Quarkonia Photoproduction at Nucleus Colliders

David d'Enterria¹

Abstract

Exclusive photoproduction of heavy quarkonia in high-energy ultraperipheral ion-ion interactions ($\gamma A \to V A$, where $V = J/\psi, \Upsilon$ and the nucleus A remains intact) offers a useful means to constrain the small- x nuclear gluon density. We discuss [\[1\]](#page-3-0) preliminary results on J/ψ photoproduction in Au-Au collisions at RHIC [\[2\]](#page-3-1), as well as full simulationreconstruction studies of photo-produced Υ in Pb-Pb interactions at the LHC [\[3\]](#page-3-2).

1 Introduction

The gluon density, $xG(x, Q^2)$, at small fractional momenta $x = p_{\text{parton}}/p_{\text{proton}} \lesssim 0.01$ and low, yet perturbative, Q^2 is a subject of intensive experimental and theoretical activity. On the one hand, DGLAP analyses based on DIS e -p data cannot reliably determine xG (Fig. [1\)](#page-0-0) [\[4\]](#page-3-3) as it is only indirectly constrained by the $log(Q^2)$ dependence of the *quark* distributions $(F_2 \text{ scaling violations}).$ On the other, there are well funded theoretical arguments [\[5\]](#page-3-4) that support the inapplicability of linear QCD (DGLAP- or BFKL-type) evolution equations at low enough values of x , due to the increasing importance of gluongluon fusion processes ("parton saturation"). This regime is theoretically described e.g. in the Colour-Glass-Condensate [\[6\]](#page-3-5) or "blackdisk limit" [\[7\]](#page-3-6) approaches. Our knowledge of the low- x gluon distribution in the *nucleus* is even more scarce. Nuclear DIS data only cover the range above $x \approx 10^{-2}$ (Fig. [2\)](#page-0-1), and gluon saturation effects are expected to be much larger in nuclei than in the proton due to their larger transverse parton density.

Figure 1: Comparison of recent parametrizations of the low- x gluon distribution at scales $Q^2 = 2.4$ (left) and 10 GeV² (right) [\[4\]](#page-3-3).

Figure 2: Kinematic (x, Q^2) plane probed in e-,γ-A collisions: DIS data compared to ultraperipheral QQ photoproduction ranges.

2 $Q\overline{Q}$ photoproduction in ultraperipheral A-A interactions

Exclusive quarkonia photoproduction offers an attractive opportunity to constrain the $low-x$ gluon density at moderate virtualities, since in such processes the gluon couples di-rectly to the c or b quarks (see Fig. [3\)](#page-1-0) and the cross section is proportional to the gluon density squared (see [\[4\]](#page-3-3) and refs. therein). The mass of the $Q\overline{Q}$ vector meson introduces a relatively large scale, amenable to a perturbative QCD (pQCD) treatment.

Figure 3: Schematic diagram for diffractive quarkonia photoproduction in γA collisions.

High-energy nuclear photoproduction studies are possible in Ultra-Peripheral Collisions (UPCs) of heavy-ions [\[8\]](#page-3-7) in which the strong electromagnetic fields involved are equivalent to the exchange of quasi-real photons with maximum energies $\omega_{max} \approx 3$ GeV (100 GeV) at RHIC (LHC). Correspondingly, the maximum photonnucleus c.m. energies are of the order $W_{\gamma A}^{max} \approx 35$ GeV (1 TeV) at RHIC (LHC). Thus, in $\gamma A \to J/\psi(\Upsilon) A^{(*)}$ processes, the gluon distribution can be probed at values as low as $x = M_V^2/W_{\gamma A}^2 \approx 10^{-2}(10^{-4})$ (Fig. [2\)](#page-0-1). Gluon saturation effects are expected to reveal themselves through strong suppression of hard exclusive diffraction relative to the leading-twist approximation [\[7\]](#page-3-6). While this suppression may be beyond the kinematics achievable for J/ψ

photoproduction in UPCs at RHIC, $x \approx 0.01$ and $Q_{\text{eff}}^2 \approx M_V^2/4 \approx 3 \text{ GeV}^2$, it could be important in UPCs at the LHC [\[8\]](#page-3-7).

3 J/ψ photoproduction in Au-Au at RHIC (PHENIX)

The PHENIX experiment has measured J/ψ photoproduction at mid-rapidity in Au-Au UPCs at $\sqrt{s_{NN}}$ = 200 GeV in the dielectron channel [\[2\]](#page-3-1). The UPC events were triggered requiring (i) a cluster in the electromagnetic calorimeter (EMCal) above 0.8 GeV, (ii) a rapidity gap in one or both $3.0 < |\eta| < 3.9$ ranges, and (iii) at least 30 GeV energy deposited in one or both of the Zero-Degree-Calorimeters (ZDCs). This last condition very efficiently selects ultra-peripheral events accompanied by forward neutron emission (X_n) coming from the electromagnetic dissociation of one (or both) Au^* nuclei, which occurs with a large probability, $P_{Xn} \sim 0.64$ (at $y = 0$) at RHIC energies [\[9\]](#page-3-8). Electron reconstruction is done combining the central tracking devices, Ring Imaging Čerenkov (RICH) counters, and the EMCal.

