**ANALYSIS OF THE DATA  
FROM DECEMBER 1990 TO JULY 1991**

D. Drijard, M. Ferro-Luzzi, N. Hamann, R. Jones, B. Mouëllic, J-M. Perreau, S. Ohlsson  
with the participation of M. Lo Vetere (Genova)

## 1. INTRODUCTION

This is essentially a collection of figures with little or no text. It represents the preliminary results of the analysis of data taken from the beginning of the experiment up to and including the July 1991 run. None of the results presented here should be taken as definitive. The procedure followed to obtain them is in a state of evolution and it may well be that in a few weeks the results will look different. All the same, we think it is useful to present in a coherent form what we have obtained up to now even if the results may be ephemeral. In the spirit of keeping the Collaboration informed we plan a regular updating of this report with the amended results in their latest form.

As for the present conclusions we notice that among the "4-forward" events (referred to in the following as **4F**) there is clear production of  $\phi\phi$  albeit with an unexplained erratic behaviour as a function of momentum. This is not the case for the "1-barrel 3-forward" events (referred to in the following as **1B3F**) where the evidence for  $\phi\phi$  production is much flimsier and the background<sup>1</sup> much heavier. We do not understand this difference and attribute it to either a possible misalignment of the barrel-forward detectors or an uncorrect calibration of the z-coordinate of the barrel straws. Even worse, it could be due to an inadequacy of our track reconstruction method as applied to the barrel.

An intriguing side observation allowed by the large statistics available when all the runs are put together is that within the  $\phi\phi$  region the events seem to be clustered along separate  $\phi$  lines rather than around a single central point. We believe that this is a clue for some as yet undetected anomaly in either the fitting procedure or the accelerator beam-momentum setting.

Notice that at this stage we are still far from being able to put forward even tentative values of the cross sections. Not only are we still missing a reliable calculation of the detector acceptance and the analysis efficiency but we also lack the normalisation to the data taken and to the luminosity. It is hoped that in later editions of this report we will be able to answer the above points.

This report is composed of : (a) plots of mass distributions, (b) tables of event numbers and related information, (c) program listings.

---

<sup>1</sup> By background here we do not necessarily mean physics background but rather a mixture of wrong tracks, wrong angles, wrong event types, all this resulting from detector accidentals and any other conceivable source of pollution which we may have failed to filter out.

## 2. ANALYSIS

The analysis has followed the three stages illustrated in figure 1. The original raw data were “reduced” in the first stage by applying basic cuts to eliminate events other than the “4K triggers”. The latter were retained only when the data were compatible with a reconstructable event, in particular if there was a number of detector-hits sufficient to eventually allow track-fitting and if the pipe-scintillators configuration was compatible with momentum balance<sup>2</sup>. Notice that this first stage was the only part of the analysis to be done on the central computers at CERN. All the rest was performed on our *Macintosh* farm after converting the cartridge data unto 8-mm cassettes readable via Exabyte units connected to the *Macintosh*.

The second stage consisted in repeating the momentum balance test — more strictly this time — and in performing a systematical track-fitting operation with all the possible straw hits as long as the event had a number of hits compatible with a suitably determined upper and lower limit. At the conclusion of this procedure we ended up with a certain number of “projected tracks” (separate xz and yz projections). If this number was such as to provide the sufficient and necessary components for the “space tracks” then all possible matching associations were attempted using the pipe scintillators and the forward pixels in the association criterium. If the number of space tracks thus obtained was the required four (all in the forward direction for the **4F** configuration or three forward and one in the barrel for the **1B3F** configuration) the event was accepted. Matching ambiguities were tolerated up to a maximum of 10. The event was then passed on to the “kinematical reconstruction” procedure and retained when this succeeded. The average computing time of this stage was typically 100 ms per event (on the *Macintosh-fx*). The accepted events of this stage were collected in separate files for further treatment.

The third stage consisted of analysing the above selected events applying stricter criteria concerning track-fitting and kinematical reconstruction and verifying the direction and momentum attribution of the tracks with the signals from the external detectors. Each track was thus examined for agreement with the measurements of the Cherenkov and Silicon counters. A rudimentary energy-loss calculation was also performed and the tracks were required to have enough energy to reach the outer part of the detector. Typical computing time of this stage was 250 ms per event (on the *Macintosh-fx*). Section 3 describes the rejection criteria in some detail.

