Abstract

To determine the complex refractive indices of aerosol particles in the atmospheric boundary layer, simultaneous measurements of scattering coefficients at 450, 550, and 700 nm wavelengths, absorption coefficient at 565 nm, and aerosol particle number size distributions were performed during a voyage of the icebreaker *Shirase* from Tokyo to the offing of the Philippines over the northwestern Pacific in November 2010. Three sets of Ångström exponents were calculated using the three observed scattering coefficients. Using the observed number size distributions, three sets of Ångström exponents were reproduced by assuming their complex refractive indices. Appropriate complex refractive indices for aerosol particles in the atmospheric boundary layer can be obtained when the difference between the observed and reproduced Ångström exponents is minimal. Absorbing substances were assumed to be present in the fine particles. For polluted air masses, if the refractive index for aerosol particles was uniform regardless of the particle size, the estimated Ångström exponents were consistent with the observed values. The refractive index must be the normal dispersion, which increases with a decrease in wavelength. For pristine air masses, the refractive index was estimated to be higher for coarse particles than for fine particles. This could be explained by preferential condensation of organic compounds onto coarse particles, which is observed to alter the number size distribution over Chichi-jima of the Ogasawara Islands in the northwestern

52   Pacific in August 2014 and February 2015. This study is the first to report that the

53   increase in the refractive index of coarse particles is likely caused by the optical

54   properties of volatile organic compounds and/or secondary organic aerosols condensed

55   on coarse particles.

1. Introduction

New aerosol particles are generally formed by the nucleation of aerosol particles with diameter $D < 0.01$ μm (Kulmala et al., 2004). Number size distributions in the Aitken ($0.01 < D < 0.1$ μm) and accumulation ($0.1 < D < 1$ μm) modes change when vapor compounds condense onto pre-existing aerosol particles or evaporate from the particles to the gas phase, and when particles coagulate (Heintzenberg et al., 2003; Kulmala et al., 2004; O'Dowd et al., 2010; Dall'Osto et al., 2012). The chemical composition of coarse particles ($D > 1$ μm) generally differs from that of fine particles ($D < 1$ μm) (Hinds, 1999; Heintzenberg et al., 2003). Matsumoto et al. (1998) investigated the seasonal characteristics of the chemical composition of aerosol particles on Haha-jima (26°38'N, 140°10'E) of the Ogasawara Islands in the northwestern Pacific and determined that sea salt and non-sea salt sulfates (nss–SO_4^{2-}) were the primary chemical species in coarse and fine particles, respectively. This is supported by the results of other studies (Campuzano-Jost et al., 2003; Heintzenberg et al., 2003).

Dimethylsulfide (DMS) is produced by marine phytoplankton and emitted from the ocean to the atmosphere. Its oxidation products in the atmosphere are then converted to sulfuric acid (H_2SO_4), making DMS the most important precursor of nss–SO_4^{2-} in aerosol particles over the ocean (Savoie and Prospero, 1982; Bates et al., 1992; Koga and Tanaka, 1999; Read et al., 2008; Mahajan et al., 2015). However, the observed H_2SO_4 mixing ratios are insufficient for binary nucleation of H_2SO_4 and H_2O (Weber et al., 1999). Using binary

80   and ternary (H_2O–H_2SO_4–NH_3) nucleation theories, Pirjola et al. (2000) analyzed the

81   possibility of particle formation in the atmospheric boundary layer and found that the

82   formation of new particles is difficult under typical atmospheric conditions. Hence, they

83   proposed the existence of condensable species other than H_2SO_4.

84   Novakov and Penner (1993) found that natural organic compounds exist in aerosol

85   particles with $0.05 < D < 0.2$ μm. In addition, O'Dowd et al. (2004) suggested that the organic

86   fraction of the mass concentration of fine particles over the North Atlantic Ocean is related

87   to biological activity. Oxidation products of volatile organic compounds (VOC) emitted by

88   phytoplankton (e.g., biogenic amines, isoprene, and monoterpenes) can form secondary

89   organic aerosols (SOA) (Facchini et al., 2008; Gantt et al., 2009; Shaw et al., 2010; Bikkina

90   et al., 2014). The enrichment of water-soluble organic carbon (WSOC) in aerosol particles

91   can be explained by the production and condensation of SOA in pristine air masses

92   (Ceburnis et al., 2008; Miyazaki et al., 2010; Decesari et al., 2011). The presence of WSOC

93   probably affects the optical properties of aerosol particles.

94   Atmospheric aerosol particles scatter and absorb incident sunlight (IPCC, 2013). The

95   optical properties of aerosols are expressed as the scattering coefficient σ_{scat} and absorption

96   coefficient σ_{abs} (Seinfeld and Pandis, 1998; Hinds, 1999). Single-scattering albedo (*SSA*),

97   defined as the ratio of σ_{scat} to σ_{ext} (σ_{scat} + σ_{abs}), is an important factor in determining warming

98   or cooling in the atmosphere–surface system (Srivastava et al., 2020). Incident sunlight is

99   scattered mainly by sulfates (SO_4^{2-}) in aerosol particles (Shiobara et al., 2007; Ohta et al.,

2013). Aerosols, including elemental carbon and soil, absorb sunlight (IPCC, 2013).

Elemental carbon is emitted from anthropogenic sources into the atmosphere (Bond and

Bergstrom, 2006; Bond et al., 2013). The scattering and absorption coefficients of individual

aerosol particles are associated with the complex refractive index m (n, k) = $n - ki$ of the

chemical composition of the aerosol particle. The real part, n, of m (n, k), represents the

phase velocity of the electromagnetic wave propagating through the medium. The imaginary

part, k, represents the attenuation rate of the amplitude of the propagating electromagnetic

wave. The optical properties of aerosol particles are determined by their size-dependent

chemical composition and number size distribution. The value of m (n, k) depends not only

on the medium, but also on the wavelength of the electromagnetic wave (Bohren and

Huffman, 1998).

Koga (2021) reported aerosol optical properties in the atmospheric boundary layer over

the northwestern Pacific and Southern Ocean during the 52nd Japanese Antarctic Research

Expedition (JARE52) voyage from November 11, 2010, to March 17, 2011. The present

study focuses on the m (n, k) of aerosol particles in polluted and pristine air masses over

the northwestern Pacific. The purpose of this study is to estimate the m (n, k) of aerosol

particles in two types of air masses using observed aerosol scattering and absorption

coefficients and number size distributions. This study also reports that the estimated high n

value of the coarse particles in pristine air masses is likely caused by the optical properties

of SOA condensed on coarse particles.

120   Results reinforcing this idea were obtained from observations of aerosol number size

121   distributions using an activated carbon fiber on Chichi-jima (27°04'N, 142°13'E) of the

122   Ogasawara Islands in the northwestern Pacific in 2014 and 2015. These observations were

123   designed to elucidate why aerosol number size distributions differ between polluted and

124   pristine air masses. When condensable species are added to the atmosphere, the formation

125   of new particles and change in number concentration occur mainly in the fine particle range.

126   However, the results of observations on Chichi-jima suggest that some volatile substances

127   condense onto coarse particles in pristine air masses.

128   The estimation of the m (n, k) of aerosol particles during the JARE52 voyage and the

129   observations on Chichi-jima provide some insight into the optical properties of the coarse

130   particles.

