Preface

Welcome to the 12th International Conference on “Recent Advances in Natural Language Processing” (RANLP 2019) in Varna, Bulgaria, 2-4 September 2019. The main objective of the conference is to give researchers the opportunity to present new results in Natural Language Processing (NLP) based on modern theories and methodologies.

The Conference is preceded by the First Summer school on Deep Learning in NLP (29-30 August 2019) and two days of tutorials (31 August – 1 September 2019).

The Summer School lectures are given by Kyunghyun Cho (New York University), Marek Rei (University of Cambridge), Tim Rocktäschel (University College London) and Hinrich Schütze (Ludwig Maximilian University, Munich). Training in practical sessions is provided by Heike Adel (University of Stuttgart), Alexander Popov (Institute of Information and Communication Technologies, Bulgarian Academy of Sciences), Omid Rohanian and Shiva Taslimipoor (University of Wolverhampton).

Tutorials are given by the following lecturers: Preslav Nakov (Qatar Computing Research Institute, HBKU), Valia Kordoni (Humboldt University, Berlin), Antonio Miceli Barone (University of Edinburgh) and Sheila Castilho (Dublin City University), Vlad Niculae and Tsvetomila Mihaylova (Institute of Telecommunications, Lisbon).

The conference keynote speakers are:

- Kyunghyun Cho (New York University),
- Ken Church (Baidu),
- Preslav Nakov (Qatar Computing Research Institute, HBKU),
- Sebastian Padó (Stuttgart University),
- Hinrich Schütze (Ludwig Maximilian University, Munich).

This year 18 regular papers, 37 short papers, 95 posters, and 7 demos have been accepted for presentation at the conference. The proceedings cover a wide variety of NLP topics, including but not limited to: deep learning; machine translation; opinion mining and sentiment analysis; semantics and discourse; named entity recognition; coreference resolution; corpus annotation; parsing and morphology; text summarisation and simplification; event extraction; fact checking and rumour analysis; NLP for healthcare; and NLP for social media.

In 2019 RANLP hosts four post-conference workshops on influential NLP topics: the 2nd Workshop on Human-Informed Translation and Interpreting Technology (HiT-IT 2019), the 12th Workshop on Building and Using Comparable Corpora (BUCC), the Multiling 2019 Workshop: Summarization Across Languages, Genres and Sources as well as an Workshop on Language Technology for Digital Historical Archives with a Special Focus on Central-, (South-)Eastern Europe, Middle East and North Africa.

We would like to thank all members of the Programme Committee and all additional reviewers. Together they have ensured that the best papers were included in the Proceedings and have provided invaluable comments for the authors.

Finally, special thanks go to the University of Wolverhampton, the Institute of Information and Communication Technologies at the Bulgarian Academy of Sciences, the Bulgarian National Science Fund, Ontotext and IRIS.AI for their generous support of RANLP.

Welcome to Varna and we hope that you enjoy the conference!

The RANLP 2019 Organisers

The International Conference RANLP–2019 is organised by:

Research Group in Computational Linguistics,
University of Wolverhampton, UK

Linguistic Modelling and Knowledge Processing Department,
Institute of Information and Communication Technologies,
Bulgarian Academy of Sciences, Bulgaria

RANLP–2019 is partially supported by:

National Scientific Fund, Ministry of Education and Science, Bulgaria

Ontotext AD

IRIS.AI

Programme Committee Chair:

Ruslan Mitkov, University of Wolverhampton, UK

Organising Committee Chair:

Galia Angelova, Bulgarian Academy of Sciences, Bulgaria

Workshop Coordinator:

Kiril Simov, Bulgarian Academy of Sciences, Bulgaria

Tutorial Coordinator:

Preslav Nakov, Qatar Computing Research Institute, HBKU, Qatar

Proceedings Printing:

Nikolai Nikolov, INCOMA Ltd., Shoumen, Bulgaria

Programme Committee Coordinators:

Ivelina Nikolova, Bulgarian Academy of Sciences
Irina Temnikova, Bulgarian Academy of Sciences

Programme Committee:

Ahmed Abdelali (Hamad Bin Khalifa University, Qatar)
Cengiz Acarturk (Middle East Technical University, Turkey)
Guadalupe Aguado-de-Cea (Polytechnic University of Madrid, Spain)
Luis Alfonso Ureña López (University of Jaén, Spain)
Hassina Aliane (Research Center on Scientific and Technical Information, Algeria)
Pascal Amsili (University of Paris Diderot, France)
Galia Angelova (Bulgarian Academy of Sciences, Bulgaria)
Riza Batista-Navarro (University of Manchester, United Kingdom)
Kalina Bontcheva (University of Sheffield, United Kingdom)
Svetla Boytcheva (Bulgarian Academy of Sciences, Bulgaria)
António Branco (University of Lisbon, Portugal)
Chris Brew (Digital Operatives)
Nicoletta Calzolari (Italian National Research Council, Italy)
Sheila Castilho (Dublin City University, Ireland)
Key-Sun Choi (Korea Advanced Institute of Science and Technology, South Korea)
Kenneth Church (Baidu, United States of America)
Kevin Cohen (University of Colorado School of Medicine, United States of America)
Gloria Corpas Pastor (University of Málaga, Spain)
Dan Cristea (University of Lași, Romania)
Antonio Ferrández Rodríguez (University of Alicante, Spain)
Fumiyo Fukumoto (University of Yamanashi, Japan)
Prószéky Gábor (Pázmány Péter Catholic University & Bionics, Hungary)
Alexander Gelbukh (National Polytechnic Institute, Mexico)
Yota Georgakopoulou (Athena Consultancy, Greece)
Ralph Grishman (New York University, United States of America)
Veronique Hoste (Ghent University, Belgium)
Diana Inkpen (University of Ottawa, Canada)
Hitoshi Isahara (Toyohashi University of Technology, Japan)
Miloš Jakubíček (Lexical Computing Ltd)
Alma Kharrat (Microsoft)
Udo Kruschwitz (University of Essex, United Kingdom)
Sandra Kübler (Indiana University, United States of America)
Katia Lida Kermanidis (Ionian University, Greece)
Natalia Loukachevitch (Lomonosov Moscow State University, Russia)
Eid Mohamed (Doha Institute for Graduate Studies, Qatar)
Emad Mohamed (University of Wolverhampton, United Kingdom)
Johanna Monti (University of Naples L'Orientale, Italy)
Andrés Montoyo (University of Alicante, Spain)
Alessandro Moschitti (Amazon)
Rafael Muñoz Guillena (University of Alicante, Spain)
Preslav Nakov (Qatar Computing Research Institute, Qatar)
Roberto Navigli (Sapienza University of Rome, Italy)
Raheel Nawaz (Manchester Metropolitan University, United Kingdom)
Mark-Jan Nederhof (University of St Andrews, United Kingdom)
Ivelina Nikolova (Bulgarian Academy of Sciences, Bulgaria)
Kemal Oflazer (Carnegie Mellon University, Qatar)
Maciej Ogrodniczuk (Polish Academy of Sciences, Poland)

Constantin Orasan (University of Wolverhampton, United Kingdom)
Petya Osenova (Sofia University and Bulgarian Academy of Sciences, Bulgaria)
Sebastian Padó (Stuttgart University, Germany)
Noa P. Cruz Diaz (Artificial Intelligence Excellence Center, Bankia, Spain)
Liviu P. Dinu (University of Bucharest, Romania)

Abstract

In this paper, we present a relationship extraction based methodology for table structure recognition in PDF documents. The proposed deep learning-based method takes a bottom-up approach to table recognition in PDF documents. We outline the shortcomings of conventional approaches based on heuristics and machine learning-based top-down approaches. In this work, we explain how the task of table structure recognition can be modeled as a cell relationship extraction task and the importance of the bottom-up approach in recognizing the table cells. We use Multilayer Feedforward Neural Network for table structure recognition and compare the results of three feature sets. To gauge the performance of the proposed method, we prepared a training dataset using 250 tables in PDF documents, carefully selecting the table structures that are most commonly found in the documents. Our model achieves an overall accuracy of 97.95% and an F1-Score of 92.62% on the test dataset.

1 Introduction

Usage of digital documents have elevated drastically over the last two decades and a need for automatic information extraction from these documents has increased. Portable Document Format (PDF) has been introduced by Adobe in 1993. PDF documents are the most common format of digital documents and are extensively used in scientific research, finance, enterprises etc. As the production and usage of PDF documents have increased massively, substantial research work has focused on automating the methods for document analysis (Correa and Zander, 2017; Kavasidis et al., 2018).

Tabular data is a powerful way to represent the data, among other elements of a document like charts, images etc. Tables are found in a variety of classes of digital documents and are very useful to readers to capture, search and compare the facts, summarizations and draw conclusions. Automatically extracting the information from the tables and representing the information in more convenient formats for digital consumption add immense value in the field of document understanding (Gilani et al., 2017; Hao et al., 2016).

Tables contain structured data but often are rendered as semi-structured and unstructured on the digital documents for human consumption. Data can be represented using a variety of layouts in tables without losing the meaning of data (Anand et al., 2019). The layout of tables can vary in alignment, line and word spaces, column and row spans, borders and other styling information. Depending on the type of documents and authors, the tables may not contain any border lines and the structure of the tables will still be understandable to readers. The data represented by the tables in itself can have different semantics. For example, in a table, a column may contain a list of prices in dollars, indicating that all the values of that column contain numeric data only. Similar semantic information is embedded in the table rows as well. Further, a column may have multiple subcolumns, making the original column to span multiple table cells horizontally. In rare cases, rows can also span multiple table cells vertically. All these characteristics of a table make the automatic extraction of table information more challenging.

Table extraction is a sub-problem of document understanding, that deals with information extraction and representation of tabular data. Extraction of information from tables in documents has challenged the researchers over the last two decades. An ample amount of research work has been carried out leading to a diverse list of approaches including heuristics, rule-engine, and recently machine learning based proposals.

We believe, generalizing the patterns across the variety of table layouts in diverse type of documents, is best solved by machine learning approach. We propose a bottom-up approach for table structure recognition as a cell relation extraction task between the table text tokens using deep learning. The way a human understands the tables can be analogous to the proposed approach. Often, relation extraction task involves classification of an entity pair to a set of known relations, using documents containing mentions of the entity pair (Kumar, 2017). By considering the table recognition task as a relationship extraction problem, we introduce a novel approach suitable for several document understanding solutions.

The proposed method deals with the basic building blocks of any table, the table cells. With this approach, we hope to solve the column and row spanning, the presence or absence of borders, and other challenges mentioned earlier. The table recognition system operates at token-level and involves learning the complex patterns in order to extract the cell relationships among the table text tokens using deep learning.

2 Related Work

According to the well-known ICDAR 2013 Table Competition (Gbel et al., 2013), the problem of table understanding can be split into table location detection, table structure recognition, and table interpretation. Each of these sub-problems has attracted a great deal of attention from researchers and has extensive work.

A peek at the literature shows that many heuristic solutions have been proposed for table structure recognition. Most of those work consider the white space and layout analysis. Yildiz et al. (2005) propose an algorithm to recognize the columns of a table using distances between lines and then identify the cells to find the rows. The algorithm makes a few assumptions about the structure of the tables. The work of Krüpl and Herzog (2006) takes a bottom-up approach towards structure recognition using heuristics but works on browser-rendered documents. The methodology aggregates words into columns by considering the spatial distance of neighboring words.

Klampfl et al. (2014) experimented with two unsupervised approaches for table recognition and showcased the importance of spatial distances between words of a table using vertical and horizontal histogram projection of words coordinates.

Experiments using rule-engine has been proposed by Shigarov (2015), considers the physical layout of a rendered table, and the logical layout representing the relationships between the elements of a table, differently. Another work of Shigarov et al. (2016) shows promising results in recognizing the columns and rows of tables by using the word and line distances, the order of appearance of text chunks. The methodology makes use of configurable thresholds in its heuristic decision making.

The heuristic and rule-based solutions make various assumptions on the visual, type and content, structural details of tables and the thresholds used in the algorithms. These assumptions may not hold on heterogeneous documents and may even break the system.

Perez-Arriaga et al. (2016) have made use of both k-nearest neighbor and layout heuristics, making it a hybrid methodology to recognize the table structure. The method groups the words into rows and columns using spatial distances of words heuristically. Interestingly, the spatial distance thresholds are learned using the k-nearest neighbor algorithm. Their work also proposes a heuristic method to identify the headers of the table. Deep learning based semantic segmentation has been used by Schreiber et al. (2017) where an image of a document is fed to the neural network to identify the rows and columns of a table. However, the work makes use of a heuristic post-processing step to improve the table structure recognition.

Clinchant et al. (2018) have made an extensive comparison of three different Machine Learning approaches to recognize the table structure in hand-written register books. The method first recognizes the cell locations and then groups the cells into rows. The experimentations do a thorough comparison of CRF, a variation of Graph-CN called Edge-CN, and conventional Logistic Regression algorithms. However, the method works on already recognized headers and columns of the table and addresses only row recognition task.

To the best of our knowledge, most of the related work of table recognition try to identify the columns and rows of tables first and then locate the intersections of rows and columns as table cells. A few heuristics based works have considered the grouping of words into blocks and then aggregating blocks into rows and columns. A common downside of these methodologies is that they fail to capture the information about rows and columns spanning multiple table cells. Few of the heuristic approaches do try to solve this issue however, they fail to generalize the solution.

We propose a purely bottom-up approach by building the table structure by recognizing the individual cells of the table and their location in the document. The task of recognizing the table cells is addressed as cell-relation extraction between the tokens present in the table.

3 Methodology

In this section, we first explain how we modeled the table structure recognition as a relation extraction task, then the training data preparation, and finally describe how the binary relationship classification is modeled using a Multilayer Feedforward Neural Network.

3.1 Cell Relationship Extraction in Table Structure Recognition

Humans will recognize the table structure even without a need for borders, based on visual clues, spatial distances and the content of the cells. These visual clues present in the tables help the readers to recognize the location of table cells easily, by bringing all the words of a cell together both visually and semantically. The proposed method is based on this idea of identification of cell relationship among the table words. The first step towards the recognition of rows or columns is the identification of table cells and thus the whole process of table structure recognition is a bottom-up process. This reasoning is based on the underlying definition of any table: Unit of a table is a cell, horizontal and vertical alignment of cells forms rows and columns, respectively. Tokens are generated by using white-space and new-line characters as delimiters. In this paper the terms *token* and *word* are used interchangeably.

Relation extraction is a well-known task in Natural Language Processing, which deals with classifying whether a given set of *n* samples have any of *m* different relationships. For example, in linguistics, determining whether two or more expressions in a text refer to the same person or thing, is a relation extraction task. We take the idea of relation extraction and formulate the task of table structure recognition as identifying the cell-relationship among all the content of individual cells of a table. When the tokens that are part of a table are considered as the smallest possible elements of a table, the relation extraction task will be to identify whether given two tokens of table text, belong to the same cell or not. If two tokens belong to the same cell, then those two tokens have a *belong-to-same-cell* relation. In our experiments, this task of binary relationship extraction is considered as a binary classification problem.

For every pair of tokens, the goal of binary relationship classifier is to determine whether the two tokens belong to the same cell or not. An important thing to note here is that this relationship between the two tokens is transitive. If a token A is related to the token B and the token B is related to the token C, then the token A is related to C. Hence, we don't need to generate feature vectors of all the possible pairs of tokens in a cell to determine all the tokens of a cell, we only need to make sure that all the tokens of a cell are connected via a chain of such transitive dependencies.

Once we predict the *belong-to-same-cell* relation between token pairs, we group all the table tokens into different cells. This is a simple task of aggregating different token pairs into their respective cells. Using this data of all the table cells and the tokens in each of the cells, we can model the recognition of rows and columns of the table again as a relation extraction task between the pairs of table cells themselves. However, in this work, we concentrate only on cell recognition.

3.2 Data Preparation

Detecting Tables and Training Data Generation

The detection of the location of tables in PDF documents is the first task in the process of table extraction and this location information is prerequisite to our system. There are several open source and free of charge tools for detecting table locations in PDF documents. In our experiments, we used *Tabula* to obtain the location details of a table in the document. The location of a table is represented by five values, *pageNum*, *(startX, startY)* and *(endX, endY)*. All the coordinates are assigned

Feature Representation Illustration

Figure 1: Features used in cell-relation extraction. A) T00, T01, T02,... are the tiles in the first row of tile matrix. B) T00, T10, T20,... are the tiles in the first column of tile matrix. C) (x1,y1) and (x2,y2) are the start and end coordinates of a token. D) sameCell=1, Pair of tokens which have sameCell relationship. E) samceCell=0, Pair of tokens which do not have sameCell relationship.

with respect to a Cartesian plane centered at the top-left corner of the document page. We used an off-the-shelf library to get the content in a PDF document inside a given region, that, along with the coordinates of characters *(x,y)*, provides the font style for every character in the document. The characters along with their coordinates and font styles are further aggregated into tokens, by using the white-space and new-line characters as delimiters.

With the help of table location and the location of individual tokens in the document, only those tokens which are within the given table location are collected by comparing their corresponding coordinate values. Specifically, all the tokens, whose *x* coordinate is between *startX* and *endX* and whose *y* coordinate is between *startY* and *endY* are collected as table text tokens.

After collecting all the tokens from table text using the table coordinates, we generate the training data for the binary relationship classification. Training data requires a pair of tokens and a target label indicating whether or not those two tokens belong to the same cell or not. Once we have a list of all the tokens that are part of the table, for every token, we create a pair of current token with every token, which is located within an imaginary rectangular window around the current token. The size of this imaginary rectangular window will help us determine the number of pairs of tokens to generate.

Training sample is a vector of all the features of a pair of tokens as denoted by 1.

$$V = [W_1F_i, W_2F_i, sameCell] \qquad (1)$$

Where, W_1F_i are *n* features of first token, W_2F_i are *n* features of second token, and *sameCell* is the target class indicating *True* if the two tokens belong to the same cell, *False* otherwise (see Figure 1).

The target class, *sameCell* is captured using *Datoin's WYSIWYG annotation tool*, that allows to select a sequence of words on the PDF document and tag those words as a table cell. The training data is generated using the annotated PDF documents and the target label *sameCell* is assigned accordingly for all the pair of words.

Cell Relationship Features

For each token in the table, we generate a set of locational and visual features. Use of semantic features of tabular data along with the mentioned features of this work can be one of the future works with the intention of improving the accuracy of the system.

We group the features used in the relation learning task as four categories as below.

Location and Tile features(LTF). The absolute location of a token is important evidence to indicate that it is indeed part of the table. Along with the absolute location, a more generalized positional information of tokens relative to the document makes the contextualization and localization of tokens easier for a reader.

To capture these relative location and distance information, for each token in the table, we consider *(x,y)* of starting of the token, and *(x,y)* of the ending of the token in documents (see Figure 1). In order to incorporate contextual information about a token, we split the entire document page into an imaginary matrix of tiles of size *(n X m)* and for each tile, we assign a tile number. For each table token, based on its coordinates we find in which tile the token is located, and we include its tile number, the row, and columns of the tile as features of that token (see Figure 1).

Neighborhood features(NF). The position of the surrounding tokens of a given token indicates the relative position of a token to its neighbors and captures the empty spatial distance around a token. For a given table token, we find a list of n nearest tokens in all the four directions, left, right, top and bottom based on the neighboring tokens' spatial distances with respect to the current token (see Figure 1). The horizontal and vertical relative distances between these neighboring tokens are used as features. The *Location and Tile features* of neighboring tokens are also included as part of the given token's feature set. This feature ensures that there exists a chain of transitive dependency connecting all the tokens of a cell.

Clustering and Alignment features(CAF). A human reader makes use of the relative closeness and horizontal and vertical alignments of a given word, especially when a table is not completely bordered, to decide which cell the word belongs to. The proximity of a pair of tokens and the presence of neighboring tokens for each token in four different directions captures the information about the relative closeness.

Among all the neighborhood tokens, we identify whether a given token is nearer to the left neighbor or right neighbor. Similarly, we identify whether that token is nearer to the top neighbor or bottom neighbor (see Figure 1). We have used the absence of neighborhood tokens as a set of four categorical features as well, indicating whether or not a given token has left, right, top and bottom neighbor token.

Type and Style features(TSF). Another significant visual clue used by humans in determining whether two words belong to the same cell or not is the content and the styles used in the words. A binary feature representing whether a token is a number or not was used to capture the data similarity within a row or a column. For every pair of tokens, the comparison of font size and bold styles are used to indicate whether the two tokens have a similar font style or not. Use of semantic features of the content of words could be another important clue in differentiating the words into cells.

We find that Neighborhood, Clustering and Alignment features play a critical role in distinguishing the tokens that do not belong to the same cell. All of the feature generation techniques are based on the coordinates of each of the tokens and the coordinates of the table itself. The number of tiles and the number of neighboring tokens are the parameters which can be tuned to achieve better table structure recognition accuracy.

3.3 Relation Classification Using Multilayer Feedforward Neural Network

We have used a *Multilayer Feedforward Neural Network* to model the binary relationship classifier in the experiments. In order to learn the complex patterns that exist in the table layouts, and generalize these patterns we decided that deep learning is the right tool. Working at token-level, we have huge training data as well and deep neural networks seemed a right candidate for the task.

The generated training data is fed into the Multilayer Feedforward Neural Network that uses *relu* activation function in the hidden layers and a sigmoid activation function in the output layer. The models were trained using *Adam optimizer* and *Binary cross-entropy* loss function as defined in 2 (Zhang, 2019).

$$Loss = -\left[y\log(p) + (1-y)\log(1-p)\right] \quad (2)$$

Where y is a binary indicator of correct prediction of a sample, p is the predicted probability for a training sample.

Feature Parameter	Value
Number of left, right, top and bottom neighbor tokens	1
Window size for token pair generation	30 x 30 pixels
Number of tiles	20 tile rows x 20 tile columns

Table 1: Word-level feature generation parameters

The input feature vector of *N* dimension is fed into the network and the sigmoid output value is decoded as binary classes, 0 indicating that the two tokens do not belong to the same cell, 1 indicating that the two tokens belong to the same cell. In our experiments, the Multilayer Feedforward neural network has been built using *Keras* backed by *Tensorflow*, for quick experimentation and development.

4 Experiments and Results

4.1 Dataset and Evaluation Metrics

Due to the lack of publicly available datasets that suit our methodology, we prepared the training data on our own. The dataset used for the experiments contains a total of 250 PDF documents, having one table per document. We ensured that the tables present in our dataset represent the possible diverse type of tables that are most commonly used. Our dataset has tables with and without borders, with and without column headings, with column and row spans, with all types of text alignments, varying line, and word spacing, and font styles. All the PDF documents were annotated using *Datoin's WYSIWYG annotation tool*.

Using the parameters listed in Table 1, we created approximately 0.3 million training samples from all the tokens of 250 tables, containing 83 different features. Training samples are split by a 9 to 1 ratio for training and testing, keeping approximately 30,000 samples for testing.