Table 1 gives the number of events per momentum setting obtained during the various analysis steps.

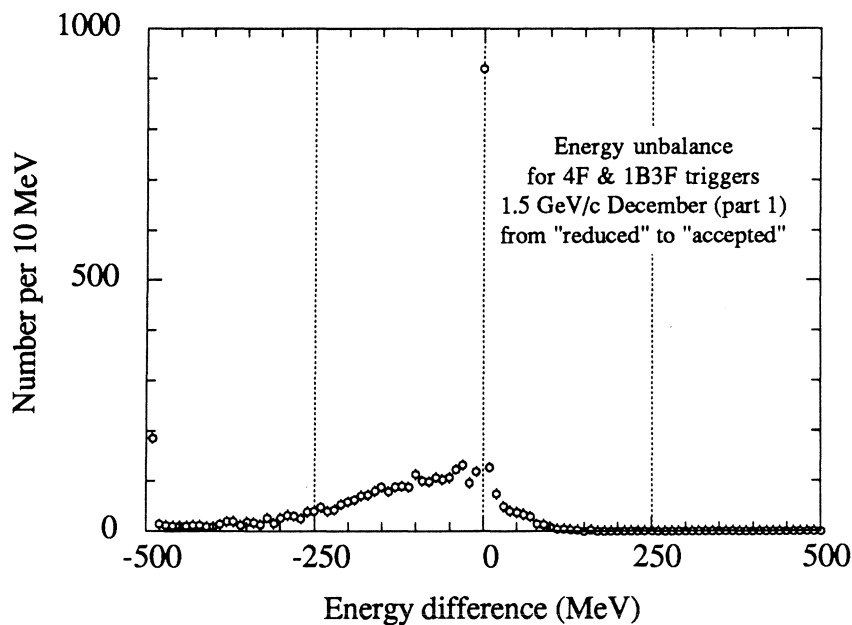

---

<sup>2</sup> For more details better ask Maurizio.

### 3. REJECTION

A few definitions are in order. The kinematical quantity  $\Delta E$  (*deltaE* in the tables) is the energy unbalance of the kinematical reconstruction. For negative values of  $\Delta E$  we only have a single solution to the momentum-energy equations. Notice that no event has been retained having  $\Delta E$  below - 100 MeV, so when we talk about "uncut data" we have actually cut something.... For positive values of  $\Delta E$  up to 20 MeV we have systematically adopted one solution (the average of the two possible solutions). Beyond 20 MeV there will be one or two solutions depending on the event configuration.

Some of us are uneasy about the  $\Delta E$  distribution particularly about the arbitrariness of the above cuts. Lacking for the moment any better argument we present the spectra observed for this quantity during the first two stages of the analysis. The peak at  $\Delta E = 0$  corresponds to those events where only one solution was available (the other solution being unphysical); these events contribute in reality to the right hand side of the spectra. How they are distributed will be answered in a future installment.

During "stage 1" of the analysis.

During "stage 2" of the analysis.

In the tables we have referred to the **4F** events and **1B3F** events as  $conf = 1$  and 2 respectively. The serial number of the solution accepted for the kinematical equations is listed under *sol*. Of the many possible track sets provided by the track-matching procedure we have accepted no more than two: they are listed under *set* = 1 or 2.

Triggers of the **4F** type were rejected if the Gamma-Veto barrel (**GVB**) or the Julich-straight barrel (**JSB**) had one or more hits with  $ADC \geq 200$ . For the **1B3F** triggers the condition for rejection was raised to two or more hits in the **JSB** or **GVB** with  $ADC \geq 200$ .

Only two sets of tracks (out of a maximum of 10 fabricated by the track-fitting and matching procedure) were considered in this analysis. A chi-squared test was applied to accept the set, the maximum allowed chi-squared being chosen to be 100 on the basis of the observed distribution (tail extending more or less uniformly up to this value). The value of the chi-squared was defined from the agreement of the tracks with the pipe-scintillators and the pixels. Only azimuthal differences were used for the pipe-scintillators; both azimuthal and polar differences were used when comparing tracks and pixels. Individual pixels were used for this test (the procedure is presently being modified to deal with "pixel clusters"). The condition for accepting the second set was that its probability be not smaller than a factor 10 with respect to that of the first set.

Notice that no test was performed to insure that the two sets were in fact distinct, so it may well be that we have been accepting degenerate sets. This problem is now being dealt with, but be warned that the results of this report may contain a (small) sample of such duplicates.