131

132   **2. Observations**

133   To be able to determine the appropriate m (n, k) for aerosol particles, the present

134   study used the optical properties and number size distributions obtained during the JARE52

135   voyage. To elucidate the difference in the number size distribution between polluted and

136   pristine air masses, observations were conducted on Chichi-jima. Details of these

137   observations are described below.

138

139

2.1. Northwestern Pacific

141   Fig. 1 shows the JARE52 voyage track of the icebreaker *Shirase* from Tokyo, Japan

142   (35°39′N, 139°46′E) to the Philippines (12°14′N, 129°16′E) in November 2010. Solid curves

143   represent backward trajectories for the preceding 3 d of air parcels at a 500 m altitude. Open

144   circles on the track indicate the vessel positions every 6 h. These trajectories were computed

145   using the hybrid single-particle Lagrangian integrated trajectory (HYSPLIT) model (Stein et

146   al., 2015; Rolph et al., 2017) based on the vertical velocity data fields from the NCEP/NCAR

147   reanalysis data.

148   The aerosol scattering coefficients ($\sigma_s{}^{\lambda}$, m^{-1}) were measured by a 3563-model

149   integrating nephelometer at three wavelengths: 450, 550, and 700 nm (3563-IN, TSI Inc.

150   Shoreview, MN). The $\sigma_s{}^{\lambda}$ measurements were repeated at intervals of 1 min during the

151   voyage. The aerosol absorption coefficients (σ_{PSAP}, m^{-1}) were measured at intervals of 1

152   min using a particle soot absorption photometer (PSAP; Radiance Research, Seattle, WA).

153   The 3563-IN and PSAP methods have errors due to the measurement principle.

154   Correction factors (C^{λ}) are linear functions of Ångström exponents (*AE*) calculated using

155   uncorrected $\sigma_s{}^{\lambda}$ values of two specific wavelengths (Anderson and Ogren, 1998). In the

156   present study, the C^{λ} values, which were within the ranges estimated by Anderson and

157   Ogren (1998), were applied to obtain the corrected $\sigma_{ts}{}^{\lambda}$ values for the uncorrected $\sigma_s{}^{\lambda}$ values

158   (Table 1). Using the $\sigma_{ts}{}^{\lambda}$ of two wavelengths, for example, a value of *AE* between 450 and

159   550 nm is defined as:

$$AE_{450-550} = -\frac{\log(\sigma_{ts}^{450}/\sigma_{ts}^{550})}{\log(450/550)}. \tag{1}$$

160

161   In the PSAP, scattering compounds on the filter could lead to the overestimation of the

162 absorption coefficients. To volatilize the scattering compounds, the sample air was

163 maintained at 300 °C. The airflow rate measured using the built–in pump and in the sample

164 spot area has uncertainties (Bond et al., 1999). The correction factors for these uncertainties

165 were applied to obtain corrected σ_a values for the σ_{PSAP} values, which led to the decrease

166 of approximately 9.7% of the σ_{PSAP} values (Koga, 2021). The wavelength of 565 nm of light

167 emitted from an LED in the PSAP was different from the wavelength of 550 nm emitted from

168 a quartz-halogen lamp in the 3563-IN. However, the difference between σ_{ts}^{550} and σ_{ts}^{565} was

169 negligible. Thus, the values of σ_{ts}^{550} and σ_a were immediately used to determine *SSA*. The

170 measurements and correction methods for σ_{ts}^{λ} and σ_a are reported in Koga (2021).

171   The number size distributions of aerosol particles with $D > 0.3$ μm were measured using

172 an optical particle counter (OPC, KC–01D, RION Co., LTD). The light source of the OPC is

173 a semiconductor laser that emits light at a wavelength of 780 nm. Measurements were

174 repeated every 1 min and categorized into five classes: $D > 0.3$ μm, $D > 0.5$ μm, $D > 1$ μm,

175 $D > 2$ μm, and $D > 5$ μm. The OPC was calibrated by the manufacturer using polystyrene

176 latex (PSL) particles with m (1.595, 0). The coefficients of variation (σ/x, that is, sample

177 standard deviation/arithmetic mean) were calculated using a 15 min moving average in the

178 number concentrations of $D > 0.3$ μm. When the coefficients of variation were > 0.25 at a

179 certain time, the values of all classes at that time were excluded.

180   Fig. 2 displays the $\sigma_{ts}{}^{\lambda}$, σ_a, and *AE* from Tokyo to the offing of the Philippines, which

181   corresponds to part of the latitudinal distributions of aerosol optical properties from Tokyo to

182   Fremantle (32°03′S, 115°45′E) in Australia, as shown in Koga (2021). The backward

183   trajectories suggest that the air masses from 35.5°N to 28.1°N contained anthropogenic

184   pollution from East Asia. Meanwhile, from 25.3°N to 12.2°N were pristine air masses from

185   the central North Pacific unaffected by anthropogenic pollution (Fig. 1). Fig. 3 shows the

186   time series of number size distributions in four classes reported by the OPC from 30.5°N

187   and 137.5°E to the offing of the Philippines. Relatively stable values were found from 30.5°N

188   to 29.5°N in the polluted air masses, and from 17.5°N to 16.0°N and 14.5°N to 13.5°N in the

189   pristine air masses. The complex refractive indices of aerosol particles were estimated for

190   these latitudinal ranges.

191   Fig. 4 shows the number size distributions averaged from 30.5°N to 29.5°N and from

192   17.5°N to 16.0°N. The averages and one standard deviations of C^{λ}, $\sigma_{ts}{}^{\lambda}$, σ_a, and *SSA* for

193   three latitudinal ranges are listed in Table 1. The standard deviation values of *SSA* were

194   calculated using law of propagation of errors. The *AE* values were calculated from the

195   averages of $\sigma_{ts}{}^{\lambda}$. The *r* values are correlation coefficients between $\sigma_{ts}{}^{450}$ and $\sigma_{ts}{}^{550}$, $\sigma_{ts}{}^{450}$ and

196    $\sigma_{ts}{}^{700}$, and $\sigma_{ts}{}^{550}$ and $\sigma_{ts}{}^{700}$.

197

198

199

2.2. Chichi-jima of the Ogasawara Islands

200

201   Chichi-jima is located approximately 1000 km south of Tokyo, Japan and is an ideal site

202   for monitoring both polluted air masses from East Asia during winter and pristine air masses

203   from the central North Pacific during summer (Koga et al., 2008), which correspond to the

204   first and second types during the JARE52 voyage, respectively (Koga, 2021). The island is

205   located downwind of polluted air masses and upwind of pristine air masses relative to the

206   JARE52 voyage track.

207   Observations were conducted at the Ogasawara downrange station (27°04'N,

208   142°13'E, 230 m above sea level) of the Japan aerospace exploration agency. The number

209   size distribution with $D > 0.3$ μm was measured using an optical particle sizer (OPS,

210   Model3330, TSI Inc., Shoreview, MN). Measurements were repeated every 1 min. To

211   remove aerosol particles with $D > 10$ μm, a PM_{10} impactor was attached to an air inlet port

212   with a 4.25 cm inside diameter on the wall of a facility for switchboard equipment. A stainless

213   steel sampling probe was inserted into the inlet pipe and aligned parallel to the gas

214   streamlines made with an air pump. Aerosol sampling was done isokinetically. The inside

215   diameter of the sampling probe was 1.47 cm at the upper end, decreasing gradually to a

216   minimum of approximately 0.64 cm (1/4 inch) at a 7 cm distance.

