Error Analysis of Programmable Metasurfaces for Beam Steering

Hamidreza Taghvaee, Albert Cabellos-Aparicio, Julius Georgiou, and Sergi Abadal

Abstract—**Recent years have seen the emergence of programmable metasurfaces, where the user can modify the EM response of the device via software. Adding reconfigurability to the already powerful EM capabilities of metasurfaces opens the door to novel cyber-physical systems with exciting applications in domains such as holography, cloaking, or wireless communications. This paradigm shift, however, comes with a non-trivial increase of the complexity of the metasurfaces that will pose new reliability challenges stemming from the need to integrate tuning, control, and communication resources to implement the programmability. While metasurfaces will become prone to failures, little is known about their tolerance to errors. To bridge this gap, this paper examines the reliability problem in programmable metamaterials by proposing an error model and a general methodology for error analysis. To derive the error model, the causes and potential impact of faults are identified and discussed qualitatively. The methodology is presented and exemplified for beam steering, which constitutes a relevant case for programmable metasurfaces. Results show that performance degradation depends on the type of error and its spatial distribution and that, in beam steering, error rates over 20% can still be considered acceptable.**

Index Terms—**Error analysis, Programmable Metasurface, millimeter-wave**

I. INTRODUCTION

Metamaterials have garnered significant attention in the last decade as they enable unprecedented levels of electromagnetic (EM) control [1] and have opened the door to disruptive advances across domains such as imaging, integrated optics, or wireless communications [2]–[5]. Metasurfaces, the thin-film analog of metamaterials, are generally comprised of a planar array of subwavelength elements over a substrate, i.e. the unit cells, and inherit the unique properties of their 3D counterparts while minimizing bulkiness, losses, and cost. Functionalities such as beam steering, focusing, vorticity control, or RCS reduction have been demonstrated across the spectrum, from microwaves [6]–[8] to terahertz [9]–[13], or optical frequencies [14], [15].

Early works in the field of metamaterials had two main drawbacks, namely, non-adaptivity and non-reconfigurability. This is because, due to their highly resonant nature, unit cells are generally designed for a particular EM function and scope. To address this issue, tunable elements or materials have been introduced in the unit cell design loop in order to provide

global or local reconfigurability [16]. Further, recent years have seen the emergence of programmable metasurfaces, this is, metasurfaces that incorporate local tunability and digital logic to easily reconfigure the EM behavior from the outside.

Two main approaches have been proposed for the implementation of programmable metasurfaces, namely, (i) by interfacing the tunable elements through an external Field-Programmable Gate Array (FPGA) [17], [18], or (ii) by integrating sensors, control units, and actuators within the metasurface structure [19]–[22].

Programmable metasurfaces have opened the door to disruptive paradigms such as Software-Defined Metamaterials (SDMs) and Reconfigurable Intelligent Surfaces (RISs), leading to the interconnection of metasurfaces, the use of machine learning and, eventually, the implementation of software-driven distributed intelligence on EM control [19], [23]–[25]. This has potential to exert a disruptive impact in a plethora of application domains, including but not limited to holographic displays [7], stealth technology [26] or wireless communications [21], [28]. In the latter case, the metasurfaces allow modifying the wireless channel by controlling the direction and phase of reflection. Figure 1 illustrates a plausible scenario where service would normally be disrupted due to blockage, but that metasurfaces are capable of redress by directing the reflections to the user. This is a true paradigm shift for wireless communications, as the recent explosion of works can attest [21], [25], [28]–[32], because the wireless channel has traditionally been an inescapable limiting factor.

Alas, the transition from static to intelligent programmable metasurfaces has come at the cost of added design, fabrication, and embedding complexity. Programmable metasurfaces need to integrate tuning and control elements on a per-cell basis, electronic circuits to implement intelligence within the device, as well as mechanisms to interface the surface with the world. This poses important challenges at fabrication, calibration, deployment, and run time that, among others, affect reliability. In other words, metasurfaces will become prone to failure as they continue integrating sophisticated tuning, control and sensing circuits. However, the impact of faults on the performance of individual metasurfaces is not well understood yet.

We claim that error analysis is a necessary first step to understand the impact of transient or permanent failures on the performance of both a single metasurface and, crucially, a complete system. In the scenario of Figure 1, for instance, faults might lead to inaccuracies in the steering of the reflection and cause a drop in quality of service. Further, an error analysis would also allow to derive guidelines for the implementation of robust programmable metasurfaces, estimate the

Fig. 1. Graphical illustration of an environment augmented with potentially faulty programmable metasurfaces. Since Line-of-Sight (LoS) propagation is not possible, the metasurfaces attempt to maximize the non-LoS power at the receiver by directing the reflections and altering the phase for coherent detection. A faulty metasurface may lead to service disruption by not pointing the reflected beam accurately.

Fig. 2. Progression of metasurface design, from static to programmable with fully integrated tuning and control electronics.

lifetime of the deployed ones, or even develop methods to save energy by power-gating a portion of the internal circuitry of the metasurface.

However, error analyses have not been carried out taking the particularities of metasurfaces into consideration. In [33], the authors evaluate the impact of phase errors in RIS panels that shift the phase of impinging waves aiming for a coherent combination at the receiver. In that case, each RIS is spaced apart and treated independently, ignoring the directions of impinging or reflected waves and limiting errors to system inaccuracies, i.e. quantization and estimation error, but no faults. This resembles the classical works that analyze the impact of errors in phased antenna arrays [34]–[37]. Such an analysis is therefore not directly applicable to metasurfaces, where (1) the causes of failures can be more varied due to the amount of control circuitry, and (2) the focus is on the impact of a number of failures (or the chained effect of a few of them) rather than on individual faulty components.

This paper proposes a framework to evaluate the impact of failures in programmable metasurfaces, distinguishing between the type of faults and their spatial distribution. Despite being applicable to any EM functionality, here we use the methodology to study a beam steering metasurface at 26 GHz as a particular yet very relevant use case in metasurface-enabled 5G communications as shown in Fig. 1 [21]. This contribution extends our previous work [38] where the error model and the methodology were outlined, and a generic beam steering device was evaluated in a limited amount of cases. Here, we deepen the analysis by (i) introducing a realistic unit cell to improve the system model, (ii) exemplifying the effects of failures in the components of a tunable unit cell, (iii) evaluating the impact of faults in multiple performance metrics such as deviation from the target direction, and (iv) evaluating the impact of a much wider range of error type combinations.