Each track was checked for consistency with the requirements of the trigger type. Thus we rejected tracks in the **4F** configuration if they turned out to have polar angles outside the  $15^\circ - 45^\circ$  region. For the **1B3F** configuration the limits for the "barrel track" were taken to be  $45^\circ - 70^\circ$ . An additional test was performed on the latter trigger to ascertain that none of the "forward tracks" was uncomfortably close to the "barrel track"; if both the azimuth and the polar angle of the "barrel track" were within  $15^\circ$  of the direction of any forward track the event was rejected.

The kinematical reconstruction was performed according to the procedure outlined in an earlier note by JMP<sup>3</sup>. The difference in energy to satisfy the momentum-energy constraints ( $\Delta E$ ) was calculated in each case and used as a basis both to accept or reject the event and to derive its kinematics. As already mentioned we have retained only events with  $\Delta E$  above -100 MeV and have used for the kinematics one or two solutions depending on  $\Delta E$  being respectively below or above an arbitrarily fixed upper limit of 20 MeV (notice that not all the  $\Delta E \geq 0$  cases have a physical second solution).

The momentum of each track was used to calculate the expected signal in the Forward Cherenkovs (no attempt has yet been made to use the Barrel Cherenkovs). The relationship between track momentum and Cherenkov ADC channel has been concocted on the basis of (a) the theoretical beta dependence of the Cherenkov emission, (b) the experimental angular dependence observed in beam tests and (c) the signal conversion into ADC channels obtained from the LED calibration. All this boils down to the following empirical (and possibly wrong) formula :

$$S_{\text{expected}} = S_{\text{max}} \frac{1 - \left(\frac{\beta_{\text{threshold}}}{\beta}\right)^2}{\left(1 - \beta_{\text{threshold}}^2\right) \cos \theta} (1.822 - 0.087x + 0.003x^2)$$

where  $x$  is the distance of the impact point measured from the interface where light-guide ends and radiator begins

$$x = 52.2 - 53.6 \tan \theta$$

and  $S_{\text{max}} = 300$  ADC channels is our estimate of the  $\beta = 1$  response of the Cherenkov signal at normal incidence.

---

<sup>3</sup> J.-M. Perreau : "Reconstruction of 4K events The special property of this kinematical analysis demonstrated". 17/1/1989. Private note, ask the author.

The comparison between expected and measured values was introduced in a chi-squared calculation with an experimental variance of 400 (ADC channels squared). The number of tracks entering this calculation was taken into account when going from chi-squared to probability. The event was accepted when its probability was  $\geq 1\%$ .

While applying the above tests the impact position of the track on the counter (x in the above formulae) was used to decide if the test should or should not be done. If x was outside the sensitive counter region (such as on the light-guide or altogether outside the counter) the test was not performed.

A decay probability was also performed at this stage. The event was rejected if the lifetime of any track turned out to be smaller than that required to reach in one piece the counter itself. The rejection level was taken at 3 decay lengths.

The trajectory of each track was followed from target to Cherenkov and a rough estimate was made of its energy loss. The event was discarded if the track stopped before reaching the counter. The calculation is a straightforward repetition of what was described (and listed) in an earlier note<sup>4</sup>.

The agreement between track momenta and values of  $dE/dx$  measured by the silicon counters was performed using the following empirical prescription for the expected signal :

$$S_{\text{expected}} = \frac{17.0}{\beta^2}$$

As "measured value" of  $dE/dx$  we have taken the smallest of the two readings along the track (from the two silicon planes). When only one was available we have ignored the measurement. The measured value was used for a track-by-track calculation of the chi-squared to obtain an overall probability for the event to be in agreement with the 4K hypothesis. The variance employed here for the measured quantities was 100 (ADC channels squared). The event was rejected if the probability turned out to be  $\leq 1\%$ .

## 4. RESULTS

### 4.1 Separate momenta

Plots and tables are given in the same order for each momentum setting:

The first page shows plots referring to the **4F** events; (a) effective-mass plot with no cut on  $\Delta E$  (beside the general cut on  $\Delta E \geq -100$  MeV); (b) same with a cut on negative values of  $\Delta E$  (rejecting all events with  $\Delta E \leq -20$  MeV); this cut seems to eliminate some background, as witnessed by the cleaner appearance of the gap around the  $\phi\phi$  region; (c) same but specifically for the  $\phi\phi$  region; (d) cosine of the c.m. angle of the events in (c).