217   The amount of VOCs condensed onto aerosols can be evaluated from the difference in

218   the number size distributions between VOC-removed and untreated air samples. Kynol

219   (novoloid)-based activated carbon fabric (ACC507-20, Gunei Chemical Industry Co., Ltd.,

220 Gunma, Japan) was inserted into a 50 cm stainless steel tube with an outside diameter of

221 1.27 cm (1/2 inch). The inside diameter of this tube was approximately 0.64 cm (1/4 inch)

222 because Kynol fabric was placed along the inner wall. The inside diameter was the same as

223 the fit diameter of the conductive tubing for the piping to avoid steps in the flow path. Kynol

224 fabric can adsorb non-polar substances such as organic compounds (nominal toluene

225 adsorption, 30–80 w%) but it cannot or poorly adsorbs polar substances such as water vapor

226 (Sullivan et al., 2007). Kynol fabrics are superior to granular activated charcoal in terms of

227 adsorption rate and amount. The stainless steel tube with the Kynol fabric was connected

228 to the upper stream of the OPS to remove VOCs from the air samples.

229 In August 2014, two OPSs were simultaneously used to measure number size

230 distributions, but the Kynol tube was connected to only one of these. The flow splitter (Model

231 3708, TSI Inc.) was used to divide air samples into two flow paths. After the measurement

232 started, the values obtained by the two OPSs became almost identical within 2 h because

233 Kynol fabrics were saturated with VOCs. Judging from this result, particle loss by the Kynol

234 tube is negligible. The saturated Kynol was regenerated as a result of VOC desorption by

235 heating the tube for 30 min at 100 °C with an airflow rate of 20 L min^{-1}. In February 2015,

236 only one OPS was available, and therefore measurements were taken alternately by

237 connecting and disconnecting the Kynol tube.

238 Fig. 5 shows the number and surface area size distributions in the pristine air masses

239 in summer and polluted air masses in winter, obtained using the OPS. The dew point

12

240 temperatures in the ambient atmosphere were 27 °C on August 22, 2014, and 12 °C on

241 February 18, 2015. The inlet temperature recorded by the OPS, 38 °C in August and 33 °C

242 in February, was consistently higher than the dew point temperature. The relative humidity

243 inside the OPS was estimated to be 54% in August and 29% in February. The number size

244 distributions were obtained under dry conditions.

245   The distinct maxima of the number concentrations were always approximately 2–3 μm

246 in diameter during summer. When the Kynol tube was used, the number concentrations of

247 coarse particles always showed a sharp decrease from the original concentrations. In

248 contrast, the number concentrations in winter decreased with increasing diameter, with an

249 inflection point of approximately 1–2 μm in diameter. The number size distributions, however,

250 hardly changed despite the use of a Kynol tube.

251

252 **3. Methods**

253   Three sets of *AE* were calculated using the three observed $\sigma_{ts}{}^{\lambda}$. Using the observed

254 number size distributions, the values of $\sigma_{ts}{}^{\lambda}$, σ_{a}, and *AE* were reproduced by assuming

255 complex refractive indices. The procedure for reproducing the values of $\sigma_{ts}{}^{\lambda}$ and σ_{a} is shown

256 below. Appropriate complex refractive indices for aerosol particles in the atmospheric

257 boundary layer can be obtained when the sum of the three sets of differences between the

258 observed and reproduced *AE* is minimal.

259

3.1. Refractive index correction of the particle sizing in the OPC

261   The particle sizing diameters are based on the threshold voltage from the photodetector

262   receiving light scattered by the PSL particles. In the ambient atmosphere, m (n, k) for aerosol

263   particles is different from that for PSL particles. The particle sizing diameters must be

264   corrected according to the values of m (n, k) to obtain realistic values for the number size

265   distributions.

266   The photodetector in the OPC was placed at an angle ψ of 70° to the irradiated optical

267   axis. The scattered light was focused by the collecting aperture with a semi-angle β of 27°.

268   The angular distribution of light scattered by a single particle with diameter D was calculated

269   from 43° ($\theta = \psi - \beta$) to 97° ($\theta = \psi + \beta$) at intervals of 1° using the geometry of the collecting

270   aperture by Hodkinson and Greenfield (1965). The range of particle diameters covered by

271   the calculation was from 0.05 to 25 μm, dividing into 1000 increments on a logarithmic scale.

272   For each particle diameter, the total intensity of light received by the photodetector was

273   calculated as the sum of the scattered light intensity per 1° from 43° to 97°. The same

274   procedure was repeated for n from 1.30 to 1.70 in increments of 0.01. As a result, the particle

275   sizing diameters of the 41 sets were obtained as a function of n at a wavelength of 780 nm

276   from the laser light in the OPC.

277

278

279

14

3.2. Expansion of number size distribution

281   For the size range between log$D$ and log$D$ + $d$log$D$, the number size distribution n (log

282   D) can be expressed by a power-law function of size as follows:

283
$$n(\log D) = \frac{dN}{d\log D} = cD^{-b}, \qquad (2)$$

284   where N is the number concentration, D is the particle diameter, c is a proportionality

285   constant, a factor that determines the number concentration, and b is the slope of the

286   number size distribution on a log–log plot.

287   The values from N_4 to N_8 in Fig. 6 averaged from 30.5°N to 29.5°N in the polluted air

288   masses and was originally obtained using the OPC. The boundaries from D_4 to D_8

289   corresponded to the original boundaries for m (1.595, 0) of the PSL particles. The values of

290   N_i represent the number concentration at the midpoint between D_i and D_{i+1}. Equation (2) is

291   available between D_i and D_{i+1}, where b_i and c_i are defined in the same diameter range.

292   The observed number size distribution from D_4 to D_8 alone was insufficient to reproduce

293    $\sigma_{ts}{}^{\lambda}$ and σ_a. Therefore, for particles with $D < D_4$, the widths from D_1 to D_2, D_2 to D_3, and D_3

294   to D_4 were assumed to be the same as the width l from D_4 *to* D_5. To obtain the upper limit

295   D_9, the width L from D_7 to D_8 was applied to that from D_8 to D_9. The slope of the red line

296   between N_2 at D_3 and N_4 was assumed to be the same as that between N_4 and N_5. The N_1

297   value was the same as the N_3 value.

298   All N_i were multiplied by an adjustable factor df to reproduce the same values as the

299   observed $\sigma_{ts}{}^{\lambda}$ and σ_a values. This probably corresponded to the correction for the uncertainty

300   in the airflow rate of the internal pump of the OPC. The values from N_4 to N_8 in Fig. 6 are

301   original values from the OPC in the case of df = 1. The value of df had no effect on the value

302   of AE. The N_3 value at the midpoint between D_3 and D_4 was further multiplied by an

303   adjustable factor sf to obtain AE values consistent with the observed values because the AE

304   values depend on the slope of the number size distribution.

305   The values of N_1 and N_2 were automatically determined using this operation. For

306   example, in the cases of sf = 1.0 and 0.3, the number size distributions are shown by the

307   red and blue lines in Fig. 6, respectively. Henceforth, the number size distribution consisting

308   of black and blue solid lines will be referred to as a column model. The values of D_i were

309   obtained as the particle sizing corrected by m (n, 0). The k values were determined such

310   that the estimated σ_a values were consistent with the observed σ_a values.

