. Virginia) (us-east-1)
- US West (N. California) (us-west-1)
- Asia Pacific (Tokyo) (ap-northeast-1)
- Europe (Ireland) (eu-west-1)
- Europe (Stockholm) (eu-north-1)

You can also create a preview workgroup to test Data Catalog views. You can't use those features in production or move your workgroup to another workgroup. For preview terms and conditions, see Beta and Previews in [AWS Service Terms](#). For instructions on how to create a preview workgroup, see [Creating a preview workgroup](#).

Use the ALTER EXTERNAL VIEW command to update your external view. Depending on which parameters you use, other SQL engines such as Amazon Athena and Amazon EMR Spark that can also reference this view might be affected. For more information about Data Catalog views, see [Creating Data Catalog views \(preview\)](#).

Syntax

```
ALTER EXTERNAL VIEW schema_name.view_name
{catalog_name.schema_name.view_name | awsdatacatalog.dbname.view_name |
 external_schema_name.view_name}
[FORCE] { AS (query_definition) | REMOVE DEFINITION }
```

Parameters

schema_name.view_name

The schema that's attached to your AWS Glue database, followed by the name of the view.

catalog_name.schema_name.view_name | awsdatacatalog.dbname.view_name |
external_schema_name.view_name

The notation of the schema to use when altering the view. You can specify to use the AWS Glue Data Catalog, a Glue database that you created, or an external schema that you created. See [CREATE DATABASE](#) and [CREATE EXTERNAL SCHEMA](#) for more information.

FORCE

Whether AWS Lake Formation should update the definition of the view even if the objects referenced in the table are inconsistent with other SQL engines. If Lake Formation updates the view, the view is considered stale for the other SQL engines until those engines are updated as well.

AS query_definition

The definition of the SQL query that Amazon Redshift runs to alter the view.

REMOVE DEFINITION

Whether to drop and recreate the views. Views must be dropped and recreated to mark them as PROTECTED.

Examples

The following example alters a Data Catalog view named `sample_schema.glue_data_catalog_view`.

```
ALTER EXTERNAL VIEW sample_schema.glue_data_catalog_view
FORCE
REMOVE DEFINITION
```

ALTER FUNCTION

Renames a function or changes the owner. Both the function name and data types are required. Only the owner or a superuser can rename a function. Only a superuser can change the owner of a function.

Syntax

```
ALTER FUNCTION function_name ( { [ py_arg_name py_arg_data_type | sql_arg_data_type ]
[ , ... ] } )
    RENAME TO new_name
```

```
ALTER FUNCTION function_name ( { [ py_arg_name py_arg_data_type | sql_arg_data_type ]
[ , ... ] } )
    OWNER TO { new_owner | CURRENT_USER | SESSION_USER }
```

Parameters

function_name

The name of the function to be altered. Either specify the name of the function in the current search path, or use the format `schema_name.function_name` to use a specific schema.

py_arg_name py_arg_data_type | sql_arg_data_type

Optional. A list of input argument names and data types for the Python user-defined function, or a list of input argument data types for the SQL user-defined function.

new_name

A new name for the user-defined function.

new_owner | CURRENT_USER | SESSION_USER

A new owner for the user-defined function.

Examples

The following example changes the name of a function from `first_quarter_revenue` to `quarterly_revenue`.

```
ALTER FUNCTION first_quarter_revenue(bigint, numeric, int)
    RENAME TO quarterly_revenue;
```

The following example changes the owner of the `quarterly_revenue` function to `etl_user`.

```
ALTER FUNCTION quarterly_revenue(bigint, numeric) OWNER TO etl_user;
```

ALTER GROUP

Changes a user group. Use this command to add users to the group, drop users from the group, or rename the group.

Syntax

```
ALTER GROUP group_name
{
    ADD USER username [, ... ] |
```

```
DROP USER username [, ... ] |  
RENAME TO new_name  
}
```

Parameters

group_name

Name of the user group to modify.

ADD

Adds a user to a user group.

DROP

Removes a user from a user group.

username

Name of the user to add to the group or drop from the group.

RENAME TO

Renames the user group. Group names beginning with two underscores are reserved for Amazon Redshift internal use. For more information about valid names, see [Names and identifiers](#).

new_name

New name of the user group.

Examples

The following example adds a user named DWUSER to the ADMIN_GROUP group.

```
ALTER GROUP admin_group  
ADD USER dwuser;
```

The following example renames the group ADMIN_GROUP to ADMINISTRATORS.

```
ALTER GROUP admin_group  
RENAME TO administrators;
```

The following example adds two users to the group ADMIN_GROUP.

```
ALTER GROUP admin_group
ADD USER u1, u2;
```

The following example drops two users from the group ADMIN_GROUP.

```
ALTER GROUP admin_group
DROP USER u1, u2;
```

ALTER IDENTITY PROVIDER

Alters an identity provider to assign new parameters and values. When you run this command, all previously set parameter values are deleted before the new values are assigned. Only a superuser can alter an identity provider.

Syntax

```
ALTER IDENTITY PROVIDER identity_provider_name
[PARAMETERS parameter_string]
[NAMESPACE namespace]
[IAM_ROLE iam_role]
[DISABLE | ENABLE]
```

Parameters

identity_provider_name

Name of the new identity provider. For more information about valid names, see [Names and identifiers](#).

parameter_string

A string containing a properly formatted JSON object that contains parameters and values required for the specific identity provider.

namespace

The organization namespace.

iam_role

The IAM role that provides permissions for the connection to IAM Identity Center. This parameter is applicable only when the identity-provider type is AWSIDC.

DISABLE or ENABLE

Turns an identity provider on or off. The default is ENABLE

Examples

The following example alters an identity provider named *oauth_standard*. It applies specifically to when Microsoft Azure AD is the identity provider.

```
ALTER IDENTITY PROVIDER oauth_standard
PARAMETERS '{"issuer":"https://sts.windows.net/2sdfdsf-d475-420d-b5ac-667adad7c702/",
"client_id":"87f4aa26-78b7-410e-bf29-57b39929ef9a",
"client_secret":"BUAH~ewrqewrqwerUUY^%tHe1oNZShoiU7",
"audience":["https://analysis.windows.net/powerbi/connector/AmazonRedshift"]}
}'
```

The following sample shows how to set the identity-provider namespace. This can apply to Microsoft Azure AD, if it follows a statement like the previous sample, or to another identity provider. It can also apply to a case where you connect an existing Amazon Redshift provisioned cluster or Amazon Redshift Serverless workgroup to IAM Identity Center, if you have a connection set up through a managed application.

```
ALTER IDENTITY PROVIDER "my-redshift-idc-application"
NAMESPACE 'MYCO';
```

The following sample sets the IAM role and works in the use case for configuring Redshift integration with IAM Identity Center.

```
ALTER IDENTITY PROVIDER "my-redshift-idc-application"
IAM_ROLE 'arn:aws:iam::123456789012:role/myadministratorrole';
```

For more information about setting up a connection to IAM Identity Center from Redshift, see [Connect Redshift with IAM Identity Center to give users a single sign-on experience](#).

Disabling an identity provider

The following sample statement shows how to disable an identity provider. When it's disabled, federated users from the identity provider can't login to the cluster until it's enabled again.

```
ALTER IDENTITY PROVIDER "redshift-idc-app" DISABLE;
```

ALTER MASKING POLICY

Alters an existing dynamic data masking policy. For more information on dynamic data masking, see [Dynamic data masking](#).

Superusers and users or roles that have the sys:secadmin role can alter a masking policy.

Syntax

```
ALTER MASKING POLICY policy_name  
  USING (masking_expression);
```

Parameters

policy_name

The name of the masking policy. This must be the name of a masking policy that already exists in the database.

masking_expression

The SQL expression used to transform the target columns. It can be written using data manipulation functions such as String manipulation functions, or in conjunction with user-defined functions written in SQL, Python, or with AWS Lambda.

The expression must match the original expression's input columns and data types. For example, if the original masking policy's input columns were `sample_1 FLOAT` and `sample_2 VARCHAR(10)`, you wouldn't be able to alter the masking policy to take a third column, or make the policy take a `FLOAT` and a `BOOLEAN`. If you use a constant as your masking expression, you must explicitly cast it to a type that matches the input type.

You must have the `USAGE` permission on any user-defined functions that you use in the masking expression.

ALTER MATERIALIZED VIEW

Enables automatic refreshing of a materialized view.

Syntax

```
ALTER MATERIALIZED VIEW mv_name
[ AUTO REFRESH { YES | NO } ]
[ ROW LEVEL SECURITY { ON | OFF } [ CONJUNCTION TYPE { AND | OR } ] [FOR DATASHARES] ];
```

Parameters

mv_name

The name of the materialized view to alter.

AUTO REFRESH { YES | NO }

A clause that turns on or off automatic refreshing of a materialized view. For more information about automatic refresh of materialized views, see [Refreshing a materialized view](#).

ROW LEVEL SECURITY { ON | OFF } [CONJUNCTION TYPE { AND | OR }] [FOR DATASHARES]

A clause that turns on or off row-level security for a relation.

When row-level security is turned on for a relation, you can only read the rows that the row-level security policy permits you to access. When there isn't any policy granting you access to the relation, you can't see any rows from the relation. Only superusers and users or roles that have the `sys:secadmin` role can set the ROW LEVEL SECURITY clause. For more information, see [Row-level security](#).

- [CONJUNCTION TYPE { AND | OR }]

A clause that allows you to choose the conjunction type of row-level security policy for a relation. When multiple row-level security policies are attached to a relation, you can combine the policies with the AND or OR clause. By default, Amazon Redshift combines RLS policies with the AND clause. Superusers, users, or roles that have the `sys:secadmin` role can use this clause to define the conjunction type of row-level security policy for a relation. For more information, see [Combining multiple policies per user](#).

- FOR DATASHARES

A clause that determines whether an RLS-protected relation can be accessed over datashares. By default, an RLS-protected relation can't be accessed over a datashare. An ALTER MATERIALIZED VIEW ROW LEVEL SECURITY command run with this clause only affects the relation's datashare accessibility property. The ROW LEVEL SECURITY property isn't changed.

If you make an RLS-protected relation accessible over datashares, the relation doesn't have row-level security in the consumer-side datashared database. The relation retains its RLS property on the producer side.

Examples

The following example enables the `tickets_mv` materialized view to be automatically refreshed.

```
ALTER MATERIALIZED VIEW tickets_mv AUTO REFRESH YES
```

ALTER RLS POLICY

Alter an existing row-level security policy on a table.

Superusers and users or roles that have the `sys:secadmin` role can alter a policy.

Syntax

```
ALTER RLS POLICY policy_name  
USING ( using_predicate_exp );
```

Parameters

policy_name

The name of the policy.

USING (*using_predicate_exp*)

Specifies a filter that is applied to the WHERE clause of the query. Amazon Redshift applies a policy predicate before the query-level user predicates. For example, `current_user = 'joe' and price > 10` limits Joe to see only records with the price greater than \$10.

The expression has access to the variables declared in the WITH clause of the CREATE RLS POLICY statement that was used to create the policy with name *policy_name*.

Examples

The following example alters a RLS policy.

```
-- First create an RLS policy that limits access to rows where catgroup is 'concerts'.
CREATE RLS POLICY policy_concerts
WITH (catgroup VARCHAR(10))
USING (catgroup = 'concerts');

-- Then, alter the RLS policy to only show rows where catgroup is 'piano concerts'.
ALTER RLS POLICY policy_concerts
USING (catgroup = 'piano concerts');
```

ALTER ROLE

Renames a role or changes the owner. For a list of Amazon Redshift system-defined roles, see [the section called “Amazon Redshift system-defined roles”](#).

Required permissions

Following are the required permissions for ALTER ROLE:

- Superuser
- Users with the ALTER ROLE permissions

Syntax

```
ALTER ROLE role [ WITH ]
  { { RENAME TO role } | { OWNER TO user_name } }[, ...]
  [ EXTERNALID TO external_id ]
```

Parameters

role

The name of the role to be altered.

RENAME TO

A new name for the role.

OWNER TO *user_name*

A new owner for the role.

EXTERNALID TO *external_id*

A new external ID for the role, which is associated with an identity provider. For more information, see [Native identity provider \(IdP\) federation for Amazon Redshift](#).

Examples

The following example changes the name of a role from `sample_role1` to `sample_role2`.

```
ALTER ROLE sample_role1 WITH RENAME TO sample_role2;
```

The following example changes the owner of the role.

```
ALTER ROLE sample_role1 WITH OWNER TO user1
```

The syntax of the ALTER ROLE is similar to ALTER PROCEDURE following.

```
ALTER PROCEDURE first_quarter_revenue(bigint, numeric) RENAME TO quarterly_revenue;
```

The following example changes the owner of a procedure to `etl_user`.

```
ALTER PROCEDURE quarterly_revenue(bigint, numeric) OWNER TO etl_user;
```

The following example updates a role `sample_role1` with a new external ID that is associated with an identity provider.

```
ALTER ROLE sample_role1 EXTERNALID TO "XYZ456";
```

ALTER PROCEDURE

Renames a procedure or changes the owner. Both the procedure name and data types, or signature, are required. Only the owner or a superuser can rename a procedure. Only a superuser can change the owner of a procedure.

Syntax

```
ALTER PROCEDURE sp_name [ ( [ [ argname ] [ argmode ] argtype [, ...] ] ) ]
```

```
RENAME TO new_name
```

```
ALTER PROCEDURE sp_name [ ( [ [ argname ] [ argmode ] argtype [, ...] ] ) ]  
OWNER TO { new_owner | CURRENT_USER | SESSION_USER }
```

Parameters

sp_name

The name of the procedure to be altered. Either specify just the name of the procedure in the current search path, or use the format `schema_name.sp_procedure_name` to use a specific schema.

[argname] [argmode] argtype

A list of argument names, argument modes, and data types. Only the input data types are required, which are used to identify the stored procedure. Alternatively, you can provide the full signature used to create the procedure including the input and output parameters with their modes.

new_name

A new name for the stored procedure.

new_owner | CURRENT_USER | SESSION_USER

A new owner for the stored procedure.

Examples

The following example changes the name of a procedure from `first_quarter_revenue` to `quarterly_revenue`.

```
ALTER PROCEDURE first_quarter_revenue(volume INOUT bigint, at_price IN numeric,  
result OUT int) RENAME TO quarterly_revenue;
```

This example is equivalent to the following.

```
ALTER PROCEDURE first_quarter_revenue(bigint, numeric) RENAME TO quarterly_revenue;
```

The following example changes the owner of a procedure to `etl_user`.

```
ALTER PROCEDURE quarterly_revenue(bigint, numeric) OWNER TO etl_user;
```

ALTER SCHEMA

Changes the definition of an existing schema. Use this command to rename a schema or change the owner of a schema. For example, rename an existing schema to preserve a backup copy of that schema when you plan to create a new version of that schema. For more information about schemas, see [CREATE SCHEMA](#).

To view the configured schema quotas, see [SVV_SCHEMA_QUOTA_STATE](#).

To view the records where schema quotas were exceeded, see [STL_SCHEMA_QUOTA_VIOLATIONS](#).

Required privileges

Following are required privileges for ALTER SCHEMA:

- Superuser
- User with the ALTER SCHEMA privilege
- Schema owner

When you change a schema name, note that objects using the old name, such as stored procedures or materialized views, must be updated to use the new name.

Syntax

```
ALTER SCHEMA schema_name
{
  RENAME TO new_name |
  OWNER TO new_owner |
  QUOTA { quota [MB | GB | TB] | UNLIMITED }
}
```

Parameters

schema_name

The name of the database schema to be altered.

RENAME TO

A clause that renames the schema.

new_name

The new name of the schema. For more information about valid names, see [Names and identifiers](#).

OWNER TO

A clause that changes the owner of the schema.

new_owner

The new owner of the schema.

QUOTA

The maximum amount of disk space that the specified schema can use. This space is the collective size of all tables under the specified schema. Amazon Redshift converts the selected value to megabytes. Gigabytes is the default unit of measurement when you don't specify a value.

For more information about configuring schema quotas, see [CREATE SCHEMA](#).

Examples

The following example renames the SALES schema to US_SALES.

```
alter schema sales
rename to us_sales;
```

The following example gives ownership of the US_SALES schema to the user DWUSER.

```
alter schema us_sales
owner to dwuser;
```

The following example changes the quota to 300 GB and removes the quota.

```
alter schema us_sales QUOTA 300 GB;
alter schema us_sales QUOTA UNLIMITED;
```

ALTER SYSTEM

Changes a system-level configuration option for the Amazon Redshift cluster or Redshift Serverless workgroup.

Required privileges

One of the following user types can run the ALTER SYSTEM command:

- Superuser
- Admin user

Syntax

```
ALTER SYSTEM SET system-level-configuration = {true| t | on | false | f | off}
```

Parameters

system-level-configuration

A system-level configuration. Valid value: `data_catalog_auto_mount` and `metadata_security`.

{true| t | on | false | f | off}

A value to activate or deactivate the system-level configuration. A `true`, `t`, or `on` indicates to activate the configuration. A `false`, `f`, or `off` indicates to deactivate the configuration.

Usage notes

For a provisioned cluster, changes to `data_catalog_auto_mount` take effect on the next reboot of the cluster. For more information, see [Rebooting a cluster](#) in the *Amazon Redshift Management Guide*.

For a serverless workgroup, changes to `data_catalog_auto_mount` do not take effect immediately.

Examples

The following example turns on automounting the AWS Glue Data Catalog.

```
ALTER SYSTEM SET data_catalog_auto_mount = true;
```

The following example turns on metadata security.

```
ALTER SYSTEM SET metadata_security = true;
```

Setting a default identity namespace

This example is specific to working with an identity provider. You can integrate Redshift with IAM Identity Center and an identity provider to centralize identity management for Redshift and other AWS services.

The following sample shows how to set the default identity namespace for the system. Doing this subsequently makes it more simple to run GRANT and CREATE statements, because you don't have to include the namespace as a prefix for each identity.

```
ALTER SYSTEM SET default_identity_namespace = 'MYCO';
```

After running the command, you can run statements like the following:

```
GRANT SELECT ON TABLE mytable TO alice;

GRANT UPDATE ON TABLE mytable TO salesrole;

CREATE USER bob password 'md50c983d1a624280812631c5389e60d48c';
```

The effect of setting the default identity namespace is that each identity doesn't require it as a prefix. In this example, `alice` is replaced with `MYCO:alice`. This happens with any identity included. For more information about using an identity provider with Redshift, see [Connect Redshift with IAM Identity Center to give users a single sign-on experience](#).

For more information about settings that pertain to Redshift configuration with IAM Identity Center, see [SET](#) and [ALTER IDENTITY PROVIDER](#).

ALTER TABLE

This command changes the definition of a Amazon Redshift table or Amazon Redshift Spectrum external table. This command updates the values and properties set by [CREATE TABLE](#) or [CREATE EXTERNAL TABLE](#).

You can't run ALTER TABLE on an external table within a transaction block (BEGIN ... END). For more information about transactions, see [Serializable isolation](#).

ALTER TABLE locks the table for read and write operations until the transaction enclosing the ALTER TABLE operation completes, unless it's specifically stated in the documentation that you can query data or perform other operations on the table while it is altered.

Required privileges

The user that alters a table needs the proper privilege for the command to succeed. Depending on the ALTER TABLE command, one of the following privileges is required.

- Superuser
- Users with the ALTER TABLE privilege
- Table owner with the USAGE privilege on the schema

Syntax

```
ALTER TABLE table_name
{
ADD table_constraint
| DROP CONSTRAINT constraint_name [ RESTRICT | CASCADE ]
| OWNER TO new_owner
| RENAME TO new_name
| RENAME COLUMN column_name TO new_name
| ALTER COLUMN column_name TYPE updated_varchar_data_type_size
| ALTER COLUMN column_name ENCODE new_encode_type
| ALTER COLUMN column_name ENCODE encode_type,
| ALTER COLUMN column_name ENCODE encode_type, .....;
| ALTER DISTKEY column_name
| ALTER DISTSTYLE ALL
| ALTER DISTSTYLE EVEN
| ALTER DISTSTYLE KEY DISTKEY column_name
| ALTER DISTSTYLE AUTO
| ALTER [COMPOUND] SORTKEY ( column_name [,...] )
| ALTER SORTKEY AUTO
| ALTER SORTKEY NONE
| ALTER ENCODE AUTO
| ADD [ COLUMN ] column_name column_type
  [ DEFAULT default_expr ]
  [ ENCODE encoding ]
```

```
[ NOT NULL | NULL ]
[ COLLATE { CASE_SENSITIVE | CASE_INSENSITIVE } ] |
| DROP [ COLUMN ] column_name [ RESTRICT | CASCADE ]
| ROW LEVEL SECURITY { ON | OFF } [ CONJUNCTION TYPE { AND | OR } ] [ FOR DATASHARES ]}]
```

where *table_constraint* is:

```
[ CONSTRAINT constraint_name ]
{ UNIQUE ( column_name [, ... ] )
| PRIMARY KEY ( column_name [, ... ] )
| FOREIGN KEY ( column_name [, ... ] )
  REFERENCES reftable [ ( refcolumn ) ]}
```

The following options apply only to external tables:

```
SET LOCATION { 's3://bucket/folder/' | 's3://bucket/manifest_file' }
| SET FILE FORMAT format |
| SET TABLE PROPERTIES ('property_name'='property_value')
| PARTITION ( partition_column=partition_value [, ...] )
  SET LOCATION { 's3://bucket/folder' | 's3://bucket/manifest_file' }
| ADD [IF NOT EXISTS]
  PARTITION ( partition_column=partition_value [, ...] ) LOCATION
{ 's3://bucket/folder' | 's3://bucket/manifest_file' }
  [, ... ]
| DROP PARTITION ( partition_column=partition_value [, ...] )
```

To reduce the time to run the ALTER TABLE command, you can combine some clauses of the ALTER TABLE command.

Amazon Redshift supports the following combinations of the ALTER TABLE clauses:

```
ALTER TABLE tablename ALTER SORTKEY (column_list), ALTER DISTKEY column_Id;
ALTER TABLE tablename ALTER DISTKEY column_Id, ALTER SORTKEY (column_list);
ALTER TABLE tablename ALTER SORTKEY (column_list), ALTER DISTSTYLE ALL;
ALTER TABLE tablename ALTER DISTSTYLE ALL, ALTER SORTKEY (column_list);
```

Parameters

table_name

The name of the table to alter. Either specify just the name of the table, or use the format *schema_name.table_name* to use a specific schema. External tables must be qualified by an external schema name. You can also specify a view name if you're using the ALTER TABLE

statement to rename a view or change its owner. The maximum length for the table name is 127 bytes; longer names are truncated to 127 bytes. You can use UTF-8 multibyte characters up to a maximum of four bytes. For more information about valid names, see [Names and identifiers](#).

ADD *table_constraint*

A clause that adds the specified constraint to the table. For descriptions of valid *table_constraint* values, see [CREATE TABLE](#).

Note

You can't add a primary-key constraint to a nullable column. If the column was originally created with the NOT NULL constraint, you can add the primary-key constraint.

DROP CONSTRAINT *constraint_name*

A clause that drops the named constraint from the table. To drop a constraint, specify the constraint name, not the constraint type. To view table constraint names, run the following query.

```
select constraint_name, constraint_type
from information_schema.table_constraints;
```

RESTRICT

A clause that removes only the specified constraint. RESTRICT is an option for DROP CONSTRAINT. RESTRICT can't be used with CASCADE.

CASCADE

A clause that removes the specified constraint and anything dependent on that constraint. CASCADE is an option for DROP CONSTRAINT. CASCADE can't be used with RESTRICT.

OWNER TO *new_owner*

A clause that changes the owner of the table (or view) to the *new_owner* value.

RENAME TO *new_name*

A clause that renames a table (or view) to the value specified in *new_name*. The maximum table name length is 127 bytes; longer names are truncated to 127 bytes.

You can't rename a permanent table to a name that begins with '#'. A table name beginning with '#' indicates a temporary table.

You can't rename an external table.

ALTER COLUMN *column_name* TYPE *updated_varchar_data_type_size*

A clause that changes the size of a column defined as a VARCHAR data type. This clause only supports altering the size of a VARCHAR data type. Consider the following limitations:

- You can't alter a column with compression encodings BYTEDICT, RUNLENGTH, TEXT255, or TEXT32K.
- You can't decrease the size less than maximum size of existing data.
- You can't alter columns with default values.
- You can't alter columns with UNIQUE, PRIMARY KEY, or FOREIGN KEY.
- You can't alter columns within a transaction block (BEGIN ... END). For more information about transactions, see [Serializable isolation](#).

ALTER COLUMN *column_name* ENCODE *new_encode_type*

A clause that changes the compression encoding of a column. If you specify compression encoding for a column, the table is no longer set to ENCODE AUTO. For information on compression encoding, see [Column compression to reduce the size of stored data](#).

When you change compression encoding for a column, the table remains available to query.

Consider the following limitations:

- You can't alter a column to the same encoding as currently defined for the column.
- You can't alter the encoding for a column in a table with an interleaved sortkey.

ALTER COLUMN *column_name* ENCODE *encode_type*, **ALTER COLUMN** *column_name* ENCODE *encode_type*,;

A clause that changes the compression encoding of multiple columns in a single command. For information on compression encoding, see [Column compression to reduce the size of stored data](#).

When you change compression encoding for a column, the table remains available to query.

Consider the following limitations:

- You can't alter a column to the same or different encoding type multiple times in a single command.

- You can't alter a column to the same encoding as currently defined for the column.
- You can't alter the encoding for a column in a table with an interleaved sortkey.

ALTER DISTSTYLE ALL

A clause that changes the existing distribution style of a table to ALL. Consider the following:

- An ALTER DISTSTYLE, ALTER SORTKEY, and VACUUM can't run concurrently on the same table.
 - If VACUUM is currently running, then running ALTER DISTSTYLE ALL returns an error.
 - If ALTER DISTSTYLE ALL is running, then a background vacuum doesn't start on a table.
- The ALTER DISTSTYLE ALL command is not supported for tables with interleaved sort keys and temporary tables.
- If the distribution style was previously defined as AUTO, then the table is no longer a candidate for automatic table optimization.

For more information about DISTSTYLE ALL, see [CREATE TABLE](#).

ALTER DISTSTYLE EVEN

A clause that changes the existing distribution style of a table to EVEN. Consider the following:

- An ALTER DISTSYTLE, ALTER SORTKEY, and VACUUM can't run concurrently on the same table.
 - If VACUUM is currently running, then running ALTER DISTSTYLE EVEN returns an error.
 - If ALTER DISTSTYLE EVEN is running, then a background vacuum doesn't start on a table.
- The ALTER DISTSTYLE EVEN command is not supported for tables with interleaved sort keys and temporary tables.
- If the distribution style was previously defined as AUTO, then the table is no longer a candidate for automatic table optimization.

For more information about DISTSTYLE EVEN, see [CREATE TABLE](#).

ALTER DISTKEY *column_name* or ALTER DISTSTYLE KEY DISTKEY *column_name*

A clause that changes the column used as the distribution key of a table. Consider the following:

- VACUUM and ALTER DISTKEY can't run concurrently on the same table.
 - If VACUUM is already running, then ALTER DISTKEY returns an error.

- If ALTER DISTKEY is running, then background vacuum doesn't start on a table.
- If ALTER DISTKEY is running, then foreground vacuum returns an error.
- You can only run one ALTER DISTKEY command on a table at a time.
- The ALTER DISTKEY command is not supported for tables with interleaved sort keys.
- If the distribution style was previously defined as AUTO, then the table is no longer a candidate for automatic table optimization.

When specifying DISTSTYLE KEY, the data is distributed by the values in the DISTKEY column. For more information about DISTSTYLE, see [CREATE TABLE](#).

ALTER DISTSTYLE AUTO

A clause that changes the existing distribution style of a table to AUTO.

When you alter a distribution style to AUTO, the distribution style of the table is set to the following:

- A small table with DISTSTYLE ALL is converted to AUTO(ALL).
- A small table with DISTSTYLE EVEN is converted to AUTO(ALL).
- A small table with DISTSTYLE KEY is converted to AUTO(ALL).
- A large table with DISTSTYLE ALL is converted to AUTO(EVEN).
- A large table with DISTSTYLE EVEN is converted to AUTO(EVEN).
- A large table with DISTSTYLE KEY is converted to AUTO(KEY) and the DISTKEY is preserved. In this case, Amazon Redshift makes no changes to the table.

If Amazon Redshift determines that a new distribution style or key will improve the performance of queries, then Amazon Redshift might change the distribution style or key of your table in the future. For example, Amazon Redshift might convert a table with a DISTSTYLE of AUTO(KEY) to AUTO(EVEN), or vice versa. For more information about behavior when distribution keys are altered, including data redistribution and locks, see [Amazon Redshift Advisor recommendations](#).

For more information about DISTSTYLE AUTO, see [CREATE TABLE](#).

To view the distribution style of a table, query the SVV_TABLE_INFO system catalog view. For more information, see [SVV_TABLE_INFO](#). To view the Amazon Redshift Advisor recommendations for tables, query the SVV_ALTER_TABLE_RECOMMENDATIONS system catalog view. For more information, see [SVV_ALTER_TABLE_RECOMMENDATIONS](#). To view the

actions taken by Amazon Redshift, query the `SVL_AUTO_WORKER_ACTION` system catalog view. For more information, see [SVL_AUTO_WORKER_ACTION](#).

ALTER [COMPOUND] SORTKEY (*column_name* [,...])

A clause that changes or adds the sort key used for a table. ALTER SORTKEY isn't supported for temporary tables.

When you alter a sort key, the compression encoding of columns in the new or original sort key can change. If no encoding is explicitly defined for the table, then Amazon Redshift automatically assigns compression encodings as follows:

- Columns that are defined as sort keys are assigned RAW compression.
- Columns that are defined as BOOLEAN, REAL, or DOUBLE PRECISION data types are assigned RAW compression.
- Columns that are defined as SMALLINT, INTEGER, BIGINT, DECIMAL, DATE, TIME, TIMETZ, TIMESTAMP, or TIMESTAMPTZ are assigned AZ64 compression.
- Columns that are defined as CHAR or VARCHAR are assigned LZ0 compression.

Consider the following:

- You can define a maximum of 400 columns for a sort key per table.
- You can alter an interleaved sort key to a compound sort key or no sort key. However, you can't alter a compound sort key to an interleaved sort key.
- If the sort key was previously defined as AUTO, then the table is no longer a candidate for automatic table optimization.
- Amazon Redshift recommends using RAW encoding (no compression) for columns defined as sort keys. When you alter a column to choose it as a sort key, the column's compression is changed to RAW compression (no compression). This can increase the amount of storage required by the table. How much the table size increases depend on the specific table definition and table contents. For more information about compression, see [Compression encodings](#)

When data is loaded into a table, the data is loaded in the order of the sort key. When you alter the sort key, Amazon Redshift reorders the data. For more information about SORTKEY, see [CREATE TABLE](#).

ALTER SORTKEY AUTO

A clause that changes or adds the sort key of the target table to AUTO. ALTER SORTKEY AUTO isn't supported for temporary tables.

When you alter a sort key to AUTO, Amazon Redshift preserves the existing sort key of the table.

If Amazon Redshift determines that a new sort key will improve the performance of queries, then Amazon Redshift might change the sort key of your table in the future.

For more information about SORTKEY AUTO, see [CREATE TABLE](#).

To view the sort key of a table, query the SVV_TABLE_INFO system catalog view. For more information, see [SVV_TABLE_INFO](#). To view the Amazon Redshift Advisor recommendations for tables, query the SVV_ALTER_TABLE_RECOMMENDATIONS system catalog view. For more information, see [SVV_ALTER_TABLE_RECOMMENDATIONS](#). To view the actions taken by Amazon Redshift, query the SVL_AUTO_WORKER_ACTION system catalog view. For more information, see [SVL_AUTO_WORKER_ACTION](#).