This is followed by a table of the  $\phi\phi$  events from (c) above listing their run and event number in addition to mass values, cosine of the cm angle and other information. When there is an ambiguity in the run number attribution (we forgot to record it during the analysis and had to look for it afterwards..) we have listed the alternative number under “run?”.

The third page contains only one plot (e) showing the mass-squared version of the events (without  $\Delta E$  cuts). This is provided because some of us feel more comfortable staring at this type of plot. Notice that, in view of the unfortunate fact of life that the  $\phi$  mass is close to 1 and the extreme mass values are not much further than 1.3, there is little visual difference between the two kinds of plot.

The fourth page refers to the **1B3F** events and contains two mass plots — (f) and (g) — without and with  $\Delta E$  cuts respectively.

Following these we give — more for estetic reasons then else — some Lego plots, each of them clearly labelled as to its content. The same **4F** data appear in two different stereo projections. They all refer to uncut  $\Delta E$  data (beside the -100 MeV general cut).

The last page lists a table of entries in each bin of the Lego plot (only for the **4F** events). Bins are  $20 \times 20$  MeV<sup>2</sup>. This table may be useful when estimating the number of events we are dealing with.

Yes, we have noticed that there is a surprising prominent enhancement in the mass region near 1.25 GeV where nothing known is expected to show up. Alas, rather than a new resonance we find that this enhancement is a reflection of the  $\phi\phi$  peak; on the other hand we don't understand why it should be so concentrated on a narrow region and not spread out more evenly over the much wider available reflection area.

### 4.2 All momenta together

The temptation of putting together all these data was irresistible. So here we present a series of plots (same data in all plots but different scales) showing the superposition of the **4F** data from all incident momenta. We didn't think it was worth presenting the same thing for the **1B3F** data. Legends on the plots are self-explanatory.

