## ABSTRACT

Continuous Group Key Agreement (CGKA) – or Group Ratcheting – lies at the heart of a new generation of *scalable* End-to-End secure (E2E) cryptographic multi-party applications. One of the most important (and first deployed) CGKAs is ITK which underpins the IETF’s upcoming Messaging Layer Security E2E secure group messaging standard. To scale beyond the group sizes possible with earlier E2E protocols, a central focus of CGKA protocol design is to minimize bandwidth requirements (i.e. communication complexity).

In this work, we advance both the theory and design of CGKA culminating in an extremely bandwidth efficient CGKA. To that end, we first generalize the standard CGKA communication model by introducing *server-aided* CGKA (saCGKA) which generalizes CGKA and more accurately models how most E2E protocols are deployed in the wild. Next, we introduce the SAIK protocol; a modification of ITK, designed for real-world use, that leverages the new capabilities available to an saCGKA to greatly reduce its communication (and computational) complexity in practical concrete terms.

Further, we introduce an intuitive, yet precise, security model for saCGKA. It improves upon existing security models for CGKA in several ways. It more directly captures the intuitive security goals of CGKA. Yet, formally it also relaxes certain requirements allowing us to take advantage of the saCGKA communication model. Finally, it is significantly simpler making it more tractable to work with and easier to build intuition for. As a result, the security proof of SAIK is also simpler and more modular.

Finally, we provide empirical data comparing the (at times, quite dramatically improved) complexity profile of SAIK to state-of-the-art CGKAs. For example, in a newly created group with 10K members, to change the group state (e.g. add/remove parties) ITK requires each group member download 1.38MB. However, with SAIK, members download no more than 2.7KB.

## 1 INTRODUCTION

End-to-end (E2E) secure applications have become one of the most widely used class of cryptographic applications on the internet with billions of daily users. Accordingly, the E2E protocols upon which these applications are built have evolved over several distinct generations, adding functionality and new security guarantees along the way. Modern protocols are generally expected to support features like multi-device accounts, continuous refreshing of secrets and asynchronous communication. Here, *asynchronous* refers to the property that parties can communicate even when they are not simultaneously online. To make this possible, the network provides an (untrusted) mailboxing service for buffering packets until recipients come online.

The growing demand for E2E security motivates increasingly capable E2E protocols; in particular, supporting ever larger groups. For example, in the enterprise setting organizations regularly have natural sub-divisions with far more members than practically supported by today’s real-world E2E protocols. Support for large groups opens the door to entirely new applications; especially in the realm of machine-to-machine communication such as in mesh networks and IoT. The desire for large groups is compounded by the fact that many applications treat each device registered to an account as a separate party at the E2E protocol level. For example, a private chat between Alice and Bob who each have a phone and laptop registered to their accounts is actually a 4-party chat from the point of view of the underlying E2E protocol.

*Next Generation E2E Protocols.* The main reason current protocols (at least those enjoying state-of-the-art security, e.g. post compromise forward security) only support small groups is that their communication cost grows linearly in the group size. This has imposed limits on real-world group sizes (generally at or below 1000 members).

Consequently, a new generation of E2E protocols is being developed both in academia (e.g. [1, 3–5, 7, 9, 26, 31]) and industry [14]. Their primary design goal is to support extremely large groups (e.g. 10s of thousands of users) while still meeting, or exceeding, the security and functionality of today’s state-of-the-art deployed E2E protocols. Technically, the new protocols do this by reducing their communication complexity to *logarithmic* in the group size; albeit, only under favorable conditions in the execution. This informal property is sometimes termed the *fair-weather complexity*.

To date, the most important of these new E2E protocols is the IETF’s upcoming secure group messaging (SGM) standard called the *Messaging Layer Security* (MLS) protocol. MLS is in the final stages of standardization and its core components are already seeing initial deployment [25].

*Continuous Group Key Agreement.* To the best of our knowledge, all next gen. E2E protocols share the following basic design paradigm. At their core lies a *Continuous Group Key Agreement* (CGKA) protocol; a generalization to the group setting of the *Continuous Key Agreement* 2-party primitive [4, 28] underlying the Double Ratchet.

Intuitively, a CGKA protocol provides *E2E secure group management* for dynamic groups, i.e., groups whose properties may change mid-session. By properties we mean things like the set of members

currently in the group, their attributes, the group name, the set of moderators, etc. Any change to a group’s properties initiates a fresh *epoch* in the session. A CGKA protocol ensures all group members in an epoch agree on the group’s current properties. Members will only transition to the same next epoch if they agree on which properties were changed and by whom. Each epoch is equipped with its own symmetric *epoch key* known to all epoch members but indistinguishable from random to anyone else. Higher-level protocols typically (deterministically) expand the epoch key into a complete key schedule which in turn can be used to, say, protect application data sent between members (e.g. messages or VoIP data).

MLS too, is (implicitly) based on a CGKA, originally dubbed *TreeKEM* [17]. Since its inception, TreeKEM has undergone several substantial revisions [11, 12] before reaching its current form [9, 13]. For clarity, we refer to its current version at the time of this writing as *Insider-Secure TreeKEM* (ITK) (using the terminology of [9] where that version was analyzed). ITK has already seen its first real world deployment as a core component of Cisco’s Webex conferencing protocol [25].

*Why Consider CGKA?* CGKA is interesting because of the following two observations. First, CGKA seems to be the minimal functionality encapsulating almost all of the cryptographic challenges inherent to building next generation E2E protocols. Second, building typical higher-level E2E applications (e.g. SGM or conference calling) from a CGKA can be done via relatively generic, and comparatively straightforward mechanisms. Moreover, the resulting application directly inherits many of its key properties from the underlying CGKA; notably their security guarantees and their communication and computational complexities. In this regard, CGKA is to, say, SGM what a KEM is to hybrid PKE. For the case of SGM, this intuitive paradigm and the relationship between properties of the CGKA and resulting SGM was made formal in [6]. In particular, that work abstracts and generalizes MLS’s construction from ITK.

### 1.1 Our Contributions

This work makes progress on the central challenge in CGKA protocol design: reducing communication complexity so as to support larger groups (without compromising on security or functionality).

*Server-Aided CGKA.* We begin by revisiting one of the most basic assumptions about CGKA in prior work; namely that participants communicate via an insecure broadcast channel. Instead, we note that in almost all modern deployments of E2E protocols parties actually communicate via an untrusted mailboxing service implemented using an (often highly scalable) *server*. In light of this, we modify the standard communication model to make the server explicit. We define a generalization of CGKA called *server-aided CGKA* (saCGKA). In contrast to CGKA, an saCGKA protocol includes an *Extract* procedure run by the server to convert a “full packet” uploaded by a sender into an individualized “sub-packet” for a particular recipient. CGKA corresponds to the special case where the full and individual packets are the same. Intuitively, the server remains untrusted and security should hold no matter what it does. However, should it choose to follow the Extract procedure, the saCGKA protocol additionally ensures correctness and availability.

*Security for CGKA.* We define a new security notion for (sa)CGKA capturing the same intuitive guarantees as those shown for ITK [9] for example. Like other notions based on the history graph paradigm of [6], our notion is parameterized by *safety* predicates that together decide the security of a given epoch key in a given execution.

However, at a technical level our notion departs significantly from past ones. Essentially, it relaxes the requirement that group members in an epoch agree on and authenticate the *history of network traffic* leading to the epoch. Instead, the new notion “only” ensures they agree on and authenticate the *semantics* of the history; i.e. the “meaning” of the traffic rather than exact packet contents. This has several interesting consequences. First, it more directly captures our intuitive security goals. E.g. it avoids subtle questions about what intuition is really captured when, say, an AEAD ciphertext in a packet can be decrypted to different plaintexts using different keys.<sup>1</sup> Second, the relaxation creates wiggle room we can use to prove security despite group members no longer having the same view of network traffic. Finally, it allows us to relax the security of the encryption scheme used in our construction from CCA to *replayable CCA* (RCCA) [23].<sup>2</sup>

Further, the new saCGKA security notion is significantly simpler (though just as precise) compared to past ones. Indeed, past notions have been criticised for being all but inaccessible to non-domain experts due to their complexity. In an effort to improve this, our new notion omits/simplifies various security features of a CGKA as long as A) they can be formalized using known techniques and B) they can be easily achieved by known, practical and straightforward extensions of a generic CGKA protocol (including SAIK) satisfying our notion. Thus we obtain a definition focused on the basic properties of an (sa)CGKA with the idea that a protocol satisfying our notion can easily be extended to a “full-fledged” (sa)CGKA using standard techniques.

*The SAIK Protocol.* Next, we introduce a new saCGKA protocol called *Server-Aided ITK* (SAIK), designed for real-world use. For example, it relies exclusively on standard cryptographic primitives and can be implemented using the API of various off-the-shelf cryptographic libraries. To obtain SAIK, we start with ITK and make the following modifications.

*Multi-message multi-recipient PKE.* First, we replace ITK’s use of standard (CCA secure) PKE by multi-message multi-recipient PKE (mmPKE) [36]. mmPKE has the functionality of a parallel composition of standard PKE schemes (both in terms of ciphertext sizes and computation cost of encryption). Constructing mmPKE directly can result in a significantly more efficient scheme.

We introduce a new security notion for mmPKE, more aligned with the needs of (the security targeted by) SAIK. It both strengthens and weakens past notions: On the one hand, proving SAIK secure demands that we equip the mmPKE adversary of [36] with adaptive key compromise capabilities. On the other hand, thanks to the relaxation to semantic agreement, we “only” require RCCA security rather than full-blown CCA used in previous works [7, 9].

<sup>1</sup>This can happen for widely used AEADs like AES-GCM [27].

<sup>2</sup>This makes sense as RCCA was designed to relax the “syntactic non-malleability” of CCA to a form of “semantic non-malleability”.

We prove that the mmPKE construction of [36] satisfies our new notion based on a form of gap Diffie-Hellman assumption, the same as in [36]. The reduction is tight in that the security loss is independent of the number of parties (i.e. key pairs) in the execution (although it does depend on the number of corrupted key pairs). Moreover, we extend the proof to capture mmPKE constructions based on “nominal groups” [2]. Nominal groups abstract the algebraic structure over bit-strings implicit to the X25519 and X448 scalar multiplication functions and corresponding twisted Edwards curves.[35]. In practical terms, this means our proofs also apply to instantiations of [36] based on the X25519 and X448 functions.

*Authentication.* Second, we modify the mechanisms used by ITK to ensure members transitioning to a new epoch authenticate the sender announcing a new epoch. Rather than sign the full packet like in ITK, the sender in SAIK only signs a small tag which “binds” all salient properties of the new epoch, i.e., its secrets, the set of group members, the history of applied operations, etc. In fact, we use a tag that already exists in ITK (called the “confirmation tag”).

*Performance Evaluation.* Finally, we compare the communication complexity of SAIK, ITK and the CGKA of [31] called CmPKE. We break down the communication cost into sender and receiver bandwidth, i.e., the size of a packet uploaded, resp., downloaded (by one receiver) from the server. This metric reflects the resources needed from an individual client.

We note that the sender bandwidth of CmPKE grows linearly in the group size, while for SAIK and ITK it varies depending on both the group size and the history of preceding operations. Meanwhile, the receiver bandwidth is independent of both the size and the history for CmPKE, grows logarithmically in the group size for SAIK and varies with both the size and history for ITK.

We find that compared to ITK, SAIK always requires less bandwidth (regardless of history and group size). However, compared to CmPKE, SAIK requires slightly more receiver bandwidth but anywhere from the same to far less sender bandwidth. Concretely, in a group with 10K parties, CmPKE’s sender bandwidth is 0.8MB while SAIK and ITK’s bandwidths range between 3.6KB - 0.8MB and 4.4KB - 1.5MB, respectively (depending on the history). Meanwhile for receivers CmPKE and SAIK require 0.8KB and 2KB respectively while ITK requires between 4.4KB - 1.5MB.

In addition, we also compare the total bandwidth considered in [31], i.e., the size of the uploaded packet and all downloaded packets together. This metric reflects the resources required from the server, or equivalently from all clients together. We find that SAIK requires more total bandwidth than CmPKE but *much* less than ITK.

*Outline.* The paper is structured as follows. Sec. 2 (and App. A) covers preliminaries. Sec. 3 focuses on mmPKE. Sec. 4 describes the new security model for saCGKA with details outsourced to App. D. Sec. 5 describes the SAIK protocol with details found in App. F. Sec. 6 formally states SAIK’s security. Sec. 7 contains empirical evaluation and comparison of SAIK to previous constructions. Finally, Sec. 8 contains extensions to stronger security guarantees. Finally, SAIK’s security proof is formalized in App. H.

## 1.2 Related Work

*Next generation CGKA protocols.* The study of next generation CGKA protocols for very large groups was initiated by Cohn-Gorden et al. in [26]. This was soon followed by the first version of TreeKEM [37] which evolved to add stronger security [11, 37, 39] and more flexible functionality [12] culminating in its current form ITK [9] reflected in the current draft of the MLS RFC [13].

Reducing the communication complexity of TreeKEM and its descendants is not a new goal. *Tainted TreeKEM* [3] exhibits an alternate complexity profile optimized for a setting where the group is managed by a small set of moderators. Recently, [1] introduced new techniques for ‘multi-group’ CGKAs (i.e. CGKAs that explicitly accommodate multiple, possibly intersecting, groups) with better complexity than obtained by running a ‘single-group’ CGKA for each group. Other work has focused on stronger security notions for CGKA both in theory [7] and with an eye towards practice [5, 9]. Supporting more concurrency has also been a topic of focus as witnessed by the protocols in [12, 19, 40]. Recently [30] present CGKA with novel membership hiding properties.

*Cryptographic models of CGKA security.* Defining CGKA security in a simple yet meaningful way has proven to be a serious challenge. Many notions fall short in at least one of the two following senses. Either they do not capture key guarantees desired (and designed for) by practitioners (such as providing guarantees to newly joined members) or they place unrealistic constraints on the adversary. Above all, they do not consider fully active adversaries. For instance, in [3], the adversary is not allowed to modify packets while in [5, 6], new packets can be injected but only when authenticity can be guaranteed despite past corruptions (thus limiting what is captured about how session’s regain security after corruptions). Meanwhile, the work of [20] permits a large class of active attacks but only in the context of the key derivation process of ITK. So while their adversaries can arbitrarily modify secrets in an honest party’s key derivation procedure, they can not deliver arbitrary packets to honest parties. This is a significant limitation, e.g., it does not capture adversaries that deliver packets with ciphertexts for which they do not know the plaintexts.

Indeed, a good indication that such simplifications can be problematic can be found in [9]. They present an attack on TreeKEM (that can easily be adapted to the CGKAs in the above works except for [20]) which uses honest group members as decryption oracles to clearly violate the intuitive security expected of a CGKA. Yet, each of the above works (except for [20]) proves security of their CGKA using only IND-CPA secure encryption.

In contrast to the above works, [7] aimed to capture the full capabilities a realistic adversary might have. Thus, they model a fully active adversary that can leak parties local states at will and even set their random coins. In [9] this setting is extended to capture *insider* security. That is adversaries which can additionally corrupt the PKI. This captures the standard design criterion for deployed E2E applications that key servers are *not* considered trusted third parties. Unfortunately, this level of real-world accuracy has resulted in a (probably somewhat inherently) complicated model.

*Symbolic models of CGKA security.* Complementing the above line of work, several versions of TreeKEM have been analyzed using

a symbolic approach and automated provers [18]. Their models consider fully active attackers and capture relatively wide ranging security properties which the authors are able to convincingly tackle by using automated proofs.

*The CGKA of [31].* The work [31] presents a variant of CGKA, called here *filtered* CGKA (fCGKA), along with a protocol called CmpPKE. In fCGKA, like in saCGKA, receivers download personalized sub-packets. However, fCGKA achieves this differently — an uploaded fCGKA packet has a particular form, namely, a header delivered to all receivers, followed by a number of ciphertexts, one for each receiver. Note that fCGKA is a special case of saCGKA where the Extract procedure outputs the header and the receiver’s ciphertext.

The fCGKA security notion in [31] is essentially the model of [9]. The only difference is that [9] requires agreement on the history of the network packets leading to a given epoch. To adapt this to the fCGKA syntax, [31] requires instead agreement on the history of *packet headers*. Compared to our saCGKA notion, this is still syntactic agreement and e.g., requires CCA security. See Sec. 4.5.

Regarding the communication cost, CmpPKE is designed to reduce the *total bandwidth*, i.e., for an operation, it minimizes the size of the sent packet and all downloaded packets together. In contrast, SAIK is designed to reduce the *maximum bandwidth*, i.e., it minimizes the size of each sent or downloaded packet. Accordingly, CmpPKE has smaller total bandwidth than SAIK. In fact, the maximum size of a downloaded packet is also smaller for CmpPKE. However, the size of a sent packet is usually much bigger for CmpPKE. In summary, SAIK is designed to support clients with poor bandwidth, i.e., it minimizes the size of a single uploaded or downloaded packet. Thus, while the server load is a bit higher, the network requirements for clients are usually much lower.

*mmpPKE.* mmpPKE was introduced by Kurosawa [34] though their security model was flawed as pointed out and fixed by Bellare et.al [15, 16]. Yet, those works too lacked generality as they demanded malicious receivers know a secret key for their public key. This restriction was lifted by Poettering et.al. in [36] who show that well-known PKE schemes such as ElGamal[29] are secure even when reusing coins across ciphertexts. Indeed, reusing coins this way can also reduce the computational complexity of encapsulation and the size of ciphertexts for KEMs as shown in the Multi-Recipient KEM (mKEM) of [24, 33, 38] for example. All previous security notions (for mmpPKE and mKEM) allow an adversary to provide malicious keys (with or without knowing corresponding secret keys), but only [31] allows for adaptive corruption of honest keys, which is necessary for ITK’s security against adaptive adversaries.

## 2 NOTATION

For  $n \in \mathbb{Z}$ , we define  $[n] := \{1, 2, \dots, n\}$ . We write  $x \stackrel{\$}{\leftarrow} X$  for sampling an element  $x$  uniformly at random from a (finite) set  $X$  as well as for the output of a randomized algorithm, i.e.  $x \stackrel{\$}{\leftarrow} A(y)$  denotes the output of the probabilistic algorithm  $A$  on input  $y$  using fresh random coins. For a deterministic algorithm  $A$ , we write  $x = A(y)$ . Adding an element  $y$  to a set  $Y$  is denoted by  $Y \leftarrow y$  and appending an entry  $z$  to a list  $L$  is written as  $Z \leftarrow z$ . Appending a whole list  $L_2$  to a list  $L_1$  is denoted by  $L_1 \leftarrow L_2$ . For a vector  $\vec{x}$ , we

denote its length as  $|\vec{x}|$  and  $\vec{x}[i]$  denotes the  $i$ -th element of  $\vec{x}$  for  $i \in [|\vec{x}|]$ . Note that we use vectors as in programming, i.e. we don't require any algebraic structure on them. For clarity, we use  $\text{len}$  to denote the length of collections.

### 3 MULTI-MESSAGE MULTI-RECIPIENT PKE

We first recall the syntax of mmPKE from [16]. At a high level, mmPKE is standard encryption that supports batching a number of encryption operations together, in order to improve efficiency.<sup>3</sup>

*Definition 3.1 (mmPKE).* A Multi-Message Multi-Receiver Public Key Encryption (mmPKE) scheme  $\text{mmPKE} = (\text{KG}, \text{Enc}, \text{Dec}, \text{Ext})$  consists of the following four algorithms:

$\text{KG} \xrightarrow{\$} (\text{ek}, \text{dk})$ : Generates a new key pair.

$\text{Enc}(\vec{\text{ek}}, \vec{m}) \xrightarrow{\$} C$ : On input of a vector of public keys  $\vec{\text{ek}}$  and a vector of messages  $\vec{m}$  of the same length, outputs a *multi-recipient ciphertext*  $C$  encrypting each message in  $\vec{m}$  to the corresponding key in  $\vec{\text{ek}}$ .

$\text{Ext}(C, i) \rightarrow c_i$ : A deterministic function. On input of a multi-recipient ciphertext  $C$  and a position index  $i$ , outputs an *individual ciphertext*  $c_i$  for the  $i$ -th recipient.

$\text{Dec}(\text{dk}, c) \rightarrow m \vee \perp$ : On input of an individual ciphertext  $c$  and a secret key  $\text{dk}$ , outputs either the decrypted message  $m$  or, in case decryption fails,  $\perp$ .

#### 3.1 Security with Adaptive Corruptions

Our security notion for mmPKE, called mmIND-RCCA, requires indistinguishability in the presence of active adversaries who can adaptively corrupt secret keys of recipients. The notion builds upon the (strengthened) IND-CCA security of mmPKE from [36], but there are two important differences: First, [36] does not consider corruptions. Second, instead of CCA, we define the slightly weaker notion of Replayable CCA (RCCA). Roughly, RCCA [23] is the same as CCA except modifying a ciphertext so that it encrypts the exact same message is not considered an attack. RCCA security is implied by CCA security.

We note that an almost identical security definition was presented in parallel by Hashimoto et.al.[31]. However, they only consider multi-recipient PKE (mPKE), where all recipients receive the same message.

mmIND-RCCA is similar to RCCA security of regular encryption in the multi-user setting. The main difference is that the challenge ciphertext is computed by encrypting one of two *vectors* of messages  $\vec{m}_0^*$  and  $\vec{m}_1^*$  under a *vector* of public keys  $\vec{\text{ek}}^*$ . The vector  $\vec{\text{ek}}^*$  is chosen by the adversary and can contain keys generated by the challenger as well as arbitrary keys. The adversary also gets access to standard decrypt and corrupt oracles for each recipient. To disable trivial wins, we require that  $\vec{m}_0^*$  and  $\vec{m}_1^*$  have equal lengths and that if the  $i$ -th key in  $\vec{\text{ek}}^*$  is corrupted, then the  $i$ -th components of  $\vec{m}_0^*$  and  $\vec{m}_1^*$  are identical. Moreover, we require that for each  $i$ , the lengths of the  $i$ -th components of  $\vec{m}_0^*$  and  $\vec{m}_1^*$  are the same.

The last requirement means that a secure mmPKE scheme may leak the lengths of components of encrypted vectors. We note that

<sup>3</sup>The majority of works on mmPKE uses a different syntax, where there is no Ext and instead Enc outputs a vector of individual ciphertexts. Since Ext is deterministic, the syntaxes are equivalent.

SAIK is also secure when instantiated with an mmPKE scheme that leaks more (see App. G), e.g. whether two messages in a vector are the same. The formal definitions are in App. A.3.

#### 3.2 Construction

The mmPKE of [36] is straightforward. It requires a data encapsulation scheme DEM, a hash  $H$  and a group  $\mathbb{G}$  of prime order  $p$  generated by  $g$ .<sup>4</sup> Recall that ElGamal encryption of  $m$  to public key  $g^x$  requires sampling coins  $r$  to obtain ciphertext  $(g^r, \text{DEM}(k_m, m))$  where  $k_m = H(g^{rx}, g^x)$ . The mmPKE variant reuses coins  $r$  from the first ElGamal ciphertext to encrypt all subsequent plaintexts. Thus, the final ciphertext has the form  $(g^r, \text{DEM}(k_1, m_1), \text{DEM}(k_2, m_2), \dots)$  where  $k_i = H(g^{rx_i}, g^{x_i})$  for all  $i$ . We call the construction DH-mmPKE $[\mathbb{G}, g, p, \text{DEM}, H]$ ; a formal description is in App. B.

*Optimizing for Short Messages.* Normally, when messages  $m$  can have arbitrary size, a sensible mmPKE would use a KEM/DEM style construction to avoid having to re-encrypt  $m$  multiple times. In other words, for each  $m$  in the encrypted vector, we choose a fresh key  $k'_m$  for an AEAD and encrypt  $m$  with  $k'_m$ . Then use the mmPKE of [36] to encrypt  $k'_m$  to each public key receiving  $m$ . However, since the secrets encrypted in SAIK have the same length as AEAD keys, in our case it is more efficient to encrypt the secrets directly.

*Tight security bound.* In App. B, we prove the following upper bound on the advantage of any adversary against the mmPKE from [36]. Our bound is tighter than the bound that follows from the straightforward adaptation of the bound from [36] (i.e. using the hybrid argument and guessing the uncorrupted key). In particular, that bound would depend (linearly) on the total number of public keys, which may get very large. In contrast, our bound depends only on the number of corrupted keys and the length of encrypted vectors.

**THEOREM 3.2.** *Let  $\mathbb{G}$  be a group of prime order  $p$  with generator  $g$ , let DEM be a data encapsulation mechanism and let  $\text{mmPKE} = \text{DH-mmPKE}[\mathbb{G}, g, p, \text{DEM}, H]$ . For any adversary  $\mathcal{A}$  and any  $N \in \mathbb{N}$ , there exist adversaries  $\mathcal{B}_1$  and  $\mathcal{B}_2$  with runtime roughly the same as  $\mathcal{A}$ 's s.t.*

$$\text{Adv}_{\text{mmPKE}, N}^{\text{mmIND-RCCA}}(\mathcal{A}) \leq \text{Adv}_{\text{DEM}}^{\text{IND-RCCA}}(\mathcal{B}_2) + 2n \cdot (e^2 q_c \text{Adv}_{(\mathbb{G}, g, p)}^{\text{DSSDH}}(\mathcal{B}_1) + \frac{q_{d_1}}{p} + \frac{q_h}{p}),$$

where  $H$  is a random oracle,  $e$  is the Euler number,  $n$  is the length of the challenge vector, and  $q_{d_1}$ ,  $q_c$  and  $q_h$  are the number of queries to the decrypt and corrupt oracles and the random oracle, resp.

*Remark 1.* Some practical applications of Diffie-Hellman, most notably CURVE25519 and CURVE448 [35], implement a Diffie-Hellman operation that is not exponentiation in a prime-order group. Such operations can be formalized as so-called nominal groups [2]. In App. C, we generalize and prove Theorem 3.2 for nominal groups. In particular, this means that DH-mmPKE is secure if instantiated with CURVE25519 and CURVE448.

<sup>4</sup>In SAIK we can instantiate DEM with an off-the-shelf AEAD such as AES-GCM and  $H$  with HKDF.