	Training data	Test Data
True Class	60,000	9,000
False Class	2,10,000	21,000
Samples size	2,70,000	30,000

Table 2: Approximate distribution of target labels

The distribution of target labels in our training and testing dataset is shown in Table 2. The imbalance in the distribution of classes makes sense because for every token in the table, within an imaginary rectangular window around that token, the number of tokens that are in the same cell will be less than the number of tokens that are not in the same cell.

Measuring how many predicted cells are actual cells in a given table, would be a more explanatory metric for evaluation. However, if one token among all the tokens of a cell is wrongly predicted by the relationship classification model as belonging to a different cell, then measuring the correctness of this prediction at a cell-level would be challenging. So we decided to use the accuracy of the binary classification model itself as our evaluation metric. This token-level metric is simpler and straightforward.

4.2 Hyperparameters

We have experimented with the hyperparameters of the neural network architecture itself. Table 3 defines the set of hyperparameters used in our experiments. In terms of the number of weights, *Set-1* is a simpler network with fewer weights to learn and *Set-2* is a more complex network.

Hyperparameter	Set-1	Set-2
Number of layers	4	5
Number of Epochs	200	300
Batch size	300	100
Learning Rate	0.001	0.001

Table 3: Hyperparameters used in Multilayer Feedforward Neural Network

Feature Set	Features
LTF	Location and Tile features
NF_CAF	Neighborhood features, Clustering and Alignment features
TSF	Type and Style features

Table 4: Feature sets used in the experiments

It is important to note here that a smaller batch size and a higher number of epochs do increase the F1-Scores and help the model to learn more com-

Feature Set	Class	Precision	Recall	F1-Score
LTF	True	77.89%	91.33%	83.51%
	False	95.13%	85.91%	90.29%
LTF & NF_CAF	True	93.65%	89.50%	91.07%
	False	94.07%	96.10%	95.73%
LTF, NF_CAF & TSF	**True**	**94.10%**	**90.85%**	**92.62%**
	False	**97.56%**	**98.27%**	**98.15%**

Table 5: Results of binary relation classification using Hyperparameter Set-2

plex patterns in the data, at the cost of increased training time.

4.3 Experiments

We have experimented with many combinations of feature sets and feature generation parameters and selected the best three sets of features, as listed in Table 4. The *Neighborhood features* and *Clustering and Alignment features* are combined into one set because both the features measure the togetherness of two given table tokens.

In each of these experiments, we have further experimented with 2 sets of neural network hyperparameters listed in Table 3.

4.4 Results and Discussion

All the experiments with the two sets of neural network hyperparameters listed in Table 3, indicated that *Set-2* outperforms the *Set-1*. So, we have listed only the results of experiments carried out using hyperparameters *Set-2* in Table 5.

Multiple experiments indicated that neighborhood features have sufficient information to capture the table structure and the use of visual clues does increase accuracy. However, one experiment showed that increasing the number of neighboring tokens for each token, reduces the *Recall* measure of *True* class. Increased number of *False* classes could be a possible explanation for this behavior. Also, increasing the number of hidden layers or hidden units of the network did not improve the accuracy further.

The model achieved an overall accuracy of *97.95%* on the test set after training the network for about an hour. Clearly, the model is predicting the cell-relationships on unseen token pairs with very high accuracy. A set of 20 documents containing a variety of tables, which are not part of training documents, are considered as a validation set.

The F1-Score of *False* class is much better than that of *True* class. One possible reason for this could be, the tokens that are not likely to be in the same cell will clearly have a distinguishable set of locational and neighboring features. It is clear that the recall of *True* class is causing the F1-Score to be low. Our training dataset has comparably fewer training samples for the *True* class this could be a possible reason for the low recall scores.

Manual verification of individual table cells with the prediction of the relation classifier shows that the model is able to generalize the cell recognition task across a variety of table cells. The cell relationships are identified accurately irrespective of the presence of borders lines, column, and row spans and text alignments. The relationship among the tokens of a table is learned by the model based on Neighborhood, Clustering and Alignment features of the tokens. However, for a few tokens where the neighborhood features do not have a clear separation with tokens from nearby cells, the model combines the tokens from adjacent cells, producing wrong predictions. Because of the absence of visual separation among the tokens of two closely aligned cells, the model predicts those multiple cells as a single cell.

5 Conclusion and Future Work

By applying the idea of relation extraction in table structure recognition task, we have shown the possibility of high accuracy information extraction in unstructured documents. Table structure recognition as relation extraction task is a novel approach in table extraction process and to the best of our knowledge has never been explored. We have taken the first step towards this direction and have proved that a bottom-up approach of cell relationship extraction is the right way towards table structure recognition task. We have compared three sets of features and showcased the significance of cognitive features in our experiments.

For a few of the tables, closely aligned adjacent cells are wrongly identified as one cell. Incorporating the semantic features of the content of the words, especially using Natural Language Processing, will enrich the feature vector and should help the model to do better generalizations. Exploring the different layout and visual features and improving the accuracy of the proposed method could be one of the possible future works.

Building on top of cell-relationship recognition work, we hope to explore the table structure extraction further. The knowledge of table cells can be used to build up the rest of the table structures from bottom-up. We believe that the relation extraction methodologies apply to other document understanding tasks and we hope to explore them as well.

Identification of Good and Bad News on Twitter

Piush Aggarwal
University of Duisburg-Essen
piush.aggarwal@stud.uni-due.de

Ahmet Aker
University of Duisburg-Essen
a.aker@is.inf.uni-due.de

Abstract

Social media plays a great role in news dissemination which includes good and bad news. However, studies show that news, in general, has a significant impact on our mental stature and that this influence is more in bad news. An ideal situation would be that we have a tool that can help to filter out the type of news we do not want to consume. In this paper, we provide the basis for such a tool. In our work, we focus on Twitter. We release a manually annotated dataset containing 6,853 tweets from 5 different topical categories. Each tweet is annotated with good and bad labels. We also investigate various machine learning systems and features and evaluate their performance on the newly generated dataset. We also perform a comparative analysis with sentiments showing that sentiment alone is not enough to distinguish between good and bad news.

1 Introduction

Social media sites like Twitter, Facebook, Reddit, etc. have become a major source of information seeking. They provide chances to users to shout to the world in search of vanity, attention or just shameless self-promotion. There is a lot of personal discussions but at the same time, there is a base of useful knowledgeable content which is worthy enough to consider for the public interest. For example in Twitter, tweets may report about news related to recent events such as natural or man-made disasters, discoveries made, local or global election outcomes, health reports, financial updates, etc. In all cases, there are good and bad news scenarios.

Studies show that news, in general, has a significant impact on our mental stature (Johnston and Davey, 1997). However, it is also demonstrated that the influence of bad news is more significant than good news (Soroka, 2006; Baumeister et al., 2001) and that due to the natural negativity bias, as described by (Rozin and Royzman, 2001), humans may end up consuming more bad than good news. Since bad news travels faster than good news (Kamins et al., 1997; Hansen et al., 2011) the consumption may increase. This is a real threat to the society as according to medical doctors and, psychologists exposure to bad news may have severe and long-lasting negative effects for our well being and lead to stress, anxiety, and depression (Johnston and Davey, 1997). (Milgrom, 1981; BRAUN et al., 1995; Conrad et al., 2002; Soroka, 2006) describe crucial role of good and bad news on financial markets. For instance, bad news about unemployment is likely to affect stock markets and in turn, the overall economy (Boyd et al., 2005). Differentiating between good and bad news may help readers to combat this issue and a system that filters news based on the content may enable them to control the amount of bad news they are consuming.

The aim of this paper is to provide the basis to develop such a filtering system to help readers in their selection process. We focus on Twitter and aim to develop such a filtering system for tweets. On this respect the contributions of this work are:

- We introduce a new task, namely the distinction between good and bad news on Twitter.
- We provide the community with a new gold standard dataset containing 6,893 tweets. Each tweet is labeled either as good or bad. To the best of our knowledge, this is the first dataset containing tweets with good and bad

labels. The dataset is publicly accessible and can be used for further research[1].

- Provide guidelines to annotate good/bad news on Twitter.
- We implement several features approaches and report their performances.
- The dataset covers diverse domains. We also show out-of-domain experiments and report system performances when they are trained on in-domain and tested on out-of-domain data.

In the following, we first discuss related work. In Section 3 we discuss the guidelines that we use to annotate tweets and gather our dataset. Section 4 provides description about the data itself. In Section 5 we describe several baseline systems performing the good and bad news classification as well as features used to guide the systems. Finally, we conclude the paper in Section 7.

2 Related Work

In terms of classifying tweets into the good and bad classes no prior work exists. The closest studies to our work, are those performing sentiment classification in Twitter (Nakov et al., 2016; Rosenthal et al., 2017). Kouloumpis et al. (2011) use n-gram, lexicon, part of speech and micro-blogging features for detecting sentiment in tweets. Similar features are used by Go (2009). More recently researchers also investigated deep learning strategies to tackle the tweet level sentiment problem (Severyn and Moschitti, 2015; Ren et al., 2016). Twitter is multi-lingual and in Mozetič et al. (2016) the idea of multi-lingual sentiment classification is investigated. The task, as well as approaches proposed for determining tweet level sentiment, are nicely summarized in the survey paper of Kharde et al. (2016). However, Balahur et al. (2010) reports that there is no link between good and bad news with positive and negative sentiment respectively.

Thus, unlike related work, we do tweet level good vs. bad news classification. We also show that similar to Balahur et al. (2010), there is no evidence that positive sentiment implies good news and negative sentiment bad news.

3 Good vs Bad News

News can be good for one section of society but bad for other section. For example, win or loss related news are always subjective. In such cases, agreement towards news types (good or bad) is quite low. On the other hand, news related to natural disaster, geographical changes, humanity, women empowerment, etc. show very high agreement. Therefore, while defining news types, topicality plays an important role.

We consider news as good news if it relates to low subjective topics and includes positive overtones such as recoveries, breakthroughs, cures, wins, and celebrations (Harcup and ONeill, 2017) and also beneficial for an individual, a group or society. An example of good news is shown in Figure 1. In contrary to that, the bad news is defined as when it relates to the low subjective topic and include negative overtones such as death, injury, defeat, loss and is not beneficial for an individual, a group or society. An example of bad news is shown in Figure 2. Based on these definitions/guidelines we have gathered our dataset (see next Section) of tweets containing the good and bad labels.

4 Dataset

Data collection To collect tweets for annotation, we first choose low subjective ten topics which can be divided into five different categories. Then,

	Total	**7,212**	**6,853**

Table 1: Categories, their topics, and distributions for the dataset generation.

we retrieve the examples from Twitter using its API[2]. Next, we discard non-English tweets and re-tweets. We also remove duplicates based on lower-cased first four words of tweets keeping only the first one. Thereafter, we filter only those tweets which can be regarded as news by using an in house SVM classifier (Aggarwal, 2019). This classifier is trained on tweets annotated with the labels news and not news. We use this classifier to remove *not news* tweets from the annotation task[3]. We select only tweets where the classifier prediction probability is greater than or equal to 80%. In Table 1, we provide information about the topics and categories as well as statistics about the collected tweets that will be used for annotation (column *collected*).

Data Annotation For data annotation, we use the figure-eight crowdsourcing service[4]. Before uploading our collected examples, we carried out a round of trial annotation of 300 randomly selected instances from our tweet collection corpus. The aim of the trial annotation was

- to ensure the newsworthiness quality of our collected examples.
- to create test questions to ensure the quality of the annotators, for the rest of the data, which was carried out using crowdsourcing.
- to test our guidelines described in Section 3.

We ask three annotators[5] to classify the selected examples into good and bad news. We also allowed a third category *cannot say*. We computed Fleiss' kappa Fleiss (1971) on the trial dataset for the three annotators. The value is 0.605 which indicates rather a high agreement. We used 247 instances agreed by all the three annotators as test questions for the crowdsourcing platform.

During the crowd annotation, we showed each annotator 5 tweets per page and paid 3 US Cents per tweet. For maintaining quality standards, in addition to the test questions, we applied a restriction so that annotation could be performed only by people from English speaking countries. We also made sure that each annotation was performed maximum by 7 annotators and that an annotator agreement of min. 70% was met. Note if the agreement of 70% was met with fewer annotators then the system would not force an annotation to be done by 7 annotators but would finish earlier. The system requires 7 annotators if the minimum agreement requirement is not met. We only choose instances that are annotated by atleast 3 annotators. In addition to the good and bad news categories we also ask annotators to mandatory provide their confidence score (range between 0-100%) for the label they have annotated[6]. We discarded all the tweets where we did not have at least 3 annotators with each having min. 50% confidence value. We also discarded tweets that are annotated by less than three annotators. We

[2] https://www.tweepy.org

[3] Since we want humans to annotate tweets as good and bad news we apply this approach to filter tweets that are not news at all and so avoid our annotators spending valuable time on annotating tweets that are not our target.

[4] https://www.figure-eight.com/

[5] All are post-graduate students who are fluent in English and use Twitter to post information on a daily basis.

[6] We found this strategy better than providing the option *cannot say* and later allowed us to discard annotations where the confidence score was less than 50%.

use a total 7,212 tweets to annotate. After all filterings, we remained with 6,853 instances which were classified as good and bad news. Topic-wise number of successful annotations are displayed in the fourth column of Table 1.

Inter Annotator Agreement To calculate agreement between the annotators of the crowdsourcing annotation results, we select the top three confident annotator labels for each sample. Based on this, we record an agreement of 0.614 as Fleiss' Kappa (Fleiss, 1971) score indicating a good agreement among the annotators. We also claim stability in our annotation task because of the score similarity with that of trail annotation.

5 Method

We experiment with several machine learning approaches and features. Before using the tweets in decision making, we also apply a simple preprocessing on them. In the following, we briefly outline these.

5.1 Preprocessing

We use the ArkTokenizer (Gimpel et al., 2011) to tokenize the tweets. In addition to tokenization, we do lowercasing and remove digits if available in text.

5.2 Features

We extract nine features for each tweet and divide them into *Structural*, *TF-IDF* and *Embeddings* features.

5.2.1 Structural features

Emoticons: We extract all the emoticons from the training data and use them as a binary feature, i.e. does a tweet contain a particular emoticon or not.

Interjections: We use existing list of interjections[7] and use them similar to *Emoticons* as binary feature.

Lexicons: We use existing positive and negative lexicons[8] and use them as a binary feature.

Sentiment: We use the textblob[9] tool to compute sentiment score over each tweet. The score varies between -1 (negative) to 1 (positive).

POS-Tag: This feature includes 36 different pos-tags (uni-gram) and are used as binary features.

Significant terms: Using tf-idf values we also extract the top 300 terms (uni-gram and bi-gram, 300 in each case) from the training data and use them as binary features. Note, we extract for good and bad news separate uni-grams and bi-grams.

Tweet Characteristics: This feature contains tweet specific *characterstics* such as the number of favorite counts, tweet replies count and number of re-tweets.

5.2.2 TF-IDF

In this case, we simply use the training data to create a vocabulary of terms and use this vocabulary to extract features from each tweet. We use tf-idf representation for each vocabulary term.

5.2.3 Embeddings

Finally, we also use fasttext based embedding (Mikolov et al., 2018) vectors which are trained on common crawl having 600 billion tokens.

5.3 Classifiers

We investigate 8 classifiers for our task including Multi-Layer Perceptron (MLPC), Support Vector Machine with linear (LSVC) and rbf (SVC) kernel, K Nearest Neighbour (KNN), Logistic Regression (LR), Random Forest (RF), XGBoost (XGB) and Decision Tree (DT). In addition, we also fine-tune BERT-base model (Devlin et al., 2018). Each classifier, except the BERT, has been trained and tested on each possible combination of the three feature types.

6 Results

Overall results We performed a stratified 5-fold cross-validation. We evaluate each resulting model on a held-back development dataset containing 264 good news postings and 764 bad news ones. The 5-fold cross validation has been performed on the training data containing 4,332 bad news and 1,493 good news instances. For

Multi-Layer Perceptron (MLPC), Support Vector Machine with linear (LSVC) and rbf (SVC) kernel, K Nearest Neighbour (KNN), Logistic Regression (LR), Random Forest (RF), XGBoost (XGB) and Decision Tree (DT).

each model, we use grid-search method to select the hyper-parameters with best model's efficiency. The results reported are those obtained on the test data and are summarized in Table 2. Overall we see that the performances of the classifiers are all highly satisfactory. Among the more traditional approaches, the best performance is obtained through SVC, LSVC, and LR. We see also that these approaches work best when embeddings along with tf-idf features are used, although LSVC achieves the same results when all features are used. However, the best performance is achieved with the BERT-base model leading to 92% F_1 score. We computed also significance test using paired t-test between BERT and more traditional machine learning approaches[10]. However, after Bonferroni correction ($p < 0.007$) we found no significant difference between BERT and the other systems.

Structural feature analysis We also evaluate the structural features of the task independently (Figure 3). For this, we use the SVC classifier as it is one of the best performing traditional methods. From the figure, we see that the significant term feature gives the best performance. The difference to the other features is greater than the 23% F_1 score. The differences are also significant after Bonferroni correction ($p < 0.008$). In Table 3 we list some frequent uni-grams from the significant good and bad term lists. From the table, we see that the terms are certainly good indicators for distinguishing between the two classes.

Bad news	**Good news**
fake	services
racism	cured
fox	resistant
attack	energy
migrants	support
fears	arrested

Table 3: Top uni-grams from the good and bad news significant term lists.

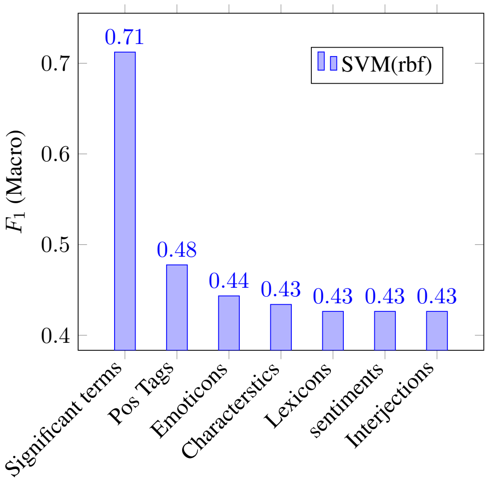

Figure 3: Structural features' performance using the SVM classifier evaluated on the test set.

[10] We always use the best result for every system.

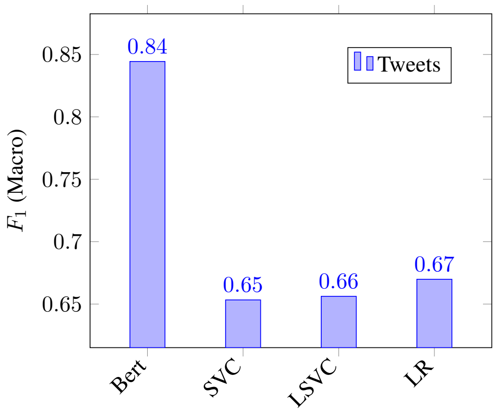

Figure 4: Out-of-domain performance of different systems.

Sentiment for good-vs-bad news We also tested whether sentiment score can predict good vs. bad news as Naveed et al. (2011) found a relationship between these two. For this, we use the textblob sentiment scorer and classify any tweet as good news when its sentiment score is greater than 0 otherwise bad. Using this strategy we could only achieve an F_1 score of 55%. This shows that tackling the good/bad news classification task using sentiment scores is not appropriate. This also confirms the findings of Balahur et al. (2010).

Out-of-domain experiments We also investigate how stable the models are when they are trained on in-domains and tested on out-of-domain data. For this purpose, we split our dataset into a training set consisting of all examples except instances belonging to the health category. We use four of the best-performing systems (BERT, SVC, LSVC, and LR) to train on this training set. The resulting models are tested on the held-out health data. Results are shown in Figure 4. From Figure 4 we see that BERT is stable and achieve an F_1 score of 84%. The performance of the other system drop by a great margin to the max. 67% F_1 score. From this, we can conclude that BERT is a better system to use for good-vs-bad Twitter news classification.

Detailed analysis on BERT Our overall but also the out-of-domain experiments show that BERT is outperforming the more traditional machine learning approaches. On the overall (1,028 testing instances) results, BERT fails only to classify 63 cases correctly. Using t-SNE distribution (van der Maaten and Hinton, 2008), we analyse BERT's 12th layer embedding vectors (having 300 dimensions) for random 100 test points (Figure 5). The analysis shows that BERT can classify semantics of good and bad news instances correctly even the instances are in proximity. From Figure 5, we see that mostly outliers are misclassified.

7 Conclusion and Future Work

In this paper, we presented a new dataset having 6,853 tweet post examples annotated with good and bad news labels. This dataset will be publicly available for the research community. We also presented a comparative analysis of supervised classification methods. We investigated nine different feature types and 8 different machine learning classifiers. The most robust result in our analysis was the contribution of the BERT-base model in in-domain but also in out-of-domain evaluations. Among structural features, significant terms significantly outperform the rest. We also showed that sentiment scores are not appropriate to classify good-vs-bad news.

In our future work, we plan to expand our investigation by including other features. We also plan to propose this model for the good-bad classification of news articles.

Abstract

The quality of Neural Machine Translation (NMT), as a data-driven approach, massively depends on quantity, quality and relevance of the training dataset. Such approaches have achieved promising results for bilingually high-resource scenarios but are inadequate for low-resource conditions. This paper describes a round-trip training approach to bilingual low-resource NMT that takes advantage of monolingual datasets to address training data scarcity, thus augmenting translation quality. We conduct detailed experiments on Persian-Spanish as a bilingually low-resource scenario. Experimental results demonstrate that this competitive approach outperforms the baselines.

1 Introduction

Neural Machine Translation (NMT) has made considerable progress in recent years. However, to achieve acceptable translation output, large sets of aligned parallel sentences are required for the training phase. Thus, as a data-driven paradigm, the quality of NMT output strongly depends on the quality as well as quantity of the provided training data (Bahdanau et al., 2015). Unfortunately, in practice, collecting such parallel text by human labeling is very costly and time consuming (Ahmadnia and Serrano, 2017).

Low-resource languages are those that have fewer technologies and datasets relative to some measure of their international importance. The biggest issue with low-resource languages is the extreme difficulty of obtaining sufficient resources. Natural Language Processing (NLP) methods that have been created for analysis of low-resource languages are likely to encounter similar issues to those faced by documentary and descriptive linguists whose primary endeavor is the study of minority languages. Lessons learned from such studies are highly informative to NLP researchers who seek to overcome analogous challenges in the computational processing of these types of languages.

Assuming that large monolingual texts are available, an obvious next step is to leverage these texts to augment the NMT systems' performance. Various approaches have been developed for this purpose. In some approaches, target monolingual texts are employed to train a Language Model (LM) that is then integrated with MT models trained from parallel texts to enhance translation quality (Brants et al., 2007; Gülçehre et al., 2015). Although these approaches utilize monolingual text to train a LM, they do not address the shortage of bilingual training datasets.