ALTER SORTKEY NONE

A clause that removes the sort key of the target table.

If the sort key was previously defined as AUTO, then the table is no longer a candidate for automatic table optimization.

ALTER ENCODE AUTO

A clause that changes the encoding type of the target table columns to AUTO. When you alter encoding to AUTO, Amazon Redshift preserves the existing encoding type of the columns in the table. Then, if Amazon Redshift determines that a new encoding type can improve query performance, Amazon Redshift can change the encoding type of the table columns.

If you alter one or more columns to specify an encoding, Amazon Redshift no longer automatically adjusts encoding for all columns in the table. The columns retain the current encode settings.

The following actions don't affect the ENCODE AUTO setting for the table:

- Renaming the table.
- Altering the DISTSTYLE or SORTKEY setting for the table.
- Adding or dropping a column with an ENCODE setting.
- Using the COMPUPDATE option of the COPY command. For more information, see [Data load operations](#).

To view the encoding of a table, query the `SVV_TABLE_INFO` system catalog view. For more information, see [SVV_TABLE_INFO](#).

`RENAME COLUMN column_name TO new_name`

A clause that renames a column to the value specified in *new_name*. The maximum column name length is 127 bytes; longer names are truncated to 127 bytes. For more information about valid names, see [Names and identifiers](#).

`ADD [COLUMN] column_name`

A clause that adds a column with the specified name to the table. You can add only one column in each ALTER TABLE statement.

You can't add a column that is the distribution key (DISTKEY) or a sort key (SORTKEY) of the table.

You can't use an ALTER TABLE ADD COLUMN command to modify the following table and column attributes:

- UNIQUE
- PRIMARY KEY
- REFERENCES (foreign key)
- IDENTITY or GENERATED BY DEFAULT AS IDENTITY

The maximum column name length is 127 bytes; longer names are truncated to 127 bytes. The maximum number of columns you can define in a single table is 1,600.

The following restrictions apply when adding a column to an external table:

- You can't add a column to an external table with the column constraints DEFAULT, ENCODE, NOT NULL, or NULL.
- You can't add columns to an external table that's defined using the AVRO file format.
- If pseudocolumns are enabled, the maximum number of columns that you can define in a single external table is 1,598. If pseudocolumns aren't enabled, the maximum number of columns that you can define in a single table is 1,600.

For more information, see [CREATE EXTERNAL TABLE](#).

column_type

The data type of the column being added. For CHAR and VARCHAR columns, you can use the MAX keyword instead of declaring a maximum length. MAX sets the maximum length to 4,096

bytes for CHAR or 65,535 bytes for VARCHAR. The maximum size of a GEOMETRY object is 1,048,447 bytes.

For information about the data types that Amazon Redshift supports, see [Data types](#).

DEFAULT *default_expr*

A clause that assigns a default data value for the column. The data type of *default_expr* must match the data type of the column. The DEFAULT value must be a variable-free expression. Subqueries, cross-references to other columns in the current table, and user-defined functions aren't allowed.

The *default_expr* is used in any INSERT operation that doesn't specify a value for the column. If no default value is specified, the default value for the column is null.

If a COPY operation encounters a null field on a column that has a DEFAULT value and a NOT NULL constraint, the COPY command inserts the value of the *default_expr*.

DEFAULT isn't supported for external tables.

ENCODE *encoding*

The compression encoding for a column. By default, Amazon Redshift automatically manages compression encoding for all columns in a table if you don't specify compression encoding for any column in the table or if you specify the ENCODE AUTO option for the table.

If you specify compression encoding for any column in the table or if you don't specify the ENCODE AUTO option for the table, Amazon Redshift automatically assigns compression encoding to columns for which you don't specify compression encoding as follows:

- All columns in temporary tables are assigned RAW compression by default.
- Columns that are defined as sort keys are assigned RAW compression.
- Columns that are defined as BOOLEAN, REAL, DOUBLE PRECISION, GEOMETRY, or GEOGRAPHY data type are assigned RAW compression.
- Columns that are defined as SMALLINT, INTEGER, BIGINT, DECIMAL, DATE, TIME, TIMETZ, TIMESTAMP, or TIMESTAMPTZ are assigned AZ64 compression.
- Columns that are defined as CHAR, VARCHAR, or VARBYTE are assigned LZO compression.

Note

If you don't want a column to be compressed, explicitly specify RAW encoding.

The following [compression encodings \(p. 63\)](#) are supported:

- AZ64
- BYTEDICT
- DELTA
- DELTA32K
- LZO
- MOSTLY8
- MOSTLY16
- MOSTLY32
- RAW (no compression)
- RUNLENGTH
- TEXT255
- TEXT32K
- ZSTD

ENCODE isn't supported for external tables.

NOT NULL | NULL

NOT NULL specifies that the column isn't allowed to contain null values. NULL, the default, specifies that the column accepts null values.

NOT NULL and NULL aren't supported for external tables.

COLLATE { CASE_SENSITIVE | CASE_INSENSITIVE }

A clause that specifies whether string search or comparison on the column is CASE_SENSITIVE or CASE_INSENSITIVE. The default value is the same as the current case sensitivity configuration of the database.

To find the database collation information, use the following command:

```
SELECT db_collation();

db_collation
-----
case_sensitive
(1 row)
```

DROP [COLUMN] *column_name*

The name of the column to delete from the table.

You can't drop the last column in a table. A table must have at least one column.

You can't drop a column that is the distribution key (DISTKEY) or a sort key (SORTKEY) of the table. The default behavior for DROP COLUMN is RESTRICT if the column has any dependent objects, such as a view, primary key, foreign key, or UNIQUE restriction.

The following restrictions apply when dropping a column from an external table:

- You can't drop a column from an external table if the column is used as a partition.
- You can't drop a column from an external table that is defined using the AVRO file format.
- RESTRICT and CASCADE are ignored for external tables.
- You can't drop the columns of the policy table referenced inside the policy definition unless you drop or detach the policy. This also applies when the CASCADE option is specified. You can drop other columns in the policy table.

For more information, see [CREATE EXTERNAL TABLE](#).

RESTRICT

When used with DROP COLUMN, RESTRICT means that column to be dropped isn't dropped, in these cases:

- If a defined view references the column that is being dropped
- If a foreign key references the column
- If the column takes part in a multipart key

RESTRICT can't be used with CASCADE.

RESTRICT and CASCADE are ignored for external tables.

CASCADE

When used with DROP COLUMN, removes the specified column and anything dependent on that column. CASCADE can't be used with RESTRICT.

RESTRICT and CASCADE are ignored for external tables.

The following options apply only to external tables.

```
SET LOCATION { 's3://bucket/folder/' | 's3://bucket/manifest_file' }
```

The path to the Amazon S3 folder that contains the data files or a manifest file that contains a list of Amazon S3 object paths. The buckets must be in the same AWS Region as the Amazon Redshift cluster. For a list of supported AWS Regions, see [Amazon Redshift Spectrum limitations](#). For more information about using a manifest file, see LOCATION in the CREATE EXTERNAL TABLE [Parameters](#) reference.

```
SET FILE FORMAT format
```

The file format for external data files.

Valid formats are as follows:

- AVRO
- PARQUET
- RCFILE
- SEQUENCEFILE
- TEXTFILE

```
SET TABLE PROPERTIES ( 'property_name'='property_value' )
```

A clause that sets the table definition for table properties for an external table.

 **Note**

Table properties are case-sensitive.

```
'numRows'='row_count'
```

A property that sets the numRows value for the table definition. To explicitly update an external table's statistics, set the numRows property to indicate the size of the table. Amazon Redshift doesn't analyze external tables to generate the table statistics that the query optimizer uses to generate a query plan. If table statistics aren't set for an external table, Amazon Redshift generates a query execution plan. This plan is based on an assumption that external tables are the larger tables and local tables are the smaller tables.

```
'skip.header.line.count'='line_count'
```

A property that sets number of rows to skip at the beginning of each source file.

```
PARTITION ( partition_column=partition_value [, ...] SET LOCATION { 's3://bucket/folder' | 's3://bucket/manifest_file' }
```

A clause that sets a new location for one or more partition columns.

```
ADD [ IF NOT EXISTS ] PARTITION ( partition_column=partition_value [, ...] ) LOCATION { 's3://bucket/folder' | 's3://bucket/manifest_file' } [, ... ]
```

A clause that adds one or more partitions. You can specify multiple PARTITION clauses using a single ALTER TABLE ... ADD statement.

 **Note**

If you use the AWS Glue catalog, you can add up to 100 partitions using a single ALTER TABLE statement.

The IF NOT EXISTS clause indicates that if the specified partition already exists, the command should make no changes. It also indicates that the command should return a message that the partition exists, rather than terminating with an error. This clause is useful when scripting, so the script doesn't fail if ALTER TABLE tries to add a partition that already exists.

```
DROP PARTITION ( partition_column=partition_value [, ...] )
```

A clause that drops the specified partition. Dropping a partition alters only the external table metadata. The data on Amazon S3 isn't affected.

```
ROW LEVEL SECURITY { ON | OFF } [ CONJUNCTION TYPE { AND | OR } ] [ FOR DATASHARES ]
```

A clause that turns on or off row-level security for a relation.

When row-level security is turned on for a relation, you can only read the rows that the row-level security policy permits you to access. When there isn't any policy granting you access to the relation, you can't see any rows from the relation. Only superusers and users or roles that have the `sys:secadmin` role can set the ROW LEVEL SECURITY clause. For more information, see [Row-level security](#).

- [CONJUNCTION TYPE { AND | OR }]

A clause that allows you to choose the conjunction type of row-level security policy for a relation. When multiple row-level security policies are attached to a relation, you can combine the policies with the AND or OR clause. By default, Amazon Redshift combines RLS policies with the AND clause. Superusers, users, or roles that have the `sys:secadmin` role

can use this clause to define the conjunction type of row-level security policy for a relation. For more information, see [Combining multiple policies per user](#).

- **FOR DATASHARES**

A clause that determines whether an RLS-protected relation can be accessed over datashares. By default, an RLS-protected relation can't be accessed over a datashare. An ALTER TABLE ROW LEVEL SECURITY command run with this clause only affects the relation's datashare accessibility property. The ROW LEVEL SECURITY property isn't changed.

If you make an RLS-protected relation accessible over datashares, the relation doesn't have row-level security in the consumer-side datashared database. The relation retains its RLS property on the producer side.

Examples

For examples that show how to use the ALTER TABLE command, see the following.

- [ALTER TABLE examples](#)
- [ALTER EXTERNAL TABLE examples](#)
- [ALTER TABLE ADD and DROP COLUMN examples](#)

ALTER TABLE examples

The following examples demonstrate basic usage of the ALTER TABLE command.

Rename a table or view

The following command renames the USERS table to USERS_BKUP:

```
alter table users
rename to users_bkup;
```

You can also use this type of command to rename a view.

Change the owner of a table or view

The following command changes the VENUE table owner to the user DWUSER:

```
alter table venue
```

```
owner to dwuser;
```

The following commands create a view, then change its owner:

```
create view vdate as select * from date;
alter table vdate owner to vuser;
```

Rename a column

The following command renames the VENUESEATS column in the VENUE table to VENUESIZE:

```
alter table venue
rename column venueseats to venuesize;
```

Drop a table constraint

To drop a table constraint, such as a primary key, foreign key, or unique constraint, first find the internal name of the constraint. Then specify the constraint name in the ALTER TABLE command. The following example finds the constraints for the CATEGORY table, then drops the primary key with the name category_pkey.

```
select constraint_name, constraint_type
from information_schema.table_constraints
where constraint_schema = 'public'
and table_name = 'category';
```

```
constraint_name | constraint_type
-----+-----
category_pkey  | PRIMARY KEY
```

```
alter table category
drop constraint category_pkey;
```

Alter a VARCHAR column

To conserve storage, you can define a table initially with VARCHAR columns with the minimum size needed for your current data requirements. Later, to accommodate longer strings, you can alter the table to increase the size of the column.

The following example increases the size of the EVENTNAME column to VARCHAR(300).

```
alter table event alter column eventname type varchar(300);
```

Alter the compression encoding for a column

You can alter the compression encoding of a column. Below, you can find a set of examples demonstrating this approach. The table definition for these examples is as follows.

```
create table t1(c0 int encode lzo, c1 bigint encode zstd, c2 varchar(16) encode lzo, c3  
varchar(32) encode zstd);
```

The following statement alters the compression encoding for column c0 from LZ0 encoding to AZ64 encoding.

```
alter table t1 alter column c0 encode az64;
```

The following statement alters the compression encoding for column c1 from Zstandard encoding to AZ64 encoding.

```
alter table t1 alter column c1 encode az64;
```

The following statement alters the compression encoding for column c2 from LZ0 encoding to Byte-dictionary encoding.

```
alter table t1 alter column c2 encode bytedict;
```

The following statement alters the compression encoding for column c3 from Zstandard encoding to Runlength encoding.

```
alter table t1 alter column c3 encode runlength;
```

Alter a DISTSTYLE KEY DISTKEY column

The following examples show how to change the DISTSTYLE and DISTKEY of a table.

Create a table with an EVEN distribution style. The SVV_TABLE_INFO view shows that the DISTSTYLE is EVEN.

```
create table inventory(  

```

```

inv_date_sk int4 not null ,
inv_item_sk int4 not null ,
inv_warehouse_sk int4 not null ,
inv_quantity_on_hand int4
) diststyle even;

```

```

Insert into inventory values(1,1,1,1);

```

```

select "table", "diststyle" from svv_table_info;

```

```

table  | diststyle
-----+-----
inventory |      EVEN

```

Alter the table DISTKEY to `inv_warehouse_sk`. The SVV_TABLE_INFO view shows the `inv_warehouse_sk` column as the resulting distribution key.

```

alter table inventory alter diststyle key distkey inv_warehouse_sk;

```

```

select "table", "diststyle" from svv_table_info;

```

```

table  | diststyle
-----+-----
inventory | KEY(inv_warehouse_sk)

```

Alter the table DISTKEY to `inv_item_sk`. The SVV_TABLE_INFO view shows the `inv_item_sk` column as the resulting distribution key.

```

alter table inventory alter distkey inv_item_sk;

```

```

select "table", "diststyle" from svv_table_info;

```

```

table  | diststyle
-----+-----
inventory | KEY(inv_item_sk)

```

Alter a table to DISTSTYLE ALL

The following examples show how to change a table to DISTSTYLE ALL.

Create a table with an EVEN distribution style. The SVV_TABLE_INFO view shows that the DISTSTYLE is EVEN.

```
create table inventory(
  inv_date_sk int4 not null ,
  inv_item_sk int4 not null ,
  inv_warehouse_sk int4 not null ,
  inv_quantity_on_hand int4
) diststyle even;
```

```
Insert into inventory values(1,1,1,1);
```

```
select "table", "diststyle" from svv_table_info;
```

table	diststyle
inventory	EVEN

Alter the table DISTSTYLE to ALL. The SVV_TABLE_INFO view shows the changed DISTSYTLE.

```
alter table inventory alter diststyle all;
```

```
select "table", "diststyle" from svv_table_info;
```

table	diststyle
inventory	ALL

Alter a table SORTKEY

You can alter a table to have a compound sort key or no sort key.

In the following table definition, table t1 is defined with an interleaved sortkey.

```
create table t1 (c0 int, c1 int) interleaved sortkey(c0, c1);
```

The following command alters the table from an interleaved sort key to a compound sort key.

```
alter table t1 alter sortkey(c0, c1);
```

The following command alters the table to remove the interleaved sort key.

```
alter table t1 alter sortkey none;
```

In the following table definition, table `t1` is defined with column `c0` as a sortkey.

```
create table t1 (c0 int, c1 int) sortkey(c0);
```

The following command alters the table `t1` to a compound sort key.

```
alter table t1 alter sortkey(c0, c1);
```

Alter a table to ENCODE AUTO

The following example shows how to alter a table to ENCODE AUTO.

The table definition for this example follows. Column `c0` is defined with the encoding type AZ64, and column `c1` is defined with the encoding type LZ0.

```
create table t1(c0 int encode AZ64, c1 varchar encode LZ0);
```

For this table, the following statement alters the encoding to AUTO.

```
alter table t1 alter encode auto;
```

The following example shows how to alter a table to remove the ENCODE AUTO setting.

The table definition for this example follows. The table columns are defined without encoding. In this case, the encoding defaults to ENCODE AUTO.

```
create table t2(c0 int, c1 varchar);
```

For this table, the following statement alters the encoding of column `c0` to LZ0. The table encoding is no longer set to ENCODE AUTO.

```
alter table t2 alter column c0 encode lzo;;
```

Alter row-level security control

The following command turns RLS off for the table:

```
ALTER TABLE tickit_category_redshift ROW LEVEL SECURITY OFF;
```

The following command turns RLS on for the table:

```
ALTER TABLE tickit_category_redshift ROW LEVEL SECURITY ON;
```

The following command turns RLS on for the table and makes it accessible over datashares:

```
ALTER TABLE tickit_category_redshift ROW LEVEL SECURITY ON;  
ALTER TABLE tickit_category_redshift ROW LEVEL SECURITY FOR DATASHARES OFF;
```

The following command turns RLS on for the table and makes it inaccessible over datashares:

```
ALTER TABLE tickit_category_redshift ROW LEVEL SECURITY ON;  
ALTER TABLE tickit_category_redshift ROW LEVEL SECURITY FOR DATASHARES ON;
```

The following command turns RLS on and sets RLS conjunction type to OR for the table:

```
ALTER TABLE tickit_category_redshift ROW LEVEL SECURITY ON CONJUNCTION TYPE OR;
```

The following command turns RLS on and sets RLS conjunction type to AND for the table:

```
ALTER TABLE tickit_category_redshift ROW LEVEL SECURITY ON CONJUNCTION TYPE AND;
```

ALTER EXTERNAL TABLE examples

The following examples use an Amazon S3 bucket located in the US East (N. Virginia) Region (us-east-1) AWS Region and the example tables created in [Examples](#) for CREATE TABLE. For more information about how to use partitions with external tables, see [Partitioning Redshift Spectrum external tables](#).

The following example sets the numRows table property for the SPECTRUM.SALES external table to 170,000 rows.

```
alter table spectrum.sales  
set table properties ('numRows'='170000');
```

The following example changes the location for the SPECTRUM.SALES external table.

```
alter table spectrum.sales  
set location 's3://redshift-downloads/tickit/spectrum/sales/';
```

The following example changes the format for the SPECTRUM.SALES external table to Parquet.

```
alter table spectrum.sales
set file format parquet;
```

The following example adds one partition for the table SPECTRUM.SALES_PART.

```
alter table spectrum.sales_part
add if not exists partition(saledate='2008-01-01')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-01/';
```

The following example adds three partitions for the table SPECTRUM.SALES_PART.

```
alter table spectrum.sales_part add if not exists
partition(saledate='2008-01-01')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-01/'
partition(saledate='2008-02-01')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-02/'
partition(saledate='2008-03-01')
location 's3://redshift-downloads/ticket/spectrum/sales_partition/saledate=2008-03/';
```

The following example alters SPECTRUM.SALES_PART to drop the partition with saledate='2008-01-01'.

```
alter table spectrum.sales_part
drop partition(saledate='2008-01-01');
```

The following example sets a new Amazon S3 path for the partition with saledate='2008-01-01'.

```
alter table spectrum.sales_part
partition(saledate='2008-01-01')
set location 's3://redshift-downloads/ticket/spectrum/sales_partition/
saledate=2008-01-01/';
```

The following example changes the name of sales_date to transaction_date.

```
alter table spectrum.sales rename column sales_date to transaction_date;
```

The following example sets the column mapping to position mapping for an external table that uses optimized row columnar (ORC) format.

```
alter table spectrum.orc_example
set table properties('orc.schema.resolution'='position');
```

The following example sets the column mapping to name mapping for an external table that uses ORC format.

```
alter table spectrum.orc_example
set table properties('orc.schema.resolution'='name');
```

ALTER TABLE ADD and DROP COLUMN examples

The following examples demonstrate how to use ALTER TABLE to add and then drop a basic table column and also how to drop a column with a dependent object.

ADD then DROP a basic column

The following example adds a standalone FEEDBACK_SCORE column to the USERS table. This column simply contains an integer, and the default value for this column is NULL (no feedback score).

First, query the PG_TABLE_DEF catalog table to view the schema of the USERS table:

column	type	encoding	distkey	sortkey
userid	integer	delta	true	1
username	character(8)	lzo	false	0
firstname	character varying(30)	text32k	false	0
lastname	character varying(30)	text32k	false	0
city	character varying(30)	text32k	false	0
state	character(2)	bytedict	false	0
email	character varying(100)	lzo	false	0
phone	character(14)	lzo	false	0
likesports	boolean	none	false	0
liketheatre	boolean	none	false	0
likeconcerts	boolean	none	false	0
likejazz	boolean	none	false	0
likeclassical	boolean	none	false	0
likeopera	boolean	none	false	0
likerock	boolean	none	false	0
likevegas	boolean	none	false	0
likebroadway	boolean	none	false	0

```
likemusicals | boolean | none | false | 0
```

Now add the `feedback_score` column:

```
alter table users
add column feedback_score int
default NULL;
```

Select the `FEEDBACK_SCORE` column from `USERS` to verify that it was added:

```
select feedback_score from users limit 5;

feedback_score
-----
NULL
NULL
NULL
NULL
NULL
```

Drop the column to reinstate the original DDL:

```
alter table users drop column feedback_score;
```

Dropping a column with a dependent object

The following example drops a column that has a dependent object. As a result, the dependent object is also dropped.

To start, add the `FEEDBACK_SCORE` column to the `USERS` table again:

```
alter table users
add column feedback_score int
default NULL;
```

Next, create a view from the `USERS` table called `USERS_VIEW`:

```
create view users_view as select * from users;
```

Now, try to drop the `FEEDBACK_SCORE` column from the `USERS` table. This `DROP` statement uses the default behavior (`RESTRICT`):

```
alter table users drop column feedback_score;
```

Amazon Redshift displays an error message that the column can't be dropped because another object depends on it.

Try dropping the FEEDBACK_SCORE column again, this time specifying CASCADE to drop all dependent objects:

```
alter table users  
drop column feedback_score cascade;
```

ALTER TABLE APPEND

Appends rows to a target table by moving data from an existing source table. Data in the source table is moved to matching columns in the target table. Column order doesn't matter. After data is successfully appended to the target table, the source table is empty. ALTER TABLE APPEND is usually much faster than a similar [CREATE TABLE AS](#) or [INSERT INTO](#) operation because data is moved, not duplicated.

Note

ALTER TABLE APPEND moves data blocks between the source table and the target table. To improve performance, ALTER TABLE APPEND doesn't compact storage as part of the append operation. As a result, storage usage increases temporarily. To reclaim the space, run a [VACUUM](#) operation.

Columns with the same names must also have identical column attributes. If either the source table or the target table contains columns that don't exist in the other table, use the IGNOREEXTRA or FILLTARGET parameters to specify how extra columns should be managed.

You can't append an identity column. If both tables include an identity column, the command fails. If only one table has an identity column, include the FILLTARGET or IGNOREEXTRA parameter. For more information, see [ALTER TABLE APPEND usage notes](#).

You can append a GENERATED BY DEFAULT AS IDENTITY column. You can update columns defined as GENERATED BY DEFAULT AS IDENTITY with values that you supply. For more information, see [ALTER TABLE APPEND usage notes](#).

The target table must be a permanent table. However, the source can be a permanent table or a materialized view configured for streaming ingestion. Both objects must use the same distribution style and distribution key, if one is defined. If the objects are sorted, both objects must use the same sort style and define the same columns as sort keys.

An ALTER TABLE APPEND command automatically commits immediately upon completion of the operation. It can't be rolled back. You can't run ALTER TABLE APPEND within a transaction block (BEGIN ... END). For more information about transactions, see [Serializable isolation](#).

Required privileges

Depending on the ALTER TABLE APPEND command, one of the following privileges is required:

- Superuser
- Users with the ALTER TABLE system privilege
- Users with DELETE and SELECT privileges on the source table, and INSERT privilege on the target table

Syntax

```
ALTER TABLE target_table_name APPEND FROM [ source_table_name  
| source_materialized_view_name ]  
[ IGNOREEXTRA | FILLTARGET ]
```

Appending from a materialized view works only in the case where your materialized view is configured for [Streaming ingestion to a materialized view](#).

Parameters

target_table_name

The name of the table to which rows are appended. Either specify just the name of the table or use the format *schema_name.table_name* to use a specific schema. The target table must be an existing permanent table.

FROM *source_table_name*

The name of the table that provides the rows to be appended. Either specify just the name of the table or use the format *schema_name.table_name* to use a specific schema. The source table must be an existing permanent table.

FROM *source_materialized_view_name*

The name of a materialized view that provides the rows to be appended. Appending from a materialized view works only in the case where your materialized view is configured for [Streaming ingestion to a materialized view](#). The source materialized view must already exist.

IGNOREEXTRA

A keyword that specifies that if the source table includes columns that are not present in the target table, data in the extra columns should be discarded. You can't use IGNOREEXTRA with FILLTARGET.

FILLTARGET

A keyword that specifies that if the target table includes columns that are not present in the source table, the columns should be filled with the [DEFAULT](#) column value, if one was defined, or NULL. You can't use IGNOREEXTRA with FILLTARGET.

ALTER TABLE APPEND usage notes

ALTER TABLE APPEND moves only identical columns from the source table to the target table. Column order doesn't matter.

If either the source table or the target table contains extra columns, use either FILLTARGET or IGNOREEXTRA according to the following rules:

- If the source table contains columns that don't exist in the target table, include IGNOREEXTRA. The command ignores the extra columns in the source table.
- If the target table contains columns that don't exist in the source table, include FILLTARGET. The command fills the extra columns in the target table with either the default column value or IDENTITY value, if one was defined, or NULL.
- If both the source table and the target table contain extra columns, the command fails. You can't use both FILLTARGET and IGNOREEXTRA.

If a column with the same name but different attributes exists in both tables, the command fails. Like-named columns must have the following attributes in common:

- Data type
- Column size

- Compression encoding
- Not null
- Sort style
- Sort key columns
- Distribution style
- Distribution key columns

You can't append an identity column. If both the source table and the target table have identity columns, the command fails. If only the source table has an identity column, include the `IGNOREEXTRA` parameter so that the identity column is ignored. If only the target table has an identity column, include the `FILLTARGET` parameter so that the identity column is populated according to the `IDENTITY` clause defined for the table. For more information, see [DEFAULT](#).

You can append a default identity column with the `ALTER TABLE APPEND` statement. For more information, see [CREATE TABLE](#).

ALTER TABLE APPEND examples

Suppose your organization maintains a table, `SALES_MONTHLY`, to capture current sales transactions. You want to move data from the transaction table to the `SALES` table, every month.

You can use the following `INSERT INTO` and `TRUNCATE` commands to accomplish the task.

```
insert into sales (select * from sales_monthly);
truncate sales_monthly;
```

However, you can perform the same operation much more efficiently by using an `ALTER TABLE APPEND` command.

First, query the [PG_TABLE_DEF](#) system catalog table to verify that both tables have the same columns with identical column attributes.

```
select trim(tablename) as table, "column", trim(type) as type,
encoding, distkey, sortkey, "notnull"
from pg_table_def where tablename like 'sales%';
```

table	column	type	encoding	distkey	sortkey	notnull
-------	--------	------	----------	---------	---------	---------

```

-----+-----+-----+-----+-----+-----
+-----
sales    | salesid  | integer          | lzo      | false    | 0 |
true
sales    | listid   | integer          | none     | true     | 1 |
true
sales    | sellerid | integer          | none     | false    | 2 |
true
sales    | buyerid  | integer          | lzo      | false    | 0 |
true
sales    | eventid  | integer          | mostly16 | false    | 0 |
true
sales    | dateid   | smallint         | lzo      | false    | 0 |
true
sales    | qtysold  | smallint         | mostly8  | false    | 0 |
true
sales    | pricepaid | numeric(8,2)     | delta32k | false    | 0 |
false
sales    | commission | numeric(8,2)     | delta32k | false    | 0 |
false
sales    | saletime | timestamp without time zone | lzo      | false    | 0 |
false
salesmonth | salesid  | integer          | lzo      | false    | 0 |
true
salesmonth | listid   | integer          | none     | true     | 1 |
true
salesmonth | sellerid | integer          | none     | false    | 2 |
true
salesmonth | buyerid  | integer          | lzo      | false    | 0 |
true
salesmonth | eventid  | integer          | mostly16 | false    | 0 |
true
salesmonth | dateid   | smallint         | lzo      | false    | 0 |
true
salesmonth | qtysold  | smallint         | mostly8  | false    | 0 |
true
salesmonth | pricepaid | numeric(8,2)     | delta32k | false    | 0 |
false
salesmonth | commission | numeric(8,2)     | delta32k | false    | 0 |
false
salesmonth | saletime | timestamp without time zone | lzo      | false    | 0 |
false

```

Next, look at the size of each table.

```
select count(*) from sales_monthly;
```

```
count
-----
  2000
(1 row)
```

```
select count(*) from sales;
```

```
count
-----
412,214
(1 row)
```

Now run the following ALTER TABLE APPEND command.

```
alter table sales append from sales_monthly;
```

Look at the size of each table again. The SALES_MONTHLY table now has 0 rows, and the SALES table has grown by 2000 rows.

```
select count(*) from sales_monthly;
```

```
count
-----
     0
(1 row)
```

```
select count(*) from sales;
```

```
count
-----
414214
(1 row)
```

If the source table has more columns than the target table, specify the IGNOREEXTRA parameter. The following example uses the IGNOREEXTRA parameter to ignore extra columns in the SALES_LISTING table when appending to the SALES table.

```
alter table sales append from sales_listing ignoreextra;
```

If the target table has more columns than the source table, specify the `FILLTARGET` parameter. The following example uses the `FILLTARGET` parameter to populate columns in the `SALES_REPORT` table that don't exist in the `SALES_MONTH` table.

```
alter table sales_report append from sales_month filltarget;
```

The following example shows an example of how to use `ALTER TABLE APPEND` with a materialized view as a source.

```
ALTER TABLE target_tbl APPEND FROM my_streaming_materialized_view;
```

The table and materialized view names in this example are samples. Appending from a materialized view works only in the case where your materialized view is configured for [Streaming ingestion to a materialized view](#). It moves all records in the source materialized view to a target table with the same schema as the materialized view and leaves the materialized view intact. This is the same behavior as when the source of the data is a table.

ALTER USER

Changes a database user.

Required privileges

Following are required privileges for `ALTER USER`:

- Superuser
- Users with the `ALTER USER` privilege
- Current user who wants to change their own password

Syntax

```
ALTER USER username [ WITH ] option [, ... ]
```

where *option* is

```
CREATEDB | NOCREATEDB  
| CREATEUSER | NOCREATEUSER  
| SYSLOG ACCESS { RESTRICTED | UNRESTRICTED }  
| PASSWORD { 'password' | 'md5hash' | DISABLE }
```

```
[ VALID UNTIL 'expiration_date' ]
| RENAME TO new_name |
| CONNECTION LIMIT { limit | UNLIMITED }
| SESSION TIMEOUT limit | RESET SESSION TIMEOUT
| SET parameter { TO | = } { value | DEFAULT }
| RESET parameter
| EXTERNALID external_id
```

Parameters

username

Name of the user.

WITH

Optional keyword.

CREATEDB | NOCREATEDB

The CREATEDB option allows the user to create new databases. NOCREATEDB is the default.

CREATEUSER | NOCREATEUSER

The CREATEUSER option creates a superuser with all database privileges, including CREATE USER. The default is NOCREATEUSER. For more information, see [superuser](#).

SYSLOG ACCESS { RESTRICTED | UNRESTRICTED }

A clause that specifies the level of access that the user has to the Amazon Redshift system tables and views.