The remainder of this paper is as follows. Section II provides background on programmable metasurfaces along with design factors such as coding and architecture. Section III introduces the metasurface model for the far field. Section IV analyzes possible causes of errors and derives an error model. Section V presents the evaluation methodology, instantiated for the beam steering case. Section VI shows the results of the analysis and Section VII concludes the paper.
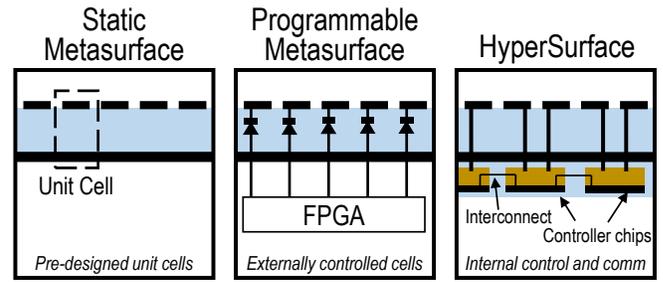

II. BACKGROUND: PROGRAMMABLE METASURFACES

Metasurfaces are structures generally composed of an array of subwavelength resonators referred to as *unit cells*. The characteristics of these building blocks determine the metasurface response, this is, its absorption, reflection, and transmission characteristic [4], [39], [40].

With the introduction of tunable or switchable elements, metasurfaces can adapt to different environments or take multiple functionalities [12], [16], [41], [42]. Tuning has been demonstrated in several forms, including thermal [43], electrical [10], [44], and optical tuning [45]; or the use pin diodes [46], varactors [47], memristors [48], and microelectromechanical systems (MEMS) [49].

Determining the characteristics of the unit cell that will lead to the desired behavior is typically performed analytically, through methods such as impedance matching [22]. A large subset of designs has been based on the generalization of the Snell's laws of reflection and refraction [6], [50]–[52], which provides fundamental understanding on how to achieve certain functionalities through the drawing of specific phase gradients. When analytical methods are not practical, computational optimization methods [53], [54] or even machine learning approaches can be employed [55]–[57]. Another method worth remarking is that of coding metasurfaces, where the metasurface is *encoded* using a discrete set of unit cell options or states [17]. This allows drawing clear parallelism with information theory, enabling new ways to compose advanced metasurfaces by, for instance, adding or convoluting the codes of two desired EM functionalities [58], [59]. For instance, the design process is shown in Section III-C follows the principles of generalized Snell's law and coding metasurfaces.

The addition of control methods, together with the tunability on a per-cell basis, enables the programming of coding metasurfaces [17], [60], [61]. The example in [46] uses a Field-Programmable Gate Array (FPGA) to drive the pin diodes of a reconfigurable metasurface, where each pin diode determines the binary state of an individual unit cell. Such a device, however, exemplifies the potential reliability issues of programmable metasurfaces. In this particular case, the pin diodes enabling the reconfigurability may generate a considerable current density in the device, which could lead to electromigration. Also, the FPGA is a potential single point of failure, rendering the metasurface useless if the FPGA breaks down.

Beyond that, several authors have proposed to integrate a network of communicating chips within the metasurface containing actuators, control circuits, and even sensors [19],

Graphical representation of a possible HSF implementation, which includes the metasurface plane with the metallic patches and the substrate, the sensing/actuation plane with the tuning elements and sensors, the computing/control plane containing the controller chips, and the communications plane containing the routing logic and interconnects. A gateway controller interfaces the HSF with the external world.

[21], [22], [62]. This concept, referred to as HyperSurface (HSF), opens new opportunities in the design of autonomous self-adaptive programmable metasurfaces but, at the same time, poses further challenges in the implementation, co-integration, and testing of the electronics within and around the metasurface.

Figure 3 shows a graphical representation of the HSF structure, illustrating the logic planes of the device. Essentially, the HSF receives external programmatic commands from a gateway controller that are disseminated to the internal control logic at the controller chips via chip-to-chip interconnects and routing logic [63], [64]. These commands contain the state (within the discrete set of possible states) that should be applied to each unit cell. The control logic translates the state into an analog value to be applied to the tuning element, e.g. the voltage applied to a varactor to achieve a target capacitance. Additionally, embedded sensors can pick up data from the environment and send it to the control logic or external devices again via the communications plane.

From the above, it seems clear that the integration of the controller chips, the chip-to-chip network, as well as the sensors and tuning elements, complicate the HSF design from the reliability perspective. As we will see in Section IV, each of these components may fail in several ways leading to different consequences.

III. METASURFACE MODEL FOR ANOMALOUS REFLECTION

In this paper, we evaluate the impact of faults in the beam steering capability of a programmable metasurface. To that end, the metasurface needs to implement anomalous reflection with the incidence and reflection angles as potential inputs. Here, we first describe the model used in this work to obtain

the EM response of each individual unit cell (Section III-A) and of the complete metasurface in the far field (Section III-B). Finally, we outline the methods to determine the coding of the metasurface, this is the states that need to be applied to each unit cell to direct the beam to a given target direction (Section III-C).

A. Unit Cell Model

Unit cells are generally designed with a certain function in mind. For instance, the anomalous reflection will require unit cells to exhibit a reflection coefficient with high amplitude plus reconfigurable phase to change the angle of reflection [50]. As shown in several works, providing phase reconfigurability can be achieved via several tuning mechanisms [22]. Since one of the aims of this paper is to capture the possible loss of performance arising from component faults, here we provide a particular unit cell design.

The case shown here revolves around the promising application of programmable metasurfaces in millimeter-wave communications for 5G (Fig. 1). We assume a square unit cell ($c = 2$ mm) with a metallic backplane for operation around 25 GHz, aimed at giving service to one of the available $5G$ bands according to new recommendations by the International Telecommunication Union (ITU) [66]. A square metallic patch ($b = 1.85$ mm) is stacked on top of a substrate (Rogers RO4003C) with permittivity $\epsilon_r = 3.5$ and thickness $a = 0.81$ mm. It is possible to modify the phase response of the unit cell by adding capacitance to the square metallic patch. For phase tunability, this capacitance is given by varactors, which are embedded within the controllers and hidden under the backplane, but connected to the top patch with vertical vias
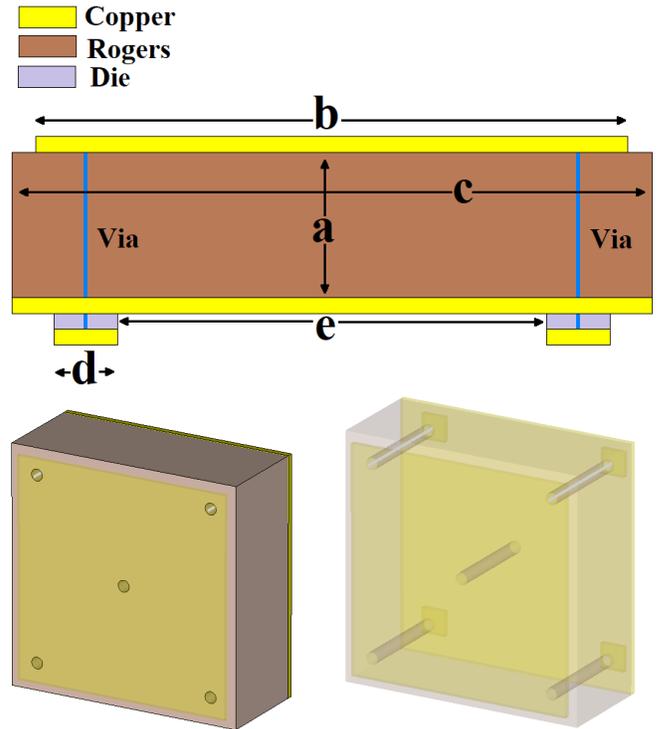

Fig. 4. Cross-section, top-view, and bottom-view of the assumed unit cell.