## 4 SERVER-AIDED CGKA

In this section, we first explain the saCGKA syntax, i.e., the interface exposed by saCGKA protocols to higher-level applications. Then, we give intuitive security properties saCGKA protocols should provide and an overview of our saCGKA security model. For details, see App. D. Finally, we highlight the additional flexibility provided by semantic agreement of saCGKA and list simplifications it makes compared with previous works on active CGKA security [7, 9, 31].

### 4.1 Syntax

A saCGKA protocol allows a dynamic group of parties to agree on a continuous sequence of symmetric group keys. An execution of a saCGKA protocol proceeds in *epochs*. During each epoch, a fixed set of current group members shares a single group key. A group member can modify the group state, that is, create a new epoch, by sending a single message to the mailboxing service. Afterwards, each group member can download a possibly personalized message and, if they accept it, transition to the new epoch. Three types of group modifications are supported: adding a member, removing a member and updating, i.e., refreshing the group key.

### 4.2 Intuitive Security Properties

saCGKA protocols are designed for the setting with *active adversaries* who fully control the mailboxing service and repeatedly expose secret states of parties. Note that, unless some additional uncorruptible resources such as a trusted signing device are assumed, the above adversary subsumes the typical notion of malicious insiders (or actively corrupted parties in MPC).

To talk about security of saCGKA, we use the language of *history graphs* introduced in [6]. A history graph is a symbolic representation of group’s evolution. Nodes represent epochs and directed edges represent group modifications. For example, when Alice in epoch  $E$  wants to add Bob, she creates an epoch  $E'$  with an edge from  $E$  to  $E'$ . The graph also stores information about parties’ current epochs, the adversary’s actions, etc.

In a perfect execution, the history graph would be a chain. However, even for benign reasons, this may not be the case. For example, if two parties simultaneously create epochs, then a fork in the graph is created. Moreover, an active adversary can deliver different messages to different parties, causing them to follow different branches. Further, it can trick parties into joining fake groups it created by injecting invitation messages. Epochs in fake groups form what we call *detached trees*. So, in full generality, the graph is a directed forest. Using history graphs we can list intuitive security properties of saCGKA.

**Consistency** Any two parties in the same epoch  $E$  agree on the group state, i.e., the set of current members, the group key, the last group modification and the previous epoch. One consequence of consistency is agreement on the history: the parties reached  $E$  by executing the same sequence of group modifications since the latter one joined.

**Confidentiality** An epoch is confidential if the adversary has no information about its group key. Corruptions may destroy

confidentiality in certain epochs. saCGKA security is parameterized by a *confidentiality predicate* which identifies confidential epochs in an execution.

**Authenticity** Authenticity for a party  $A$  in an epoch  $E$  is preserved if the following holds: If a party in  $E$  transitions to a child epoch  $E'$  and identifies  $A$  as the sender creating  $E'$ , then  $A$  indeed created  $E'$ . An active adversary may destroy authenticity in certain cases. saCGKA security is parameterized by an *authenticity predicate* which decides if authenticity of a party  $A$  in epoch  $E$  is preserved.

The confidentiality and authenticity predicates generalize forward-secrecy and post-compromise security.

### 4.3 Authenticated Key Service (AKS)

Most CGKA protocols, including ITK and SAIK, rely on a type of PKI called here the Authenticated Key Service (AKS). The AKS authentically distributes so-called one-time key packages (also called key bundles or pre-keys) used to add new members to the group without interacting with them. For simplicity, we use an idealized AKS which guarantees that a fresh, authentic, honestly generated key package of any user is always available.

### 4.4 Formal Model Intuition

We define security of saCGKA protocols in the UC framework. That is, a saCGKA protocol is secure if no environment  $\mathcal{A}$  can distinguish between the real world where it interacts with parties executing the protocol and the ideal world where it interacts with the ideal saCGKA functionality and a simulator. Readers familiar with game-based security should think of  $\mathcal{A}$  as the adversary (see also [8] for some additional discussion).

*The real world.* In the real-world experiment, the following actions are available to  $\mathcal{A}$ : First, it can instruct parties to perform different group operations, creating new epochs. When this happens, the party runs the protocol, updates its state and hands to  $\mathcal{A}$  the message meant to be sent to the mailboxing service. The mailboxing service is fully controlled by  $\mathcal{A}$ . This means that the next action it can perform is to deliver arbitrary messages to parties. A party receiving such a message updates its state (or creates it in case of new members) and hands to  $\mathcal{A}$  the semantic of the group operation it applied. Moreover,  $\mathcal{A}$  can fetch from parties group keys computed according to their current states and corrupt them by exposing their current states.<sup>5</sup>

*The ideal world.* In the ideal-world experiment  $\mathcal{A}$  can perform the same actions, but instead of the protocol, parties use the ideal CGKA functionality,  $\mathcal{F}_{\text{CGKA}}$ . Internally,  $\mathcal{F}_{\text{CGKA}}$  maintains and dynamically extends a history graph. When  $\mathcal{A}$  instructs a party to perform a group operation, the party inputs Send to  $\mathcal{F}_{\text{CGKA}}$ . The functionality creates a new epoch in its history graph and hands to  $\mathcal{A}$  an idealized message. The message is chosen by an arbitrary simulator, which means that it is arbitrary. When  $\mathcal{A}$  delivers a message, the party inputs Receive to  $\mathcal{F}_{\text{CGKA}}$ . On such an input  $\mathcal{F}_{\text{CGKA}}$  first asks the simulator to identify the epoch into which the receiver transitions.

<sup>5</sup>To make this section accessible to readers not familiar with UC, we avoid technical details, which sometimes results in inaccuracies. E.g., parties are corrupted by the (dummy) adversary, not  $\mathcal{A}$ . We hope this doesn’t distract readers familiar with UC.

The simulator can either indicate an existing epoch or instruct  $\mathcal{F}_{\text{CGKA}}$  to create a new one. The latter ability should only be used if  $\mathcal{A}$  injects a message and, accordingly, epochs created this way are marked as injected. Afterwards,  $\mathcal{F}_{\text{CGKA}}$  hands to  $\mathcal{A}$  the semantics of the message, computed based on the graph. A corruption in the real world corresponds in the ideal world to  $\mathcal{F}_{\text{CGKA}}$  executing the procedure `Expose` and the simulator computing the corrupted party's state. When  $\mathcal{A}$  fetches the group key, the party inputs `GetKey` to  $\mathcal{F}_{\text{CGKA}}$ , which outputs a key from the party's epoch. The way keys are chosen is discussed next.

*Security guarantees in the ideal world.* To formalize confidentiality,  $\mathcal{F}_{\text{CGKA}}$  is parameterized by a predicate **confidential**, which determines the epochs in the history graph in which confidentiality of the group key is guaranteed. For such a confidential epoch,  $\mathcal{F}_{\text{CGKA}}$  chooses a random and independent group key. Otherwise, the simulator chooses an arbitrary key. To formalize authenticity,  $\mathcal{F}_{\text{CGKA}}$  is parameterized by **authentic**, which determines if authenticity is guaranteed for an epoch and a party. As soon as an injected epoch with authentic parent appears in the history graph,  $\mathcal{F}_{\text{CGKA}}$  halts, making the worlds easily distinguishable. Finally,  $\mathcal{F}_{\text{CGKA}}$  guarantees consistency by computing the outputs, such as the set of group members outputted by a joining party, based on the history graph. This means that the outputs in the real world must be consistent with the graph (and hence also with each other) as well, else, the worlds would be distinguishable.

Observe that the simulator's power to choose epochs into which parties transition and create injected epochs is restricted by the above security guarantees. For example, an injected epoch can only be created if the environment exposed enough states to destroy authenticity. For consistency,  $\mathcal{F}_{\text{CGKA}}$  also requires that a party can only transition to a child of its current epoch. Another example is that if a party in the real world outputs a key from a safe epoch, then the simulator cannot make it transition to an unsafe epoch.

*Personalizing messages.* saCGKA protocols may require that the mailboxing service personalizes messages before delivering them. In our model, such processing is done by  $\mathcal{A}$ . It can deliver an honestly processed message, or an arbitrary injected message. The simulator decides if a message is honestly processed, i.e., leads to a non-injected epoch, or is injected, i.e., leads to an injected epoch. Note that this notion has an RCCA flavor. For example, delivering an otherwise honestly generated message but with some semantically insignificant bits modified can lead the receiver to an honest epoch.

*Adaptive corruptions.* Our model allows  $\mathcal{A}$  to adaptively decide which parties to corrupt, as long as this does not allow it to trivially distinguish the worlds. Specifically,  $\mathcal{A}$  can trivially distinguish if a corruption allows it to compute the real group key in an epoch where  $\mathcal{F}_{\text{CGKA}}$  already outputted to  $\mathcal{A}$  a random key. Our statement quantifies over  $\mathcal{A}$ 's that do not trivially win.

We note that, in general, there can exist protocols that achieve the following stronger guarantee: Upon a trivial-win corruption,  $\mathcal{F}_{\text{CGKA}}$  gives to the simulator the random key it chose and the simulator comes up with a fake state that matches it. However, this requires techniques which typically are expensive and/or require additional assumptions, such as a random oracle programmable by the simulator or a common-reference string. We note that the

disadvantage of the simpler weaker is restricted composition in the sense that any composed protocol can only be secure against the class of environments restricted in the same way.

*Relation to game-based security.* It may be helpful to think about distinguishing between the real and ideal world as a typical security game for saCGKA. The adversary in the game corresponds to the environment  $\mathcal{A}$ . The adversary's challenge queries correspond to  $\mathcal{A}$ 's `GetKey` inputs on behalf of parties in confidential epochs and its reveal-session key queries correspond to  $\mathcal{A}$ 's `GetKey` inputs in non-confidential epochs. To disable trivial wins, we require that if the adversary queries a challenge for some epoch, then it cannot corrupt in a way that makes it non-confidential. Apart from the keys in challenge epochs being real or random, the real and ideal world are identical unless one of the following two bad events occurs: First, the adversary breaks consistency, that is, it causes the protocol to output in the real world something different than  $\mathcal{F}_{\text{CGKA}}$  in the ideal world. Second, the adversary breaks authenticity, that is, it makes the protocol accept a message that violates the authenticity requirement in the ideal world, making  $\mathcal{F}_{\text{CGKA}}$  halt forever. Therefore, distinguishing between the worlds implies breaking consistency, authenticity or confidentiality.

*Advantages of simulators.* Using a simulator simplifies the notion, because the ideal world does not need to encode parts of the protocol that are not relevant for security. For example, in our model the epochs into which parties transition are arbitrary, as long as security holds. This means that in the ideal world we do not need a protocol function that outputs some unique epoch identifiers. Our ideal world is agnostic to the protocol, which is conceptually simple.

## 4.5 Semantic Agreement

An important difference between our model and those of [7, 9, 31] is that in [7, 9, 31] epochs are (uniquely) identified by messages creating them. This is problematic for saCGKA, because different receivers transition to a given epoch using different messages. Crucially, this means an injected message cannot be used to identify the injected epoch into which its receiver transitions. We deal with this in a clean way by allowing the simulator to identify epochs. That is, epoch identifiers are arbitrary as long as consistency, authenticity and confidentiality hold.

The work [31], which proposes a new CGKA where, similar to SAIK, receivers get personalized packets, encountered the same problem with the existing models [7, 9]. In their new model, filtered CGKA (fCGKA), an epoch is identified by the sequence of *packet headers* leading to it. The header is a part of the uploaded packet that is downloaded by all receivers. A protocol can be secure according to the fCGKA model only if the header it defines has the properties of a cryptographic commitment to the semantics of the packet.

saCGKA generalizes fCGKA (and [7, 9]) and provides additional flexibility. For instance, it enables CGKAs which, like SAIK, assume PKE with the weaker RCCA security, while fCGKA still requires the stronger notion of CCA. We believe that in the future more CGKA protocols will take advantage of saCGKA's flexibility. For example, one may consider using a different packet-authenticator for each receiver with the goal of providing some level of unlinkability – an

adversary seeing only packets downloaded by participants cannot tell if they are in the same epoch (or group) or not.

## 4.6 Simplifications

In order to make the security notion tractable, we made the following simplifications compared to the models of [7, 9, 31].

**Immediate transition** In our model, a party performing a group operation immediately transitions to the created epoch. In reality, a party would only send the message creating the epoch and wait for an ACK from the mailboxing service before transitioning. If it receives a different message before the ACK, it transitions to that epoch instead. This mitigates the problem that if many parties send at once then they end up in parallel epochs and cannot communicate.

A protocol  $Prot$  implementing immediate transition can be transformed in a black-box manner into a protocol  $Prot'$  that waits for ACK as follows: To perform a group operation,  $Prot'$  creates a copy of the current state of  $Prot$  and runs  $Prot$  to obtain the provisional updated state and the message. The message is sent and all provisional states are kept in a list. If some message is ACK'ed, the corresponding provisional state becomes the current one, and if another message is received, it is processed using the current state. In any case, all provisional states are cleared upon transition.

**Simplified PKI** The models of [9, 31] consider a realistic implementation of the AKS where parties generate key packages themselves and upload them to an untrusted server, authenticated with long-term so-called identity keys. These long-term keys are authenticated via a PKI which allows the adversary to leak registered keys and even to register their own arbitrary keys on behalf of any participant. The works [9, 31] define fine-grained security in this setting, i.e., their security predicates take into account which PKI keys delivered to parties were corrupted.

In contrast, our model avoids the complexity of keeping track of the PKI keys in  $\mathcal{F}_{CGKA}$ , at the cost of more coarse-grained guarantees. For example, it no longer captures the (subtle) security guarantees provided by (the tree-signing of) ITK to parties invited to fake groups created by the adversary (tree signing trivially works for SAIK). We stress that our model does capture most active attacks, e.g. injecting valid-looking packets that add parties with arbitrary injected key packages.

**Deleting group keys** To build a secure messaging protocol on top (sa)CGKA, it is important that (sa)CGKA removes from its state all information about the group key  $K$  immediately after outputting it. The reason is that the messaging protocol will symmetrically ratchet  $K$  forward for FS. If the initial  $K$  was kept in the (sa)CGKA state upon corruption, the adversary could recompute all symmetric ratchets in the current epoch, breaking FS. Our  $\mathcal{F}_{CGKA}$  does not enforce that  $K$  is deleted, in order to avoid additional bookkeeping. All natural protocols, including SAIK, can trivially delete  $K$ , as it is stored as a separate variable that is computationally independent of the rest of the state.

**No randomness corruptions** Our model does not capture the adversary exposing or modifying randomness used by the protocol. Capturing such attacks for (sa)CGKA causes a significant headache when defining the formal security notion. For instance, the model needs to special-case scenarios where the adversary leaks the state of a party  $A$ , uses it with randomness  $r$  to compute and inject a message to a party  $B$ , and then makes  $A$  use  $r$  to re-compute the injected message.

One can easily adapt the special-casing of [7, 9, 31] to our model. We chose not to do this for simplicity and because well-designed protocols, including ITK and SAIK, naturally have protections against bad randomness. (Looking ahead, these protocols mix a fresh “commit” secret for the new epoch with the “init” secret from the old epoch, which mitigates sampling the fresh secret with bad randomness.) Therefore, capturing the additional attack vector typically does not fundamentally improve the analysis.

**Simplified syntax** To improve efficiency, ITK and CmpKE of [31] use the so-called propose-commit syntax, originally proposed by MLS. This means that parties first send messages that *propose* adding or removing other members, or updating their own keys. This does not affect the group state immediately. Rather, a party can collect a list of proposals and send a *commit* message which applies the proposed changes and creates a new epoch. The advantage of this is avoiding the expensive operation of epoch creation after every group modification (modifications typically come in batches; for instance, lots of members are added immediately after group creation).

Unfortunately, using this syntax requires lots of additional bookkeeping from  $\mathcal{F}_{CGKA}$ , such as keeping track of two types of history-graph nodes, one for proposals and one for commits (see [9, 31]). Most protocols based on ITK, such as SAIK, can be easily adapted to the propose-commit syntax and benefit from the efficiency gain. The change is minimal and security proofs are clearly not affected.

**No correctness guarantees** Our model does not capture correctness, i.e., the simulator can always make a party reject a message. Therefore, a protocol that does nothing is secure according to the notion. This greatly simplifies the definition and the fact that a protocol is correct typically easily follows by inspection (which is often the core argument in the proof of correctness). This means that the protocol used by the mailboxing service to extract personalized packets is not part of the security notion – a fully untrusted service may anyway deliver arbitrary packets. We note that the above protocol is still a part of saCGKA.

## 5 THE SAIK PROTOCOL

SAIK inherits most of its mechanisms from ITK, the CGKA of MLS. We briefly recall ITK in Sec. 5.1. Readers familiar with ITK can jump directly to Sec. 5.2 which gives intuition how SAIK improves on ITK. The detailed description of SAIK can be found in App. F.

## 5.1 Intuition for the ITK Protocol

*Ratchet trees.* The operation of ITK relies on a data structure called ratchet trees. A ratchet tree  $\tau$  is a tree where leaves are assigned to group members, each storing its owner’s identity and signature key pair. Moreover, most non-root nodes in  $\tau$ , store encryption key pairs. Nodes without a key pair are called *blank*.

ITK maintains the following *tree invariant*: *Each member knows the secret keys of the nodes on the path from their leaf to the root, and only those, as well as all public keys in  $\tau$ .* This allows to efficiently encrypt messages to subgroups: If a node  $v$  is not blank, then a message  $m$  can be encrypted to all members in the subtree of a node  $v$  by encrypting it under  $v$ ’s public key. If  $v$  is blank, then the same can be achieved by encrypting  $m$  under each key in  $v$ ’s *resolution*, i.e., the minimal set of non-blank nodes covering all leaves in  $v$ ’s subtree (Note that leaves are never blank, so there is always a resolution covering all leaves).

*Ratchet tree evolution.* Each group modification corresponds to a modification of the ratchet tree  $\tau$ . Most importantly, an update performed by a member id corresponds to refreshing all key pairs with secret keys known to id, i.e., those in the nodes on the path from id’s leaf to the root. id generates the new key pairs and, to maintain the tree invariant, communicates the secret keys to some group members. This is done efficiently as follows.

- (1) Let  $v_1, \dots, v_n$  denote the nodes on the path from id’s leaf  $v_1$  to the root  $v_n$ . id generates a sequence of *path secrets*  $s_2, \dots, s_n$ :  $s_2$  is a random bitstring,  $s_{i+1} = \text{Hash}(s_i, \textit{path})$ .
- (2) id generates a fresh key pair for  $v_1$ . For each  $i \in [2, n - 1]$ , the new key pair of  $v_i$  is computed by running the key generation with randomness  $\text{Hash}(s_i, \textit{rand})$ . The last secret  $s_n$  will be used in the key schedule, described soon.
- (3) id encrypts each  $s_{i+1}$  to the sibling of  $v_i$ . This allows parties in the subtree of  $v_i$  (and only those) to derive  $s_{i+1}, \dots, s_n$ .

Each add and remove is immediately followed by an implicit update. Removing a member  $\text{id}_t$  corresponds to removing all keys known to it, i.e., blanking all nodes on the path from its leaf to the root. Adding a member  $\text{id}_t$  corresponds to inserting a new leaf into  $\tau$ . The leaf’s public signature and encryption keys are fetched from the AKS. Further, the new leaf becomes an *unmerged leaf* of all nodes on the path from it to the root. A leaf  $l$  being unmerged at a node  $v$  indicates that the  $l$ ’s owner doesn’t know the secret key in  $v$ , so messages should be encrypted directly to  $l$ . When  $v$ ’s key is refreshed during an update, its set of unmerged leaves is cleared.

*Key schedule.* Apart from the ratchet tree, all group members store a number of shared symmetric keys, unique to the current epoch. These are: *application secret* – the group key exported to the E2E application, *membership key* used to authenticate sent messages and the *init key* – mixed in the next epoch’s secrets for FS.

The secrets are derived when an epoch is created, i.e. after the implicit update following each modification. The update generates the last path secret  $s_n$ , which we now call the *commit secret*. Then, the following secrets are derived. First, the commit secret and the old epoch’s init secrets are hashed together to obtain the *joiner secret*. Then, the *epoch secret* is obtained by hashing the joiner secret with the new epoch’s *context*, which we explain next. (The context is not mixed directly with init and commit secrets, because the

joiner secret is needed by new members; see below.) Finally, the new epoch’s application, membership and init secrets are obtained by hashing the epoch secret with different labels.

The context includes all relevant information about the epoch, e.g. (the hash of) the ratchet tree (which includes the member set). The purpose of mixing it into the key schedule is ensuring that parties in different epochs derive independent epoch secrets.

*Joining.* When an  $\text{id}_t$  joins a group, the party inviting them encrypts to them two secrets under a key fetched from the AKS. First, this is  $\text{id}_t$ ’s path secret from the implicit update following the add. Second, this is the new joiner secret, from which  $\text{id}_t$  derives other epoch secrets. Importantly, the new member hashes the joiner secret with the context, which means that it agrees on the epoch’s state with all current members transitioning to it.

## 5.2 Intuition for the SAIK Protocol

*mmPKE.* In ITK, a member performing an update generates a sequence of path secrets  $s_1, \dots, s_n$  and encrypts each  $s_i$  to each public key from a set of recipient public keys  $S_i$  using regular encryption. In contrast, SAIK redraws its internal abstraction boundaries viewing the sequence of encryptions as a single call to mmPKE. This allows it to use the DDH-based mmPKE construction of [36]. Compared to ITK, this cuts the computational complexity of encrypting  $\bar{m}$  and the ciphertext size in half (asymptotically as  $n$  grows).

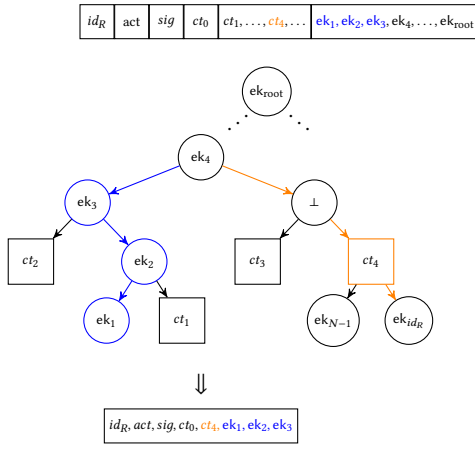

*Authentication.* The goal of authentication is to make sure that a member accepts a message from id only if id knows 1) the signing key for the verification key stored in id’s leaf in the current ratchet tree and 2) the current key schedule. In ITK, where every member gets the same message, this is achieved by simply signing it and MACing with the current membership key. In SAIK, to optimize bandwidth, the mailboxing service forwards to each receiver only the data it needs. E.g., it does not forward ciphertexts for other members. Therefore, we have to achieve authentication differently.

One trivial solution would be that the sender uploads multiple signatures, one for each receiver. However, this clearly does not scale. Can we do something better? A crucial observation is that the goal of saCGKA is to authenticate created epochs and *not message bitstrings*. That is, we want to guarantee that if Alice thinks that a message  $c$  transitions her to an epoch  $E$  created by Bob, then Bob indeed created  $E$ . It is not an attack if the adversary can make Alice accept a message that is not extracted with the honest procedure (e.g., it has reordered fields), as long as it transitions her to  $E$ .

Therefore, instead of signing the whole message, in SAIK we can sign and MAC only a single short tag that identifies the new epoch and is known to all members. In particular, this value is derived in the key schedule for the new epoch, alongside the other secrets, by hashing the epoch secret with an appropriate label. This way of efficient authentication is enabled by our new security notion.

*Extraction procedure for the server.* The task of the mailboxing server is to extract a personalized packet for a group member Alice from a packet  $C$  uploaded by another member Bob. In SAIK,  $C$  consists roughly of a single mmPKE ciphertext, a signature, the new public keys on the path from the sender to the root node and some metadata such as the sender’s identity, the group modification being applied etc. The signature and metadata are simply forwarded

to Alice. For the mmPKE ciphertext, the server runs the mmPKE Ext procedure with Alice’s recipient index  $i$  and also sends all public keys up to the lowest common ancestor (lca) of Alice and Bob in the ratchet tree. See Fig. 1 for an illustration. Observe that  $i$  and the lca are determined by the current epoch’s ratchet tree and the positions of Alice and Bob in it. Therefore, the server can obtain  $i$  and the lca in two ways: First, it can store all ratchet trees it needs (identified by the transcript hash leading to the epoch for which a tree is stored) and them itself. Second, it can ask Alice for  $i$  and the lca given that the sender is Bob. We note that the latter solution requires an additional round of interaction which may be problematic for some applications.

**Figure 1: Server extraction algorithm. Lowest common ancestor (LCA) of  $id_R$  and  $id_S$  is  $ek_4$ , so all blue public keys are included in  $id_R$ ’s packet. Since the sibling of  $ek_3$  is empty, there corresponding path secret of  $ek_4$  is encrypted to its resolution, resulting in the two ciphertext.**

*Comparison with techniques of [31].* The work [31] introduces a technique for efficient packet authentication which is quite similar to the technique used by SAIK. In particular, their CGKA uses a committing mPKE, cmPKE. A cmPKE differs from mPKE in that encryption outputs a tag  $T$  which is a cryptographic commitment to the plaintext and is delivered to each receiver. Since in [31] every recipient of a commit gets the same message, authenticating  $T$  is sufficient for CGKA authentication. We highlight a couple of differences between that technique and ours: First, it is not clear how to use cmPKE in a tree-based CGKA, where a commit executes multiple instances of cmPKE, and hence we end up with multiple tags  $T$ , each delivered to a different subset of the group. Second, using the hash of the encrypted message as  $T$  does not result in an IND-CCA secure cmPKE, since a hash allows to easily tell which of two messages is encrypted. Therefore, the construction of [31] uses key-committing encryption to both hide and bind the message.

To summarize, cmPKE introduced by [31] is very useful for the CGKA type they consider and may well find more use-cases beyond CGKA. On the other hand, SAIK’s solution fits all types of CGKA, does not require additional properties to prove CGKA security and is more direct. Albeit, it is very CGKA-specific.

## 6 SECURITY OF SAIK

To define the security we prove for SAIK we fix the two safety predicates **confidential** and **authentic** used by  $\mathcal{F}_{CGKA}$ . We next give the intuition; see Fig. 20 in App. H for the pseudocode. We define two versions of the predicates: a stronger and a weaker one. For better exposition, the stronger version is not achieved by SAIK as presented in this work. But at the cost of added complexity SAIK can easily be extended to achieve it, as described Sec. 8.1.