Regular users who have the SYSLOG ACCESS RESTRICTED permission can see only the rows generated by that user in user-visible system tables and views. The default is RESTRICTED.

Regular users who have the SYSLOG ACCESS UNRESTRICTED permission can see all rows in user-visible system tables and views, including rows generated by another user. UNRESTRICTED doesn't give a regular user access to superuser-visible tables. Only superusers can see superuser-visible tables.

Note

Giving a user unrestricted access to system tables gives the user visibility to data generated by other users. For example, STL_QUERY and STL_QUERYTEXT contain the

full text of INSERT, UPDATE, and DELETE statements, which might contain sensitive user-generated data.

All rows in SVV_TRANSACTIONS are visible to all users.

For more information, see [Visibility of data in system tables and views](#).

PASSWORD { *'password'* | *'md5hash'* | DISABLE }

Sets the user's password.

By default, users can change their own passwords, unless the password is disabled. To disable a user's password, specify DISABLE. When a user's password is disabled, the password is deleted from the system and the user can log on only using temporary AWS Identity and Access Management (IAM) user credentials. For more information, see [Using IAM authentication to generate database user credentials](#). Only a superuser can enable or disable passwords. You can't disable a superuser's password. To enable a password, run ALTER USER and specify a password.

For details about using the PASSWORD parameter, see [CREATE USER](#).

VALID UNTIL *'expiration_date'*

Specifies that the password has an expiration date. Use the value *'infinity'* to avoid having an expiration date. The valid data type for this parameter is timestamp.

Only superusers can use this parameter.

RENAME TO

Renames the user.

new_name

New name of the user. For more information about valid names, see [Names and identifiers](#).

Important

When you rename a user, you must also reset the user's password. The reset password doesn't have to be different from the previous password. The user name is used as part of the password encryption, so when a user is renamed, the password is cleared. The user will not be able to log on until the password is reset. For example:

```
alter user newuser password 'EXAMPLENewPassword11';
```

CONNECTION LIMIT { *limit* | UNLIMITED }

The maximum number of database connections the user is permitted to have open concurrently. The limit isn't enforced for superusers. Use the UNLIMITED keyword to permit the maximum number of concurrent connections. A limit on the number of connections for each database might also apply. For more information, see [CREATE DATABASE](#). The default is UNLIMITED. To view current connections, query the [STV_SESSIONS](#) system view.

Note

If both user and database connection limits apply, an unused connection slot must be available that is within both limits when a user attempts to connect.

SESSION TIMEOUT *limit* | RESET SESSION TIMEOUT

The maximum time in seconds that a session remains inactive or idle. The range is 60 seconds (one minute) to 1,728,000 seconds (20 days). If no session timeout is set for the user, the cluster setting applies. For more information, see [Quotas and limits in Amazon Redshift](#) in the *Amazon Redshift Management Guide*.

When you set the session timeout, it's applied to new sessions only.

To view information about active user sessions, including the start time, user name, and session timeout, query the [STV_SESSIONS](#) system view. To view information about user-session history, query the [STL_SESSIONS](#) view. To retrieve information about database users, including session-timeout values, query the [SVL_USER_INFO](#) view.

SET

Sets a configuration parameter to a new default value for all sessions run by the specified user.

RESET

Resets a configuration parameter to the original default value for the specified user.

parameter

Name of the parameter to set or reset.

value

New value of the parameter.

DEFAULT

Sets the configuration parameter to the default value for all sessions run by the specified user.

EXTERNALID *external_id*

The identifier for the user, which is associated with an identity provider. The user must have their password disabled. For more information, see [Native identity provider \(IdP\) federation for Amazon Redshift](#).

Usage notes

- **Attempting to alter rdsdb** – You can't alter the user named rdsdb.
- **Creating an unknown password** – When using AWS Identity and Access Management (IAM) authentication to create database user credentials, you might want to create a superuser that is able to log in only using temporary credentials. You can't disable a superuser's password, but you can create an unknown password using a randomly generated MD5 hash string.

```
alter user iam_superuser password 'md51234567890123456780123456789012';
```

- **Setting search_path** – When you set the [search_path](#) parameter with the ALTER USER command, the modification takes effect on the specified user's next login. If you want to change the search_path value for the current user and session, use a SET command.
- **Setting the time zone** – When you use SET TIMEZONE with the ALTER USER command, the modification takes effect on the specified user's next login.
- **Working with dynamic data masking and row-level security policies** – When your provisioned cluster or serverless namespace has any dynamic data masking or row-level security policies, the following commands are blocked for regular users:

```
ALTER <current_user> SET enable_case_sensitive_super_attribute/  
enable_case_sensitive_identifier/downcase_delimited_identifier
```

Only superusers and users with the ALTER USER privilege can set these configuration options. For information on row-level security, see [Row-level security](#). For information on dynamic data masking, see [Dynamic data masking](#).

Examples

The following example gives the user ADMIN the privilege to create databases:

```
alter user admin createdb;
```

The following example sets the password of the user ADMIN to adminPass9 and sets an expiration date and time for the password:

```
alter user admin password 'adminPass9'  
valid until '2017-12-31 23:59';
```

The following example renames the user ADMIN to SYSADMIN:

```
alter user admin rename to sysadmin;
```

The following example updates the idle-session timeout for a user to 300 seconds.

```
ALTER USER dbuser SESSION TIMEOUT 300;
```

Resets the user's idle-session timeout. When you reset it, the cluster setting applies. You must be a database superuser to run this command. For more information, see [Quotas and limits in Amazon Redshift](#) in the *Amazon Redshift Management Guide*.

```
ALTER USER dbuser RESET SESSION TIMEOUT;
```

The following example updates the external ID for a user named bob. The namespace is myco_aad. If the namespace isn't associated with a registered identity provider, it results in an error.

```
ALTER USER myco_aad:bob EXTERNALID "ABC123" PASSWORD DISABLE;
```

The following example sets the time zone for all sessions run by a specific database user. It changes the time zone for subsequent sessions, but not for the current session.

```
ALTER USER odie SET TIMEZONE TO 'Europe/Zurich';
```

The following example sets the maximum number of database connections that the user bob is allowed to have open.

```
ALTER USER bob CONNECTION LIMIT 10;
```

ANALYZE

Updates table statistics for use by the query planner.

Required privileges

Following are required privileges for ANALYZE:

- Superuser
- Users with the ANALYZE privilege
- Owner of the relation
- Database owner whom the table is shared to

Syntax

```
ANALYZE [ VERBOSE ]  
[ [ table_name [ ( column_name [, ...] ) ] ] ]  
[ PREDICATE COLUMNS | ALL COLUMNS ]
```

Parameters

VERBOSE

A clause that returns progress information messages about the ANALYZE operation. This option is useful when you don't specify a table.

table_name

You can analyze specific tables, including temporary tables. You can qualify the table with its schema name. You can optionally specify a *table_name* to analyze a single table. You can't specify more than one *table_name* with a single ANALYZE *table_name* statement. If you don't specify a *table_name* value, all of the tables in the currently connected database are analyzed, including the persistent tables in the system catalog. Amazon Redshift skips analyzing a table if the percentage of rows that have changed since the last ANALYZE is lower than the analyze threshold. For more information, see [Analyze threshold](#).

You don't need to analyze Amazon Redshift system tables (STL and STV tables).

column_name

If you specify a *table_name*, you can also specify one or more columns in the table (as a column-separated list within parentheses). If a column list is specified, only the listed columns are analyzed.

PREDICATE COLUMNS | ALL COLUMNS

Clauses that indicate whether ANALYZE should include only predicate columns. Specify PREDICATE COLUMNS to analyze only columns that have been used as predicates in previous queries or are likely candidates to be used as predicates. Specify ALL COLUMNS to analyze all columns. The default is ALL COLUMNS.

A column is included in the set of predicate columns if any of the following is true:

- The column has been used in a query as a part of a filter, join condition, or group by clause.
- The column is a distribution key.
- The column is part of a sort key.

If no columns are marked as predicate columns, for example because the table has not yet been queried, all of the columns are analyzed even when PREDICATE COLUMNS is specified. When this happens, Amazon Redshift might respond with a message like No predicate columns found for "*table-name*". Analyzing all columns. For more information about predicate columns, see [Analyzing tables](#).

Usage notes

Amazon Redshift automatically runs ANALYZE on tables that you create with the following commands:

- CREATE TABLE AS
- CREATE TEMP TABLE AS
- SELECT INTO

You can't analyze an external table.

You don't need to run the ANALYZE command on these tables when they are first created. If you modify them, you should analyze them in the same way as other tables.

Analyze threshold

To reduce processing time and improve overall system performance, Amazon Redshift skips ANALYZE for a table if the percentage of rows that have changed since the last ANALYZE command run is lower than the analyze threshold specified by the [analyze_threshold_percent](#) parameter. By default, `analyze_threshold_percent` is 10. To change `analyze_threshold_percent` for the current session, run the [SET](#) command. The following example changes `analyze_threshold_percent` to 20 percent.

```
set analyze_threshold_percent to 20;
```

To analyze tables when only a small number of rows have changed, set `analyze_threshold_percent` to an arbitrarily small number. For example, if you set `analyze_threshold_percent` to 0.01, then a table with 100,000,000 rows aren't skipped if at least 10,000 rows have changed.

```
set analyze_threshold_percent to 0.01;
```

If ANALYZE skips a table because it doesn't meet the analyze threshold, Amazon Redshift returns the following message.

```
ANALYZE SKIP
```

To analyze all tables even if no rows have changed, set `analyze_threshold_percent` to 0.

To view the results of ANALYZE operations, query the [STL_ANALYZE](#) system table.

For more information about analyzing tables, see [Analyzing tables](#).

Examples

Analyze all of the tables in the TICKIT database and return progress information.

```
analyze verbose;
```

Analyze the LISTING table only.

```
analyze listing;
```

Analyze the VENUEID and VENUENAME columns in the VENUE table.

```
analyze venue(venueid, venueid);
```

Analyze only predicate columns in the VENUE table.

```
analyze venue predicate columns;
```

ANALYZE COMPRESSION

Performs compression analysis and produces a report with the suggested compression encoding for the tables analyzed. For each column, the report includes an estimate of the potential reduction in disk space compared to the RAW encoding.

Syntax

```
ANALYZE COMPRESSION  
[ [ table_name ]  
[ ( column_name [, ...] ) ] ]  
[COMPROWS numrows]
```

Parameters

table_name

You can analyze compression for specific tables, including temporary tables. You can qualify the table with its schema name. You can optionally specify a *table_name* to analyze a single table. If you don't specify a *table_name*, all of the tables in the currently connected database are analyzed. You can't specify more than one *table_name* with a single ANALYZE COMPRESSION statement.

column_name

If you specify a *table_name*, you can also specify one or more columns in the table (as a column-separated list within parentheses).

COMPROWS

Number of rows to be used as the sample size for compression analysis. The analysis is run on rows from each data slice. For example, if you specify COMPROWS 1000000 (1,000,000) and

the system contains 4 total slices, no more than 250,000 rows per slice are read and analyzed. If `COMPROWS` isn't specified, the sample size defaults to 100,000 per slice. Values of `COMPROWS` lower than the default of 100,000 rows per slice are automatically upgraded to the default value. However, compression analysis doesn't produce recommendations if the amount of data in the table is insufficient to produce a meaningful sample. If the `COMPROWS` number is greater than the number of rows in the table, the `ANALYZE COMPRESSION` command still proceeds and runs the compression analysis against all of the available rows. Using `COMPROWS` results in an error if a table isn't specified.

numrows

Number of rows to be used as the sample size for compression analysis. The accepted range for *numrows* is a number between 1000 and 1000000000 (1,000,000,000).

Usage notes

`ANALYZE COMPRESSION` acquires an exclusive table lock, which prevents concurrent reads and writes against the table. Only run the `ANALYZE COMPRESSION` command when the table is idle.

Run `ANALYZE COMPRESSION` to get recommendations for column encoding schemes, based on a sample of the table's contents. `ANALYZE COMPRESSION` is an advisory tool and doesn't modify the column encodings of the table. You can apply the suggested encoding by recreating the table or by creating a new table with the same schema. Recreating an uncompressed table with appropriate encoding schemes can significantly reduce its on-disk footprint. This approach saves disk space and improves query performance for I/O-bound workloads.

`ANALYZE COMPRESSION` skips the actual analysis phase and directly returns the original encoding type on any column that is designated as a `SORTKEY`. It does this because range-restricted scans might perform poorly when `SORTKEY` columns are compressed much more highly than other columns.

Examples

The following example shows the encoding and estimated percent reduction for the columns in the `LISTING` table only:

```
analyze compression listing;
```

Table	Column	Encoding	Est_reduction_pct
-------	--------	----------	-------------------

```

-----+-----+-----+-----
listing | listid      | az64   | 40.96
listing | sellerid    | az64   | 46.92
listing | eventid     | az64   | 53.37
listing | dateid      | raw    | 0.00
listing | numtickets  | az64   | 65.66
listing | priceperticket | az64   | 72.94
listing | totalprice  | az64   | 68.05
listing | listtime    | az64   | 49.74

```

The following example analyzes the QTYSOLD, COMMISSION, and SALETIME columns in the SALES table.

```
analyze compression sales(qtysold, commission, saletime);
```

```

Table | Column | Encoding | Est_reduction_pct
-----+-----+-----+-----
sales | salesid | N/A      | 0.00
sales | listid  | N/A      | 0.00
sales | sellerid | N/A     | 0.00
sales | buyerid | N/A     | 0.00
sales | eventid  | N/A     | 0.00
sales | dateid   | N/A     | 0.00
sales | qtysold  | az64    | 83.06
sales | pricepaid | N/A    | 0.00
sales | commission | az64  | 71.85
sales | saletime | az64    | 49.63

```

ATTACH MASKING POLICY

Attaches an existing dynamic data masking policy to a column. For more information on dynamic data masking, see [Dynamic data masking](#).

Superusers and users or roles that have the sys:secadmin role can attach a masking policy.

Syntax

```

ATTACH MASKING POLICY policy_name
  ON { relation_name }
  ( { output_columns_names | output_path } ) [ USING ( { input_column_names | input_path } ) ]
  TO { user_name | ROLE role_name | PUBLIC }

```

```
[ PRIORITY priority ];
```

Parameters

policy_name

The name of the masking policy to attach.

relation_name

The name of the relation to attach the masking policy to.

output_column_names

The names of the columns that the masking policy will apply to.

output_paths

The full path of the SUPER object that the masking policy will apply to, including the column name. For example, for a relation with a SUPER type column named `person`, *output_path* might be `person.name.first_name`.

input_column_names

The names of the columns that the masking policy will take as input. This parameter is optional. If not specified, the masking policy uses *output_column_names* as inputs.

input_paths

The full path of the SUPER object that the masking policy will take as input. This parameter is optional. If not specified, the masking policy uses *output_path* for inputs.

user_name

The name of the user to whom the masking policy will attach. You can't attach two policies to the same combination of user and column or role and column. You can attach a policy to a user and another policy to the user's role. In this case, the policy with the higher priority applies.

You can only set one of *user_name*, *role_name*, and `PUBLIC` in a single `ATTACH MASKING POLICY` command.

role_name

The name of the role to which the masking policy will attach. You can't attach two policies to the same column/role pair. You can attach a policy to a user and another policy to the user's role. In this case, the policy with the higher priority applies.

You can only set one of `user_name`, `role_name`, and `PUBLIC` in a single `ATTACH MASKING POLICY` command.

PUBLIC

Attaches the masking policy to all users accessing the table. You must give other masking policies attached to specific column/user or column/role pairs a higher priority than the `PUBLIC` policy for them to apply.

You can only set one of `user_name`, `role_name`, and `PUBLIC` in a single `ATTACH MASKING POLICY` command.

priority

The priority of the masking policy. When multiple masking policies apply to a given user's query, the highest priority policy applies.

You can't attach two different policies to the same column with equal priority, even if the two policies are attached to different users or roles. You can attach the same policy multiple times to the same set of table, output column, input column, and priority parameters, as long as the user or role the policy attaches to is different each time.

You can't apply a policy to a column with the same priority as another policy attached to that column, even if they're for different roles. This field is optional. If you don't specify a priority, the masking policy defaults to attaching with a priority of 0.

ATTACH RLS POLICY

Attach a row-level security policy on a table to one or more users or roles.

Superusers and users or roles that have the `sys:secadmin` role can attach a policy.

Syntax

```
ATTACH RLS POLICY policy_name ON [TABLE] table_name [, ...]
TO { user_name | ROLE role_name | PUBLIC } [, ...]
```

Parameters

policy_name

The name of the policy.

ON [TABLE] *table_name* [, ...]

The relation that the row-level security policy is attached to.

TO { *user_name* | ROLE *role_name* | PUBLIC} [, ...]

Specifies whether the policy is attached to one or more specified users or roles.

Usage notes

When working with the ATTACH RLS POLICY statement, observe the following:

- The table being attached should have all the columns listed in the WITH clause of the policy creation statement.
- Amazon Redshift RLS doesn't support attaching RLS policies to the following objects:
 - Catalog tables
 - Cross-database relations
 - External tables
 - Temporary tables
 - Lookup tables
- You can't attach a RLS policy to superusers or to users with the `sys:secadmin` permission.

Examples

The following example attaches a policy on a table to a role.

```
ATTACH RLS POLICY policy_concerts ON tickit_category_redshift TO ROLE analyst, ROLE
dbadmin;
```

BEGIN

Starts a transaction. Synonymous with START TRANSACTION.

A transaction is a single, logical unit of work, whether it consists of one command or multiple commands. In general, all commands in a transaction run on a snapshot of the database whose starting time is determined by the value set for the `transaction_snapshot_begin` system configuration parameter.

By default, individual Amazon Redshift operations (queries, DDL statements, loads) are automatically committed to the database. If you want to suspend the commit for an operation until subsequent work is completed, you need to open a transaction with the `BEGIN` statement, then run the required commands, then close the transaction with a [COMMIT](#) or [END](#) statement. If necessary, you can use a [ROLLBACK](#) statement to stop a transaction that is in progress. An exception to this behavior is the [TRUNCATE](#) command, which commits the transaction in which it is run and can't be rolled back.

Syntax

```
BEGIN [ WORK | TRANSACTION ] [ ISOLATION LEVEL option ] [ READ WRITE | READ ONLY ]
```

```
START TRANSACTION [ ISOLATION LEVEL option ] [ READ WRITE | READ ONLY ]
```

Where *option* is

```
SERIALIZABLE  
| READ UNCOMMITTED  
| READ COMMITTED  
| REPEATABLE READ
```

Note: READ UNCOMMITTED, READ COMMITTED, and REPEATABLE READ have no operational impact and map to SERIALIZABLE in Amazon Redshift. You can see database isolation levels on your cluster by querying the `stv_db_isolation_level` table.

Parameters

WORK

Optional keyword.

TRANSACTION

Optional keyword; WORK and TRANSACTION are synonyms.

ISOLATION LEVEL SERIALIZABLE

Serializable isolation is supported by default, so the behavior of the transaction is the same whether or not this syntax is included in the statement. For more information, see [Managing concurrent write operations](#). No other isolation levels are supported.

Note

The SQL standard defines four levels of transaction isolation to prevent *dirty reads* (where a transaction reads data written by a concurrent uncommitted transaction), *nonrepeatable reads* (where a transaction re-reads data it read previously and finds that data was changed by another transaction that committed since the initial read), and *phantom reads* (where a transaction re-runs a query, returns a set of rows that satisfy a search condition, and then finds that the set of rows has changed because of another recently committed transaction):

- Read uncommitted: Dirty reads, nonrepeatable reads, and phantom reads are possible.
- Read committed: Nonrepeatable reads and phantom reads are possible.
- Repeatable read: Phantom reads are possible.
- Serializable: Prevents dirty reads, nonrepeatable reads, and phantom reads.

Though you can use any of the four transaction isolation levels, Amazon Redshift processes all isolation levels as serializable.

READ WRITE

Gives the transaction read and write permissions.

READ ONLY

Gives the transaction read-only permissions.

Examples

The following example starts a serializable transaction block:

```
begin;
```

The following example starts the transaction block with a serializable isolation level and read and write permissions:

```
begin read write;
```

CALL

Runs a stored procedure. The CALL command must include the procedure name and the input argument values. You must call a stored procedure by using the CALL statement.

Note

CALL can't be part of any regular queries.

Syntax

```
CALL sp_name ( [ argument ] [, ...] )
```

Parameters

sp_name

The name of the procedure to run.

argument

The value of the input argument. This parameter can also be a function name, for example `pg_last_query_id()`. You can't use queries as CALL arguments.

Usage notes

Amazon Redshift stored procedures support nested and recursive calls, as described following. In addition, make sure your driver support is up-to-date, also described following.

Topics

- [Nested calls](#)
- [Driver support](#)

Nested calls

Amazon Redshift stored procedures support nested and recursive calls. The maximum number of nesting levels allowed is 16. Nested calls can encapsulate business logic into smaller procedures, which can be shared by multiple callers.

If you call a nested procedure that has output parameters, the inner procedure must define INOUT arguments. In this case, the inner procedure is passed in a nonconstant variable. OUT arguments aren't allowed. This behavior occurs because a variable is needed to hold the output of the inner call.

The relationship between inner and outer procedures is logged in the `from_sp_call` column of [SVL_STORED_PROC_CALL](#).

The following example shows passing variables to a nested procedure call through INOUT arguments.

```
CREATE OR REPLACE PROCEDURE inner_proc(INOUT a int, b int, INOUT c int) LANGUAGE
plpgsql
AS $$
BEGIN
  a := b * a;
  c := b * c;
END;
$$;

CREATE OR REPLACE PROCEDURE outer_proc(multiplier int) LANGUAGE plpgsql
AS $$
DECLARE
  x int := 3;
  y int := 4;
BEGIN
  DROP TABLE IF EXISTS test_tbl;
  CREATE TEMP TABLE test_tbl(a int, b varchar(256));
  CALL inner_proc(x, multiplier, y);
  insert into test_tbl values (x, y::varchar);
END;
$$;

CALL outer_proc(5);

SELECT * from test_tbl;
 a | b
----+----
 15 | 20
(1 row)
```

Driver support

We recommend that you upgrade your Java Database Connectivity (JDBC) and Open Database Connectivity (ODBC) drivers to the latest version that has support for Amazon Redshift stored procedures.

You might be able to use your existing driver if your client tool uses driver API operations that pass through the CALL statement to the server. Output parameters, if any, are returned as a result set of one row.

The latest versions of Amazon Redshift JDBC and ODBC drivers have metadata support for stored procedure discovery. They also have CallableStatement support for custom Java applications. For more information on drivers, see [Connecting to an Amazon Redshift Cluster Using SQL Client Tools](#) in the *Amazon Redshift Management Guide*.

The following examples show how to use different API operations of the JDBC driver for stored procedure calls.

```
void statement_example(Connection conn) throws SQLException {
    statement.execute("CALL sp_statement_example(1)");
}

void prepared_statement_example(Connection conn) throws SQLException {
    String sql = "CALL sp_prepared_statement_example(42, 84)";
    PreparedStatement pstmt = conn.prepareStatement(sql);
    pstmt.execute();
}

void callable_statement_example(Connection conn) throws SQLException {
    CallableStatement cstmt = conn.prepareCall("CALL sp_create_out_in(?,?)");
    cstmt.registerOutParameter(1, java.sql.Types.INTEGER);
    cstmt.setInt(2, 42);
    cstmt.executeQuery();
    Integer out_value = cstmt.getInt(1);
}
```

Examples

The following example calls the procedure name test_sp1.

```
call test_sp1(3,'book');
INFO: Table "tmp_tbl" does not exist and will be skipped
```

```
INFO: min_val = 3, f2 = book
```

The following example calls the procedure name `test_sp12`.

```
call test_sp2(2, '2019');
```

```

      f2          | column2
-----+-----
 2019+2019+2019+2019 | 2
(1 row)
```

CANCEL

Cancels a database query that is currently running.

The CANCEL command requires the process ID or session ID of the running query and displays a confirmation message to verify that the query was canceled.

Required privileges

Following are required privileges for CANCEL:

- Superuser canceling their own query
- Superuser canceling a user's query
- Users with the CANCEL privilege canceling a user's query
- User canceling their own query

Syntax

```
CANCEL process_id [ 'message' ]
```

Parameters

process_id

To cancel a query running in an Amazon Redshift cluster, use the `pid` (Process ID) from [STV_RECENTS](#) that corresponds to the query that you want to cancel.

To cancel a query running in an Amazon Redshift Serverless workgroup, use the `session_id` from [SYS_QUERY_HISTORY](#) that corresponds to the query that you want to cancel.

'message'

An optional confirmation message that displays when the query cancellation completes. If you don't specify a message, Amazon Redshift displays the default message as verification. You must enclose the message in single quotation marks.

Usage notes

You can't cancel a query by specifying a *query ID*; you must specify the query's *process ID* (PID) or *Session ID*. You can only cancel queries currently being run by your user. Superusers can cancel all queries.

If queries in multiple sessions hold locks on the same table, you can use the [PG_TERMINATE_BACKEND](#) function to terminate one of the sessions. Doing this forces any currently running transactions in the terminated session to release all locks and roll back the transaction. To view currently held locks, query the [STV_LOCKS](#) system table.

Following certain internal events, Amazon Redshift might restart an active session and assign a new PID. If the PID has changed, you might receive the following error message.

```
Session <PID> does not exist. The session PID might have changed. Check the
stl_restarted_sessions system table for details.
```

To find the new PID, query the [STL_RESTARTED_SESSIONS](#) system table and filter on the `oldpid` column.

```
select oldpid, newpid from stl_restarted_sessions where oldpid = 1234;
```

Examples

To cancel a currently running query in a Amazon Redshift cluster, first retrieve the process ID for the query that you want to cancel. To determine the process IDs for all currently running queries, type the following command:

```
select pid, starttime, duration,
trim(user_name) as user,
trim (query) as querytxt
from stv_recents
where status = 'Running';
```

```

pid |          starttime          | duration | user  | querytxt
-----+-----+-----+-----+-----
802 | 2008-10-14 09:19:03.550885 |      132 | dwuser | select
venue name from venue where venuestate='FL', where venuecity not in
('Miami' , 'Orlando');
834 | 2008-10-14 08:33:49.473585 | 1250414 | dwuser | select *
from listing;
964 | 2008-10-14 08:30:43.290527 |   326179 | dwuser | select
sellerid from sales where qtysold in (8, 10);

```

Check the query text to determine which process id (PID) corresponds to the query that you want to cancel.

Type the following command to use PID 802 to cancel that query:

```
cancel 802;
```

The session where the query was running displays the following message:

```
ERROR: Query (168) cancelled on user's request
```

where 168 is the query ID (not the process ID used to cancel the query).

Alternatively, you can specify a custom confirmation message to display instead of the default message. To specify a custom message, include your message in single quotation marks at the end of the CANCEL command:

```
cancel 802 'Long-running query';
```

The session where the query was running displays the following message:

```
ERROR: Long-running query
```

CLOSE

(Optional) Closes all of the free resources that are associated with an open cursor. [COMMIT](#), [END](#), and [ROLLBACK](#) automatically close the cursor, so it isn't necessary to use the CLOSE command to explicitly close the cursor.

For more information, see [DECLARE](#), [FETCH](#).

Syntax

```
CLOSE cursor
```

Parameters

cursor

Name of the cursor to close.

CLOSE example

The following commands close the cursor and perform a commit, which ends the transaction:

```
close movie_cursor;  
commit;
```

COMMENT

Creates or changes a comment about a database object.

Syntax

```
COMMENT ON  
{  
TABLE object_name |  
COLUMN object_name.column_name |  
CONSTRAINT constraint_name ON table_name |  
DATABASE object_name |  
VIEW object_name  
}  
IS 'text' | NULL
```

Parameters

object_name

Name of the database object being commented on. You can add a comment to the following objects:

- TABLE
- COLUMN (also takes a *column_name*).
- CONSTRAINT (also takes a *constraint_name* and *table_name*).
- DATABASE
- VIEW
- SCHEMA

IS '*text*' | NULL

The comment text that you want to add or replace for the specified object. The *text* string is data type TEXT. Enclose the comment in single quotation marks. Set the value to NULL to remove the comment text.

column_name

Name of the column being commented on. Parameter of COLUMN. Follows a table specified in *object_name*.

constraint_name

Name of the constraint that is being commented on. Parameter of CONSTRAINT.

table_name

Name of a table containing the constraint. Parameter of CONSTRAINT.

Usage notes

You must be a superuser or the owner of a database object to add or update a comment.

Comments on databases may only be applied to the current database. A warning message is displayed if you attempt to comment on a different database. The same warning is displayed for comments on databases that don't exist.

Comments on external tables, external columns, and columns of late binding views are not supported.

Examples

The following example adds a comment to the SALES table.

```
COMMENT ON TABLE sales IS 'This table stores tickets sales data';
```

The following example displays the comment on the SALES table.

```
select obj_description('public.sales'::regclass);

obj_description
-----
This table stores tickets sales data
```

The following example removes a comment from the SALES table.

```
COMMENT ON TABLE sales IS NULL;
```

The following example adds a comment to the EVENTID column of the SALES table.

```
COMMENT ON COLUMN sales.eventid IS 'Foreign-key reference to the EVENT table.';
```

The following example displays a comment on the EVENTID column (column number 5) of the SALES table.

```
select col_description( 'public.sales'::regclass, 5::integer );

col_description
-----
Foreign-key reference to the EVENT table.
```

The following example adds a descriptive comment to the EVENT table.

```
comment on table event is 'Contains listings of individual events.';
```

To view comments, query the PG_DESCRIPTION system catalog. The following example returns the description for the EVENT table.

```
select * from pg_catalog.pg_description
where objoid =
```

```
(select oid from pg_class where relname = 'event'
and relnamespace =
(select oid from pg_catalog.pg_namespace where nsname = 'public') );
```

objoid	classoid	objsubid	description
116658	1259	0	Contains listings of individual events.

COMMIT

Commits the current transaction to the database. This command makes the database updates from the transaction permanent.

Syntax

```
COMMIT [ WORK | TRANSACTION ]
```

Parameters

WORK

Optional keyword. This keyword isn't supported within a stored procedure.

TRANSACTION

Optional keyword. WORK and TRANSACTION are synonyms. Neither is supported within a stored procedure.

For information about using COMMIT within a stored procedure, see [Managing transactions](#).

Examples

Each of the following examples commits the current transaction to the database:

```
commit;
```

```
commit work;
```

```
commit transaction;
```

COPY

Loads data into a table from data files or from an Amazon DynamoDB table. The files can be located in an Amazon Simple Storage Service (Amazon S3) bucket, an Amazon EMR cluster, or a remote host that is accessed using a Secure Shell (SSH) connection.

Note

Amazon Redshift Spectrum external tables are read-only. You can't COPY to an external table.

The COPY command appends the input data as additional rows to the table.

The maximum size of a single input row from any source is 4 MB.

Topics

- [Required permissions](#)
- [COPY syntax](#)
- [Required parameters](#)
- [Optional parameters](#)
- [Usage notes and additional resources for the COPY command](#)
- [COPY command examples](#)
- [COPY JOB \(preview\)](#)
- [COPY parameter reference](#)
- [Usage notes](#)
- [COPY examples](#)

Required permissions

To use the COPY command, you must have [INSERT](#) privilege for the Amazon Redshift table.

COPY syntax

```
COPY table-name  
[ column-list ]
```

```
FROM data_source
authorization
[ [ FORMAT ] [ AS ] data_format ]
[ parameter [ argument ] [, ... ] ]
```

You can perform a COPY operation with as few as three parameters: a table name, a data source, and authorization to access the data.

Amazon Redshift extends the functionality of the COPY command to enable you to load data in several data formats from multiple data sources, control access to load data, manage data transformations, and manage the load operation.