311   To confirm the reliability of m (n, k) estimated using the column model, the σ_{ts}^{λ} and σ_a

312   values were reproduced using the regression curves fitted to the column model. The

313   regression curves can be described as the sum of two log-normal distributions (Jaenicke,

314   1993, Seinfeld and Pandis, 1998):

$$\frac{dN}{d\log D} = \sum_{j=1}^{2} \frac{N_j}{\sqrt{2\pi} \log\sigma_j} \exp\left(-\frac{(\log D - \log D_j)^2}{2 \log^2 \sigma_j}\right), \qquad (3)$$

315

316   where N_j is the number concentration, σ_j is the standard deviation of the lognormal

317   distribution, and D_j is the mean diameter. Henceforth, the number size distribution consisting

318   of the regression curves will be referred to as a log-normal model.

319   Clarke et al. (2004) and Koga et al. (2008) reported that most of black carbon was

320   present in fine particles with $D < 1$ μm. Therefore, the light-absorbing component was only

321   present in the fine particles with $D <$ the corrected D_6 (Fig. 6) in the column model and in the

322   first log-normal distribution ($j = 1$ in Eq. (3)) in the log-normal model.

323

324   *3.3. Estimations of $\sigma_{ts}{}^\lambda$, σ_a, and m (n, k)*

325   The scattering coefficient $\sigma_{ts}{}^\lambda$ in the particle size range of Mie scattering can be

326   expressed by a power-law function of the wavelength (Seinfeld and Pandis, 1998):

332
$$\sigma_{ts}^\lambda = \int \frac{\pi D^2}{4} Q_{ts}^\lambda(m, x) n(\log D) d \log D \ \propto \ \lambda^{-AE}, \qquad (4)$$

327   where $Q_{ts}{}^\lambda(m, x)$ is the scattering efficiency of a particle with m (n, k), x is the size parameter

328   defined by the ratio of the particle diameter D to the wavelength of light (λ), n ($\log D$) is the

329   number size distribution, and *AE* was calculated from Eq. (1). A similar expression can be

330   written for σ_a in terms of the absorption efficiency, $Q_a(m, x)$, of the particle with m (n, k). The

331   values of n ($\log D$) can be obtained from Eqs. (2) or (3).

333   The values of $Q_{ts}{}^\lambda(m, x)$ at the three wavelengths, 450, 550, and 700 nm, and $Q_a(m, x)$

334   at a wavelength of 550 nm were calculated for each particle diameter divided into 1000

335   increments from 0.05 to 25 μm on a logarithmic scale. The values of n range from 1.30 to

336   1.70 in increments of 0.01. *Q* terms were computed from Mie theory using MieCalc software

337   by Bernhard Michel.

338   The values of AE observed by 3563-IN were expressed as the oAE_1 between 450 and

339   550 nm, oAE_2 between 450 and 700 nm, and oAE_3 between 550 and 700 nm. The values

340   of AE from $\sigma_{ts}{}^{\lambda}$ estimated using Eq. (4) were expressed as eAE_1 between 450 and 550 nm,

341   eAE_2 between 450 and 700 nm, and eAE_3 between 550 and 700 nm, respectively. In the

342   estimations of eAE_i, the values of k were assumed to be constant regardless of the

343   wavelength of light. The appropriate m (n, k) for aerosol particles can be obtained when the

344   following Eq. (5) is minimized:

345
$$p = \sum_{i=1}^{3} (oAE_i - eAE_i)^2. \qquad (5)$$

346

347 **4. Results**

348 *4.1. Complex refractive indices of aerosol particles in polluted air masses*

349   The $\sigma_{ts}{}^{\lambda}$ values observed at each wavelength from 30.5°N to 29.5°N were reproduced

350   using the corrected number size distribution of the column model. Here, $k = 0$ in the

351   calculation of $\sigma_{ts}{}^{\lambda}$ using Eqs. (2) and (4) was assumed to simplify the determination of an

352   appropriate n value. Values of p are shown as a function of m (n, 0) in Fig. 7. The horizontal

353   axis is the n value at a wavelength of 450 nm.

354   The three observed $\sigma_{ts}{}^{\lambda}$ values had very good correlations one another (Table 1). The

355   estimated changes of $\sigma_{ts}{}^{\lambda}$ due to a difference of 0.01 in the n value were approximately equal

356   to standard errors derived from the observed $\sigma_{ts}{}^{\lambda}$ values. The errors in the appropriate n

357   values estimated below would be less than ± 0.01.

358   Fig. 7a shows the p values when the n value is constant, independent of the wavelength

359   of light. Even for the same material, the n value generally depends on the wavelength of

360   light and increases with decreasing wavelength. The p values for this case are shown in Fig.

361   7b. The mutual difference in n values among the three wavelengths was assumed to be

362   0.01 due to the normal dispersion. Fig. 7c shows the p values when the n value at 450 nm

363   is 0.01 higher than that at 550 and 700 nm. The case of anomalous dispersion, in which n

364   values decrease with decreasing wavelength, is shown in Fig. 7d. The n values at 450 nm

365   were assumed to be 0.02 lower than at 700 nm. In all cases, the n values were assumed to

366   be uniform from D_1 to the midpoint between D_8 and D_9 (Fig. 6). The minimum p value is

367   shown in Fig. 7d.

368   The effect of the light-absorbing component was not considered to reproduce the σ_{ts}^{λ}

369   values at each wavelength. In the number size distribution under $sf = 0.475$, with the particle

370   sizing of m (1.56, 0) in Fig. 7b, the p value was 2.84×10^{-3} in the assumption of the normal

371   dispersion. If the k value was uniform for particles with $D < D_6 = 1.17$ μm, as corrected by m

372   (1.56, 0.0168) (Table 2), the σ_{ts}^{λ} and σ_a values estimated at $sf = 0.475$ and $df = 0.603$ were

373   approximately equal to the observed values (Tables 1 and 3). The p value in the case of the

374   normal dispersion was minimal at 3.34×10^{-3}, compared with the other cases with k–value

375   assumptions in Figs. 7a, 7c, and 7d.

376   The column model in Fig. 8a consists of black solid and red dashed lines under $sf =$

377   0.475 with particle sizing for m (1.55, 0). The green solid and dashed curves are the

378   regression curves obtained by fitting the log-normal models for the column models that

379   exclude and include the red dashed line, respectively. The number concentrations for m

380   (1.53–1.57, 0) were within the range of the standard deviation of its averaged number

381   concentrations (1.55, 0). Therefore, the green solid and dashed curves were used to

382   estimate $\sigma_{ts}{}^{\lambda}$ and σ_a values at wavelengths of 450, 550, and 700 nm without considering the

383   wavelength dependence of particle sizing for m (n, k). Using Eqs. (3) and (4), and the

384   assumption of the normal dispersion for the green solid and dashed curves, the estimated

385    $\sigma_{ts}{}^{\lambda}$ and σ_a values were almost identical to the observed values, although the k values were

386   higher than those in the column model (Tables 1, 2, and 3). The estimated σ_a values were

387   highest when $0.2 < D < 0.5$ μm (Fig. 9a). The number size distribution of particles with $D <$

388   0.2 μm was different among the models (Fig. 8a). Consequently, the k value increased with

389   decreasing number concentration of particles with D around 0.2 μm (Table 2).

390

391   *4.2. Complex refractive indices of aerosol particles in pristine air masses*

392   The observed $\sigma_{ts}{}^{\lambda}$ and oAE_i from 17.5°N to 16.0°N are listed in Table 1. The oAE_i values

393   showed the relationship $0 < oAE_1 < oAE_2 < oAE_3$. The $\sigma_{ts}{}^{\lambda}$ values at each wavelength were

394   estimated using Eqs. (2) and (4). Assuming that the n value was uniform from D_1 to the

395   midpoint between D_8 and D_9 in the column model (Fig. 6), the values of eAE_i were always

396   estimated to be < 0 independent of the n value. This result differed from that for oAE_i.