We implement the proposed unit cell in a full-wave solver, CST MWS [67], and evaluate the reflection coefficient when

the unit cell is illuminated by a normal incident plane wave and for a set of capacitance values.

Assuming that our design implements four coding states, it is standard practice in anomalous reflection metasurfaces that the 2π phase range is divided into evenly spaced states with $\pi/2$ separation with high reflection amplitude [22].

As shown in Figure 5, the unit cell achieves these objectives around the target frequency, 25 GHz, with a reflection amplitude Γ of 0.9 and phases Φ at $\{45, 135, 225, 315\}$ degrees. The figure plots the capacitances that have achieved such separation: 0.01 pF, 0.04 pF, 0.06 pF, and 0.9 pF. We will see that, if the capacitances deviate from such values, the unit cell may inaccurately point to different amplitude and phase.
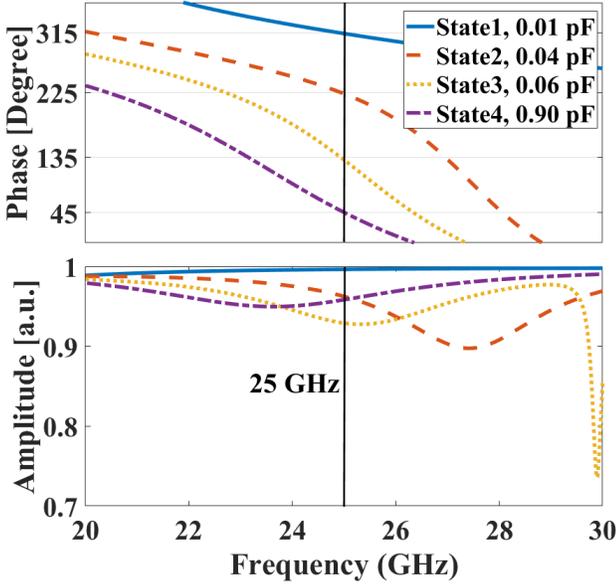

Fig. 5. Unit cell reflection phase Φ (top) and amplitude Γ (bottom) as a function of frequency for the four chosen capacitance values.

B. Metasurface Model

Beam steering is a particular case of wavefront manipulation that occurs in the far field. As such, the metasurface can be accurately modeled as a compact array following the Huygens principle [68]. This method has been validated in several works via extensive simulations [52]. Considering each unit cell as an element of the array, the far field of the metasurface can be obtained as

$$F(\theta, \phi) = f_E(\theta, \phi) \cdot f_A(\theta, \phi), \quad (1)$$

where θ is the elevation angle, ϕ is the azimuth angle of an arbitrary direction, $f_E(\theta, \phi)$ is the element factor (pattern function of unit cell) and $f_A(\theta, \phi)$ is the array factor (pattern function of unit cell arrangement). With the widespread assumption of a planar wave covering the entire metasurface, the scattering pattern will depend only on the array factor. For the metasurface with $N \times M$ unit cells, the far field pattern becomes

$$
\begin{aligned}
F(\theta, \phi) = \sum_{m=1}^{M} \sum_{n=1}^{N} A_{mn} e^{j\alpha_{mn}} f_{mn}(\theta_i, \phi_i) \\
\Gamma_{mn} e^{j\Phi_{mn}} f_{mn}(\theta, \phi) e^{jk_0\zeta_{mn}(\theta, \phi)}
\end{aligned}
\quad (2)
$$

where A_{mn} and α_{mn} are the amplitude and phase of the wave incident to the mn-th unit cell; Γ_{mn} and Φ_{mn} are the amplitude and phase of the response of the mn-th unit cell; $f_{mn}(\theta, \phi)$ denotes the scattering diagram of the mn-th unit cell towards an arbitrary direction of reflection, whereas $f_{mn}(\theta_i, \phi_i)$ denotes the response of the mn-th unit cell at the direction of incidence determined by θ_i, ϕ_i and $k_0 = 2\pi/\lambda_0$ is the wave number (air is assumed). Finally, $\zeta_{mn}(\theta, \phi)$ is the relative phase shift of the unit cells with respect to the radiation pattern coordinates, given by

$$\zeta_{mn}(\theta, \phi) = D_u \sin\theta[(m - \tfrac{1}{2})\cos\phi + (n - \tfrac{1}{2})\sin\phi] \quad (3)$$

We further make the plausible assumption of plane wave incidence, so that factors A_{mn}, α_{mn}, and $f_{mn}(\theta_i, \phi_i)$ are constants for all m, n.

Further, we model the scattering pattern of the unit cell over the positive semisphere with the function $\cos(\theta)$, which is a widespread assumption [46]. Finally, and without loss of generality, we consider the normal incidence ($\theta_i = \phi_i = 0$). Then, Eq. (2) becomes

$$E(\theta, \phi) = K \cos\theta \sum_{m=1}^{M} \sum_{n=1}^{N} \Gamma_{mn} e^{j[\Phi_{mn} + k_0\zeta_{mn}(\theta, \phi)]} \quad (4)$$

where K is a constant. By controlling the phase shift of the unit cells Φ_{mn}, we can implement anomalous reflection as described next.

C. Metasurface Coding

The coding of the cells of a programmable metasurface allows obtaining the desired functionality. In other words, we need to derive the amplitude Γ_{mn} and phase Φ_{mn} of each unit cell so that the collective response matches with the required functionality. Then, we map the required Γ and Φ to the closest available unit cell states.

In the case of anomalous reflection for beam steering, analytical methods provide high accuracy. Moreover, the error analysis performed in this work requires numerous iterations accounting for diverse combinations of faults –hence, the low computation times of analytical methods are desirable. In this work, we follow the well-known principles of wavefront manipulation whereby a phase gradient is used to determine the direction of reflection [50]. Assuming that the metasurface imposes the phase profile $\Phi(x, y)$, we assign the virtual wave vector $k_\Phi = \nabla\Phi_x \hat{x} + \nabla\Phi_y \hat{y}$ to the metasurface. In this context, the momentum conservation law for wave vectors can be expressed as

$$
\begin{aligned}
k_i \sin\theta_i \cos\phi_i + \frac{d\Phi_x}{dx} = k_r \sin\theta_r \cos\phi_r \\
k_i \sin\theta_i \sin\phi_i + \frac{d\Phi_y}{dy} = k_r \sin\theta_r \sin\phi_r
\end{aligned}
\quad (5)
$$

where $\frac{d\Phi_x}{dx}$ and $\frac{d\Phi_y}{dy}$ describe the gradients in the x and y directions, respectively.