The following sections present the required COPY command parameters, grouping the optional parameters by function. They also describe each parameter and explain how various options work together. You can go directly to a parameter description by using the alphabetical parameter list.

Required parameters

The COPY command requires three elements:

- [Table Name](#)
- [Data Source](#)
- [Authorization](#)

The simplest COPY command uses the following format.

```
COPY table-name
FROM data-source
authorization;
```

The following example creates a table named CATDEMO, and then loads the table with sample data from a data file in Amazon S3 named `category_pipe.txt`.

```
create table catdemo(catid smallint, catgroup varchar(10), catname varchar(10), catdesc
varchar(50));
```

In the following example, the data source for the COPY command is a data file named `category_pipe.txt` in the `tickit` folder of an Amazon S3 bucket named `redshift-downloads`. The COPY command is authorized to access the Amazon S3 bucket through an AWS

Identity and Access Management (IAM) role. If your cluster has an existing IAM role with permission to access Amazon S3 attached, you can substitute your role's Amazon Resource Name (ARN) in the following COPY command and run it.

```
copy catdemo
from 's3://redshift-downloads/ticket/category_pipe.txt'
iam_role 'arn:aws:iam::<aws-account-id>:role/<role-name>'
region 'us-east-1';
```

For complete instructions on how to use COPY commands to load sample data, including instructions for loading data from other AWS regions, see [Load Sample Data from Amazon S3](#) in the Amazon Redshift Getting Started Guide.

table-name

The name of the target table for the COPY command. The table must already exist in the database. The table can be temporary or persistent. The COPY command appends the new input data to any existing rows in the table.

FROM *data-source*

The location of the source data to be loaded into the target table. A manifest file can be specified with some data sources.

The most commonly used data repository is an Amazon S3 bucket. You can also load from data files located in an Amazon EMR cluster, an Amazon EC2 instance, or a remote host that your cluster can access using an SSH connection, or you can load directly from a DynamoDB table.

- [COPY from Amazon S3](#)
- [COPY from Amazon EMR](#)
- [COPY from remote host \(SSH\)](#)
- [COPY from Amazon DynamoDB](#)

Authorization

A clause that indicates the method that your cluster uses for authentication and authorization to access other AWS resources. The COPY command needs authorization to access data in another AWS resource, including in Amazon S3, Amazon EMR, Amazon DynamoDB, and Amazon EC2. You can provide that authorization by referencing an IAM role that is attached to your cluster or by providing the access key ID and secret access key for an IAM user.

- [Authorization parameters](#)

- [Role-based access control](#)
- [Key-based access control](#)

Optional parameters

You can optionally specify how COPY maps field data to columns in the target table, define source data attributes to enable the COPY command to correctly read and parse the source data, and manage which operations the COPY command performs during the load process.

- [Column mapping options](#)
- [Data format parameters](#)
- [Data conversion parameters](#)
- [Data load operations](#)

Column mapping

By default, COPY inserts field values into the target table's columns in the same order as the fields occur in the data files. If the default column order will not work, you can specify a column list or use JSONPath expressions to map source data fields to the target columns.

- [Column List](#)
- [JSONPaths File](#)

Data format parameters

You can load data from text files in fixed-width, character-delimited, comma-separated values (CSV), or JSON format, or from Avro files.

By default, the COPY command expects the source data to be in character-delimited UTF-8 text files. The default delimiter is a pipe character (|). If the source data is in another format, use the following parameters to specify the data format.

- [FORMAT](#)
- [CSV](#)
- [DELIMITER](#)
- [FIXEDWIDTH](#)

- [SHAPEFILE](#)
- [AVRO](#)
- [JSON](#)
- [ENCRYPTED](#)
- [BZIP2](#)
- [GZIP](#)
- [LZOP](#)
- [PARQUET](#)
- [ORC](#)
- [ZSTD](#)

Data conversion parameters

As it loads the table, COPY attempts to implicitly convert the strings in the source data to the data type of the target column. If you need to specify a conversion that is different from the default behavior, or if the default conversion results in errors, you can manage data conversions by specifying the following parameters.

- [ACCEPTANYDATE](#)
- [ACCEPTINVCHARS](#)
- [BLANKSASNULL](#)
- [DATEFORMAT](#)
- [EMPTYASNULL](#)
- [ENCODING](#)
- [ESCAPE](#)
- [EXPLICIT_IDS](#)
- [FILLRECORD](#)
- [IGNOREBLANKLINES](#)
- [IGNOREHEADER](#)
- [NULL AS](#)
- [REMOVEQUOTES](#)
- [ROUNDEC](#)

- [TIMEFORMAT](#)
- [TRIMBLANKS](#)
- [TRUNCATECOLUMNS](#)

Data load operations

Manage the default behavior of the load operation for troubleshooting or to reduce load times by specifying the following parameters.

- [COMPROWS](#)
- [COMPUPDATE](#)
- [IGNOREALLERRORS](#)
- [MAXERROR](#)
- [NOLOAD](#)
- [STATUPDATE](#)

Usage notes and additional resources for the COPY command

For more information about how to use the COPY command, see the following topics:

- [Usage notes](#)
- [Tutorial: Loading data from Amazon S3](#)
- [Amazon Redshift best practices for loading data](#)
- [Loading tables with the COPY command](#)
 - [Loading data from Amazon S3](#)
 - [Loading data from Amazon EMR](#)
 - [Loading data from remote hosts](#)
 - [Loading data from an Amazon DynamoDB table](#)
- [Troubleshooting data loads](#)

COPY command examples

For more examples that show how to COPY from various sources, in disparate formats, and with different COPY options, see [COPY examples](#).

COPY JOB (preview)

This is prerelease documentation for autocopy (SQL COPY JOB), which is in preview release. The documentation and the feature are both subject to change. We recommend that you use this feature only in test environments, and not in production environments. Public preview will end on October 31, 2024. Preview clusters will be removed automatically two weeks after the end of the preview. For preview terms and conditions, see [Betas and Previews in AWS Service Terms](#).

For information about using this command in preview, see [Loading tables with continuous file ingestion from Amazon S3 \(preview\)](#).

Manages COPY commands that load data into a table. The COPY JOB command is an extension of the COPY command and automates data loading from Amazon S3 buckets. When you create a COPY job, Amazon Redshift detects when new Amazon S3 files are created in a specified path, and then loads them automatically without your intervention. The same parameters that are used in the original COPY command are used when loading the data. Amazon Redshift keeps track of the loaded files to verify that they are loaded only one time.

Note

For information about the COPY command, including usage, parameters, and permissions, see [COPY](#).

Required permission

To run the COPY command of a COPY JOB, you must have INSERT privilege of the table being loaded.

The IAM role specified with the COPY command must have permission to access the data to load. For more information, see [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#).

Syntax

Create a copy job. The parameters of the COPY command are saved with the copy job.

```
COPY copy-command JOB CREATE job-name
```

```
[AUTO ON | OFF]
```

Change the configuration of a copy job.

```
COPY JOB ALTER job-name  
[AUTO ON | OFF]
```

Run a copy job. The stored COPY command parameters are used.

```
COPY JOB RUN job-name
```

List all copy jobs.

```
COPY JOB LIST
```

Show the details of a copy job.

```
COPY JOB SHOW job-name
```

Delete a copy job.

```
COPY JOB DROP job-name
```

Parameters

copy-command

A COPY command that loads data from Amazon S3 to Amazon Redshift. The clause contains COPY parameters that define the Amazon S3 bucket, target table, IAM role, and other parameters used when loading data. All COPY command parameters for an Amazon S3 data load are supported except:

- The COPY JOB does not ingest preexisting files in the folder pointed to by the COPY command. Only files created after the COPY JOB creation timestamp are ingested.
- You cannot specify a COPY command with the MAXERROR or IGNOREALLERRORS options.
- You cannot specify a manifest file. COPY JOB requires a designated Amazon S3 location to monitor for newly created files.

- You cannot specify a COPY command with authorization types like Access and Secret keys. Only COPY commands that use the IAM_ROLE parameter for authorization are supported. For more information, see [Authorization parameters](#).
- The COPY JOB doesn't support the default IAM role associated with the cluster. You must specify the IAM_ROLE in the COPY command.

For more information, see [COPY from Amazon S3](#).

job-name

The name of the job used to reference the COPY job.

[AUTO ON | OFF]

Clause that indicates whether Amazon S3 data is automatically loaded into Amazon Redshift tables.

- When ON, Amazon Redshift monitors the source Amazon S3 path for newly created files, and if found, a COPY command is run with the COPY parameters in the job definition. This is the default.
- When OFF, Amazon Redshift does not run the COPY JOB automatically.

Usage notes

The options of the COPY command aren't validated until run time. For example, an invalid IAM_ROLE or an Amazon S3 data source results in runtime errors when the COPY JOB starts.

If the cluster is paused, COPY JOBS are not run.

To query COPY command files loaded and load errors, see [STL_LOAD_COMMITS](#), [STL_LOAD_ERRORS](#), [STL_LOADERERROR_DETAIL](#). For more information, see [Verifying that the data loaded correctly](#).

Examples

The following example shows creating a COPY JOB to load data from an Amazon S3 bucket.

```
COPY public.target_table
FROM 's3://amzn-s3-demo-bucket/staging-folder'
IAM_ROLE 'arn:aws:iam::123456789012:role/MyLoadRoleName'
JOB CREATE my_copy_job_name
AUTO ON;
```

COPY parameter reference

COPY has many parameters that can be used in many situations. However, not all parameters are supported in each situation. For example, to load from ORC or PARQUET files there is a limited number of supported parameters. For more information, see [COPY from columnar data formats](#).

Topics

- [Data sources](#)
- [Authorization parameters](#)
- [Column mapping options](#)
- [Data format parameters](#)
- [File compression parameters](#)
- [Data conversion parameters](#)
- [Data load operations](#)
- [Alphabetical parameter list](#)

Data sources

You can load data from text files in an Amazon S3 bucket, in an Amazon EMR cluster, or on a remote host that your cluster can access using an SSH connection. You can also load data directly from a DynamoDB table.

The maximum size of a single input row from any source is 4 MB.

To export data from a table to a set of files in an Amazon S3, use the [UNLOAD](#) command.

Topics

- [COPY from Amazon S3](#)
- [COPY from Amazon EMR](#)
- [COPY from remote host \(SSH\)](#)
- [COPY from Amazon DynamoDB](#)

COPY from Amazon S3

To load data from files located in one or more S3 buckets, use the FROM clause to indicate how COPY locates the files in Amazon S3. You can provide the object path to the data files as part of

the FROM clause, or you can provide the location of a manifest file that contains a list of Amazon S3 object paths. COPY from Amazon S3 uses an HTTPS connection. Ensure that the S3 IP ranges are added to your allow list. To learn more about the required S3 IP ranges, see [Network isolation](#).

Important

If the Amazon S3 buckets that hold the data files don't reside in the same AWS Region as your cluster, you must use the [REGION](#) parameter to specify the Region in which the data is located.

Topics

- [Syntax](#)
- [Examples](#)
- [Optional parameters](#)
- [Unsupported parameters](#)

Syntax

```
FROM { 's3://objectpath' | 's3://manifest_file' }  
authorization  
| MANIFEST  
| ENCRYPTED  
| REGION [AS] 'aws-region'  
| optional-parameters
```

Examples

The following example uses an object path to load data from Amazon S3.

```
copy customer  
from 's3://amzn-s3-demo-bucket/customer'  
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

The following example uses a manifest file to load data from Amazon S3.

```
copy customer  
from 's3://amzn-s3-demo-bucket/cust.manifest'  
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
```

```
manifest;
```

Parameters

FROM

The source of the data to be loaded. For more information about the encoding of the Amazon S3 file, see [Data conversion parameters](#).

```
's3://copy_from_s3_objectpath'
```

Specifies the path to the Amazon S3 objects that contain the data—for example, 's3://amzn-s3-demo-bucket/custdata.txt'. The `s3://copy_from_s3_objectpath` parameter can reference a single file or a set of objects or folders that have the same key prefix. For example, the name `custdata.txt` is a key prefix that refers to a number of physical files: `custdata.txt`, `custdata.txt.1`, `custdata.txt.2`, `custdata.txt.bak`, and so on. The key prefix can also reference a number of folders. For example, 's3://amzn-s3-demo-bucket/custfolder' refers to the folders `custfolder`, `custfolder_1`, `custfolder_2`, and so on. If a key prefix references multiple folders, all of the files in the folders are loaded. If a key prefix matches a file as well as a folder, such as `custfolder.log`, COPY attempts to load the file also. If a key prefix might result in COPY attempting to load unwanted files, use a manifest file. For more information, see [copy_from_s3_manifest_file](#), following.

Important

If the S3 bucket that holds the data files doesn't reside in the same AWS Region as your cluster, you must use the [REGION](#) parameter to specify the Region in which the data is located.

For more information, see [Loading data from Amazon S3](#).

```
's3://copy_from_s3_manifest_file'
```

Specifies the Amazon S3 object key for a manifest file that lists the data files to be loaded. The 's3://copy_from_s3_manifest_file' argument must explicitly reference a single file—for example, 's3://amzn-s3-demo-bucket/manifest.txt'. It can't reference a key prefix.

The manifest is a text file in JSON format that lists the URL of each file that is to be loaded from Amazon S3. The URL includes the bucket name and full object path for the file. The files that are specified in the manifest can be in different buckets, but all the buckets must be in the

same AWS Region as the Amazon Redshift cluster. If a file is listed twice, the file is loaded twice. The following example shows the JSON for a manifest that loads three files.

```
{
  "entries": [
    {"url": "s3://amzn-s3-demo-bucket1/custdata.1", "mandatory": true},
    {"url": "s3://amzn-s3-demo-bucket1/custdata.2", "mandatory": true},
    {"url": "s3://amzn-s3-demo-bucket2/custdata.1", "mandatory": false}
  ]
}
```

The double quotation mark characters are required, and must be simple quotation marks (0x22), not slanted or "smart" quotation marks. Each entry in the manifest can optionally include a mandatory flag. If mandatory is set to true, COPY terminates if it doesn't find the file for that entry; otherwise, COPY will continue. The default value for mandatory is false.

When loading from data files in ORC or Parquet format, a meta field is required, as shown in the following example.

```
{
  "entries": [
    {
      "url": "s3://amzn-s3-demo-bucket1/orc/2013-10-04-custdata",
      "mandatory": true,
      "meta": {
        "content_length": 99
      }
    },
    {
      "url": "s3://amzn-s3-demo-bucket2/orc/2013-10-05-custdata",
      "mandatory": true,
      "meta": {
        "content_length": 99
      }
    }
  ]
}
```

The manifest file must not be encrypted or compressed, even if the ENCRYPTED, GZIP, LZOP, BZIP2, or ZSTD options are specified. COPY returns an error if the specified manifest file isn't found or the manifest file isn't properly formed.

If a manifest file is used, the MANIFEST parameter must be specified with the COPY command. If the MANIFEST parameter isn't specified, COPY assumes that the file specified with FROM is a data file.

For more information, see [Loading data from Amazon S3](#).

authorization

The COPY command needs authorization to access data in another AWS resource, including in Amazon S3, Amazon EMR, Amazon DynamoDB, and Amazon EC2. You can provide that authorization by referencing an AWS Identity and Access Management (IAM) role that is attached to your cluster (role-based access control) or by providing the access credentials for a user (key-based access control). For increased security and flexibility, we recommend using IAM role-based access control. For more information, see [Authorization parameters](#).

MANIFEST

Specifies that a manifest is used to identify the data files to be loaded from Amazon S3. If the MANIFEST parameter is used, COPY loads data from the files listed in the manifest referenced by `'s3://copy_from_s3_manifest_file'`. If the manifest file isn't found, or isn't properly formed, COPY fails. For more information, see [Using a manifest to specify data files](#).

ENCRYPTED

A clause that specifies that the input files on Amazon S3 are encrypted using client-side encryption with customer managed keys. For more information, see [Loading encrypted data files from Amazon S3](#). Don't specify ENCRYPTED if the input files are encrypted using Amazon S3 server-side encryption (SSE-KMS or SSE-S3). COPY reads server-side encrypted files automatically.

If you specify the ENCRYPTED parameter, you must also specify the [MASTER_SYMMETRIC_KEY](#) parameter or include the `master_symmetric_key` value in the [CREDENTIALS](#) string.

If the encrypted files are in compressed format, add the GZIP, LZOP, BZIP2, or ZSTD parameter.

Manifest files and JSONPaths files must not be encrypted, even if the ENCRYPTED option is specified.

MASTER_SYMMETRIC_KEY 'root_key'

The root symmetric key that was used to encrypt data files on Amazon S3. If MASTER_SYMMETRIC_KEY is specified, the [ENCRYPTED](#) parameter must also be specified.

MASTER_SYMMETRIC_KEY can't be used with the CREDENTIALS parameter. For more information, see [Loading encrypted data files from Amazon S3](#).

If the encrypted files are in compressed format, add the GZIP, LZOP, BZIP2, or ZSTD parameter.

REGION [AS] '*aws-region*'

Specifies the AWS Region where the source data is located. REGION is required for COPY from an Amazon S3 bucket or an DynamoDB table when the AWS resource that contains the data isn't in the same Region as the Amazon Redshift cluster.

The value for *aws_region* must match a Region listed in the [Amazon Redshift regions and endpoints](#) table.

If the REGION parameter is specified, all resources, including a manifest file or multiple Amazon S3 buckets, must be located in the specified Region.

 **Note**

Transferring data across Regions incurs additional charges against the Amazon S3 bucket or the DynamoDB table that contains the data. For more information about pricing, see **Data Transfer OUT From Amazon S3 To Another AWS Region** on the [Amazon S3 Pricing](#) page and **Data Transfer OUT** on the [Amazon DynamoDB Pricing](#) page.

By default, COPY assumes that the data is located in the same Region as the Amazon Redshift cluster.

Optional parameters

You can optionally specify the following parameters with COPY from Amazon S3:

- [Column mapping options](#)
- [Data format parameters](#)
- [Data conversion parameters](#)
- [Data load operations](#)

Unsupported parameters

You can't use the following parameters with COPY from Amazon S3:

- SSH
- READRATIO

COPY from Amazon EMR

You can use the COPY command to load data in parallel from an Amazon EMR cluster configured to write text files to the cluster's Hadoop Distributed File System (HDFS) in the form of fixed-width files, character-delimited files, CSV files, JSON-formatted files, or Avro files.

Topics

- [Syntax](#)
- [Example](#)
- [Parameters](#)
- [Supported parameters](#)
- [Unsupported parameters](#)

Syntax

```
FROM 'emr://emr_cluster_id/hdfs_filepath'  
authorization  
[ optional_parameters ]
```

Example

The following example loads data from an Amazon EMR cluster.

```
copy sales  
from 'emr://j-SAMPLE2B500FC/myoutput/part-*'   
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

Parameters

FROM

The source of the data to be loaded.

```
'emr://emr_cluster_id/hdfs_file_path'
```

The unique identifier for the Amazon EMR cluster and the HDFS file path that references the data files for the COPY command. The HDFS data file names must not contain the wildcard characters asterisk (*) and question mark (?).

 **Note**

The Amazon EMR cluster must continue running until the COPY operation completes. If any of the HDFS data files are changed or deleted before the COPY operation completes, you might have unexpected results, or the COPY operation might fail.

You can use the wildcard characters asterisk (*) and question mark (?) as part of the *hdfs_file_path* argument to specify multiple files to be loaded. For example, 'emr://j-SAMPLE2B500FC/myoutput/part*' identifies the files `part-0000`, `part-0001`, and so on. If the file path doesn't contain wildcard characters, it is treated as a string literal. If you specify only a folder name, COPY attempts to load all files in the folder.

 **Important**

If you use wildcard characters or use only the folder name, verify that no unwanted files will be loaded. For example, some processes might write a log file to the output folder.

For more information, see [Loading data from Amazon EMR](#).

authorization

The COPY command needs authorization to access data in another AWS resource, including in Amazon S3, Amazon EMR, Amazon DynamoDB, and Amazon EC2. You can provide that authorization by referencing an AWS Identity and Access Management (IAM) role that is attached to your cluster (role-based access control) or by providing the access credentials for a user (key-based access control). For increased security and flexibility, we recommend using IAM role-based access control. For more information, see [Authorization parameters](#).

Supported parameters

You can optionally specify the following parameters with COPY from Amazon EMR:

- [Column mapping options](#)
- [Data format parameters](#)
- [Data conversion parameters](#)
- [Data load operations](#)

Unsupported parameters

You can't use the following parameters with COPY from Amazon EMR:

- ENCRYPTED
- MANIFEST
- REGION
- READRATIO
- SSH

COPY from remote host (SSH)

You can use the COPY command to load data in parallel from one or more remote hosts, such as Amazon Elastic Compute Cloud (Amazon EC2) instances or other computers. COPY connects to the remote hosts using Secure Shell (SSH) and runs commands on the remote hosts to generate text output. The remote host can be an EC2 Linux instance or another Unix or Linux computer configured to accept SSH connections. Amazon Redshift can connect to multiple hosts, and can open multiple SSH connections to each host. Amazon Redshift sends a unique command through each connection to generate text output to the host's standard output, which Amazon Redshift then reads as it does a text file.

Use the FROM clause to specify the Amazon S3 object key for the manifest file that provides the information COPY uses to open SSH connections and run the remote commands.

Topics

- [Syntax](#)
- [Examples](#)
- [Parameters](#)
- [Optional parameters](#)

- [Unsupported parameters](#)

⚠ Important

If the S3 bucket that holds the manifest file doesn't reside in the same AWS Region as your cluster, you must use the `REGION` parameter to specify the Region in which the bucket is located.

Syntax

```
FROM 's3://'ssh_manifest_file' }  
authorization  
SSH  
| optional-parameters
```

Examples

The following example uses a manifest file to load data from a remote host using SSH.

```
copy sales  
from 's3://amzn-s3-demo-bucket/ssh_manifest'  
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
ssh;
```

Parameters**FROM**

The source of the data to be loaded.

's3://copy_from_ssh_manifest_file'

The `COPY` command can connect to multiple hosts using SSH, and can create multiple SSH connections to each host. `COPY` runs a command through each host connection, and then loads the output from the commands in parallel into the table. The `s3://copy_from_ssh_manifest_file` argument specifies the Amazon S3 object key for the manifest file that provides the information `COPY` uses to open SSH connections and run the remote commands.

The `s3://copy_from_ssh_manifest_file` argument must explicitly reference a single file; it can't be a key prefix. The following shows an example:

```
's3://amzn-s3-demo-bucket/ssh_manifest.txt'
```

The manifest file is a text file in JSON format that Amazon Redshift uses to connect to the host. The manifest file specifies the SSH host endpoints and the commands that will be run on the hosts to return data to Amazon Redshift. Optionally, you can include the host public key, the login user name, and a mandatory flag for each entry. The following example shows a manifest file that creates two SSH connections:

```
{
  "entries": [
    {
      "endpoint": "<ssh_endpoint_or_IP>",
      "command": "<remote_command>",
      "mandatory": true,
      "publickey": "<public_key>",
      "username": "<host_user_name>"
    },
    {
      "endpoint": "<ssh_endpoint_or_IP>",
      "command": "<remote_command>",
      "mandatory": true,
      "publickey": "<public_key>",
      "username": "<host_user_name>"
    }
  ]
}
```

The manifest file contains one "entries" construct for each SSH connection. You can have multiple connections to a single host or multiple connections to multiple hosts. The double quotation mark characters are required as shown, both for the field names and the values. The quotation mark characters must be simple quotation marks (0x22), not slanted or "smart" quotation marks. The only value that doesn't need double quotation mark characters is the Boolean value `true` or `false` for the "mandatory" field.

The following list describes the fields in the manifest file.

endpoint

The URL address or IP address of the host—for example, "ec2-111-222-333.compute-1.amazonaws.com", or "198.51.100.0".

command

The command to be run by the host to generate text output or binary output in gzip, lzop, bzip2, or zstd format. The command can be any command that the user "host_user_name"

has permission to run. The command can be as simple as printing a file, or it can query a database or launch a script. The output (text file, gzip binary file, lzop binary file, or bzip2 binary file) must be in a form that the Amazon Redshift COPY command can ingest. For more information, see [Preparing your input data](#).

publickey

(Optional) The public key of the host. If provided, Amazon Redshift will use the public key to identify the host. If the public key isn't provided, Amazon Redshift will not attempt host identification. For example, if the remote host's public key is `ssh-rsa AbcCbaxxx...`
Example `root@amazon.com`, type the following text in the public key field: "AbcCbaxxx...
Example"

mandatory

(Optional) A clause that indicates whether the COPY command should fail if the connection attempt fails. The default is `false`. If Amazon Redshift doesn't successfully make at least one connection, the COPY command fails.

username

(Optional) The user name that will be used to log on to the host system and run the remote command. The user login name must be the same as the login that was used to add the Amazon Redshift cluster's public key to the host's authorized keys file. The default username is `redshift`.

For more information about creating a manifest file, see [Loading data process](#).

To COPY from a remote host, the SSH parameter must be specified with the COPY command. If the SSH parameter isn't specified, COPY assumes that the file specified with FROM is a data file and will fail.

If you use automatic compression, the COPY command performs two data read operations, which means it will run the remote command twice. The first read operation is to provide a data sample for compression analysis, then the second read operation actually loads the data. If executing the remote command twice might cause a problem, you should disable automatic compression. To disable automatic compression, run the COPY command with the `COMPUPDATE` parameter set to `OFF`. For more information, see [Loading tables with automatic compression](#).

For detailed procedures for using COPY from SSH, see [Loading data from remote hosts](#).

authorization

The COPY command needs authorization to access data in another AWS resource, including in Amazon S3, Amazon EMR, Amazon DynamoDB, and Amazon EC2. You can provide that authorization by referencing an AWS Identity and Access Management (IAM) role that is attached to your cluster (role-based access control) or by providing the access credentials for a user (key-based access control). For increased security and flexibility, we recommend using IAM role-based access control. For more information, see [Authorization parameters](#).

SSH

A clause that specifies that data is to be loaded from a remote host using the SSH protocol. If you specify SSH, you must also provide a manifest file using the [s3://copy_from_ssh_manifest_file](#) argument.

Note

If you are using SSH to copy from a host using a private IP address in a remote VPC, the VPC must have enhanced VPC routing enabled. For more information about Enhanced VPC routing, see [Amazon Redshift Enhanced VPC Routing](#).

Optional parameters

You can optionally specify the following parameters with COPY from SSH:

- [Column mapping options](#)
- [Data format parameters](#)
- [Data conversion parameters](#)
- [Data load operations](#)

Unsupported parameters

You can't use the following parameters with COPY from SSH:

- ENCRYPTED
- MANIFEST
- READRATIO

COPY from Amazon DynamoDB

To load data from an existing DynamoDB table, use the FROM clause to specify the DynamoDB table name.

Topics

- [Syntax](#)
- [Examples](#)
- [Optional parameters](#)
- [Unsupported parameters](#)

Important

If the DynamoDB table doesn't reside in the same region as your Amazon Redshift cluster, you must use the REGION parameter to specify the region in which the data is located.

Syntax

```
FROM 'dynamodb://table-name'  
authorization  
READRATIO ratio  
| REGION [AS] 'aws_region'  
| optional-parameters
```

Examples

The following example loads data from a DynamoDB table.

```
copy favoritemovies from 'dynamodb://ProductCatalog'  
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
readratio 50;
```

Parameters

FROM

The source of the data to be loaded.

'dynamodb://table-name'

The name of the DynamoDB table that contains the data, for example 'dynamodb://ProductCatalog'. For details about how DynamoDB attributes are mapped to Amazon Redshift columns, see [Loading data from an Amazon DynamoDB table](#).

A DynamoDB table name is unique to an AWS account, which is identified by the AWS access credentials.

authorization

The COPY command needs authorization to access data in another AWS resource, including in Amazon S3, Amazon EMR, DynamoDB, and Amazon EC2. You can provide that authorization by referencing an AWS Identity and Access Management (IAM) role that is attached to your cluster (role-based access control) or by providing the access credentials for a user (key-based access control). For increased security and flexibility, we recommend using IAM role-based access control. For more information, see [Authorization parameters](#).

READRATIO [AS] *ratio*

The percentage of the DynamoDB table's provisioned throughput to use for the data load. READRATIO is required for COPY from DynamoDB. It can't be used with COPY from Amazon S3. We highly recommend setting the ratio to a value less than the average unused provisioned throughput. Valid values are integers 1–200.

Important

Setting READRATIO to 100 or higher enables Amazon Redshift to consume the entirety of the DynamoDB table's provisioned throughput, which seriously degrades the performance of concurrent read operations against the same table during the COPY session. Write traffic is unaffected. Values higher than 100 are allowed to troubleshoot rare scenarios when Amazon Redshift fails to fulfill the provisioned throughput of the table. If you load data from DynamoDB to Amazon Redshift on an ongoing basis, consider organizing your DynamoDB tables as a time series to separate live traffic from the COPY operation.

Optional parameters

You can optionally specify the following parameters with COPY from Amazon DynamoDB:

- [Column mapping options](#)
- The following data conversion parameters are supported:
 - [ACCEPTANYDATE](#)
 - [BLANKSASNULL](#)
 - [DATEFORMAT](#)
 - [EMPTYASNULL](#)
 - [ROUNDEC](#)
 - [TIMEFORMAT](#)
 - [TRIMBLANKS](#)
 - [TRUNCATECOLUMNS](#)
- [Data load operations](#)

Unsupported parameters

You can't use the following parameters with COPY from DynamoDB:

- All data format parameters
- ESCAPE
- FILLRECORD
- IGNOREBLANKLINES
- IGNOREHEADER
- NULL
- REMOVEQUOTES
- ACCEPTINVCHARS
- MANIFEST
- ENCRYPTED

Authorization parameters

The COPY command needs authorization to access data in another AWS resource, including in Amazon S3, Amazon EMR, Amazon DynamoDB, and Amazon EC2. You can provide that authorization by referencing an [AWS Identity and Access Management \(IAM\) role](#) that is attached to your cluster (*role-based access control*). You can encrypt your load data on Amazon S3.

The following topics provide more details and examples of authentication options:

- [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#)
- [Role-based access control](#)
- [Key-based access control](#)

Use one of the following to provide authorization for the COPY command:

- [IAM_ROLE](#) parameter
- [ACCESS_KEY_ID](#) and [SECRET_ACCESS_KEY](#) parameters
- [CREDENTIALS](#) clause

```
IAM_ROLE { default | 'arn:aws:iam::<AWS account-id>:role/<role-name>' }
```

Use the default keyword to have Amazon Redshift use the IAM role that is set as default and associated with the cluster when the COPY command runs.

Use the Amazon Resource Name (ARN) for an IAM role that your cluster uses for authentication and authorization. If you specify IAM_ROLE, you can't use ACCESS_KEY_ID and SECRET_ACCESS_KEY, SESSION_TOKEN, or CREDENTIALS.

The following shows the syntax for the IAM_ROLE parameter.

```
IAM_ROLE { default | 'arn:aws:iam::<AWS account-id>:role/<role-name>' }
```

For more information, see [Role-based access control](#).

```
ACCESS_KEY_ID 'access-key-id' SECRET_ACCESS_KEY 'secret-access-key'
```

This authorization method is not recommended.

Note

Instead of providing access credentials as plain text, we strongly recommend using role-based authentication by specifying the IAM_ROLE parameter. For more information, see [Role-based access control](#).

SESSION_TOKEN '*temporary-token*'

The session token for use with temporary access credentials. When SESSION_TOKEN is specified, you must also use ACCESS_KEY_ID and SECRET_ACCESS_KEY to provide temporary access key credentials. If you specify SESSION_TOKEN you can't use IAM_ROLE or CREDENTIALS. For more information, see [Temporary security credentials](#) in the IAM User Guide.

Note

Instead of creating temporary security credentials, we strongly recommend using role-based authentication. When you authorize using an IAM role, Amazon Redshift automatically creates temporary user credentials for each session. For more information, see [Role-based access control](#).