397   In general, the number size distributions have an inflection point at around 1 μm in

398   diameter. The refractive index n_{1-6} values for particles from D_1 to D_6 may be different from

399   the n_{6-9} values for particles from D_6 to D_9. Therefore, eAE_i values were calculated for

400   combinations of different values in n_{1-6} and n_{6-9} at 0.05 intervals of 1.35 to 1.65. Two cases,

401     $n_{1-6} > n_{6-9}$ and $n_{1-6} < n_{6-9}$, were considered in the estimation of the eAE_i values. No light-

402   absorbing component, that is, $k = 0$, was assumed to simplify the determination of n value

403   combinations.

404   In the case of $n_{1-6} > n_{6-9}$, the eAE_i values were estimated to be < 0 using n_{1-6} in particles

405   with $D < D_6$ corrected by n_{1-6}, or $eAE_1 > eAE_2 > eAE_3$ using n_{1-6} in particles with $D < D_6$

406   corrected by n_{6-9}. These results differed from the relationship among oAE_i.

407   In the case of $n_{1-6} < n_{6-9}$, the eAE_i values were always estimated to be $eAE_1 < eAE_2 <$

408   eAE_3, except for $n_{1-6} = 1.35$. The p values were always small when using n_{1-6} in particles

409   with $D < D_6$ corrected by n_{6-9}, in comparison with using n_{1-6} in particles with $D < D_6$ corrected

410   by n_{1-6}. The appropriate combinations of (n_{1-6}, n_{6-9}) were (1.45, 1.60) and (1.50, 1.65).

411   Furthermore, p values in the ranges of n_{1-6} = 1.45–1.50 and n_{6-9} = 1.60–1.65 were

412   calculated at intervals of 0.01 to determine the most suitable combination of n_{1-6} and n_{6-9}.

413   The p value was minimal in the case of $D_6 = 0.981$ μm corrected by $n_{6-9} = 1.62$. By

414   considering the k value in particles with $D < D_6$, the final appropriate values of n_{1-6}, n_{6-9}, and

415   k were estimated to be 1.47, 1.62, and 0.0030, respectively, at all three wavelengths (Table

416   2). The normal dispersion did not contribute to the convergence of p values. The estimated

417     $\sigma_{ts}{}^{\lambda}$ and σ_a values were the same as the observed values (Tables 1 and 3). In this case, sf

418   and df were 2.75 and 0.884, respectively.

419   The observed $\sigma_{ts}{}^{\lambda}$, σ_a, and oAE_i from 14.5°N to 13.5°N are listed in Table 1. The values

420   of n_{1-6} = 1.47 and n_{6-9} = 1.62 for aerosol particles from 17.5°N to 16.0°N were applied to

421   reproduce the values of $\sigma_{ts}{}^{\lambda}$ and σ_a from 14.5°N to 13.5°N. The values of p at other n values

422   were higher than the p value in (n_{1-6}, n_{6-9}) = (1.47, 1.62). The minimum p value was 6.50 ×

423   10^{-6} in k = 0 and sf = 2.5. However, D_6 must be 1.038 μm (Fig. 10). The p value was sensitive

424   to the position of D_6 because n values differ across D_6. Assuming that the k value was 0.0055

425   for particles with $D < D_6$ (Table 2) and df of 0.828, the observed $\sigma_{ts}{}^{\lambda}$ and σ_a values were

426   successfully reproduced by the column model (Tables 1 and 3).

427   The observed $\sigma_{ts}{}^{\lambda}$ and σ_a values from 17.5°N to 16.0°N and from 14.5°N to 13.5°N were

428   also reproduced using the green solid and dashed curves obtained by fitting the log-normal

429   models for the column models (Figs. 8b and 8c). The $\sigma_{ts}{}^{\lambda}$ and σ_a values estimated using

430   Eqs. (3) and (4) were almost the same as the observed values (Tables 1 and 3). The $\sigma_{ts}{}^{\lambda}$

431   values from 2 to 3 μm were slightly higher from 14.5°N to 13.5°N than 17.5°N to 16.0°N

432   (Figs. 9b and 9c). In the column model, the values of σ_a were zero for coarse particles. In

433   the log-normal model, however, the estimated σ_a values were in a comparatively wide size

434   range. Therefore, the k values in the log-normal model were lower than those in the column

435   model (Table 2).

436

5. Discussion

5.1. Polluted air masses

At a wavelength of 589 nm, the complex refractive indices are m (1.521, 0) for $(NH_4)_2SO_4$ and m (1.544, 0) for NaCl (Seinfeld and Pandis, 1998). The estimated $n = 1.55$ at a wavelength of 550 nm was close to these n values. Non-sea salt sulfates and sea salt are the primary chemical species in fine and coarse particles, respectively (Matsumoto et al., 1998; Campuzano-Jost et al., 2003; Heintzenberg et al., 2003).

Pollutants in the winter season are associated with black carbon from domestic coal burning (Dehkhoda et al., 2020). Using the shipboard measurements, Shiobara et al. (2007) estimated m (1.52−1.59, 0.002) in polluted air masses from the Asian continent over the western regions of the Ryukyu Islands of Japan. In the present study, the estimated $n = 1.55$ was within the range of Shiobara et al. (2007). Yabuki et al. (2003) estimated a maximum of $k = 0.0114$ in anthropogenic aerosols from 33.5°N to 30°N over the western North Pacific. Using sun photometer measurements, Bi et al. (2016) estimated $n = 1.521 \pm 0.025$ and $k = 0.00364 \pm 0.0014$ at a wavelength of 550 nm in the transported anthropogenic dust over East Asia. They also estimated that the refractive index at wavelengths ranging from 440 to 675 nm increased with an increase in wavelength. However, this was inconsistent with the normal dispersion estimated in the present study. Notably, these results are averages of aerosol optical properties from the surface to the top of the atmosphere. The k values

456   estimated in the present study were larger than those reported in previous studies due to

457   differences in size distribution assumptions for light–absorbing components (Table 2).

458

459   *5.2. Pristine air masses*

460   The complex refractive indices at 589 nm for NH_4HSO_4 and H_2SO_4 are m (1.473, 0) and

461   m (1.426, 0), respectively (Seinfeld and Pandis, 1998). The estimated n value for fine

462   particles was close to the real part of m (n, k) for NH_4HSO_4. Shiobara et al. (2007) estimated

463   m (1.38−1.40, < 0.001) in pristine air masses from the central North Pacific. Yabuki et al.

464   (2003) estimated m (1.35−1.37, < 0.0014) in marine aerosols from 28°N to 3°N. In the

465   present study, the estimated n and k values were higher than those reported by Shiobara et

466   al. (2007) and Yabuki et al. (2003). This is because they did not consider the size

467   dependence of m (n, k) when estimating the scattering and absorption coefficients. Virkkula

468   et al. (2006) found that the n value increased with increasing particle diameter in the

469   atmospheric boundary layer at the Finnish Antarctic Research Station. In the present study,

470   the value of n = 1.47 estimated for fine particles was close to that estimated by Virkkula et

471   al. (2006), while n = 1.62 for coarse particles was even higher than n = 1.544 for NaCl as

472   the primary chemical species. This suggests that coarse particles are composed of sea salt

473   and materials with n > 1.544. Water vapor was excluded as a candidate because m (1.333,

474   0) (Seinfeld and Pandis, 1998).