Since we can address any given (oblique) wave with a translation formulation [69], let us consider the normal incident wave case ($\theta_i = \phi_i = 0$) without loss of generality. Assuming

air as the medium of the incident and reflected wave, we can simplify the formulation above as

$$d\Phi_x = \frac{2\pi dx \cos\phi_r \sin\theta_r}{\lambda_0}, \ d\Phi_y = \frac{2\pi dy \sin\phi_r \sin\theta_r}{\lambda_0} \quad (6)$$

which express the change in phase (Φ_x and Φ_y) that needs to be performed per unit of distance (dx and dy) in the x and y directions. Then, we set the unit cell size ($d_x = d_y = D_u$) in Equation (6) to obtain the phase required at mn-th unit cell as

$$\Phi_{mn} = \frac{2\pi D_u(m\cos\phi_r \sin\theta_r + n\sin\phi_r \sin\theta_r)}{\lambda_0} \quad (7)$$

To assign states to each unit cell, the required phase Φ_{mn} is calculated for all the unit cells. Then, a closest-neighbor mapping is done between the required phase and that provided by the different unit cell states. For instance, in our particular case where the number of states is $N_s = 4$, we have $\{s_0, s_1, s_2, s_3\}$ with the respective phases of $\{45, 135, 225, 315\}$ degrees, then required phases of 53° and 188° would be mapped to s_0 and s_2 states, respectively.

IV. ERROR MODEL

This section presents the model that we propose for the error analysis of programmable metasurfaces. The model describes both the impact of faults on the behavior of individual unit cells and how the faults can be distributed across the metasurface in Sections IV-A and IV-B, respectively. We also reason about the possible sources of each type of fault and attempt to exemplify a few relevant causes.

Generally speaking, faults in electronic systems may occur for a wide variety of reasons. This is also true in the mixed-signal HSF platform, where the metasurface and its associated tuning, control, and communication subsystems are integrated together. In any case, the relevance of different types of failure will eventually depend, among others, on the maturity of the technology, the manufacturing process, or the application environment. Several examples are outlined below.

For instance, it is widely known that chip failure rates and fabrication mismatches increase as the technology nodes go down [70], which may become necessary in HSFs operating at mmWave and THz frequencies. Manufacturing defects could lead to stuck unit cells, similar to dead pixels in displays. When interconnecting the chips that drive the different unit cells, connector constraints or bad fitting can also lead to errors of different typologies. Once deployed, chip connections might fail over time due to thermal cycling or flexing. Metasurfaces could be exposed to physically challenging conditions that could lead to hard faults, such as physical damage in a conflict zone where bullets could impact the metasurface or bit flips due to cosmic radiation in space applications. Last but not least, ultra-low-power HSFs could power-gate a set of controllers in order to save energy in environments where a given performance degradation is tolerable. Here, the error analysis would help to determine which controllers should be powered off and at which state they should be kept. In any case, power gating can be regarded as an intentional transient fault.

A. Types of Errors

Here, we describe the impact that faults can have on the performance of individual unit cells. We assume that each unit cell is assigned a *valid state* $s \in \Sigma$, where Σ represents the set with cardinality N_s of valid states for a particular unit cell design. As shown in Section III, the state s basically determines the amplitude and phase of the reflection coefficient at an arbitrary unit cell.

In the presence of a fault, we assume that the unit cell will transition to a state s' which may or may not be within the set of valid states of the metasurface. The value of s' and its probability will depend on the type of fault, that we comprehensively classify as follows (see Figure 6):

- **Stuck at state:** the unit cell is stuck at a random, but valid unit cell state $s' \in \Sigma$. This type of error assumes that a failure *disconnects* the unit cell from the rest of the system, leaving it in an old state. Such a disconnection can occur due to failures in the communication or control planes (e.g. in the router or in the controller) that prevent control signals to reach the tuning element. The value of s' is picked randomly with uniform distribution.
- **Out of state:** the unit cell takes a random invalid state $s' \notin \Sigma$, which essentially means random amplitude and/or phase. Possible causes of this error may be failures that affect the tuning elements and, thus, lead to a wrong capacitance. Via disconnections arising from manufacturing defects or aging, or defects in the DAC circuits that drive the tuning element, could lead to such error.
- **Deterministic:** The unit cell stays in a known fixed, generally invalid state, which is the same across all unit cells with the same type of fault. For instance, a deterministic error could be caused by a physically damaged unit cell, i.e. a bullet making a small hole within the HSF could be approximated as zero phase and full transmittance.
- **Biased:** The unit cell is at a state which is at a fixed given distance Δ of the actual required state $s' = s + \Delta \in \Sigma$. This may be caused by flip-bit errors at the computing plane, or by external biases, perhaps due to attacks.

It is worth discriminating the mapping sequence from types of errors. In the end of Section III-C, a process is described which maps the desired phase (in the $[0^o, 360^o]$ range) to the closest available phase for four states s_0, s_1, s_2, s_3. Errors occur after the mapping done by design and, thus, may cause the unit cells states to shift to valid states (e.g. s_0, s_1, s_2, s_3; yet not the intended state for that unit cell) or invalid states (outside the phases mapped to s_0, s_1, s_2, s_3).

Next, we illustrate how single component faults can affect the performance of an individual unit cell. In particular, we evaluate the impact of biasing a single varactor to the wrong voltage or completely disconnecting it. To that end, we simulate the different combinations using our unit cell design from Section III-A as a baseline and calculate the phase error as the difference between the correct and erroneous reflection phase.

The results of this example are shown in Figure 7. Red bars represent the impact of Via disconnection with respect to
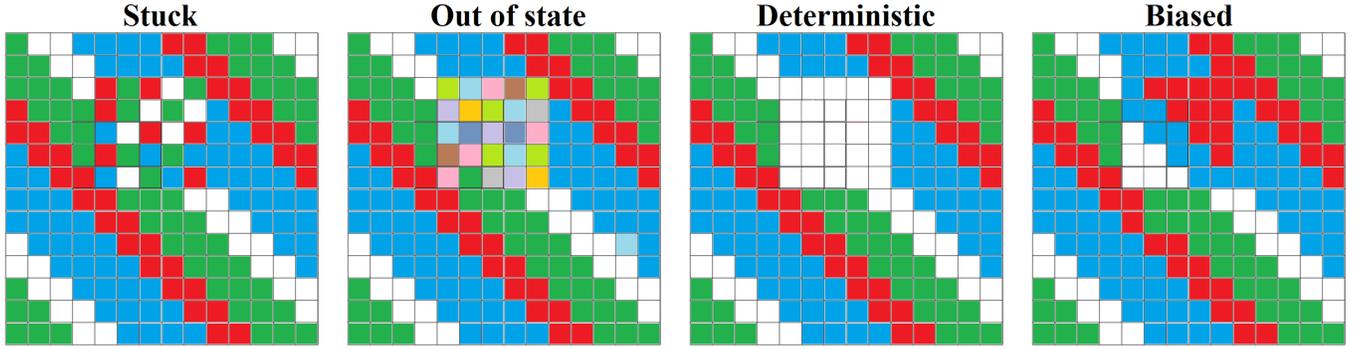

Fig. 6. Graphical representation of the different types of error in a metasurface with 15×15 unit cells. White, green, red, and blue squares indicate valid states, whereas other colors indicate invalid states.