The following shows the syntax for the SESSION_TOKEN parameter with the ACCESS_KEY_ID and SECRET_ACCESS_KEY parameters.

```
ACCESS_KEY_ID '<access-key-id>'  
SECRET_ACCESS_KEY '<secret-access-key>'  
SESSION_TOKEN '<temporary-token>';
```

If you specify SESSION_TOKEN you can't use CREDENTIALS or IAM_ROLE.

[WITH] CREDENTIALS [AS] '*credentials-args*'

A clause that indicates the method your cluster will use when accessing other AWS resources that contain data files or manifest files. You can't use the CREDENTIALS parameter with IAM_ROLE or ACCESS_KEY_ID and SECRET_ACCESS_KEY.

Note

For increased flexibility, we recommend using the [IAM_ROLE](#) parameter instead of the CREDENTIALS parameter.

Optionally, if the [ENCRYPTED](#) parameter is used, the *credentials-args* string also provides the encryption key.

The *credentials-args* string is case-sensitive and must not contain spaces.

The keywords WITH and AS are optional and are ignored.

You can specify either [role-based access control](#) or [key-based access control](#). In either case, the IAM role or user must have the permissions required to access the specified AWS resources. For more information, see [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#).

Note

To safeguard your AWS credentials and protect sensitive data, we strongly recommend using role-based access control.

To specify role-based access control, provide the *credentials-args* string in the following format.

```
'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-name>'
```

To use temporary token credentials, you must provide the temporary access key ID, the temporary secret access key, and the temporary token. The *credentials-args* string is in the following format.

CREDENTIALS

```
'aws_access_key_id=<temporary-access-key-id>;aws_secret_access_key=<temporary-secret-access-key>;token=<temporary-token>'
```

For more information, see [Temporary security credentials](#).

If the [ENCRYPTED](#) parameter is used, the *credentials-args* string is in the following format, where *<root-key>* is the value of the root key that was used to encrypt the files.

CREDENTIALS

```
'<credentials-args>;master_symmetric_key=<root-key>'
```

For example, the following COPY command uses role-based access control with an encryption key.

```
copy customer from 's3://amzn-s3-demo-bucket/mydata'
credentials
'aws_iam_role=arn:aws:iam::<account-id>:role/<role-name>;master_symmetric_key=<root-key>'
```

The following COPY command shows role-based access control with an encryption key.

```
copy customer from 's3://amzn-s3-demo-bucket/mydata'  
credentials  
'aws_iam_role=arn:aws:iam::<aws-account-id>:role/<role-  
name>;master_symmetric_key=<root-key>'
```

Column mapping options

By default, COPY inserts values into the target table's columns in the same order as fields occur in the data files. If the default column order will not work, you can specify a column list or use JSONPath expressions to map source data fields to the target columns.

- [Column List](#)
- [JSONPaths File](#)

Column list

You can specify a comma-separated list of column names to load source data fields into specific target columns. The columns can be in any order in the COPY statement, but when loading from flat files, such as in an Amazon S3 bucket, their order must match the order of the source data.

When loading from an Amazon DynamoDB table, order doesn't matter. The COPY command matches attribute names in the items retrieved from the DynamoDB table to column names in the Amazon Redshift table. For more information, see [Loading data from an Amazon DynamoDB table](#)

The format for a column list is as follows.

```
COPY tablename (column1 [,column2, ...])
```

If a column in the target table is omitted from the column list, then COPY loads the target column's [DEFAULT](#) expression.

If the target column doesn't have a default, then COPY attempts to load NULL.

If COPY attempts to assign NULL to a column that is defined as NOT NULL, the COPY command fails.

If an [IDENTITY](#) column is included in the column list, then [EXPLICIT_IDS](#) must also be specified; if an IDENTITY column is omitted, then EXPLICIT_IDS can't be specified. If no column list is specified,

the command behaves as if a complete, in-order column list was specified, with IDENTITY columns omitted if EXPLICIT_IDS was also not specified.

If a column is defined with GENERATED BY DEFAULT AS IDENTITY, then it can be copied. Values are generated or updated with values that you supply. The EXPLICIT_IDS option isn't required. COPY doesn't update the identity high watermark. For more information, see [GENERATED BY DEFAULT AS IDENTITY](#).

JSONPaths file

When loading from data files in JSON or Avro format, COPY automatically maps the data elements in the JSON or Avro source data to the columns in the target table. It does so by matching field names in the Avro schema to column names in the target table or column list.

In some cases, your column names and field names don't match, or you need to map to deeper levels in the data hierarchy. In these cases, you can use a JSONPaths file to explicitly map JSON or Avro data elements to columns.

For more information, see [JSONPaths file](#).

Data format parameters

By default, the COPY command expects the source data to be character-delimited UTF-8 text. The default delimiter is a pipe character (|). If the source data is in another format, use the following parameters to specify the data format:

- [FORMAT](#)
- [CSV](#)
- [DELIMITER](#)
- [FIXEDWIDTH](#)
- [SHAPEFILE](#)
- [AVRO](#)
- [JSON](#)
- [PARQUET](#)
- [ORC](#)

In addition to the standard data formats, COPY supports the following columnar data formats for COPY from Amazon S3:

- [ORC](#)
- [PARQUET](#)

COPY from columnar format is supported with certain restriction. For more information, see [COPY from columnar data formats](#).

Data format parameters

FORMAT [AS]

(Optional) Identifies data format keywords. The FORMAT arguments are described following.

CSV [QUOTE [AS] '*quote_character*']

Enables use of CSV format in the input data. To automatically escape delimiters, newline characters, and carriage returns, enclose the field in the character specified by the QUOTE parameter. The default quotation mark character is a double quotation mark ("). When the quotation mark character is used within a field, escape the character with an additional quotation mark character. For example, if the quotation mark character is a double quotation mark, to insert the string A "quoted" word the input file should include the string "A ""quoted"" word". When the CSV parameter is used, the default delimiter is a comma (,). You can specify a different delimiter by using the DELIMITER parameter.

When a field is enclosed in quotation marks, white space between the delimiters and the quotation mark characters is ignored. If the delimiter is a white space character, such as a tab, the delimiter isn't treated as white space.

CSV can't be used with FIXEDWIDTH, REMOVEQUOTES, or ESCAPE.

QUOTE [AS] '*quote_character*'

Optional. Specifies the character to be used as the quotation mark character when using the CSV parameter. The default is a double quotation mark ("). If you use the QUOTE parameter to define a quotation mark character other than double quotation mark, you don't need to escape double quotation marks within the field. The QUOTE parameter can be used only with the CSV parameter. The AS keyword is optional.

DELIMITER [AS] ['*delimiter_char*']

Specifies characters that are used to separate fields in the input file, such as a pipe character (|), a comma (,), a tab (\t), or multiple characters such as |~|. Non-printable characters are supported. Characters can also be represented in octal as their UTF-8 code units. For octal, use

the format '\ddd', where 'd' is an octal digit (0–7). The default delimiter is a pipe character (|), unless the CSV parameter is used, in which case the default delimiter is a comma (,). The AS keyword is optional. DELIMITER can't be used with FIXEDWIDTH.

FIXEDWIDTH '*fixedwidth_spec*'

Loads the data from a file where each column width is a fixed length, rather than columns being separated by a delimiter. The *fixedwidth_spec* is a string that specifies a user-defined column label and column width. The column label can be either a text string or an integer, depending on what the user chooses. The column label has no relation to the column name. The order of the label/width pairs must match the order of the table columns exactly. FIXEDWIDTH can't be used with CSV or DELIMITER. In Amazon Redshift, the length of CHAR and VARCHAR columns is expressed in bytes, so be sure that the column width that you specify accommodates the binary length of multibyte characters when preparing the file to be loaded. For more information, see [Character types](#).

The format for *fixedwidth_spec* is shown following:

```
'colLabel1:colWidth1,colLabel:colWidth2, ...'
```

SHAPEFILE [SIMPLIFY [AUTO] [*tolerance*]]

Enables use of SHAPEFILE format in the input data. By default, the first column of the shapefile is either a GEOMETRY or IDENTITY column. All subsequent columns follow the order specified in the shapefile.

You can't use SHAPEFILE with FIXEDWIDTH, REMOVEQUOTES, or ESCAPE.

To use GEOGRAPHY objects with COPY FROM SHAPEFILE, first ingest into a GEOMETRY column, and then cast the objects to GEOGRAPHY objects. .

SIMPLIFY [*tolerance*]

(Optional) Simplifies all geometries during the ingestion process using the Ramer-Douglas-Peucker algorithm and the given tolerance.

SIMPLIFY AUTO [*tolerance*]

(Optional) Simplifies only geometries that are larger than the maximum geometry size. This simplification uses the Ramer-Douglas-Peucker algorithm and the automatically calculated tolerance if this doesn't exceed the specified tolerance. This algorithm calculates the size to store objects within the tolerance specified. The *tolerance* value is optional.

For examples of loading shapefiles, see [Loading a shapefile into Amazon Redshift](#).

AVRO [AS] '*avro_option*'

Specifies that the source data is in Avro format.

Avro format is supported for COPY from these services and protocols:

- Amazon S3
- Amazon EMR
- Remote hosts (SSH)

Avro isn't supported for COPY from DynamoDB.

Avro is a data serialization protocol. An Avro source file includes a schema that defines the structure of the data. The Avro schema type must be `record`. COPY accepts Avro files created using the default uncompressed codec as well as the `deflate` and `snappy` compression codecs. For more information about Avro, go to [Apache Avro](#).

Valid values for *avro_option* are as follows:

- '`auto`'
- '`auto ignorecase`'
- '`s3://jsonpaths_file`'

The default is '`auto`'.

COPY automatically maps the data elements in the Avro source data to the columns in the target table. It does so by matching field names in the Avro schema to column names in the target table. The matching is case-sensitive for '`auto`' and isn't case-sensitive for '`auto ignorecase`'.

Column names in Amazon Redshift tables are always lowercase, so when you use the '`auto`' option, matching field names must also be lowercase. If the field names aren't all lowercase, you can use the '`auto ignorecase`' option. With the default '`auto`' argument, COPY recognizes only the first level of fields, or *outer fields*, in the structure.

To explicitly map column names to Avro field names, you can use a [JSONPaths file](#).

By default, COPY attempts to match all columns in the target table to Avro field names. To load a subset of the columns, you can optionally specify a column list. If a column in the target table

is omitted from the column list, COPY loads the target column's [DEFAULT](#) expression. If the target column doesn't have a default, COPY attempts to load NULL. If a column is included in the column list and COPY doesn't find a matching field in the Avro data, COPY attempts to load NULL to the column.

If COPY attempts to assign NULL to a column that is defined as NOT NULL, the COPY command fails.

Avro Schema

An Avro source data file includes a schema that defines the structure of the data. COPY reads the schema that is part of the Avro source data file to map data elements to target table columns. The following example shows an Avro schema.

```
{
  "name": "person",
  "type": "record",
  "fields": [
    {"name": "id", "type": "int"},
    {"name": "guid", "type": "string"},
    {"name": "name", "type": "string"},
    {"name": "address", "type": "string"}]
}
```

The Avro schema is defined using JSON format. The top-level JSON object contains three name-value pairs with the names, or *keys*, "name", "type", and "fields".

The "fields" key pairs with an array of objects that define the name and data type of each field in the data structure. By default, COPY automatically matches the field names to column names. Column names are always lowercase, so matching field names must also be lowercase, unless you specify the 'auto ignorecase' option. Any field names that don't match a column name are ignored. Order doesn't matter. In the previous example, COPY maps to the column names `id`, `guid`, `name`, and `address`.

With the default 'auto' argument, COPY matches only the first-level objects to columns. To map to deeper levels in the schema, or if field names and column names don't match, use a [JSONPaths](#) file to define the mapping. For more information, see [JSONPaths file](#).

If the value associated with a key is a complex Avro data type such as byte, array, record, map, or link, COPY loads the value as a string. Here, the string is the JSON representation of the data.

COPY loads Avro enum data types as strings, where the content is the name of the type. For an example, see [COPY from JSON format](#).

The maximum size of the Avro file header, which includes the schema and file metadata, is 1 MB.

The maximum size of a single Avro data block is 4 MB. This is distinct from the maximum row size. If the maximum size of a single Avro data block is exceeded, even if the resulting row size is less than the 4 MB row-size limit, the COPY command fails.

In calculating row size, Amazon Redshift internally counts pipe characters (|) twice. If your input data contains a very large number of pipe characters, it is possible for row size to exceed 4 MB even if the data block is less than 4 MB.

JSON [AS] *'json_option'*

The source data is in JSON format.

JSON format is supported for COPY from these services and protocols:

- Amazon S3
- COPY from Amazon EMR
- COPY from SSH

JSON isn't supported for COPY from DynamoDB.

Valid values for *json_option* are as follows :

- 'auto'
- 'auto ignorecase'
- 's3://*jsonpaths_file*'
- 'noshred'

The default is 'auto'. Amazon Redshift doesn't shred the attributes of JSON structures into multiple columns while loading a JSON document.

By default, COPY attempts to match all columns in the target table to JSON field name keys. To load a subset of the columns, you can optionally specify a column list. If the JSON field name keys aren't all lowercase, you can use the 'auto ignorecase' option or a [JSONPaths file](#) to explicitly map column names to JSON field name keys.

If a column in the target table is omitted from the column list, then COPY loads the target column's [DEFAULT](#) expression. If the target column doesn't have a default, COPY attempts to load NULL. If a column is included in the column list and COPY doesn't find a matching field in the JSON data, COPY attempts to load NULL to the column.

If COPY attempts to assign NULL to a column that is defined as NOT NULL, the COPY command fails.

COPY maps the data elements in the JSON source data to the columns in the target table. It does so by matching *object keys*, or names, in the source name-value pairs to the names of columns in the target table.

Refer to the following details about each *json_option* value:

'auto'

With this option, matching is case-sensitive. Column names in Amazon Redshift tables are always lowercase, so when you use the 'auto' option, matching JSON field names must also be lowercase.

'auto ignorecase'

With this option, the matching isn't case-sensitive. Column names in Amazon Redshift tables are always lowercase, so when you use the 'auto ignorecase' option, the corresponding JSON field names can be lowercase, uppercase, or mixed case.

's3://jsonpaths_file'

With this option, COPY uses the named JSONPaths file to map the data elements in the JSON source data to the columns in the target table. The *s3://jsonpaths_file* argument must be an Amazon S3 object key that explicitly references a single file. An example is 's3://amzn-s3-demo-bucket/jsonpaths.txt'. The argument can't be a key prefix. For more information about using a JSONPaths file, see [the section called "JSONPaths file"](#).

In some cases, the file specified by *jsonpaths_file* has the same prefix as the path specified by *copy_from_s3_objectpath* for the data files. If so, COPY reads the JSONPaths file as a data file and returns errors. For example, suppose that your data files use the object path *s3://amzn-s3-demo-bucket/my_data.json* and your JSONPaths file is *s3://amzn-s3-demo-bucket/my_data.jsonpaths*. In this case, COPY attempts to load *my_data.jsonpaths* as a data file.

'noshred'

With this option, Amazon Redshift doesn't shred the attributes of JSON structures into multiple columns while loading a JSON document.

JSON data file

The JSON data file contains a set of either objects or arrays. COPY loads each JSON object or array into one row in the target table. Each object or array corresponding to a row must be a stand-alone, root-level structure; that is, it must not be a member of another JSON structure.

A JSON *object* begins and ends with braces ({ }) and contains an unordered collection of name-value pairs. Each paired name and value are separated by a colon, and the pairs are separated by commas. By default, the *object key*, or name, in the name-value pairs must match the name of the corresponding column in the table. Column names in Amazon Redshift tables are always lowercase, so matching JSON field name keys must also be lowercase. If your column names and JSON keys don't match, use a [the section called "JSONPaths file"](#) to explicitly map columns to keys.

Order in a JSON object doesn't matter. Any names that don't match a column name are ignored. The following shows the structure of a simple JSON object.

```
{
  "column1": "value1",
  "column2": value2,
  "notacolumn" : "ignore this value"
}
```

A JSON *array* begins and ends with brackets ([]), and contains an ordered collection of values separated by commas. If your data files use arrays, you must specify a JSONPaths file to match the values to columns. The following shows the structure of a simple JSON array.

```
["value1", value2]
```

The JSON must be well-formed. For example, the objects or arrays can't be separated by commas or any other characters except white space. Strings must be enclosed in double quotation mark characters. Quote characters must be simple quotation marks (0x22), not slanted or "smart" quotation marks.

The maximum size of a single JSON object or array, including braces or brackets, is 4 MB. This is distinct from the maximum row size. If the maximum size of a single JSON object or array is

exceeded, even if the resulting row size is less than the 4 MB row-size limit, the COPY command fails.

In calculating row size, Amazon Redshift internally counts pipe characters (|) twice. If your input data contains a very large number of pipe characters, it is possible for row size to exceed 4 MB even if the object size is less than 4 MB.

COPY loads `\n` as a newline character and loads `\t` as a tab character. To load a backslash, escape it with a backslash (`\\`).

COPY searches the specified JSON source for a well-formed, valid JSON object or array. If COPY encounters any non-white-space characters before locating a usable JSON structure, or between valid JSON objects or arrays, COPY returns an error for each instance. These errors count toward the MAXERROR error count. When the error count equals or exceeds MAXERROR, COPY fails.

For each error, Amazon Redshift records a row in the STL_LOAD_ERRORS system table. The LINE_NUMBER column records the last line of the JSON object that caused the error.

If IGNOREHEADER is specified, COPY ignores the specified number of lines in the JSON data. Newline characters in the JSON data are always counted for IGNOREHEADER calculations.

COPY loads empty strings as empty fields by default. If EMPTYASNULL is specified, COPY loads empty strings for CHAR and VARCHAR fields as NULL. Empty strings for other data types, such as INT, are always loaded with NULL.

The following options aren't supported with JSON:

- CSV
- DELIMITER
- ESCAPE
- FILLRECORD
- FIXEDWIDTH
- IGNOREBLANKLINES
- NULL AS
- READRATIO
- REMOVEQUOTES

For more information, see [COPY from JSON format](#). For more information about JSON data structures, go to www.json.org.

JSONPaths file

If you are loading from JSON-formatted or Avro source data, by default COPY maps the first-level data elements in the source data to the columns in the target table. It does so by matching each name, or object key, in a name-value pair to the name of a column in the target table.

If your column names and object keys don't match, or to map to deeper levels in the data hierarchy, you can use a JSONPaths file to explicitly map JSON or Avro data elements to columns. The JSONPaths file maps JSON data elements to columns by matching the column order in the target table or column list.

The JSONPaths file must contain only a single JSON object (not an array). The JSON object is a name-value pair. The *object key*, which is the name in the name-value pair, must be "jsonpaths". The *value* in the name-value pair is an array of *JSONPath expressions*. Each JSONPath expression references a single element in the JSON data hierarchy or Avro schema, similarly to how an XPath expression refers to elements in an XML document. For more information, see [JSONPath expressions](#).

To use a JSONPaths file, add the JSON or AVRO keyword to the COPY command. Specify the S3 bucket name and object path of the JSONPaths file using the following format.

```
COPY tablename
FROM 'data_source'
CREDENTIALS 'credentials-args'
FORMAT AS { AVRO | JSON } 's3://jsonpaths_file';
```

The `s3://jsonpaths_file` value must be an Amazon S3 object key that explicitly references a single file, such as `'s3://amzn-s3-demo-bucket/jsonpaths.txt'`. It can't be a key prefix.

In some cases, if you're loading from Amazon S3 the file specified by `jsonpaths_file` has the same prefix as the path specified by `copy_from_s3_objectpath` for the data files. If so, COPY reads the JSONPaths file as a data file and returns errors. For example, suppose that your data files use the object path `s3://amzn-s3-demo-bucket/my_data.json` and your JSONPaths file is `s3://amzn-s3-demo-bucket/my_data.jsonpaths`. In this case, COPY attempts to load `my_data.jsonpaths` as a data file.

If the key name is any string other than "jsonpaths", the COPY command doesn't return an error, but it ignores *jsonpaths_file* and uses the 'auto' argument instead.

If any of the following occurs, the COPY command fails:

- The JSON is malformed.
- There is more than one JSON object.
- Any characters except white space exist outside the object.
- An array element is an empty string or isn't a string.

MAXERROR doesn't apply to the JSONPaths file.

The JSONPaths file must not be encrypted, even if the [ENCRYPTED](#) option is specified.

For more information, see [COPY from JSON format](#).

JSONPath expressions

The JSONPaths file uses JSONPath expressions to map data fields to target columns. Each JSONPath expression corresponds to one column in the Amazon Redshift target table. The order of the JSONPath array elements must match the order of the columns in the target table or the column list, if a column list is used.

The double quotation mark characters are required as shown, both for the field names and the values. The quotation mark characters must be simple quotation marks (0x22), not slanted or "smart" quotation marks.

If an object element referenced by a JSONPath expression isn't found in the JSON data, COPY attempts to load a NULL value. If the referenced object is malformed, COPY returns a load error.

If an array element referenced by a JSONPath expression isn't found in the JSON or Avro data, COPY fails with the following error: `Invalid JSONPath format: Not an array or index out of range`. Remove any array elements from the JSONPaths that don't exist in the source data and verify that the arrays in the source data are well formed.

The JSONPath expressions can use either bracket notation or dot notation, but you can't mix notations. The following example shows JSONPath expressions using bracket notation.

```
{  
  "jsonpaths": [  
    [
```

```
    "$['venuecity']",
    "$['venuestate']",
    "$['venuestate']",
    "$['venuestate']"
  ]
}
```

The following example shows JSONPath expressions using dot notation.

```
{
  "jsonpaths": [
    "$.venuecity",
    "$.venuecity",
    "$.venuestate",
    "$.venuestate"
  ]
}
```

In the context of Amazon Redshift COPY syntax, a JSONPath expression must specify the explicit path to a single name element in a JSON or Avro hierarchical data structure. Amazon Redshift doesn't support any JSONPath elements, such as wildcard characters or filter expressions, that might resolve to an ambiguous path or multiple name elements.

For more information, see [COPY from JSON format](#).

Using JSONPaths with Avro Data

The following example shows an Avro schema with multiple levels.

```
{
  "name": "person",
  "type": "record",
  "fields": [
    {"name": "id", "type": "int"},
    {"name": "guid", "type": "string"},
    {"name": "isActive", "type": "boolean"},
    {"name": "age", "type": "int"},
    {"name": "name", "type": "string"},
    {"name": "address", "type": "string"},
    {"name": "latitude", "type": "double"},
    {"name": "longitude", "type": "double"},
    {
```

```

    "name": "tags",
    "type": {
      "type" : "array",
      "name" : "inner_tags",
      "items" : "string"
    }
  },
  {
    "name": "friends",
    "type": {
      "type" : "array",
      "name" : "inner_friends",
      "items" : {
        "name" : "friends_record",
        "type" : "record",
        "fields" : [
          {"name" : "id", "type" : "int"},
          {"name" : "name", "type" : "string"}
        ]
      }
    }
  },
  {"name": "randomArrayItem", "type": "string"}
]
}

```

The following example shows a JSONPaths file that uses AvroPath expressions to reference the previous schema.

```

{
  "jsonpaths": [
    "$.id",
    "$.guid",
    "$.address",
    "$.friends[0].id"
  ]
}

```

The JSONPaths example includes the following elements:

jsonpaths

The name of the JSON object that contains the AvroPath expressions.

[...]

Brackets enclose the JSON array that contains the path elements.

\$

The dollar sign refers to the root element in the Avro schema, which is the "fields" array.

\$.id",

The target of the AvroPath expression. In this instance, the target is the element in the "fields" array with the name "id". The expressions are separated by commas.

\$.friends[0].id"

Brackets indicate an array index. JSONPath expressions use zero-based indexing, so this expression references the first element in the "friends" array with the name "id".

The Avro schema syntax requires using *inner fields* to define the structure of record and array data types. The inner fields are ignored by the AvroPath expressions. For example, the field "friends" defines an array named "inner_friends", which in turn defines a record named "friends_record". The AvroPath expression to reference the field "id" can ignore the extra fields to reference the target field directly. The following AvroPath expressions reference the two fields that belong to the "friends" array.

```
$.friends[0].id"  
$.friends[0].name"
```

Columnar data format parameters

In addition to the standard data formats, COPY supports the following columnar data formats for COPY from Amazon S3. COPY from columnar format is supported with certain restrictions. For more information, see [COPY from columnar data formats](#).

ORC

Loads the data from a file that uses Optimized Row Columnar (ORC) file format.

PARQUET

Loads the data from a file that uses Parquet file format.

File compression parameters

You can load from compressed data files by specifying the following parameters.

File compression parameters

BZIP2

A value that specifies that the input file or files are in compressed bzip2 format (.bz2 files). The COPY operation reads each compressed file and uncompresses the data as it loads.

GZIP

A value that specifies that the input file or files are in compressed gzip format (.gz files). The COPY operation reads each compressed file and uncompresses the data as it loads.

LZOP

A value that specifies that the input file or files are in compressed lzop format (.lzo files). The COPY operation reads each compressed file and uncompresses the data as it loads.

 **Note**

COPY doesn't support files that are compressed using the lzop *--filter* option.

ZSTD

A value that specifies that the input file or files are in compressed Zstandard format (.zst files). The COPY operation reads each compressed file and uncompresses the data as it loads.

 **Note**

ZSTD is supported only with COPY from Amazon S3.

Data conversion parameters

As it loads the table, COPY attempts to implicitly convert the strings in the source data to the data type of the target column. If you need to specify a conversion that is different from the default behavior, or if the default conversion results in errors, you can manage data conversions by

specifying the following parameters. For more information on the syntax of these parameters, see [COPY syntax](#).

- [ACCEPTANYDATE](#)
- [ACCEPTINVCHARS](#)
- [BLANKSASNULL](#)
- [DATEFORMAT](#)
- [EMPTYASNULL](#)
- [ENCODING](#)
- [ESCAPE](#)
- [EXPLICIT_IDS](#)
- [FILLRECORD](#)
- [IGNOREBLANKLINES](#)
- [IGNOREHEADER](#)
- [NULL AS](#)
- [REMOVEQUOTES](#)
- [ROUNDEC](#)
- [TIMEFORMAT](#)
- [TRIMBLANKS](#)
- [TRUNCATECOLUMNS](#)

Data conversion parameters

ACCEPTANYDATE

Allows any date format, including invalid formats such as `00/00/00 00:00:00`, to be loaded without generating an error. This parameter applies only to `TIMESTAMP` and `DATE` columns. Always use `ACCEPTANYDATE` with the `DATEFORMAT` parameter. If the date format for the data doesn't match the `DATEFORMAT` specification, Amazon Redshift inserts a `NULL` value into that field.

ACCEPTINVCHARS [AS] [*replacement_char*]

Enables loading of data into `VARCHAR` columns even if the data contains invalid UTF-8 characters. When `ACCEPTINVCHARS` is specified, `COPY` replaces each invalid UTF-8 character

with a string of equal length consisting of the character specified by *replacement_char*. For example, if the replacement character is '^', an invalid three-byte character will be replaced with '^'^'^'.

The replacement character can be any ASCII character except NULL. The default is a question mark (?). For information about invalid UTF-8 characters, see [Multibyte character load errors](#).

COPY returns the number of rows that contained invalid UTF-8 characters, and it adds an entry to the [STL_REPLACEMENTS](#) system table for each affected row, up to a maximum of 100 rows for each node slice. Additional invalid UTF-8 characters are also replaced, but those replacement events aren't recorded.

If ACCEPTINVCHARS isn't specified, COPY returns an error whenever it encounters an invalid UTF-8 character.

ACCEPTINVCHARS is valid only for VARCHAR columns.

BLANKSASNULL

Loads blank fields, which consist of only white space characters, as NULL. This option applies only to CHAR and VARCHAR columns. Blank fields for other data types, such as INT, are always loaded with NULL. For example, a string that contains three space characters in succession (and no other characters) is loaded as a NULL. The default behavior, without this option, is to load the space characters as is.

DATEFORMAT [AS] {'dateformat_string' | 'auto' }

If no DATEFORMAT is specified, the default format is 'YYYY-MM-DD'. For example, an alternative valid format is 'MM-DD-YYYY'.

If the COPY command doesn't recognize the format of your date or time values, or if your date or time values use different formats, use the ' auto ' argument with the DATEFORMAT or TIMEFORMAT parameter. The ' auto ' argument recognizes several formats that aren't supported when using a DATEFORMAT and TIMEFORMAT string. The ' auto ' keyword is case-sensitive. For more information, see [Using automatic recognition with DATEFORMAT and TIMEFORMAT](#).

The date format can include time information (hour, minutes, seconds), but this information is ignored. The AS keyword is optional. For more information, see [DATEFORMAT and TIMEFORMAT strings](#).

EMPTYASNULL

Indicates that Amazon Redshift should load empty CHAR and VARCHAR fields as NULL. Empty fields for other data types, such as INT, are always loaded with NULL. Empty fields occur when data contains two delimiters in succession with no characters between the delimiters. EMPTYASNULL and NULL AS "" (empty string) produce the same behavior.

ENCODING [AS] *file_encoding*

Specifies the encoding type of the load data. The COPY command converts the data from the specified encoding into UTF-8 during loading.

Valid values for *file_encoding* are as follows:

- UTF8
- UTF16
- UTF16LE
- UTF16BE
- ISO88591

The default is UTF8.

Source file names must use UTF-8 encoding.

The following files must use UTF-8 encoding, even if a different encoding is specified for the load data:

- Manifest files
- JSONPaths files

The argument strings provided with the following parameters must use UTF-8:

- FIXEDWIDTH '*fixedwidth_spec*'
- ACCEPTINVCHARS '*replacement_char*'
- DATEFORMAT '*dateformat_string*'
- TIMEFORMAT '*timeformat_string*'
- NULL AS '*null_string*'

Fixed-width data files must use UTF-8 encoding. The field widths are based on the number of characters, not the number of bytes.

All load data must use the specified encoding. If COPY encounters a different encoding, it skips the file and returns an error.

If you specify UTF16, then your data must have a byte order mark (BOM). If you know whether your UTF-16 data is little-endian (LE) or big-endian (BE), you can use UTF16LE or UTF16BE, regardless of the presence of a BOM.

To use ISO-8859-1 encoding specify ISO88591. For more information, see [ISO/IEC 8859-1](#) in *Wikipedia*.

ESCAPE

When this parameter is specified, the backslash character (\) in input data is treated as an escape character. The character that immediately follows the backslash character is loaded into the table as part of the current column value, even if it is a character that normally serves a special purpose. For example, you can use this parameter to escape the delimiter character, a quotation mark, an embedded newline character, or the escape character itself when any of these characters is a legitimate part of a column value.

If you specify the ESCAPE parameter in combination with the REMOVEQUOTES parameter, you can escape and retain quotation marks (' or ") that might otherwise be removed. The default null string, \N, works as is, but it can also be escaped in the input data as \\N. As long as you don't specify an alternative null string with the NULL AS parameter, \N and \\N produce the same results.

Note

The control character 0x00 (NUL) can't be escaped and should be removed from the input data or converted. This character is treated as an end of record (EOR) marker, causing the remainder of the record to be truncated.

You can't use the ESCAPE parameter for FIXEDWIDTH loads, and you can't specify the escape character itself; the escape character is always the backslash character. Also, you must ensure that the input data contains the escape character in the appropriate places.

Here are some examples of input data and the resulting loaded data when the ESCAPE parameter is specified. The result for row 4 assumes that the REMOVEQUOTES parameter is also specified. The input data consists of two pipe-delimited fields:

```
1|The quick brown fox\[newline]
jumped over the lazy dog.
2| A\\B\\C
3| A \| B \| C
4| 'A Midsummer Night\'s Dream'
```

The data loaded into column 2 looks like this:

```
The quick brown fox
jumped over the lazy dog.
A\B\C
A|B|C
A Midsummer Night's Dream
```

 **Note**

Applying the escape character to the input data for a load is the responsibility of the user. One exception to this requirement is when you reload data that was previously unloaded with the ESCAPE parameter. In this case, the data will already contain the necessary escape characters.