We begin with the simpler stronger version. First of all, both predicates give no guarantees for epochs in detached trees until they are attached and so we ignore them in this section. Then, the definition is built around the notion of secrets which make up the protocol state. There are two types of secrets: group secrets, stored in the state of all parties, and individual secrets, stored in the states of some parties. Each corruption exposes a number of secrets and each epoch change replaces a number of secrets by (possibly) secure ones. The helper predicate  $*grp-secs-secure(E)$  decides if the group secrets in  $E$  are secure, i.e., not exposed, and the predicate  $*ind-secs-secure(E, id)$  decides if  $id$ ’s individual secrets in  $E$  are secure. Then **confidential**( $E$ ) equals to  $*grp-secs-secure(E)$ , since the epoch key is itself a group secret. Further, **authentic**( $E, id$ ) is true if either  $*grp-secs-secure(E)$  or  $*ind-secs-secure(E, id)$  is true, because both group and  $id$ ’s secrets are necessary to impersonate  $id$  in  $E$ .

It remains to determine when group and individual secrets are exposed. For group secrets,  $*grp-secs-secure(E)$  is defined recursively. The base case states that the group secrets in first epoch (when the group was created) are secure if and only if no party is corrupted while in that epoch. Intuitively, we assume the group was created by an honest party using good randomness. Moreover, capturing perfect forward secrecy, corruptions in the descendant epochs do not affect the confidentiality of earlier group secrets.

The induction step states that the group secrets in a non-root epoch  $E$  are secure if no party is corrupted in  $E$ , the epoch is not created by an injected packet from the adversary and either the group secrets in  $E$ ’s parent  $E_p$  are secure or all individual secrets in  $E$  are secure. Intuitively, this formalizes the requirement that the adversary can learn the group secrets in only three ways: A) by corrupting a party currently in epoch  $E$ . B) by injecting the secrets (though most injections are disallowed by the authenticity predicate). C) by computing them the same way an honest receiver transitioning to  $E$  would. The latter requires knowing the group secrets of  $E_p$  and the individual secrets of at least one receiver. Note that the possible receivers are those parties that are group members in  $E$  and that are not  $E$ ’s creator (who transitions on sending). Note also that the fact that even knowing an epoch creator’s individual secrets in  $E_p$  we can treat them as secure in  $E$  which captures so called *post compromise security* (aka. *healing* or *backwards security*). Indeed, in SAIK, part of creating a new epoch requires refreshing all ones individual secrets.

Finally, individual secrets of  $id$  in  $E$  are exposed whenever there is some other epoch  $E'$  where  $id$ ’s secrets are the same as in  $E$  and where  $id$  was corrupted or its secrets were injected on its behalf. The secrets of  $id$  are the same in two epochs if no epoch between them replaces the secrets, i.e., is created by  $id$ , removes it or adds it.

*Weaker guarantees.* In the weaker version of the security predicates, individual secrets of  $\text{id}$  in  $E$  are not secure in an additional scenario, formalized by `*exposed-ind-secs-weak`. In this scenario, an  $\text{id}_s$  first honestly adds  $\text{id}$  and the adversary  $\mathcal{A}$  injects a message adding  $\text{id}$  to some other epoch. Finally,  $\text{id}$  joins  $\mathcal{A}$ 's epoch and is corrupted before sending any message. We explain why SAIK is insecure in this case and how it can be modified to be secure in Sec. 8.1.

*Security.* For the mmPKE scheme we assume a security property called mmOW-RCCA, defined in App. G. The notion is strictly weaker than mmIND-CCA; in App. G we prove the implication. Formally, the AKS is modeled as the functionality  $\mathcal{F}_{\text{AKS}}$  defined in App. E. SAIK works in the  $\mathcal{F}_{\text{AKS}}$ -hybrids model, i.e.,  $\mathcal{F}_{\text{AKS}}$  is available in the real world and emulated by the simulator in the ideal world. The formal proof of Theorem 6.1 can be found in App. H.

**THEOREM 6.1.** *Let  $\mathcal{F}_{\text{CGKA}}$  be the CGKA functionality with predicates **confidential** and **authentic** defined in Fig. 20. Let SAIK be instantiated with an mmPKE mmPKE, a signature scheme Sig and MAC, and with the HKDF functions modelled as a random oracle Hash. Let  $\mathcal{A}$  be any environment. Denote the output of  $\mathcal{A}$  from the real execution with SAIK and the hybrid functionality  $\mathcal{F}_{\text{AKS}}$  from Fig. 15 as  $\text{REAL}_{\text{SAIK}, \mathcal{F}_{\text{AKS}}}(\mathcal{A})$  and the output of  $\mathcal{A}$  from the ideal execution with  $\mathcal{F}_{\text{CGKA}}$  and a simulator  $\mathcal{S}$  as  $\text{IDEAL}_{\mathcal{F}_{\text{CGKA}}, \mathcal{S}}(\mathcal{A})$ . There exists a simulator  $\mathcal{S}$  and adversaries  $\mathcal{B}_1$  to  $\mathcal{B}_4$  such that*

$$\begin{aligned} \Pr[\text{IDEAL}_{\mathcal{F}_{\text{CGKA}}, \mathcal{S}}(\mathcal{A}) = 1] - \Pr[\text{REAL}_{\text{SAIK}, \mathcal{F}_{\text{AKS}}}(\mathcal{A}) = 1] \leq & \\ & \text{Adv}_{\text{Hash}}^{\text{CR}}(\mathcal{B}_1) \\ & + q_e^2(q_e + 1) \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e \log(q_n), q_n}^{\text{mmOW-RCCA}}(\mathcal{B}_2) \\ & + 2q_e \cdot \text{Adv}_{\text{Sig}}^{\text{EUF-CMA}}(\mathcal{B}_3) \\ & + q_e \cdot \text{Adv}_{\text{MAC}}^{\text{EUF-CMA}}(\mathcal{B}_4) + 3q_h q_e^2(q_e + 1)/2^\kappa, \end{aligned}$$

where  $q_e$ ,  $q_n$  and  $q_h$  denote bounds on the number of epochs, the group size and the number of  $\mathcal{A}$ 's queries to the random oracle modeling the Hash, respectively.

## 7 EVALUATION

We compare the communication complexity or, informally, the “bandwidth” of SAIK, ITK and CmPKE from [31]. For the sake of this comparison (and to simplify the description), one can think of CmPKE as a protocol similar to SAIK but where the ratchet tree is an  $N$ -ary tree of height 1, where  $N$  is the number of group members. This means that CmPKE only needs single-message multi-recipient PKE, mPKE (which is a special case of mmPKE). To make a fair comparison, we instantiate CmPKE with the same DH-based mPKE as SAIK instead of the less efficient but post-quantum secure mPKE given in [31].

*Methodology.* We compare the communication complexity of a single group modification with respect to three metrics:

- *sender bandwidth* – the size of the packet uploaded to the server,
- *maximum receiver bandwidth* – the maximum size of a (personalized) packet downloaded by a single receiver, and
- *total bandwidth* – the sum of the sizes of the uploaded packet and all downloaded packets.

**Figure 2: A ratchet tree for SAIK or ITK without blanks or unmerged leaves.**

**Figure 3: A ratchet tree for SAIK or ITK with all nodes blank.**

**Figure 4: A tree with some blank and non-blank nodes. Here, sender bandwidth depends on the position in the tree. For example, a packet by the leftmost leaf would contain 5 ciphertexts, while the rightmost leaf would require 6.**

The sender and maximum-receiver bandwidths give an idea about the resources a single client needs to invest to perform the group modification. In contrast, the total bandwidth gives the idea about the resources used by the server (or, equivalently, all clients together). However, it makes no assertions about the distribution of this bandwidth, i.e. some clients might use a significantly larger portion of the total bandwidth than others. (We note that the total bandwidth was the (only) metric used in [31].)

There is one caveat when calculating the bandwidth requirements for SAIK (and ITK) due to the underlying tree structure: The bandwidth can vary quite significantly depending on the “tree topology”, which is in turn determined by the execution history. Roughly, the reason is that add and remove operations may destroy the good properties of the tree (by “blanking” nodes), increasing the number of public keys to which some message must be encrypted. In the best case, called the *tree-best-case*, there are only  $\log(N)$  public keys (this happens when the ratchet has no blank nodes or unmerged leaves, as depicted in Fig. 2). However, in the worst case, called the *tree-worst-case*, there can be  $N$  public keys (this happens e.g. when all non-leaf nodes are blank; see Fig. 3). In general, the number of public keys can be anything in between; see Fig. 4.

Therefore, we compare each bandwidth in the tree-best-case and the tree-worst-case. Note that any other case results in a bandwidth

between these cases. We remark that comparing the average over all histories of group operations would not be meaningful, since the probability of a given execution depends on user and administrator behavior, general application policies and runtime conditions, etc. It is an important topic of future research to better understand which kinds of policies governing when and which parties initiate CGKA operations lead to more bandwidth efficient executions for realistic deployments. However, it is outside the scope of this work. We note that SAIK is *very* flexible as to kinds of policies that are possible and the types of data that can be leveraged to guide executions towards efficient behavior. Thus, we conjecture that in practice a well designed implementation (of both server and client) will be able to ensure that under relatively mild real-time conditions the vast majority of executions will spend the overwhelming majority of their time tending towards the tree-best-case scenario in bandwidth.

*Results.* We estimated the bandwidth for all protocols using the formulas in Figs. 5 and 7 with bit lengths indicated in Fig. 8. This is further visualized in Fig. 6 for growing group sizes  $N$ . We highlight some interesting observations.

In terms of the sender bandwidth, SAIK is always at least as good as the other protocols. For example, in a group of 10K parties, SAIK sender’s require between 83% and 55% of the bandwidth of ITK (due to the smaller mmPKE ciphertexts compared to PKE). SAIK’s tree-worst-case sender bandwidth is the same as CmPKE but its tree-best-case bandwidth can be as small as 0.52% by using only 4KB in stead of CmPKE’s 783KB. (Recall that, unlike in CmPKE, in SAIK sender bandwidth varies depending on the history of preceding operations.)

In terms of the maximum receiver bandwidth, ITK is much worse than SAIK and CmPKE. For example, SAIK receivers (at most) need between 62% (tree-best-case execution) to about .2% (tree-worst-case execution) of ITK’s. On the other hand, CmPKE is the best for receivers. SAIK requires up to 126% of CmPKE’s bandwidth, i.e. an increase from  $\sim 2.4$ KB to  $\sim 3.02$ KB for 10K parties.

Finally, the total bandwidth is by far the smallest for CmPKE and by far the largest for ITK. For instance, for 10K parties, SAIK requires  $\sim 1.3$  times more total bandwidth, while ITK requires anywhere from  $\sim 2$  times (tree-best-case) to  $\sim 50$  times (tree-worse-case) more.

In summary, the results show that SAIK achieves the lowest bandwidth required from a single client (i.e.  $O(\log(N))$  for SAIK vs.  $O(N)$  for CmPKE), while CmPKE has the lowest total bandwidth (i.e.  $O(N \log(N))$  for SAIK vs.  $O(N)$  for CmPKE). (Hence, both protocols meet their design goals.) For instance, for 10K parties, CmPKE requires a client to upload 783KB of data, while in scenarios close to the tree-best-case (which we believe to occur most of the time), the sender or receiver bandwidth of SAIK is roughly 4KB. On the other hand, the total bandwidth is roughly 25MB for CmPKE and 30MB for SAIK.

*Server computation.* Lastly, we consider the server-side computation for SAIK and CmPKE. In CmPKE, the server only picks the  $i$ -th mPKE ciphertext for the  $i$ -th user and forwards all common data. For SAIK, we can consider two possibilities: Either the server keeps track of the shape of the ratchet tree (which it can do based on the header data sent in all packages) and computes the lowest common ancestor of sender and receiver in the tree, computes its

resolution and then forwards the corresponding ciphertext and public keys. This takes at most logarithmic time in the size of the group (however, no expensive public-key operations are required). Alternatively, the user can compute its indices in the tree and send them to the server, reducing the server computation to effectively the same as in CmPKE at the cost of an additional round of communication.

## 8 EXTENSIONS

In this section we describe extensions of SAIK which we did not include for simplicity.

### 8.1 Better Security Predicates

We sketch the reason why SAIK does not achieve the better security predicates and how it can be modified to achieve them.

Roughly, SAIK achieves the worse security predicates because of the following attack: Say  $id_s$ , the only corrupted party, creates a new epoch  $E$  adding a new member  $id$ . According to SAIK, in this case  $id_s$  fetches from the Authenticated Key Service, AKS, (a type of PKI setup) a public key  $ek$  for mmPKE and a verification key  $spk$  for Sig, both registered earlier by  $id$ . In epochs after  $E$ , parties use  $ek$  to encrypt messages to  $id$  (even before  $id$  actually joins) and  $spk$  to verify messages from  $id$ . Now the adversary  $\mathcal{A}$  can create a fake epoch  $E'$  adding  $id$  with the same  $ek$  and  $spk$ . Then,  $id$  joins  $E'$  and is corrupted, leaking  $dk$  and  $ssk$ . This allows  $\mathcal{A}$  to compute the group key in  $E$  and inject messages to parties in  $E$ . However, the expectation is that this is not possible, since no party is corrupted in  $E$  (and  $id_s$  healed). The better security predicates (formally, the predicates in Fig. 20 in App. H) achieve just this: security in an honest epoch  $E$  does not depend on whether some member joins a fake group in  $E'$ .

The following modification to SAIK achieves better security: We note that in SAIK,  $id$  registers in the AKS an additional public key  $ek'$  which is used to send secrets needed for joining. The corresponding  $dk'$  is deleted immediately after joining. In the modified SAIK, when  $id_s$  adds  $id$ , it generates for  $id$  new key pairs  $(ek_s, dk_s)$  and  $(spk_s, ssk_s)$ . It sends  $dk_s$  and  $ssk_s$  to  $id$ , encrypted under  $ek'$ . Now messages to  $id$  are encrypted such that *both*  $dk$  and  $dk_s$  are needed to decrypt them. In particular, to encrypt  $m$ , a sender chooses a random  $r$  and encrypts  $r$  under  $ek$  and  $m \oplus r$  under  $ek_s$ . Similarly, messages from  $id$  have two signatures, one verified under  $spk$ , and one under  $spk_s$ . As soon as  $id$  creates an epoch, it generates a new single mmPKE key pair and a single HRS key pair.

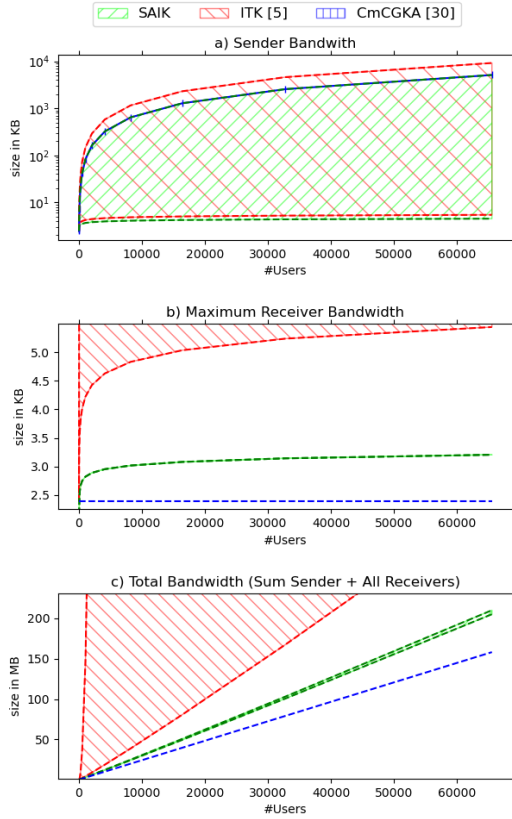

The attack is prevented, because even after corrupting  $id$  in  $E'$ ,  $\mathcal{A}$  does not know  $dk'$  needed to decrypt  $dk_s$  and  $ssk_s$ . Therefore, confidentiality and authenticity in  $E$  is not affected.

### 8.2 Primitives with Imperfect Correctness

While the proofs of SAIK security assume primitives with perfect correctness, they can be easily modified to work with imperfect correctness. While most classically secure primitives have perfect correctness, many post-quantum constructions (e.g. from lattices) only have statistical correctness. So this extension can be seen as a preparation for when SAIK has to be adapted to post-quantum security.

		ITK	SAIK	CmPKE
Sender	tree-best-case	$\log(N) \cdot (Pk + Ctx)$	$\log(N) \cdot Pk + mCtx(\log(N))$	$Pk + mCtx(N)$
	tree-worst-case	$\log(N) \cdot Pk + N \cdot Ctx$	$\log(N) \cdot Pk + mCtx(N)$	$Pk + mCtx(N)$
Maximum receiver	tree-best-case	$\log(N) \cdot (Pk + Ctx)$	$\log(N) \cdot Pk + Ctx$	$Pk + Ctx$
	tree-worst-case	$\log(N) \cdot Pk + N \cdot Ctx$	$\log(N) \cdot Pk + Ctx$	$Pk + Ctx$
Total	tree-best-case	$N \log(N) \cdot (Pk + Ctx)$	$N \log(N) \cdot Pk + N \cdot Ctx + mCtx(\log(N))$	$N \cdot (Pk + Ctx) + mCtx(N)$
	tree-worst-case	$N(\log(N) \cdot Pk + N \cdot Ctx)$	$N \log(N) \cdot Pk + N \cdot Ctx + mCtx(N)$	$N \cdot (Pk + Ctx) + mCtx(N)$

**Figure 5: Sender, receiver and total bandwidth for a group of size  $N$  expressed as the number of ciphertexts and public keys included in the packet (apart from this, packets include only a constant-size header).  $Pk$  denotes the size of a public key (the same for PKE and mmPKE).  $mCtx(X)$  denotes the size of an mmPKE multi-recipient ciphertext with overall number of receivers  $X$ . Note that for the DH-based construction  $X$  fully determines the size (i.e., it is not affected by who gets which message).  $Ctx$  denotes the size of a PKE ciphertext, equal to the size of an individual ciphertext in the DH-based construction.**

**Figure 6: Bandwidth comparison of SAIK, ITK and CmPKE (instantiated with 256-bit security). Lower lines denote the tree-best-case execution history, while upper lines denote the tree-worst-case. All other possible cases are marked as the regions between the lines. Plot (a) shows the sender bandwidth on a  $\log$  scale and plot (b) shows average individual receiver bandwidth on a  $linear$  scale. Plot (c) shows the total bandwidth, i.e. the sum of sender bandwidth and  $n$  times the receiver bandwidth. Note that in the first plot, the lines for tree-worst-case SAIK and all-case CmPKE coincide.**

		ITK	SAIK	CmPKE
Sender	best case	$3 \log(N)$	$2 \log(N)$	$N$
	worst case	$2N$	$N$	$N$
(Maximum) receiver	best case	$3 \log(N)$	$\log(N)$	$3$
	worst case	$2N$	$\log(N)$	$3$
Total	best case	$3N \log(N)$	$N \log(N)$	$4N$
	worst case	$2N^2$	$N \log(N)$	$4N$

**Figure 7: Sender, receiver and total bandwidth for a group of size  $N$  expressed as the (approximate) number of group elements. Best/Worst case refers to the state of the tree, while we always consider the average receiver bandwidth over all receivers.**

	Bitsize
Group element	512
Hash	512
Signature	1024
Header	17784
Pk	512
Ctx	1152
$mCtx(N)$	$512 + N \cdot 640$

**Figure 8: Bitsizes used to generate Fig. 6. The header consists of the sender's id, the epoch id and some authenticated data required by the protocol. The individual ciphertexts consist of a group element and an AEAD encryption, while the mPKE ciphertext all share the same group element. The header contains signatures, tags, epoch and sender identifier as well as a key package. The latter makes up the bulk of the header, as it contains credentials, more public keys and some application data. Our estimation is based on MLS.**

This is achieved by adding one game hop where we abort in the new game if a correctness error occurs. This loses an additive term in the security bound that depends on the correctness parameter and the number of possible occurrences. Additionally, the usage of primitives with imperfect correctness generally yields imperfect correctness guarantees for the application as well (potentially with multiplicative correctness error when using multiple primitives). For completeness, we give definitions of imperfect correctness of the primitives used directly by SAIK in this section.

*Definition 8.1.* We call an mmPKE scheme  $\delta$ -correct, if for all  $n \in \mathbb{N}$ ,  $(ek_i, dk_i) \in \text{KG}$  for  $i \in [n]$ ,  $(m_1, \dots, m_n) \in \mathcal{M}^n$  and  $\forall j \in [n]$

$$\Pr \left[ \begin{array}{l} c_j \leftarrow \text{Ext}(j, C) \\ m_j \neq \text{Dec}(dk_j, c_j) \end{array} \middle| C \stackrel{s}{\leftarrow} \text{Enc} \left( \begin{array}{l} (ek_1, \dots, ek_n), \\ (m_1, \dots, m_n) \end{array} \right) \right] \leq \delta$$

## Supplementary Material

### A ADDITIONAL PRELIMINARIES

#### A.1 Universal Composability

We formalize security in the universal composability (UC) framework [22]. We moreover use the modification of responsive environments introduced by Camenisch et al. [21] to avoid artifacts arising from seemingly local operations (such as sampling randomness or producing a ciphertext) to involve the adversary.

The UC framework requires a real-world execution of the protocol to be indistinguishable from an ideal world, to an interactive environment. The real-world experiment consists of the group members executing the protocol (and interacting with the PKI setup). In the ideal world, on the other hand, the protocol gets replaced by dummy instances that just forward all inputs and outputs to an *ideal functionality* characterizing the appropriate guarantees.

The functionality interacts with a so-called simulator, that translates the real-world adversary's actions into corresponding ones in the ideal world. Since the ideal functionality is secure by definition, this implies that the real-world execution cannot exhibit any attacks either.

*The Corruption Model.* We use the – standard for CGKA/SGM but non-standard for UC – corruption model of continuous state leakage (transient passive corruptions) [7].<sup>6</sup> In a nutshell, this corruption model allows the adversary to repeatedly corrupt parties by sending corruption messages of the form (Expose, id), which causes the party id to send its current state to the adversary (once).

*Restricted Environments.* In order to avoid the so-called commitment problem, caused by adaptive corruptions in simulation-based frameworks, we restrict the environment not to corrupt parties at certain times. (This roughly corresponds to ruling out “trivial attacks” in game-based definitions. In simulation-based frameworks, such attacks are no longer trivial, but security against them requires strong cryptographic tools and is not achieved by most protocols.) To this end, we use the technique used in [7] (based on prior work by Backes et al. [10] and Jost et al. [32]) and consider a weakened variant of UC security that only quantifies over a restricted set of so-called admissible environments that do not exhibit the commitment problem. Whether an environment is admissible or not is defined as part of the ideal functionality  $\mathcal{F}$ : The functionality can specify certain boolean conditions, and an environment is then called admissible (for  $\mathcal{F}$ ), if it has negligible probability of violating any such condition when interacting with  $\mathcal{F}$ .

#### A.2 Assumptions

The security of our mmPKE construction, same as that of [36], is based on a variant of the Computational Diffie-Hellman (CDH) assumption called the *Double-Sided Strong Diffie-Hellman Assumption* (or just *Static Diffie-Hellman Assumption* in [36]). We recall it in Definition A.1. Intuitively, it states that CDH is hard given access to a DDH-oracle for both CDH inputs.

<sup>6</sup>Passive corruptions together with full network control allow to emulate active corruptions.

*Definition A.1 (Double-Sided Strong Diffie-Hellman Assumption).* Let  $\mathcal{G} = (\mathbb{G}, p, g)$  be a cyclic group of prime order  $p$  with generator  $g$ . We define the advantage of an algorithm  $\mathcal{A}$  in solving the *Double-Sided Strong Diffie-Hellman problem* (DSSDH) with respect to  $\mathcal{G}$  as

$$\text{Adv}_{\mathcal{G}}^{\text{DSSDH}}(\mathcal{A}) = \Pr \left[ Z = g^{xy} \mid \begin{array}{l} x, y \xleftarrow{\$} \mathbb{Z}_p^2 \\ Z \xleftarrow{\$} \mathcal{A}^{\mathbf{O}}(\mathbb{G}, p, g, g^x, g^y), \end{array} \right]$$

with  $\mathbf{O} = \{\mathbf{O}_x(\cdot, \cdot), \mathbf{O}_y(\cdot, \cdot)\}$ , where  $\mathbf{O}_x, \mathbf{O}_y$  are oracles which on input  $U, V$  output 1, iff  $U^x = V$  or  $U^y = V$  respectively. The probability is taken over the random coins of the group generator, the choice of  $x$  and  $y$  and the adversary's random coins.

#### A.3 Multi-Recipient Multi-Message PKE(mmPKE) Definitions

The notion of mmIND-RCCA security for mmPKE is described by the experiment in Fig. 9.

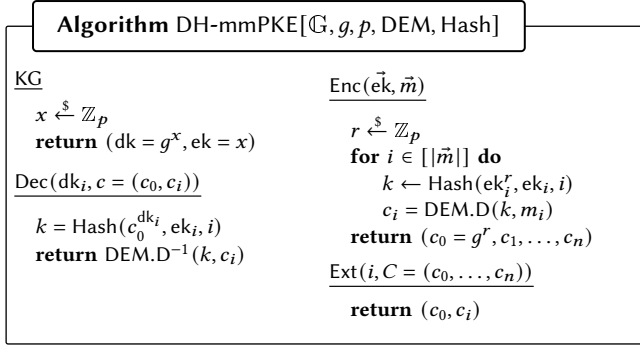

We define the security of an mmPKE in a left-right style in the following Definition A.2.

*Definition A.2 (mmIND-RCCA).* Let  $N \in \mathbb{N}$ . For a scheme mmPKE, we define the advantage of an adversary  $\mathcal{A}$  against *Indistinguishability Against Replayable Chosen Ciphertext Attacks* (mmIND-RCCA) security of mmPKE as

$$\text{Adv}_{\text{mmPKE}, N}^{\text{mmIND-RCCA}}(\mathcal{A}) = \Pr \left[ \text{Exp}_{\text{mmPKE}, N, 0}^{\text{mmIND-RCCA}}(\mathcal{A}) = 1 \right] - \Pr \left[ \text{Exp}_{\text{mmPKE}, N, 1}^{\text{mmIND-RCCA}}(\mathcal{A}) = 1 \right],$$

where  $\text{Exp}_{\text{mmPKE}, N, b}^{\text{mmIND-RCCA}}$  is described in Fig. 9.