In other approaches, bilingual datasets are automatically generated from monolingual texts by utilizing the Translation Model (TM) trained on aligned bilingual text; the resulting sentence pairs are used to enlarge the initial training dataset for subsequent learning iterations (Ueffing et al., 2008; Sennrich et al., 2016). Although these approaches enlarge the bilingual training dataset, there is no quality control and, thus, the accuracy of the generated bilingual dataset cannot be guaranteed (Ahmadnia et al., 2018).

To tackle the issues described above, we apply a new round-tripping approach that incorporates *dual learning* (He et al., 2016) for automatic learning from unlabeled data, but transcends this prior work through effective leveraging of monolingual text. Specifically, the round-tripping approach takes advantage of the bootstrapping methods including self-training and co-training. These methods start their mission from a small set of labelled examples, while also considering one or two weak translation models, and makes improvement through the incorporation of unlabeled data into the training dataset.

In the round-tripping approach, the two translation tasks (forward and backward) together make a *closed loop*, i.e., one direction produces informative *feedback* for training the TM for the other direction, and vice versa. The feedback signals—which consist of the language model likelihood of the output model and the reconstruction error of the original sentence—drive the process of iterative updates of the forward and backward TMs.

For the purpose of evaluation, we apply this approach to a bilingually low-resource language pair (Persian-Spanish) to leverage monolingual data in a more effective way. By utilizing the round-tripping approach, the monolingual data play a similar role to the bilingual data, effectively reducing the requirement for parallel data. In particular, each model provides guidance to the other throughout the learning process. Our results show that round-tripping for NMT works well in the Persian-Spanish low-resource scenario. By learning from monolingual data, this approach achieves comparable accuracy to a NMT approach trained from the full bilingual data for the two translation tasks (forward and backward).

The remainder of this paper is organized as follows; Section 2 presents the previous related work. In Section 3, we briefly review the relevant mathematical background of NMT paradigm. Section 4 describes the round-trip training approach. The experiments and results are presented in Section 5. Conclusions and future work are discussed in Section 6.

2 Related Work

The integration of monolingual data for NMT models was first proposed by (Gülçehre et al., 2015), who train monolingual LMs independently, and then integrate them during decoding through rescoring of the beam (adding the recurrent hidden state of the LM to the decoder state of the encoder-decoder network). In this approach, an additional controller mechanism controls the magnitude of the LM signal. The controller parameters and output parameters are tuned on further parallel training data, but the LM parameters are fixed during the fine tuning stage.

Jean et al. (2015) also report on experiments with reranking of NMT output with a 5-gram LM, but improvements are small. The production of synthetic parallel texts bears resemblance to data augmentation techniques, where datasets are often augmented with rotated, scaled, or otherwise distorted variants of the (limited) training set (Rowley et al., 1998).

A similar avenue of research is self-training (McClosky et al., 2006). The self-training approach as a bootstrapping method typically refers to the scenario where the training dataset is enhanced with training instances with artificially produced output labels (whereas we start with neural network based output, i.e., the translation, and artificially produce an input). We expect that this is more robust towards noise in MT.

Hoang et al. (2018) showed that the quality of back translation matters and proposed an iterative back translation, in which back translated data are used to build better translation systems in forward and backward directions. These, in turn, are used to reback translate monolingual data. This process is iterated several times.

Improving NMT with monolingual source data, following similar work on phrase-based SMT (Schwenk, 2008), remains possible future work. Domain adaptation of neural networks via continued training has been shown to be effective for neural language models by (Ter-Sarkisov et al., 2015).

Round-tripping has already been utilized in SMT by (Ahmadnia et al., 2019). In this work, forward and backward models produce informative feedback to iteratively update the TMs during the training of the system.

3 Neural Machine Translation

NMT consists of an encoder and a decoder. Following (Bahdanau et al., 2015), we adopt an *attention-based* encoder-decoder model, i.e., one that selectively focuses on sub-parts of the sentence during translation. Consider a source sentence $X = \{x_1, x_2, ..., x_J\}$ and a target sentence $Y = \{y_1, y_2, ..., y_I\}$. The problem of translation from the source language to the target is solved by finding the best target language sentence $\hat{y}$ that maximizes the conditional probability:

$$\hat{y} = \arg\max_{y} P(y|x) \tag{1}$$

The conditional word probabilities given the source language sentence and preceding target language words compose the conditional probability as follows:

$$P(y|x) = \prod_{i=1}^{I} P(y_i|y_{<i}, x) \tag{2}$$

where y_i is the target word emitted by the decoder at step i and $y_{<_i} = (y_1, y_2, ..., y_{i-1})$.

To compose the model, both the encoder and decoder are implemented employing Recurrent neural Networks (RNNs) (Rumelhart et al., 1986), i.e., the encoder converts source words into a sequence of vectors, and the decoder generates target words one-by-one based on the conditional probability shown in the Equation (2). More specifically, the encoder takes a sequence of source words as inputs and returns forward hidden vectors $\overrightarrow{h_j}(1 \leq j \leq J)$ of the forward-RNN:

$$\overrightarrow{h_j} = f(\overrightarrow{h_{j-1}}, x) \tag{3}$$

Similarly, we obtain backward hidden vectors $\overleftarrow{h_j}(1 \leq j \leq J)$ of the backward-RNN, in the reverse order.

$$\overleftarrow{h_j} = f(\overleftarrow{h_{j-1}}, x) \tag{4}$$

These forward and backward vectors are concatenated to make source vectors $h_j(1 \leq j \leq J)$ based on Equation (5):

$$h_j = \left[\overrightarrow{h_j}; \overleftarrow{h_j}\right] \tag{5}$$

The decoder takes source vectors as input and returns target words. It starts with the initial hidden vector h_J (concatenated source vector at the end), and generates target words in a recurrent manner using its hidden state and an output context.

The conditional output probability of a target language word y_i is defined as follows:

$$P(y_i|y_{<i}, x) = \mathit{softmax}\left(f(d_i, y_{i-1}, c_i)\right) \tag{6}$$

where f is a non-linear function and d_i is the hidden state of the decoder at step i:

$$d_i = g(d_{i-1}, y_{i-1}, c_i) \tag{7}$$

where g is a non-linear function taking its previous state vector with the previous output word as inputs to update its state vector. c_i is a context vector to retrieve source inputs in the form of a weighted sum of the source vectors h_j, first taking as input the hidden state d_i at the top layer of a stacking LSTM (Hochreiter and Schmidhuber, 1997). The goal is to derive a context vector c_i that captures relevant source information to help predict the current target word y_i.

While these models differ in how the context vector c_i is derived, they share the same subsequent steps. c_i is calculated as follows:

$$c_i = \sum_{j=1}^{J} \alpha_{t,j} h_j \tag{8}$$

where h_j is the annotation of source word x_j and $\alpha_{t,j}$ is a weight for the j^{th} source vector at time step t to generate y_i:

$$\alpha_{t,j} = \frac{\mathit{exp}\left(\mathit{score}\left(d_i, h_j\right)\right)}{\sum_{j'=1}^{J} \mathit{exp}\left(\mathit{score}\left(d_i, h_{j'}\right)\right)} \tag{9}$$

The score function above may be defined in a variety of ways as discussed by Luong et al. (2015).

In this paper, we denote all the parameters to be optimized in the neural network as Θ and denote C as the dataset that contains source-target sentence pairs for the training phase. Hence, the learning objective is to seek the optimal parameters Θ^*:

$$\Theta^* = \arg\max_{\Theta} \sum_{(x,y)\in C} \sum_{(i=1)}^{I} \log P(y_t|y_{<t}, x; \Theta) \tag{10}$$

4 Method Description

Round-tripping involves two related translation tasks: the outbound-trip (source-target direction) and the inbound-trip (target-source direction). The defining traits of these forward and backward tasks are that they form a closed loop and both produce informative feedback that enables simultaneous training of the TMs.

We assume availability of: (1) monolingual datasets (C_X and C_Y) for the source and target languages; and (2) two weak TMs (emergent from training on initial small bilingual corpora) that bidirectionally translate sentences from source and target languages. The goal of the round-tripping approach is to augment the accuracy of the two TMs by employing the two monolingual datasets instead of a bilingual text.

We start by translating a sample sentence in one of the monolingual datasets, as the outbound-trip (forward) translation to the target language. This step generates more bilingual sentence pairs between the source and target languages. We then translate the resulting sentence pairs backward through the inbound-trip translation to the original language. This step finds high-quality sentences throughout the entirety of the generated sentence pairs. Evaluating the results of this round-tripping approach will provide an indication of the quality of the two TMs, and will enable their enhancement, accordingly. This process is iterated for several rounds until both TMs converge.

We define K_X as the number of sentences in C_X and K_Y as the number of sentences in C_Y. We take $P(.|S;\Theta_{XY})$ and $P(.|S;\Theta_{YX})$ to be two neural TMs in which Θ_{XY} and Θ_{YX} are supposed as their parameters. We also assume the existence of two LMs for languages X and Y, trained in advance either by using other resources or using the monolingual data (C_X and C_Y). Each LM takes a sentence as input and produces a real number, based on target-language fluency (LM correctness) together translation accuracy (TM correctness). This number represents the confidence of the translation quality of the sentence in its own language.

We start with a sentence in C_X and denote S_{sample} as a translation output sample. This step has a score as follows:

$$R_1 = LM_Y(S_{sample}) \qquad (11)$$

The R_1 score indicates the well-formedness of the output sentence in language Y.

Given the translation output S_{sample}, we employ the log probability value of s recovered from the S_{sample} as the score of the construction:

$$R_2 = \log P(S|S_{sample};\Theta_{YX}) \qquad (12)$$

We then adopt the LM score and construction score as the total reward score:

$$R_{total} = \alpha R_1 + (1-\alpha)R_2 \qquad (13)$$

where α is an input hyper-parameter.

The total reward score is considered a function of S, S_{sample}, Θ_{XY} and Θ_{YX}. To maximize this score, we optimize the parameters in the TMs utilizing Stochastic Gradient Descent (SGD) (Sutton et al., 2000). According to the forward TM, we sample the s_{sample} and then compute the gradient of the expected score ($E[R_{total}]$), where E is taken from S_{sample}:

$$\nabla_{\Theta_{XY}} E[R_{total}] = E[R_{total} \nabla_{\Theta_{XY}} \log P(S_{sample}|S;\Theta_{XY})] \qquad (14)$$

$$\nabla_{\Theta_{YX}} E[R_{total}] = E[(1-\alpha) \nabla_{\Theta_{YX}} \log P(S|S_{sample};\Theta_{YX})] \qquad (15)$$

Algorithm 1 shows the round-tripping procedure.

Algorithm 1 Round-trip training for NMT

```
Input: Monolingual dataset in source and target languages ($C_X$ and $C_Y$), initial translation
       models in outbound and inbound trips ($\Theta_{XY}$ and $\Theta_{YX}$), language models in source
       and target languages ($LM_X$ and $LM_Y$), trade-off parameter between 0 and 1 ($\alpha$),
       beam search size ($N$), learning rates ($\gamma_{1,t}$ and $\gamma_{2,t}$).
 1: repeat:
 2:   $t = t + 1$.
 3:   Sample sentences $S_X$ and $S_Y$ from $C_X$ and $C_Y$ respectively.
 4:   // Update model starting from language $X$.
      Set $S = S_X$.
 5:   // Generate top-$N$ translations using $\Theta_{XY}$.
      Generate sentences $S_{sample,1}, ..., S_{sample,N}$.
 6:   for $n = 1, ..., N$ do
 7:     // Set LM score for $n^{th}$ sampled sentence.
        $R_{1,n} = LM_Y(S_{sample,n})$.
 8:     // Set TM score for $n^{th}$ sampled sentence.
        $R_{2,n} = logP(S|S_{sample,n};\Theta_{YX})$.
 9:     // Set total score of $n^{th}$ sampled sentence.
        $R_n = \alpha R_{1,n} + (1-\alpha)R_{2,n}$.
10:   end for
11:   // SDG computing for $\Theta_{XY}$.
      $\nabla_{\Theta_{XY}} \hat{E}[R_{total}] = \frac{1}{N}\sum_{n=1}^{N} [R_n \nabla_{\Theta_{XY}} \log P(S_{sample,n}|S;\Theta_{XY})]$.
12:   // SDG computing for $\Theta_{YX}$.
      $\nabla_{\Theta_{YX}} \hat{E}[R_{total}] = \frac{1}{N}\sum_{n=1}^{N} [(1-\alpha)\nabla_{\Theta_{YX}} \log P(S|S_{sample,n};\Theta_{YX})]$.
13:   // Model update.
      $\Theta_{XY} \leftarrow \Theta_{XY} + \gamma_{1,t}\nabla_{\Theta_{XY}} \hat{E}[R_{total}]$.
14:   // Model update.
      $\Theta_{YX} \leftarrow \Theta_{YX} + \gamma_{2,t}\nabla_{\Theta_{YX}} \hat{E}[R_{total}]$.
15:   // Update model starting from language $Y$.
      Set $S = S_Y$.
16:   Go through lines $5 - 14$ symmetrically.
17: until convergence.
```

To achieve reasonable translations we use beam search. We generate N-best sample translations and use the averaged value on the beam search results to estimate the true gradient value.[1]

[1] We used beam sizes 500 and 1000.

5 Experiments and Results

We apply the round-trip training approach to bilingual Persian-Spanish translation, and evaluate the results. We used the Persian-Spanish small bilingual corpora from the *Tanzil* corpus (Tiedemann, 2012),[2] which contains about 50K parallel sentence pairs. We also used 5K and 10K parallel sentences extracted from the *OpenSubtitles2018* collection (Tiedemann, 2012),[3] as the validation and test datasets, respectively. Finally, we utilized 70K parallel sentences from the *KDE4* corpus (Tiedemann, 2012),[4] as the monolingual data.

We implemented the DyNet-based model architecture (Mi et al., 2016) on top of *Mantis* (Cohn et al., 2016) which is an implementation of the attention sequence-to-sequence (Seq-to-Seq) NMT. For each language, we constructed a vocabulary with the most common 50K words in the parallel corpora, and OOV words were replace with a special token <*UNK*>. For monolingual corpora, sentences containing at least one OOV word were removed. Additionally, sentences with more than 80 words were removed from the training set.[5] The encoders and decoders make use of Long Short-Term Memory (LSTM) with 500 embedding dimensions, 500 hidden dimensions. For training, we used the SGD algorithm as the optimizer. The batch size was set as 64 with 20 batches pre-fetched and sorted by sentence lengths.

Below we compare the system based on the optimized round-trip training (round-tripping) through two translation systems; the first one is the standard NMT system (baseline), and the second one is the system that generates pseudo bilingual sentence pairs from monolingual corpora to assist the training step (self-training). For the pseudo-NMT we used the trained NMT model to generate pseudo bilingual sentence pairs from monolingual text, removed sentences with more than 80 words (as above), merged the generated data with the original parallel training data, and then trained the model for testing. Each of the translation systems was trained on a single GPU until their performances stopped improving on the validation set. This approach required an LM for each language. We trained an RNN-based LM (Mikolov et al., 2010) for each language using its corresponding monolingual corpus. The LM was then fixed and the log-likelihood of a received message was utilized for scoring the TM.

To start the round-trip training approach, the systems are initialized using warm-start TMs trained from initial small bilingual data. The goal is to see whether the round-tripping augments the baseline accuracy. We retrain the baseline systems by enlarging the initial small bilingual corpus: we add the optimized generated bilingual sentences to the initial parallel text. The new enlarged translation system contains both the initial and optimized generated bilingual text. For each translation task, we train the round-trip training approach.

We employ Bilingual Evaluation Understudy (BLEU) (Papineni et al., 2001) (using *multi-bleu.perl* script from Moses) as the evaluation metric. BLEU is calculated for individual translated segments by comparing them with a data set of reference translations. The scores of each segment, ranging between 0 and 100, are averaged over the entire evaluation dataset to yield an estimate of the overall translation quality (higher is better).

The baseline systems for Persian-Spanish are first trained, while our round-trip method conducts joint training. We summarize the overall performances in Table 1:

NMT systems	**Pe-Es**	**Es-Pe**
baseline	31.12	29.56
self-train	29.29	27.36
round-trip	34.91	33.43

Table 1: BLEU scores for Persian-Spanish translation task and vice-versa.

As seen in Table 1, the round-tripping systems outperform the others in both translation directions. In Persian to Spanish translation, the round-tripping system outperforms the baseline by about 3.87 BLEU points and also outperforms the self-training system by about 6.07 BLEU points. In the back translation from Spanish to Persian, the improvement of the round-tripping outperforms both the baseline and self-training by about 3.79 and 5.62 BLEU points, respectively.

These results demonstrate the effectiveness of the round-trip training approach. The baseline systems outperform the self-training ones in all cases

[4] http://opus.nlpl.eu/KDE4-v2.php

[5] The average sentence length is 47; an upper bound of 80 ensured exclusion of non-sentential and other spurious material.

because of the noise in the generated bilingual sentences used by self-training. Upon further examination, this result might have been expected given that the aim of round-trip training is to optimize the generated bilingual sentences by selecting the high-quality sentences to get better performance over self-training systems. When the size of bilingual corpus is small, the round-tripping makes a larger improvement. This outcome is an indication that round-trip training approach makes effective use of monolingual data.

Table 2 shows the performance of the baseline alongside of the enlarged translation systems, where the latter leverages the training text of the baseline and the round-tripping systems as well.

NMT systems	Pe-Es	Es-Pe
baseline	31.12	29.56
enlarged	34.21	33.03

Table 2: BLEU scores comparing the baseline and enlarged NMT systems for Persian-Spanish translation task and vice-versa.

As seen in Table 2, the BLEU scores of the enlarged NMT systems are better than the baseline ones in both translation directions. The enlarged system in the Persian-Spanish direction outperforms the baseline by about 3.47 BLEU points, and outperforms the baseline by about 3.09 BLEU points in the back translation. The improvements show that the optimized round-trip training system is promising for tackling the training data scarcity and it also helps to enhance translation quality.

6 Conclusions and Future Work

In this paper, we applied a round-tripping approach based on a retraining scenario to tackle training data scarcity in NMT systems. An exciting finding of this work is that it is possible to learn translations directly from monolingual data of the two languages. We employed a low-resource language pair and verified the hypothesis that, regardless of the amount of training resources, this approach outperforms the baseline. The results demonstrate that round-trip training is promising and better utilizes the monolingual data.

Many Artificial Intelligence (AI) tasks are naturally in dual form. Some examples are: (1) speech recognition paired with text-to-speech; (2) image captioning paired with image generation; and (3) question answering paired with question generation. Thus, a possible future direction would be to design and test the round-tripping approach for more tasks beyond MT. We note that round-tripping is not restricted to two tasks only. Indeed, the key idea is to form a closed loop so feedback signals are extracted by comparing the original input data with the final output data. Therefore, if more than two associated tasks form a closed loop, this approach can applied in each task for improvement of the overall model, even in the face of unlabeled data.

Acknowledgments

We would like to express our sincere gratitude to Dr. Michael W. Mislove (Tulane University, USA), Dr. Javier Serrano (Universitat Autònoma de Barcelona, Spain) and Dr. Gholamreza Haffari (Monash University, Australia) for all their support. We also would like to acknowledge the financial support received from the School of Science and Engineering, Tulane University (USA).

Abstract

Phrases play a key role in Machine Translation (MT). In this paper, we apply a Long Short-Term Memory (LSTM) model over conventional Phrase-Based Statistical MT (PBSMT). The core idea is to use an LSTM encoder-decoder to score the phrase table generated by the PBSMT decoder. Given a source sequence, the encoder and decoder are jointly trained in order to maximize the conditional probability of a target sequence. Analytically, the performance of a PBSMT system is enhanced by using the conditional probabilities of phrase pairs computed by an LSTM encoder-decoder as an additional feature in the existing log-linear model. We compare the performance of the phrase tables in the PBSMT to the performance of the proposed LSTM and observe its positive impact on translation quality. We construct a PBSMT model using the Moses decoder and enrich the Language Model (LM) utilizing an external dataset. We then rank the phrase tables using an LSTM-based encoder-decoder. This method produces a gain of up to 3.14 BLEU score on the test set.

1 Introduction

The three most essential components of a Statistical Machine Translation (SMT) system are: (1) Translation Model (TM); (2) Language Model (LM); and (3) Reordering Model (RM). Among these models, the RM plays an important role in Phrase-Based SMT (PBSMT) (Marcu and Wong, 2002; Koehn et al., 2003), and it still remains a major focus of intense study (Kanouchi et al., 2016; Du and Way, 2017; Chen et al., 2019).

The RM is required since different languages exercise different syntactic ordering. For instance, adjectives in English precede the noun, while they typically follow the noun in Spanish (*the cloudy sky* versus *el cielo nublado*); in Persian the verb precedes the subject, and in Chinese the verb comes last. As a result, source language phrases cannot be translated and placed in the same order in the generated translation in the target language, but phrase movements have to be considered. This is the role of the RM. Estimating the exact distance of movement for each phrase is too sparse; therefore, instead, the lexicalized RM (Koehn, 2009) estimates phrase movements using only a few reordering types, such as a monotonous order, where the order is preserved, or a swap, when the order of two consecutive source phrases is inverted when their translations are placed in the target side.

Neural Machine Translation (NMT) has been receiving significant attention due to its impressive translation performance (Bahdanau et al., 2015). NMT differs from SMT in its adoption of a large neural network to perform the entire translation process in one shot, for which an encoder-decoder architecture is widely used. In this approach, a source sentence is encoded into a continuous vector representation. Subsequently, the decoder uses that representation to generate the corresponding target translation.

NMT's word-by-word translation generation strategy makes it difficult to translate phrases. This is a significant MT challenge as the meaning of a phrase is not always deducible from the meanings of its individual words or parts. Unfortunately, current NMT systems are word-based or character-based where phrases are not considered as translation units. By contrast, phrases are more effective than words as translation units in SMT. Indeed, leveraging phrases has had a significant impact on translation quality (Wang et al., 2017).

Proceedings of Recent Advances in Natural Language Processing, pages 25–32,
Varna, Bulgaria, Sep 2–4 2019.

Recurrent Neural Networks (RNNs) (Rumelhart et al., 1986) are a class of artificial neural network that has recently resurfaced in the field of MT (Schwenk, 2012). Unlike feed-forward networks, RNNs leverage recurrent connections that enable the network to refer to prior states and, thus, to process arbitrary sequences of input. The cornerstone of RNNs is their ability to connect previous information to the present task. For example, given a LM that predicts the next word based on previous words, no further context is needed to predict the last word in *the clouds are in the sky*.