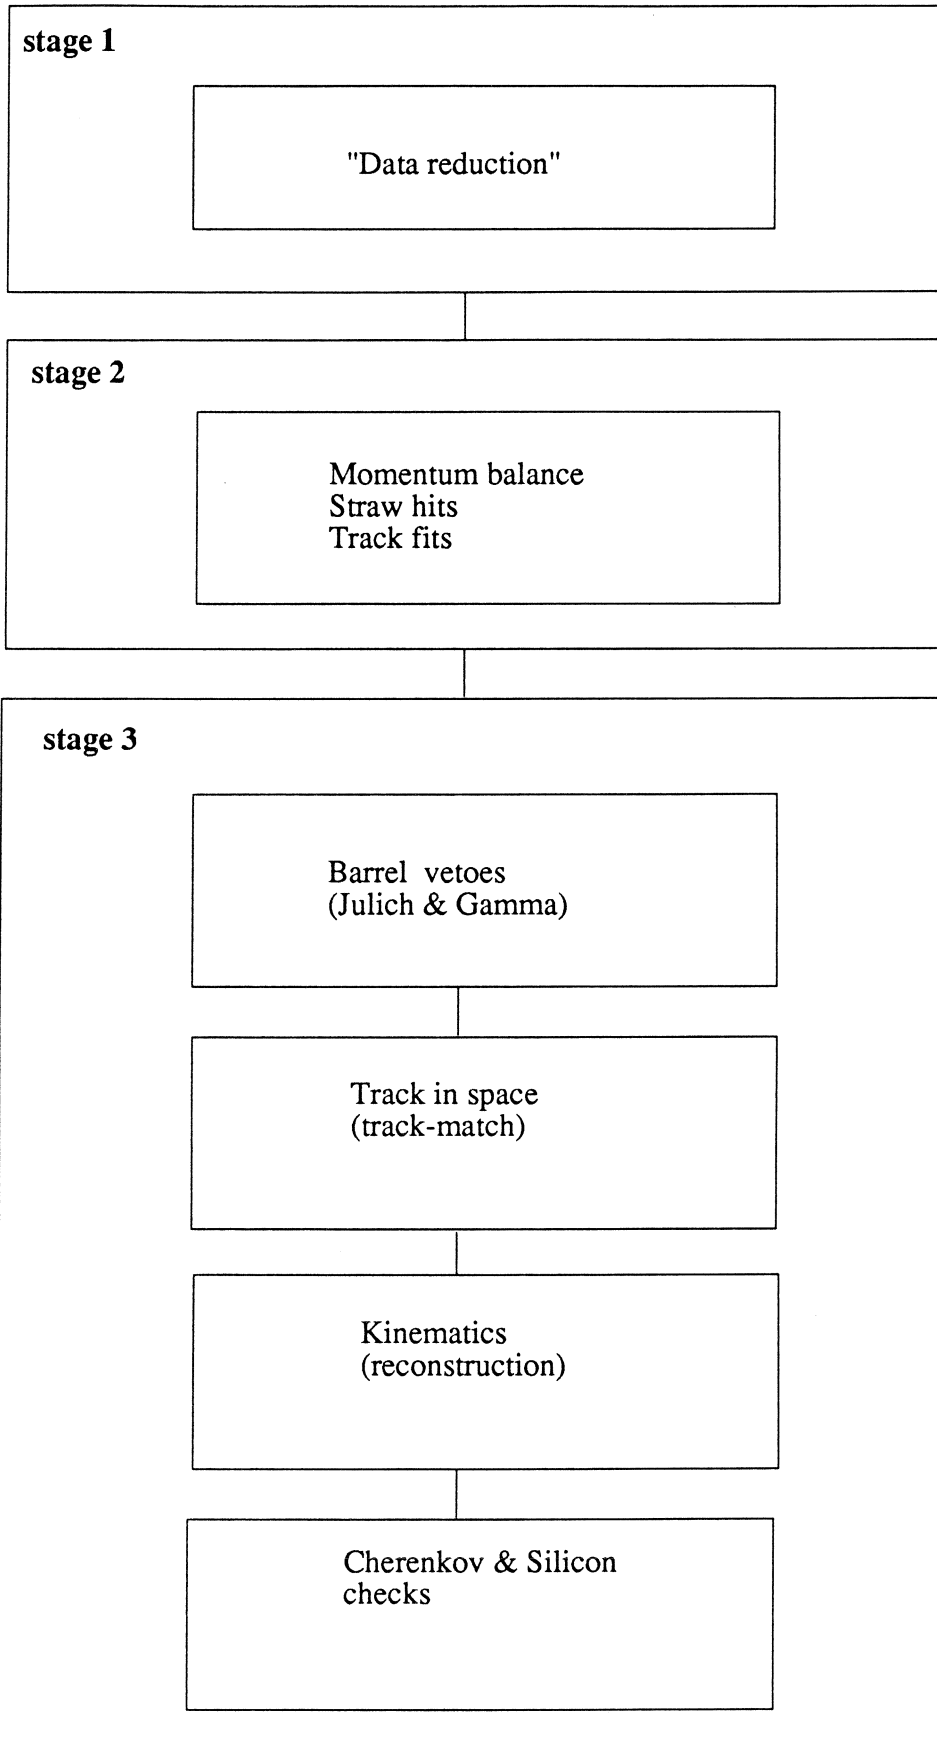

Notice the curious agglomeration of points along fixed  $\phi$  lines not stretching along the full plot. We don't understand what this is trying to tell us: a displacement between assumed and real momentum setting ? a systematic angular shift between reconstructed tracks ? a physical effect ? a trivial mistake ? Your guess is welcome.

## 5. PROGRAM LISTINGS

For those of you who may prefer the real thing to the cursory description offered above we have prepared an appendix containing the full listing of the FORTRAN programs used for the analysis. This is not joined to this report because of its unmanageable bulk, but available under request. Also under request we are ready to provide the same in executable form together with the necessary framework (MacSys, data tapes, etc.).

The main analysis steps can be found in the *USER* subroutines (*Mass4K*, *Usersub1* and *Usersub2* with their common *UserCDE*), while the projection and space track-fitting and reconstructing routines are in *StrawFit*, *Match* and *Kine* respectively. The general common is in *CDE1*. The other routines deal with general purpose chores such as event reading and decoding (*InOut*), calorimeter and silicon decoding (*CaloDec*), main steering (*JetSet*), straw reading and decoding (*StrawDec*), vertex fitting (*Vertex*). Parts such as *Draw* and *DiaMenu* have more to do with the "display" features of the program than with the analysis but are given anyway. Various constants and utilities defining the run momentum, detector calibration etc. are contained in the sections labelled *Util*, *Const* and *JetTitles*.