The ESCAPE parameter doesn't interpret octal, hex, Unicode, or other escape sequence notation. For example, if your source data contains the octal line feed value (`\012`) and you try to load this data with the ESCAPE parameter, Amazon Redshift loads the value `012` into the table and doesn't interpret this value as a line feed that is being escaped.

In order to escape newline characters in data that originates from Microsoft Windows platforms, you might need to use two escape characters: one for the carriage return and one for the line feed. Alternatively, you can remove the carriage returns before loading the file (for example, by using the `dos2unix` utility).

EXPLICIT_IDS

Use EXPLICIT_IDS with tables that have IDENTITY columns if you want to override the autogenerated values with explicit values from the source data files for the tables. If the command includes a column list, that list must include the IDENTITY columns to use this parameter. The data format for EXPLICIT_IDS values must match the IDENTITY format specified by the CREATE TABLE definition.

When you run a COPY command against a table with the EXPLICIT_IDS option, Amazon Redshift does not check the uniqueness of IDENTITY columns in the table.

If a column is defined with GENERATED BY DEFAULT AS IDENTITY, then it can be copied. Values are generated or updated with values that you supply. The EXPLICIT_IDS option isn't required. COPY doesn't update the identity high watermark.

For an example of a COPY command using EXPLICIT_IDS, see [Load VENUE with explicit values for an IDENTITY column](#).

FILLRECORD

Allows data files to be loaded when contiguous columns are missing at the end of some of the records. The missing columns are loaded as NULLs. For text and CSV formats, if the missing column is a VARCHAR column, zero-length strings are loaded instead of NULLs. To load NULLs to VARCHAR columns from text and CSV, specify the EMPTYASNULL keyword. NULL substitution only works if the column definition allows NULLs.

For example, if the table definition contains four nullable CHAR columns, and a record contains the values apple, orange, banana, mango, the COPY command could load and fill in a record that contains only the values apple, orange. The missing CHAR values would be loaded as NULL values.

IGNOREBLANKLINES

Ignores blank lines that only contain a line feed in a data file and does not try to load them.

IGNOREHEADER [AS] *number_rows*

Treats the specified *number_rows* as a file header and doesn't load them. Use IGNOREHEADER to skip file headers in all files in a parallel load.

NULL AS '*null_string*'

Loads fields that match *null_string* as NULL, where *null_string* can be any string. If your data includes a null terminator, also referred to as NUL (UTF-8 0000) or binary zero (0x000), COPY treats it as any other character. For example, a record containing '1' || NUL || '2' is copied as string of length 3 bytes. If a field contains only NUL, you can use NULL AS to replace the null terminator with NULL by specifying '\0' or '\000'—for example, NULL AS '\0' or NULL AS '\000'. If a field contains a string that ends with NUL and NULL AS is specified, the string is inserted with NUL at the end. Do not use '\n' (newline) for the *null_string* value. Amazon Redshift reserves '\n' for use as a line delimiter. The default *null_string* is '\N'.

Note

If you attempt to load nulls into a column defined as NOT NULL, the COPY command will fail.

REMOVEQUOTES

Removes surrounding quotation marks from strings in the incoming data. All characters within the quotation marks, including delimiters, are retained. If a string has a beginning single or double quotation mark but no corresponding ending mark, the COPY command fails to load that row and returns an error. The following table shows some simple examples of strings that contain quotation marks and the resulting loaded values.

Input String	Loaded Value with REMOVEQUOTES Option
"The delimiter is a pipe () character"	The delimiter is a pipe () character
'Black'	Black
"White"	White
Blue'	Blue'
'Blue	<i>Value not loaded: error condition</i>
"Blue	<i>Value not loaded: error condition</i>
''Black''	'Black'
''	<white space>

ROUNDEC

Rounds up numeric values when the scale of the input value is greater than the scale of the column. By default, COPY truncates values when necessary to fit the scale of the column. For example, if a value of 20.259 is loaded into a DECIMAL(8,2) column, COPY truncates the value to 20.25 by default. If ROUNDEC is specified, COPY rounds the value to 20.26. The

INSERT command always rounds values when necessary to match the column's scale, so a COPY command with the ROUNDDEC parameter behaves the same as an INSERT command.

TIMEFORMAT [AS] {'*timeformat_string*' | 'auto' | 'epochsecs' | 'epochmillisecs' }

Specifies the time format. If no TIMEFORMAT is specified, the default format is YYYY-MM-DD HH:MI:SS for TIMESTAMP columns or YYYY-MM-DD HH:MI:SSOF for TIMESTAMPTZ columns, where OF is the offset from Coordinated Universal Time (UTC). You can't include a time zone specifier in the *timeformat_string*. To load TIMESTAMPTZ data that is in a format different from the default format, specify 'auto'; for more information, see [Using automatic recognition with DATEFORMAT and TIMEFORMAT](#). For more information about *timeformat_string*, see [DATEFORMAT and TIMEFORMAT strings](#).

The 'auto' argument recognizes several formats that aren't supported when using a DATEFORMAT and TIMEFORMAT string. If the COPY command doesn't recognize the format of your date or time values, or if your date and time values use formats different from each other, use the 'auto' argument with the DATEFORMAT or TIMEFORMAT parameter. For more information, see [Using automatic recognition with DATEFORMAT and TIMEFORMAT](#).

If your source data is represented as epoch time, that is the number of seconds or milliseconds since January 1, 1970, 00:00:00 UTC, specify 'epochsecs' or 'epochmillisecs'.

The 'auto', 'epochsecs', and 'epochmillisecs' keywords are case-sensitive.

The AS keyword is optional.

TRIMBLANKS

Removes the trailing white space characters from a VARCHAR string. This parameter applies only to columns with a VARCHAR data type.

TRUNCATECOLUMNS

Truncates data in columns to the appropriate number of characters so that it fits the column specification. Applies only to columns with a VARCHAR or CHAR data type, and rows 4 MB or less in size.

Data load operations

Manage the default behavior of the load operation for troubleshooting or to reduce load times by specifying the following parameters.

- [COMPROWS](#)
- [COMPUPDATE](#)
- [IGNOREALLERRORS](#)
- [MAXERROR](#)
- [NOLOAD](#)
- [STATUPDATE](#)

Parameters

COMPROWS *numrows*

Specifies the number of rows to be used as the sample size for compression analysis. The analysis is run on rows from each data slice. For example, if you specify `COMPROWS 1000000` (1,000,000) and the system contains four total slices, no more than 250,000 rows for each slice are read and analyzed.

If `COMPROWS` isn't specified, the sample size defaults to 100,000 for each slice. Values of `COMPROWS` lower than the default of 100,000 rows for each slice are automatically upgraded to the default value. However, automatic compression will not take place if the amount of data being loaded is insufficient to produce a meaningful sample.

If the `COMPROWS` number is greater than the number of rows in the input file, the `COPY` command still proceeds and runs the compression analysis on all of the available rows. The accepted range for this argument is a number between 1000 and 2147483647 (2,147,483,647).

COMPUPDATE [PRESET | { ON | TRUE } | { OFF | FALSE }],

Controls whether compression encodings are automatically applied during a `COPY`.

When `COMPUPDATE` is `PRESET`, the `COPY` command chooses the compression encoding for each column if the target table is empty; even if the columns already have encodings other than `RAW`. Currently specified column encodings can be replaced. Encoding for each column is based on the column data type. No data is sampled. Amazon Redshift automatically assigns compression encoding as follows:

- Columns that are defined as sort keys are assigned `RAW` compression.
- Columns that are defined as `BOOLEAN`, `REAL`, or `DOUBLE PRECISION` data types are assigned `RAW` compression.

- Columns that are defined as SMALLINT, INTEGER, BIGINT, DECIMAL, DATE, TIMESTAMP, or TIMESTAMPTZ are assigned AZ64 compression.
- Columns that are defined as CHAR or VARCHAR are assigned LZO compression.

When COMPUPDATE is omitted, the COPY command chooses the compression encoding for each column only if the target table is empty and you have not specified an encoding (other than RAW) for any of the columns. The encoding for each column is determined by Amazon Redshift. No data is sampled.

When COMPUPDATE is ON (or TRUE), or COMPUPDATE is specified without an option, the COPY command applies automatic compression if the table is empty; even if the table columns already have encodings other than RAW. Currently specified column encodings can be replaced. Encoding for each column is based on an analysis of sample data. For more information, see [Loading tables with automatic compression](#).

When COMPUPDATE is OFF (or FALSE), automatic compression is disabled. Column encodings aren't changed.

For information about the system table to analyze compression, see [STL_ANALYZE_COMPRESSION](#).

IGNOREALLERRORS

You can specify this option to ignore all errors that occur during the load operation.

You can't specify the IGNOREALLERRORS option if you specify the MAXERROR option. You can't specify the IGNOREALLERRORS option for columnar formats including ORC and Parquet.

MAXERROR [AS] *error_count*

If the load returns the *error_count* number of errors or greater, the load fails. If the load returns fewer errors, it continues and returns an INFO message that states the number of rows that could not be loaded. Use this parameter to allow loads to continue when certain rows fail to load into the table because of formatting errors or other inconsistencies in the data.

Set this value to 0 or 1 if you want the load to fail as soon as the first error occurs. The AS keyword is optional. The MAXERROR default value is 0 and the limit is 100000.

The actual number of errors reported might be greater than the specified MAXERROR because of the parallel nature of Amazon Redshift. If any node in the Amazon Redshift cluster detects that MAXERROR has been exceeded, each node reports all of the errors it has encountered.

NOLOAD

Checks the validity of the data file without actually loading the data. Use the NOLOAD parameter to make sure that your data file loads without any errors before running the actual data load. Running COPY with the NOLOAD parameter is much faster than loading the data because it only parses the files.

STATUPDATE [{ ON | TRUE } | { OFF | FALSE }]

Governs automatic computation and refresh of optimizer statistics at the end of a successful COPY command. By default, if the STATUPDATE parameter isn't used, statistics are updated automatically if the table is initially empty.

Whenever ingesting data into a nonempty table significantly changes the size of the table, we recommend updating statistics either by running an [ANALYZE](#) command or by using the STATUPDATE ON argument.

With STATUPDATE ON (or TRUE), statistics are updated automatically regardless of whether the table is initially empty. If STATUPDATE is used, the current user must be either the table owner or a superuser. If STATUPDATE is not specified, only INSERT permission is required.

With STATUPDATE OFF (or FALSE), statistics are never updated.

For additional information, see [Analyzing tables](#).

Alphabetical parameter list

The following list provides links to each COPY command parameter description, sorted alphabetically.

- [ACCEPTANYDATE](#)

Permissions to access other AWS Resources

To move data between your cluster and another AWS resource, such as Amazon S3, Amazon DynamoDB, Amazon EMR, or Amazon EC2, your cluster must have permission to access the resource and perform the necessary actions. For example, to load data from Amazon S3, COPY must have LIST access to the bucket and GET access for the bucket objects. For information about minimum permissions, see [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#).

To get authorization to access the resource, your cluster must be authenticated. You can choose either of the following authentication methods:

- [Role-based access control](#) – For role-based access control, you specify an AWS Identity and Access Management (IAM) role that your cluster uses for authentication and authorization. To safeguard your AWS credentials and sensitive data, we strongly recommend using role-based authentication.
- [Key-based access control](#) – For key-based access control, you provide the AWS access credentials (access key ID and secret access key) for a user as plain text.

Role-based access control

With role-based access control, your cluster temporarily assumes an IAM role on your behalf. Then, based on the authorizations granted to the role, your cluster can access the required AWS resources.

Creating an IAM *role* is similar to granting permissions to a user, in that it is an AWS identity with permissions policies that determine what the identity can and can't do in AWS. However, instead of being uniquely associated with one user, a role can be assumed by any entity that needs it. Also, a role doesn't have any credentials (a password or access keys) associated with it. Instead, if a role is associated with a cluster, access keys are created dynamically and provided to the cluster.

We recommend using role-based access control because it provides more secure, fine-grained control of access to AWS resources and sensitive user data, in addition to safeguarding your AWS credentials.

Role-based authentication delivers the following benefits:

- You can use AWS standard IAM tools to define an IAM role and associate the role with multiple clusters. When you modify the access policy for a role, the changes are applied automatically to all clusters that use the role.
- You can define fine-grained IAM policies that grant permissions for specific clusters and database users to access specific AWS resources and actions.
- Your cluster obtains temporary session credentials at run time and refreshes the credentials as needed until the operation completes. If you use key-based temporary credentials, the operation fails if the temporary credentials expire before it completes.
- Your access key ID and secret access key ID aren't stored or transmitted in your SQL code.

To use role-based access control, you must first create an IAM role using the Amazon Redshift service role type, and then attach the role to your cluster. The role must have, at a minimum, the

permissions listed in [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#). For steps to create an IAM role and attach it to your cluster, see [Authorizing Amazon Redshift to Access Other AWS Services On Your Behalf](#) in the *Amazon Redshift Management Guide*.

You can add a role to a cluster or view the roles associated with a cluster by using the Amazon Redshift Management Console, CLI, or API. For more information, see [Associating an IAM Role With a Cluster](#) in the *Amazon Redshift Management Guide*.

When you create an IAM role, IAM returns an Amazon Resource Name (ARN) for the role. To specify an IAM role, provide the role ARN with either the [IAM_ROLE](#) parameter or the [CREDENTIALS](#) parameter.

For example, suppose the following role is attached to the cluster.

```
"IamRoleArn": "arn:aws:iam::0123456789012:role/MyRedshiftRole"
```

The following COPY command example uses the `IAM_ROLE` parameter with the ARN in the previous example for authentication and access to Amazon S3.

```
copy customer from 's3://amzn-s3-demo-bucket/mydata'  
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

The following COPY command example uses the `CREDENTIALS` parameter to specify the IAM role.

```
copy customer from 's3://amzn-s3-demo-bucket/mydata'  
credentials  
'aws_iam_role=arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

In addition, a superuser can grant the `ASSUMEROLE` privilege to database users and groups to provide access to a role for COPY operations. For information, see [GRANT](#).

Key-based access control

With key-based access control, you provide the access key ID and secret access key for an IAM user that is authorized to access the AWS resources that contain the data. You can use either the [ACCESS_KEY_ID](#) and [SECRET_ACCESS_KEY](#) parameters together or the [CREDENTIALS](#) parameter.

Note

We strongly recommend using an IAM role for authentication instead of supplying a plain-text access key ID and secret access key. If you choose key-based access control, never use

your AWS account (root) credentials. Always create an IAM user and provide that user's access key ID and secret access key. For steps to create an IAM user, see [Creating an IAM User in Your AWS Account](#).

To authenticate using ACCESS_KEY_ID and SECRET_ACCESS_KEY, replace *<access-key-id>* and *<secret-access-key>* with an authorized user's access key ID and full secret access key as shown following.

```
ACCESS_KEY_ID '<access-key-id>'  
SECRET_ACCESS_KEY '<secret-access-key>';
```

To authenticate using the CREDENTIALS parameter, replace *<access-key-id>* and *<secret-access-key>* with an authorized user's access key ID and full secret access key as shown following.

```
CREDENTIALS  
'aws_access_key_id=<access-key-id>;aws_secret_access_key=<secret-access-key>';
```

The IAM user must have, at a minimum, the permissions listed in [IAM permissions for COPY, UNLOAD, and CREATE LIBRARY](#).

Temporary security credentials

If you are using key-based access control, you can further limit the access users have to your data by using temporary security credentials. Role-based authentication automatically uses temporary credentials.

Note

We strongly recommend using [role-based access control](#) instead of creating temporary credentials and providing access key ID and secret access key as plain text. Role-based access control automatically uses temporary credentials.

Temporary security credentials provide enhanced security because they have short lifespans and can't be reused after they expire. The access key ID and secret access key generated with the token can't be used without the token, and a user who has these temporary security credentials can access your resources only until the credentials expire.

To grant users temporary access to your resources, you call AWS Security Token Service (AWS STS) API operations. The AWS STS API operations return temporary security credentials consisting of a security token, an access key ID, and a secret access key. You issue the temporary security credentials to the users who need temporary access to your resources. These users can be existing IAM users, or they can be non-AWS users. For more information about creating temporary security credentials, see [Using Temporary Security Credentials](#) in the IAM User Guide.

You can use either the [ACCESS_KEY_ID](#) and [SECRET_ACCESS_KEY](#) parameters together with the [SESSION_TOKEN](#) parameter or the [CREDENTIALS](#) parameter. You must also supply the access key ID and secret access key that were provided with the token.

To authenticate using `ACCESS_KEY_ID`, `SECRET_ACCESS_KEY`, and `SESSION_TOKEN`, replace `<temporary-access-key-id>`, `<temporary-secret-access-key>`, and `<temporary-token>` as shown following.

```
ACCESS_KEY_ID '<temporary-access-key-id>'  
SECRET_ACCESS_KEY '<temporary-secret-access-key>'  
SESSION_TOKEN '<temporary-token>';
```

To authenticate using `CREDENTIALS`, include `session_token=<temporary-token>` in the credentials string as shown following.

```
CREDENTIALS  
'aws_access_key_id=<temporary-access-key-id>;aws_secret_access_key=<temporary-secret-access-key>;session_token=<temporary-token>';
```

The following example shows a `COPY` command with temporary security credentials.

```
copy table-name  
from 's3://objectpath'  
access_key_id '<temporary-access-key-id>'  
secret_access_key '<temporary-secret-access-key>'  
session_token '<temporary-token>';
```

The following example loads the `LISTING` table with temporary credentials and file encryption.

```
copy listing  
from 's3://amzn-s3-demo-bucket/data/listings_pipe.txt'  
access_key_id '<temporary-access-key-id>'
```

```
secret_access_key '<temporary-secret-access-key>'
session_token '<temporary-token>'
master_symmetric_key '<root-key>'
encrypted;
```

The following example loads the LISTING table using the CREDENTIALS parameter with temporary credentials and file encryption.

```
copy listing
from 's3://amzn-s3-demo-bucket/data/listings_pipe.txt'
credentials
'aws_access_key_id=<temporary-access-key-id>;aws_secret_access_key=<temporary-secret-
access-key>;session_token=<temporary-token>;master_symmetric_key=<root-key>'
encrypted;
```

Important

The temporary security credentials must be valid for the entire duration of the COPY or UNLOAD operation. If the temporary security credentials expire during the operation, the command fails and the transaction is rolled back. For example, if temporary security credentials expire after 15 minutes and the COPY operation requires one hour, the COPY operation fails before it completes. If you use role-based access, the temporary security credentials are automatically refreshed until the operation completes.

IAM permissions for COPY, UNLOAD, and CREATE LIBRARY

The IAM role or user referenced by the CREDENTIALS parameter must have, at a minimum, the following permissions:

- For COPY from Amazon S3, permission to LIST the Amazon S3 bucket and GET the Amazon S3 objects that are being loaded, and the manifest file, if one is used.
- For COPY from Amazon S3, Amazon EMR, and remote hosts (SSH) with JSON-formatted data, permission to LIST and GET the JSONPaths file on Amazon S3, if one is used.
- For COPY from DynamoDB, permission to SCAN and DESCRIBE the DynamoDB table that is being loaded.
- For COPY from an Amazon EMR cluster, permission for the ListInstances action on the Amazon EMR cluster.

- For UNLOAD to Amazon S3, GET, LIST, and PUT permissions for the Amazon S3 bucket to which the data files are being unloaded.
- For CREATE LIBRARY from Amazon S3, permission to LIST the Amazon S3 bucket and GET the Amazon S3 objects being imported.

Note

If you receive the error message `S3ServiceException: Access Denied`, when running a COPY, UNLOAD, or CREATE LIBRARY command, your cluster doesn't have proper access permissions for Amazon S3.

You can manage IAM permissions by attaching an IAM policy to an IAM role that is attached to your cluster, to a user, or to the group to which your user belongs. For example, the `AmazonS3ReadOnlyAccess` managed policy grants LIST and GET permissions to Amazon S3 resources. For more information about IAM policies, see [Managing IAM Policies](#) in the *IAM User Guide*.

Using COPY with Amazon S3 access point aliases

COPY supports Amazon S3 access point aliases. For more information, see [Using a bucket-style alias for your access point](#) in the *Amazon Simple Storage Service User Guide*.

Loading multibyte data from Amazon S3

If your data includes non-ASCII multibyte characters (such as Chinese or Cyrillic characters), you must load the data to VARCHAR columns. The VARCHAR data type supports four-byte UTF-8 characters, but the CHAR data type only accepts single-byte ASCII characters. You can't load five-byte or longer characters into Amazon Redshift tables. For more information, see [Multibyte characters](#).

Loading a column of the GEOMETRY or GEOGRAPHY data type

You can COPY to GEOMETRY or GEOGRAPHY columns from data in a character-delimited text file, such as a CSV file. The data must be in the hexadecimal form of the well-known binary format (either WKB or EWKB) or the well-known text format (either WKT or EWKT) and fit within the maximum size of a single input row to the COPY command. For more information, see [COPY](#).

For information about how to load from a shapefile, see [Loading a shapefile into Amazon Redshift](#).

For more information about the GEOMETRY or GEOGRAPHY data type, see [Querying spatial data in Amazon Redshift](#).

Loading the HLLSKETCH data type

You can copy HLL sketches only in sparse or dense format supported by Amazon Redshift. To use the COPY command on HyperLogLog sketches, use the Base64 format for dense HyperLogLog sketches and the JSON format for sparse HyperLogLog sketches. For more information, see [HyperLogLog functions](#).

The following example imports data from a CSV file into a table using CREATE TABLE and COPY. First, the example creates the table t1 using CREATE TABLE.

```
CREATE TABLE t1 (sketch hllsketch, a bigint);
```

Then it uses COPY to import data from a CSV file into the table t1.

```
COPY t1 FROM s3://amzn-s3-demo-bucket/unload/' IAM_ROLE  
'arn:aws:iam::0123456789012:role/MyRedshiftRole' NULL AS 'null' CSV;
```

Loading a column of the VARBYTE data type

You can load data from a file in CSV, Parquet, and ORC format. For CSV, the data is loaded from a file in hexadecimal representation of the VARBYTE data. You can't load VARBYTE data with the FIXEDWIDTH option. The ADDQUOTES or REMOVEQUOTES option of COPY is not supported. A VARBYTE column can't be used as a partition column.

Errors when reading multiple files

The COPY command is atomic and transactional. In other words, even when the COPY command reads data from multiple files, the entire process is treated as a single transaction. If COPY encounters an error reading a file, it automatically retries until the process times out (see [statement_timeout](#)) or if data can't be download from Amazon S3 for a prolonged period of time (between 15 and 30 minutes), ensuring that each file is loaded only once. If the COPY command fails, the entire transaction is canceled and all changes are rolled back. For more information about handling load errors, see [Troubleshooting data loads](#).

After a COPY command is successfully initiated, it doesn't fail if the session terminates, for example when the client disconnects. However, if the COPY command is within a BEGIN ... END transaction

block that doesn't complete because the session terminates, the entire transaction, including the COPY, is rolled back. For more information about transactions, see [BEGIN](#).

COPY from JSON format

The JSON data structure is made up of a set of objects or arrays. A JSON *object* begins and ends with braces, and contains an unordered collection of name-value pairs. Each name and value are separated by a colon, and the pairs are separated by commas. The name is a string in double quotation marks. The quotation mark characters must be simple quotation marks (0x22), not slanted or "smart" quotation marks.

A JSON *array* begins and ends with brackets, and contains an ordered collection of values separated by commas. A value can be a string in double quotation marks, a number, a Boolean true or false, null, a JSON object, or an array.

JSON objects and arrays can be nested, enabling a hierarchical data structure. The following example shows a JSON data structure with two valid objects.

```
{
  "id": 1006410,
  "title": "Amazon Redshift Database Developer Guide"
}
{
  "id": 100540,
  "name": "Amazon Simple Storage Service User Guide"
}
```

The following shows the same data as two JSON arrays.

```
[
  1006410,
  "Amazon Redshift Database Developer Guide"
]
[
  100540,
  "Amazon Simple Storage Service User Guide"
]
```

COPY options for JSON

You can specify the following options when using COPY with JSON format data:

- 'auto' – COPY automatically loads fields from the JSON file.
- 'auto ignorecase' – COPY automatically loads fields from the JSON file while ignoring the case of field names.
- `s3://jsonpaths_file` – COPY uses a JSONPaths file to parse the JSON source data. A *JSONPaths file* is a text file that contains a single JSON object with the name "jsonpaths" paired with an array of JSONPath expressions. If the name is any string other than "jsonpaths", COPY uses the 'auto' argument instead of using the JSONPaths file.

For examples that show how to load data using 'auto', 'auto ignorecase', or a JSONPaths file, and using either JSON objects or arrays, see [Copy from JSON examples](#).

JSONPath option

In the Amazon Redshift COPY syntax, a JSONPath expression specifies the explicit path to a single name element in a JSON hierarchical data structure, using either bracket notation or dot notation. Amazon Redshift doesn't support any JSONPath elements, such as wildcard characters or filter expressions, that might resolve to an ambiguous path or multiple name elements. As a result, Amazon Redshift can't parse complex, multi-level data structures.

The following is an example of a JSONPaths file with JSONPath expressions using bracket notation. The dollar sign (\$) represents the root-level structure.

```
{
  "jsonpaths": [
    "$['id']",
    "$['store']['book']['title']",
    "$['location'][0]"
  ]
}
```

In the previous example, `$['location'][0]` references the first element in an array. JSON uses zero-based array indexing. Array indexes must be positive integers (greater than or equal to zero).

The following example shows the previous JSONPaths file using dot notation.

```
{
  "jsonpaths": [
    "$.id",
    "$.store.book.title",
  ]
}
```

```
    "$.location[0]"  
  ]  
}
```

You can't mix bracket notation and dot notation in the `jsonpaths` array. Brackets can be used in both bracket notation and dot notation to reference an array element.

When using dot notation, the JSONPath expressions can't contain the following characters:

- Single straight quotation mark (')
- Period, or dot (.)
- Brackets ([]) unless used to reference an array element

If the value in the name-value pair referenced by a JSONPath expression is an object or an array, the entire object or array is loaded as a string, including the braces or brackets. For example, suppose that your JSON data contains the following object.

```
{  
  "id": 0,  
  "guid": "84512477-fa49-456b-b407-581d0d851c3c",  
  "isActive": true,  
  "tags": [  
    "nisi",  
    "culpa",  
    "ad",  
    "amet",  
    "voluptate",  
    "reprehenderit",  
    "veniam"  
  ],  
  "friends": [  
    {  
      "id": 0,  
      "name": "Martha Rivera"  
    },  
    {  
      "id": 1,  
      "name": "Renaldo"  
    }  
  ]  
}
```

The JSONPath expression `['tags']` then returns the following value.

```
"["nisi","culpa","ad","amet","voluptate","reprehenderit","veniam"]"
```

The JSONPath expression `['friends'][1]` then returns the following value.

```
"{"id": 1,"name": "Renaldo}"
```

Each JSONPath expression in the `jsonpaths` array corresponds to one column in the Amazon Redshift target table. The order of the `jsonpaths` array elements must match the order of the columns in the target table or the column list, if a column list is used.

For examples that show how to load data using either the `'auto'` argument or a JSONPaths file, and using either JSON objects or arrays, see [Copy from JSON examples](#).

For information on how to copy multiple JSON files, see [Using a manifest to specify data files](#).

Escape characters in JSON

COPY loads `\n` as a newline character and loads `\t` as a tab character. To load a backslash, escape it with a backslash (`\\`).

For example, suppose you have the following JSON in a file named `escape.json` in the bucket `s3://amzn-s3-demo-bucket/json/`.

```
{
  "backslash": "This is a backslash: \\",
  "newline": "This sentence\n is on two lines.",
  "tab": "This sentence \t contains a tab."
}
```

Run the following commands to create the `ESCAPES` table and load the JSON.

```
create table escapes (backslash varchar(25), newline varchar(35), tab varchar(35));

copy escapes from 's3://amzn-s3-demo-bucket/json/escape.json'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
format as json 'auto';
```

Query the `ESCAPES` table to view the results.

```
select * from escapes;

      backslash      |      newline      |      tab
-----+-----+-----
This is a backslash: \ | This sentence      | This sentence      contains a tab.
                        : is on two lines.
```

(1 row)

Loss of numeric precision

You might lose precision when loading numbers from data files in JSON format to a column that is defined as a numeric data type. Some floating point values aren't represented exactly in computer systems. As a result, data you copy from a JSON file might not be rounded as you expect. To avoid a loss of precision, we recommend using one of the following alternatives:

- Represent the number as a string by enclosing the value in double quotation characters.
- Use [ROUNDEC](#) to round the number instead of truncating.
- Instead of using JSON or Avro files, use CSV, character-delimited, or fixed-width text files.

COPY from columnar data formats

COPY can load data from Amazon S3 in the following columnar formats:

- ORC
- Parquet

For examples of using COPY from columnar data formats, see [COPY examples](#).

COPY supports columnar formatted data with the following considerations:

- The Amazon S3 bucket must be in the same AWS Region as the Amazon Redshift database.
- To access your Amazon S3 data through a VPC endpoint, set up access using IAM policies and IAM roles as described in [Using Amazon Redshift Spectrum with Enhanced VPC Routing](#) in the *Amazon Redshift Management Guide*.
- COPY doesn't automatically apply compression encodings.
- Only the following COPY parameters are supported:
 - [ACCEPTINVCHARS](#) when copying from an ORC or Parquet file.

- [FILLRECORD](#)
- [FROM](#)
- [IAM_ROLE](#)
- [CREDENTIALS](#)
- [STATUPDATE](#)
- [MANIFEST](#)
- [EXPLICIT_IDS](#)
- If COPY encounters an error while loading, the command fails. ACCEPTANYDATE and MAXERROR aren't supported for columnar data types.
- Error messages are sent to the SQL client. Some errors are logged in STL_LOAD_ERRORS and STL_ERROR.
- COPY inserts values into the target table's columns in the same order as the columns occur in the columnar data files. The number of columns in the target table and the number of columns in the data file must match.
- If the file you specify for the COPY operation includes one of the following extensions, we decompress the data without the need for adding any parameters:
 - .gz
 - .snappy
 - .bz2
- COPY from the Parquet and ORC file formats uses Redshift Spectrum and the bucket access. To use COPY for these formats, be sure there are no IAM policies blocking the use of Amazon S3 presigned URLs. The presigned URLs generated by Amazon Redshift are valid for 1 hour so that Amazon Redshift has enough time to load all the files from the Amazon S3 bucket. A unique presigned URL is generated for each file scanned by COPY from columnar data formats. For bucket policies that include an `s3:signatureAge` action, make sure to set the value to at least 3,600,000 milliseconds. For more information, see [Using Amazon Redshift Spectrum with enhanced VPC routing](#).

DATEFORMAT and TIMEFORMAT strings

The COPY command uses the DATEFORMAT and TIMEFORMAT options to parse date and time values in your source data. DATEFORMAT and TIMEFORMAT are formatted strings that must match the format of your source data's date and time values. For example, a COPY command loading source data with the date value `Jan-01-1999` must include the following DATEFORMAT string:

```
COPY ...
    DATEFORMAT AS 'MON-DD-YYYY'
```

For more information on managing COPY data conversions, see [Data conversion parameters](#).

DATEFORMAT and TIMEFORMAT strings can contain datetime separators (such as '-', '/', or ':'), as well the datepart and timepart formats in the following table.