the initial states. Exponential growth from state 1 (0.01 pF) to state 4 (0.9 pF) is observed, revealing that the disconnection of large capacitances has a more significant impact. Blue, black, green and yellow bars indicate the phase error resulting from the wrong biasing of a single Via from the state indicated in the X-axis to state 1, 2, 3, and 4 respectively. For instance, the first black bar indicates the phase error of biasing the Via to state 2 instead of state 1. The impact of each change is subtle and does not follow a clear trend. In this particular example, then, we could approximate single Via failures as an *out of state* error with a random phase.
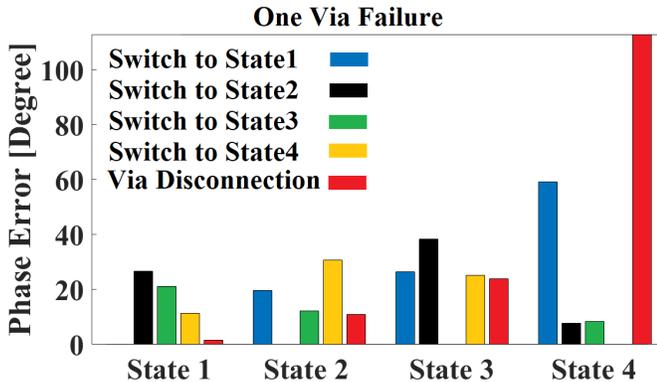

Fig. 7. Phase error resulting from the biasing of a single Via to an incorrect state, or its complete disconnection, for the proposed unit cell design at 26 GHz. The X-axis depicts the state at which the other Vias are biased.

B. Spatial Distribution

Next, we describe the possible spatial distribution of errors across the metasurface. We base our reasoning on the fact that faults may impact multiple unit cells or have cascading effects, this is, lead to further faults. We distinguish between the following distributions, represented in Figure 8:

- **Independent:** The errors are randomly distributed over the metasurface and can be modeled with a spatial Poisson process. Individual uncorrelated faults, maybe with different origins, could yield such a distribution.
- **Clustered:** The errors appear around a given area. Cascading effects of a fault or faults that affect several unit cells can lead to such behavior. For instance, faults rendering a controller chip useless will impact all its associated unit cells. Another example would relate to the loss of connectivity at the network: faults in a few

interconnects can leave an entire region of the metasurface isolated and stuck in an old state [63].
- **Aligned:** The errors are spatially co-located following a line. For instance, let us assume that power or ground signals are distributed through the HSF through a matrix of electrical lines. We speculate that, in such a case, if one line representing a row or column fails, the whole row and column could be affected.
- **State-specific:** Another speculative type of spatial distribution would be that all unit cells that are supposed to be in a specific state, behave incorrectly. This could happen if the actuator uses an external value (e.g. voltage from a centralized regulator) to determine the given state; if that value is incorrect, the state will be erroneous.

V. METHODOLOGY

A general methodology for the analysis of errors in metasurfaces would simply evaluate the metasurface in the presence of an increasing number of errors, and compare it with the performance of a golden reference.

Basically, the golden reference is coded according to the EM functionality and evaluated using the methods exemplified in Section III for beam steering. Then, faults are introduced using the guidelines discussed in Section V-A. To better understand the impact of errors, a set of representative metrics is used to characterize the performance degradation as discussed in Section V-B.

A. Introducing Errors

The analytical formulation allows to trivially introduce errors by modifying the terms Γ_{mn} and Φ_{mn} of the affected unit cells in Equation (4). The type of error, its spatial distribution, together with the percentage of faulty unit cells, define the error scenario as represented in Figure 9. To apply a particular error scenario, the steps are:

1) To set the number of faulty unit cells according to the input percentage.
2) To set the position of the faulty unit cells according to the spatial distribution, setting the m and n values in Γ_{mn} and Φ_{mn}, using spatial Poisson processes if required.
3) To set the Γ and Φ values of each particular unit cell, either within the discrete set of valid states Σ or within a continuous range (valid or invalid states), depending to

Independent **Clustered** **Aligned** **State specific**
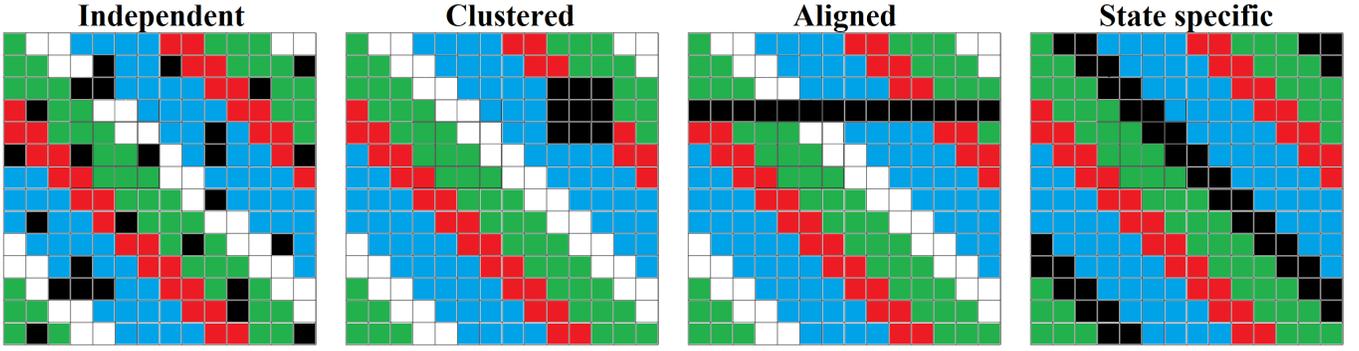

Fig. 8. Graphical representation of the different error distributions in a metasurface with 15×15 unit cells. Black squares represent faulty unit cells.

the type of error and using random number generators if required.
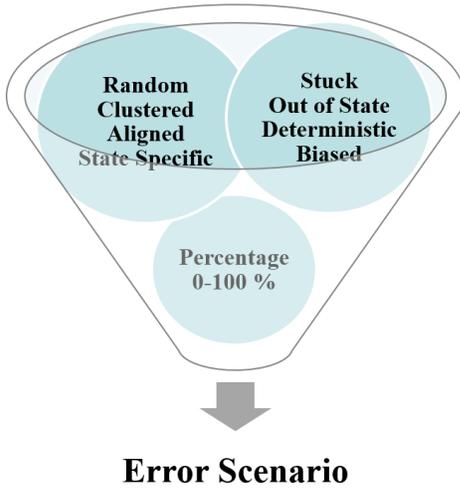

Fig. 9. Error scenario generation process.

Fig. 10. Far field pattern, in dB, of a metasurface steering the beam towards $\theta_r = \phi_r = \pi/4$ with 30% of faulty unit cells with deterministic, clustered characteristics, obtained (a) analytically and (b) through full-wave simulation.

To assess the validity of the analytical model, the far field obtained in a particular case is compared with that of a full-wave simulation performed with CST Microwave Studio [67].