475 The uptake and volatilization rates of gas-phase species by aerosol particles depend

476 on the aerosol surface area per unit volume of air (Jacob, 2000). In the VOC-removed air

477 samples on Chichi-jima, the total surface area of the particles was smaller in August 2014

478 than in February 2015 (Fig. 5). However, in August 2014, the surface area with $D > 1.1$ μm

479 was approximately 3 times greater than that of $0.3 < D < 1.1$ μm. The surface area of the

480 pre-existing particles in the VOC-removed air samples was maximum at approximately $D =$

481 3 μm. In addition, the effective diffusion rates for biogenic secondary organic materials

482 (SOM) were at least 1000 times greater than those of anthropogenic SOM (Liu et al., 2016).

483 Thus, VOCs appear to preferentially condense onto coarse particles. In the VOC-removed

484 air sample from February 2015, the surface area of $D > 1.1$ μm was about 0.7 times smaller

485 than that of $0.3 < D < 1.1$ μm. In addition, the atmospheric VOC mixing ratios likely

486 decreased due to low biological activity. For these reasons, the differences in the number

487 size distributions between VOC-removed and untreated air samples would be more

488 conspicuous in summer than in winter.

489

490 *5.3. VOCs onto coarse particles in pristine air masses*

491 Colomb et al. (2009) measured DMS, isoprene, carbonyls, and organohalogens over

492 the Southern Indian Ocean. DMS was the most abundant VOC, with a mixing ratio ranging

493 from 50 to 885 pptv. The simultaneous enhancement of DMS, methyl bromide,

494 dibromomethane, and methyl iodine was associated with high biological activity. They also

25

495   showed that isoprene, terpenes, acetone, and acetaldehyde were biologically produced in

496   the ocean. According to Rinaldi et al. (2010), increased VOC emissions by marine biota

497   during the warm season results in relatively high WSOC concentrations in aerosol particles.

498   Thus, atmospheric VOC mixing ratios are likely to be substantially higher in summer than in

499   winter. This suggests that the volume of VOCs condensed on individual particles is larger in

500   summer than in winter.

501   Most SOA masses consist of oligomeric compounds produced through gas-phase

502   reactions between organic compounds and oxidants, such as O_3, OH, and NO_X

503   (Denkenberger et al., 2007; Heaton et al., 2007). Kim et al. (2012) performed chamber

504   experiments to investigate the refractive indices of SOA generated from the photooxidation

505   of limonene and α–pinene with different HC/NOx ratios (ppbC ppb^{-1}). At a wavelength of

506   532 nm ranging from 1.34 to 1.56 for limonene and from 1.36 to 1.52 for α–pinene, the

507   refractive indices increased with decreasing HC/NOx. Varma et al. (2013) reported the

508   refractive indices for SOA from the reaction between β–pinene and NO_3. The refractive index

509   was 1.61 ± 0.03 at wavelengths of 655−687 nm, under the condition of approximately 2

510   ppbC ppb^{-1}, which was lower than the lower limit of the experimental conditions in Kim et al.

511   (2012). The results of Kim et al. (2012) and Varma et al. (2013) suggest that high refractive

512   indices are associated with either a high proportion of organic nitrates or the possibility of

513   oligomerization in SOA. The increase in H:C ratios was measured in the SOA formed by the

514   photooxidation of limonene and α–pinene; as the particles grow, and the oxidation

26

515   progresses. The H:C ratio showed the best correlation with the refractive index. These

516   results are consistent with oligomerization reactions (Kim et al., 2014). Hall and Johnston

517   (2012) obtained MS/MS product ion spectra for many oligomers in SOAs produced by α–

518   pinene ozonolysis. They reported that a gas-phase monomer collided with the particle

519   surface and rapidly formed an oligomer.

520   Over the northwestern Pacific, WSOC mass concentrations were higher in coarse

521   particles than in fine particles under marine background conditions (Matsumoto et al., 1998;

522   Miyazaki et al., 2010). VOCs incorporated into aerosol particles could produce WSOC

523   through oxidation processes. The considerably high refractive index of coarse particles in

524   pristine air masses appears to be associated with the optical properties of VOCs and/or

525   SOAs condensed onto coarse particles.

6. Summary and conclusions

Scattering substances in aerosol particles disperse sunlight, whereas light-absorbing substances absorb sunlight. These optical properties depend on the m (n, k) of the materials contained in aerosol particles. In addition to the aerosol scattering and absorption coefficients, to elucidate the difference in the number size distribution between polluted and pristine air masses, the number size distributions of aerosol particles were measured on Chichi-jima of the Ogasawara Islands and the JARE52 voyage track of the icebreaker *Shirase* from Tokyo to the offing of the Philippines in the atmospheric boundary layer over the northwestern Pacific.

Scattering and absorption coefficients were reproduced from the observed number size distribution and the assumption of m (n, k). The following requirements were needed for the estimated values to be in harmony with the observed values: In polluted air masses from 30.5°N to 29.5°N, a refractive index of 1.55 for aerosol particles at a wavelength of 550 nm was estimated to be uniform regardless of the number size distribution, which was close to the values for $(NH_4)_2SO_4$ and NaCl. If $k = 0$ for coarse particles, the k values in the fine particles were 0.0168−0.0188. In addition, the refractive index, n, exhibits normal dispersion. In the pristine air masses from 17.5°N to 16.0°N and 14.5°N to 13.5°N, the refractive indices were estimated to be 1.47 for fine particles and 1.62 for coarse particles. The k values for fine particles were 0.0006−0.0030 from 17.5°N to 16.0°N and 0.0015−0.0055 from 14.5°N

545   to 13.5°N. The refractive index of the fine particles was close to that of NH_4HSO_4 while the

546   refractive index of the coarse particles was even higher than the 1.544 of NaCl.

547   Based on the differences in number size distribution between the VOC-removed and

548   untreated air samples observed on Chichi-jima, VOCs appear to preferentially condense

549   onto coarse particles. Previous laboratory experiment studies have suggested that high

550   refractive indices are associated with the oligomerization of SOA. The results of the present

551   study indicate that the m (n, k) of coarse particles in real air masses was most likely affected

552   by organic compounds originating from biological activity.

553   Coarse particles probably act as the sink for VOCs and/or SOA, and the reaction media

554   of reactive species; they could also affect the production of cloud droplets, chemical lifetimes

555   of reactive species, and radiative effects of aerosol particles. Therefore, in the marine

556   atmosphere, further investigation should be conducted on the relationship between optical

557   properties and organic compounds in coarse particles.