**Figure 11: The mmPKE scheme based on Diffie-Hellman from [36]. The scheme requires a group  $\mathbb{G}$  of prime order  $p$  generated by  $g$ , a data encapsulation mechanism DEM and a hash function Hash.**

#### A.4 Data Encapsulation Mechanism (DEM)

A DEM is the symmetric equivalent of a PKE scheme. We recall it in Definition A.3.

*Definition A.3 (DEM).* A data encapsulation mechanism (DEM) is described by a (efficiently samplable) keyspace  $\mathcal{K}$  and the two algorithms  $D, D^{-1}$ :

$D(k, m) \xrightarrow{\$} c$ : The encryption algorithm takes a key  $k \in \mathcal{K}$  and a message  $m$ . It returns a ciphertext  $c$ .

$D^{-1}(k, c) \xrightarrow{\$} m' \vee \perp$ : The decryption algorithm takes a key  $k \in \mathcal{K}$  and a ciphertext  $c$  and outputs either a decrypted message or  $\perp$ .

A DEM DEM is  $\delta$ -correct, if for all messages  $m$  and all keys  $k \in \mathcal{K}$

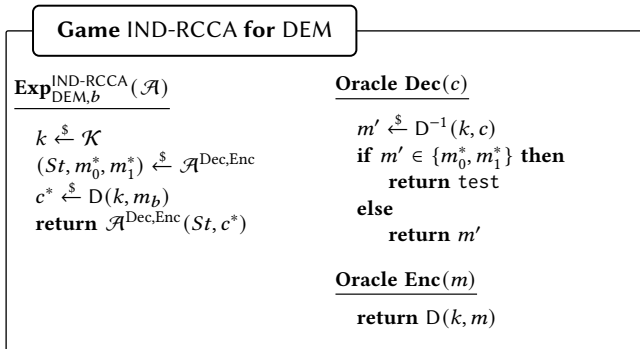

$$\Pr[D^{-1}(k, D(k, m)) = m] \geq \delta$$

Analogue to mmPKE, we consider IND-RCCA security for DEMs. It is described in Definition A.4.

*Definition A.4.* The advantage of an adversary  $\mathcal{A}$  against the IND-RCCA security of a DEM DEM is defined as

$$\text{Adv}_{\text{DEM}}^{\text{IND-RCCA}}(\mathcal{A}) = \Pr[\text{Exp}_{\text{DEM},0}^{\text{IND-RCCA}}(\mathcal{A}) = 1] - \Pr[\text{Exp}_{\text{DEM},1}^{\text{IND-RCCA}}(\mathcal{A}) = 1],$$

where  $\text{Exp}_{\text{DEM},b}^{\text{IND-RCCA}}(\mathcal{A})$  is defined in Fig. 10.

**Figure 10: IND-RCCA security for DEMs.**

#### A.5 Message Authentication Codes (MAC)

Message authentication codes are defined in Definition A.5.

*Definition A.5.* A message authentication code  $\text{MAC} = (\text{MAC.tag}, \text{MAC.vrf})$  consist of a keyspace  $\mathcal{K}$  and the following two algorithms:

$\text{MAC.tag}(k, m) \xrightarrow{\$} \text{tag}$ : The tagging algorithm takes a key  $k$  and a message  $m$  and outputs a tag  $t$ .

$\text{MAC.vrf}(k, m, \text{tag}) \xrightarrow{\$} \{0, 1\}$ : The verification algorithm takes a key  $k$ , a message  $m$  and a tag tag and outputs 0 or 1.

A mac MAC is correct, if for all  $k \in \mathcal{K}$  and messages  $m$

$$\Pr[\text{MAC.vrf}(k, m, \text{MAC.tag}(k, m)) = 1] = 1$$

The security notion for MACs we consider is *Unforgeability against chosen message attacks*(EUF-CMA).

*Definition A.6.* A mac MAC is EUF-CMA secure, if for all PPT adversaries  $\mathcal{A}$  the advantage

$$\text{Adv}_{\text{MAC}}^{\text{EUF-CMA}}(\mathcal{A}) = \Pr \left[ \begin{array}{l} m \notin Q \wedge \\ \text{MAC.vrf}(k, m^*, \text{tag}^*) = 1 \end{array} \mid \begin{array}{l} k \xleftarrow{\$} \mathcal{K} \\ (m^*, t^*) \xleftarrow{\$} \mathcal{A}^{\text{Tag,Ver}} \end{array} \right]$$

is negligible, where the Tag oracle computes a tag under key  $k$  on a given message  $m$  and adds it to  $Q$  and Ver takes a message and a tag and outputs the result of the MAC.vrf algorithm on the two inputs with  $k$ .

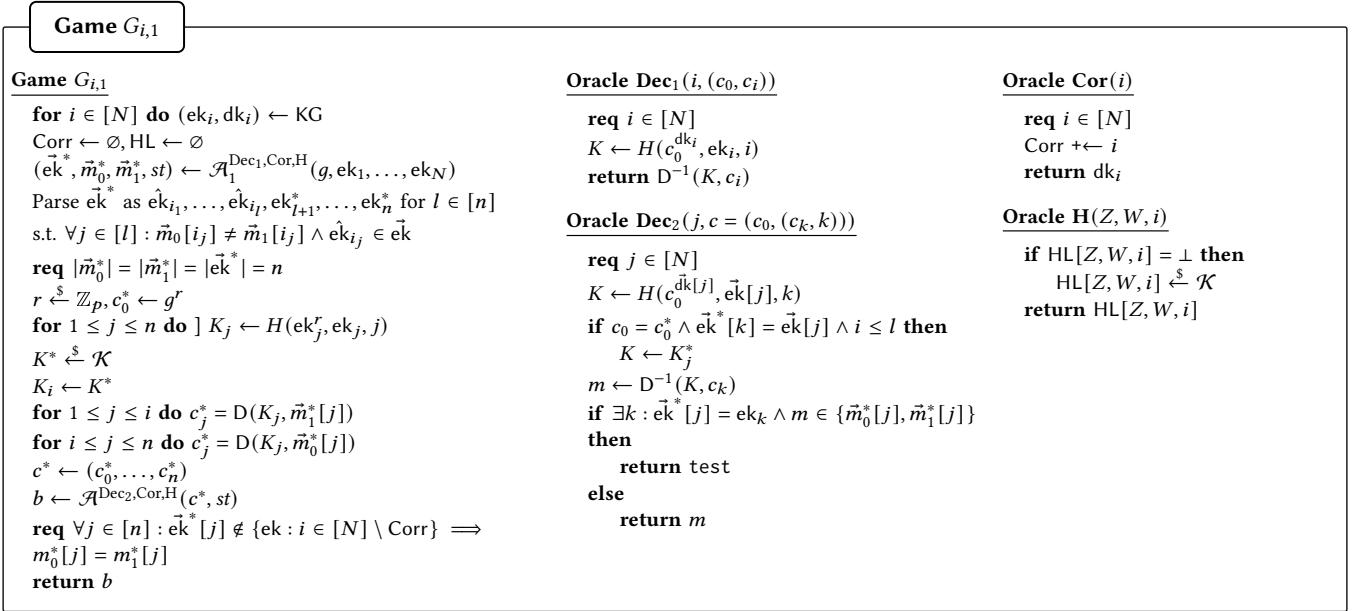

## B SECURITY OF THE MMPKE SCHEME

**THEOREM 3.2.** Let  $\mathbb{G}$  be a group of prime order  $p$  with generator  $g$ , let DEM be a data encapsulation mechanism and let mmPKE = DH-mmPKE $[\mathbb{G}, g, p, \text{DEM}, H]$ . For any adversary  $\mathcal{A}$  and any  $N \in \mathbb{N}$ , there exist adversaries  $\mathcal{B}_1$  and  $\mathcal{B}_2$  with runtime roughly the same as  $\mathcal{A}$ 's s.t.

$$\text{Adv}_{\text{mmPKE},N}^{\text{mmIND-RCCA}}(\mathcal{A}) \leq \text{Adv}_{\text{DEM}}^{\text{IND-RCCA}}(\mathcal{B}_2) + 2n \cdot (e^2 q_c \text{Adv}_{(\mathbb{G},g,p)}^{\text{DSSDH}}(\mathcal{B}_1) + \frac{q_{d_1}}{p} + \frac{q_h}{p}),$$

where  $H$  is a random oracle,  $e$  is the Euler number,  $n$  is the length of the challenge vector, and  $q_{d_1}$ ,  $q_c$  and  $q_h$  are the number of queries to the decrypt and corrupt oracles and the random oracle, resp.

**PROOF.** We define  $n$  hybrids  $G_0$  through  $G_n$ , where  $G_0$  is identical to  $\text{Exp}_{\text{mmPKE},N,0}^{\text{mmIND-RCCA}}$ ,  $G_n$  is identical to  $\text{Exp}_{\text{mmPKE},N,1}^{\text{mmIND-RCCA}}$  and in  $G_i$ , the first  $i$  challenge ciphertexts contain encryptions of  $\vec{m}_1$  and the others from  $\vec{m}_0$ . Additionally, for  $i \in [n]$ , we define the four hybrids  $G_{i,0}$  to  $G_{i,3}$ .  $G_{i,0}$  and  $G_{i,3}$  are identical to  $G_i$  and  $G_{i+1}$  respectively. In  $G_{i,1}$ , we set the  $i$ -th DEM key to a random key and in  $G_{i,2}$  we swap the plaintext in the  $i$ -th challenge ciphertext from  $\vec{m}_0[i]$  to  $\vec{m}_1[i]$ . We will split the proofs into the following lemmas.

Figure 12: Description of the hybrid  $G_{i,1}$ 

LEMMA B.1. Let  $n \in \mathbb{N}$ . For all  $1 \leq i \leq n$ , there exists an adversary  $\mathcal{B}_1$  against the DSSDH assumption s.t. for all adversaries  $\mathcal{A}$

$$|\Pr[G_{i,0}(\mathcal{A}) \Rightarrow 1] - \Pr[G_{i,1}(\mathcal{A}) = 1]| \leq e^2 q_C \cdot \text{Adv}_{\mathcal{G}}^{\text{DSSDH}}(\mathcal{B}_1) + \frac{q_{D_1}}{p} + \frac{q_H}{p},$$

where  $q_H, q_C$  and  $q_{D_1}$  denote the number of hash queries, corruption queries and decryption queries in phase 1 respectively made by  $\mathcal{A}$ .

Remark 2. Since the changes from  $G_{i,2}$  to  $G_{i,3}$  are the same as from  $G_{i,0}$  to  $G_{i,1}$ , Lemma B.1 applies there as well.

LEMMA B.2. Let  $n \in \mathbb{N}$ . Then for all  $1 \leq i \leq n$ , there exists an adversary  $\mathcal{B}_2$  against the IND-RCCA security of DEM s.t. for all adversaries  $\mathcal{A}$

$$|\Pr[G_{i,1}^{\mathcal{A}} \Rightarrow 1] - \Pr[G_{i,2}^{\mathcal{A}} \Rightarrow 1]| \leq \text{Adv}_{\text{DEM}}^{\text{IND-RCCA}}(\mathcal{B}_2)$$

Combining the two lemmas and the remark yields Corollary B.3. The theorem follows by a standard hybrid argument over  $G_i$ .

COROLLARY B.3. Let  $n \in \mathbb{N}$ . Then for all  $1 \leq i \leq n$ , there exist adversaries  $\mathcal{B}_1, \mathcal{B}_2$  against the DSSDH assumption and the IND-RCCA security of DEM respectively s.t. for all adversaries  $\mathcal{A}$

$$|\Pr[G_i^{\mathcal{A}} \Rightarrow 1] - \Pr[G_{i+1}^{\mathcal{A}} \Rightarrow 1]| \leq \text{Adv}_{\text{DEM}}^{\text{IND-RCCA}}(\mathcal{B}_2) + 2(e^2 q_C \cdot \text{Adv}_{\mathcal{G}}^{\text{DSSDH}}(\mathcal{B}_1) + \frac{q_{D_1}}{p} + \frac{q_H}{p})$$

with  $q_{D_1}, q_C$  and  $q_H$  from Lemma B.1.

So all that is left is proving the lemmas. We will start by proving Lemma B.1. Consider the formal definition of  $G_{i,1}$  in Fig. 12.

Next, we describe adversary  $\mathcal{B}_1$  against the DSSDH assumption in Fig. 13 First, we argue that  $\mathcal{B}_1$  simulates the game  $G_{i,1}$  perfectly, unless one of the events  $\text{Bad}_1$  or  $\text{Bad}_2$  occurs. We will bound the

probabilities of these events happening. The games differ only in the secret key of the  $i$ -th message, therefore  $G_{i,0}$  and  $G_{i,1}$  are identical to  $\mathcal{A}$ , unless it queries the hash oracle on  $(Z, U, i)$  as in line 1 of H. If the corresponding public key was a key in which the challenge was embedded, i.e.  $\text{Bad}_3$  is false,  $\mathcal{B}_1$  breaks the DSSDH assumption.

$\text{Bad}_1$  and  $\text{Bad}_2$  prevent that  $\mathcal{A}$  already knows the challenge randomness before its challenge query. If it doesn't know this value, all answers of  $\mathcal{B}_1$  to both oracles are distributed as in the real games  $G_{i,0}$  and  $G_{i,1}$ . Specifically, the oracles are kept consistent and the hash oracle is programmed such that the keys chosen for the adversaries challenge are included at the right points.

$\text{Bad}_3$  occurs if  $\mathcal{A}$  tries to corrupt a public key for which  $\mathcal{B}_1$  doesn't know the corresponding secret key or  $\mathcal{A}$  chooses a key without the challenge embedded for the  $i$ -th message. If the first part doesn't happen, the corruption oracle is simulated perfectly. The adversary doesn't notice the second part in this case, but if it occurs,  $\mathcal{B}_1$  isn't successful, so it is still a bad case for the simulation.

Now we bound the probability of these events occurring. Since  $Y$  is completely hidden from  $\mathcal{A}$ , it can only find it by guessing. Therefore, for an adversary  $\mathcal{A}$  making at most  $q_H$  (resp.  $q_{D_1}$ ) hash (resp. decryption) queries,

$$\Pr[\text{Bad}_1 = \text{True}] \leq \frac{q_H}{p}$$

$$\Pr[\text{Bad}_2 = \text{True}] \leq \frac{q_{D_1}}{p}$$

For  $\text{Bad}_3$ , consider the probability with which  $b[j] = 1$ . This is independent for each public key  $ek_j$ , so the probability that  $\text{Bad}_3$  does *not* occur is the case that for  $q_C$  public keys  $ek_{i_1}, \dots, ek_{i_{q_C}}$   $b[i_j] = 0$  and for one public key the bit is 1, so

$$\Pr[\text{Bad}_3 = \text{False}] = (1 - \frac{1}{q_C})^{q_C} \cdot \frac{1}{q_C} \stackrel{(1)}{\leq} \frac{1}{e^2 q_C}$$

**Figure 13: Description of adversary  $\mathcal{B}_1$  from Theorem 3.2.**

For (1), we use that  $\ln(1+x) \geq \frac{x}{x+1}$  for all  $x \geq -1$  and rewrite  $(1 - \frac{1}{q_C})^{q_C} = e^{\ln((1 - \frac{1}{q_C})^{q_C})} = e^{q_C \cdot \ln(1 - \frac{1}{q_C})} \geq e^{-1/(1 - \frac{1}{q_C})} \geq e^{-2}$  for  $q_C > 1$ . Combining the probabilities yields the lemma.

The proof of Lemma B.2 is a straight forward application of the IND-RCCA security of the DEM. Since the key at position  $i$  is random, an IND-RCCA adversary can simulate encryptions for this position with its encryption oracle and embeds its own challenge at the  $i$ -th challenge ciphertext for the adversary  $\mathcal{A}$ . If  $\mathcal{A}$  can distinguish between  $G_{i,1}$  and  $G_{i,2}$  then  $\mathcal{B}_2$  distinguishes its challenges as well.  $\square$

**C NOMINAL GROUPS**

We recall the definition and parameters for nominal groups from [2].

*Definition C.1 (Nominal Group).* A nominal group  $\mathcal{N} = (\mathcal{G}, g, p, \mathcal{E}_H, \mathcal{E}_U, \text{exp})$  consists of a finite set of elements  $\mathcal{G}$ , a base element

$g \in \mathcal{G}$ , a prime  $p$ , a finite set of “good” exponents  $\mathcal{E}_H \subset \mathbb{Z}$ , a set of exponents  $\mathcal{E}_U \subset \mathbb{Z} \setminus p\mathbb{Z}$  and an efficiently computable exponentiation function  $\text{exp} : \mathcal{G} \times \mathbb{Z} \rightarrow \mathcal{G}$ . We write  $X^y$  as shorthand for  $\text{exp}(X, y)$  and call elements of  $\mathcal{G}$  “group elements”.  $\mathcal{N}$  has to fulfil the following properties:

- (1)  $\mathcal{G}$  is efficiently recognizable.
- (2)  $(X^y)^z = X^{yz}$  for all  $X \in \mathcal{G}, y, z \in \mathbb{Z}$
- (3) the function  $\phi$  defined by  $\phi(x) = g^x$  is a bijection from  $\mathcal{E}_U$  to  $\{g^x | x \in [p-1]\}$ .

A nominal group  $\mathcal{N}$  is called *rerandomisable*, when additionally

- (4)  $g^{x+py} = g^x$  for all  $x, y \in \mathbb{Z}$
- (5) for all  $y \in \mathcal{E}_U$ , the function  $\phi_y$  defined by  $\phi_y(x) = g^{xy}$  is a bijection from  $\mathcal{E}_U$  to  $\{g^x | x \in [p-1]\}$ .

Property 3 (and 5) ensure that discrete logarithms are unique in  $\mathcal{N}$  in  $\mathcal{E}_U$ . Additionally, we define the two statistical parameters

$$\Delta_{\mathcal{N}} := \Delta[G_H, G_U],$$

Name	P-256	P-384	P-512	CURVE25519	CURVE448
Security Level	128	192	256	128	224
$P_{\mathcal{N}}$	$2^{-255}$	$2^{-383}$	$2^{-520}$	$2^{-250}$	$2^{-444}$
$\Delta_{\mathcal{N}}$	0	0	0	$2^{-125}$	$2^{-220}$
Size in bits	256	384	512	256	512

**Table 1: Statistical parameters of NIST curves and nominal group curves.**

with  $G_H$  is the uniform distribution over  $\mathcal{E}_H$  and  $G_U$  is the uniform distribution over  $\mathcal{E}_U$  and

$$P_{\mathcal{N}} = \max_{Y \in \mathcal{G}} \Pr_{x \leftarrow \mathcal{E}_H} [Y = g^x].$$

Any cyclic group, such as NIST curves, can be seen as a rerandomizable nominal group with the special properties that  $\Delta_{\mathcal{N}} = 0$  and  $P_{\mathcal{N}} = p - 1$ . Other popular examples of rerandomizable nominal groups are CURVE25519 and CURVE448. Table 1 lists the parameters for these nominal groups.

For a more detailed explanation of these values, see [2]. Nominal groups and prime-order groups behave indistinguishably except when group elements are sampled with exponents outside of  $\mathcal{E}_H$  or a collision occurs which wouldn't have been a collision in a prime-order group. Since these two events are statistical in nature and occur with low probability, this only adds a negligible additive security loss compared to Theorem 3.2.

The DSSDH assumption is almost identical over nominal groups except for the choice of exponents.

*Definition C.2 (Double-Sided Strong Diffie-Hellman Assumption).* Let  $\mathcal{N} = (\mathcal{G}, g, p, \mathcal{E}_H, \mathcal{E}_U, \text{exp})$  be a nominal group. We define the advantage of an algorithm  $\mathcal{A}$  in solving the *Double-Sided Strong Diffie-Hellman problem* (DSSDH) with respect to  $\mathcal{N}$  as

$$\text{Adv}_{\mathcal{N}}^{\text{DSSDH}}(\mathcal{A}) = \left[ Z = g^{xy} \mid \begin{array}{l} x, y \leftarrow \mathcal{E}_U^2 \\ Z \leftarrow \mathcal{A}^{\mathbf{O}}(\mathcal{N}, p, g, g^x, g^y) \end{array} \right]$$

with  $\mathbf{O} = \{\mathbf{O}_x(\cdot, \cdot), \mathbf{O}_y(\cdot, \cdot)\}$ , where  $\mathbf{O}_x, \mathbf{O}_y$  are oracles which on input  $U, V$  output 1, iff  $U^x = V$  or  $U^y = V$  respectively. The probability is taken over the random coins of the group generator, the choice of  $x$  and  $y$  and the adversaries random coins.

*Remark 3.* Since  $x, y$  are sampled from  $\mathcal{E}_U$ , the second property of nominal groups guarantees that the oracles  $\mathbf{O}_x$  and  $\mathbf{O}_y$  are well-defined.

**THEOREM C.3.** *Let  $\mathcal{N} = (\mathcal{G}, g, p, \mathcal{E}_H, \mathcal{E}_U, \text{exp})$  be a nominal group. If the DSSDH assumption holds relative to  $\mathcal{N}$  and if DEM is an IND-RCCA secure DEM, then mmPKE from Fig. 11 is mmIND-RCCA secure with adaptive corruptions in the random oracle model and leakage function leak revealing the length of each plaintext. Specifically, there are adversaries  $\mathcal{B}_1, \mathcal{B}_2$  against DSSDH and IND-RCCA of DEM respectively, s.t. for all adversaries  $\mathcal{A}$  against the mmIND-RCCA*

$$\begin{aligned} \text{Adv}_{\text{mmPKE}}^{\text{mmIND-RCCA}}(\mathcal{A}) &\leq \\ &2e^2 q_C \cdot n \cdot \left( \text{Adv}_{\mathcal{N}}^{\text{DSSDH}}(\mathcal{B}_1) + \frac{q_{D_1}}{p} + \frac{q_H}{p} \right) \\ &+ n \cdot \text{Adv}_{\text{DEM}}^{\text{IND-RCCA}}(\mathcal{B}_2) \\ &+ 2(n+1) \cdot \Delta_{\mathcal{N}} + \mathcal{O}(q_D, q_H) \cdot P_{\mathcal{N}}, \end{aligned}$$

where the runtime of  $\mathcal{B}_1$  and  $\mathcal{B}_2$  is roughly the same as  $\mathcal{A}$  and  $q_{D_1}, q_H$  and  $q_C$  denote the number of queries to the decryption oracle  $D$  in phase 1, the random oracle  $H$  and the corruption oracle  $\text{Cor}$  respectively.

**PROOF.** Mainly, the proof of Theorem 3.2 still applies. That is because all operations performed by the adversary are well-defined over nominal groups. The main difference occurs when rerandomising the keys in each hybrid. Here, not every exponent yields a valid group element, i.e. a valid key. Formally, we would add an additional hybrid for each chosen key, sampling its exponent from  $\mathcal{E}_U$  instead of  $\mathcal{E}_H$ , which adds an additive term in  $\Delta_{\mathcal{N}}$  to the advantage function. It is imperative that  $\mathcal{N}$  is rerandomisable as otherwise embedding the (randomised) challenge would be problematic.

Secondly, whenever group elements are submitted to one of the oracles, there is a (tiny) probability of collisions of group elements. As it is comparable to the chances of guessing discrete logarithms in prime order groups, which is mostly ignored in proofs, we omit a complete analysis as it wouldn't contribute any meaningful insights.

In conclusion, after sampling all keys from  $\mathcal{E}_U$  and accounting for possible collisions in the gap oracles, the proof for nominal groups works as shown in Theorem 3.2.  $\square$

## D DETAILS OF THE (SA)CGKA SECURITY MODEL

In this section, we formally define  $\mathcal{F}_{\text{CGKA}}$ . The code of  $\mathcal{F}_{\text{CGKA}}$  is in Fig. 14.

*Notation.* We use the keyword **assert cond** to restrict the simulator's actions. Formally, if the condition *cond* is false, then the functionality permanently halts, making the real and ideal worlds easily distinguishable. Further, we use **only allowed if cond** to restrict the environment. That is, our statements quantify only over environments who, when interacting with  $\mathcal{F}_{\text{CGKA}}$  and any simulator, never make *cond* false<sup>7</sup>. We write *receive from the simulator* to denote that the functionality sends a dummy value to it, waits until it sends a value back and asserts via **assert** that the received value is of the correct format. Lastly, all functions prefixed with a \* are *helper functions* and not exposed outside the protocol.

*State.*  $\mathcal{F}_{\text{CGKA}}$  maintains a history graph represented as an array HG, where HG[epid] denotes the epoch identified by an integer epid. We use the standard object-oriented notation for epochs. In particular, each epoch  $E$  has a number of attributes listed in Table 2 ( $E.\text{inj}$ ,  $E.\text{exp}$  and  $E.\text{chall}$  are related to corruptions). Apart from HG,  $\mathcal{F}_{\text{CGKA}}$  stores an array CurEp, where CurEp[id] denotes the current epoch of the party id.

<sup>7</sup>A relaxed restriction would require that  $\mathcal{A}$  makes *cond* false with a small probability  $\epsilon$ . In our case  $\mathcal{A}$  knows if it violates *cond*, so fixing  $\epsilon = 0$  is without loss of generality.