The metasurface contains 15 unit cells per dimension. As shown in Figure 10, the analytical method is in close agreement with the simulation. It is worth noting that while the simulation takes 30–40 minutes in a high-end workstation, the analytical method calculates the results within several seconds.

B. Performance Metrics

Far field analysis can provide valuable, yet mainly qualitative information about the impact of errors. To quantify the performance degradation and extract behavioral trends, the use of a set of performance metrics is suggested.

In this work, we consider the following performance metrics related to beam steering:

- **Target deviation** (TD)**:** The main purpose of beam steering is to reflect the EM wave toward a determined angle. However, there is usually a difference between the targeted angle and the actual reflected angle due to inaccuracies in the phase profile or, in our case, the appearance of errors. We call this factor target deviation and calculate it as the Euclidean distance between the

angle pointing to the direction of the reflected main lobe (θ_a, ϕ_a) and the desired angle for steering (θ_r, ϕ_r) as

$$TD = \sqrt{(\theta_r - \theta_a)^2 + (\phi_r - \phi_a)^2}. \qquad (8)$$

- **Directivity** ($D(\theta, \phi)$)**:** As a fundamental antenna parameter, the directivity describes concentration of energy at a given direction. We evaluate it in specific relevant angles such as the target angle of reflection $D(\theta_r, \phi_r)$ and the actual angle of reflection $D(\theta_a, \phi_a)$ (see Figure 11).
- **Secondary lobe level** (SLL)**:** The SLL is defined as the ratio (in dB) of the far field strength in the direction of the side-lobe nearest to the main beam to the far field strength of the main beam.
- **Side Lobe Accumulation** (SLA)**:** In addition to the secondary beam, a set of minor reflected beams may appear due to the fundamental operation of MS structure. We measure the accumulation of power within these lobes and report it normalized to the power of the main beam.
- **Half power beam width** ($HPBW$)**:** The waist of the main reflected beam defines the resolution of steering. The HPBW, that calculates the beam width at the -3dB

of a normalized lobe, is a conventional factor to assess the beam width.
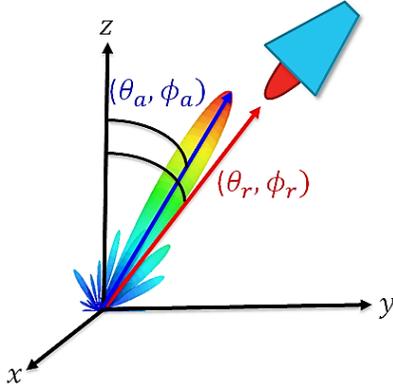

Fig. 11. Discrimination between the target angle (θ_r, ϕ_r) and the actual reflected angle (θ_a, ϕ_a).

VI. RESULTS

This section applies the proposed methodology on a particular case of beam steering metasurface. We take, as the basic building block, the unit cell described in Section III-A with the four states represented in Figure 5.

We consider a metasurface of 15×15 unit cells, coded to target $\theta_r = \phi_r = \pi/4$ from normal incidence, using the methods described in Section III-C. The far field is obtained with equations from Section III-B. Indexing the performance metrics, we get $D(\theta_r, \phi_r) = 0$ dB, $D(\theta_a, \phi_a) = 0$ dB, $TD = 1.5^o$, $HPBW = 14.47^o$, $SLL = -11.43$ dB and $SLA = 11.14$ dB. Note that the directivity values are normalized to the strength at the direction of maximum radiation, which is why we obtain a value of 0 dB.

A. Overview

Figure 12 demonstrates how different types of error and their spatial distribution can have a significantly different impact. The far field is plotted for increasing fault rates for four representative combinations of error type and spatial distributions. It is observed that the metasurface points most of the energy towards the intended direction of $\theta_r = \phi_r = \pi/4$ for relatively low error percentages and starts losing its functionality as the percentage increases.

The differences between the distinct types of errors are clearly distinguishable. For instance, Figure 12(a) shows the far field for the metasurface with stuck-at errors clustered around the center. We can see that increasing the error ratio gives more power to the side lobes and decreases the width of the main lobe. The clustered-biased scenario shown in Figure 12(b), on the other hand, illustrates that biasing errors are less impactful because, in the end, the phase gradient is largely conserved. Similar studies performed for the (independent, out of state) and (independent, deterministic) scenarios, shown in Figures 12(c) and 12(d), respectively, allow to conclude that completely random errors tend to average out and minimize impact, whereas deterministic errors tend to destroy the functionality by increasing the importance of specular reflection,

which becomes the main lobe for more than 30% of error ratio.

Here we set the deterministic error to be s_0, which ends up with a strong secondary lobe at $\theta = 0$ and arbitrary ϕ. This reflection angle is independent of the determined value of the error and we would obtain the same results with any other determined value (s_1, s_2, s_3). This reflection, namely specular, is only characterized by the incident angle. In other words, deterministic errors react as a mirror reflecting the incident wave according to Snell's law ($\theta_i = \theta_r$ and $\phi_i = \phi_r$) irrespective to the erroneous value, as long as it is the same in all erroneous unit cells. In our case (normal incident of plane wave), where we put $\theta_i = 0$ and arbitrary ϕ_i, we obtain $\theta_r = 0$ and arbitrary $\theta_r = 0$.

The next sections complement this qualitative analysis with the evaluation of performance metrics for different combinations of type of error and spatial distribution. For the sake of brevity, we consider the combinations outlined in Table I. The rest of the possible combinations have been evaluated, but are not shown due to their behavioral similarity with the combinations from Table I.

TABLE I
ERROR SCENARIO ACRONYMS.

Error scenario	acronym
Clustered-Stuck	CS
Clustered-Out of State	CO
Clustered-Deterministic	CD
Clustered-Biased	CB
Independent-Stuck	IS
Independent-Out of State	IO
Independent-Deterministic	ID
Independent-Biased	IB

B. Directivity

Figure 13 illustrates the impact of the different types of errors by plotting the Directivity at the desired reflection angle $D(\theta_r, \phi_r)$ over the error percentage. As expected, the most detrimental type of error is deterministic because all wrong values are mapped to the same phase, which has a more detrimental effect in the beam steering case due to its phase-gradient requirements. This reasoning also implies that different types of errors may have a completely different impact on metasurfaces implementing different functionalities: for instance, absorbers may set the same value to all unit cells and, therefore, deterministic errors may not reduce performance vitally. Assuming a 3 dB threshold as the acceptable performance degradation, we observe that CD is the most degrading option as error rates beyond 20% cannot be tolerated, while Out of state and Biased errors (IO, IB, CO and CB) guarantee good performance beyond 40% of erroneous cells.

The story is different for the directivity at the direction of maximum radiation, $D(\theta_a, \phi_a)$, as shown in Figure 14. In this case, the curves of $D(\theta_a, \phi_a)$ corresponding to deterministic errors with fault rates beyond 33% start to increase regardless of their spatial distribution. The reason for this behavior underlies behind the fact that deterministic errors posses the same reflection phase and, by the accumulation of many of these errors, a secondary beam starts to grow. The 33% error figure represents the inflection point where the secondary lobe

Fig. 12. Qualitative analysis of performance degradation of a beam steering metasurface for different error scenarios.

becomes the main lobe. This is illustrated in Figure 15 for the independent-deterministic combination of errors, revealing how the secondary lobe emerges at $\theta = 0$ and becomes the main beam.