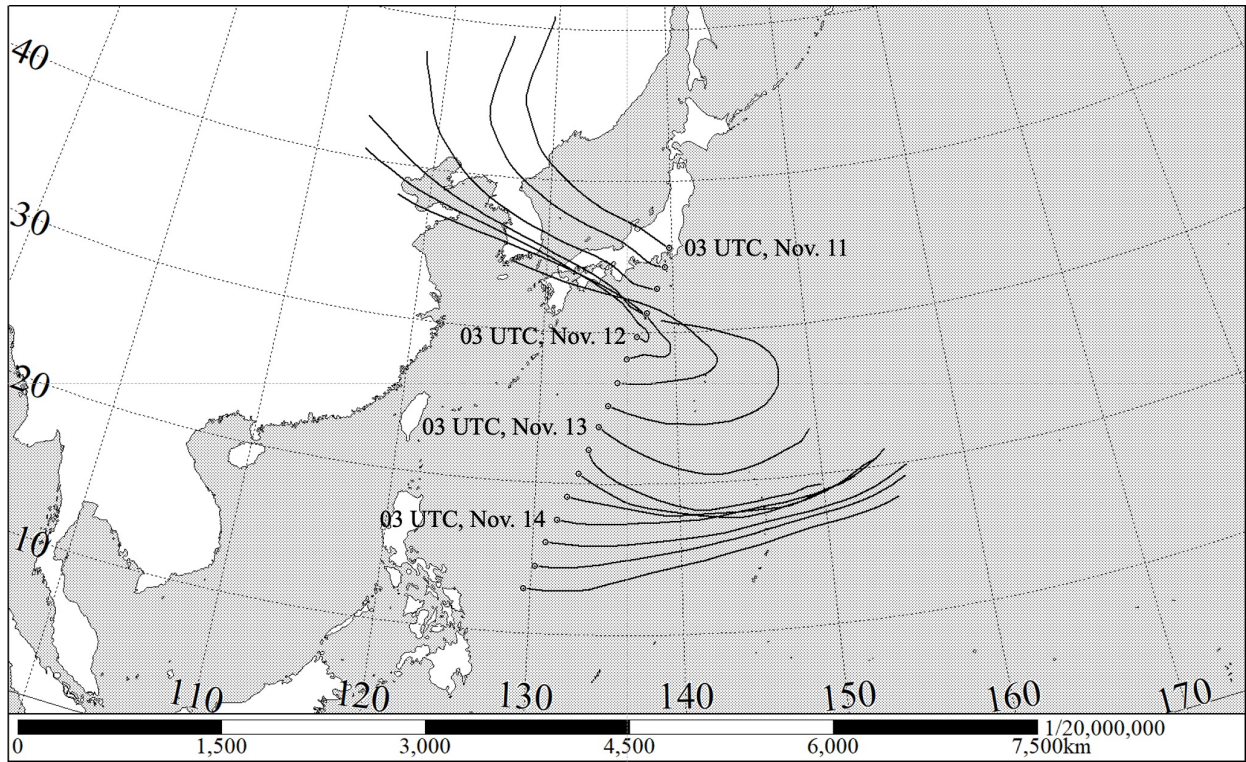

Fig. 1 The JARE52 voyage track of the icebreaker *Shirase* from Tokyo, Japan, to the offing

of the Philippines on November 11−14, 2010.

760

Fig. 2 Observed σ_{ts}^{λ} at wavelengths of 450, 550, and 700 nm, σ_a at 565 nm, and *AE* at

three wavelength ranges. The values of σ_{ts}^{λ} and σ_a are values at 1 min intervals. The
values of *AE* are 1 h moving averages.

41

766

Fig. 3 Number size concentrations of 0.3−5.0 µm diameter aerosol particles at 1 min

intervals, and air temperature (AT), dew point (DP), wind speed (WS), and relative
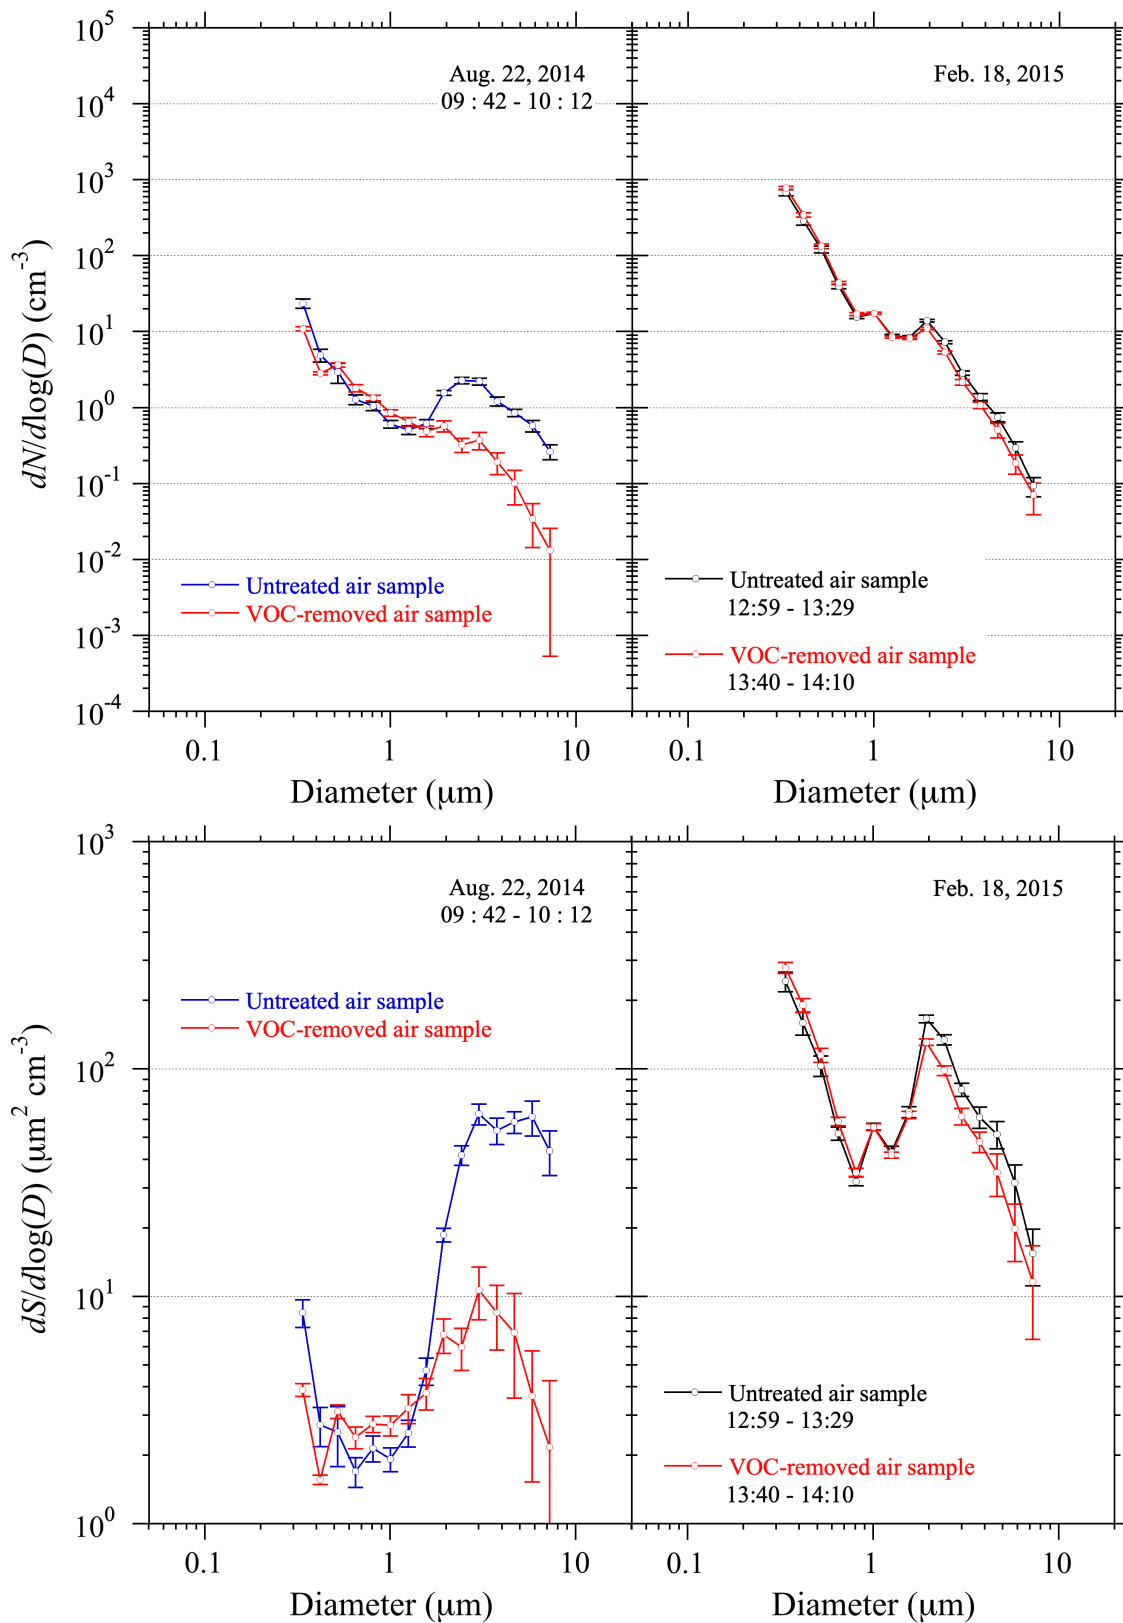