When the gap between the relevant information and the place that it is needed is small, RNNs learn the next word from past information. But there are cases where more context is needed, e.g., in the prediction of the last word in *I grew up in Spain and I speak fluent Spanish*. The word *Spain* suggests that the last word is probably the name of a language, but to narrow down that language, access to a larger context is needed. It is entirely possible for the gap between the relevant information and the point where it is needed to become indefinitely large. Unfortunately, as that gap grows, RNNs are increasingly unable to learn to connect the information.

Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) are an extension of RNNs, capable of learning such long-term dependencies. RNNs are a chain of repeating modules of neural network and, in their simplest form, the repeating module has a single layer. LSTMs also have this chain-like structure, but the repeating modules have four interacting layers.

This paper presents a PBSMT model based on the Moses decoder (Koehn et al., 2007) with a LM that is enriched by an external dataset. Scoring of the phrase table generated by Moses is achieved through a LSTM encoder-decoder, and the result is then evaluated in an English-to-Spanish translation task. Specifically, the model is trained to learn the translation probabilities between English phrases and their corresponding Spanish ones. The trained model is then used as a part of a classical PBSMT system, with each phrase pair scored in the phrase table. Our evaluation proves that this approach enhances the translation performance. Although Moses itself is able to score phrases as a part of the coding process, our approach includes the scoring of phrases using the LSTM-based encoder-decoder, thus yielding improvements in quality. Sentences with the highest scores are selected as the translation output.

The rest of this paper is organized as follows: Section 2 discusses the previous related work. Sections 3 and 4 describe our PBSMT framework and LSTM encoder-decoder integration, respectively. Section 5 presents the key elements of our approach, bringing together PBSMT and LSTM encoder-decoder for phrase scoring. The experimental results are covered in Section 6. Finally, Section 7 presents conclusions and future work.

2 Related Work

Recently, various neural network models have been applied to MT. However, few approaches have made effective use of neural networks to enhance the translation quality of SMT.

Sundermeyer et al. (2014) designed a neural TM that uses LSTM-based RNNs and Bidirectional RNNs, wherein the target word is conditioned not only on the history but also on the future source context. The result was a fully formed source sentence for predicting target words.

Feed-forward neural LMs, first proposed by Bengio et al. (2003), were a breakthrough in language modeling. Mikolov et al. (2011) proposed the use of recurrent neural network in language modeling, thus enabling a much longer context history for predicting the next word. Experimental results showed that the RNN-based LM significantly outperforms the standard feed-forward LM.

Schwenk (2012) proposed a feed-forward neural network to score phrase pairs. They employed a feed-forward neural network with fixed-size phrasal inputs consisting of seven words, and with zero padding for shorter phrases. The system also had fixed-size phrasal output consisting of seven words. Similarly, Devlin et al. (2014) utilized a feed-forward neural network to generate translations, but they simultaneously predicted one word in a target phrase. The use of feed-forward neural networks demands the use of fixed-size phrases to work properly.

Zou et al. (2013) also proposed bilingual learning of word and phrase embeddings, which were used to compute the distance between phrase pairs. The result was an additional annotation to score the phrase pairs of an SMT system.

Chandar et al. (2014) trained a feed-forward neural networks to learn the mapping of an input phrase to its corresponding output phrase using a bag-of-words approach. This is closely related to the model proposed by Schwenk (2012), except that their input representation of a phrase was a Bag-Of-Words (BOW). A similar encoder-decoder approach that used two RNNs was proposed by Socher et al. (2011), but their model was restricted to a monolingual setting.

More recently, an encoder-decoder model using an RNN was proposed by Auli et al. (2013), where the decoder was conditioned on a representation of either a source sentence or a source context. Kalchbrenner and Blunsom (2013) proposed a similar model that uses the concept of an encoder and decoder. They used an n-gram LM for the encoder part and a combination of inverse LM and an RNN for the decoder part. The evaluation of their model was based on rescoring the K-best list of the phrases from the SMT phrase table.

3 From SMT to PBMST

Our enhancement to SMT takes a noisy channel model as a starting point, where translation is modeled by decoding a source text, thereby eliminating the noise (e.g., adjusting lexical and syntactic divergences) to uncover the intended translation. However, as in our prior work (Ahmadnia et al., 2017), we adopt a more general, log-linear variant to accommodate an unlimited number of features and to provide a more general framework for controlling each feature's influence on the overall output. Standard probabilities are scaled to their logarithmic counterparts that are then added together, rather than multiplying, following standard logarithmic rules. The log-linear model is derived via direct modelling of the posterior probability $P(y_1^I|x_1^J)$:

$$\hat{y} = \arg\max_{y_1^I} P(y_1^I|x_1^J) \tag{1}$$

where x is a source sentence.

The PBSMT model is an example of the noisy channel approach, where the translation hypothesis y is presented as the target sentence (given x as a source sentence), and the log-linear combination of feature functions is maximized:

$$\hat{y} = \arg\max_{y_1^I} \left\{ \sum_{m=1}^{M} \lambda_m h_m(x_1^J, y_1^I) \right\} \tag{2}$$

In the log-linear model of Equation (2), λ_m corresponds to the weighting coefficients of the log-linear combination. Feature functions $h_m(x_1^J, y_1^I)$ correspond to a logarithmic scaling of the probabilities of each model. The translation process involves segmenting the source sentence into source phrases x, each of which is translated into a target phrase y, and reordering these target phrases to yield the target sentence $\hat{y}$. This model is considered superior in comparison to the noisy-channel model because of the ability to adjust the importance of individual features, thus controlling each feature's influence on the overall output.

In the PBSMT model, the TM is factored into the translation probabilities of matching phrases in the source and target sentences (Ahmadnia and Serrano, 2015). These are considered additional features in the log-linear model and are weighted accordingly to maximize the performance as measured by Bilingual Evaluation Understudy (BLEU) (Papineni et al., 2001). The neural LM Bengio et al. (2003) has become a community standard for SMT system development, i.e., neural networks have been used to rescore translation hypotheses (k-best lists). Recently, however, there has been an emerging interest in training neural networks to score the translated phrase pairs using a source-sentence representation as an additional input (Zou et al., 2013). We adopt this approach for our own PBSMT enrichment, as further detailed below.

4 Integration of LSTM Encoder-Decoder

Following Ahmadnia et al. (2018), we enhance NMT performance by estimating the conditional probability $P(y_i^I|x_j^J)$ where $(x_j, ..., x_J)$ is a source sequence and $(y_i, ..., y_I)$ is its corresponding target sequence whose length I may differ from J. The LSTM computes this conditional probability by first obtaining the fixed-dimensional representation ν of the source sequence given by the last hidden state of the LSTM, and then computing the probability of the target sequence with a standard LSTM as the neural LM formulation whose initial hidden state is set to the representation ν of the source sequence. This is specified as follows:

$$P(y_i^I|x_j^J) = \prod_{i=1}^{I} P(y_i|\nu, y_1^{i-1}) \tag{3}$$

where the $P(y_i|\nu, y_1^{i-1})$ distribution is represented with a softmax over all words in the vocabulary.

To compose the model, both the encoder and decoder are implemented employing RNNs, i.e., the encoder converts source words into a sequence of vectors, and the decoder generates target words one-by-one based on the conditional probability shown in Equation (3). Specifically, the encoder takes a sequence of source words as inputs and returns forward hidden vectors $\overrightarrow{h_j}(1 \leq j \leq J)$ of the forward-RNN:

$$\overrightarrow{h_j} = f(\overrightarrow{h_{j-1}}, x) \tag{4}$$

Similarly, backward hidden vectors $\overleftarrow{h_j}(1 \leq j \leq J)$ of the backward-RNN are obtained, in reverse order.

$$\overleftarrow{h_j} = f(\overleftarrow{h_{j-1}}, x) \tag{5}$$

These forward and backward vectors are concatenated to make source vectors $h_j(1 \leq j \leq J)$ based on Equations (4) and (5):

$$h_j = \left[\overrightarrow{h_j}; \overleftarrow{h_j}\right] \tag{6}$$

The decoder takes source vectors as inputs and returns target words, starting with the initial hidden vector h_J.[1] Target words are generated in a recurrent manner using the decoder's hidden state and an output context. The conditional output probability of a target language word y_i is defined as follows:

$$P_\theta(y_t|y_{<t}, X) = softmax\ (W_s\tilde{h}_t) \tag{7}$$

where W_s is a parameter matrix in the output layer and $\tilde{h}_t$ is a vector:

$$\tilde{h}_t = tanh(W_c[c_t; h_t]) \tag{8}$$

where W_c is a parameter matrix and $h_t = g(h_{t-1}, y_{t-1})$. Here, g is an RNN function that takes its previous state vector and previous output word as input and updates its state vector. c_t is a context vector to retrieve source inputs in the form of a weighted sum of the source vectors h_j, first taking as input the hidden state h_t at the top layer of a stacking LSTM.

The goal of the approach above is to derive a context vector c_t that captures relevant source information, thus enabling the prediction of the current target word y_t. While a variety of models may be used to derive a range of different context vectors c_t, the same subsequent steps are taken. Equation (8) defines our choice for c_t:

$$c_t = \sum_{j=1}^{S} \alpha_{ij} h_j \tag{9}$$

where α_{ij} is a weight for the j^{th} source vector at time step t to generate y_i:

$$\alpha_{ij} = \frac{exp\ (score\ (h_t, h_j))}{\sum_{j'=1}^{J} exp\ (score\ (h_t, h_{j'}))} \tag{10}$$

The score function above is calculated as follows:[2]

$$score(h_t, h_j) = h_t^T h_j \tag{11}$$

Given training data with K bilingual sentences, we train the model by maximizing the log-likelihood as follows:

$$L(\theta) = \sum_{k=1}^{K} \sum_{i=1}^{J} \log P(y_i^k | y_{<i}^k, x^k) \tag{12}$$

5 Phrase Scoring by LSTM

The centerpiece of our PBSMT enhancements is the inclusion of two stages: (1) training of a LSTM encoder-decoder on a phrase table; and (2) subsequent use of training output scores as additional features in the log-linear model when tuning the SMT decoder.

During LSTM encoder-decoder training, the frequencies of each phrase pair in the original corpora are ignored. This measure is taken to reduce the computational expense of randomly selecting phrase pairs from a large phrase table according to the frequencies. Additionally, this measure ensures that the LSTM encoder-decoder does not learn to rank each phrase pair according to its frequency of occurrence.

Regarding the latter point, one reason behind this choice is that the existing translation probability in the phrase table already reflects the frequency of phrase pair occurrence in the original corpus. With a fixed capacity of the LSTM encoder-decoder, we need to ensure that most of the capacity of the model is focused on learning linguistic regularities, i.e., distinguishing between translations, or learning the manifold[3] of translations. Once the LSTM encoder-decoder is trained, we add a new score for each phrase pair to the existing phrase table. This allows the new scores to enter into the existing tuning algorithm with minimal additional overhead in computation.

An alternative to what is described above is the replacement of the existing phrase table with the

[1] Concatenated source vector at the end.

[2] The decoder puts more attention (weights) on source vectors close to the state vector.

[3] Region of probability concentration.

LSTM encoder-decoder. In such an approach, the problem would be recast in the form of the following implementation: given a source phrase, the LSTM encoder-decoder generates a list of target phrases (Schwenk, 2012). However, in this alternative, an expensive sampling procedure must be performed repeatedly. In our approach, the only phrase pairs that are rescored are those in the phrase table.

6 Experiments and Results

Numerous large resources are available for building an English-Spanish SMT system, many of which have become community standards, used in translation tasks in annual workshops and conferences on SMT hosted by ACL, NAACL, EACL, and EMNLP (SMT 2006-2015 and WMT 2016-2019). Bilingual datasets include Europarl, News-Commentary, UN, and two crawled corpora.[4] For our purposes, we have trained the Spanish LM using about 700M words of crawled newspaper material.[5]

We select a subset of 350M words for language modeling as well as a subset of 300M words for training the LSTM encoder-decoder. We use the test set newstest2011 and newstest2012 for data selection and weight tuning with Minimum Error rate Training (MERT) (Och, 2003), and newstest2013 as our test set. Each set has more than 70K words and a single reference translation.

For training the neural networks, including our LSTM encoder-decoder, we limited the source and target vocabulary to the most frequent 10K words for both English and Spanish. This covers approximately 90% of the dataset. All the Out-Of-Vocabulary (OOV) words were mapped to a special token (<*UNK*>).

The baseline PBSMT system is built on top of Moses (Koehn et al., 2007) with default settings. Moses is an SMT decoder that enables automatic training of TMs for any language pair using a large parallel corpus. Once the model is trained, an efficient search algorithm finds the highest probability translation among the exponential number of candidates. Training the Moses decoder yields a phrase model as well as a TM which, together, support translation between source and target languages. Moses scores each phrase in the phrase table with respect to a given source sentence and produces the best-scored phrases as output.

For the training phase of SMT, we apply the following steps:

- Tokenization: Insert spaces and punctuation between words.
- True-casing: Convert initial words in each sentence to their most probable casing, to reduce data sparsity.
- Cleaning: Remove both long and empty sentences, as they may cause misalignment issues within the training pipeline.

The LM is built with the target language (in our case-study, Spanish is the target language) to ensure fluent and well-formed output. KenLM (Heafield, 2011), which comes bundled with the Moses toolkit, is used for building our LM. Also to train the TM, GIZA++ (Och and Ney, 2003) is used for word alignment. Finally, the phrases are extracted and scored as well. The generated phrase table is later used to translate test sentences that are compared to the results of the LSTM encoder-decoder.

The following steps are applied to build the NMT system with the LSTM Encoder-Decoder:

- Vocabulary building: Generate vocabulary corpus for both source and target sides.
- Corpus shuffle: Shuffle the vocabulary corpus of both source and target languages.
- Dictionary building: Create dictionary by leveraging an alignment file to replace the <*UNK*> words.

The files mentioned above are fed to the LSTM encoder for the training phase of the NMT system. The number of epochs is set to 1000. LSTM cells are used with the Adam optimizer (Kingma and Ba, 2014), also 0.001 and 512 are as error rate and batch size, respectively. The validation split of 0.1 is used for the training as well. After the training step, the LSTM decoder will be used to translate given sentences.

In order to analyze the improvement of the performance of LSTM encoder-decoder over the SMT system analyzing the scores of the phrase pairs, we did the same as (Cho et al., 2014); selecting those phrase pairs that are scored higher by the LSTM encoder-decoder compared to the

[4] These two corpora are quite noisy.

[5] Word counts refer to Spanish words, after tokenization.

SMT system with respect to a given source sentence. The scoring of the phrases provided by the LSTM encoder-decoder is similar to the scoring of the phrases provided by the phrase table of the SMT system as the quality of the translation is approximately the same.

We employ BLEU (Papineni et al., 2001) as the evaluation metric. BLEU is calculated for individual translated segments by comparing them with a dataset of reference translations. The scores, between 0 and 100 are averaged over the whole evaluation dataset to reach an estimate of the translation overall quality. Table 1 shows the results on both development set as well as test set.

Model	**BLEU-dev**	**BLEU-test**
PBSMT	30.84	28.51
NMT-baseline	31.95	30.53
LSTM	33.49	31.65

Table 1: BLEU scores computed on the development and test sets using PBSMT, NMT-baseline and LSTM systems.

LSTM encoder-decoder scores indicate in overall improvement in translation performance in terms of BLEU scores. As seen in Table 1, our LSTM encoder-decoder outperforms the NMT-baseline by 1.12 BLEU points while it outperforms the PBSMT by 3.14 BLEU points. Our LSTM encoder-decoder is able to score a pair of sequences (in terms of a conditional probability) or to generate a target sequence given a source sequence.

We evaluated the proposed model with the SMT task, using the LSTM encoder-decoder to score each phrase pair in the phrase table. Qualitatively, we showed that this model captures linguistic regularities in the phrase pairs and also that the LSTM encoder-decoder proposes well-formed target phrases. We also found that the LSTM encoder-decoder contribution is orthogonal to the existing use of neural networks in the SMT system. We conclude that further performance improvements are likely if we were to use the LSTM encoder-decoder and the neural LM together.

7 Conclusions and Future Work

In this paper, we described a PBSMT implementation within which the phrase table is generated by using an LSTM encoder-decoder, and sentences with the highest scores are selected as output. We compared the resulting translation quality of the LSTM against PBSMT and a NMT baseline, and demonstrated a BLEU score increase of up to 3.14 and 1.12, respectively. We also noticed that SMT works well for long sentences while NMT works well for short sentences.

Since NMT systems usually have to apply a certain-sized vocabulary to avoid time-consuming training and decoding, such systems suffer from OOV issues. Furthermore, NMT lacks a mechanism to guarantee/control translation of all the source words and favors short translations, resulting in fluent but inadequate translations.

Issues outlined above are fodder for future work. For example, the incorporation of SMT features into the NMT model within the log-linear framework may be a future next step to address the training/decoding issue above.

Acknowledgments

We would like to express our sincere gratitude to Dr. Michael W. Mislove (Tulane University, USA) for all his support. We also would like to acknowledge the financial support received from the School of Science and Engineering, Tulane University (USA). In addition, we are grateful to the RANLP anonymous reviewers for all their helpful comments and discussions.

Abstract

Semantic role labeling (SRL) is an important task for understanding natural languages, where the objective is to analyse propositions expressed by the verb and to identify each word that bears a semantic role. It provides an extensive dataset to enhance NLP applications such as information retrieval, machine translation, information extraction, and question answering. However, creating SRL models are difficult. Even in some languages, it is infeasible to create SRL models that have predicate-argument structure due to lack of linguistic resources. In this paper, we present our method to create an automatic Turkish PropBank by exploiting parallel data from the translated sentences of English PropBank. Experiments show that our method gives promising results.

1 Introduction

Semantic role labeling (SRL) is a well defined task that identifies semantic roles of the words in a sentence. Event characteristics and participants are simply identified by answering "Who did what to whom" questions. Having this semantic information facilitates NLP applications such as machine translation, information extraction, and question answering. After the development of statistical machine learning methods in the area of computational linguistics, learning complex linguistic knowledge has became feasible for NLP applications. Recent semantic resources specifically for SRL which provides input for developing statistical approaches are FrameNet (Fillmore et al., 2004), PropBank (Kingsbury and Palmer, 2002) (2003), (2005), (Bonial et al., 2014) and NomBank (2004). These resources enables us to understand language structure by providing a stable semantic representation.

Among these resources PropBank is a commonly used semantic resource which includes predicate - argument structure by stating the roles that each predicate can take along with the annotated corpora. It has been applied to more than 15 different languages. However, manually creating such semantic resource is labor-intensive, time-consuming and most importantly requires a professional linguistic perspective. Also limited linguistic data further blocks generating PropBank-like resources.

Various studies such as Zhuang and Zong (2010), Van der Plas et al. (2011) (2014), Kozhevnikov and Titov (2013), Akbik et al. (2015), which transfer semantic information using parallel corpus, are presented to cope with these problems. In this way, semantic information projected from a resource-rich language (English) to a language with inadequate resources and PropBank of the target language is automatically generated. Here the assumption is translated parallel sentences generally share same semantic information. Word and constituent based alignment techniques are widely used to construct mapping between source and target languages for annotation projection. Previous studies report translation divergences and language specific differences affect the quality of the projection. Filtering projections using learning methods is suggested to increase precision. In this paper, we present our study to create automatic Turkish PropBank using parallel sentences from English PropBank.

This paper is organized as follows: we first give brief information about English and Turkish PropBanks in Section 2. In Section 3, Studies for the automatic proposition bank generation are discussed. In the next section proposed methods are presented. First, we explain the annotation projection using parallel sentence trees. Then, we propose methods for aligning parallel sentence phrases not aligned with tree structure. Finally, in

Section 5, we conclude with the results.

2 PropBank

2.1 English PropBank

PropBank is the bank of propositions where predicate-argument information of the corpora is annotated and semantic roles or arguments that each verb can take are posited. It is constituted on the Penn Treebank (Marcus et al., 1993) Wall Street Journal [WSJ]. The primary goal is to label syntactic elements in a sentence with specific argument roles to standardize labels for the similar arguments such as *the window* in John broke *the window* and *the window* broke. PropBank uses conceptual labels for arguments from Arg0 to Arg5. Only Arg0 and Arg1 indicate the same roles across different verbs where Arg0 means agent or causer and Arg1 is the patient or theme. The rest of the argument roles can vary across different verbs. They can be instrument, start point, end point, beneficiary, or attribute.

Moreover, PropBank uses ArgM's as modifier labels where the role is not specific to the verb group and generalizes over the corpora such as location, temporal, purpose, or cause etc. arguments. The first version of English PropBank, named as The Original PropBank, is constructed for only verbal predicates whereas the latest version includes all syntactic realizations of event and state semantics by focusing different expressions in form of nouns, adjectives and multi-word expressions to represent complete event relations within and across sentences.

2.2 PropBank Studies for Turkish

There have been different attempts to construct Turkish PropBank in the literature. Şahin (2016a; 2016b), Şahin and Adalı (2017) report semantic role annotation of arguments in the Turkish dependency treebank. They construct PropBank by using ITU-METU-Sabancı Treebank (IMST). In these studies, frame files of Turkish PropBank are constructed and extended by utilizing crowdsourcing. 20,060 semantic roles are annotated in 5,635 sentences. The size of the resource is stated as a drawback in the study. Recently, Ak et al. (2018) construct another Turkish Proposition Bank using translated sentences of English PropBank. So far, 9,560 of 17,000 translated sentences are annotated with semantic roles. Also, framesets are created for 1,330 verbs and 1,914 verb senses. These studies constitute a base for Turkish proposition bank, but their size is limited and construction of these proposition banks consumed a lot of time.

3 Automatic PropBank Generation Studies

PropBanks are also generated automatically for resource-scarce languages by using parallel corpus. In this section, proposition bank studies for automatic generation are presented. Zhuang and Zong (2010) proposed performing SRL on parallel corpus of different languages and merging the result via a joint inference model can improve SRL results for both input languages. In the study an English and Chinese parallel corpus is used. First each predicate is processed by monolingual SRL systems separately for producing argument candidates. After the candidates formed, a Joint Inference model selects the candidate that is reasonable to the both languages. Also, a log-linear model is formulated to evaluate the consistency. This approach increased F1 scores 1.52 and 1.74 respectively for Chinese and English.

Van der Plas et al. (2011) presents cross-lingual semantic transfer from English to French. English syntactic-semantic annotations were transferred using word alignments to French language. French semantic annotations gathered from the first step were then trained with a French joint syntactic-semantic parser along with the French syntactic annotations trained separately. Joint syntactic-semantic parser is used for learning the relation between semantic and syntactic structure of the target language and reduces the errors arising from the first step. This approach reaches 4% lower than the upper bound for predicates and 9% for arguments.

Kozhevnikov (2013) shows SRL model transfer from one language to another can be achieved by using shared feature representation. Shared feature representation for language pairs is constructed based on syntactic and lexical information. Afterwards, a semantic role labeling model is trained for source language and then used for the target language. As a result SRL model of the target language is generated. Process only requires a source language model and parallel data to construct target SRL model. Approach is applied for English, French, Czech and Chinese languages.