C. Target Deviation

In this part, we want to emphasize the importance of the differences between the desired and actual position of the main beam. Figure 16 shows the accuracy of the beam steering metasurface versus different error scenarios. As mentioned

above, deterministic errors may make the main beam shift from the target direction to specular reflection. This is the main cause of the jump observed at 33% for TD. Beside CS that forces the main beam to deviate, other kinds of errors are not affecting TD considerably. In fact, TD takes values below 2 degrees, which is acceptable for most applications. This suggests that loss of directivity or increase of side lobe may be more critical in the present scenario.
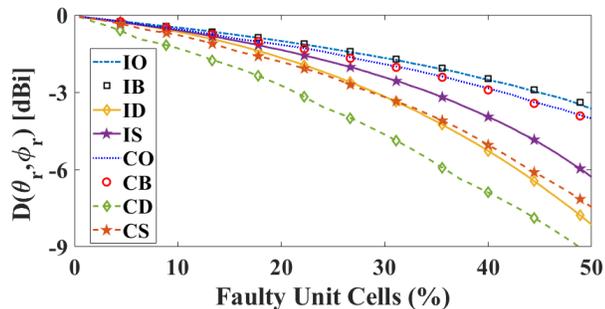

Fig. 13. Directivity on target direction $D(\theta_r, \phi_r)$ of the beam steering metasurface as a function of the error percentage for different error types and spatial distribution.
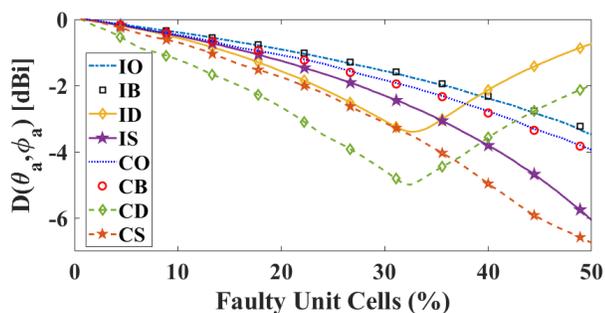

Fig. 14. Directivity on the direction of maximum reflection $D(\theta_a, \phi_a)$ of the beam steering metasurface as a function of the error percentage for different error types and spatial distribution.
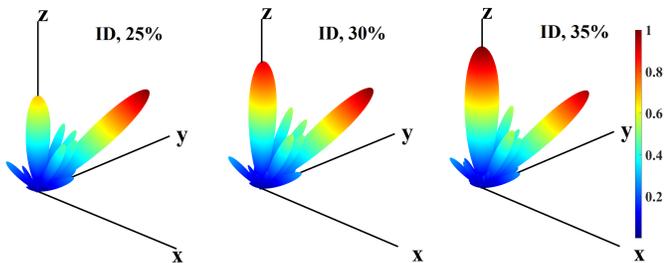

Fig. 15. The normalized radiation pattern for ID errors as an example of an emerging secondary lobe in the wrong direction. The color bar is common to all figures.
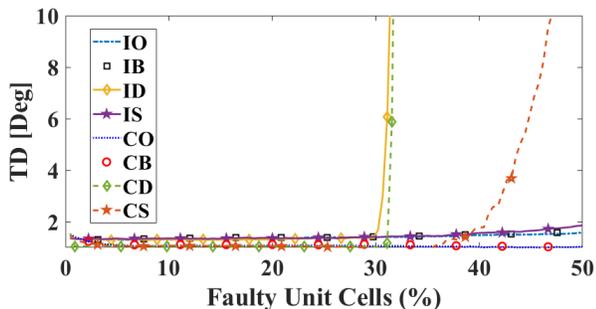

Fig. 16. Deviation from the target versus the percentage of the faulty unit cells for different error types and spatial distribution.

D. Half-Power Beamwidth

From Figure 17 it can be inferred that, on one hand, the $HPBW$ is not affected by the IS, IO and IB combinations

of errors. However, their associated types with cluster distributions, CS, CO, and CB smoothly decrease the $HPBW$. We can relate this effect to the consolidated spot of errors leading to a united constructive response. On the other hand, for Deterministic cases (i.e., ID and CD), a jump at 33% is observed due to the deterministic values of errors. At this turning point, anomalous reflection (i.e. the desired behaviour) is very weak, while specular reflection (emerged from deterministic errors) is strong enough to take over as the main beam. This is the reason for the jumps for $HPBW$ in Figure 17. In other words, before 33% we have the $HPBW$ of anomalous reflection and after that of specular reflection.
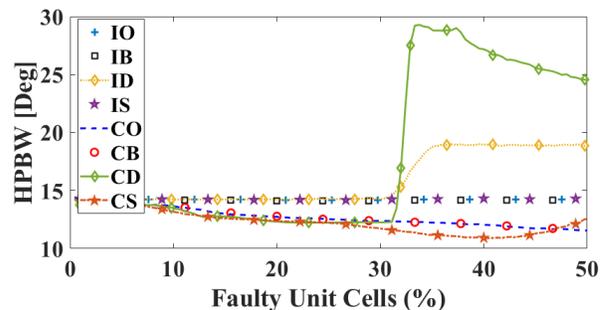

Fig. 17. Half power beam width versus the percentage of the faulty unit cells for different error types and spatial distribution.

E. Side-Lobe Level

Figure 18 illustrates the performance degradation in terms of side lobe level. It is quickly observed that SLL is the most sensitive performance metric so far.

Fundamentally, SLL grows proportionally to the ratio of errors for all kinds. Among the monotonically increasing cases, clustered distributions seem to have a higher impact in this metric, whereas independent and out of state errors are the least relevant. Since random coding [51] leads to random scattering, we argue that uncorrelated random errors generate scattering that does not accumulate as a large secondary lobe. On the other hand, clustered and deterministic errors, which tend to group unit cells together and to apply a uniform state, lead to large secondary lobes.

Deterministic errors lead to a characteristic behaviour that we elucidated with several simulations at specific points for CD and ID. The dip appearing between 29% and 37% is due to the fact that a secondary lobe starts to disappear while another minor lobe begins to rise. At 32%, this minor lobe takes the place of secondary lobe then at 37% main and secondary beams are exchanging their roles and SLL starts to decline once again.