**Functionality  $\mathcal{F}_{\text{CGKA}}$**

 Parameters: **confidential**(epid), **authentic**(epid, id),  $\text{id}_{\text{creator}}$ 
**Initialization** // Executed on first input.

```

CurEp[*], HG[*]  $\leftarrow \perp$ 
epCtr  $\leftarrow 0$ 
 $E \leftarrow *new\text{-}ep$ ;  $E.\text{sndr} \leftarrow \text{id}_{\text{creator}}$ ;  $E.\text{mem} \leftarrow \{\text{id}_{\text{creator}}\}$ 
HG[0]  $\leftarrow E$ 
CurEp[ $\text{id}_{\text{creator}}$ ]  $\leftarrow 0$ 

```

**Input** (Send, act), act  $\in \{ 'up', 'add'\text{-}id_t, 'rem'\text{-}id_t \}$  from id

```

// Send inputs to sim. and allow it to reject them.
Send (Send, id, act) to the sim. and receive ack.
req ack
// Compute the new epoch E created by the action.
 $E \leftarrow *new\text{-}ep$ ;  $E.\text{par} \leftarrow \text{CurEp}[\text{id}]$ ;  $E.\text{sndr} \leftarrow \text{id}$ 
 $E.\text{act} \leftarrow \text{act}$ ;  $E.\text{mem} \leftarrow *mem(\text{CurEp}[\text{id}], \text{act})$ 
epCtr++; HG[epCtr]  $\leftarrow E$ 
// Enforce security after possible changes to HG.
assert *HG-is-consistent  $\wedge$  *auth-is-preserved
// Immediately transition id into the created epoch.
CurEp[id]  $\leftarrow \text{epCtr}$ 
// Output the idealized message chosen by adv.
Receive from the simulator C.
return C

```

**Input** GetKey from id

```

Send (Key, id) to the simulator and receive I.
epid  $\leftarrow \text{CurEp}[\text{id}]$ 
req epid  $\neq \perp$ 
if HG[epid].key =  $\perp$  then
  // Set the key according to confidential.
  if confidential(epid) then
    HG[epid].key  $\xleftarrow{\$}$   $\{0, 1\}^k$ 
    HG[epid].chall  $\leftarrow \text{true}$ 
  else
    HG[epid].key  $\leftarrow I$ 
return HG[epid].key

```

**Corruption** (Expose, id)

```

if CurEp[id]  $\neq \perp$  then // Record exposure.
  HG[CurEp[id]].exp  $\leftarrow \text{id}$ 
// Disallow adaptive corruptions to avoid commitment problem.
only allowed if  $\nexists \text{epid} : \text{HG}[\text{epid}].\text{chall} \wedge \neg \text{confidential}(\text{epid})$ 

```

**Helper** \*new-ep

```

return new epoch with sndr =  $\perp$ , par =  $\perp$ , act =  $\perp$ , mem =  $\emptyset$ ,
inj = false, key =  $\perp$ , exp =  $\emptyset$ , chall = false.

```

**Helper** \*mem(epid, act)

```

G  $\leftarrow \text{HG}[\text{epid}].\text{mem}$ 
if act = 'add'\text{-}id_t then
  G  $\leftarrow \text{id}_t$ 
else if act = 'rem'\text{-}id_t then
  G  $\leftarrow \text{id}_t$ 
if act  $\neq 'up'$   $\wedge$  G = HG[epid].mem then
  return  $\perp$ 
return G

```

**Input** (Receive, c) from id

```

// Send inputs to sim. and allow it to reject them.
Send (Receive, id, c) to the simulator and receive ack.
req ack
// Ask sim. to interpret the packet.
Receive from the simulator (sndr', act').
if act' = 'rem'\text{-}id then
  // Check that sndr' removed id or auth. not guaranteed.
  honestRem  $\leftarrow \exists \text{epid} : (\text{HG}[\text{epid}].\text{par} = \text{CurEp}[\text{id}]$ 
   $\wedge \text{HG}[\text{epid}].\text{sndr} = \text{sndr}' \wedge \text{HG}[\text{epid}].\text{act} = 'rem'\text{-}id)$ 
  assert honestRem  $\vee \neg \text{authentic}(\text{HG}[\text{CurEp}[\text{id}]], \text{sndr}')$ 
  CurEp[id]  $\leftarrow \perp$ 
  return (sndr', act')

```

 // Ask sim, to identify the epoch epid where id transitions. If epid =  $\perp$ , a new injected epoch is created.

Receive from the simulator epid.

**if** epid =  $\perp$  **then**

```

E  $\leftarrow *new\text{-}ep$ 
E.sndr  $\leftarrow \text{sndr}'$ ; E.act  $\leftarrow \text{act}'$ ; E.inj  $\leftarrow \text{true}$ 

```

**if** CurEp[id]  $\neq \perp$  **then**

// If id is a member, compute E.par and E.mem using its epoch.

```

E.par  $\leftarrow \text{CurEp}[\text{id}]$ 
E.mem  $\leftarrow *mem(\text{CurEp}[\text{id}], \text{act}')$ 

```

**else**

// If id joined, E is a detached root with arbitrary member set.

```

Receive E.mem from the simulator; set E.par  $\leftarrow \perp$ .
epCtr++; HG[epCtr]  $\leftarrow E$ 
epid  $\leftarrow \text{epCtr}$ 

```

**assert** HG[epid]  $\neq \perp$ 

// If a current group member transitions to a detached root, attach it.

**if** CurEp[id]  $\neq \perp \wedge \text{HG}[\text{epid}].\text{par} = \perp$  **then** HG[epid].par  $\leftarrow \text{CurEp}[\text{id}]$ 
**assert** CurEp[id] =  $\perp \vee \text{HG}[\text{epid}].\text{par} = \text{CurEp}[\text{id}]$ 
**assert** CurEp[id]  $\neq \perp \vee \text{HG}[\text{epid}].\text{act} = 'add'\text{-}id$ 

// Enforce security after possible changes to HG.

**assert** \*HG-is-consistent  $\wedge$  \*auth-is-preserved

// Transition id and compute its output.

 CurEp[id]  $\leftarrow \text{epid}$ 
**if** HG[epid].act = 'add'\text{-}id **then return** (HG[epid].sndr, HG[epid].mem)

**else return** (HG[epid].sndr, HG[epid].act)

**Helper** \*HG-is-consistent

// True if HG is a forest and membership is consistent.

**return** true **iff**

- a)  $\forall \text{id}$  s.t. CurEp[id]  $\neq \perp$  :  $\text{id} \in \text{HG}[\text{CurEp}[\text{id}]].\text{mem}$
- b) HG has no cycles
- c)  $\forall \text{epid} \in [\text{epCtr}]$  : HG[epid].mem  $\neq \perp$
- d)  $\forall \text{epid} \in [\text{epCtr}]$  s.t. HG[epid].par  $\neq \perp$  :  
HG[epid].mem = \*mem(HG[epid].par, HG[epid].act)

**Helper** \*auth-is-preserved

// True if there is no authentic epoch created by injected packet.

Observe that the root epid = 0 cannot be injected by definition.

```

return  $\nexists \text{epid} : 1 \leq \text{epid} \leq \text{epCtr} \wedge \text{HG}[\text{epid}].\text{inj}$ 
 $\wedge \text{authentic}(\text{HG}[\text{epid}].\text{par}, \text{HG}[\text{epid}].\text{sndr})$ 

```

Figure 14: The ideal CGKA functionality.

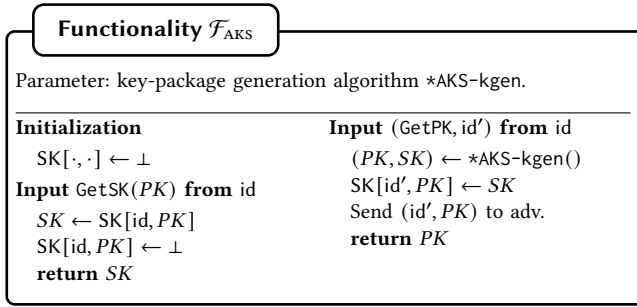

Figure 15: The Authenticated Key service Functionality.

$E.\text{par}$	The integer identifier of the parent epoch.
$E.\text{sndr}$	The party who created the epoch by performing a group operation.
$E.\text{act}$	The group modification performed when $E$ was created: either 'up' for update, or 'add'-id <sub><math>t</math></sub> for adding id <sub><math>t</math></sub> , or 'rem'-id <sub><math>t</math></sub> for removing id <sub><math>t</math></sub> .
$E.\text{mem}$	The set of group members.
$E.\text{key}$	The shared group key.
$E.\text{inj}$	A boolean flag indicating if the epoch is injected.
$E.\text{exp}$	The set of group members exposed (i.e., corrupted) in this epoch.
$E.\text{chall}$	A flag indicating if a random group key has been outputted.

Table 2: Attributes on an epoch in  $\mathcal{F}_{\text{CGKA}}$ .

*Inputs from parties.* The first two inputs, Send and Receive, are handled quite similarly. First, all inputted values are sent to the simulator (there are no private inputs). Second, the simulator sends a flag *ack* which decides if sending/receiving succeeds (or fails with output  $\perp$ ). Third,  $\mathcal{F}_{\text{CGKA}}$  updates the history graph and enforces that this does not destroy authenticity and consistency by checking that  $*\text{auth-is-preserved}$  and  $*\text{HG-is-consistent}$  are true. Finally,  $\mathcal{F}_{\text{CGKA}}$  transitions the sender/receiver to the new epoch (or removes its pointer in case it is removed) and computes the output using the new graph.

One aspect that needs more explanation is updating the graph when a party id receives  $c$ . In this case, the simulator interprets  $c$  for  $\mathcal{F}_{\text{CGKA}}$  (which abstracts away ciphertexts) by providing the sender  $\text{sndr}'$  and the action  $\text{act}'$ . If  $\text{act}'$  removes id, then the only possible authenticity check is that either  $\text{sndr}'$  removed id in its current epoch or the epoch is not authentic for  $\text{sndr}'$ . If id is not removed, the simulator identifies the epoch  $\text{epid}$  into which id transitions or joins. The epoch can be  $\perp$ , in which case  $\mathcal{F}_{\text{CGKA}}$  creates a new epoch  $E$  with the infected flag  $\text{inj}$  set. If id is a current group member, then  $E$  is a child of its current epoch. Otherwise, if id joins, then  $E$  is a detached root. Afterwards,  $\mathcal{F}_{\text{CGKA}}$  checks if  $\text{epid}$  identifies a detached root into which a current group member id transitions. If this is the case, the root is attached as a child of id's current epoch. For instance, this implies that any other party transitioning to  $\text{epid}$  must do so from id's current epoch and the epoch semantic must be consistent between it, id and the party who joined into  $\text{epid}$ .

The last input to  $\mathcal{F}_{\text{CGKA}}$  is GetKey, which simply outputs the group key from the party's current epoch. The key is set to a random or arbitrary value the first time it is retrieved by some party.

*Corruptions.* When a party is corrupted,  $\mathcal{F}_{\text{CGKA}}$  simply adds it to the exposed set  $\text{exp}$  of its current epoch. The set is later used by the security predicates. Then  $\mathcal{F}_{\text{CGKA}}$  disallows corruptions in case extending the  $\text{exp}$  set switched **confidential** of some epoch  $E$  with  $E.\text{chall}$  set from true to false.

## E THE AUTHENTICATED KEY SERVICE FUNCTIONALITY (AKS)

The AKS is modeled as the functionality  $\mathcal{F}_{\text{AKS}}$  in Fig. 15. Formally, SAIK works in the  $\mathcal{F}_{\text{AKS}}$ -hybrids model, i.e.,  $\mathcal{F}_{\text{AKS}}$  is available in the real world and emulated by the simulator in the ideal world.

$\mathcal{F}_{\text{AKS}}$  works as follows. When a party id wants to fetch a key package of another party id',  $\mathcal{F}_{\text{AKS}}$  generates a new key package for id' using SAIK's key-package generation algorithm (formally, the algorithm is a parameter of  $\mathcal{F}_{\text{AKS}}$ ). It sends (the public part of) the package to id and to the adversary. (Note that since  $\mathcal{F}_{\text{AKS}}$  exists in the real world, the adversary should be thought of as the UC environment.) The secrets for the key package can be fetched by id <sub>$t$</sub>  later, when it decides to join the group. Once fetched, secrets are deleted, which means that  $\mathcal{F}_{\text{AKS}}$  cannot be used as secure storage.

## F DETAILS OF SAIK

In this section we give the details of the SAIK protocol. The pseudocode can be found in Figs. 16 and 17.

### F.1 Ratchet Trees

A ratchet tree is a left-balanced  $q$ -ary tree (a formal definition can be found in App. H.5). This generalizes ITK' binary trees. Using  $q \neq 2$  can be beneficial in certain situations. A ratchet tree, as well as its nodes, have a number of labels listed in Table 3. We also define a number of helper methods in Table 6.

Importantly, the *direct path* of a leaf  $u$  consists of (the ordered list of) all nodes on the path from  $u$  to the root, without  $u$ . The *resolution* of a node  $v$  is the minimal set of descendant non-blank nodes that covers the whole sub-tree rooted at  $v$ .

### F.2 SAIK State and Algorithms

The state of SAIK consists of a number of variables, outlined in Table 4. The table also includes short descriptions of the roles of the secrets in the key schedule, which is extended by the intermediary secrets described in Table 5. The protocol will ensure that states of any two parties in the same epoch differ at most in labels of nodes of  $\gamma.\tau$  that describe secret keys and the label  $\gamma.\text{leaf}$ . This means that they agree on the secrets  $\gamma.\text{appSec}$  and  $\gamma.\text{initSec}$ , as well as on the public context, computed by the helper method  $\text{grpCtx}()$  in Table 4.

SAIK's algorithms are defined in Figs. 16 and 17. Apart from initialization, there are three main algorithms (the rest of the code are subroutines) exposed to a user (or a higher-level application). They are identified by keywords Send, Receive and Key, respectively. First, Send is used to create a new epoch. When the user inputs Send followed by the intended group modification (update,

$\tau$ .root	The root.
$v$ .isroot	True iff $v = \tau$ .root.
$v$ .isleaf	True iff $v$ has no children.
$v$ .parent	The parent node of $v$ (or $\perp$ if $v$ .isroot).
$v$ .children	If $\neg v$ .isleaf: ordered list of $v$ 's children.
$v$ .nodIdx	The node index of $v$ .
$v$ .depth	The length of the path from $v$ to $\tau$ .root.
$v$ .ek	An mmPKE encryption key.
$v$ .dk	The corresponding decryption key.
$v$ .vk	If $v$ .isleaf: a signature verification key.
$v$ .sk	If $v$ .isleaf: the corresponding signing key.
$v$ .unmLvs	The set of indices of the leaves below $v$ whose owner id does not know $v$ .sk.
$v$ .id	If $v$ .isleaf: the id associated with that leaf.

**Table 3: Labels of a ratchet-tree  $\tau$  and its nodes.**

$\gamma$ .grpId	The identifier of the group.
$\gamma$ . $\tau$	The ratchet tree.
$\gamma$ .leaf	The party's leaf in $\tau$ .
$\gamma$ .treeHash	A hash of the public part of $\tau$ .
$\gamma$ .lastAct	The last modification of the group state and the user who initiated it.
$\gamma$ .appSec	The current epoch's CGKA key. Exposed to the application layer.
$\gamma$ .initSec	The next epoch's init secret.
$\gamma$ .membKey	The next epoch's membership secret for authenticating messages.
$\gamma$ .grpCtxt()	Returns $(\gamma$ .grpId, $\gamma$ .treeHash, $\gamma$ .lastAct).
$\gamma$ .confTag	The confirmation tag, which is signed to ensure authenticity.

**Table 4: The protocol state of a party id and the helper method for computing the context.**

pathSec	The path secrets $s_2, \dots, s_n$ used to derive the key-pairs in each node. Sent via the mmPKE encryption to keep tree invariant intact.
commitSec	The path secret in the root node. Used as seed for the key schedule together with initSec from the previous epoch
joinerSec	Secret sent to new group members. Together with the group context, enables computation of the epSec.
epSec	Base secret used to derive all other secrets, i.e. appSec, membKey, initSec, confTag

**Table 5: Intermediate values computed by the protocol that are not part of the state.**

$\tau$ .clone()	Returns a copy of $\tau$ .
$\tau$ .public()	Returns a copy of $\tau$ with all labels $v$ .sk and $v$ .sk set to $\perp$ .
$\tau$ .roster()	Returns id's of all parties in $\tau$ .
$\tau$ .leaves()	Returns the list of all leaves in the tree, sorted from left to right.
$\tau$ .leafOf(id)	Returns the leaf $v$ with $v$ .id = id.
$\tau$ .getLeaf()	Returns leftmost $v$ s.t. $\neg v$ .inuse(). If no such $v$ exists, adds a new leaf using addLeaf( $\tau$ ) and returns it.
$\tau$ .blankPath( $v$ )	For all $u \in \tau$ .directPath( $v$ ) calls $u$ .blank().
$\tau$ .inSubtree( $u, v$ )	Returns true if $u$ is in $v$ 's subtree.
$v$ .inuse()	Returns false iff all labels are $\perp$ .
$v$ .blank()	Sets all labels of $v$ to $\perp$ .

**Table 6: Helper methods for a ratchet tree  $\tau$  and its nodes.**

$\tau$ .lca( $u, v$ )	Returns the lowest common ancestor of the two leaves.
$\tau$ .directPath( $v$ )	Returns the path from $v$ 's parent to the root.
$\tau$ .mergeLvs( $v$ )	Sets $u$ .unmLvs $\leftarrow \emptyset$ for all $u \in \tau$ .directPath( $v$ )
$\tau$ .unmerge( $v$ )	Sets $u$ .unmLvs $\leftarrow v$ for all $u$ returned by $\tau$ .directPath( $v$ )
$v$ .resolution()	If $v$ .inuse, return ( $v$ ) $\# v$ .unmLvs. Else if $v$ .isleaf, return (). Else, return $v$ .children[1].resolution() $\# \dots \# v$ .children[ $n$ ].resolution()
$v$ .resolvent( $u$ )	Returns the ancestor of $u$ in $v$ .resolution() $\setminus (v)$ (or $\perp$ if $u$ is not a descendant of $v$ ).

add or remove), the protocol applies the modification and returns a message, which the user can upload to the mailboxing service. Second, Receive is used to process messages downloaded from the service. Third, withKey user gets the current group key.

The formal syntax of saCGKA protocols is defined as part of our security definition in App. D. In particular, an saCGKA protocol must expose the same interface as the ideal CGKA functionality.

### F.3 Extraction Procedure for the Server

Finally, we describe a procedure  $\text{*extract}(C, \text{id}) \rightarrow c$  used by the mailboxing service to take an uploaded message  $C$  and compute the message  $c$  delivered to user id. Formally, this procedure is not part of our syntax or security definitions, since for simplicity our model does not consider correctness (see Sec. 4.6) and an untrusted service