In the next study, Van der Plas (2014) improves the labeling results with respect to the previous work

(Van der Plas et al., 2011) by building separate models for arguments and predicates. Also, problems of transferring semantic annotations using parallel corpus is examined in the paper. Token-to-token basis annotation transfer, translation shifts, and alignment errors in the previous work is replaced with a global approach that aggregates information at corpus level. Instead of using English semantic annotations of roles and predicate together with French PoS tags to generate French semantic annotations, English annotations of predicates and roles used separately to generate one predicate and one role semantic annotations separately.

Akbik *et al.* propose a two stage approach (Akbik et al., 2015). In the first stage only filtered semantic annotation is projected. Since high confidence semantic labels projected, resulting target semantic labels will be high in precision and low in recall. In the next stage, completed target language sentences sampled and a classifier is trained to add new labels to boost recall and preserve precision. Proposed system is applied on 7 different languages from 3 different language family. These languages are Chinese, Arabic, French, German, Hindi, Russian, and Spanish.

4 Methods

Among the studies for Turkish proposition bank, Ak et al. (2018) is constructed on parallel English - Turkish sentences from the Original English PropBank. We have used the corpus provided in this study to automatically generate proposition bank.

4.1 Automatic Turkish PropBank Using Parallel Sentence Trees

Penn Treebank structure offers advantages for building fully tagged data set in accordance with syntactic labels, morphological labels and parallel sentences. We used this structure to add English PropBank labels for each word in the corpus. In this manner, we exploited this parallel dataset to transfer English PropBank annotations to an automatic Turkish PropBank.

4.1.1 English PropBank Labels

Original English PropBank corpus (Palmer et al., 2004) is accessible through Linguistic Data Consortium (LDC). This resource is the initial version of the English PropBank and it only includes the relations with verbal predicates. In the newer versions adjective and noun relations are also annotated. Since we compare projection results with manually annotated corpus (Ak et al., 2018) which only contains verbal relations, we use the initial version of the English PropBank. We downloaded this dataset and imported annotations for the selected sentences. After this step 6,060 sentences among 9,558 were enhanced with the English annotations. Below in Figure 1, a sample sentence is presented. English annotations are inserted inside "englishPropbank" tags right after Turkish annotations which reside in "propbank" tags. Some of the words have only English annotation, because there is no word translated in the Turkish sentence for this node. As an example, "their" in Figure 1 has annotations in the englishPropbank tag but there is no equivalent translation in Turkish, presented as "*NONE*", so propbank tag does not exist. English tags have predicate information that annotation belongs to. "Müşterilerinin" (customers) in the same example has "ARG0$like_01#ARG1$think_01" in the englishPropbank tag which means there exists at least two words whose root is in verb form. Here the word is annotated with respect to "like" and "think" separately. We have separated multiple annotations with "#" sign and in each annotation predicate label and role is distinguished by "$" sign. In the Turkish annotation, WordNet id of the predicate was used instead of predicate label.

4.1.2 Transfering Annotations to Automatic Turkish PropBank Using Parallel Sentences

After importing English annotations, it is necessary to determine predicate(s) of the Turkish sentences. Morphological structures of the words are examined to detect predicate candidates. Words were morphologically and semantically analyzed in translated Penn TreeBank. We have used "morphologicalAnalysis" tag to check the morphological structure of the words. In Figure 1, sample morphological structure is displayed.

The word which has a verb root and verb according to last inflectional group is treated as the predicate of the sentence. Once we found a word suitable for these conditions, we gathered English PropBank annotation. If it is also labeled as predicate in English proposition bank, we got the predicate label, e.g. like_01, to find annotations with respect to this predicate. We searched for the found

predicate label in the annotations and transfered annotations matching with the predicate label. If we could not find a predicate in Turkish sentence or the corresponding English label did not contain Predicate role annotation, we skipped to the next predicate candidate.

During the transfer, a mapping was needed due to the difference between English and Turkish (Ak et al., 2018) argument labeling. English PropBank corpus has “-” sign in ArgM’s like ARGM-TMP and also some of the arguments from Arg1 to Arg5 are labeled with the prepositions such as ARG1-AT, ARG2-BY etc. We processed these differences and then transferred labels into the “propbank” tags. After analyzing Turkish sentences we found out some sentences have more than one predicate, so we continued to search for another predicate in the sentence and ran the same procedure for each predicate candidate.

4.1.3 Experiments

Annotations gathered from the English sentence were compared with the Turkish hand-annotated proposition bank (Ak et al., 2018). Comparisons were done at the word level by checking the annotations for each corpus. Among the 6,060 sentences enhanced with English PropBank roles, 848 sentences did not have a predicate in Turkish proposition bank. Therefore, in 5,212 sentences, 44,779 word annotations were compared. 31,813 annotations were transferred from English to Turkish. Results of the comparison are presented in Table 1. 19,373 words annotated with PropBank roles correctly . 6,441 annotations are incorrect, PropBank tags are different in both corpus. 5,999 annotations are undetermined, valid PropBank labels transferred from English annotations but no annotation exists in hand annotated proposition bank. Annotations to be compared is not valid so we did not include this set in the evaluation.

Transferred		Untransferred	
Correct Incorrect Undetermined	19,373 6,441 5,999	Not H.A. H.A.	8,837 4,129
Total	31,813	**Total**	12,966

Table 1: Results of the comparison between automatic proposition bank and hand annotated (H.A.) proposition bank.

When we remove undetermined 5,999 words in the comparison; 19,373 annotations from 25,814 annotations are correct, which gives us ~75% accuracy for transferred and comparable set. These 5,999 annotations may be hand-annotated and recompared for validity of the transferred annotations.

In Table 2, we present occurrences of erroneous annotation transfers. Only top ten occurrences are presented. Arg0-Arg1 transfers are the most occurred incorrect transfers 1,843 among 6,441 incorrect annotations. Second most occurred error is in Arg1-Arg2 labels. Errors in Arg0-Arg1 and Arg1-Arg2 labels forms ~44% of the transfer errors.

On the other hand, when we look at the all word results, 12,966 roles were not transferred. If we take these untransferred instances as incorrect; 19,373 annotations out of 38,780 annotation are true and the accuracy drops to ~50%. However, 8,837 of untransferred annotation are not an-

Different Arguments	# of Occurrence
ARG0-ARG1	1,843

ARG1-ARGMMNR	186
ARG1-ARGMTMP	160
ARG1-ARGMLOC	148

Table 2: Counts of different argument annotations between transferred annotations and hand annotations.

notated in the hand-annotated corpus. Only 4,129 are valid PropBank arguments. In this respect, if we count only valid arguments for untransferred annotations, accuracy is ~65%.

4.2 Automatic Turkish PropBank Using Parallel Sentence Phrases

In the previous method, annotation projection using parallel sentence trees is discussed. However, finding such a resource in a special format is difficult especially if you are working with a resource-scarce language. Most of the time creating a formatted parallel resource like tree structured sentences complicates translation procedure. In this section, automatic generation with translated sentences without tree structure will be examined.

4.2.1 Phrase Sentence Structure

For the phrase sentences, English sentences re-translated without tree structure. Prior the annotation projection, linguists in the team annotated phrase sentences and populated “propbank” and “shallowParse” tags so that we check the correctness after the annotation transfer. 6,511 sentences among 9,557 phrase sentences have predicate according to hand annotations for newly translated sentences. However, only 5,259 sentences have English PropBank annotation, so we take this set to transfer annotations. As you remember, the same number in the previous section was 5,212. Here translation and annotation differences change the processed sentence count.

Tag structure of Penn Treebank is preserved to simplify morphologic and semantic analysis requirements during the annotation transfer. In Figure 2, sample phrase sentence can be seen. Unlikely Figure 1, syntactic tags which indicate tree structure are not included. We used original tree formatted English sentence to extract English propbank annotations. However, since the target sentence do not have tree structure definition we used other word alignment methods to determine annotation projection.

4.2.2 Semantic Alignment Using WordNet

In order to transfer annotations, first we tried to match predicates of English sentence and Turkish translation. Again we utilize “morphological-Analysis” tags to determine predicate candidates in the phrase sentence. Words which have a verb root and verb according to last inflectional group is treated as the predicate candidates of the sentence. Once we found all the words ensuring these conditions, we gathered all English PropBank annotation labels which are tagged as “Predicate” in ‘englishPropbank” tag. To align predicates in different languages, we tried to exploit WordNet’s (Ehsani et al., 2018) interlingual mapping capabilities. For each predicate in English sentence we find Turkish translation by searching English synset id in the WordNet. English synset id is located in englishSemantics tags as in the sample in Figure 1. If there exists any translation in the WordNet, we take Turkish synset id and search it in the predicate candidates found for phrase sentence. Whenever translation found, we align predicates and try to transfer annotation with respect to aligned English label. For annotation transfer of other arguments we again align words using WordNet’s interlingual mapping. An example WordNet record is presented in Figure 3.

First results gathered with only WordNet mapping were very low. True annotation count is 2,195 among 29,168 annotations tagged manually which yields 7.53%. However, transferred false annotation count is only 342. System heavily relies on semantic annotations for both English and Turkish words where some of the words failed to have semantic annotation. We look deeper into dataset provided by Ak et al. (2018), 11,006 English words do not have semantic annotation so we failed to match these words with Turkish counterparts.

Some words are not annotated semantically such as, proper nouns, time, date, numbers, ordinal numbers, percentiles, fractional numbers, number intervals, and reel numbers. Most of these words are same in Turkish translation so we matched English and Turkish words by string match. For example if a sentence contains proper

noun “Dow Jones”, the same string also exists in the Turkish translation too. However, it may take additional suffixes, so we only check whether English words starts with Turkish root word. Also, translational differences are encountered like decimal separator in English is “.” where some Turkish translations “,” is used. We replace this differences by looking whether the first morphological tag is “NUM”. After these tunings, we rerun the procedure and get 2,680 true and 531 false annotations which increases true annotations to 9.19%. Another problem is erroneous semantic annotations. If English and Turkish semantic annotation is not right, alignment is not possible. Even in the best scenario where both word is annotated, if WordNet mapping is incomplete, an alignment can not be established.

As an alternative we decided to reinforce annotation transfer by using constituent boundaries identified with shallowParse tags by our linguist team mates. Example of shallowParse tags can be seen in Figure 2. Prior to the annotation transfer, phrase sentences are annotated for constituent boundaries which can be used to group argument roles in the sentence. After transferring annotations with respect to semantic annotations, we run another method over phrase sentences which calculates maximum argument types for each constituent and tags any untagged word with the calculated max argument role within the constituent boundary. This procedure further enhance true annotations to 4,255 but also increase false annotations to 1,202. After constituent boundary calculation, correct annotation transfer percent is increased to ~14.59%. In Figure 4 annotation of the sentence 7076.train is presented. Untagged words in “Özne” and “Zarf Tümleci” constituent boundaries are tagged with the found argument role within the boundary. Note that, we did not use the constituent types but we use boundaries of the constituents.

4.2.3 Word Alignment Using IBM Alignment Models

Word alignment through semantic relation requires fair semantic annotation for both languages and also sufficient semantic mapping between languages. We search different word alignment methods between English and Turkish sentences. IBM

alignment models offer solution to our word alignment problem. IBM Models are mainly used for statistical machine translation to train a translation model and an alignment model. IBM Model 1 (Brown et al., 1993) is the primary word alignment model offered by IBM. It is widely used for solving word alignments while working with parallel corpora. It is a generative probabilistic model that calculates probabilities for each word alignment from source sentence to target sentence. It takes a corpus of paired sentences from two languages as training data. These paired sentences are possible translation of the sentences from source language to target. With this training corpus, parameters of the model estimated using EM (expectation maximization). IBM Model 2 has an additional model for alignment and introduce alignment distortion parameters. We decided to use IBM model 1 & 2 to establish word alignments instead of WordNet's interligual mapping. We input sentence pairs and gather alignment probabilities for each English word to Turkish equivalent. 244,024 word pairs are taken as output where for each English word, 10 most probable Turkish words are listed. Alignment probabilities for word "Reserve" is presented in Table 3 and 4 for IBM Model 1 and 2 respectively.

After gathering alignment data, we transfer annotations to phrase sentences from English PropBank labels in the tree structured sentences. All words tagged with "PREDICATE" tag in English sentence are stored into a map which includes predicate label from the "englishPropbank" tag *e.g.* "like_01" and English word from the "english" tag *e.g.* "like". Then we search alignments for each found English predicate. Here we observed that aligned Turkish words may not occur in the phrase sentence as they found in the alignment table. Words may include additional suffixes, so we use Finite State Machine(FSM) morphological analyzer available in our NLP Toolkit of Ak et al. (2018) to extract roots of the aligned Turkish words. Since we have several possible morphological parse for each aligned word, we created an array for possible roots. In parallel, we found predicate candidates from the phrase sentence as we stated in the previous methods. Then we tried to match aligned words and possible roots with the found predicate candidates. If there exists a predicate candidate that matches with the aligned word or one of its roots in the array, we tagged the candidate as "PREDICATE" and update map as predicate label and synset id of Turkish predicate.

After finishing predicate discovery, we transfer annotations for found predicates. To do that we look for the annotations with respect to the predicate labels in the map. For each record in map we took the predicate label and corresponding Turkish synset id. When we found an annotation with this predicate label, first we extract the argument and try to find aligned word for the processed English word. For the alignment again we find the most probable word from the table and use FSM morphological analyzer to extract possible roots. Then for each word we search Turkish sentence to match words with aligned word or possible roots extracted. If matched Turkish words do not have argument annotation, we transfer argument with the synset id found in the map record.

As we discuss in the previous annotation transfer procedure 4.2.2, some of the English words such as proper nouns, time, date, numbers, ordinal numbers, percentiles, fractional numbers, number intervals, and reel numbers stay same or take additional suffixes in Turkish translation. So we include the same method used for matching these words. In a case words are not aligned with the information from alignment table, and a valid annotation present in English word, we search exact string match or any word starts with the root of English word in the Turkish sentence.

We run our procedure with IBM Model 1 & 2 separately. We add reinforce step previously used in Section 4.2.2. Unlikely previous attempts, after examining language structure we decided to add rules to tag any untagged words after annotation transfer. We observed argument types affect noun inflections, for some argument types the last word in constituent boundary is taking certain suffixes. So first we find untagged word and select the last word in its constituent boundary. Since we run reinforce step beforehand, only untagged constituents exists in the sentence. In this respect, we set the following rules to determine argument annotation for untransfered words;

- For nouns and proper nouns:
  - Have no suffix then ARG0
  - Last morpheme tag is "ACCUSATIVE" (-(y)H, -nH) or "DATIVE" (-(y)A, -nA) then ARG1
  - Last morpheme tag is "LOCATIVE" (-DA, -nDA) or "ABLATIVE" (-DAn, -nDAn) then ARGMLOC
  - Last morpheme tag is "INSTRUMENTAL" (-(y)lA) then ARG2
- For all word types
  - Morphological parse contains date, time then ARGMTMP
  - Morphological parse contains cardinal number, fraction, percent, range, real number, ordinal number then ARGMEXT

We use these rules to tag any untagged word. After applying these rules annotation transfer result is as shown in Table 5 and 6. Results show that rules applied slightly change the correct annotations. For model 1 rules output much more correct annotation than the incorrect ones whereas in model 2 the number of correct and incorrect annotations gathered are nearly same. However, precision for model 1 is improved to 59.44% and for model 2 precision become 59.86%.

5 Conclusion

We proposed methods to generate automatic Turkish proposition bank by transferring cross-language semantic information. Using the parallelism with English proposition bank gives us an opportunity to create a proposition bank in a short time with less effort. We currently have 64% accuracy with the hand-annotated proposition bank (Ak et al., 2018) for parallel sentence trees. When we consider only transferred annotations, accuracy is rising to ~75%. We also present annotation projection to phrase sentences using WordNet and IBM alignment models. WordNet alignment heavily relies on semantic annotations, correct annotations transferred after this method is ~14.59%. However, 4,255 correct argument roles are transferred among 5,457 arguments which means 79% of the transferred roles are correct. To increase annotation transfer for phrase sentences, we have also proposed alignment with IBM Model 1 and 2. Both models yields ~60% correct annotations. Annotations transferred with these methods can provide a basis for proposition bank creation in resource-scarce languages. Annotations may then be checked quickly by the annotators and proposition bank reach the final state.

Multilingual Sentence-Level Bias Detection in Wikipedia

Abstract

We propose a multilingual method for the extraction of biased sentences from Wikipedia, and use it to create corpora in Bulgarian, French and English. Sifting through the revision history of the articles that at some point had been considered biased and later corrected, we retrieve the last tagged and the first untagged revisions as the before/after snapshots of what was deemed a violation of Wikipedia's neutral point of view policy. We extract the sentences that were removed or rewritten in that edit. The approach yields sufficient data even in the case of relatively small Wikipedias, such as the Bulgarian one, where 62k articles produced 5k biased sentences. We evaluate our method by manually annotating 520 sentences for Bulgarian and French, and 744 for English. We assess the level of noise and analyze its sources. Finally, we exploit the data with well-known classification methods to detect biased sentences. Code and datasets are hosted at https://github.com/crim-ca/wiki-bias.

1 Introduction

Our goal is to automatically detect neutral point of view (NPOV) violations at the sentence level with a procedure replicable in multiple languages. Sentence-level bias detection is a type of sentiment analysis, closely related to subjectivity detection (Riloff and Wiebe, 2003; Wiebe and Riloff, 2005; Wilson and Raaijmakers, 2008; Murray and Carenini, 2009; Lin et al., 2011; Al Khatib et al., 2012), where an opinion is considered subjective, and a fact, objective. Yet, as far as bias in writing is concerned, both subjective opinions and objective fact reporting (cf. §5) may, in some cases, be sources of impartiality. The importance of the context is one of the main difficulties in detecting bias at the sentence level. Some types of point-of-view bias are equally challenging for humans to detect. Partisanship in editorials, for example, tends to go unnoticed when in line with the reader's own ideas and beliefs (Yano et al., 2010). A further complication arises from the ambiguity of the term bias, which stands for a lack of fairness or neutrality in realms as varied as human cognition (Tversky and Kahneman, 1974), society (Ross et al., 1977), media (Entman, 2007), internet (Baeza-Yates, 2018; Pitoura et al., 2018) or statistical models and algorithms (O'Neil, 2016; Shadowen, 2019), to name a few. With so many different types of bias and their varying definitions, it is not trivial to set the scope of a bias-detection study.

The majority of the work on this task is performed on news articles (Hirning et al., 2017; Baly et al., 2018; Bellows, 2018) and political blogs (Yano et al., 2010; Iyyer et al., 2014) rather than Wikipedia, because of the relative scarcity of examples an encyclopedia provides. Yet, unlike alternative data sources, Wikipedia comes with a definition of bias outlined in its content policy for neutrality of point of view (NPOV). The core guidelines in NPOV are to: (1) avoid stating opinions as facts, (2) avoid stating seriously contested assertions as facts, (3) avoid stating facts as opinions, (4) prefer nonjudgemental language, and (5) indicate the relative prominence of opposing views. In addition, Wikipedia provides lists of bias-inducing words to avoid,[1] such as positively loaded language (puffery) in the form of *peacock* words (e.g., *best, great, iconic*); unsupported attributions, or *weasel words* (e.g., *some people say,*

[1] https://en.wikipedia.org/wiki/Wikipedia:Manual_of_Style/Words_to_watch

it is believed, science says); uncertainty markers, known as *hedges* (e.g., *very, much, a bit, often, approximately*), editorializing (e.g., *without a doubt, arguably, however*) and more. When an article is considered biased, an editor can flag it by adding a tag such as {{POV}} to its source, which displays a disputed neutrality warning banner on the page. These explicit guidelines (and the editors who apply them) help reduce biased language in Wikipedia over time through a continuous process of collaborative content revision (Pavalanathan et al., 2018). Still, new instances of bias are introduced just as often as old ones are overlooked because of humans' inherent difficulty with subtle expressions of point-of-view partiality. Recasens et al. (2013) showed that when presented with a biased sentence from Wikipedia, annotators manage to correctly identify the loaded word in only 37% of the cases.

2 Related Work

Bias detection approaches vary primarily in terms of corpora, vectorization methods, and classification algorithms. We present a review of the related literature along this division.

2.1 Corpora

Among those who tackle NPOV violations in Wikipedia, some rely on available datasets (Vincze, 2013), others perform manual annotation (Hube and Fetahu, 2018; Ganter and Strube, 2009; Herzig et al., 2011; Al Khatib et al., 2012), still others attempt to automatically extract labeled examples (Ganter and Strube, 2009; Recasens et al., 2013; Hube and Fetahu, 2018). Our approach is in line with the latter.

Using existing corpora, while being the cheapest method, predetermines which types of bias will be explored and in which languages. Vincze (2013) uses WikiWeasel, the Wikipedia subset of the CoNLL-2010 Shared Task corpora (Farkas et al., 2010) to study discourse-level uncertainty by manually annotating linguistic cues for three overt manifestations of bias: weasel, hedge and peacock words. Ganter and Strube (2009) focus on detecting hedges in a corpus of 1000 extracted sentences tagged with {{weasel}}, Bhosale et al. (2013) try to detect promotional content, while Kuang and Davison (2016) train their model on the English corpus of Recasens et al. (2013).

Manual annotation ensures higher quality but is too costly for large multilingual datasets. Hube and Fetahu (2018) learn to detect bias in Wikipedia on a manually annotated corpus of sentences from the inherently biased Conservapedia, with a precision of 0.74. When tested on an unlabeled dataset extracted from Wikipedia however, the classifier obtains a precision of 0.66 for the sentences classified with a certainty over 0.8.

Recasens et al. (2013) first propose a heuristic to automatically build a labeled corpus with biased sentences. Out of all revisions of NPOV-tagged articles, they identify the bias-driven edits based on the comments the editors left at commit. Although reliable, this method yields a fairly small set of examples for English (2,235 sentences) and none for smaller Wikipedias, first because of its dependence on revision comments (which are optional), and second, because it limits the examples to bias-driven edits containing five or fewer words.

2.2 Vectorization

As for data vectorization, previous work on bias detection relies either on features from pre-trained language models, custom feature-engineering or both. Bellows (2018) finds no significant difference in performance for classifiers trained on Word2vec, GloVe, or fastText representations. Several studies (Recasens et al., 2013; Ganter and Strube, 2009; Hube and Fetahu, 2018) employ multiple lexical, contextual, and linguistic features which, while boosting performance, remain dependant on handcrafted word lists, specialized lexical resources such as SentiWordNet (Baccianella et al., 2010), subjClue (Gitari et al., 2015), etc., and grammatical parsers that often cover only English. Yano et al. (2010) combine word vector representations from GloVe (as semantic features), 32 boolean lexicon-based features from Recasens et al. (2013) and document vector representations (as contextual features) to distinguish between different uses of the same word. They find that when training a logistic regression classifier, the semantic features alone perform better than both the contextual and the combination of the two.