F. Side-Lobe Accumulated Energy

SLL cannot accurately describe the distribution of energy around the main lobe, so we evaluate the SLA metric in Figure 19 to consider the impact of all the minor lobes. This figure demonstrates that, as expected, increasing fault rates reduce the power at the main beam and distribute it around a set of side-lobes. The main lobe is debilitated very similarly for
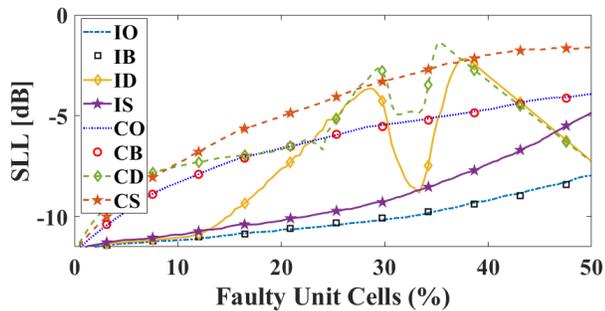

Fig. 18. Secondary lobe level versus the percentage of the faulty unit cells for different error types and spatial distribution.

all error combinations. Likewise, deterministic errors exhibit abnormal behaviour for SLA showing a dip between [29%-32%] and decline after 37%. The reason being of such trend is similar to that discussed in Section VI-E.
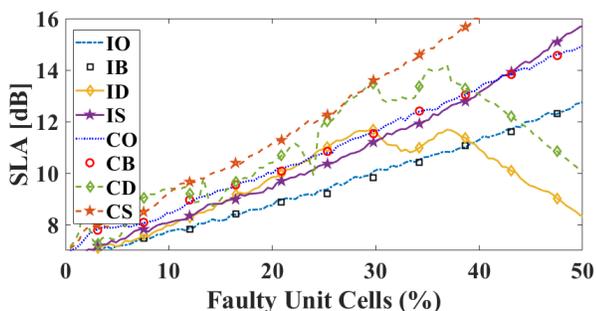

Fig. 19. Accumulated energy of the side lobes versus percentage of the faulty unit cells for different error types and spatial distribution.

VII. CONCLUSION

We have proposed an error model and a methodology for error analysis in metasurfaces. Beam steering metasurfaces, where the functionality depends on the phase gradient, are robust against spatially uncorrelated errors with random values and to attacks that only bias the state of the unit cells. On the contrary, clustered errors that set all the unit cells to the same state are very detrimental. These results show the value of the error analysis and suggest that the error model is comprehensive enough to cover all possible cases. Future works will further analyze the impact of errors in metasurfaces with different sizes or functionalities, to then derive useful design guidelines and power-gating directives.

Julius Georgiou (IEEE M98-SM08) is an Associate Professor at the University of Cyprus. He received his M.Eng degree in Electrical and Electronic Engineering and Ph.D. degree from Imperial College London in 1998 and 2003, respectively. For two years he worked as Head of Micropower Design in a technology start-up company, Toumaz Technology. In 2004, he joined the Johns Hopkins University as a Postdoctoral Fellow, before becoming a faculty member at the University of Cyprus in 2005, to date. Prof. Georgiou is a member of the IEEE Circuits and Systems Society, is the Chair of the IEEE Biomedical and Life Science Circuits and Systems (BioCAS) Technical Committee, as well as a member of the IEEE Circuits and Systems Society Analog Signal Processing Technical Committee. He served as the General Chair of the 2010 IEEE Biomedical Circuits and Systems Conference and is the Action Chair of the EU COST Action ICT-1401 on Memristors-Devices, Models, Circuits, Systems and Applications - MemoCIS. Prof. Georgiou has been selected as an IEEE Circuits and Systems Society Distinguished Lecturer for 2016-2017. He is also an Associate Editor of the IEEE Transactions on Biomedical Circuits and Systems and Associate Editor of the Frontiers in Neuromorphic Engineering Journal. He is a recipient of a best paper award at the IEEE ISCAS 2011 International Symposium and a best Paper awarded at the IEEE BioDevices 2008 Conference. In 2016, he received the 2015 ONE Award from the President of the Republic of Cyprus for his research accomplishments related to the development of an Infrared Fluorescence-Based Cancer Screening Capsule for the Small Intestine. His research interests include Low-power analog and digital ASICs, implantable biomedical devices, bioinspired electronic systems, electronics for space, brain-computer-interfaces (BCIs), memristive devices, electronics for adaptive metamaterials, inertial and optical sensors and related systems.

Hamidreza Taghvaee received the M.Sc. in Telecommunication Engineering majored in Field&Wave from K. N. Toosi University of Technology, Tehran, Iran, in 2016. He was an optical engineer in transmission department of Huawei leading field service engineers for network development. In 2018 he started a PhD degree at Universitat Politècnica de Catalunya (UPC), where he joined the NaNoNetworking Center in Catalunya being researcher in the VISORSURF FET-OPEN project. Currently, he is a visiting researcher at Aalto University where he conducts multidisciplinary research in programmable metasurfaces. His main research interests includes Electromagnetic, Metamaterial and Antenna.

Sergi Abadal received the PhD in Computer Architecture from the Department of Computer Architecture, Universitat Politècnica de Catalunya (UPC), Barcelona, Spain, in July 2016. Previously, he had obtained the M.Sc. in Information and Communication Technologies (MINT) and the B.Sc. in Telecommunication Engineering from the Telecommunication Engineering School (Telecom BCN), UPC, Barcelona, Spain, in 2011 and 2010, respectively. He has held several visiting positions in Georgia Tech in 2009, University of Illinois Urbana-Champaign in 2015 and 2016, and the Foundation of Research and Technology Hellas in 2018. Currently, he is coordinator of the WIPLASH FET-OPEN project and Area Editor of the Nano Communication Networks (Elsevier) Journal, where he was named Editor of the Year 2019. Abadal has also served as TPC member of more than 10 conferences and organized 3 special sessions, and published over 60 articles in top-tier journals and conferences. Abadal was the recipient of the Nano Communication Networks Young Researcher Award in 2019, INTEL Doctoral Fellowship in 2013, Accenture Award for M.Sc. students in 2012 and Vodafone Fellowship for outgoing B.Sc students in 2010. His current research interests are in the areas of chip-scale wireless communications, including channel modeling and protocol design, the application of these techniques for the creation next-generation wireless networks for on-chip or within metamaterial networks, and their implications at the architecture/system design level.

Albert Cabellos-Aparicio received a MSc (2005) and PhD (2008) degree in Computer Science Engineering from the Technical University of Catalonia (www.upc.edu). In september 2005 he became an assistant professor of the Computer Architecture Department and as a researcher in the Broadband Communications Group (http://cba.upc.edu/). In 2010 he joined the NaNoNetworking Center in Catalunya (http://www.n3cat.upc.edu) where he is the Scientific Director. He is an editor of the Elsevier Journal on Nano Computer Network and founder of the ACM NANOCOM conference, the IEEE MONACOM workshop and the N3Summit. He has also founded the LISPmob open-source initiative (http://lispmob.org) along with Cisco. He has been a visiting researcher at Cisco Systems and Agilent Technologies and a visiting professor at the Royal Institute of Technology (KTH) and the Massachusetts Institute of Technology (MIT). He has given more than 10 invited talks (MIT, Cisco, INTEL, MIET, Northeastern Univ. etc.) and co-authored more than 40 journal and 100 conference papers. His main research interests are future architectures for the Internet and nano-scale communications.