## SAIK: Algorithms

## Initialization

```

Figure 17: Additional helper methods for SAIK.

can anyway deliver arbitrary messages. It is formally defined in Fig. 18.

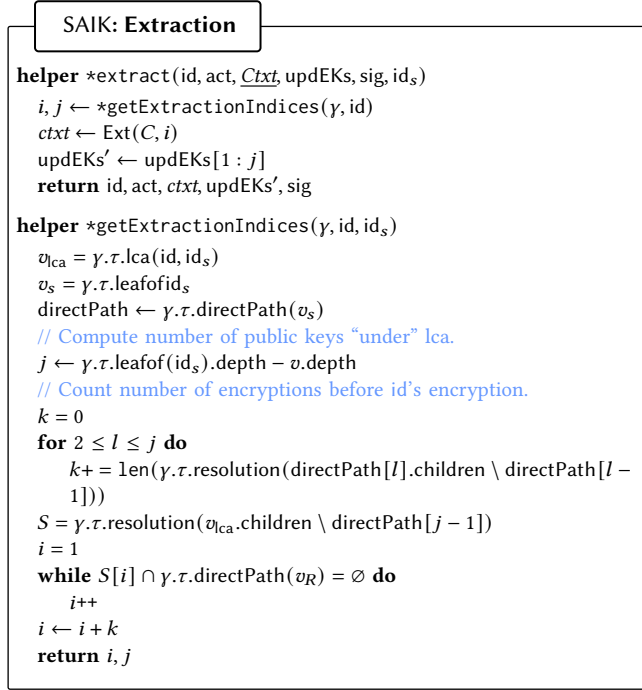

Figure 18: Helper functions for extraction.

Recall that  $C$  contains the executed group operation act and the sender  $id_s$ , a multi-recipient ciphertext  $Ctxt$  and a vector of updated public keys updEKs. Roughly, \*extract only needs to compute  $id$ 's individual mmpKE ciphertext mmpKE.Ext( $Ctxt$ ,  $i$ ) and the prefix of the first  $j$  elements of updEKs. This requires that it knows the indices  $i$  and  $j$  for  $id$ . We notice that they can be easily computed using the public part of the ratchet tree, act and  $id_s$ . Therefore, the indices can be obtained in two ways. First, the service can send act and  $id_s$  to  $id$ , who replies with  $i$  and  $j$ . This requires interaction, but both  $id$  and the service are online at the time. Second, the service can store the current ratchet trees and compute  $i$  and  $j$  itself. The disadvantage of this is that it requires keeping a large state — in case members are out of sync (e.g. a user is 10 epochs behind), the service needs to store one tree for each epoch which has an active member in it. Once  $i$  and  $j$  are known, \*extract works as follows.

If act = 'up', set  $ctxt$  = mmpKE.Ext( $Ctxt$ ,  $i$ ) and updEKs' = (updEKs[1], ..., updEKs[ $j$ ]). Output  $c$  = ( $id_s$ , act,  $ctxt$ , updEKs', sig), where sig is a field of  $C$ . If act = 'rem'- $id$ , then output  $c$  = ( $id_s$ , 'removed', sig <sub>$t$</sub> , tag <sub>$t$</sub> ) where sig <sub>$t$</sub>  and tag <sub>$t$</sub>  are taken from  $C$ . Finally, if act = 'add'- $id$ ,  $C$  contains welcomeData, which in turn contains a ratchet tree. Based on this, compute  $id$ 's index  $i$  in  $Ctxt$ , the number  $n$  of recipients of  $Ctxt$ , and  $ctxt_1$  = mmpKE.Ext( $Ctxt$ ,  $i$ ) and  $ctxt_2$  = mmpKE.Ext( $Ctxt$ ,  $n + 1$ ). Output  $c$  = ( $id_s$ , act,  $ctxt_1$ ,  $ctxt_2$ , welcomeData).

## F.4 Propose-Commit Syntax

As discussed in Sec. 4.6, in order to tame the complexity of (sa)CGKA, we use a simplified syntax instead of the more general (and more efficient) propose-commit syntax. In this section we explain in detail how to transform SAIK to the propose-commit syntax.

In the propose-commit syntax, an (sa)CGKA protocol takes the following inputs from a party  $id$ :

**Add proposal:**  $id$  proposes to add  $id_t$ . The protocol outputs a proposal packet  $p$ .

**Remove proposal:**  $id$  proposes to remove  $id_t$ . The protocol outputs a proposal packet  $p$ .

**Update proposal:**  $id$  proposes to update their key material. The protocol outputs a proposal packet  $p$ .

**Commit:**  $id$  inputs a list of proposal packets ( $p_1, \dots, p_n$ ) (after receiving them from other parties). The protocol outputs a commit packet  $c$ .

**Process:**  $id$  inputs a commit packet  $c$  and a list ( $p_1, \dots, p_n$ ) of proposals it commits (after receiving all these packets from other parties). The protocol outputs the semantics of applied group operations.

**Key:**  $id$  fetches the current group key.

Observe that if an application always commits a single proposal immediately after creating it, the propose-commit syntax collapses to our (sa)CGKA syntax.

*Proposals in SAIK.* SAIK deals with proposals in the same way as ITK. First, it computes the proposal content act which identifies the proposed modification:

**Add proposal:** To add  $id_t$ , query (GetPk,  $id_t$ ) to  $\mathcal{F}_{KS}$ , receive ( $ek_t$ ,  $vk_t$ ,  $ek'_t$ ) and set act = 'add'- $id_t$ -( $ek_t$ ,  $vk_t$ ,  $ek'_t$ ).

**Remove proposal:** To remove  $id_t$ , set act = 'rem'- $id_t$ .

**Update proposal:** Sample new key pairs ( $vk, sk$ ) ← Sig.KG() and ( $ek, dk$ ) ← mmpKE.KG() and store  $dk$  and  $sk$  for later. Set act = 'upd'-( $ek, vk$ ).

The proposal packet is act signed with the sender's current key  $\gamma$ .leaf( $id$ ).sk and MACed with the current membKey.

*Commit in SAIK.* A commit in SAIK is almost identical to its Send input. It proceeds in two steps.

- (1) *Applying proposed group modifications to the ratchet tree:* Currently, SAIK applies only a single modification in the \*create-epoch helper. The propose-commit SAIK extends this step and applies all proposed actions one by one. This is done by calling the helper \*apply-act( $\gamma$ ,  $id_s$ , act) for each act (after verifying the signature and the MAC). Further, we extend the \*apply-act helper to deal with update proposals — such actions simply replace proposer's leaf public keys with the ones in act. In addition, if the update proposal is applied by its sender, they replace their leaf's secret keys by  $dk$  and  $sk$  stored when generating the update.
- (2) *Rekeying the sender's path:* The remaining part of Send remains mostly unchanged. The only difference is related to the possibility of there being many add proposals:
  - In line 9 of Send (excluding comments), the joinerSec is currently encrypted to one new member. In the propose-commit SAIK, it is instead encrypted to  $N$  new members, who are the last  $N$  recipients of the mmpKE ciphertext.

- In line 18 of Send, SAIK currently computes the welcome data needed by new members. In the propose-commit SAIK, this includes the public keys  $(ek'_1, \dots, ek'_N)$ , of all  $N$  new members, instead of only one.

*Processing a commit in SAIK.* The receive procedure of SAIK is modified analogous to its send procedure. In case the receiver is a member and is not removed, it applies all proposed actions and then processes the committer's path exactly like the current SAIK.

Finally, to join, a new member finds their public key in the list  $(ek'_1, \dots, ek'_N)$  contained in the welcome data. Let  $i$  denote the index of that key. They decrypt the joinerSec as the  $(N - i)$ -th to last recipient of the mmPKE ciphertext. Then they proceed as in the current SAIK.

## G ONE-WAYNESS SECURITY OF MMPKE

In this section, we define One-Wayness under Relaxed Chosen Ciphertext Attacks security of mmPKE, mmOW-RCCA. Moreover, we prove that mmOW-RCCA security is implied by mmIND-RCCA security for schemes with large message spaces.

*Motivation.* We note that one-wayness security for mmPKE is less straightforward to define than for standard PKE schemes. Roughly, for standard PKE, one-wayness requires that given an encryption of a random message chosen by the challenger, no adversary can find the encrypted message. For mmPKE, the input to encryption is not a single message but a vector of messages. Moreover, even if the adversary corrupts recipients of some messages in the vector, it still should not be able to find the remaining messages. Therefore, it is now less clear how the challenge message vector should be chosen. The definition presented in this section is precisely what is needed for the security proof of ITK. We do not claim that it is the "right" notion, as it may not be suited to other applications.

*The game.* The mmOW-RCCA game is defined in Fig. 19, the challenge ciphertext is computed as follows: The adversary sends a public-key vector, as well as a message vector  $\vec{m}$  and a set of indices  $S$  within this vector. The challenger then inserts the same random message  $m^*$  into all positions in  $\vec{m}$  indicated by  $S$  (the previous values of  $\vec{m}$  at these positions are ignored). It encrypts the result and sends the ciphertext to the adversary, whose goal is to find  $m^*$ .

*Remarks.* First, we note that the mmOW-RCCA game has no notion of leakage. Instead, the leakage is implicit in how the vector encrypted by the challenger is chosen — the "leakage" is everything the adversary knows about that vector, such as whether two slots contain the same message or not.

Second, the game allows the adversary to verify if some message  $m'$  is the correct solution  $m^*$ . This can be done by sending  $m'$  to the decrypt oracle and checking if it returns 'test'. This additional ability makes the notion stronger (i.e., more difficult to achieve). We show that mmIND-RCCA security is sufficient to achieve it.

*Definition G.1 (mmOW-RCCA).* For an mmPKE with message space  $\mathcal{M}$ , the advantage of an adversary  $\mathcal{A}$  against One-Wayness under Replayable Chosen Ciphertext Attacks (mmOW-RCCA) security of mmPKE is defined as

$$\text{Adv}_{\text{mmPKE}, N}^{\text{mmOW-RCCA}}(\mathcal{A}) = \Pr \left[ \text{Exp}_{\text{mmPKE}, N}^{\text{mmOW-RCCA}}(\mathcal{A}) \Rightarrow 1 \right],$$

where  $\text{Exp}_{\text{mmPKE}, N}^{\text{mmOW-RCCA}}(\mathcal{A})$  is defined in Fig. 19.

*Relation to mmIND-CCA.* We prove that mmOW-RCCA security is implied by mmIND-RCCA for schemes with large message spaces.

**THEOREM G.2.** *Let mmPKE be an mmPKE scheme with message space  $\mathcal{M}$ . For any adversary  $\mathcal{A}$ , there exists an adversary  $\mathcal{B}$  such that*

$$\text{Adv}_{\text{mmPKE}, N}^{\text{mmOW-RCCA}}(\mathcal{A}) \leq \text{Adv}_{\text{mmPKE}, N}^{\text{mmIND-RCCA}}(\mathcal{B}) + \frac{2}{\mathcal{M}}.$$

**PROOF.** The proof closely follows the typical proofs showing that IND security implies OW security for standard encryption.

Given an adversary  $\mathcal{A}$  against mmOW-RCCA security, the reduction  $\mathcal{B}$  attacking mmIND-RCCA simply runs  $\mathcal{A}$  on the public keys it receives in the mmIND-RCCA experiment and forwards all  $\mathcal{A}$ 's oracle queries to its mmIND-RCCA oracles. When  $\mathcal{A}$  outputs the triple  $(ek, \vec{m}, S)$ ,  $\mathcal{B}$  computes the challenge ciphertext as follows. First, it initializes  $\vec{m}_0^*, \vec{m}_1^* \leftarrow \vec{m}$ . Then, it picks two random messages  $m_0^*$  and  $m_1^*$  and for each  $j \in S$  sets  $\vec{m}_0^*[j] \leftarrow m_0^*$  and  $\vec{m}_1^*[j] \leftarrow m_1^*$ . It sends  $ek$  together with  $\vec{m}_0^*$  and  $\vec{m}_1^*$  to the mmIND-RCCA experiment, receives the challenge ciphertext  $c^*$  and sends it to  $\mathcal{A}$ . At the end of the experiment,  $\mathcal{A}$  outputs a guess  $m'$ . If  $m' = m_1^*$ , then  $\mathcal{B}$  outputs 1. Else, it outputs 0.

First, it is easy to see that if  $\mathcal{A}$  does not violate any **req** statements in the emulation, then  $\mathcal{B}$  does not violate any **req** statements in the mmIND-RCCA game. In particular,  $\vec{m}_0^*$  and  $\vec{m}_1^*$  clearly have the same leakage. It is also easy to see that if  $\mathcal{A}$  does not trivially win by corruptions then  $\mathcal{B}$  does not either.

Second, observe that if  $\mathcal{B}$ 's challenger uses the bit  $b = 1$ , then  $\mathcal{B}$  emulates  $\mathcal{A}$ 's experiment perfectly, unless  $\mathcal{A}$  inputs to **Dec**<sub>2</sub> something that decrypts to  $m_0^*$ . The reason is that in this case  $\mathcal{B}$  replies with 'test' (forwarded from its oracle), while  $\mathcal{A}$  should receive  $m_0^*$ . Since  $m_0^*$  is random and independent of  $\mathcal{A}$ 's view, this happens with probability at most  $1/\mathcal{M}$ . Thus, it is easy to see that

$$\Pr \left[ \text{Exp}_{\text{mmPKE}, N, n, 1}^{\text{mmIND-RCCA}}(\mathcal{B}) \Rightarrow 1 \right] \leq \text{Adv}_{\text{mmPKE}, N, n}^{\text{mmIND-RCCA}}(\mathcal{A}) + \frac{1}{\mathcal{M}}.$$

If  $\mathcal{B}$  is in the experiment with the bit  $b = 0$ , then  $m_1^*$  is independent of  $\mathcal{A}$ 's view, so the probability that it outputs  $m' = m_1^*$  and hence also that  $\mathcal{B}$  outputs 1 is at most  $\frac{1}{\mathcal{M}}$ .  $\square$

## H SECURITY OF SAIK

The security predicates for SAIK are defined in Fig. 20. See Sec. 6 for the intuition. The stronger version of the predicates that is not achieved by SAIK skips the code in `boxes` while the weaker version includes the whole code. In Sec. 8.1 we sketch how to modify SAIK to achieve the stronger version.

For the mmPKE scheme we assume a security property called mmOW-RCCA, defined in App. G. The notion is strictly weaker than mmIND-CCA; in App. G we prove the implication.

**THEOREM H.1.** *Let  $\mathcal{F}_{\text{CGKA}}$  be the CGKA functionality with predicates **confidential** and **authentic** defined in Fig. 20. Let SAIK be instantiated with schemes mmPKE, Sig and MAC, and with the HKDF functions modelled as a random oracle Hash. Let  $\mathcal{A}$  be any environment. Denote the output of  $\mathcal{A}$  from the real execution with SAIK and the hybrid functionality  $\mathcal{F}_{\text{AKS}}$  from Fig. 15 as  $\text{REAL}_{\text{SAIK}, \mathcal{F}_{\text{AKS}}}(\mathcal{A})$  and*

the output of  $\mathcal{A}$  from the ideal execution with  $\mathcal{F}_{\text{CGKA}}$  and a simulator  $\mathcal{S}$  as  $\text{IDEAL}_{\mathcal{F}_{\text{CGKA}}, \mathcal{S}}(\mathcal{A})$ . There exists a simulator  $\mathcal{S}$  and adversaries  $\mathcal{B}_1$  to  $\mathcal{B}_4$  such that

$$\begin{aligned} & \Pr[\text{IDEAL}_{\mathcal{F}_{\text{CGKA}}, \mathcal{S}}(\mathcal{A}) = 1] - \Pr[\text{REAL}_{\text{SAIK}, \mathcal{F}_{\text{AKS}}}(\mathcal{A}) = 1] \leq \\ & \quad \text{Adv}_{\text{Hash}}^{\text{CR}}(\mathcal{B}_1) \\ & \quad + q_e^2 (q_e + 1) \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e \log(q_n), q_n}^{\text{mmOW-RCCA}}(\mathcal{B}_2) \\ & \quad + 2q_e \cdot \text{Adv}_{\text{Sig}}^{\text{EUF-CMA}}(\mathcal{B}_3) \\ & \quad + q_e \cdot \text{Adv}_{\text{MAC}}^{\text{EUF-CMA}}(\mathcal{B}_4) + 3q_h q_e^2 (q_e + 1) / 2^k, \end{aligned}$$

where  $q_e$ ,  $q_n$  and  $q_h$  denote bounds on the number of epochs, the group size and the number of  $\mathcal{A}$ 's queries to the random oracle modelling the Hash, respectively.

## H.1 Proof Outline

In the remaining subsections we prove Theorem H.1.

The proof proceeds in a sequence of hybrids, transitioning from the real to the ideal world. Hybrid 1 differs from the real world only syntactically. That is, the environment  $\mathcal{A}$  interacts with a dummy CGKA functionality  $\mathcal{F}_{\text{CGKA}}^1$  which allows the simulator to set all outputs. This means that  $\mathcal{F}_{\text{CGKA}}^1$  gives no security guarantees. The next three hybrids introduce the guarantees of consistency, confidentiality and authenticity, one by one. More precisely, in hybrid 2,  $\mathcal{A}$  interacts with  $\mathcal{F}_{\text{CGKA}}^2$  which is the same as  $\mathcal{F}_{\text{CGKA}}$ , except it uses **confidential** and **authentic** set to false. In particular, this means that  $\mathcal{F}_{\text{CGKA}}^2$  builds a history graph, enforces its consistency and uses it to compute outputs. In hybrid 3,  $\mathcal{A}$  interacts with  $\mathcal{F}_{\text{CGKA}}^3$

which uses the original **confidential** predicate, and in hybrid 4 it interacts with  $\mathcal{F}_{\text{CGKA}}^4$  which also uses the original **authentic** predicate. Notice that  $\mathcal{F}_{\text{CGKA}}^4$  is  $\mathcal{F}_{\text{CGKA}}$ .

In the next subsections, we define the hybrids and show that each pair of consecutive hybrids is indistinguishable for  $\mathcal{A}$ . Intuitively, each such statement means that SAIK provides the introduced security guarantee.

**Hybrid 1.** This is the experiment  $\text{IDEAL}_{\mathcal{F}_{\text{CGKA}}^1, \mathcal{S}^1}$  where the dummy functionality  $\mathcal{F}_{\text{CGKA}}^1$  sends all inputs to the simulator  $\mathcal{S}^1$  and allows it to set all outputs.  $\mathcal{S}^1$  executes SAIK.

## H.2 SAIK Guarantees Consistency

The following hybrid introduces consistency.

**Hybrid 2:**  $\text{IDEAL}_{\mathcal{F}_{\text{CGKA}}^2, \mathcal{S}^2}$ . The functionality  $\mathcal{F}_{\text{CGKA}}^2$  is the same as  $\mathcal{F}_{\text{CGKA}}$  except it uses **confidential** = **authentic** = false. The simulator  $\mathcal{S}^2$  is described later in this section.

In the remainder of this section, we construct the simulator  $\mathcal{S}^2$  and show that hybrids 1 and 2 are indistinguishable.

**THEOREM H.2.** *For any environment  $\mathcal{A}$ , there exists an adversary  $\mathcal{B}$  such that*

$$\Pr \left[ \text{IDEAL}_{\mathcal{F}_{\text{CGKA}}^2, \mathcal{S}^2}(\mathcal{A}) \Rightarrow 1 \right] - \Pr \left[ \text{IDEAL}_{\mathcal{F}_{\text{CGKA}}^1, \mathcal{S}^1}(\mathcal{A}) \Rightarrow 1 \right] \leq \text{Adv}_{\text{Hash}}^{\text{CR}}(\mathcal{B}) + q_e/2^\kappa,$$

where  $\text{Hash}$  models the  $\text{HKDF.Exp}$  and  $\text{HKDF.Ext}$  functions and  $q_e$  denotes an upper bound on the number of epochs.

**The simulator.** We first describe  $\mathcal{S}^2$ . In general, it runs SAIK just like  $\mathcal{S}^1$ , only its interaction with the functionality is different. Most importantly,  $\mathcal{F}_{\text{CGKA}}^2$  requires that  $\mathcal{S}^2$  identifies epochs into which parties transition. Doing this correctly is crucial for proving that SAIK guarantees consistency, because  $\mathcal{F}_{\text{CGKA}}^2$  enforces it by computing outputs and asserting conditions relative to parties' current epochs. (It must also be done so that we can later prove that SAIK guarantees confidentiality and authenticity.)

$\mathcal{S}^2$  identifies epochs by their epoch secrets  $\text{epSec}$ , computed by SAIK on Receive and Send. Recall that a party  $\text{id}$  transitioning from an epoch  $E[1]$  to  $E_2$  computes  $E_2$ 's  $\text{epSec}$  by hashing  $E[1]$ 's  $\text{initSec}$ , the new  $\text{commitSec}$  (combined into the  $\text{joiner}$ ) generated by  $E_2$ 's creator and  $E_2$ 's context. We will show that these values contain enough information for  $\text{epSec}$  to *uniquely* identify  $E_2$ . Recall also that the group and  $\text{initKey}$  of  $E_2$  are derived from  $\text{epSec}$ . The simulator is described in more detail in Fig. 21.

**Proof.** We next prove Theorem H.2. Observe that hybrids 1 and 2 are identical unless one of the following two events occurs in hybrid 2:

**BreaksCons** : Either the output of a party on Receive or Key computed according to  $\mathcal{F}_{\text{CGKA}}^2$  and  $\mathcal{S}^2$  is different than the output  $\mathcal{S}^1$  would compute according to SAIK in hybrid 1, or an **assert** condition is false.

**EpidColl** : An honestly created epoch has the same  $\text{epSec}$  as an existing epoch.

Observe that since an honest sender mixes a fresh  $\text{commitSec}$  into the derivation of  $\text{epSec}$ , the probability of **EpidColl** is at most  $q_e/2^\kappa$  (where  $\kappa$  is the length of all secrets). It remains to show that if  $\mathcal{A}$

triggers **BreaksCons**, then a reduction  $\mathcal{B}$  can extract from a hash collision. (Theorem H.2 follows by the standard difference lemma.)

Let  $\mathcal{A}$  be any environment and assume that at the end of hybrid 2 with  $\mathcal{A}$  there are no hash between values hashed by  $\mathcal{S}^2$  while running SAIK on behalf of honest parties. We show that in this case **BreaksCons** cannot occur. This proves the claim, because if there was a hash collision between values hashed by honest parties, then  $\mathcal{B}$  could extract them by emulating  $\mathcal{S}^1$ .

Observe that if two parties transition to the same epoch  $\text{epid}$ , then by definition of  $\mathcal{S}^2$  they compute the same  $\text{epSec}$ . Recall that they compute  $\text{epSec} \leftarrow \text{Hash}(\text{joinerSec}, \text{grpCtxt})$  (Fig. 17), where  $\text{grpCtxt} = (\text{grpId}, \text{treeHash}, \text{id}_s\text{-act})$  (Table 4). Since there are no hash collisions, this means that the parties also agree on:

- The creator  $\text{HG}_s$  of  $\text{epid}$ , the action  $\text{act}$  it performed and the public part of the ratchet tree, included in  $\text{treeHash}$ . This implies agreement on the roster, which is encoded in the tree leaves.
- The group key in  $\text{epid}$ , derived as  $\text{Hash}(\text{epSec}, \text{'app'})$ .

Moreover, let  $\text{epSec}'$  denote the epoch secret of  $\text{epid}$ 's parent. We have  $\text{joinerSec} = \text{Hash}(\text{initSec}', \text{commitSec})$ , where  $\text{initSec}' = \text{Hash}(\text{epSec}', \text{'init'})$  and  $\text{commitSec}$  is freshly chosen for  $\text{epid}$  by its creator. Therefore, parties in  $\text{epid}$  also agree on:

- The parent epoch  $\text{epid}'$  identified by  $\text{epSec}'$ .

Observe that the check  $\text{Hash}(\text{initSec}', \text{commitSec}) = \text{joinerSec}$  is verified by current members transitioning to  $\text{epid}$  but not by joiners. However, joiners implicitly agree with current members on the parent  $\text{epid}'$ . That is, if an  $\text{id}_r$  joins into  $\text{epid}$ , then  $\text{epid}$  has parent  $\text{epid}'$  (unknown to  $\text{id}_r$ ) or no parent at all (for detached roots).

We next show that agreement on a), b) and c) implies that **BreaksCons** does not occur. First, a) and b) imply that all parties joining an epoch  $\text{epid}$  output the same value, all parties transitioning there output the same, and afterwards all output the same key. Second, c) implies that  $\text{HG}$  is a forest, i.e., epoch has one parent.

Third, we have to argue that parties' outputs are the same as computed by  $\mathcal{F}_{\text{CGKA}}^2$ . This is obvious for the key (always chosen by  $\mathcal{S}^2$  to match), sender and action. For the member set, we will show that the ratchet tree of parties in an epoch  $\text{epid}$  is consistent with  $\text{HG}[\text{epid}].\text{mem}$  computed by  $\mathcal{F}_{\text{CGKA}}^2$ . We use induction on the distance of  $\text{epid}$  to the root. If  $\text{epid}$  is the main root, then the statement is true by definition and if it is a detached roots, then  $\mathcal{S}^2$  chooses  $\text{mem}$  to match the ratchet tree. For any non-root  $\text{epid}$ , some party  $\text{id}$  must have transitioned there from its parent  $\text{epid}'$  (on Receive or Send). By induction hypothesis, the ratchet tree in  $\text{epid}'$  is consistent with  $\text{HG}[\text{epid}'].\text{mem}$ . By agreement on  $\text{act}$  in a),  $\text{id}$  modifies the tree the same way as  $\mathcal{F}_{\text{CGKA}}^2$  modifies  $\text{HG}[\text{epid}].\text{mem}$ , which proves the statement.

## H.3 SAIK Guarantees Confidentiality

The third hybrid introduces confidentiality, which is formalized by restoring the original confidentiality predicate of  $\mathcal{F}_{\text{CGKA}}$ .

**Hybrid 3:**  $\text{IDEAL}_{\mathcal{F}_{\text{CGKA}}^3, \mathcal{S}^3}$ . The functionality  $\mathcal{F}_{\text{CGKA}}^3$  uses the original **confidential** predicate from  $\mathcal{F}_{\text{CGKA}}$ . The simulator  $\mathcal{S}^3$  is the same as  $\mathcal{S}^2$ .

In the remainder of this section, we show that if  $\text{mmPKE}$  is  $\text{mmOW-RCCA}$  secure, then SAIK guarantees confidentiality, that

### Simulator $\mathcal{S}^2$

$\mathcal{S}^2$  keeps a list  $\text{EpSecs}$ , where  $\text{EpSecs}[\text{epid}]$  stores the epoch secret identifying epoch  $\text{epid}$ . It runs SAIK and interacts with  $\mathcal{F}_{\text{CGKA}}^2$  as follows:

- If SAIK outputs  $\perp$  on Send or Receive,  $\mathcal{S}^2$  sends  $\text{ack}$  set to false.
- On each Send,  $\mathcal{S}^2$  computes the new epoch's  $\text{epSec}$  and appends it to  $\text{EpSecs}$ . It sends to  $\mathcal{F}_{\text{CGKA}}$  the message  $C$  computed using SAIK.
- On each Receive,  $\mathcal{S}^2$  first sends to  $\mathcal{F}_{\text{CGKA}}$  the values  $\text{sndr}'$ ,  $\text{act}'$  from the message. If the receiver is not removed,  $\mathcal{S}^2$  sends  $\text{epid}$  into which id transitions chosen as follows:
  - If there is a  $\text{epid}$  s.t.  $\text{EpSecs}[\text{epid}] = \text{epSec}$ , then  $\mathcal{S}^2$  sends this (unique)  $\text{epid}$  to  $\mathcal{F}_{\text{CGKA}}^2$ .
  - Else,  $\mathcal{S}^2$  appends  $\text{epid}$  to  $\text{EpSecs}$  and sends  $\text{epid} = \perp$  to  $\mathcal{F}_{\text{CGKA}}^2$ .

Finally, if a detached root is created and  $\mathcal{F}_{\text{CGKA}}^2$  asks for the member set  $\text{mem}'$ ,  $\mathcal{S}^2$  computes it from the new member's ratchet tree.

Figure 21: The simulator for the proof of the security of SAIK.

is, that hybrids 2 and 3 are indistinguishable. Formally, we prove the following theorem.

**THEOREM H.3.** *For any environment  $\mathcal{A}$ , there exists an adversary  $\mathcal{B}$  such that*

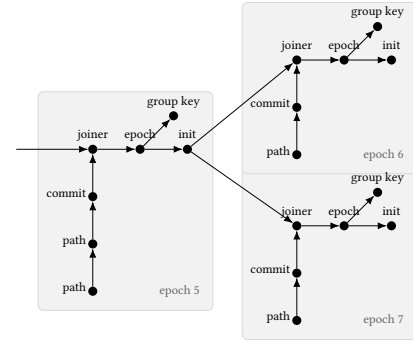

$$\Pr \left[ \text{IDEAL}_{\mathcal{F}_{\text{CGKA}}^3, \mathcal{S}^3}(\mathcal{A}) \Rightarrow 1 \right] - \Pr \left[ \text{IDEAL}_{\mathcal{F}_{\text{CGKA}}^2, \mathcal{S}^2}(\mathcal{A}) \Rightarrow 1 \right] \leq 4q_e^2 q_h / 2^K + q_e^2 \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e \log(q_n), q_n}^{\text{mmOW-RCCA}}(\mathcal{B}),$$

where the HKDF functions are modeled as a random oracle and where  $q_n$ ,  $q_h$  and  $q_e$  are upper bounds on, respectively, the group size, the number of  $\mathcal{A}$ 's hash queries and the number of epochs.