2.3 Classification Algorithms

Also performing bias classification at the sentence level, Vincze (2013) detects sentences containing weasel, hedge or peacock words from the WikiWeasel corpus with a precision of 0.74, recall of 0.69 and F_1 of 0.71, by using a dictionary lookup approach. Bellows (2018) reports an accuracy of

0.68 on a corpus of 2,143 biased sentences from news articles, vectorized using tf-idf and classified with a Mutlinomial Naive Bayes, and an accuracy of 0.77 for a CNN and 0.78 with a RNN. Finally, Hube and Fetahu (2018) achieve an F_1 measure of 0.70 using Random Forest on 686 manually annotated sentences from Conservapedia.

3 Dataset Description

We propose a procedure to semi-automatically derive a labeled corpus of biased sentences from a Wikipedia dump in any language, which, for this paper, we applied to the April 2019 dumps[2] for Bulgarian, French and English.

3.1 Tagset Curation

First, we manually compile a list of NPOV-related tags for each of the target languages using the names of relevant Wikipedia maintenance templates[3] (`{{POV}}`, `{{NPOV}}`, `{{neutral point of view}}`, `{{peacock}}`, etc.).

Most tags, however, vary in spelling, not only based on the context (e.g., inline or at the beginning of an article), but also because of the open and collaborative nature of Wikipedia. Table 1 shows the sixteen most frequent "weasel" tag variations, only five of which (in bold) are documented on Wikipedia. While the official tag is the most frequently used, the unofficial variations account for almost 35% of the most frequent ways to tag a page containing weasel words.

While it may be effortless for human editors to interpret the meaning of these variations, it is not trivial to automatically identify all NPOV-related ones. Simply extracting all the tags starting with the official form of "weasel" yields unrelated tags such as "weasel, back-striped" (an animal) or "weasel, ben" (a punk singer). For that reason, we automatically compiled exhaustive tag frequency lists in each language, and then manually selected the relevant variations of each.

3.2 Revision Extraction

We look for occurrences of the selected tags across all revisions of each page, going forward from the oldest one. When a biased revision is found, we follow its evolution until the POV tag disappears, at which point we assume the problematic content has been either rewritten or edited out. Next, we extract the tag together with the pair of adjacent revisions, where the older one is tagged as biased and the newer one is not. We opted for this diachronic retrieval method, rather than relying on the repertoire of articles in Wikipedia's "NPOV dispute" section (Herzig et al., 2011; Recasens et al., 2013) since the latter only features currently tagged articles, while our method digs NPOV violations from revision histories.

Tag	Count	Ratio
weasel	201,092	0.5748
weasel-inline	89,352	0.2554
weasel words	21,755	0.0622
weasel word	16,991	0.0486
weasel section	3,954	0.0113
weasel-section	3,743	0.0107
weasel inline	2,631	0.0075
weaselinline	2,213	0.0063
weasel-words	2,176	0.0062
weasel-word	2,102	0.0060
weaselword	1,967	0.0056
weasel-name	956	0.0027
weaselwords	503	0.0014
weasel_section	225	0.0007
weasel_words	124	0.0004
weasel_word	80	0.0002

Table 1: "Weasel" tag variation in English

3.3 Processing and Filtering

Each of these revision pairs undergoes a cleaning process using regular expressions to strip as much of the Wikipedia markup, links, and page references as possible, while preserving visible text and essential punctuation. At this point, we proceed to tokenize the text and split it into sentences using the rule-based tokenizer and sentencizer methods of spaCy (Honnibal and Montani, 2017), whose 2.1.3 version supports 51 languages. Finally, we replace all numbers with a special token (`numtkn`), strip all remaining punctuation, and convert everything to lowercase.

Our algorithm also extracts revision pairs where the second member was the subject of a redirect or vandalism, which we filter out. We then compare the revisions to obtain the lists of deleted and inserted sentences for each pair. In about 20% of the cases, the difference consists in simply deleting the NPOV tag, which we believe is an artifact of editorial wars (Sumi et al., 2011; Yasseri et al.,

[2] https://dumps.wikimedia.org

[3] For English, see https://en.wikipedia.org/wiki/Category:Neutrality_templates

2012), given the contentiousness of most NPOV-flagged topics. Another 20% of the revision differences we set aside are punctuation or case-related.

We further clear the dataset from outliers (mostly acts of vandalism) by removing those with more than 400 edited sentences. Finally, we exclude revision pairs with minor differences (character-based Levenshtein distance of 1), which are spelling corrections rather than bias resolution. Table 2 gives the number of initial, final and excluded revisions per language.

Revision pairs	BG	FR	EN
initial number	1,021	46,331	197,953
tag removal	–257	–10,255	–61,397
punct./case	–194	–5,967	–44,345
redir./vandalism	–56	–1,524	–17,154
deletions only	–33	–2,740	–11,331
insertions only	–28	–2,819	–2,938
spelling	–3	–136	–400
outliers	–2	–153	–609
Total pairs	448	22,737	59,779

Table 2: Number of revision pairs per language

To build the final corpora, we take all removed and added sentences (under 300 tokens) from the pre-filtered revisions for the positive and negative classes respectively. We balance the dataset by using unchanged sentences (also treated as negatives), as shown in Table 3.

Sentences	BG	FR	EN
Removed	4,756	105,939	800,191
Added	3,288	72,183	494,993
Unchanged	1,468	33,756	305,198
Total	9,512	211,878	1,600,382

Table 3: Number of sentences per language

4 Dataset Evaluation

Once we have collected the tagged/untagged revision pairs for each language (as per §3.2), we evaluate their potential for automatic bias detection. Our intuition is that the sentences that were removed together with the NPOV tag in the same edit likely contain some form of bias. Insertions, on the other hand, come with little guarantee of neutrality, so we focus on the removed sentences.

4.1 Protocol

For each language, we distribute the tagged/ untagged revision pairs into four bins, based on the number of sentences that were removed in the edit (bin 1: 1 or 2 sentences removed, bin 2: 3–6, bin 3: 7–15, bin 4: 16 or more; these values were determined empirically to yield balanced bins in terms of revision pairs). Each annotator labeled 296 randomly picked sentences for a given language, distributed equally across the four bins. 72 of these sentences (24%) were shared by all annotators working on the same language, while the remaining 224 were labeled by a single annotator (cf. Table 4), thus allowing us to annotate more sentences while maintaining enough overlap to measure inter-annotator agreement (IAA). The Bulgarian sample was annotated by two native speakers, English by three with near-native proficiency, and French by two natives.

Lang	All	Ann1	Ann2	Ann3	Total
BG	72	224	224	—	520
FR	72	224	224	—	520
EN	72	224	224	224	744

Table 4: Number of sentences per annotator

The annotators were given identical instructions. For each sentence in their sample, they had to say whether it violated any of the NPOV principles stated in §1. The annotators were always presented with the full revision pair, so they had access to the context.

4.2 Dataset Evaluation Results

Since we had three annotators for English, we used Fleiss' κ to measure IAA. Tables 5 and 6 give the rate of positive annotations and IAA per language and per bin. On average, across all languages and bins, the annotators found 48% of positives in their samples, with an overall IAA of 0.41. Leaving out BG bin 4 (the only one with a negative κ), we get an average positive rate of 47% (std = 0.08) and an average κ value of 0.46 (std = 0.14). Our IAA coefficients are consistent with Vincze (2013), who had 200 English Wikipedia articles annotated by two linguists for weasel, peacock and hedge words, with IAA rates of 0.48, 0.45 and 0.46, respectively, and higher than the 0.35 reported by Hube and Fetahu (2018), who crowdsourced the annotation of sentences from Conservapedia into biased and unbiased. Identifying such phenomena is thus not trivial but reasonable agreement can be expected.

Bin	BG	EN	FR	avg	std
1	0.34	0.51	0.47	0.44	0.07
2	0.64	0.45	0.45	0.52	0.09
3	0.63	0.45	0.38	0.48	0.11
4	0.63	0.52	0.34	0.50	0.12
avg	0.56	0.48	0.41	0.48	0.06
std	0.13	0.03	0.05	0.03	0.10

Table 5: Positives in annotations

Bin	BG	EN	FR	avg	std

std	0.23	0.11	0.10	0.08	0.21

Table 6: Inter-annotator agreement (Fleiss' κ)

About half of the annotated sentences turn out to be neutral. Below, we discuss the sources of the noise we have observed in our dataset (including the added sentences).

4.3 Sources of Noise

We identified two types of noise: pipeline-related and human-related. Pipeline-related noise is either noise introduced at the pre-processing phase (e.g., due to inconsistent sentence segmentation) or noise that remains despite our filtering and cleaning efforts (e.g., NPOV-unrelated edits longer than one character, differences resulting from the introduction of an infobox, differences consisting in changing the spelling of numbers).

Human editor-related noise comes from the data itself and stems from the behaviour of Wikipedia's editors. It includes edits which introduce bias (often intentionally, as in (1) below), vandalism, corrections of factual mistakes unrelated to bias, replacing bias with another bias (cf. (2)), and collateral edits, i.e., neutral sentences neighbouring biased ones indirectly targeted by a large-scope edit (cf. (3)). Below are some examples.

(1) a. *(before)* cardinal health inc is a holding company

b. *(after)* cardinal health is a healthcare company **dedicated to making healthcare safer and more productive**

(2) a. *(before)* its support is low only in the cholla province which has for nearly numtkn years supported kim dae jung a well known **leftist** politician born in that province who also served as president of south korea numtkn numtkn

b. *(after)* its support is low only in the jeolla province which has for nearly numtkn years supported kim dae jung a well known **progressive** politician born in that province who also served as president of south korea numtkn numtkn

(3) a. *(before)* from the numtkn th century confucianism was losing its influence on vietnamese society monetary economy began to develop but unfortunately in negative ways

b. *(after)* from the numtkn th century confucianism was losing its influence on vietnamese society and a monetary economy began to develop

5 Expressions of Bias

The manual annotation also highlighted the variety of bias expression. Previously, Recasens et al. (2013) had identified two major classes: epistemological and framing bias (subjective intensifiers and one-sided terms), where they considered the first one to group more implicit expressions such as factive and assertive verbs, entailment and hedges. Based on their work and Wikipedia's Manual of Style, we present biased examples from our corpus[4] and discuss them in terms of the overt/ covert nature of the biased statement, its length (one or more words), and its level of ambiguity.

Subjective intensifiers are mostly expressed through single-word verbal and nominal modifiers (adverbs and adjectives) as in (4) and (5), but may also take the form of superlatives or quantifiers. They explicitly undermine tone neutrality by introducing overstatements and exaggerations (6).

(4) a. *(before)* some prominent liberals including scott reid were **strongly** critical of volpe s response

b. *(after)* some prominent liberals including scott reid **criticized** volpe s response

(5) *(before)* he is **truly** one of the greatest americans

(6) a. *(before)* this is an **absurd** statement because the cavalry of any age is designed first and foremost to run over the enemy and separate them as to make

[4] Examples are taken from the English evaluation subsets, where sentences are in lowercase, stripped of punctuation and numbers are replaced by `numtkn`.

them far more vulnerable to being overwhelmed and overrun

b. *(after)* this is **wrong** because the cavalry of any age is designed first and foremost to run over the enemy and separate them as to make them far more vulnerable to being overwhelmed and overrun

Clichés and jargon tend to be non-ambiguous but introduce low-frequency words in the corpus, as a result of being discouraged by Wikipedia.

(7) *(before)* x force was **concocted** by illustrator rob liefeld who started **penciling** the new mutants comic book in numtkn

Describing or analyzing rather than reporting events is a form of partiality harder to model, as it may not necessarily contain explicitly proscribed vocabulary.

(8) *(before)* he was a former club rugby and an opening batsman in club cricket but did not have the ability to make it all the way to the top level these two sports have become his particular area of expertise however he is very knowledgable on all sports that are played

(9) *(before)* however the most important consequence of the battle was that president lincoln was able to sieze upon the victory claim it as a strategic victory for the north and release his emancipation proclamation

Active voice may be used in cases like (10) to stress the agency of a participant in a situation, alongside a positively loaded support verb.

(10) a. *(before)* the united states department of justice indicted the company but **amway secured an acquittal**

b. *(after)* the united states department of justice indicted the company but **amway were acquitted**

To state a fact as an opinion is to use a weasel word to undermine the fact (11) or hide its source. While previous research shows the success of word-lists in detecting this particular type of bias (Recasens et al., 2013; Ganter and Strube, 2009), Vincze (2013) warns against the ambiguity of many of them. For example, *most* can be a weasel word (*Most agree that...*), a hedge (*most of his time*), a peacock (*the most touristic beach*) or neutral (*He did the most he could.*)

(11) a. *(before)* in the first invasion operation litani in numtkn the israeli military and south lebanon army sla occupied a narrow strip of land **ostensibly** as a security zone

b. *(after)* in the first operation litani in numtkn the israel defense forces and south lebanon army occupied a narrow strip of land **described** as the security zone

To state an opinion as a fact may be done with the use of an adverb (12) or an omission (13).

(12) a. *(before)* **in fact** the need for fast and secure fund transfers is growing and in the next year instant payments will quickly become the new normal for electronic fund transfers

b. *(after)* it is predicted that in the next year instant payments will become the standard for electronic fund transfers

(13) a. *(before)* in numtkn the journal won the praise of fascist leaders

b. *(after)* **there are some authors who retain** that the journal won the praise of fascist leaders

Intentional vagueness or the omission of factual information (14), is arguably the hardest type of bias expression to detect not only for machines, which are expected to recognize the lack of data as an informative feature, but also for humans, since filling factual gaps requires a fair amount of domain-specific knowledge.

(14) a. *(before)* as of numtkn it is the ethnic minority party in romania with representation in the romanian parliament

b. *(after)* as of numtkn it is the ethnic minority party in romania with representation in the romanian parliament **and is part of the governing coalition along with the justice and truth alliance and the conservatives**

6 Classification Experiments

The goal of the experiments is to assess the usefulness of the dataset in a sentence classification task. Our hypothesis is that having similar examples in both the biased and non-biased classes would help to single out discriminative words targeted by the NPOV-related edits.

Each dataset was split into a training set (80%), a development set (10%) on which we tuned the parameters, and a test set (10%) on which we ran a single evaluation with the best parameters.

6.1 Embeddings

We used fastText's classification function (Joulin et al., 2017), which implements a multinomial logistic regression algorithm on top of pretrained word embeddings. It uses word and character level embeddings to predict the class value of an instance. The parameter optimization was done by altering values for epoch (5, 10, 25), learning rate (0.1, 0.01, 0.05), word n-grams (1 to 5), minimum count (1–5), embedding dimensions (100, 300), loss function (softmax, ns, hs), minimum character level n-gram size (2, 3), using pretrained vectors or not, and learning rate update rate (50, 100).

When applying fastText's pretrained vectors,[5] we obtained comparable results for English and French without any significant gain, and with lower performance on Bulgarian. Thus, the final model chosen for its overall best performance across all three languages was trained without the use of an additional language model. The best performing values were then tried out on the test set.

6.2 Bag-of-Words Vectorization

We also experimented with classic bag-of-word vectorization with the stochastic gradient descent (SGD) (LeCun et al., 1998) and logistic regression (Hosmer and Lemeshow, 2000) algorithms. Each algorithm was run with the same settings on all three datasets to get the best average overall performances for precision, recall and F_1 measure. Parameter optimization was done using a grid search. Stop word lists were used for each language, which is the only language-specific aspect of the experiment.

The optimization for SGD ran 72 permutations with the following parameters:

- Bag-of-word n-gram size: unigrams only, unigrams and bigrams, unigrams to trigrams.
- Bag-of-word size: 100, 150, 300, 500, 1,000 and 3,000.
- Use idf reweighting or not.
- α value: 0.01, 0.001.

All the other parameters were set to their default values.[6] For logistic regression, 504 permutations were tested using the following settings:

- Same BOW n-gram size and BOW size and value type as SGD.
- C: 1.0e–3, 1.0e–2, 1.0e–1, 1.0e0, 1.0e+1, 1.0e+2 and 1.0e+3.
- Solver: sag, saga.

Using the training and development sets to run the grid search optimization on all three languages, the average F_1 measure was used to see which parameter values offered the best average performance across the board. The selected values were then used to run the same algorithm once on each language's training and test sets.

7 Results and Discussion

Table 7 shows the results for the experiments detailed in §6 for the SGD, fastText and logistic regression (LR) algorithms. For each performance measure, dataset section, algorithm and language, we provide results with respect to the *biased* class. The highest performance obtained on the test dataset of each language is in bold.

For the LR algorithm, the best performances were obtained using a C value of 0.001 with the saga solver using a unigram model of 100 features without inverse document frequency (idf) reweighting. The best parameters for the SGD used a model of unigrams to trigrams, with an α of 0.001 and idf reweighting. For fastText, the best performing parameter set used the default values[7] and a minimum of 5 occurrences per token.

Overall, the similar results between the development and test sets for each algorithm confirm that they did not overfit. Furthermore, all three measures have relatively low variance across languages, except for recall with SGD, which is considerably lower for Bulgarian (also impacting F_1) than for the other two languages.

We observe that FastText's vectorization and classification methods deliver higher precision upon larger datasets, but SGD and LR assure a much higher recall regardless of the number of examples.

While relatively better, the SGD performance level on the test set leaves room for improvement. This is likely due to the noise level in the sentences labeled as biased, which count many non-biased examples (see §4.2). The results are equally likely affected by the lexical and contextual ambiguity of the biased expressions, as discussed in §5. However, we do observe comparable best performance

Table 7: Results for each language, dataset and classification method for the biased class

across corpora of varying size and languages from different families.

On the test set, our best overall average F_1 measure ranged between 0.56 and 0.62. This is lower than Vincze (2013)'s 0.71 or Hube and Fetahu (2018)'s 0.70, but our approach uses a large corpus, automatically derived from Wikipedia in any language with minimal language-specific input, applied to sentence-level bias detection, while Vincze (2013) used a monolingual, dictionary-based approach, and Hube and Fetahu (2018) relied on language-specific resources to extract multiple lexical and grammatical features. Our results set the baseline for sentence-level bias detection across the three languages of this corpus. Higher performance for a specific language may be achieved by a reconfiguration of the parameters or by the introduction of additional features.

8 Conclusion and Future Work

We presented a semi-automatic method to extract biased sentences from Wikipedia in Bulgarian, French and English. As this method does not rely on language-specific features, apart from the NPOV tag list and a stop word list, it can be easily applied to Wikipedia archives in other languages. It relies on the tags added by human editors in the articles that they considered biased. We retrieve the last tagged revision and the untagged revision following it and regard them respectively as biased and unbiased. By comparing the revisions, we get the lists of removed and added sentences.

We manually annotated 1,784 of the removed sentences, for all three languages combined, and found that only about half of them were actually biased. An average Fleiss' κ of 0.41 (0.46 if ignoring an outlier), consistent with the literature, indicates that the task is not trivial even for humans.

Using our corpora, we tested three classification algorithms: bag-of-word vectorization with SGD, fastText, and logistic regression.

In future work, we would like to improve the quality of the dataset by addressing issues uncovered during the human evaluation, such as incoherent sentence segmentation, enumerations, minor edits and remaining noise. Another conceivable optimization is to segment the dataset into two or more subsets according to the main forms of bias expression (e.g., explicit vs implicit). It would allow to explore and evaluate different forms of bias separately, which in turn might motivate differential classification techniques. Finally, populating the negative examples class with sentences from Wikipedia's Featured Articles (in line with Bhosale et al. 2013) might help reduce class ambiguity by reinforcing the contrast between neutral encyclopedic tone and expressions of bias.

Abstract

Morphological segmentation of words is the process of dividing a word into smaller units called morphemes; it is tricky especially when a morphologically rich or polysynthetic language is under question. In this work, we designed and evaluated several Recurrent Neural Network (RNN) based models as well as various other machine learning based approaches for the morphological segmentation task. We trained our models using annotated segmentation lexicons. To evaluate the effect of the training data size on our models, we decided to create a large hand-annotated morphologically segmented corpus of Persian words, which is, to the best of our knowledge, the first and the only segmentation lexicon for the Persian language. In the experimental phase, using the hand-annotated Persian lexicon and two smaller similar lexicons for Czech and Finnish languages, we evaluated the effect of the training data size, different hyperparameters settings as well as different RNN-based models.

1 Introduction

Morphological analysis must be tackled somehow in all natural language processing tasks, such as machine translation, speech recognition, and information retrieval. Morphological segmentation of words is the process of dividing a word into smaller units called morphemes. Morphological segmentation task is harder for those languages which are morphologically rich and complex like Persian, Arabic, Czech, Finnish or Turkish, especially when there are not enough annotated data for those languages. In this paper, we designed and evaluated various supervised setups to perform morphological segmentation using a hand-annotated segmented lexicon for training.

The efficiency of supervised approaches (especially of deep neural network models) is naturally highly dependent on the size of training data. In order to evaluate the effect of the training data size on our segmentation models, we created a rich Persian hand-annotated segmentation lexicon, which is, as far as we know, the first and the only such computer-readable dataset for Persian. Persian (Farsi) is one of the languages of the Indo-European language family within the Indo-Iranian branch and is spoken in Iran, Afghanistan, Tajikistan and some other regions related to ancient Persian. In addition, we evaluated our models on Czech and Finnish, however, the amount of annotated data for them is substantially lower.

Automatic morphological segmentation was firstly introduced by Harris (1970). More recent research on morphological segmentation has been usually focused on unsupervised learning (Goldsmith, 2001; Creutz and Lagus, 2002; Poon et al., 2009; Narasimhan et al., 2015; Cao and Rei, 2016), whose goal is to find the segmentation boundaries using an unlabeled set of word forms (or possibly a corpus too). Probably the most popular unsupervised systems are LINGUISTICA (Goldsmith, 2001) and MORFESSOR, with a number of variants (Creutz and Lagus, 2002; Creutz et al., 2007; Grönroos et al., 2014). Another version of the latter which includes a semi-supervised extension was introduced by (Kohonen et al., 2010). Poon et al. (2009) presented a log-linear model which uses overlapping features for unsupervised morphological segmentation.

In spite of the dominance of the unsupervised systems, as soon as even just a small amount of

Proceedings of Recent Advances in Natural Language Processing, pages 52–61,
Varna, Bulgaria, Sep 2–4 2019.

segmented training data is available, then the entirely unsupervised systems tend not to be competitive. Furthermore, unsupervised segmentation still has considerable weaknesses, including over-segmentation of roots and erroneous segmentation of affixes (Wang et al., 2016). To deal with those limitations, recent works show a growing interest in semi-supervised and supervised approaches (Kohonen et al., 2010; Ruokolainen et al., 2013, 2014; Sirts and Goldwater, 2013; Wang et al., 2016; Kann and Schütze, 2016; Kann et al., 2018; Cotterell and Schütze, 2017; Grönroos et al., 2019) which employ annotated morpheme boundaries in the training phase.