Figure 4: Invariant mass distribution of $e^+e^$ pairs measured in UPC Au-Au fitted to the combination of a $\gamma \gamma \to e^+e^-$ continuum plus a $\gamma A \rightarrow J/\psi A$ signal [\[2\]](#page-3-1).

Photon 2007

The invariant mass distribution of all reconstructed e^{\pm} pairs is shown in Fig. [4.](#page-1-1) The plot shows the expected $\gamma \gamma \rightarrow e^+e^-$ continuum curve combined with a fit to a Gaussian at the J/ψ peak. The total number of J/ψ 's is 10 ± 3 (stat) ± 3 (syst.), where the systematic uncertainty is dominated by the di-electron continuum subtraction. Within the (still large) experimental errors, the preliminary J/ψ cross-section of $d\sigma/dy|_{|y|<0.5}$ = $48 \pm 14(\text{stat}) \pm 16(\text{syst})$ µb is consistent with various theoretical predictions [\[10,](#page-3-9) [11,](#page-3-10) [12,](#page-3-11) [13\]](#page-3-12) (see Fig. [5,](#page-2-0) where the FGS and KST rapidity distributions have been scaled down according to [\[9\]](#page-3-8) to account for the reduction of the yield expected when requiring coincident forward neutron emission). The band covered by the FGS predictions includes the J/ψ cross sections with and without gluon shadowing [\[11\]](#page-3-10). The current experimental uncertainties preclude yet any detailed conclusion regarding the nuclear gluon distribution. The possible contribution of an additional incoherent (γ -nucleon $\rightarrow J/\psi$) component – amounting to about ∼50% of the coherent (γA) yield at $y = 0$ [\[11\]](#page-3-10) – should be taken under consideration too.

Figure 5: Preliminary cross-section of coherent J/ψ production at $y = 0$ in UPC Au-Au at $\sqrt{s_{NN}}$ = 200 GeV compared to various theoretical calculations [\[10,](#page-3-9) [11,](#page-3-10) [12,](#page-3-11) [13\]](#page-3-12).

4 Υ photoproduction in Pb-Pb at the LHC (CMS)

At the LHC energies, the cross section for $\Upsilon(1S)$ photoproduction in UPC Pb-Pb at $\sqrt{s_{_{NN}}}$ = 5.5 TeV is of the order of 150 μ b [\[10,](#page-3-9) [14\]](#page-3-13). Inclusion of leading-twist shadowing effects in the nuclear PDFs reduces the yield by up to a factor of two, $\sigma_{\Upsilon} = 78 \mu b$ [\[14\]](#page-3-13). Even larger reductions are expected in calculations including gluon-saturation (Colour Glass Condensate) effects [\[15\]](#page-3-14).

Figure 6: Expected e^+e^- (top) and $\mu^+\mu^-$ (bottom) invariant mass distributions from $\gamma \text{Pb} \rightarrow \Upsilon \text{Pb}^*$ $(\Upsilon \rightarrow l^+l^-$, signal) and $\gamma \gamma \rightarrow l^+ l^-$ (background) in UPC Pb-Pb at $\sqrt{s_{NN}}$ = 5.5 TeV in CMS.

Full simulation+reconstruction studies [\[3\]](#page-3-2)

Photon 2007

of input distributions generated with the starlight MC [\[10\]](#page-3-9) have shown that CMS can measure $\Upsilon \rightarrow e^+e^-$, $\mu^+\mu^-$ within $|\eta|$ < 2.5, in UPCs tagged with neutrons detected in the ZDCs [\[16\]](#page-3-15), with large efficiencies $(\epsilon_{rec} \times \text{Acc} \times \epsilon_{yield-extract} \approx 20\%).$ Figure [6](#page-2-1) shows the reconstructed $dN/dm_{l+ l-}$ around the Υ mass (only the ground-state, $\Upsilon(1S)$, of the bottomonium family was generated). The signal over continuum background is around one for both decay modes. The total expected number of Υ events, normalised to the nominal 0.5 nb−¹ Pb-Pb integrated luminosity, is \sim 500, and the p_T resolution is good enough to separate the coherent (peaked at very low $p_T \approx M_V/\gamma \approx 30 \text{ MeV}/c$ from the incoherent components. With such a statistics, detailed p_T , η studies can be carried out, that will help constrain the low- x gluon density in the nucleus.

5 Summary

High-energy quarkonia photoproduction provides a particularly useful means to constrain the poorly known low- x gluon distribution of the nucleus in the clean environment of ultra-peripheral (electromagnetic) ion-ion collisions. Gluon saturation effects in the small- x domain of the nuclear wavefunction are expected to result in a suppression of hard exclusive diffraction yields relative to linear QCD expectations. We have presented preliminary PHENIX results of exclusive J/ψ photoproduction in 200-GeV Au-Au interactions, as well as the perspectives of the CMS experiment in 5.5-TeV Pb-Pb collisions at the LHC. In the absence of strong non-linear QCD effects, around 500 photo-produced Υ will be reconstructed in the CMS acceptance with nominal integrated luminosities.

Acknowledgments

My gratitude to the organisers of PHOTON'07 conference – in particular Gerhard Baur and Maarten Boonekamp – for their kind invitation and for the stimulating programme. Special thanks due to Joakim Nystrand for providing the STARLIGHT predictions and for useful discussions, as well as to Mark Strikman for informative exchanges.