**Game-based perspective.** For better intuition, observe that hybrids 2 and 3 are almost identical. In both experiments, the environment interacts with the CGKA functionality and the same simulator. The only difference is that group keys in confidential epochs are real in hybrid 2 (technically, computed by the simulator according to SAIK) and random and independent in hybrid 3 (technically, sampled by  $\mathcal{F}_{\text{CGKA}}^3$ ). This means that distinguishing between hybrids 2 and 3 can be seen as a typical confidentiality game for CGKA schemes. The adversary's challenge queries correspond to  $\mathcal{A}$ 's  $\text{GetKey}$  inputs on behalf of parties in confidential epochs and its reveal-session key queries correspond to  $\mathcal{A}$ 's  $\text{GetKey}$  inputs in non-confidential epochs. To disable trivial wins, confidential epochs where a random key has been outputted are marked by setting a flag  $\text{chall}$ .  $\mathcal{A}$  and the adversary in the game are not allowed to corrupt if this makes such an epoch non-confidential.

**Key Graphs.** A key graph visualizes different secrets created in an execution of SAIK and hash relations between them. Each node in the graph corresponds to a secret, e.g. the group key in epoch 5, and has assigned its value. The directed edges are interpreted as follows: the value of a node is the hash of the values of all its in-neighbors with an appropriate label. If a node has many out-neighbors, then the value of each out-neighbor is computed by hashing with a different label (i.e., the values of out-neighbors are domain-separated). Values of source nodes are either chosen at random by the protocol or injected by the adversary. The key-graph nodes are partitioned by epochs: Secrets of an epoch  $\text{epid}$  are those created when  $\text{epid}$  is created. We distinguish two types of secrets: *group secrets* which include the  $\text{init}$ ,  $\text{joiner}$  and epoch secrets as

well as the group key, and *individual secrets*, which include path secrets, the last being the commit secret. An example key graph is given below. We removed membership secrets for simplicity. Note that the epochs 6 and 7 are created in parallel, that is, we have a group fork.

Note that in case of injections the values of nodes may not be unique. However, the values of epoch secrets uniquely identify epochs. Note also that the values of group secrets of  $\text{epid}$  appear only in the states of parties in  $\text{epid}$ . On the other hand,  $\text{mmPKE}$  keys derived from path secrets of  $\text{epid}$  appear in ratchet trees stored by parties in multiple epochs.

**Bad events.** Let  $\mathcal{A}$  be any environment. The goal is to show that  $\mathcal{A}$  cannot distinguish the real group keys of confidential epochs it sees in hybrid 2 from random and independent keys in hybrid 3. Since epochs in detached trees are not confidential, in the remainder of the proof we only consider epochs in the main history-graph tree.

Observe that there are only two dependencies between the real group key  $\text{appSec}$  of an epoch  $\text{epid}$  and the rest of the experiment:  $\text{appSec}$  is stored by parties in  $\text{epid}$  and it is the hash of  $\text{epid}$ 's unique epoch secret  $\text{epSec}$ . If  $\text{epid}$  is confidential, then no party in  $\text{epid}$ , i.e., no party storing  $\text{appSec}$  is corrupted. Therefore, unless  $\mathcal{A}$  inputs  $\text{epSec}$  to the RO, the real group key is independent of the rest of the experiment. In other words, unless  $\mathcal{A}$  inputs  $\text{epSec}$  to the RO, the real group key outputted in hybrid 2 is distributed identically as the random key in hybrid 3.

Therefore,  $\mathcal{A}$ 's distinguishing advantage is upper-bounded by the probability that the following event  $\text{SecsHashed}_{\text{epid}}$  occurs for at least one epoch  $\text{epid}$ . For convenience, the event is more general and also considers  $\text{init}$  and  $\text{joiner}$  secrets.

**Event**  $\text{SecsHashed}_{\text{epid}}$  : At the end of the experiment,  $\text{epid}$  is confidential and  $\text{epid}$ 's  $\text{init}$ ,  $\text{epoch}$  or  $\text{joiner}$  secret is contained in a value inputted by  $\mathcal{A}$  to RO.

Formally, it is left to prove the following lemma.

LEMMA H.4. *There exists a reduction  $\mathcal{B}$  such that*

$$\Pr[\exists \text{epid} : \text{SecsHashed}_{\text{epid}}] \leq 4q_e^2 q_h / 2^K + q_e^2 \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e \log(q_n), q_n}^{\text{mmIND-RCCA}}(\mathcal{B}).$$

**Bounding probability of bad events.** An epoch  $\text{epid}$  is confidential if  $\text{*grp-secs-secure}(\text{epid})$  is true (all predicates are defined in Fig. 20). The latter predicate is recursive, starting at the root epoch with  $\text{epid} = 0$ . Accordingly, we will prove a recursive upper bound on the probability of  $\text{SecsHashed}_{\text{epid}}$ . Formally, Lemma H.4 is implied by the following lemma.

LEMMA H.5. *There exists a reduction  $\mathcal{B}$  and (arbitrary) events  $\text{BreaksRCCA}_{\text{epid}}$ <sup>8</sup> for  $\text{epid} \in \mathbb{N}$  such that*

- a)  $\Pr[\exists \text{epid} : \text{SecsHashed}_0] \leq 4q_h / 2^K$ .
- b) *For each  $\text{epid} > 0$  with parent  $\text{epid}_p$ , we have*  

$$\Pr[\text{SecsHashed}_{\text{epid}}] \leq 4q_h / 2^K + \Pr[\text{SecsHashed}_{\text{epid}_p}] + \Pr[\text{BreaksRCCA}_{\text{epid}}].$$
- c)  $\Pr[\exists \text{epid} : \text{BreaksRCCA}_{\text{epid}}] \leq q_e \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e \log(q_n), q_n}^{\text{mmIND-RCCA}}(\mathcal{B})$ .

Lemma H.5 implies Lemma H.4, because by Lemma H.5

$$\begin{aligned} \Pr[\text{SecsHashed}_{\text{epid}}] &\leq \sum_{i=0}^{\text{epid}-1} (4q_h / 2^K + \Pr[\text{BreaksRCCA}_i]) \\ &\leq 4q_e q_h / 2^K + \Pr[\exists \text{epid} : \text{BreaksRCCA}_{\text{epid}}] \\ &\leq 4q_e q_h / 2^K + q_e \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e \log(q_n), q_n}^{\text{mmIND-RCCA}}(\mathcal{B}), \end{aligned}$$

where the first step follows from a) and b) in Lemma H.5. We arrive at Lemma H.4, since by union bound  $\Pr[\exists \text{epid} : \text{SecsHashed}_{\text{epid}}] \leq q_e \cdot \max_{\text{epid}} \Pr[\text{SecsHashed}_{\text{epid}}]$ .

**Proof of Lemma H.5 a).** The root epoch does not have  $\text{joiner}$  and  $\text{epoch}$  secrets. The  $\text{init}$  secret of epoch 0 is chosen at random by the group creator  $\text{id}_{\text{creator}}$ . Moreover, it is independent of the rest of the experiment apart from being stored by  $\text{id}_{\text{creator}}$  in epoch 0. The reason is that any other values are derived by first hashing it, and outputs of the RO are independent of the inputs. If epoch 0 is confidential, then  $\text{id}_{\text{creator}}$  is not corrupted in epoch 0, so  $\mathcal{A}$  has no information about the  $\text{init}$  secret. Therefore, the best strategy for  $\mathcal{A}$  to trigger  $\text{SecsHashed}_0$  is by guessing the  $\text{init}$  secret, which succeeds with probability at most  $q_h / 2^K < 4q_h / 2^K$ .

**Proof of Lemma H.5 b).** Take any non-root epoch  $\text{epid} > 0$  with parent  $\text{epid}_p$ . Let  $\text{initSec}$ ,  $\text{epSec}$ ,  $\text{joinerSec}$  and  $\text{commitSec}$  denote  $\text{epid}$ 's  $\text{init}$ ,  $\text{epoch}$ ,  $\text{joiner}$  and  $\text{commit}$  secrets. Let  $\text{initSec}_p$  denote  $\text{epid}_p$ 's  $\text{init}$  secret.

Observe that the only dependencies between  $\text{initSec}$ ,  $\text{epSec}$ ,  $\text{joinerSec}$  and the rest of the experiment are as follows: 1)  $\text{initSec}$  is stored by parties in  $\text{epid}$ , 2)  $\text{joinerSec}$  is the output of the RO on

input  $\text{commitSec}$  together with  $\text{initSec}_p$ , 3)  $\text{joinerSec}$  is encrypted to new members. (Note that any other values are derived by first hashing it, and outputs of the RO are independent of the inputs.)

Assume for a moment that  $\text{epid}$  is confidential. Then, no party in  $\text{epid}$  is corrupted, so dependency 1) does not exist. Recall that confidentiality requires either  $\text{*grp-secs-secure}(\text{epid}_p)$  is true or  $\text{*all-ind-secs-secure}(\text{epid})$  is true. Observe that dependency 2) does not exist either unless one of the following events occurs:

**Event**  $\text{InitHashed}_{\text{epid}_p}$  : At the end of the experiment, the value of  $\text{*grp-secs-secure}(\text{epid}_p)$  is true and  $\text{initSec}_p$  (of  $\text{epid}_p$ ) is contained in some value inputted by  $\mathcal{A}$  to the RO.

**Event**  $\text{CommHashed}_{\text{epid}}$  : At the end of the experiment, the predicate  $\text{*all-ind-secs-secure}(\text{epid})$  is true and  $\text{commitSec}$  (of  $\text{epid}$ ) is contained in some value inputted by  $\mathcal{A}$  to RO.

This means that unless  $\text{InitHashed}_{\text{epid}_p}$  or  $\text{CommHashed}_{\text{epid}}$  occurs,  $\mathcal{A}$  has no information about  $\text{initSec}$  and  $\text{epSec}$ . Therefore, the best strategy for  $\mathcal{A}$  to trigger  $\text{SecsHashed}_{\text{epid}}$  is to either guess  $\text{initSec}$  or  $\text{epSec}$  at random, or trigger one of the above events, or input the  $\text{joiner}$  secret based only on dependency 3). We capture the last event by

**Event**  $\text{joinerSec}_{\text{epid}}$  : At the end of the experiment, none of the values inputted by  $\mathcal{A}$  to the RO includes  $\text{initSec}_p$  (of  $\text{epid}_p$ ) and  $\text{commitSec}$  (of  $\text{epid}$ ) together, but some value contains  $\text{joinerSec}$  (of  $\text{epid}$ ).

Therefore, we have

$$\Pr[\text{SecsHashed}_{\text{epid}}] \leq 2q_h / 2^K + \Pr[\text{InitHashed}_{\text{epid}_p}] + \Pr[\text{CommHashed}_{\text{epid}}].$$

By definition,  $\Pr[\text{InitHashed}_{\text{epid}_p}] \leq \Pr[\text{SecsHashed}_{\text{epid}_p}]$ . Moreover, we define

**Event**  $\text{BreaksRCCA}_{\text{epid}}$  : Either  $\text{CommHashed}_{\text{epid}}$  or  $\text{JoinHashed}_{\text{epid}}$  occurs.<sup>9</sup>

This proves the claim.

**Proof of Lemma H.5 c).** We construct two reductions  $\mathcal{B}_1$  and  $\mathcal{B}_2$  whose advantages bound the probability of the event  $\exists \text{epid} : \text{JoinHashed}_{\text{epid}}$  and of  $\exists \text{epid} : \text{CommHashed}_{\text{epid}}$ , respectively.

LEMMA H.6. *There exists a reduction  $\mathcal{B}_1$  such that*

$$\Pr(\exists \text{epid} : \text{JoinHashed}_{\text{epid}}) \leq q_e \cdot \text{Adv}_{\text{mmPKE}, 1, q_n}^{\text{mmIND-RCCA}}(\mathcal{B}_1).$$

**PROOF.** Take any epoch  $\text{epid}$  with parent  $\text{epid}_p$  (the root does not have a  $\text{joiner}$  secret). Observe that the  $\text{joiner}$  secret of  $\text{epid}$  is never stored in the state of SAIK. Moreover, the only message that may include it is the message creating  $\text{epid}$  which potentially encrypts it to a new member. This means that if  $\mathcal{A}$  does not input to the RO the  $\text{init}$  secret of  $\text{epid}_p$  together with the  $\text{commit}$  secret of  $\text{epid}$ , then the only part of its view that may depend on the  $\text{joiner}$  of  $\text{epid}$  is the ciphertext in the message creating  $\text{epid}$ . In particular, if  $\text{epid}$  is honestly created and adds a party  $\text{id}_r$ , then the ciphertext encrypts the  $\text{joiner}$  under  $\text{id}_r$ 's key from the AKS (i.e., our PKI). Since the AKS is uncorruptible and  $\text{id}_r$  deletes the secret key immediately after using it, this means that inputting the  $\text{joiner}$  to the RO implies breaking security of  $\text{mmPKE}$ .

<sup>8</sup>The lemma implies Lemma H.4 no matter what  $\text{BreaksRCCA}_{\text{epid}}$  is. The name will become clear later in the proof.

<sup>9</sup>Intuitively, the only dependency between the  $\text{commit}$  and  $\text{joiner}$  secrets comes from encryptions, so inputting the secrets to the RO requires breaking  $\text{IND-RCCA}$ .

More formally, consider the following reduction  $\mathcal{B}_1$  playing the mmOW-RCCA game with 1 user.  $\mathcal{B}_1$  guesses an epoch  $\text{epid}^* \in [q_e]$  and runs  $\mathcal{A}$ , emulating the CGKA functionality and the simulator as in hybrid 2. If  $\text{epid}^*$  is injected or not created on an add,  $\mathcal{B}_1$ 's emulation is identical to hybrid 2. Otherwise,  $\mathcal{B}_1$ 's emulation will be identical to hybrid 2 but where the joiner secret  $\text{joinerSec}^*$  of  $\text{epid}^*$  is replaced the mmOW-RCCA challenge message  $m^*$ .  $\mathcal{B}_1$  will use a special symbol 'test' to denote this unknown value of  $m^*$  in the emulation.

In particular, when an  $\text{id}_s$  creates  $\text{epid}^*$  while adding an  $\text{id}_r$ ,  $\mathcal{B}_1$  embeds the single public key  $\text{ek}^*$  from its game as the key generated for  $\text{id}_r$  by the AKS (recall that the AKS generates the key pair  $(\text{ek}^*, \text{dk}^*)$  at the moment  $\text{id}_s$  requests it to create the epoch). Further,  $\mathcal{B}_1$  computes SAIK's state for  $\text{epid}^*$  according to the protocol. It then replaces the (fresh) joiner secret generated by SAIK by 'test' in all places, including the programmed RO inputs and outputs. Finally,  $\mathcal{B}_1$  sends to the challenger the message vector  $\vec{m}$  encrypted by  $\text{id}_s$  and the last index in this vector, denoting the (only) position of the joiner secret. The challenger sends back a ciphertext  $C^*$ , which  $\mathcal{B}_1$  uses in the message sent by  $\text{id}_s$ .

If  $\text{id}_r$  uses  $\text{dk}^*$ ,  $\mathcal{B}_1$  uses the Dec oracle. Note that Dec may output 'test', which is used consistently with the symbol for the unknown joiner  $m^*$ . If  $\mathcal{A}$  inputs to the RO the init secret  $\text{initSec}^*$  of  $\text{epid}^*$ 's parent together with the commit  $\text{commitSec}^*$  of  $\text{epid}^*$ ,  $\mathcal{B}_1$  halts and gives up. At the end of the experiment,  $\mathcal{B}_1$  searches all  $\mathcal{A}$ 's queries to the RO for an  $m^*$  that allows it to win.

We first claim that, until  $\mathcal{B}_1$  gives up or the experiment ends, its emulation is perfect. In particular, since  $\mathcal{A}$  does not input  $\text{initSec}^*$  with  $\text{commitSec}^*$  to the RO, which means that, apart from  $C^*$ , its experiment is independent of  $\text{joinerSec}^*$ . This means that  $\mathcal{B}_1$  simulates it perfectly by using 'test' instead of  $\text{joinerSec}^*$ . Second, we claim that if  $\text{JoinHashed}_{\text{epid}^*}$  occurs, then  $\mathcal{B}_1$  wins. Indeed, the event guarantees that  $\mathcal{A}$  inputs  $m^*$  to the RO and  $\mathcal{B}_1$  does not give up  $\mathcal{A}$  does not input  $\text{initSec}^*$  with  $\text{commitSec}^*$  to the RO.

Therefore, we have

$$\begin{aligned} \text{Adv}_{\text{mmPKE}, 1, q_n}^{\text{mmIND-RCCA}}(\mathcal{B}_1) &\geq \Pr(\text{JoinHashed}_{\text{epid}^*}) \\ &\geq 1/q_e \Pr(\exists \text{epid} : \text{JoinHashed}_{\text{epid}}). \end{aligned}$$

□

LEMMA H.7. *There exists a reduction  $\mathcal{B}_2$  such that*

$$\Pr(\exists \text{epid} : \text{CommHashed}_{\text{epid}}) \leq q_e \cdot \text{Adv}_{\text{mmPKE}, q_e, \log(q_n), q_n}^{\text{mmIND-RCCA}}(\mathcal{B}_2).$$

PROOF. We start by describing the reduction  $\mathcal{B}$ . Recall that SAIK generates mmPKE key pairs and ciphertexts when epochs are created: When a party  $\text{id}_s$  creates an epoch, it generates a hash chain of secrets, consisting of  $\log(q_n)$  path secrets and the commit secret. Each path secret is then hashed to obtain randomness used to generate a single key pair. Moreover, if a new member is added, its new mmPKE key pair is generated by the AKS. Then,  $\text{id}_s$  sends out all new public keys and a single ciphertext encrypting secrets to different recipients.

The reduction  $\mathcal{B}$  runs  $\mathcal{A}$ , emulating the functionality and the simulator executing SAIK as in hybrid 2 with the following differences. First  $\mathcal{B}$  embeds public keys from the mmOW-RCCA game as public keys sent when epochs are created. It generates all secrets itself independently of the key pairs. Further, it picks a random

epoch  $\text{epid}^*$  and a random index  $i^* \in [\log(q_n)]$ . When  $\text{epid}^*$  is created,  $\mathcal{B}$  asks the challenger for an encryption  $C^*$  of the secrets  $\mathcal{B}$  generated, but with the  $i^*$ -th secret replaced by the challenge message  $s^*$ .  $\mathcal{B}$  is supposed to compute  $C^*$  is then embedded in the sent message. For the the unknown value of the  $i^*$ -th secret,  $\mathcal{B}_{\text{epid}}$  uses a special symbol 'test' (it is used for bookkeeping, e.g. to consistently program the RO).<sup>10</sup>

When a party is corrupted,  $\mathcal{B}$  corrupts all receivers whose secret keys are in the party's state. When  $\mathcal{A}$  sends a new value to the RO,  $\mathcal{B}$  checks if it contains its solution  $s^*$  and, if so, sends it to the challenger and halts. Otherwise,  $\mathcal{B}$  programs the RO consistently with already generated values. Importantly, if the output is key-generation randomness for an mmOW-RCCA receiver,  $\mathcal{B}$  corrupts this receiver to obtain it. (Here we use programmability to deal with adaptive corruptions.)

When a party  $\text{id}_r$  receives a message,  $\mathcal{B}$  runs  $\text{id}_r$ 's protocol with the help of the Dec oracle. Note that Dec may output 'test', which  $\mathcal{B}$  uses for the unknown value of the  $i^*$ -th secret.

PRECISE DESCRIPTION OF  $\mathcal{B}$ . At the beginning,  $\mathcal{B}$  guesses an epoch  $\text{epid}^* \in [q_e]$  and an index  $i^* \in [\log(q_n)]$ . Then, it runs  $\mathcal{A}$ , emulating for it the functionality and the simulator by running their code with the following differences.

Recall that the simulator stores a single ratchet tree per epoch.  $\mathcal{B}$  modifies these trees by assigning to each node two additional labels: one storing a receiver in the mmOW-RCCA game and one storing a secret. The root's secret stores the epoch's commit secret. The secret of any other internal node stores the path secret from which its key pair was derived. The leaf's secrets are not used. Alternatively, a secret can be set to  $\perp$  in case of injections or 'test' to denote the unknown mmOW-RCCA challenge  $s^*$ . A joiner secret can also take value 'test'. Secret keys in the ratchet tree will not be used.

To emulate the RO,  $\mathcal{B}$  keeps a table of programmed input-output pairs. Some inputs and outputs may contain a special symbol 'test'. The symbol is not in the RO input domain, so it cannot be inputted by  $\mathcal{A}$  (but it will be used by  $\mathcal{B}$  when the protocol evaluates hashes). Whenever  $\mathcal{A}$  sends a new input,  $\mathcal{B}$  first checks if it contains its solution and halts if this is the case. Else, it checks if the output should be equal to key-generation randomness derived from a path secret in some ratchet tree node. If so,  $\mathcal{B}$  corrupts the node's receiver to obtain the RO output. Else, it programs a fresh value.

Further,  $\mathcal{B}$  makes the following changes to how the functionality and simulator process different inputs of  $\mathcal{A}$ .

- $\text{id}_s$  SENDS.  $\mathcal{B}$  generates the new epoch and the message handed to  $\mathcal{A}$  as follows:
  - (1) Generate the new epoch's path secrets, as well as all secrets in the key schedule at random. If the created epoch is  $\text{epid}^*$ , replace the  $i^*$ -th secret (a path, commit or joiner secret) by 'test'. Program the RO according to how the secrets are derived.
  - (2) Generate the new epoch's ratchet tree: Copy the ratchet tree from  $\text{id}_s$ 's epoch, apply the action and (re-)assign node labels as follows: For each node on  $\text{id}_s$ 's path

<sup>10</sup>One may expect that if  $\text{CommHashed}_{\text{epid}}$  occurs, then the challenge can be embedded in the commit secret inputted by  $\mathcal{A}$  to the RO. Intuitively, this cannot work, because confidentiality of the commit secret clearly relies on the confidentiality of path secrets before it and of path secrets from which encryption keys were derived.

and, in case of an add, the node of the new member, set the mmOW-RCCA receiver to the next receiver not appearing in any ratchet tree, and set the public key to the public key of its receivers. The path secret of  $\text{id}_s$  leaf is  $\perp$  (since its key pair is generated using fresh randomness) and the path secret of each node above it is set to the secret chosen in Step 1.

- (3) Generate the ciphertext included in the sent packet: If the created epoch is not  $\text{epid}^*$ , then simply encrypt the secrets. Else, compute the public key vector  $\vec{ek}$  and message vector  $\vec{m}$  with the secrets as in the protocol. Let  $S$  be the set of all  $i$  such that  $\vec{m}[i] = \text{'test'}$ .  $\mathcal{B}$  sends  $\vec{ek}$ ,  $\vec{m}$  and  $S$  to the challenger to obtain the sent ciphertext.
  - (4) Use the above values to complete emulating the functionality and the simulator as in their code.
- $\text{id}_r$  RECEIVES A MESSAGE REMOVING IT. If the message removes  $\text{id}_r$ , then it carries no secrets, so  $\mathcal{B}$  simply runs  $\text{id}_r$ 's protocol.
  - A CURRENT MEMBER  $\text{id}_r$  RECEIVES A MESSAGE NOT REMOVING IT.  $\mathcal{B}$  first decrypts the path secret  $s$  from the packet. Say  $\text{id}_r$  uses the keys in a ratchet-tree node  $v$  to decrypt. If  $v$  has an mmOW-RCCA receiver assigned,  $\mathcal{B}$  sets  $s$  to the output of the decryption oracle. Else, if  $v$  has no receiver but it has a path secret,  $\mathcal{B}$  derives  $v$ 's key pair by hashing the secret, programming the RO if necessary, and decrypts  $s$ . Else, it rejects the packet on behalf of the simulator. After decrypting,  $\mathcal{B}$  checks if  $s$  is the solution  $s^*$  and halts if this is the case. If not, it proceeds as follows.

$\mathcal{B}$  computes the epoch secret  $\text{epSec}$  that identifies the epoch into which  $\text{id}_r$  transitions. The value of  $\text{epSec}$  is derived from  $s$  the same way as in the protocol, where hashes are evaluated using the RO table and the RO is programmed to a fresh value if necessary. Note that some evaluations may involve the symbol  $\text{'test'}$ .

If  $\text{id}$  transitions to an injected epoch,  $\mathcal{B}$  creates or updates the epoch as follows:

- (1) If the epoch does not exist, create its ratchet tree by applying the action specified in the packet to the ratchet tree from  $\text{id}$ 's current epoch and set public keys, secrets and mmOW-RCCA receivers of all nodes on the re-keyed path to  $\perp$ . Set the init, epoch and joiner secrets to those derived from  $\text{epSec}$ .
- (2) Let  $u$  be the least common ancestor of the sender's and  $\text{id}$ 's leaves in the ratchet tree. Use the decrypted secret  $s$  to derive and assign the path secrets and public keys for  $u$  and each node above it by evaluating the RO, programming if necessary. (In case the tree already existed, this potentially adds missing secrets to it.)
- (3) Assign to each node below  $u$  the public key from the packet.

Finally,  $\mathcal{B}$  verifies if  $\text{id}_r$  accepts the packet, as in the simulator. If it does, then  $\mathcal{B}$  transitions  $\text{id}_r$ . Else, it undoes all changes.

- A NEW MEMBER  $\text{id}_r$  RECEIVES A MESSAGE. In this case  $\text{id}_r$  receives two ciphertexts, one with its path secret and one

with the joiner secret.  $\mathcal{B}$  decrypts these secrets as in case a current member receives a message. If one of them is the solution  $s^*$ ,  $\mathcal{B}$  sends it to the challenger and halts.

Then,  $\mathcal{B}$  computes the epoch secret of the epoch into which  $\text{id}_r$  transitions by hashing the decrypted joiner secret. If this epoch is injected,  $\mathcal{B}$  creates or updates it the same way as when current member receives. Note that if the epoch does not exist,  $\mathcal{B}$  uses the public part of the ratchet tree from  $\text{id}_r$ 's packet.

- EXPOSE. When  $\text{id}$  is exposed,  $\mathcal{B}$  computes its mmPKE secret keys by hashing the path secrets from the ratchet tree in  $\text{id}$ 's current epoch.  $\mathcal{B}$  corrupts the mmOW-RCCA receivers if necessary.

**The reduction wins.** Assume  $\text{CommHashed}_{\text{epid}}$  occurs. We show that there exist  $\text{epid}^*$  and  $i^*$  such that  $\mathcal{B}$  wins. We start with a simple observation.

LEMMA H.8. *If  $\text{*all-ind-secs-secure}(\text{epid})$  is true, then for each  $v$  in  $\tau$ ,  $v.\text{ek}$  is generated during an honest send.*

PROOF. Take any  $v$  in  $\tau$ . Let  $\text{epid}_0$  be the epoch which introduces  $v.\text{ek}$  and let  $\text{id}_s$  be its (alleged) creator. Assume towards a contradiction that  $\text{epid}_0$  is injected. If  $\text{epid}_0 = \text{epid}$ , then we immediately get a contradiction with  $\text{CommHashed}_{\text{epid}}$ . Else, this means that  $\text{*ind-secs-bad}(\text{epid}_0, \text{id}_s)$  is true. Moreover, no epoch between  $\text{epid}_0$  and  $\text{epid}$ , including  $\text{epid}$ , is created by  $\text{id}_s$  or removes it, since this would replace  $v$ 's keys. Therefore,  $\text{*ind-secs-secure}(\text{epid}, \text{id}_s)$  is false and  $\text{*all-ind-secs-secure}(\text{epid})$  is false, which contradicts with  $\text{CommHashed}_{\text{epid}}$  being true.  $\square$

Let  $\tau$  be the ratchet tree in  $\text{epid}$ . By Lemma H.8, we can assign to each internal node  $v$  in  $\tau$  a secret: each non-root node is assigned the path secret  $s$  encrypted by  $\mathcal{B}$  when  $v$ 's public key was introduced and the root is assigned the commit secret of  $\text{epid}$ .  $\text{CommHashed}_{\text{epid}}$  guarantees that  $\mathcal{A}$  inputs to the RO the secret of at least one node, namely the root. Let  $v^*$  be a node in  $\tau$  with the maximal distance from the root whose secret  $s^*$  is inputted by  $\mathcal{A}$  to the RO. Let  $\text{epid}^*$  be the epoch before  $\text{epid}$  which creates  $v^*$ 's secret  $s^*$ . We claim that  $\mathcal{B}$  wins with the guess  $\text{epid}^*$  and  $i^*$  set to  $v^*$ 's index.