In our work we designed and evaluated various machine learning models and trained them using only the annotated lexicon in a supervised manner. Our models do not leverage the unannotated data nor context information and only use the primary hand-annotated segmentation lexicons.

Experimental results show that our Bi-LSTM model perform slightly better than other models in boundary prediction for our hand-segmented Persian lexicon, while KNN (K-Nearest Neighbors algorithm) performs better when the whole word accuracy is under question.

The paper is organized as follows: Section 2 addresses the related work on morphological segmentation. Section 3 describes the methodology and machine learning models used in this work. Section 4 introduces our hand-segmented Persian lexicon as well as related preprocessing phases. Section 5 presents the experiment results compared to some other baseline systems and finally Section 6 concludes the paper.

2 Related Work

Supervised morphological segmentation, i.e. using a lexicon (or a corpus) with annotated morpheme boundaries in the training phase, has attracted increasing attention in recent years. One of the most recent successful research directions on supervised morphological segmentation is the work of (Ruokolainen et al., 2013), whose authors employ CRF (Conditional Random Fields), a popular discriminative log-linear model to predict morpheme boundaries given their local sub-string contexts instead of learning a morpheme lexicon. (Ruokolainen et al., 2014) extended their work to semi-supervised learning version by exploiting some available unsupervised segmentation techniques into their CRF-based model via a feature set augmentation. (Ruokolainen et al., 2014)

Long Short Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997) have recently achieved great success in sequence learning tasks, including outstanding results on sequential tasks such as machine translation (Sutskever et al., 2014). Wang et al. (2016) proposed three types of window-based LSTM neural network models named Window LSTM, Multi-window LSTMs and Bidirectional Multi-Window LSTMs, in order to automatically learn sequence structures and predict morphological segmentations of words in a raw text. They used only word boundary information without any need for extra feature engineering in the training phase. The authors compared their models with selected supervised models as well as with an LSTM architecture (Wang et al., 2016), and similarly to the work of Ruokolainen et al. (2013), their architecture is based on the whole text and context information instead of using only the lexicon. Cotterell and Schütze (2017) increased the segmentation accuracy by employing semantic coherence information in their models. They used RNN (Recurrent Neural Network) to design a composition model. They also found that using RNN with dependency vector has the best results on vector approximation (Cotterell and Schütze, 2017).

Recently, using encoder-decoder models Bahdanau et al. (2014) (attention-based models) made some great successes in machine translation systems. Kann and Schütze (2016) used an encoder-decoder model which encodes the input as a sequence of morphological tags of source and targets and feeds the model by sequence of letters of a source form. They select the final answer using a majority voting amongst their five different ensembled RNN encoder-decoder models. Kann and Schütze (2016), proposed a seq2seq (sequence-to-sequence network) architecture for the word segmentation task. They used a bi-directional RNN to encode the input word (i.e. sequence of characters) and concatenated forward and backward hidden states yielded from two GRUs and pass the result vector to decoder part. The decoder is a single GRU which uses segmentation symbols for training. She introduced two multi-task training approaches as well as data augmentations to improve the quality of the presented model. She shows that neural seq2seq models perform on par with or better than other strong baselines for polysynthetic languages in a minimal-resource setting. Their suggested neural seq2seq models constitute the state of the art for morphological segmentation in high-resource settings and for (mostly) European languages (Kann et al., 2018).

The main studied language in our work is Persian, which belongs to morphologically rich languages and which is powerful and versatile in word building. Having many affixes to form new words (over a hundred), and the ability to build affixes and especially prefixes from nouns, the Persian language is considered as an agglutinative language since it also frequently uses derivational agglutination to form new words from nouns, adjectives, and verbal stems. Hesabi (1988) claimed that Persian can derive more than 226 million words (Hesabi, 1988).

To the best of our knowledge, the research on morphology of the Persian language is very limited. Rasooli et al. (2013) claimed that performing morphological segmentation in the pre-processing phase of statistical machine translation could improve the quality of translations for morphology rich and complex languages. Although they segmented very low portion of Persian words (only some Persian verbs), the quality of their machine translation system increases by 1.9 points of BLEU score. Arabsorkhi and Shamsfard (2006) proposed a Minimum Description Length (MDL) based algorithm with some improvements for discovering the morphemes of Persian language through automatic analysis of corpora.

3 Our Machine Learning Models

In this work we decided to evaluate selected machine learning models including those feature-based machine learning approaches in which the task of word segmentation is reformulated as a classification task, as well as various deep-learning (DL for short) neural network models.

Because of huge number of learned parameters in DL, having enough training data is critical. The fact that we decided to create a large hand-annotated dataset for Persian allows evaluating the effect of the training data size on a relatively wide scale, as described in Section 4.

We convert all segmentations into a simple string format in which letters "B" and "L" encode the presence of the boundary letter and the continuation letter, respectively. For example for word "goes", the encoded segmentation is "LLBL", which shows that there is a segmentation boundary in front of the third letter ("e"). While in our model we consider only morphologically segmented lexicon and we do not employ any other information like corpus contexts or lists of unannotated words, this encoding is sufficient and make the specification of boundary location easy.

In the case of presence of a semi-space letter (a feature specific for the Persian written language), the semi-space letter is always considered as a boundary letter. An experiments focused on this feature is described in Subsection 5.2.3, which shows that our models could perform better when this information exists in the annotated lexicon.

3.1 Classification-Based Segmentation Models

In the first setup, we convert the segmentation task (the task of segmenting a word into a sequence morphemes) simply to a set of independent binary decisions capturing the presence or absence of a segmentation boundary in front of each letter in the word. For this task, we use various standard off-the-shelf classifiers available in the Scikit-learn toolkit (Pedregosa et al., 2011).

So far, we provide the classifiers only with features that are extractable from the word alone. More specifically, we use only character-based features. These character-based features include letters and letter sequences (and their combinations) before and after under the character under question, which is subsequently assigned one out of two classes: "B" for boundary characters, and "L" which stands for continuation characters. The main task of these methods is then to train a classification model to classify all characters in the word into those two classes, given binary features based on surrounding characters. For example, for the fifth character of word "hopeless", some of our features could be: "e", "le", and "ope". The classification predictions are performed independently.

3.2 Deep Neural Network Based Models

Besides the classification-based segmentation models, we designed and evaluated five DL models based on GRU, LSTM, Bi-LSTM, seq2seq and Bi-LSTM with the attention mechanism, respectively. The first three models are illustrated in Figures 1 and 2. The presented seq2seq model, is similar to the model described in (Grönroos et al., 2019). The last presented model is an attention based model, which is shown in Figure 3. In this model, we use Bi-LSTM as encoder and LSTM as attention layer, and finally, outputs of encoder and attention layers are added together.

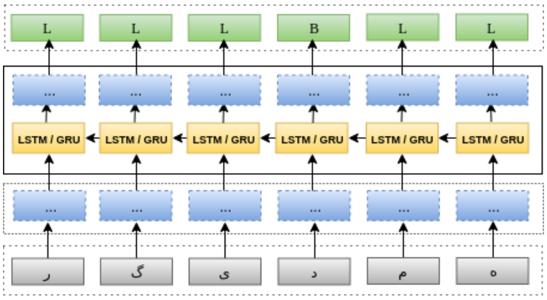

Figure 1: The schema of the LSTM/GRU models used in this experiments.

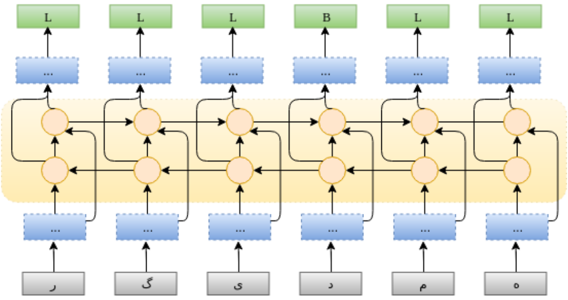

Figure 2: The schema of the Bi-LSTM model used in this experiments.

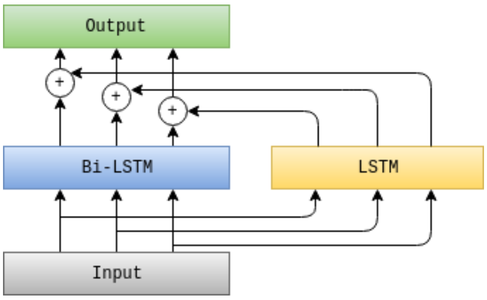

Figure 3: The schema of the Bi-LSTM with the attention mechanism model used in this experiments.

4 Morphological Segmentation Lexicons

In this section, the rich Persian hand-annotated dataset and the existing Finnish datasets from the Morpho-Challenge shared task 2010 (Virpioja et al., 2011) as well as the Czech dataset used in our experiments are described.

4.1 Persian Hand-Annotated Morphological Segmentation Dataset

We extracted our primary word list from three different corpora. The first corpus contains sentences extracted from the Persian Wikipedia (Karimi et al., 2018). The second one is popular Persian mono-lingual corpus BijanKhan (Bijankhan et al., 2011), and the last one is Persian-NER[1] (Poostchi et al., 2018).

For all introduced corpora, using Hazm toolset (Persian preprocessing and tokenization tools)[2] and the stemming tool presented by Taghi-Zadeh et al. (2015), we extracted and normalized all sentences and in the final steps using our rule-based stemmer and a Persian lemma collection, all words are lemmatized and stemmed. Finally all semi-spaces are automatically detected and fixed. Words with more than 10 occurrences in the corpora were selected for manual annotation. We decided to send all 80K words to our 16 annotators in the way that each word is checked and annotated by two independent persons. Annotators decided about the lemma of a word under question, segmentation parts, plurality, ambiguity (whether a word has more than one meaning) or they might delete the word if they think is not a proper Persian word. Moreover, some segmentations predicted by our automatic segmentator with high confidence score were offered to our annotators. We removed almost 30K words which were selected to be deleted by both annotators. And remaining 50K words sent for inter-annotation comparison part. In this step, all disagreements were checked and corrected by the authors of this paper and finally all words were quickly reviewed by two Persian linguists. The whole process took around six weeks. In order to use a hand-annotated lexicon in our work, we extracted the segmentation part from the dataset and converted it to our binary model which is described in Section 3.

The total number of words we used in our Persian dataset is 40K. The dataset is publicly available in the LINDAT/CLARIN repository (Ansari et al., 2019).

4.2 Existing Finnish and Czech Segmentation Datasets

We downloaded the Finnish segmentation dataset from the Morpho-Challenge shared task 2010[3] (Virpioja et al., 2011) and converted them into our binary format. The Finnish dataset contains 2000 segmented words. While comparing to our hand-annotated Persian dataset these datasets are small, we used them to see the efficiency of our presented models when the size of training dataset is limited.

The Czech dataset results from a prototype segmentation annotation of Czech words. A sample of 1000 lemmas were selected randomly from DeriNet, which is a lexical database focus on derivation in Czech (Žabokrtský et al., 2016). The lemmas were manually segmented by two independent annotators, and all annotation differences were resolved subsequently during a third pass through the data. The annotation resulted in 4.6 morphemes per word, partially as a result of the fact that the lemmas were sampled uniformly, regardless of their corpus frequency, and thus the selection is biased towards longer words.

5 Experimental Results

To partition our dataset (Persian, Czech and Finnish) into training, development and test sets a commonly used method is used (Ruokolainen et al., 2013), which involves sorting words according to their frequency and assigning every eighth term starting from the first one into the test set and every eighth term from the second into the development set, while moving the remaining terms into the training set.

In order to evaluate the effect of the training data size, we randomly select the first 1/64, 1/32, 1/16, 1/8, 3/8, 1/4, 1/2, 3/4 and all amount of data from the training set to carry out experiments with different training sizes. In all experiments, we report three evaluation measures: the number of correctly predicted morpheme boundaries (in terms of precision, recall, and f-measure), the percentage of correct binary predictions on all characters, and the percentage of correctly segmented words.

As described in Section 2, some previous works reported accuracy in terms of the number of correct predictions (boundary and word) in a running text, instead of considering unique words sampled from a lexicon. Hence we decided to also report such accuracy in our experiments in addition to our lexicon evaluation. For this new experiment, we selected a part of a mono-lingual text and after removing all presented words in the text from our training lexicon, the remaining segmented words are considered as the training set and finally accuracy of word segmentation of words in test sentences is reported separately.

5.1 Baselines

We used two baseline systems which we selected to compare our models with. The first baseline is an unsupervised version of MORFESSOR, which is introduced and implemented by Creutz et al. (2007). The second baseline is FlatCat (Grönroos et al., 2014), which is a well-known semi-supervised version of MORFESSOR that uses the Hidden Markov Model for segmentation. In addition to the annotated data, semi-supervised MORFESSOR (i.e. FlatCat) uses a set of 100,000 word types following their frequency in the corpus as their unannotated training dataset. For both baselines, the best performing model is selected and compared with our neural network based models.

5.2 Results and Discussion

As described in Section 4, we designed various models for the morphological segmentation task. In the following subsections, different experiments done in this work are reviewed. In all tables, the column entitled by **W%** indicates the proportion of perfectly segmented words. The column entitled by **Ch%** indicated the accuracy of characters which are classified as boundary or non-boundary. Finally, **P%**, **R%**, and **F%** indicate precision, recall and F-measure score respectively for the morpheme boundary detection, naturally excluding the trivial final position characters from our evaluation.

5.2.1 Comparison of Different Models

Table 1 shows the evaluation results of morphological segmentation using our Persian hand-annotated dataset if the whole training data is used. For each model, only results of the best-performing hyperparameter configuration are reported. As is shown in Table 1, our Bi-LSTM model performs slightly better than the rest in boundary prediction, however, the classification models are surprisingly almost on the par with our complex DL model. Considering word accuracy,

classification models are performing better than DL models. A possible explanation for this is that the classification models make use of n-gram features and handle the characteristics of the whole word more efficiently than sequence-based models. Moreover, regarding our experiments, the presented seq2seq model does not perform well. An explanation could be that while there is not any available context information, the used attention mechanism does not have any far parts to make a relation between them. Moreover, our Bi-LSTM with the attention mechanism does not perform better than normal Bi-LSTM either. Finally, Tables 2 and 3 show the results of this experiment on two other languages, Finnish and Czech, for which the sizes of training data are very limited comparing the Persian dataset. As we expected, with so small training data, the classification methods perform better than more complex DL strategies.

Table 4 shows a comparison of our DL models, when different LSTM output sizes and drop-out thresholds are tested. Only two best-performing models (LSTM and Bi-LSTM) are shown.

Table 4: Effect of using different hyper-parameters on LSTM and Bi-LSTM models, two best performing deep neural network models for Persian dataset

As is seen in the tables, the classification models perform well when compared to more complex DL models. One explanation for this evidence is the lack of any external information (other than a segmented lexicon) which limits the number of possible features from the training data. For example there is no information about some previous words, and consequently RNN-based models can not learn any information about distant previous characters in the training phase. Possibly, this also explains the inferior performance of our seq2seq model compared to the Bi-LSTM model implemented for this work.

Finally, Table 5 shows results of selected models when the segmentation is done on all words occurring in a corpus instead of a segmented lexicon. In this experiments we expected those words with more frequency has higher effect on results comparing with less frequent words.

5.2.2 Effect of Training Data Size

In order to evaluate the effect of the training data size on our DL models, different amount of training data are selected from and feed to our models. Figure 4 and Figure 5 demonstrate an experiment in which the baseline line is the results of unsupervised version of MORFESSOR for similar test dataset. Only four best performing feature-based models in addition to two DL-based models are selected to be shown here. As this figure shows, after having more than 10K training instances, increasing the training data further does not have a substantial effect any more.

5.2.3 Semi-Space Feature for Persian Words

An important feature of the Persian and Arabic languages is the existence of semi-space. For example word "کتاب‌ها" (books) is a combination of word "کتاب" and "ها", in which the former is Persian translation of word "book" and the latter is morpheme for a plural form. We can say these semi-space signs segment words into smaller morphemes. However, in formal writing and in all Persian normal corpora, this space is neglected frequently and it could make a lot of problems in Persian and Arabic morphological segmentation task. For example both forms for the previous example, "کتاب‌ها" and "کتابها" , are considered correct in Persian text and have the same meaning. To deal with this problem and in order to improve the quality of our segmentation dataset, we implemented a preprocessor to distinguish this kind of space in Persian words and consequently our hand-annotated dataset contains these semi-spaces correctly. While we wanted to test the effect of having this prior knowledge in the lexicon, we evaluated our models in two different forms. In the first case, we used our hand annotated dataset as is. In the second case, we removed all semi-spaces from the lexicon. Table 6 shows a comparison for deploying our models on these two different datasets and as could be seen in this table, having the accurate dataset which is created by our preprocessing strategy could improve results drastically.

Model	**P% / R% / F%**	**W%**	**Ch%**
LSTM	94.42 / 92.93 / 93.67	78.14	95.13
Bi-LSTM	95.97 / 93.69 / **94.89**	**78.37**	**95.79**
SVC, Kernel: poly, Degree: 3	93.88 / 92.11 / 92.99	89.85	97.02

6 Conclusion

The main task of this work is to evaluate different supervised models to find the best segmentation of a word when only a segmented lexicon without any extra information is available in the training phase. In recent years, recurrent neural networks (RNN) attracted a growing interest in morphological analysis, that is why we decided to design and evaluate various neural network based models (LSTM, Bi-LSTM, GRU, and attention based models) as well as some machine learning classification models including SVM, Random Forest, Logistic Regression and others for our morphological segmentation task. While a critical point in any DL model is the training data size, we decided to create a rich hand annotated Persian lexicon which is the only segmented corpus for Persian words. Using this lexicon we evaluated our presented models as well as the effect of training data size on results. Moreover, we evaluated and tested our models on some limited datasets for Czech and Finnish languages. Experimental results show our Bi-LSTM model performs slightly better in boundary prediction, however the results of classification-based approaches overcome the DL models in percentage of completely correctly segmented words.

Abstract

Word Sense Induction (WSI) is the task of grouping of occurrences of an ambiguous word according to their meaning. In this work, we improve the approach to WSI proposed by Amrami and Goldberg (2018) based on clustering of lexical substitutes for an ambiguous word in a particular context obtained from neural language models. Namely, we propose methods for combining information from left and right context and similarity to the ambiguous word, which result in generating more accurate substitutes than the original approach. Our simple yet efficient improvement establishes a new state-of-the-art on WSI datasets for two languages. Besides, we show improvements to the original approach on a lexical substitution dataset.

1 Introduction

Ambiguity, including lexical ambiguity, is one of the fundamental properties of natural languages and is a central challenge for NLP and its applications. Lexical ambiguity is a common situation when a single word has several meanings which can be either closely related (*coffee* as a plant, as a drink, or as beans for preparing that drink) or entirely unrelated (*band* as a musical group or as a strip of material). Consider the word *book* in *book a flight* or *buy a book*. Depending on the expressed meaning, machine translation systems should translate this word differently, search engines should find different information, personal digital assistants should take different actions, etc.

Word sense induction (WSI) is the task of clustering of occurrences of an ambiguous word according to their meaning. For evaluation of WSI systems, text fragments containing ambiguous words are hand-labeled with senses from some sense inventory (a dictionary or a lexical ontology). WSI systems are given text fragments only and should cluster them into some a priori unknown number of clusters (unlike Word Sense Disambiguation systems, which are also given the sense inventory).

Words that can appear instead of an ambiguous word in a particular context, also known as lexical contextual substitutes, are very helpful for WSI because possible substitutes strongly depend on the expressed meaning of the ambiguous word. For instance, for the word *build* possible substitutes are *manufacture*, *make*, *assemble*, *ship*, *export* if it is used in the *manufacturing some goods* sense and *erect*, *rebuild*, *open* for the *constructing a building* sense. Baskaya et al. (2013) proposed generating substitutes using n-gram language models and had shown one of the best results at the SemEval-2013 WSI shared task for English (Jurgens and Klapaftis, 2013). Later Amrami and Goldberg (2018) proposed generating contextual substitutes with a bidirectional neural language model (biLM) ELMo (Peters et al., 2018). With several other improvements, they had achieved new state-of-the-art results on the same dataset. However, their method simply unites substitutes generated independently from probability distributions $P(w_i|w_{i-1}...w_1)$ and $P(w_i|w_{i+1}...w_T)$ estimated by the forward and the backward ELMo LM independently, each given only one-sided context. This results in noisy substitutes when either left or right context is short or non-informative.

The **main contribution** of this paper is an approach that combines the forward and the backward distributions into a single distribution and fuses the similarity to the ambiguous word into the combined distribution. This allows taking into account all information we have about a particular ambiguous word occurrence for better substitutes generation. We compare several methods for combining distributions. Substitutes retrieved from the combined distribution perform much better for WSI achieving the a state-of-the-art on the SemEval 2013 dataset for English as well two datasets for Russian.

2 Related Work

The first methods to word sense induction were proposed already in the late 90s (Pedersen and Bruce, 1997; Schütze, 1998; Lin, 1998) with several competitions being organized to systematically evaluate various methods, including SemEval 2007 task 2 (Agirre and Soroa, 2007), SemEval 2010 task 14 (Manandhar et al., 2010) and SemEval 2013 task 13 (Jurgens and Klapaftis, 2013) for the English language, and RUSSE 2018 (Panchenko et al., 2018) for the Russian language.[1] Navigli (2012) provides a survey of word sense induction and related approaches. Methods for word sense induction can be broadly classified into three groups: context clustering approaches, word (ego-network) clustering, and latent variable models. We discuss these approaches below. Also, note that methods for learning word sense embedding (Camacho-Collados and Pilehvar, 2018) can be used to induce vector representations of senses from text.

2.1 Context/Vector Clustering Methods

This methods from this group represent a word instance by a vector that characterizes its context, where the definition of context can vary greatly. These vectors are subsequently clustered.

Early approaches, such as (Pedersen and Bruce, 1997; Schütze, 1998; Reisinger and Mooney, 2010) used sparse vector representations. Later approaches dense vector representations were adopted, e.g. Arefyev et al. (2018) and Kutuzov (2018) used weighted word embeddings (Mikolov et al., 2013) pre-trained on a large corpus to represent context of an ambiguous target word. Anwar et al. (2019) used contextualized (Peters et al., 2018) and non-contextualized (Mikolov et al., 2013) word embeddings to cluster occurrences of ambiguous occurrences of verbs according to their semantic frames.