humidity (%) at 1 h intervals.

770

771

Fig. 4 Number size distributions averaged from 30.5°N to 29.5°N and from 17.5°N to

16.0°N in Fig. 3. Vertical bars represent the range of one standard deviation.

Fig. 5 Number and surface area size distributions measured on Chichi-jima, the

Ogasawara Islands, in the northwestern Pacific. Vertical bars represent the range of one
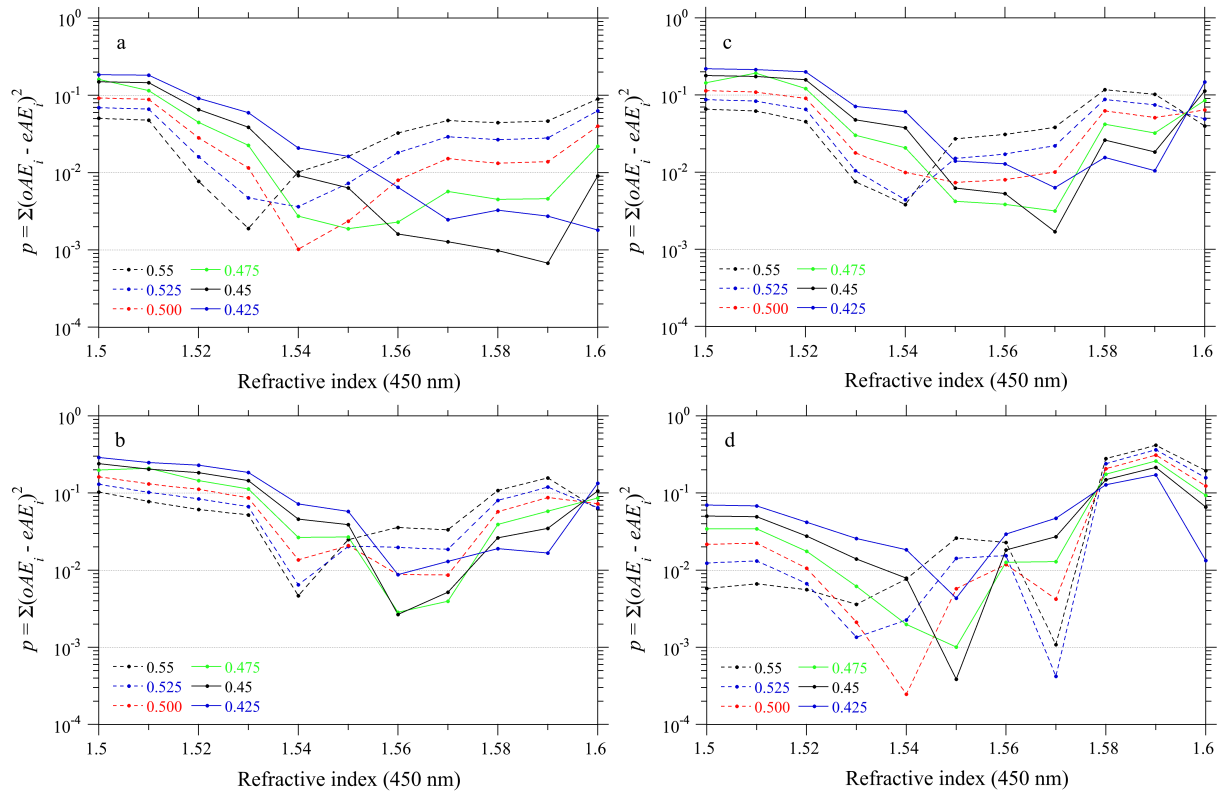

standard deviation.

779

780   Fig. 6 Conceptual diagram of the column model. The black dots show the number size

781   distributions of aerosol particles reported by the OPC in polluted air masses from 30.5°N

782   to 29.5°N. Vertical bars represent the range of one standard deviation. For more

783   information, see text.

784

785

Fig. 7 Variations of the *p* value as a function of *m*(*n*, 0) at a wavelength of 450 nm. These

values are obtained by *sf* from 0.425 to 0.55 at intervals of 0.025. (a) The refractive

index is constant, independent of wavelength of light. (b) The mutual difference in the

refractive indices among the 450, 550, and 700 nm wavelengths is assumed to be 0.01

due to normal dispersion. (c) The refractive index at 450 nm is 0.01 higher than those at

550 and 700 nm. (d) The case, anomalous dispersion, that refractive index decreases

with decreasing the wavelength. The refractive index at 450 nm is assumed to be 0.02

lower than at 700 nm.

Fig. 8 Number size distributions in (a) polluted, and (b) and (c) pristine air masses. Open circles show the arithmetic means with one standard deviations of the corrected number size distributions. The black solid and red dashed lines are the expanded number size distribution, as the column model. The green solid and dashed curves, as the log–normal model, are composed of the blue and red solid curves, and the blue and red dashed curves, respectively.
803

804   Fig. 9 Scattering and absorption coefficients at wavelengths of 450 nm (blue), 550 nm

805   (green), and 700 nm (red) as a function of particle diameter (a) from 30.5°N to 29.5°N,

806   (b) from 17.5°N to 16.0°N, and (c) from 14.5°N to 13.5°N. Dashed curves represent

807   absorption coefficients.

808
809

810   Fig.10 Variations of the *p* value as a function of particle diameter D_6 in the column model

811   from 14.5°N to 13.5°N. These values are obtained by *sf* from 2.0 to 3.0 at intervals of 0.25.

812   The red solid line shows the *p* values in *sf* = 2.5 and *k* = 0.0055.

813

Table 1 C^λ, σ_{ts}^λ ($\times10^{-6}$ m^{-1}), σ_a ($\times10^{-6}$ m^{-1}), SSA, and AE averaged in polluted and

pristine air masses, and r.

	Wavelength nm	Polluted air 30.5°N - 29.5°N	Pristine air 17.5°N - 16.0°N	Pristine air 14.5°N - 13.5°N