Indeed,  $\text{epid}^*$  is honestly created (by Lemma H.8), so  $\mathcal{B}$  can embed the challenge. It is left to show that each public key used to encrypt  $s^*$  belongs to an uncorrupted mmOW-RCCA receiver. For this, observe that each such key belongs to a node  $v$  in  $v^*$ 's sub-tree in the ratchet tree  $\tau^*$  of  $\text{epid}^*$ . Moreover,  $v$ 's key does not change between  $\text{epid}^*$  and  $\text{epid}$ , since this would replace  $v$ 's keys as well. By Lemma H.8, this means that  $v$ 's key belongs to some mmOW-RCCA receiver.

It remains to show that this receiver is not corrupted. This can happen in two cases: 1) if  $\mathcal{A}$  inputs to the RO the path secret from which  $v$ 's key pair was derived or 2)  $\mathcal{A}$  corrupts a party holding  $v$ 's secret key. Case 1) cannot occur for the following reason:  $v$ 's key pair can only be derived from the secret of an internal node  $u$  below  $v$  in  $\tau^*$ . Note that  $u$  is also below  $v^*$  in  $\tau^*$ . Therefore,  $u$ 's secret (and keys) do not change between  $\text{epid}^*$  and  $\text{epid}$ , since this would replace  $v^*$ 's keys as well. Since  $v^*$  has the maximal distance among nodes with secrets inputted to the RO,  $\mathcal{A}$  does not input  $u$ 's secret. Finally, we show that case 2) cannot occur as well.

LEMMA H.9. *If  $\text{*all-ind-secs-secure}(\text{epid})$  is true, then for each  $v$  in  $\tau$ , no party holding  $v.\text{dk}$  is corrupted.*

PROOF. Take any  $v$  in  $\tau$ . Let  $\text{epid}_0$  be the epoch which introduces  $v.\text{ek}$  and let  $\text{epid}[1], \dots, \text{epid}_\ell$  be the epochs after  $\text{epid}_0$  that can be reached from it without  $v$ 's keys being replaced. Note that these epochs form a tree rooted at  $\text{epid}_0$ .

We first observe that  $v$ 's subtree is the same in the ratchet trees of all epochs  $\text{epid}_0, \dots, \text{epid}_\ell$ , because any modification replaces  $v$ 's keys. Moreover,  $\text{epid}$  is one of these epochs, so this subtree is the same as in  $\tau$ . Let  $\text{id}[1], \dots, \text{id}_n$  be the parties in  $v$ 's subtree in  $\tau$ .

Second, we observe that if  $\text{*all-ind-secs-secure}(\text{epid})$  is true, then no  $\text{id}_i$  is corrupted in any epoch  $\text{epid}_j$ . The reason is that for any  $\text{id}_i$ , each  $\text{epid}_j$  is connected to  $\text{epid}$ , and  $\text{epid}$  is one of  $\text{epid}_0, \dots, \text{epid}_\ell$ , by a sequence of epochs not created by  $\text{id}_i$  and not removing or adding it. This is because any such operation would replace  $v$ 's keys. Therefore, if  $\text{id}_i$  was corrupted in some  $\text{epid}_j$ , then the predicate  $\text{*ind-secs-secure}(\text{epid}, \text{id}_i)$  would be false and the predicate  $\text{*all-ind-secs-secure}(\text{epid})$  would be false, which contradicts  $\text{CommitHashed}_{\text{epid}}$ .

Finally, it is left to show that  $v.\text{dk}$  is held only by  $\text{id}[1], \dots, \text{id}_n$  in epochs  $\text{epid}_0, \dots, \text{epid}_\ell$ . It is easy to see that this is implied by the following statement:

*Statement* : Assume an  $\text{id}^\perp$  in an epoch  $\text{epid}^\perp$  stores a secret key for a ratchet tree node  $v^\perp$  such that  $v^\perp.\text{dk} = v.\text{ek}$  for some  $v$  in  $\tau$ . Then, there is party  $\text{id}_i$  and a path between  $\text{epid}$  and  $\text{epid}^\perp$  that does not *heal*  $\text{id}_i$ , i.e., no epoch on the path is created by  $\text{id}_i$ , removes it or adds it.

We next prove the above statement by induction on the height of  $v^\perp$ . For the base case where  $v^\perp$  is a leaf, observe that  $v^\perp$ 's keys are not generated from a seed and that  $v^\perp.\text{dk}$  is only stored by  $v^\perp$ 's owner after it generates it while creating an epoch. So,  $v^\perp.\text{dk} = v.\text{dk}$  can only happen if  $v^\perp.\text{dk}$  is generated by an  $\text{id}_i$  when it creates an epoch  $\text{epid}_0$  before  $\text{epid}$ . Therefore,  $\text{epid}_0$  is a common ancestor of  $\text{epid}^\perp$  and  $\text{epid}$  and can be reached from both epochs by a path that does not heal  $\text{id}_i$ .

Now assume  $v^\perp$  is an internal node and the statement holds for any node with smaller height. Let  $\text{epid}_0^\perp$  be the epoch before  $\text{epid}^\perp$  that introduces  $v^\perp.\text{dk}$  into the state of  $\text{id}^\perp$ . Further, let  $\text{epid}_0$  be the epoch that introduces  $v.\text{dk}$  into  $\tau$ .

We have two cases: First, if  $\text{epid}_0^\perp$  is not injected, then we must have  $\text{epid}_0^\perp = \text{epid}_0$ . The reason is that the only non-injected epoch introducing  $v.\text{ek}$  is  $\text{epid}_0$ . Moreover, all parties transitioning to  $\text{epid}_0^\perp = \text{epid}_0$  agree on the public ratchet tree, so  $v^\perp = v$  and the subtree of  $v^\perp = v$  is the same in  $\text{epid}$  and  $\text{epid}^\perp$ . Therefore, the statement is obvious in this case.

Second, assume  $\text{epid}_0^\perp$  is injected. Let  $u^\perp$  be the node in the ratchet tree of  $\text{epid}_0^\perp$  used by  $\text{id}^\perp$  to decrypt  $v^\perp$ 's path secret  $s$ . For this proof sketch, we assume that there exists a node  $u$  such that  $u.\text{ek}$  corresponds to  $u^\perp.\text{dk}$  and  $u.\text{ek}$  was used to encrypt  $s$  when  $\text{epid}_0$  was created.<sup>11</sup> This means that  $u$  is in the subtree of  $v$  in

<sup>11</sup>This is only false if  $\mathcal{A}$  manages to re-encrypt a securely encrypted  $s$  under a different key. Being able to do so implies breaking security of mmPKE. Formally, the reduction  $\mathcal{B}_{\text{epid}}$  in the full proof searches for the solution  $s^*$  in both  $\mathcal{A}$ 's RO queries and injected messages that it decrypts using the Dec oracle or some other known keys. Accordingly,  $v^*$  is taken to be the lowest whose secret is not inputted to the RO or re-encrypted and injected.

$\text{epid}_0$  and, since this tree is the same as in  $\tau$ , also in the subtree of  $v$  in  $\text{epid}$ . Further,  $u^\perp$  is in the subtree of  $v^\perp$  in  $\text{epid}_0^\perp$  and, since this tree is the same as in  $v^\perp$ 's subtree in  $\text{epid}^\perp$ , also in the subtree of  $v^\perp$  in  $\text{epid}^\perp$ . Moreover,  $u^\perp$  is strictly below  $v^\perp$  and  $u^\perp.\text{dk} = u.\text{dk}$ , so by induction hypothesis, there is  $\text{and}_i$  and a path between  $\text{epid}$  and  $\text{epid}^\perp$  that does not *heal*  $\text{id}_i$ .  $\square$

$\square$

## H.4 SAIK Guarantees Authenticity

The fourth and final Hybrid introduces authenticity, which is formalized by restoring the **authentic** predicate. It is the ideal experiment with  $\mathcal{F}_{\text{CGKA}}$ .

**Hybrid 4:**  $\text{IDEAL}_{\mathcal{F}_{\text{CGKA}}, \mathcal{S}^4}$ . The functionality  $\mathcal{F}_{\text{CGKA}}^4$  uses the original **authentic** predicate from  $\mathcal{F}_{\text{CGKA}}$ . The simulator  $\mathcal{S}^4$  is the same as  $\mathcal{S}^4$ .

In the remainder of this section, we show that if Sig and MAC are unforgeable and if mmPKE is mmOW-RCCA secure, then SAIK guarantees authenticity, that is, hybrids 3 and 4 are indistinguishable. We note that security of mmPKE is needed e.g. to guarantee secrecy of MAC keys.

**Game-based perspective.** We observe that hybrids 3 and 4 are identical unless a bad event *Forges* occurs. Roughly, *Forges* happens if  $\mathcal{A}$  breaks authenticity, that is, if it successfully impersonates an  $\text{id}_s$  towards  $\text{id}_r$  in an epoch  $\text{epid}$  such that **authentic** is true for  $\text{id}_s$  in  $\text{epid}$ . Therefore,  $\mathcal{A}$ 's advantage in distinguishing the hybrids is upper bounded by the probability of *Forges*. This means that distinguishing hybrids 3 and 4 can be seen as a typical authenticity game, where the adversary wins by forging messages accepted by the protocol, as expressed by *Forges*.

**Bad events.** Let  $\mathcal{A}$  be any environment. The hybrids are identical unless the following event *Forges* occurs: There exists an epoch  $\text{epid}$  with two members  $\text{id}_s$  and  $\text{id}_r$  s.t. the following condition holds:

**Condition** *Forges*( $\text{epid}, \text{id}_s, \text{id}_r$ ): **authentic**( $\text{epid}, \text{id}_s$ ) is true and  $\mathcal{A}$  makes  $\text{id}_r$  accept a message that either (A) makes  $\text{id}_r$  transition to a new epoch  $\text{epid}'$  with  $\text{HG}[\text{epid}'].\text{inj}$  true ( $\text{epid}'$  is injected) and  $\text{HG}[\text{epid}].\text{sndr} = \text{id}_s$  or (B) removes  $\text{id}_r$  and  $\text{id}_s$  did not remove  $\text{id}_r$ .

Note that (A) implies that asserting  $\text{*auth-is-preserved}$  in  $\mathcal{F}_{\text{CGKA}}$  fails, and (B) implies that the assertion on input *Receive* that removes the receiver fails. These are the only places where  $\mathcal{F}_{\text{CGKA}}$  uses **authentic**.

Since epochs in detached trees are not authentic, in the remainder of the proof we only consider epochs in the main history-graph tree. For such an epoch  $\text{epid}$ , **authentic**( $\text{epid}, \text{id}_s$ ) is true if either the group secrets in  $\text{epid}$  or the individual secrets of  $\text{id}_s$  are secure. Accordingly, we define two sub-events of *Forges* depending on which secrets are secure:

**Event** *ForgesSym*: There exists an epoch  $\text{epid}$  with two members  $\text{id}_s$  and  $\text{id}_r$  such that  $\text{*grp-secs-secure}(\text{epid})$  and *Forges*( $\text{epid}, \text{id}_s, \text{id}_r$ ) are true.

**Event** *ForgesAsym*: There exists an epoch  $\text{epid}$  with two members  $\text{id}_s$  and  $\text{id}_r$  such that  $\text{*ind-secs-secure}(\text{epid}, \text{id}_s)$  and *Forges*( $\text{epid}, \text{id}_s, \text{id}_r$ ) are true.

It remains to bound the probability of each  $\text{ForgesAsym}$  and  $\text{ForgesSym}$ .

**Asymmetric forgery.** We next prove the following lemma

LEMMA H.10. *There exists a reduction  $\mathcal{B}_1$  such that*

$$\Pr[\text{ForgesAsym}] \leq 2q_e \cdot \text{Adv}_{\text{Sig}}^{\text{EUF-CMA}}(\mathcal{B}_1).$$

$\mathcal{B}_1$  emulates hybrid 3 for  $\mathcal{A}$  and embeds the challenge key  $vk^*$  as one of the verification keys honestly generated during the execution. Keys are honestly generated when group members create epochs during send: each send introduces one new key pair for the sender and, in case of an add, one for the added member (in this case, it is generated by the AKS at the moment of send). Therefore, there are at most  $2q_e$  key pairs.  $\mathcal{B}_1$  chooses the index of the key to replace by  $vk^*$  at random. It uses the Sign oracle to sign honestly sent messages that verify with  $vk^*$ . If a party holding the corresponding  $ssk^*$  is corrupted, it gives up.

We first show that if  $\text{ForgesAsym}$  occurs, then the receiver  $id_r$  (see the definition of  $\text{ForgesAsym}$ ) verifies the injected message with an honestly generated key  $vk_r$ . This means that  $\mathcal{B}_1$  has a chance of embedding  $vk^*$  as  $vk_r$ .

*Claim 1.* If  $\text{ForgesAsym}$  occurs then the key  $vk_r$  used by  $id_r$  to verify the injected message is honestly generated.

PROOF. Assume  $\text{ForgesAsym}$  occurs. Notice that  $vk_r$  is introduced into  $id_r$ 's state when it accepts a message from  $id_s$  that transitions it into an ancestor  $epid_0$  of  $epid_s$ . Observe first that  $epid_0$  is not injected. The reason is that no epoch between  $epid_0$  and  $epid_s$  is created by  $id_s$  or removes it, since this would remove  $vk_r$  from  $id_r$ 's state. So, if  $epid_0$  was injected,  $*\text{ind-secs-bad}(epid_0, id_s)$  would be true and  $*\text{ind-secs-secure}(epid_s, id_s)$  would be false, which contradicts  $\text{ForgesAsym}$ .

This means that  $id_s$  created  $epid_0$  during a send operation and at that point generated an honest verification key  $vk_s$  for itself. We know (from the proof that SAIK guarantees consistency) that parties in the same epoch agree on the ratchet tree, which contains all verification keys. Therefore,  $vk_r = vk_s$ , so  $vk_r$  is honestly generated.  $\square$

We next show that no party holding the secret key  $sk_r$  corresponding to  $vk_r$  used by  $id_r$  is corrupted. This means that if  $\text{ForgesAsym}$  occurs and  $\mathcal{B}_1$  guesses correctly and embeds  $vk^*$  as  $vk_r$ , then  $\mathcal{B}_1$  does not give up when  $sk^*$  is corrupted.

*Claim 2.* If  $\text{ForgesAsym}$  occurs then no party holding  $sk_r$  corresponding to  $vk_r$  used by  $id_r$  to verify the injected message is corrupted.

PROOF. Assume towards a contradiction that  $\text{ForgesAsym}$  occurs and a party holding  $sk_r$  is corrupted in some epoch  $epid^\perp$ . Let  $epid_0^\perp$  be the epoch before  $epid^\perp$  which introduces  $sk_r$  into its state.

Observe that (honest) parties only store the signing keys that they generate themselves while creating epochs or that the AKS generates for them when they are added. Moreover, such honestly generated keys are not re-computed and the AKS generates a fresh key pair each time a party is added. This means that the corrupted party is  $id_s$ . Moreover, if  $epid_0^\perp$  is not injected, then it is the epoch  $epid_0$  which introduces  $vk_r$  into the state of  $id_r$ . On the other hand if  $epid_0^\perp$  is injected, then it must add  $id_s$  (and not be created by it).

Observe further that  $epid_0^\perp$  and  $epid^\perp$  are connected by a path of epochs not created by  $id_s$  and not removing it, as this would

remove  $sk_r$ . The epochs  $epid_0$  and  $epid_s$  are connected by a path with the same property. Therefore, if  $epid_0^\perp$  is not injected, then  $epid_s$  can be reached, through  $epid_0^\perp = epid_0$ , from  $epid^\perp$  where  $id_s$  is corrupted via a path with above property. This makes the predicate  $*\text{ind-secs-secure}(epid_s, id_s)$  false, contradicting  $\text{ForgesAsym}$ . Moreover, it is easy to see that if  $epid_0^\perp$  is injected, then the predicate  $*\text{exposed-ind-secs-weak}(epid_s, id_s)$  would be true, which again makes  $*\text{ind-secs-secure}(epid_s, id_s)$  false.  $\square$

By the two claims, with probability at least  $\Pr[\text{ForgesAsym}]/(2q_e)$ , both  $\text{ForgesAsym}$  occurs and  $id_r$  uses  $vk_r = vk^*$  (since there are at most  $2q_e$  honestly generated keys). It is left to show that if this happens, then  $\mathcal{B}_1$  wins.

*Claim 3.* If  $\text{ForgesAsym}$  occurs and  $vk_r = vk^*$ , then  $\mathcal{B}_1$  wins.

PROOF. Assume  $\text{ForgesAsym}$  occurs and  $vk = vk^*$ . There are two cases: (A)  $id_r$  transitions into an injected epoch  $epid'$ , (B)  $id_r$  is removed.

In case (A),  $id_r$  checks that  $\text{Sig.vrf}(vk^*, \text{confTag}', \text{sig})$  is true. Notice that  $\text{confTag}'$  uniquely identifies  $epid'$ , because it is derived by hashing  $epSec$  which identifies  $epid$  by definition (see the proof of SAIK consistency). Since the epoch is injected and not created by an honest party, no honest party signed  $\text{confTag}'$ . In particular  $\mathcal{B}_1$  never had to send  $\text{confTag}'$  to the sign oracle. Therefore,  $\mathcal{B}_1$  wins with the forgery ( $\text{confTag}', \text{sig}$ ).

For case (B),  $id_r$  checks that  $\text{Sig.vrf}(vk^*, (id_s, 'rem'-id_r, \text{confTag}), \text{sig})$  is true, where  $\text{confTag}$  uniquely identifies  $epid$ .  $\text{ForgesAsym}$  guarantees that  $id_s$  did not remove  $id_r$  in  $epid$ , so it did not sign such a triple. Therefore,  $\mathcal{B}_1$  wins with  $((id_s, 'rem'-id_r, \text{confTag}), \text{sig})$ .  $\square$

**Symmetric forgery.** We next bound the probability of symmetric forgery.

LEMMA H.11. *There exist reductions  $\mathcal{B}_2$  and  $\mathcal{B}_3$  such that*

$$\Pr[\text{ForgesSym}] \leq q_e \cdot \text{Adv}_{\text{MAC}}^{\text{EUF-CMA}}(\mathcal{B}_2) + q_e^3 \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e \log(q_n), q_n}^{\text{mmOW-RCCA}}(\mathcal{B}_3) + 3q_e^2 q_h / 2^k.$$

At a high level, recall that  $\text{ForgesSym}$  occurs for epoch  $epid$  when the adversary  $\mathcal{A}$  injects to some  $id_r$  in  $epid$  a message that either (A) makes  $id_r$  transition to a new injected epoch or (B) removes  $id_r$  although it was not honestly removed. Triggering (A) requires from  $\mathcal{A}$  computing the confirmation tag which is the hash output on  $epid$ 's  $\text{initSec}$  and the injected epoch's context. Triggering (B) requires forging a MAC under  $epid$ 's secret  $\text{membKey}$ .

To bound the probability of each (A) and (B), we first replace  $epid$ 's  $\text{initSec}$  and  $\text{membKey}$  by random values, independent of the rest of the experiment. To make this possible, the adversary first commits to the epoch  $epid$ . This results in a security loss of  $q_e$  (for guessing the epoch). Now assuming  $\text{mmPKE}$  is secure, the change cannot be noticed as long as  $*\text{grp-secs-secure}$  in  $epid$  (part of the **confidential** predicate) is true. Since  $\text{ForgesSym}$  requires this to be true at the moment it occurs (and the predicate is monotone), the change does not affect the probability that  $\text{ForgesSym}$  occurs (for the first time).

Once  $\text{initSec}$  is random, in the ROM, the probability of (A) is negligible. Once  $\text{membKey}$  is random, the probability of (B) is negligible, assuming that MAC is unforgeable.

Formally, we first define the new hybrid.

**Hybrid 3\***: The same as hybrid 3, except at the beginning  $\mathcal{A}$  announces an epoch epid and membKey and initSec in epid are random and independent.

Further, the following event is analogous to ForgesSym but in hybrid 3\*.

**Event ForgesSym\***: In hybrid 3\*, there exist two members  $id_s$  and  $id_r$  in epid announced by  $\mathcal{A}$  s.t. \*grp-secs-secure(epid) and Forges(epid,  $id_s$ ,  $id_r$ ) are true.

Next, we show that changing to hybrid 3\* does not affect the probability of the bad event much.

*Claim 4.* There exists a reduction  $\mathcal{B}_3$  such that

$$\Pr(\text{ForgesSym}^*) - \Pr(\text{ForgesSym}) \leq q_e^3 \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e, q_e \log(q_n), q_n}^{\text{mmOW-RCCA}}(\mathcal{B}_3) + 3q_e^3 q_n / 2^K.$$

**PROOF.** First, observe that if  $\mathcal{A}$  triggers ForgesSym in hybrid 3 with probability at least  $\epsilon$ , then  $\mathcal{A}'$  who guesses epid at random triggers ForgesSym\* but in hybrid 3 (i.e., membKey and initSec are not random) with probability at least  $\epsilon/q_e$ .

Second, observe that membKey and initSec are derived the same way as the group key — each key is the result of hashing the epoch secret with a different label. Therefore, the proof analogous to the proof of Theorem H.3 shows that the difference between the probability of ForgesSym\* in hybrid 3 and ForgesSym\* in hybrid 3\* is bounded by  $q_e^2 \log(q_n) \cdot \text{Adv}_{\text{mmPKE}, q_e, q_e \log(q_n), q_n}^{\text{mmOW-RCCA}}(\mathcal{B}_3) + 3q_e^2 q_n / 2^K$ .  $\square$

Finally, it is left to bound the probability of ForgesSym\*. To this end, we define two sub-events:

**Event ForgesSym\*(A)**: In hybrid 3\*, there exist two members  $id_s$  and  $id_r$  in epid announced by  $\mathcal{A}$  such that the predicate \*grp-secs-secure(epid) is true and (A)  $id_r$  accepts a message that makes it transition to an epoch epid' with  $\text{HG}[\text{epid}'].\text{inj}$  true.

**Event ForgesSym\*(B)**: In hybrid 3\*, there exist two members  $id_s$  and  $id_r$  in epid announced by  $\mathcal{A}$  such that the predicate \*grp-secs-secure(epid) is true and (B)  $id_r$  accepts a message that removes it but  $id_s$  did not remove  $id_r$  in epid.

We next bound the probability of each sub-event.

*Claim 5.* In the ROM, we have

$$\Pr(\text{ForgesSym}^*(A)) \leq q_d / 2^K,$$

where  $q_d$  is the number of delivered messages.

**PROOF.** Recall that epid' is identified by its unique epoch secret  $\text{epSec}'$ , computed as the hash of initSec of epid and the context of epid'. Since in hybrid 3\* initSec is random and independent of the experiment, so is  $\text{epSec}'$ . Further, recall that  $id_r$  accepts the message only if the attached confirmation tag  $\text{confTag}'$  is equal to the hash of  $\text{epSec}'$  with appropriate label. This matches with the number of injection attempts.  $\square$

*Claim 6.* There exists a reduction  $\mathcal{B}_2$  such that

$$\Pr(\text{ForgesSym}^*(B)) \leq \text{Adv}_{\text{MAC}}^{\text{EUF-CMA}}(\mathcal{B}_2).$$

**PROOF.**  $\mathcal{B}_2$  emulates hybrid 3\* for  $\mathcal{A}$ , except instead of the MAC key \*mem in epid announced by  $\mathcal{A}$ ,  $\mathcal{B}_2$  uses its EUF-CMA Sign and Verify oracles. Since membKey is random and independent in hybrid 3\*,  $\mathcal{B}_2$  simulates the experiment perfectly.

It is left to show that if ForgesSym\*(B) occurs, then  $\mathcal{B}_2$  wins. Assume the event occurs.  $\mathcal{B}_2$  outputs the forgery consisting of the tag  $\text{tag}_t$  from the injected packet removing  $id_r$  and the message  $(id_s, \text{'rem'-}id_r, \text{confTag})$  where  $\text{confTag}$  is the confirmation tag in epid. Since  $id_r$  accepted the message, MAC verification passes.

Finally, we claim that  $\mathcal{B}_2$  did not query this message to the Sign oracle. Observe that this only happens if an honest party in sends out a MAC over  $(id_s, \text{'rem'-}id_r, \text{confTag})$ . Since only  $id_s$  MAC's its identity and only parties in epid MAC  $\text{confTag}$ , this only happens if  $id_s$  removes  $id_r$  in epid. This is a contradiction with ForgesSym\*(B).  $\square$

## H.5 Left-Balanced Trees

In this section, we formally define  $q$ -ary trees used by SAIK to implement ratchet trees.

*Definition H.12 (LBT).* For  $q, n \in \mathbb{N}$  with  $q > 1$ , the  $n^{\text{th}}$  left-balanced  $q$ -ary tree (LBT), denoted  $\text{LBT}_{q,n}$ , is defined as follows.  $\text{LBT}_{q,1}$  is the tree consisting of one node. For  $n > 1$ , if  $m = \max\{q^p : p \in \mathbb{N} \wedge q^p < n\}$  and  $k = \lfloor n/m \rfloor$ , then  $\text{LBT}_{q,n}$  is the tree whose root has the first  $k$  children equal to  $\text{LBT}_{q,m}$  and, if  $n - mk > 0$ , the  $(m+1)$ -st child equal to  $\text{LBT}_{q,n-mk}$ .

*Definition H.13 (Full LBT).* For  $q, n \in \mathbb{N}$ ,  $\text{LBT}_{q,n}$  is full if  $n$  is a power of  $q$ .

Operation of SAIK requires a procedure  $\text{addLeaf}(\tau, v)$  which inserts a leaf  $v$  into a ratchet tree  $\tau$  while preserving certain properties of  $\tau$ . In particular,  $\text{addLeaf}$  should preserve node indices  $v.\text{nodeIdx}$ . They are computed as follows: all nodes are numbered left to right — i.e., according to an in-order depth-first traversal of the tree — starting with 0. See Fig. 22 for an example.

**Figure 22: The trees  $\text{LBT}_{3,7}$  (left) and  $\text{LBT}_{3,8}$  (right) with node indices.**

*Definition H.14 (addLeaf).* The algorithm  $\text{addLeaf}(\tau, v)$  takes as input a  $q$ -ary tree  $\tau$  with root  $r$  and  $n$  nodes, and a fresh leaf  $v$  and returns a new tree  $\tau'$  with  $v$  inserted and  $v.\text{nodeIdx} = n + 1$ .

- If  $\tau$  is full, then create a new root  $r'$  for  $\tau'$ . Attach  $r$  as the first child of  $r'$  and  $v$  as the second child.
- Else if  $r.\text{children}$  contains only nodes with full subtrees, let  $\tau' = \tau$  except  $v$  is attached as the next child of  $r$ .
- Else, let  $u$  be the first in  $r.\text{children}$  s.t. its subtree  $\tau_u$  is not full. Let  $\tau' = \tau$  except  $\tau_u$  is replaced by  $\text{addLeaf}(\tau_u, v)$ .

The following lemma formalizes the correctness of  $\text{addLeaf}$ . We prove it in App. H.5.

**THEOREM H.15.**  $\tau = \text{LBT}_{q,n} \implies \text{addLeaf}(\tau, v) = \text{LBT}_{q,n+1}$ .

PROOF. The proof is by strong induction on  $n$ . If  $n < q$ , then the statement easily follows by inspection (only cases a) and b) of `addLeaf` apply). Fix  $n \geq q$  and assume the statement holds for all  $k < n$ . Let  $r$  be the root of  $\tau$  and let  $\text{max-pow}(n) = \max\{q^p + 1 : p \in \mathbb{N} \wedge q^p < n\}$ .

If  $\tau$  is full, then  $\text{max-pow}(n+1) = n$ . Furthermore, the root of  $\tau'$  has only two children:  $\tau = \text{LBT}_{q,n} = \text{LBT}_{q,\text{max-pow}(n+1)}$  and  $\text{LBT}_{q,1}$ , so  $\tau' = \text{LBT}_{q,n+1}$  per definition.

Else,  $\text{max-pow}(n) = \text{max-pow}(n+1)$  (this holds since  $n \geq q$ ). Moreover, it is easy to see that only the last node in  $r.\text{children}$  can

be non-full. This means that the root  $r'$  of  $\tau'$  has the following children (in order):

- All children of the root  $r$  of  $\tau$  which have full subtrees. These subtrees are equal to  $\text{LBT}_{q,\text{max-pow}(n)}$  which is the same as  $\text{LBT}_{q,\text{max-pow}(n+1)}$ .
- If  $r$  has no non-full subtrees, then the last child of  $r'$  is  $v$  with subtree  $\text{LBT}_{q,1}$ .
- Else if the last child  $u$  of  $r$  is non-full and equals to  $\text{LBT}_{q,x}$  for  $x < \text{max-pow}(n)$ , then the last child of  $r'$  is  $\text{LBT}_{q,x+1}$  by induction hypothesis.

Clearly,  $\tau' = \text{LBT}_{q,n+1}$  in all cases. □