Note

If you can't match the format of your date or time values with the following dateparts and timeparts, or if you have date and time values that use formats different from each other, use the 'auto' argument with the DATEFORMAT or TIMEFORMAT parameter. The 'auto' argument recognizes several formats that aren't supported when using a DATEFORMAT or TIMEFORMAT string. For more information, see [Using automatic recognition with DATEFORMAT and TIMEFORMAT](#).

Datepart or timepart	Meaning
YY	Year without century
YYYY	Year with century
MM	Month as a number
MON	Month as a name (abbreviated name or full name)
DD	Day of month as a number
HH or HH24	Hour (24-hour clock)

 **Note**

In DATETIME format strings for SQL functions, HH is the same as HH12. However, in DATEFORMAT and

Datepart or timepart	Meaning
	TIMEFORMAT strings for COPY, HH is the same as HH24.
HH12	Hour (12-hour clock)
MI	Minutes
SS	Seconds
AM or PM	Meridian indicator (for 12-hour clock)

The default date format is YYYY-MM-DD. The default timestamp without time zone (TIMESTAMP) format is YYYY-MM-DD HH:MI:SS. The default timestamp with time zone (TIMESTAMPTZ) format is YYYY-MM-DD HH:MI:SSOF, where OF is the offset from UTC (for example, -8:00. You can't include a time zone specifier (TZ, tz, or OF) in the timeformat_string. The seconds (SS) field also supports fractional seconds up to a microsecond level of detail. To load TIMESTAMPTZ data that is in a format different from the default format, specify 'auto'.

Following are some sample dates or times you can encounter in your source data, and the corresponding DATEFORMAT or TIMEFORMAT strings for them.

Example of source data date or time	DATEFORMAT or TIMEFORMAT Syntax
03/31/2003	DATEFORMAT AS 'MM/DD/YY YY'
March 31, 2003	DATEFORMAT AS 'MON DD, YYYY'
03.31.2003 18:45:05	TIMEFORMAT AS 'MM.DD.YY YY HH:MI:SS'
03.31.2003 18:45:05.123456	

Example

For an example of using TIMEFORMAT, see [Load a timestamp or datestamp](#).

Using automatic recognition with DATEFORMAT and TIMEFORMAT

If you specify 'auto' as the argument for the DATEFORMAT or TIMEFORMAT parameter, Amazon Redshift will automatically recognize and convert the date format or time format in your source data. The following shows an example.

```
copy favoritemovies from 'dynamodb://ProductCatalog'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
dateformat 'auto';
```

When used with the 'auto' argument for DATEFORMAT and TIMEFORMAT, COPY recognizes and converts the date and time formats listed in the table in [DATEFORMAT and TIMEFORMAT strings](#). In addition, the 'auto' argument recognizes the following formats that aren't supported when using a DATEFORMAT and TIMEFORMAT string.

Format	Example of Valid Input String
ISO 8601	2019-02-11T05:09:12.195Z
Julian	J2451187
BC	Jan-08-95 BC
YYYYMMDD HHMISS	19960108 040809
YYMMDD HHMISS	960108 040809
YYYY.DDD	1996.008
YYYY-MM-DD HH:MI:SS. SSS	1996-01-08 04:05:06.789
DD Mon HH:MI:SS YYYY TZ	17 Dec 07:37:16 1997 PST
MM/DD/YYYY HH:MI:SS.SS TZ	12/17/1997 07:37:16.00 PST

Format	Example of Valid Input String
YYYY-MM-DD HH:MI:SS+/-TZ	1997-12-17 07:37:16-08
DD.MM.YYYY HH:MI:SS TZ	12.17.1997 07:37:16.00 PST

Automatic recognition doesn't support epochsecs and epochmilliseconds.

To test whether a date or timestamp value will be automatically converted, use a CAST function to attempt to convert the string to a date or timestamp value. For example, the following commands test the timestamp value 'J2345678 04:05:06.789':

```
create table formattest (test char(21));
insert into formattest values('J2345678 04:05:06.789');
select test, cast(test as timestamp) as timestamp, cast(test as date) as date from
formattest;
```

test	timestamp	date
J2345678 04:05:06.789	1710-02-23 04:05:06	1710-02-23

If the source data for a DATE column includes time information, the time component is truncated. If the source data for a TIMESTAMP column omits time information, 00:00:00 is used for the time component.

COPY examples

Note

These examples contain line breaks for readability. Do not include line breaks or spaces in your *credentials-args* string.

Load FAVORITEMOVIES from an DynamoDB table

The AWS SDKs include a simple example of creating a DynamoDB table called *Movies*. (For this example, see [Getting Started with DynamoDB](#).) The following example loads the Amazon Redshift MOVIES table with data from the DynamoDB table. The Amazon Redshift table must already exist in the database.

```
copy favoritemovies from 'dynamodb://Movies'  
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'  
readratio 50;
```

Load LISTING from an Amazon S3 bucket

The following example loads LISTING from an Amazon S3 bucket. The COPY command loads all of the files in the `/data/listing/` folder.

```
copy listing
from 's3://amzn-s3-demo-bucket/data/listing/'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

Load LISTING from an Amazon EMR cluster

The following example loads the SALES table with tab-delimited data from lzop-compressed files in an Amazon EMR cluster. COPY loads every file in the myoutput/ folder that begins with part-.

```
copy sales
from 'emr://j-SAMPLE2B500FC/myoutput/part-*'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter '\t' lzop;
```

The following example loads the SALES table with JSON formatted data in an Amazon EMR cluster. COPY loads every file in the myoutput/json/ folder.

```
copy sales
from 'emr://j-SAMPLE2B500FC/myoutput/json/'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
JSON 's3://amzn-s3-demo-bucket/jsonpaths.txt';
```

Using a manifest to specify data files

You can use a manifest to ensure that your COPY command loads all of the required files, and only the required files, from Amazon S3. You can also use a manifest when you need to load multiple files from different buckets or files that don't share the same prefix.

For example, suppose that you need to load the following three files: custdata1.txt, custdata2.txt, and custdata3.txt. You could use the following command to load all of the files in amzn-s3-demo-bucket that begin with custdata by specifying a prefix:

```
copy category
from 's3://amzn-s3-demo-bucket/custdata'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

If only two of the files exist because of an error, COPY loads only those two files and finishes successfully, resulting in an incomplete data load. If the bucket also contains an unwanted file that

happens to use the same prefix, such as a file named `custdata.backup` for example, COPY loads that file as well, resulting in unwanted data being loaded.

To ensure that all of the required files are loaded and to prevent unwanted files from being loaded, you can use a manifest file. The manifest is a JSON-formatted text file that lists the files to be processed by the COPY command. For example, the following manifest loads the three files in the previous example.

```
{
  "entries": [
    {
      "url": "s3://amzn-s3-demo-bucket/custdata.1",
      "mandatory": true
    },
    {
      "url": "s3://amzn-s3-demo-bucket/custdata.2",
      "mandatory": true
    },
    {
      "url": "s3://amzn-s3-demo-bucket/custdata.3",
      "mandatory": true
    }
  ]
}
```

The optional `mandatory` flag indicates whether COPY should terminate if the file doesn't exist. The default is `false`. Regardless of any mandatory settings, COPY terminates if no files are found. In this example, COPY returns an error if any of the files isn't found. Unwanted files that might have been picked up if you specified only a key prefix, such as `custdata.backup`, are ignored, because they aren't on the manifest.

When loading from data files in ORC or Parquet format, a `meta` field is required, as shown in the following example.

```
{
  "entries": [
    {
      "url": "s3://amzn-s3-demo-bucket1/orc/2013-10-04-custdata",
      "mandatory": true,
      "meta": {
        "content_length": 99
      }
    }
  ]
}
```

```

    }
  },
  {
    "url": "s3://amzn-s3-demo-bucket2/orc/2013-10-05-custdata",
    "mandatory": true,
    "meta": {
      "content_length": 99
    }
  }
]
}

```

The following example uses a manifest named `cust.manifest`.

```

copy customer
from 's3://amzn-s3-demo-bucket/cust.manifest'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
format as orc
manifest;

```

You can use a manifest to load files from different buckets or files that don't share the same prefix. The following example shows the JSON to load data with files whose names begin with a date stamp.

```

{
  "entries": [
    {"url": "s3://amzn-s3-demo-bucket/2013-10-04-custdata.txt", "mandatory": true},
    {"url": "s3://amzn-s3-demo-bucket/2013-10-05-custdata.txt", "mandatory": true},
    {"url": "s3://amzn-s3-demo-bucket/2013-10-06-custdata.txt", "mandatory": true},
    {"url": "s3://amzn-s3-demo-bucket/2013-10-07-custdata.txt", "mandatory": true}
  ]
}

```

The manifest can list files that are in different buckets, as long as the buckets are in the same AWS Region as the cluster.

```

{
  "entries": [
    {"url": "s3://amzn-s3-demo-bucket1/custdata1.txt", "mandatory": false},
    {"url": "s3://amzn-s3-demo-bucket2/custdata1.txt", "mandatory": false},
    {"url": "s3://amzn-s3-demo-bucket2/custdata2.txt", "mandatory": false}
  ]
}

```

```
]
}
```

Load LISTING from a pipe-delimited file (default delimiter)

The following example is a very simple case in which no options are specified and the input file contains the default delimiter, a pipe character ('|').

```
copy listing
from 's3://amzn-s3-demo-bucket/data/listings_pipe.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole';
```

Load LISTING using columnar data in Parquet format

The following example loads data from a folder on Amazon S3 named parquet.

```
copy listing
from 's3://amzn-s3-demo-bucket/data/listings/parquet/'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
format as parquet;
```

Load LISTING using columnar data in ORC format

The following example loads data from a folder on Amazon S3 named orc.

```
copy listing
from 's3://amzn-s3-demo-bucket/data/listings/orc/'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
format as orc;
```

Load EVENT with options

The following example loads pipe-delimited data into the EVENT table and applies the following rules:

- If pairs of quotation marks are used to surround any character strings, they are removed.
- Both empty strings and strings that contain blanks are loaded as NULL values.
- The load fails if more than 5 errors are returned.
- Timestamp values must comply with the specified format; for example, a valid timestamp is `2008-09-26 05:43:12`.

```
copy event
from 's3://amzn-s3-demo-bucket/data/allevnts_pipe.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
removequotes
emptyasnull
blanksasnull
maxerror 5
delimiter '|'
timeformat 'YYYY-MM-DD HH:MI:SS';
```

Load VENUE from a fixed-width data file

```
copy venue
from 's3://amzn-s3-demo-bucket/data/venue_fw.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
fixedwidth 'venueid:3,venueid:25,venueid:12,venueid:2,venueid:6';
```

The preceding example assumes a data file formatted in the same way as the sample data shown. In the sample following, spaces act as placeholders so that all of the columns are the same width as noted in the specification:

```
1 Toyota Park           Bridgeview  IL0
2 Columbus Crew Stadium Columbus    OH0
3 RFK Stadium           Washington  DC0
4 CommunityAmerica BallparkKansas City KS0
5 Gillette Stadium      Foxborough  MA68756
```

Load CATEGORY from a CSV file

Suppose you want to load the CATEGORY with the values shown in the following table.

catid	catgroup	catname	catdesc
12	Shows	Musicals	Musical theatre
13	Shows	Plays	All "non-musical" theatre
14	Shows	Opera	All opera, light, and "rock" opera

catid	catgroup	catname	catdesc
15	Concerts	Classical	All symphony, concerto, and choir concerts

The following example shows the contents of a text file with the field values separated by commas.

```
12,Shows,Musicals,Musical theatre
13,Shows,Plays,All "non-musical" theatre
14,Shows,Opera,All opera, light, and "rock" opera
15,Concerts,Classical,All symphony, concerto, and choir concerts
```

If you load the file using the `DELIMITER` parameter to specify comma-delimited input, the `COPY` command fails because some input fields contain commas. You can avoid that problem by using the `CSV` parameter and enclosing the fields that contain commas in quotation mark characters. If the quotation mark character appears within a quoted string, you need to escape it by doubling the quotation mark character. The default quotation mark character is a double quotation mark, so you need to escape each double quotation mark with an additional double quotation mark. Your new input file looks something like this.

```
12,Shows,Musicals,Musical theatre
13,Shows,Plays,"All ""non-musical"" theatre"
14,Shows,Opera,"All opera, light, and ""rock"" opera"
15,Concerts,Classical,"All symphony, concerto, and choir concerts"
```

Assuming the file name is `category_csv.txt`, you can load the file by using the following `COPY` command:

```
copy category
from 's3://amzn-s3-demo-bucket/data/category_csv.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
csv;
```

Alternatively, to avoid the need to escape the double quotation marks in your input, you can specify a different quotation mark character by using the `QUOTE AS` parameter. For example, the following version of `category_csv.txt` uses `'` as the quotation mark character.

```
12,Shows,Musicals,Musical theatre
```

```
13,Shows,Plays,%All "non-musical" theatre%
14,Shows,Opera,%All opera, light, and "rock" opera%
15,Concerts,Classical,%All symphony, concerto, and choir concerts%
```

The following COPY command uses QUOTE AS to load category_csv.txt:

```
copy category
from 's3://amzn-s3-demo-bucket/data/category_csv.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
csv quote as '%';
```

Load VENUE with explicit values for an IDENTITY column

The following example assumes that when the VENUE table was created that at least one column (such as the venueid column) was specified to be an IDENTITY column. This command overrides the default IDENTITY behavior of autogenerating values for an IDENTITY column and instead loads the explicit values from the venue.txt file. Amazon Redshift does not check if duplicate IDENTITY values are loaded into the table when using the EXPLICIT_IDS option.

```
copy venue
from 's3://amzn-s3-demo-bucket/data/venue.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
explicit_ids;
```

Load TIME from a pipe-delimited GZIP file

The following example loads the TIME table from a pipe-delimited GZIP file:

```
copy time
from 's3://amzn-s3-demo-bucket/data/timerows.gz'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
gzip
delimiter '|';
```

Load a timestamp or datestamp

The following example loads data with a formatted timestamp.

Note

The TIMEFORMAT of HH:MI:SS can also support fractional seconds beyond the SS to a microsecond level of detail. The file `time.txt` used in this example contains one row, `2009-01-12 14:15:57.119568`.

```
copy timestamp1
from 's3://amzn-s3-demo-bucket/data/time.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
timeformat 'YYYY-MM-DD HH:MI:SS';
```

The result of this copy is as follows:

```
select * from timestamp1;
c1
-----
2009-01-12 14:15:57.119568
(1 row)
```

Load data from a file with default values

The following example uses a variation of the VENUE table in the TICKIT database. Consider a VENUE_NEW table defined with the following statement:

```
create table venue_new(
venueid smallint not null,
venue_name varchar(100) not null,
venue_city varchar(30),
venue_state char(2),
venue_seats integer not null default '1000');
```

Consider a `venue_noseats.txt` data file that contains no values for the VENUESEATS column, as shown in the following example:

```
1|Toyota Park|Bridgeview|IL|
2|Columbus Crew Stadium|Columbus|OH|
3|RFK Stadium|Washington|DC|
4|CommunityAmerica Ballpark|Kansas City|KS|
5|Gillette Stadium|Foxborough|MA|
```

```
6|New York Giants Stadium|East Rutherford|NJ|
7|BMO Field|Toronto|ON|
8|The Home Depot Center|Carson|CA|
9|Dick's Sporting Goods Park|Commerce City|CO|
10|Pizza Hut Park|Frisco|TX|
```

The following COPY statement will successfully load the table from the file and apply the DEFAULT value ('1000') to the omitted column:

```
copy venue_new(venueid, venue_name, venuecity, venuestate)
from 's3://amzn-s3-demo-bucket/data/venue_noseats.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter '|';
```

Now view the loaded table:

```
select * from venue_new order by venueid;
venueid |          venue_name          | venuecity | venuestate | venue_seats
-----+-----+-----+-----+-----
1 | Toyota Park                  | Bridgeview | IL         |          1000
2 | Columbus Crew Stadium       | Columbus   | OH         |          1000
3 | RFK Stadium                  | Washington | DC         |          1000
4 | CommunityAmerica Ballpark   | Kansas City | KS        |          1000
5 | Gillette Stadium            | Foxborough | MA         |          1000
6 | New York Giants Stadium     | East Rutherford | NJ        |          1000
7 | BMO Field                    | Toronto    | ON         |          1000
8 | The Home Depot Center       | Carson     | CA         |          1000
9 | Dick's Sporting Goods Park  | Commerce City | CO        |          1000
10 | Pizza Hut Park              | Frisco     | TX         |          1000
(10 rows)
```

For the following example, in addition to assuming that no VENUESEATS data is included in the file, also assume that no VENUENAME data is included:

```
1||Bridgeview|IL|
2||Columbus|OH|
3||Washington|DC|
4||Kansas City|KS|
5||Foxborough|MA|
6||East Rutherford|NJ|
7||Toronto|ON|
8||Carson|CA|
```

```
9||Commerce City|CO|
10||Frisco|TX|
```

Using the same table definition, the following COPY statement fails because no DEFAULT value was specified for VENUENAME, and VENUENAME is a NOT NULL column:

```
copy venue(venueid, venuecity, venuestate)
from 's3://amzn-s3-demo-bucket/data/venue_pipe.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter '|';
```

Now consider a variation of the VENUE table that uses an IDENTITY column:

```
create table venue_identity(
venueid int identity(1,1),
venuename varchar(100) not null,
venuecity varchar(30),
venuestate char(2),
venueseats integer not null default '1000');
```

As with the previous example, assume that the VENUESEATS column has no corresponding values in the source file. The following COPY statement successfully loads the table, including the predefined IDENTITY data values instead of autogenerating those values:

```
copy venue(venueid, venuename, venuecity, venuestate)
from 's3://amzn-s3-demo-bucket/data/venue_pipe.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter '|' explicit_ids;
```

This statement fails because it doesn't include the IDENTITY column (VENUEID is missing from the column list) yet includes an EXPLICIT_IDS parameter:

```
copy venue(venuename, venuecity, venuestate)
from 's3://amzn-s3-demo-bucket/data/venue_pipe.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter '|' explicit_ids;
```

This statement fails because it doesn't include an EXPLICIT_IDS parameter:

```
copy venue(venueid, venuename, venuecity, venuestate)
```

```
from 's3://amzn-s3-demo-bucket/data/venue_pipe.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter '|';
```

COPY data with the ESCAPE option

The following example shows how to load characters that match the delimiter character (in this case, the pipe character). In the input file, make sure that all of the pipe characters (|) that you want to load are escaped with the backslash character (\). Then load the file with the ESCAPE parameter.

```
$ more redshiftinfo.txt
1|public\|event\|dwuser
2|public\|sales\|dwuser

create table redshiftinfo(infoid int,tableinfo varchar(50));

copy redshiftinfo from 's3://amzn-s3-demo-bucket/data/redshiftinfo.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
delimiter '|' escape;

select * from redshiftinfo order by 1;
infoid |      tableinfo
-----+-----
1      | public|event|dwuser
2      | public|sales|dwuser
(2 rows)
```

Without the ESCAPE parameter, this COPY command fails with an `Extra column(s) found error`.

Important

If you load your data using a COPY with the ESCAPE parameter, you must also specify the ESCAPE parameter with your UNLOAD command to generate the reciprocal output file. Similarly, if you UNLOAD using the ESCAPE parameter, you need to use ESCAPE when you COPY the same data.

Copy from JSON examples

In the following examples, you load the CATEGORY table with the following data.

CATID	CATGROUP	CATNAME	CATDESC
1	Sports	MLB	Major League Baseball
2	Sports	NHL	National Hockey League
3	Sports	NFL	National Football League
4	Sports	NBA	National Basketball Association
5	Concerts	Classical	All symphony, concerto, and choir concerts

Topics

- [Load from JSON data using the 'auto' option](#)
- [Load from JSON data using the 'auto ignorecase' option](#)
- [Load from JSON data using a JSONPaths file](#)
- [Load from JSON arrays using a JSONPaths file](#)

Load from JSON data using the 'auto' option

To load from JSON data using the 'auto' option, the JSON data must consist of a set of objects. The key names must match the column names, but the order doesn't matter. The following shows the contents of a file named `category_object_auto.json`.

```
{
  "catdesc": "Major League Baseball",
  "catid": 1,
  "catgroup": "Sports",
  "catname": "MLB"
}
{
  "catgroup": "Sports",
  "catid": 2,
  "catname": "NHL",
  "catdesc": "National Hockey League"
}
{
  "catid": 3,
```

```

    "catname": "NFL",
    "catgroup": "Sports",
    "catdesc": "National Football League"
  }
  {
    "bogus": "Bogus Sports LLC",
    "catid": 4,
    "catgroup": "Sports",
    "catname": "NBA",
    "catdesc": "National Basketball Association"
  }
  {
    "catid": 5,
    "catgroup": "Shows",
    "catname": "Musicals",
    "catdesc": "All symphony, concerto, and choir concerts"
  }
}

```

To load from the JSON data file in the previous example, run the following COPY command.

```

copy category
from 's3://amzn-s3-demo-bucket/category_object_auto.json'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
json 'auto';

```

Load from JSON data using the 'auto ignorecase' option

To load from JSON data using the 'auto ignorecase' option, the JSON data must consist of a set of objects. The case of the key names doesn't have to match the column names and the order doesn't matter. The following shows the contents of a file named category_object_auto-ignorecase.json.

```

{
  "CatDesc": "Major League Baseball",
  "CatID": 1,
  "CatGroup": "Sports",
  "CatName": "MLB"
}
{
  "CatGroup": "Sports",
  "CatID": 2,
  "CatName": "NHL",

```

```
    "CatDesc": "National Hockey League"
  }{
    "CatID": 3,
    "CatName": "NFL",
    "CatGroup": "Sports",
    "CatDesc": "National Football League"
  }
  {
    "bogus": "Bogus Sports LLC",
    "CatID": 4,
    "CatGroup": "Sports",
    "CatName": "NBA",
    "CatDesc": "National Basketball Association"
  }
  {
    "CatID": 5,
    "CatGroup": "Shows",
    "CatName": "Musicals",
    "CatDesc": "All symphony, concerto, and choir concerts"
  }
}
```

To load from the JSON data file in the previous example, run the following COPY command.

```
copy category
from 's3://amzn-s3-demo-bucket/category_object_auto ignorecase.json'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
json 'auto ignorecase';
```

Load from JSON data using a JSONPaths file

If the JSON data objects don't correspond directly to column names, you can use a JSONPaths file to map the JSON elements to columns. The order doesn't matter in the JSON source data, but the order of the JSONPaths file expressions must match the column order. Suppose that you have the following data file, named `category_object_paths.json`.

```
{
  "one": 1,
  "two": "Sports",
  "three": "MLB",
  "four": "Major League Baseball"
}
{
```

```

    "three": "NHL",
    "four": "National Hockey League",
    "one": 2,
    "two": "Sports"
  }
  {
    "two": "Sports",
    "three": "NFL",
    "one": 3,
    "four": "National Football League"
  }
  {
    "one": 4,
    "two": "Sports",
    "three": "NBA",
    "four": "National Basketball Association"
  }
  {
    "one": 6,
    "two": "Shows",
    "three": "Musicals",
    "four": "All symphony, concerto, and choir concerts"
  }
}

```

The following JSONPaths file, named `category_jsonpath.json`, maps the source data to the table columns.

```

{
  "jsonpaths": [
    "$['one']",
    "$['two']",
    "$['three']",
    "$['four']"
  ]
}

```

To load from the JSON data file in the previous example, run the following COPY command.

```

copy category
from 's3://amzn-s3-demo-bucket/category_object_paths.json'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
json 's3://amzn-s3-demo-bucket/category_jsonpath.json';

```

Load from JSON arrays using a JSONPaths file

To load from JSON data that consists of a set of arrays, you must use a JSONPaths file to map the array elements to columns. Suppose that you have the following data file, named `category_array_data.json`.

```
[1,"Sports","MLB","Major League Baseball"]
[2,"Sports","NHL","National Hockey League"]
[3,"Sports","NFL","National Football League"]
[4,"Sports","NBA","National Basketball Association"]
[5,"Concerts","Classical","All symphony, concerto, and choir concerts"]
```

The following JSONPaths file, named `category_array_jsonpath.json`, maps the source data to the table columns.

```
{
  "jsonpaths": [
    "$[0]",
    "$[1]",
    "$[2]",
    "$[3]"
  ]
}
```

To load from the JSON data file in the previous example, run the following COPY command.

```
copy category
from 's3://amzn-s3-demo-bucket/category_array_data.json'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
json 's3://amzn-s3-demo-bucket/category_array_jsonpath.json';
```

Copy from Avro examples

In the following examples, you load the CATEGORY table with the following data.

CATID	CATGROUP	CATNAME	CATDESC
1	Sports	MLB	Major League Baseball
2	Sports	NHL	National Hockey League

CATID	CATGROUP	CATNAME	CATDESC
3	Sports	NFL	National Football League
4	Sports	NBA	National Basketball Association
5	Concerts	Classical	All symphony, concerto, and choir concerts

Topics

- [Load from Avro data using the 'auto' option](#)
- [Load from Avro data using the 'auto ignorecase' option](#)
- [Load from Avro data using a JSONPaths file](#)

Load from Avro data using the 'auto' option

To load from Avro data using the 'auto' argument, field names in the Avro schema must match the column names. When using the 'auto' argument, order doesn't matter. The following shows the schema for a file named `category_auto.avro`.

```
{
  "name": "category",
  "type": "record",
  "fields": [
    {"name": "catid", "type": "int"},
    {"name": "catdesc", "type": "string"},
    {"name": "catname", "type": "string"},
    {"name": "catgroup", "type": "string"},
  ]
}
```

The data in an Avro file is in binary format, so it isn't human-readable. The following shows a JSON representation of the data in the `category_auto.avro` file.

```
{
  "catid": 1,
  "catdesc": "Major League Baseball",
  "catname": "MLB",
  "catgroup": "Sports"
```

```
}
{
  "catid": 2,
  "catdesc": "National Hockey League",
  "catname": "NHL",
  "catgroup": "Sports"
}
{
  "catid": 3,
  "catdesc": "National Basketball Association",
  "catname": "NBA",
  "catgroup": "Sports"
}
{
  "catid": 4,
  "catdesc": "All symphony, concerto, and choir concerts",
  "catname": "Classical",
  "catgroup": "Concerts"
}
```

To load from the Avro data file in the previous example, run the following COPY command.

```
copy category
from 's3://amzn-s3-demo-bucket/category_auto.avro'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
format as avro 'auto';
```

Load from Avro data using the 'auto ignorecase' option

To load from Avro data using the 'auto ignorecase' argument, the case of the field names in the Avro schema does not have to match the case of column names. When using the 'auto ignorecase' argument, order doesn't matter. The following shows the schema for a file named `category_auto-ignorecase.avro`.

```
{
  "name": "category",
  "type": "record",
  "fields": [
    {"name": "CatID", "type": "int"},
    {"name": "CatDesc", "type": "string"},
    {"name": "CatName", "type": "string"},
    {"name": "CatGroup", "type": "string"},
  ]
}
```

```
}
```

The data in an Avro file is in binary format, so it isn't human-readable. The following shows a JSON representation of the data in the `category_auto-ignorecase.avro` file.

```
{
  "CatID": 1,
  "CatDesc": "Major League Baseball",
  "CatName": "MLB",
  "CatGroup": "Sports"
}
{
  "CatID": 2,
  "CatDesc": "National Hockey League",
  "CatName": "NHL",
  "CatGroup": "Sports"
}
{
  "CatID": 3,
  "CatDesc": "National Basketball Association",
  "CatName": "NBA",
  "CatGroup": "Sports"
}
{
  "CatID": 4,
  "CatDesc": "All symphony, concerto, and choir concerts",
  "CatName": "Classical",
  "CatGroup": "Concerts"
}
```

To load from the Avro data file in the previous example, run the following COPY command.

```
copy category
from 's3://amzn-s3-demo-bucket/category_auto-ignorecase.avro'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
format as avro 'auto ignorecase';
```

Load from Avro data using a JSONPaths file

If the field names in the Avro schema don't correspond directly to column names, you can use a JSONPaths file to map the schema elements to columns. The order of the JSONPaths file expressions must match the column order.

Suppose that you have a data file named `category_paths.avro` that contains the same data as in the previous example, but with the following schema.

```
{
  "name": "category",
  "type": "record",
  "fields": [
    {"name": "id", "type": "int"},
    {"name": "desc", "type": "string"},
    {"name": "name", "type": "string"},
    {"name": "group", "type": "string"},
    {"name": "region", "type": "string"}
  ]
}
```

The following JSONPaths file, named `category_path.avropath`, maps the source data to the table columns.

```
{
  "jsonpaths": [
    "$['id']",
    "$['group']",
    "$['name']",
    "$['desc']"
  ]
}
```

To load from the Avro data file in the previous example, run the following COPY command.

```
copy category
from 's3://amzn-s3-demo-bucket/category_object_paths.avro'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
format avro 's3://amzn-s3-demo-bucket/category_path.avropath ';
```

Preparing files for COPY with the ESCAPE option

The following example describes how you might prepare data to "escape" newline characters before importing the data into an Amazon Redshift table using the COPY command with the ESCAPE parameter. Without preparing the data to delimit the newline characters, Amazon Redshift returns load errors when you run the COPY command, because the newline character is normally used as a record separator.

For example, consider a file or a column in an external table that you want to copy into an Amazon Redshift table. If the file or column contains XML-formatted content or similar data, you need to make sure that all of the newline characters (`\n`) that are part of the content are escaped with the backslash character (`\`).

A file or table containing embedded newlines characters provides a relatively easy pattern to match. Each embedded newline character most likely always follows a `>` character with potentially some white space characters (`' '` or tab) in between, as you can see in the following example of a text file named `n1Test1.txt`.

```
$ cat n1Test1.txt
<xml start>
<newline characters provide>
<line breaks at the end of each>
<line in content>
</xml>|1000
<xml>
</xml>|2000
```

With the following example, you can run a text-processing utility to pre-process the source file and insert escape characters where needed. (The `|` character is intended to be used as delimiter to separate column data when copied into an Amazon Redshift table.)

```
$ sed -e ':a;N;$!ba;s/>[[[:space:]]*\n/>\\\n/g' n1Test1.txt > n1Test2.txt
```

Similarly, you can use Perl to perform a similar operation:

```
cat n1Test1.txt | perl -p -e 's/>\s*\n/>\\\n/g' > n1Test2.txt
```

To accommodate loading the data from the `n1Test2.txt` file into Amazon Redshift, we created a two-column table in Amazon Redshift. The first column `c1`, is a character column that holds XML-formatted content from the `n1Test2.txt` file. The second column `c2` holds integer values loaded from the same file.

After running the `sed` command, you can correctly load data from the `n1Test2.txt` file into an Amazon Redshift table using the `ESCAPE` parameter.

Note

When you include the ESCAPE parameter with the COPY command, it escapes a number of special characters that include the backslash character (including newline).

```
copy t2 from 's3://amzn-s3-demo-bucket/data/nlTest2.txt'
iam_role 'arn:aws:iam::0123456789012:role/MyRedshiftRole'
escape
delimiter as '|';

select * from t2 order by 2;

c1          | c2
-----+-----
<xml start>
<newline characters provide>
<line breaks at the end of each>
<line in content>
</xml>
| 1000
<xml>
</xml>      | 2000
(2 rows)
```

You can prepare data files exported from external databases in a similar way. For example, with an Oracle database, you can use the REPLACE function on each affected column in a table that you want to copy into Amazon Redshift.

```
SELECT c1, REPLACE(c2, \n',\n' ) as c2 from my_table_with_xml
```

In addition, many database export and extract, transform, load (ETL) tools that routinely process large amounts of data provide options to specify escape and delimiter characters.

Loading a shapefile into Amazon Redshift

The following examples demonstrate how to load an Esri shapefile using COPY. For more information about loading shapefiles, see [Loading a shapefile into Amazon Redshift](#).

Loading a shapefile

The following steps show how to ingest OpenStreetMap data from Amazon S3 using the COPY command. This example assumes that the Norway shapefile archive from [the download site of Geofabrik](#) has been uploaded to a private Amazon S3 bucket in your AWS Region. The .shp, .shx, and .dbf files must share the same Amazon S3 prefix and file name.

Ingesting data without simplification

The following commands create tables and ingest data that can fit in the maximum geometry size without any simplification. Open the `gis_osm_natural_free_1.shp` in your preferred GIS software and inspect the columns in this layer. By default, either IDENTITY or GEOMETRY columns are first. When a GEOMETRY column is first, you can create the table as shown following.

```
CREATE TABLE norway_natural (  
  wkb_geometry GEOMETRY,  
  osm_id BIGINT,  
  code INT,  
  fclass VARCHAR,  
  name VARCHAR);
```

Or, when an IDENTITY column is first, you can create the table as shown following.

```
CREATE TABLE norway_natural_with_id (  
  fid INT IDENTITY(1,1),  
  wkb_geometry GEOMETRY,  
  osm_id BIGINT,  
  code INT,  
  fclass VARCHAR,  
  name VARCHAR);
```

Now you can ingest the data using COPY.

```
COPY norway_natural FROM 's3://bucket_name/shapefiles/norway/  
gis_osm_natural_free_1.shp'  
FORMAT SHAPEFILE  
CREDENTIALS 'aws_iam_role=arn:aws:iam::123456789012:role/MyRoleName';  
INFO: Load into table 'norway_natural' completed, 83891 record(s) loaded successfully
```

Or you can ingest the data as shown following.

```
COPY norway_natural_with_id FROM 's3://bucket_name/shapefiles/norway/
gis_osm_natural_free_1.shp'
FORMAT SHAPEFILE
CREDENTIALS 'aws_iam_role=arn:aws:iam::123456789012:role/MyRoleName';
INFO: Load into table 'norway_natural_with_id' completed, 83891 record(s) loaded
successfully.
```

Ingesting data with simplification

The following commands create a table and try to ingest data that can't fit in the maximum geometry size without any simplification. Inspect the `gis_osm_water_a_free_1.shp` shapefile and create the appropriate table as shown following.

```
CREATE TABLE norway_water (
  wkb_geometry GEOMETRY,
  osm_id BIGINT,
  code INT,
  fclass VARCHAR,
  name VARCHAR);
```

When the COPY command runs, it results in an error.

```
COPY norway_water FROM 's3://bucket_name/shapefiles/norway/gis_osm_water_a_free_1.shp'
FORMAT SHAPEFILE
CREDENTIALS 'aws_iam_role=arn:aws:iam::123456789012:role/MyRoleName';
ERROR: Load into table 'norway_water' failed. Check 'stl_load_errors' system table
for details.
```

Querying STL_LOAD_ERRORS shows that the geometry is too large.

```
SELECT line_number, btrim(colname), btrim(err_reason) FROM stl_load_errors WHERE query
= pg_last_copy_id();
line_number |      btrim      |                                btrim
-----+-----
+-----+-----
      1184705 | wkb_geometry | Geometry size: 1513736 is larger than maximum supported
size: 1048447
```

To overcome this, the `SIMPLIFY AUTO` parameter is added to the COPY command to simplify geometries.

```
COPY norway_water FROM 's3://bucket_name/shapefiles/norway/gis_osm_water_a_free_1.shp'
FORMAT SHAPEFILE
SIMPLIFY AUTO
CREDENTIALS 'aws_iam_role=arn:aws:iam::123456789012:role/MyRoleName';

INFO: Load into table 'norway_water' completed, 1989196 record(s) loaded successfully.
```

To view the rows and geometries that were simplified, query SVL_SPATIAL_SIMPLIFY.

```
SELECT * FROM svl_spatial_simplify WHERE query = pg_last_copy_id();
query | line_number | maximum_tolerance | initial_size | simplified | final_size |
final_tolerance
-----+-----+-----+-----+-----+-----+-----
+-----+
      20 |      1184704 |                -1 |      1513736 | t         |      1008808 |
1.276386653895e-05
      20 |      1664115 |                -1 |      1233456 | t         |      1023584 |
6.11707814796635e-06
```

Using SIMPLIFY AUTO *max_tolerance* with the tolerance lower than the automatically calculated ones probably results in an ingestion error. In this case, use MAXERROR to ignore errors.

```
COPY norway_water FROM 's3://bucket_name/shapefiles/norway/gis_osm_water_a_free_1.shp'
FORMAT SHAPEFILE
SIMPLIFY AUTO 1.1E-05
MAXERROR 2
CREDENTIALS 'aws_iam_role=arn:aws:iam::123456789012:role/MyRoleName';

INFO: Load into table 'norway_water' completed, 1989195 record(s) loaded successfully.
INFO: Load into table 'norway_water' completed, 1 record(s) could not be loaded.
Check 'stl_load_errors' system table for details.
```

Query SVL_SPATIAL_SIMPLIFY again to identify the record that COPY didn't manage to load.

```
SELECT * FROM svl_spatial_simplify WHERE query = pg_last_copy_id();
query | line_number | maximum_tolerance | initial_size | simplified | final_size |
final_tolerance
-----+-----+-----+-----+-----+-----+-----
+-----+
      29 |      1184704 |          1.1e-05 |      1513736 | f         |           0 |
0
```

```
29 |      1664115 |      1.1e-05 |      1233456 | t      |      794432 |
    |      1.1e-05
```

In this example, the first record didn't manage to fit, so the `simplified` column is showing `false`. The second record was loaded within the given tolerance. However, the final size is larger than using the automatically calculated tolerance without specifying the maximum tolerance.

Loading from a compressed shapefile

Amazon Redshift COPY supports ingesting data from a compressed shapefile. All shapefile components must have the same Amazon S3 prefix and the same compression suffix. As an example, suppose that you want to load the data from the previous example. In this case, the files `gis_osm_water_a_free_1.shp.gz`, `gis_osm_water_a_free_1.dbf.gz`, and `gis_osm_water_a_free_1.shx.gz` must share the same Amazon S3 directory. The COPY command requires the GZIP option, and the FROM clause must specify the correct compressed file, as shown following.

```
COPY norway_natural FROM 's3://bucket_name/shapefiles/norway/compressed/
gis_osm_natural_free_1.shp.gz'
FORMAT SHAPEFILE
GZIP
CREDENTIALS 'aws_iam_role=arn:aws:iam::123456789012:role/MyRoleName';
INFO: Load into table 'norway_natural' completed, 83891 record(s) loaded successfully.
```

Loading data into a table with a different column order

If you have a table that doesn't have GEOMETRY as the first column, you can use column mapping to map columns to the target table. For example, create a table with `osm_id` specified as a first column.

```
CREATE TABLE norway_natural_order (
  osm_id BIGINT,
  wkb_geometry GEOMETRY,
  code INT,
  fclass VARCHAR,
  name VARCHAR);
```

Then ingest a shapefile using column mapping.

```
COPY norway_natural_order(wkb_geometry, osm_id, code, fclass, name)
FROM 's3://bucket_name/shapefiles/norway/gis_osm_natural_free_1.shp'
FORMAT SHAPEFILE
CREDENTIALS 'aws_iam_role=arn:aws:iam::123456789012:role/MyRoleName';
INFO: Load into table 'norway_natural_order' completed, 83891 record(s) loaded
successfully.
```

Loading data into a table with a geography column

If you have a table that has a GEOGRAPHY column, you first ingest into a GEOMETRY column and then cast the objects to GEOGRAPHY objects. For example, after you copy your shapefile into a GEOMETRY column, alter the table to add a column of the GEOGRAPHY data type.

```
ALTER TABLE norway_natural ADD COLUMN wkb_geography GEOGRAPHY;
```

Then convert geometries to geographies.

```
UPDATE norway_natural SET wkb_geography = wkb_geometry::geography;
```

Optionally, you can drop the GEOMETRY column.

```
ALTER TABLE norway_natural DROP COLUMN wkb_geometry;
```

COPY command with the NOLOAD option

To validate data files before you actually load the data, use the NOLOAD option with the COPY command. Amazon Redshift parses the input file and displays any errors that occur. The following example uses the NOLOAD option and no rows are actually loaded into the table.

```
COPY public.zipcode1
FROM 's3://amzn-s3-demo-bucket/mydata/zipcode.csv'
DELIMITER ';'
IGNOREHEADER 1 REGION 'us-east-1'
NOLOAD
CREDENTIALS 'aws_iam_role=arn:aws:iam::123456789012:role/myRedshiftRole';
```

Warnings:

```
Load into table 'zipcode1' completed, 0 record(s) loaded successfully.
```

COPY command with a multibyte delimiter and the ENCODING option

The following example loads LATIN1 from an Amazon S3 file that contains multibyte data. The COPY command specifies the delimiter in octal form `\302\246\303\254` to separate the fields in the input file which is encoded as ISO-8859-1. To specify the same delimiter in UTF-8, specify `DELIMITER 'ï¿½'`.

```
COPY latin1
FROM 's3://amzn-s3-demo-bucket/multibyte/myfile'
IAM_ROLE 'arn:aws:iam::123456789012:role/myRedshiftRole'
DELIMITER '\302\246\303\254'
ENCODING ISO88591
```

CREATE DATABASE

Creates a new database.

To create a database, you must be a superuser or have the CREATEDB privilege. To create a database associated with a zero-ETL integration, you must be a superuser or have both CREATEDB and CREATEUSER privileges.

You can't run CREATE DATABASE within a transaction block (BEGIN ... END). For more information about transactions, see [Serializable isolation](#).

Syntax

```
CREATE DATABASE database_name
[ { [ WITH ]
    [ OWNER [=] db_owner ]
    [ CONNECTION LIMIT { limit | UNLIMITED } ]
    [ COLLATE { CASE_SENSITIVE | CASE_INSENSITIVE } ]
    [ ISOLATION LEVEL { SERIALIZABLE | SNAPSHOT } ]
  }
| { [ WITH PERMISSIONS ] FROM DATASHARE datashare_name ] OF [ ACCOUNT account_id ]
  NAMESPACE namespace_guid }
| { FROM { { ARN '<arn>' } { WITH DATA CATALOG SCHEMA '<schema>' | WITH NO DATA
  CATALOG SCHEMA } }
    | { INTEGRATION '<integration_id>' } }
| { IAM_ROLE { default | 'SESSION' | 'arn:aws:iam::<account-id>:role/<role-name>' } }
```

Parameters

database_name

Name of the new database. For more information about valid names, see [Names and identifiers](#).

WITH

Optional keyword.

OWNER

Specifies a database owner.

=

Optional character.

db_owner

Username for the database owner.

CONNECTION LIMIT { *limit* | UNLIMITED }

The maximum number of database connections users are permitted to have open concurrently. The limit isn't enforced for superusers. Use the UNLIMITED keyword to permit the maximum number of concurrent connections. A limit on the number of connections for each user might also apply. For more information, see [CREATE USER](#). The default is UNLIMITED. To view current connections, query the [STV_SESSIONS](#) system view.

Note

If both user and database connection limits apply, an unused connection slot must be available that is within both limits when a user attempts to connect.

COLLATE { CASE_SENSITIVE | CASE_INSENSITIVE }

A clause that specifies whether string search or comparison is CASE_SENSITIVE or CASE_INSENSITIVE. The default is CASE_SENSITIVE.

ISOLATION LEVEL { SERIALIZABLE | SNAPSHOT }

A clause that specifies the isolation level used when queries run against a database.

- SERIALIZABLE isolation – Provides full serializability for concurrent transactions. For more information, see [Serializable isolation](#).

- **SNAPSHOT isolation** – Provides an isolation level with protection against update and delete conflicts. This is the default for a database created in a provisioned cluster or serverless namespace.

You can view which concurrency model your database is running as follows:

- Query the `STV_DB_ISOLATION_LEVEL` catalog view. For more information, see [STV_DB_ISOLATION_LEVEL](#).

```
SELECT * FROM stv_db_isolation_level;
```

- Query the `PG_DATABASE_INFO` view.

```
SELECT datname, datconfig FROM pg_database_info;
```

The isolation level per database appears next to the key `concurrency_model`. A value of 1 denotes SNAPSHOT. A value of 2 denotes SERIALIZABLE.

In Amazon Redshift databases, both SERIALIZABLE and SNAPSHOT isolation are types of serializable isolation levels. That is, dirty reads, non-repeatable reads, and phantom reads are prevented according to the SQL standard. Both isolation levels guarantee that a transaction operates on a snapshot of data as it exists when the transaction begins, and that no other transaction can change that snapshot. However, SNAPSHOT isolation doesn't provide full serializability, because it doesn't prevent write skew inserts and updates on different table rows.

The following scenario illustrates write skew updates using the SNAPSHOT isolation level. A table named `Numbers` contains a column named `digits` that contains 0 and 1 values. Each user's UPDATE statement doesn't overlap the other user. However, the 0 and 1 values are swapped. The SQL they run follows this timeline with these results:

Time	User 1 action	User 2 action
1	BEGIN;	
2		BEGIN;
3	SELECT *	

Time	User 1 action	User 2 action
	FROM Number <pre> digits - ----- 0 1 </pre>	
4		SELECT * FROM Numbers; <pre> digits ----- 0 1 </pre>
5	UPDATE Number SET digits=0 WHERE digits=1	
6	SELECT * FROM Number <pre> digits - ----- 0 0 </pre>	

Time	User 1 action	User 2 action
7	COMMIT	
8		Update Numbers SET digits=1 WHERE digits=0;
9		SELECT * FROM Numbers; <pre> digits ----- 1 1 </pre>
10		COMMIT;
11	SELECT * FROM Number <pre> digits - ----- 1 0 </pre>	
12		SELECT * FROM Numbers; <pre> digits ----- 1 0 </pre>

If the same scenario is run using serializable isolation, then Amazon Redshift terminates user 2 due to a serializable violation and returns error 1023. For more information, see [How to fix](#)

[serializable isolation errors](#). In this case, only user 1 can commit successfully. Not all workloads require serializable isolation as a requirement, in which case snapshot isolation suffices as the target isolation level for your database.

FROM ARN '<ARN>'

The AWS Glue database ARN to use to create the database.

{ DATA CATALOG SCHEMA '<schema>' | WITH NO DATA CATALOG SCHEMA }

Note

This parameter is only applicable if your CREATE DATABASE command also uses the FROM ARN parameter.

Specifies whether to create the database using a schema to help access objects in the AWS Glue Data Catalog.

FROM INTEGRATION '<integration_id>'

Specifies whether to create the database using a zero-ETL integration identifier. You can retrieve the `integration_id` from `SVV_INTEGRATION` system view. For an example, see [Create databases to receive results of zero-ETL integrations](#). For more information about creating databases with zero-ETL integrations, see [Creating destination databases in Amazon Redshift](#) in the *Amazon Redshift Management Guide*.

IAM_ROLE { default | 'SESSION' | 'arn:aws:iam::<AWS account-id>:role/<role-name>' }

Note

This parameter is only applicable if your CREATE DATABASE command also uses the FROM ARN parameter.

If you specify an IAM role that is associated with the cluster when running the CREATE DATABASE command, Amazon Redshift will use the role's credentials when you run queries on the database.

Specifying the default keyword means to use the IAM role that's set as the default and associated with the cluster.

Use 'SESSION' if you connect to your Amazon Redshift cluster using a federated identity and access the tables from the external schema created using this command. For an example of using a federated identity, see [Using a federated identity to manage Amazon Redshift access to local resources and Amazon Redshift Spectrum external tables](#), which explains how to configure federated identity.

Use the Amazon Resource Name (ARN) for an IAM role that your cluster uses for authentication and authorization. As a minimum, the IAM role must have permission to perform a LIST operation on the Amazon S3 bucket to be accessed and a GET operation on the Amazon S3 objects the bucket contains. To learn more about using IAM_ROLE when creating a database using AWS Glue Data Catalog for datashares, see [Working with Lake Formation-managed datashares as a consumer](#).

The following shows the syntax for the IAM_ROLE parameter string for a single ARN.

```
IAM_ROLE 'arn:aws:iam::<aws-account-id>:role/<role-name>'
```

You can chain roles so that your cluster can assume another IAM role, possibly belonging to another account. You can chain up to 10 roles. For more information, see [Chaining IAM roles in Amazon Redshift Spectrum](#).

To this IAM role, attach an IAM permissions policy similar to the following.

```
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Sid": "AccessSecret",
      "Effect": "Allow",
      "Action": [
        "secretsmanager:GetResourcePolicy",
        "secretsmanager:GetSecretValue",
        "secretsmanager:DescribeSecret",
        "secretsmanager:ListSecretVersionIds"
      ],
      "Resource": "arn:aws:secretsmanager:us-west-2:123456789012:secret:my-rds-secret-VNenFy"
    },
    {
      "Sid": "VisualEditor1",
      "Effect": "Allow",
```

```

        "Action": [
            "secretsmanager:GetRandomPassword",
            "secretsmanager:ListSecrets"
        ],
        "Resource": "*"
    }
]
}

```

For the steps to create an IAM role to use with federated query, see [Creating a secret and an IAM role to use federated queries](#).

Note

Don't include spaces in the list of chained roles.

The following shows the syntax for chaining three roles.

```

IAM_ROLE 'arn:aws:iam::<aws-account-id>:role/<role-1-name>,arn:aws:iam::<aws-account-id>:role/<role-2-name>,arn:aws:iam::<aws-account-id>:role/<role-3-name>'

```

Syntax for using CREATE DATABASE with a datashare

The following syntax describes the CREATE DATABASE command used to create databases from a datashare for sharing data within the same AWS account.

```

CREATE DATABASE database_name
[ [ WITH PERMISSIONS ] FROM DATASHARE datashare_name ] OF [ ACCOUNT account_id ]
NAMESPACE namespace_guid

```

The following syntax describes the CREATE DATABASE command used to create databases from a datashare for sharing data across AWS accounts.

```

CREATE DATABASE database_name
[ [ WITH PERMISSIONS ] FROM DATASHARE datashare_name ] OF ACCOUNT account_id
NAMESPACE namespace_guid

```

Parameters for using CREATE DATABASE with a datashare

FROM DATASHARE

A keyword that indicates where the datashare is located.

datashare_name

The name of the datashare that the consumer database is created on.

WITH PERMISSIONS

Specifies that the database created from the datashare requires object-level permissions to access individual database objects. Without this clause, users or roles granted the USAGE permission on the database will automatically have access to all database objects in the database.

NAMESPACE *namespace_guid*

A value that specifies the producer namespace that the datashare belongs to.

ACCOUNT *account_id*

A value that specifies the producer account that the datashare belongs to.

Usage notes for CREATE DATABASE for data sharing

As a database superuser, when you use CREATE DATABASE to create databases from datashares within the AWS account, specify the NAMESPACE option. The ACCOUNT option is optional. When you use CREATE DATABASE to create databases from datashares across AWS accounts, specify both the ACCOUNT and NAMESPACE from the producer.

You can create only one consumer database for one datashare on a consumer cluster. You can't create multiple consumer databases referring to the same datashare.

CREATE DATABASE from AWS Glue Data Catalog

To create a database using an AWS Glue database ARN, specify the ARN in your CREATE DATABASE command.

```
CREATE DATABASE sampledb FROM ARN <glue-database-arn> WITH NO DATA CATALOG SCHEMA;
```

Optionally, you can also supply a value into the IAM_ROLE parameter. For more information about the parameter and accepted values, see [Parameters](#).

The following are examples that demonstrate how to create a database from an ARN using an IAM role.

```
CREATE DATABASE sampledb FROM ARN <glue-database-arn> WITH NO DATA CATALOG SCHEMA
IAM_ROLE <iam-role-arn>
```

```
CREATE DATABASE sampledb FROM ARN <glue-database-arn> WITH NO DATA CATALOG SCHEMA
IAM_ROLE default;
```

You can also create a database using a DATA CATALOG SCHEMA.

```
CREATE DATABASE sampledb FROM ARN <glue-database-arn> WITH DATA CATALOG SCHEMA
<sample_schema> IAM_ROLE default;
```

Create databases to receive results of zero-ETL integrations

To create a database using a zero-ETL integration identity, specify the `integration_id` in your `CREATE DATABASE` command.

```
CREATE DATABASE destination_db_name FROM INTEGRATION 'integration_id';
```

For example, first, retrieve the integration ids from `SVV_INTEGRATION`;

```
SELECT integration_id FROM SVV_INTEGRATION;
```

Then use one of the integration ids retrieved to create the database that receives zero-ETL integrations.

```
CREATE DATABASE sampledb FROM INTEGRATION 'a1b2c3d4-5678-90ab-cdef-EXAMPLE11111';
```

CREATE DATABASE limits

Amazon Redshift enforces these limits for databases:

- Maximum of 60 user-defined databases per cluster.
- Maximum of 127 bytes for a database name.
- A database name can't be a reserved word.

Database collation

Collation is a set of rules that defines how database engine compares and sorts the character type data in SQL. Case-insensitive collation is the most commonly used collation. Amazon Redshift uses case-insensitive collation to facilitate migration from other data warehouse systems. With the native support of case-insensitive collation, Amazon Redshift continues to use important tuning or optimization methods, such as distribution keys, sort keys, or range restricted scan.

The COLLATE clause specifies the default collation for all CHAR and VARCHAR columns in the database. If CASE_INSENSITIVE is specified, all CHAR or VARCHAR columns use case-insensitive collation. For information about collation, see [Collation sequences](#).

Data inserted or ingested in case-insensitive columns will keep its original case. But all comparison-based string operations including sorting and grouping are case-insensitive. Pattern matching operations such as LIKE predicates, similar to, and regular expression functions are also case-insensitive.

The following SQL operations support applicable collation semantics:

- Comparison operators: =, <>, <, <=, >, >=.
- LIKE operator
- ORDER BY clauses
- GROUP BY clauses
- Aggregate functions that use string comparison, such as MIN and MAX and LISTAGG
- Window functions, such as PARTITION BY clauses and ORDER BY clauses
- Scalar functions greatest() and least(), STRPOS(), REGEXP_COUNT(), REGEXP_REPLACE(), REGEXP_INSTR(), REGEXP_SUBSTR()
- Distinct clause
- UNION, INTERSECT and EXCEPT
- IN LIST

For external queries, including Amazon Redshift Spectrum and Aurora PostgreSQL federated queries, collation of VARCHAR or CHAR column is the same as the current database-level collation.

The following example queries a Amazon Redshift Spectrum table:

```
SELECT ci_varchar FROM spectrum.test_collation
```

```
WHERE ci_varchar = 'AMAZON';

ci_varchar
-----
amazon
Amazon
AMAZON
AmaZon
(4 rows)
```

For information on how to create tables using database collation, see [CREATE TABLE](#).

For information on the COLLATE function, see [COLLATE function](#).

Database collation limitations

The following are limitations when working with database collation in Amazon Redshift:

- All system tables or views, including PG catalog tables and Amazon Redshift system tables are case-sensitive.
- When consumer database and producer database have different database-level collations, Amazon Redshift doesn't support cross-database and cross-cluster queries.
- Amazon Redshift doesn't support case-insensitive collation in leader node-only query.

The following example shows an unsupported case-insensitive query and the error that Amazon Redshift sends:

```
SELECT collate(username, 'case_insensitive') FROM pg_user;
ERROR: Case insensitive collation is not supported in leader node only query.
```

- Amazon Redshift doesn't support interaction between case-sensitive and case-insensitive columns, such as comparison, function, join, or set operations.

The following examples show errors when case-sensitive and case-insensitive columns interact:

```
CREATE TABLE test
  (ci_col varchar(10) COLLATE case_insensitive,
   cs_col varchar(10) COLLATE case_sensitive,
   cint int,
   cbigint bigint);
```

```
SELECT ci_col = cs_col FROM test;  
ERROR: Query with different collations is not supported yet.
```

```
SELECT concat(ci_col, cs_col) FROM test;  
ERROR: Query with different collations is not supported yet.
```

```
SELECT ci_col FROM test UNION SELECT cs_col FROM test;  
ERROR: Query with different collations is not supported yet.
```

```
SELECT * FROM test a, test b WHERE a.ci_col = b.cs_col;  
ERROR: Query with different collations is not supported yet.
```

```
Select Coalesce(ci_col, cs_col) from test;  
ERROR: Query with different collations is not supported yet.
```

```
Select case when cint > 0 then ci_col else cs_col end from test;  
ERROR: Query with different collations is not supported yet.
```

- Amazon Redshift doesn't support collation for SUPER data type. Creating SUPER columns in case-insensitive databases and interactions between SUPER and case-insensitive columns aren't supported.

The following example creates a table with the SUPER as the data type in the case-insensitive database:

```
CREATE TABLE super_table (a super);  
ERROR: SUPER column is not supported in case insensitive database.
```

The following example queries data with a case-insensitive string comparing with the SUPER data:

```
CREATE TABLE test_super_collation  
(s super, c varchar(10) COLLATE case_insensitive, i int);
```

```
SELECT s = c FROM test_super_collation;  
ERROR: Coercing from case insensitive string to SUPER is not supported.
```

To make these queries work, use the `COLLATE` function to convert collation of one column to match the other. For more information, see [COLLATE function](#).

Examples

Creating a database

The following example creates a database named `TICKIT` and gives ownership to the user `DWUSER`.

```
create database tickit
with owner dwuser;
```

To view details about databases, query the `PG_DATABASE_INFO` catalog table.

```
select datname, datdba, datconlimit
from pg_database_info
where datdba > 1;
```

datname	datdba	datconlimit
admin	100	UNLIMITED
reports	100	100
tickit	100	100

The following example creates a database named `sampledb` with `SNAPSHOT` isolation level.

```
CREATE DATABASE sampledb ISOLATION LEVEL SNAPSHOT;
```

The following example creates the database `sales_db` from the datashare `salesshare`.

```
CREATE DATABASE sales_db FROM DATASHARE salesshare OF NAMESPACE
'13b8833d-17c6-4f16-8fe4-1a018f5ed00d';
```

Database collation examples

Creating a case-insensitive database

The following example creates the `sampledb` database, creates the `T1` table, and inserts data into the `T1` table.

```
create database sampledb collate case_insensitive;
```

Connect to the new database that you just created using your SQL client. When using Amazon Redshift query editor v2, choose the `sampledb` in the **Editor**. When using RSQL, use a command like the following.

```
\connect sampledb;
```

```
CREATE TABLE T1 (  
  col1 Varchar(20) distkey sortkey  
);
```

```
INSERT INTO T1 VALUES ('bob'), ('john'), ('Mary'), ('JOHN'), ('Bob');
```

Then the query finds results with John.

```
SELECT * FROM T1 WHERE col1 = 'John';  
  
 col1  
-----  
 john  
 JOHN  
(2 row)
```

Ordering in a case-insensitive order

The following example shows the case-insensitive ordering with table T1. The ordering of *Bob* and *bob* or *John* and *john* is nondeterministic because they are equal in case-insensitive column.

```
SELECT * FROM T1 ORDER BY 1;  
  
 col1  
-----  
 bob  
 Bob  
 JOHN  
 john  
 Mary  
(5 rows)
```

Similarly, the following example shows case-insensitive ordering with the GROUP BY clause. *Bob* and *bob* are equal and belong to the same group. It is nondeterministic which one shows up in the result.

```
SELECT col1, count(*) FROM T1 GROUP BY 1;
```

```
col1 | count
-----+-----
Mary | 1
bob  | 2
JOHN | 2
(3 rows)
```

Querying with a window function on case-insensitive columns

The following example queries a window function on a case-insensitive column.

```
SELECT col1, rank() over (ORDER BY col1) FROM T1;
```

```
col1 | rank
-----+-----
bob  | 1
Bob  | 1
john | 3
JOHN | 3
Mary | 5
(5 rows)
```

Querying with the DISTINCT keyword

The following example queries the T1 table with the DISTINCT keyword.

```
SELECT DISTINCT col1 FROM T1;
```

```
col1
-----
bob
Mary
john
(3 rows)
```

Querying with the UNION clause

The following example shows the results from the UNION of the tables T1 and T2.

```
CREATE TABLE T2 AS SELECT * FROM T1;
```

```
SELECT col1 FROM T1 UNION SELECT col1 FROM T2;
```

```
col1  
-----  
john  
bob  
Mary  
(3 rows)
```

CREATE DATASHARE

Creates a new datashare in the current database. The owner of this datashare is the issuer of the CREATE DATASHARE command.

Amazon Redshift associates each datashare with a single Amazon Redshift database. You can only add objects from the associated database to a datashare. You can create multiple datashares on the same Amazon Redshift database.

For information about datashares, see [Managing data sharing tasks](#).

To view information about the datashares, use [SHOW DATASHARES](#).

Required privileges

Following are required privileges for CREATE DATASHARE:

- Superuser
- Users with the CREATE DATASHARE privilege
- Database owner

Syntax

```
CREATE DATASHARE datashare_name  
[[SET] PUBLICACCESSIBLE [=] TRUE | FALSE ];
```

Parameters

datashare_name

The name of the datashare. The datashare name must be unique in the cluster namespace.

[[SET] PUBLICACCESSIBLE]

A clause that specifies whether the datashare can be shared to clusters that are publicly accessible.

The default value for SET PUBLICACCESSIBLE is FALSE.

Usage notes

By default, the owner of the datashare only owns the share but not objects within the share.

Only superusers and the database owner can use CREATE DATASHARE and delegate ALTER privileges to other users or groups.

Examples

The following example creates the datashare salesshare.

```
CREATE DATASHARE salesshare;
```

The following example creates the datashare demoshare that AWS Data Exchange manages.

```
CREATE DATASHARE demoshare SET PUBLICACCESSIBLE TRUE, MANAGEDBY ADX;
```

CREATE EXTERNAL FUNCTION

Creates a scalar user-defined function (UDF) based on AWS Lambda for Amazon Redshift. For more information about Lambda user-defined functions, see [Scalar Lambda UDFs](#).

Required privileges

Following are required privileges for CREATE EXTERNAL FUNCTION:

- Superuser

- Users with the CREATE [OR REPLACE] EXTERNAL FUNCTION privilege

Syntax

```
CREATE [ OR REPLACE ] EXTERNAL FUNCTION external_fn_name ( [data_type] [, ...] )
RETURNS data_type
{ VOLATILE | STABLE }
LAMBDA 'lambda_fn_name'
IAM_ROLE { default | 'arn:aws:iam::<AWS account-id>:role/<role-name>' }
RETRY_TIMEOUT milliseconds
MAX_BATCH_ROWS count
MAX_BATCH_SIZE size [ KB | MB ];
```

Parameters

OR REPLACE

A clause that specifies that if a function with the same name and input argument data types, or *signature*, as this one already exists, the existing function is replaced. You can only replace a function with a new function that defines an identical set of data types. You must be a superuser to replace a function.

If you define a function with the same name as an existing function but a different signature, you create a new function. In other words, the function name is overloaded. For more information, see [Overloading function names](#).

external_fn_name

The name of the external function. If you specify a schema name (such as `myschema.myfunction`), the function is created using the specified schema. Otherwise, the function is created in the current schema. For more information about valid names, see [Names and identifiers](#).

We recommend that you prefix all UDF names with `f_`. Amazon Redshift reserves the `f_` prefix for UDF names. By using the `f_` prefix, you help ensure that your UDF name won't conflict with any built-in SQL function names for Amazon Redshift now or in the future. For more information, see [Preventing UDF naming conflicts](#).

data_type

The data type for the input arguments. For more information, see [Data types](#).

RETURNS *data_type*

The data type of the value returned by the function. The RETURNS data type can be any standard Amazon Redshift data type. For more information, see [Python UDF data types](#).

VOLATILE | STABLE

Informs the query optimizer about the volatility of the function.

To get the best optimization, label your function with the strictest volatility category that is valid for it. In order of strictness, beginning with the least strict, the volatility categories are as follows:

- VOLATILE
- STABLE

VOLATILE