The approach presented in this paper is also an instance of vector clustering methods. More specifically, it exploits contextual substitutes for the ambiguous word to differentiate between its senses. Baskaya et al. (2013) proposed using substitute vectors for WSI, and their system *AI-KU* was one of the best-performing systems at SemEval 2013. Alagić et al. (2018) proposed another approach which leverages lexical substitutes for unsupervised word sense induction. They perform clustering of contexts using the affinity propagation algorithm (Dueck and Frey, 2007). The similarity between instances is measured using three different measures based on cosine similarities between pre-trained word embeddings by Mikolov et al. (2013). One measure relies on an average of embeddings of context words. Another one relies on an average of embeddings of lexical substitutes (also combination of both measures is tested). Finally, Amrami and Goldberg (2018) proposed using neural language models and dynamic symmetric patterns establishing a new best result on this dataset. Their approach is described in details in Section 3 as a starting point for our method.

2.2 Word/Graph Clustering Methods

This group of methods cluster word ego-networks consisting of a single node (ego) together with the nodes they are connected to (alters) and all the edges among those alters. Nodes of an ego-network can be words semantically similar to the target word or context features relevant to the target. This line of work starts from the seminal work of (Widdows and Dorow, 2002) who used graph-based methods for unsupervised lexical acquisition. In this work, senses of the word were defined as connected components in a graph which excludes the ego. Véronis (2004), Biemann (2006), and Hope and Keller (2013) further developed this idea by performing clustering of nodes instead of the simple search for connected components. Pelevina et al. (2016) proposed to transform word embeddings to sense embeddings using graph clustering (Biemann, 2006). The obtained sense embeddings were used to solve the WSI task based on similarity computations between the context and the induced sense.

2.3 Latent Variable Methods

Methods from this group, define a generative process of the documents which include word senses as a latent variable and then perform estimation

[1] https://russe.nlpub.org

of the model from unlabeled textual data. For instance, Lau et al. (2013) relies on the Hierarchical Dirichlet Process (HDP) (Teh et al., 2006). Latent topics discovered in the training instances, specific to every word, are interpreted as word senses. Since the HDP is generative, also new instances can be assigned a sense topic. Latent variable model of Bartunov et al. (2016) is a Bayesian extension of Skip-gram (Mikolov et al., 2013) that automatically learns the number of word senses; it relies on the stick-breaking process. Amplayo et al. (2019) propose another graphical model which tackles the sense granularity problem, setting new state-of-the-art results for the SemEval 2010/2013 WSI datasets.

3 Bayesian Fusion of Lexical Substitutes from Bidirectional Language Models

In this section, we describe the method of word sense induction proposed by Amrami and Goldberg (2018), which is based on lexical substitutes generated given left and right context separately and then united together. Then we propose several methods to build a combined distribution incorporating information from left and right context as well as the similarity to the target word for better substitutes generation. For qualitative comparison, Table 1 lists lexical substitutes generated by different methods for several randomly selected sentences from the TWSI dataset (Biemann, 2012). For readability, we select either the top 10 predictions from the combined distributions or the union of the top 5 predictions from the forward and the backward distributions. The actual number of substitutes may be smaller due to duplicates appearing after lemmatization of substitutes.

3.1 Baselines: No Fusion (Union of Substitutes)

We base our approach on the method by Amrami and Goldberg (2018) (named **original** hereafter), which has achieved state-of-the-art results on the SemEval-2013 dataset for English WSI. Suppose c is the target ambiguous word and l, r are its left and right contexts. First, the method employs pretrained forward and backward ELMo LMs (Peters et al., 2018) to estimate probabilities for each word w to be a substitute for c given only the left context $P_{fwd}(w|l)$ or only the right context $P_{bwd}(w|r)$. Second, from the top K most probable words of each distribution L substitutes are sampled. This is done S times resulting in S representatives of the original example consisting of $2L$ substitutes each. Then TF-IDF BoW vectors for all representatives of all examples of a particular ambiguous word are built. Finally, agglomerative clustering is performed on the obtained representations with a fixed number of clusters. To provide more information to the LMs the target word can be included in the context using the technique called dynamic patterns. For example, given the sentence *These apples are sold everywhere* instead of *'These _'* the forward LM receives *'These apples and _'* and instead of *'_ are sold everywhere'* the backward LM receives *'_ and apples are sold everywhere'*. The underscore denotes the position for which the language model predicts possible words.

Thus, lexical substitutes are obtained **independently** from the forward and the backward LM and then **united**. For soft clustering required by the SemEval-2013 dataset, the probability distribution over clusters for each example is estimated from the number of representatives of this example put in each cluster. For the RUSSE (the Russian WSI) datasets we further convert soft clustering into hard clustering by selecting the most probable cluster for each example.

The second baseline (named **base**) simplifies the **original** method by skipping sampling and using $S = 1$ representative consisting of the union of the top K predictions from each LM. While being simpler and deterministic, this modification also delivers better results on RUSSE. Additionally, we have found that baselines with dynamic patterns translated into Russian perform worse than their counterparts without patterns (**original-no-pat** and **base-no-pat**) on RUSSE. This is in line with the ablations study from Amrami and Goldberg (2018) who found that the patterns are useful for verbs and adjectives but almost useless for nouns which the RUSSE datasets consist of. Interestingly, our best models perform better without dynamic patterns on all datasets.

3.2 Fusion at the Level of LM Distributions

During preliminary experiments, we have found that uniting substitutes retrieved from the forward and the backward LM independently results in lots of substitutes not related to the target word sense. For instance, consider the first example in Table 1 where the ambiguous word is the last word of the sentence. The backward LM simply

Table 1: **Examples of generated lexical substitutes**: baselines and our models. Contexts are from the TWSI dataset. Ambiguous word is underlined, substitutes intersecting with human-generated are **bold**. Here **base** is the baseline approach of Amrami and Goldberg (2018) and **base-no-pat** is its simplified version without patterns, while **BComb-LMs** and **BComb-3** are our models described in Section 3.

predicts all words which can appear before dot resulting mostly infrequent abbreviations. Dynamic patterns help a little, but there is still no context available for the backward LM to disambiguate the target word. To solve this problem we propose combining distributions from the forward and the backward LM first and then taking the top K words from this combined distribution. We experiment with the following combinations.

3.2.1 Average (avg)

This straightforward method of fusion of two distributions computes an average of forward and backward distributions (no information about the target word is used):

$$\begin{aligned} P(w|l,r) &= \frac{1}{2}(P(w|l) + P(w|r)) \\ &= \frac{1}{2}(P_{fwd} + P_{bwd}). \end{aligned} \tag{1}$$

3.2.2 Bayesian Combination of LMs (BComb-LMs)

Using Bayes' rule and supposing left and right context are independent given possible substitutes we estimate fused distribution as follows:

$$\begin{aligned} P(w|l,r) &= \frac{P(l,r|w)P(w)}{P(l,r)} \\ &= \frac{P(l|w)P(r|w)P(w)}{P(l,r)} \\ &\propto \frac{P(w|l)P(w|r)}{P(w)}. \end{aligned} \tag{2}$$

The numerator is estimated as $P_{fwd}P_{bwd}$, but pretrained ELMo LMs don't contain frequencies of the words in the vocabulary, so we cannot directly estimate the denominator. Instead we approximate it with Zipf distribution (the vocabulary is sorted by frequency):

$$P(w) \propto \frac{1}{(k + rank(w))^s}, \tag{3}$$

where k and s are hyperparameters: the first is needed to perform adjustment for frequent words while the second defines how quickly word frequency drops as its rank grows.

3.2.3 Three-Way Bayesian Combination (BComb-3)

Substitutes should not only be compatible with context, but also similar to the target word c. Amrami and Goldberg (2018) integrate information about the target word using dynamic patterns, but here we propose a probabilistic approach of fusion of forward and backward distribution with the information about the target word. Namely, we estimate similarity using a scaled dot product of output embeddings from ELMo:

$$P(w|c) \propto \exp(\frac{emb_w^T emb_c}{Temperature}), \quad (4)$$

where $Temperature$ is a hyperparameter which allows scaling this distribution to fit to the LM distributions. Similarly to *BComb-LMs* and supposing the target word is independent from the context given possible substitutes (which can be interpreted as fixing a particular sense of the target):

$$P(w|l, c, r) \propto \frac{P(w|l)P(w|r)P(w|c)}{P^2(w)}. \quad (5)$$

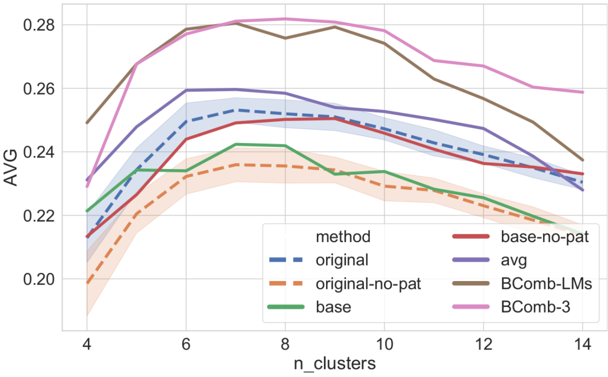

Figure 1: **SemEval 2013 task 13**: geometric average of fNMI and fB^3 with respect to the number of clusters per word. Hyperparameters are selected on the TWSI dataset (Biemann, 2012).

4 Evaluation and Results

To evaluate the quality of our proposed approach, we performed three experiments. Two of them are based on WSI datasets coming from the shared tasks for English (Jurgens and Klapaftis, 2013) and Russian (Panchenko et al., 2018). The last experiment compares substitutes generated by the original and our methods to the human-generated substitutes using a lexical substitution dataset for English (Biemann, 2012).

4.1 Experiment 1: SemEval 2013 WSI Task

4.1.1 Experimental Setup

First, we evaluate our methods on the SemEval-2013 dataset for English WSI (Jurgens and Klapaftis, 2013). The dataset contains contexts for 50 ambiguous words, including 20 nouns, 20 verbs, and 10 adjectives. It provides 20-100 contexts per word, and 4,664 contexts in total, which were gathered from the Open American National Corpus and annotated with senses from WordNet. We used this dataset as the test set and tuned all hyperparameters except for the number of clusters on the TWSI dataset (Biemann, 2012).

Evaluation metrics. Performance is measured with two cluster comparison measures: Fuzzy NMI (fNMI) and Fuzzy B-Cubed (fB^3) as defined in (Jurgens and Klapaftis, 2013).

4.1.2 Discussion of Results

Figure 1 shows a geometric average (AVG) between Fuzzy Normalized Mutual Information (fNMI) and Fuzzy B-Cubed F1 (fB^3) depending on the number of clusters. Following Amrami and Goldberg (2018), Table 2 reports the results for the number of clusters equal to 7 which is the average number of senses in SemEval-2013. BComb-3 shows the best results closely followed by BComb-LMs, while the *avg* combination methods performs worse but still outperforms baseline methods.

4.2 Experiment 2: RUSSE 2018 WSI Task

4.2.1 Experimental Setup

For the Russian language we test our methods on the *active-dict* and the *bts-rnc* datasets from the RUSSE 2018 WSI shared task (Panchenko et al., 2018). These datasets are split into dev and test parts containing non-overlapping ambiguous words. The *bts-rnc* dataset relies on contexts sampled from the Russian National Corpus (RNC)[2] and annotated based on the sense inventory of the Large Explanatory Dictionary of Russian[3]. The dev set contains 30 ambiguous words and 3,491 contexts. The test set contains 51 ambiguous words and 6,556 contexts. The *active-dict* dataset is based on the Active Dictionary of Russian, which is an explanatory dictionary (Apresjan, 2011). For each sense, contexts were extracted from the glosses and examples of this dictionary. The train/development set has 85 ambiguous words and 2,073 contexts. The test set has 168 ambiguous words and 3,729 contexts.

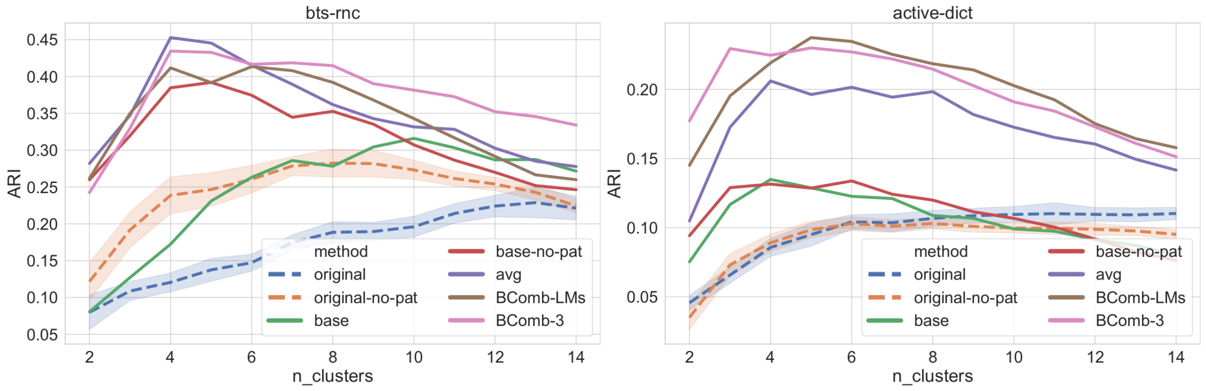

Figure 2: **RUSSE-2018 development sets**: ARI with respect to the number of clusters per word. Hyperparameters are selected on the TWSI dataset.

Evaluation metrics. Performance is measured using Adjusted Rand Index (ARI) (Hubert and Arabie, 1985).

4.2.2 Discussion of Results

Figure 2 shows results on the development set using the same hyperparameters used for SemEval-2013. Despite being selected on an English WSI dataset, they perform surprisingly well. Similarly to SemEval-2013, on *active-dict* BComb methods outperform Avg by a large margin. However, on *bts-rnc* dataset, Avg seems to be the best performing method which we attribute to suboptimal hyperparameters. For our final submissions to the leaderboard reported in Table 3 we selected hyperparameters on the development set corresponding to each dataset and with these hyperparameters BComb methods are indeed better than Avg. We report results for (i) a fixed number of clusters (selected on the development sets) and for (ii) individual number of clusters for each word selected by maximizing the silhouette score of clustering[4]. Using individual number of clusters consistently improves results for all our methods.

4.3 Experiment 3: TWSI Lexical Substitution

4.3.1 Experimental Setup

In the third experiment, we evaluated the quality of lexical substitutes generated by our methods comparing them with human-generated ones from the

[4] https://scikit-learn.org/stable/modules/clustering.html#silhouette-coefficient

Model	bts-rnc Test	active-dict Test
avg	0.355 / 0.436	0.254 / 0.255

competition 1st best result	0.351	0.264
competition 2nd best result	0.281	0.236

Table 3: **RUSSE 2018 test sets**: comparison to the previous best results. The number of clusters is selected on corresponding development sets (like other hyperparameters) / using silhouette score.

TWSI dataset by Biemann (2012). Version 2.0 of the dataset was used in our experiments. The dataset is composed of 1,012 frequent nouns with 2.26 senses per word on average. For these nouns, the dataset provides 145,140 annotated sentences sampled from Wikipedia. Besides, it features a sense inventory, where each sense is represented with a list of words that can substitutes.

Evaluation Metrics Performance is measured using precision and recall among top $K = 10$ lexical substitutions.

4.3.2 Discussion of Results

Table 4 reports the results. One should carefully interpret these results since humans generate precise but not exhaustive lists of substitutes. For instance, for the sentence *Henry David Thoreau wrote the famous phrase, "In wildness is the preservation of the world."* BComb-3 model generates the following substitutes: *dictum, proverb, poem, motto, epitaph, slogan, quote, aphorism, maxim* from which only *slogan* and *maxim* were generated by humans. As one may observe, according to metrics, both base methods with patterns and BComb-3 generate much more human-like substitutes than their counterparts that do not take into account the target word (base-no-pat and BComb-LMs) with BComb-3 being a little better. Examples of generated substitutes are shown in Table 1.

Model	rec.@10	prec.@10
base	0.115	0.035
base-no-pat	0.058	0.020
avg	0.093	0.032
BComb-LMs	0.073	0.025
BComb-3	**0.127**	**0.041**

Table 4: **TWSI lexical substitution**: comparison our method to the baseline model by Amrami and Goldberg (2018) on the dataset of human-generated lexical substitutes.

5 Conclusion

We proposed a new method for neural word sense induction which improves the approach of Amrami and Goldberg (2018). We show that substantially better results can be obtained if the information from the forward and the backward LMs is combined in a more principled way using Bayesian fusion of distributions rather than a simple union of substitutes generated independently from each distribution. More specifically, this work shows that integration of the forward and the backward distributions retrieved from neural LMs and the similarity to the target word results in better-generated substitutes for ambiguous words, which enabled achieving a new state-of-the-art for WSI for two languages.

Detecting Clitics Related Orthographic Errors in Turkish

Uğurcan Arıkan **Onur Güngör** **Suzan Uskudarli**
Department of Computer Engineering, Bogazici University, Istanbul, Turkey
{ugurcan.arikan,onurgu,suzan.uskudarli}@boun.edu.tr

Abstract

For the spell correction task, vocabulary based methods have been replaced with methods that take morphological and grammar rules into account. However, such tools are fairly immature, and, worse, nonexistent for many low resource languages. Checking only if a word is well-formed with respect to the morphological rules of a language may produce false negatives due to the ambiguity resulting from the presence of numerous homophonic words. In this work, we propose an approach to detect and correct the “de/da” clitic errors in Turkish text. Our model is a neural sequence tagger trained with a synthetically constructed dataset consisting of positive and negative samples. The model’s performance with this dataset is presented according to different word embedding configurations. The model achieved an F_1 score of 86.67% on a synthetically constructed dataset. We also compared the model’s performance on a manually curated dataset of challenging samples that proved superior to other spelling correctors with 71% accuracy compared to the second best (Google Docs) with 34% accuracy.

1 Introduction

Misspellings can change the meanings of words and, consequently, of sentences, which can lead to major miscommunication and frustration. This paper focuses on a common spelling error in Turkish, namely the spelling of the “de/da” clitic. Its written form (“de” and “da”) depends on the vowel harmony rule that is based on the last vowel of the word previous to the conjunction. When the final vowel of the prior word is in {e,i,ö,ü} the clitic is written as “de”, otherwise (in {a,ı,o,u}) it is written as “da”. For example, in the sentence “Selin de burada” meaning “Selin is also here”, the last word before the clitic (“de”) is “Selin” whose final vowel is “i”. Thus, the clitic is written as “de”. Whereas, in the sentence “Fatma da burada” meaning “Fatma is also here”, the last word before the clitic (“da”) is “Fatma” whose final vowel is “a”, causing the clitic to be written as “da”.

The “de/da” clitic in Turkish is a conjunction when it is written separately and has the same meaning as "as well", "too", and "also" in English. In addition to being a conjunction, the “de” and “da” homonyms may be used as locative suffixes meaning “at” or “in”. For example, the word “araba” (car) with the suffix “-da” (“arabada”) means “in the car”. Although the “de/da” clitic in the meaning of conjunction must always be written separately, it is commonly confused with the locative suffix "de/da" and incorrectly written concatenated to the previous word.

The misspelling of the "de/da" clitics alter the meaning of a sentence, and possibly render it meaningless. For example, when the clitic in the sentence "Araba da gördüm" is misspelled as "Arabada gördüm", changes the meaning from “I also saw a car” to “I saw it in the car”. This type of misspelling happens to be one of the most pervasive and annoying misspellings in Turkish. One can frequently encounter expressions of criticism and frustration in this regard.

Morphological analysis is not very useful in spelling correction of “de/da” since in most cases new meaningful words form when it is written as a suffix. As such, most of the Turkish spell checkers perform poorly or not at all. The only way to differentiate between them is to take the sentence context into account.

This work proposes a neural sequence tagger model to detect and correct “de/da” errors. The model employs a conditional random field (CRF) for choosing the best prediction based on score vectors that are provided by a multilayered bidirectional LSTM. Words in input sentences are replaced with word embeddings trained with different algorithms. The model is tested with various combinations of these pretrained embeddings on a synthetically constructed dataset, where the best scores were obtained when all three embeddings were used that yielded an F1-Measure of 86.67%. It was also tested on a manually created more challenging dataset.

The main contributions of this work are:

- state-of-the-art spelling corrector that handles the "de/da" misspellings in Turkish,
- a comparative analysis of alternative word embedding models for spell checking Turkish sentences,
- a dataset of Turkish sentences with difficult to detect "de/da" errors, and
- a demo website for spellchecking sentences including "de/da" cases.

The remainder of the paper is organized as follows: Section 2 presents background information needed to follow this work, Section 3 discusses the state-of-the-art and current solutions to spelling corrections in Turkish, Section 4 discusses the model and experiments, Section 5 presents an evaluation of the proposed model, Section 6 reflects on observations and provides insights about the future work, and finally concluding remarks are given in Section 7.

2 Background

2.1 Clitic, Conjunction and Locative Suffix

A clitic is a morpheme that is syntactically independent but phonologically dependent and attached to a host. It has the syntactic characteristics of a word, but depends phonologically on another word or phrase.

A conjunction is a word that syntactically connects other words or larger constituents while also expressing a semantic relationship between them. Some conjunction examples from English include *and*, *or*, *but* and *if*. The clitic "de/da" can be given as an example conjunction in Turkish.

The locative suffix indicates the locative case, which is the grammatical case that conveys a location. In Turkish, the locative case is specified by the suffix "-de/-da".

Our model focuses on the Turkish clitic "de/da" that means "also, as well, too" and must always be written separately. It is commonly confused with the locative suffix "de/da" that means "at" or "in" as explained in Section 1.

2.2 The CoNLL Sentence Representation

In 2003 a data format was introduced for the *CoNLL-2003 shared task: Language-independent named entity recognition* (Kim Sang and De Meulder, 2003). In this format, each word is on a separate line with an empty line after each sentence. The first item of a line is a word, the second is a part-of-speech (POS) tag, the third is a syntactic chunk tag, and the fourth is the named entity tag. To represent sequences of meaningful words, the chunks and entities use B-TYPE to indicate the beginning and I-TYPE to indicate being *inside* the phrase. The TYPE refers to the type of the entity (i.e., person). Numerous datasets for NLP tasks utilize this format for interoperability. A word with tag "O" (outside) is considered as not being a part of a phrase. The CoNLL format is often used for publishing datasets. We use a variant of this format for representing correct and incorrect sentence samples as detailed in Section 4.1.

2.3 Word Embeddings

Word embeddings are the vector representations of different sets of words. They are one of the most widely utilized methods used for language representation. Word embeddings are capable of capturing the semantic and syntactic similarity between words. In this work the word embeddings that are used are GloVe (Pennington et al., 2014), fastText (Grave et al., 2018) and Word2Vec (Mikolov et al., 2013).

Global Vectors for Word Representation (GloVe) (Pennington et al., 2014) is an unsupervised learning algorithm to acquire word vectors form words. It works on word to word global co-occurrence matrices and is successful in capturing semantic information. It combines global matrix factorization and local context window methods to create word embeddings.

FastText (Grave et al., 2018) is an open-source, lightweight library for very fast text classification introduced by Facebook in 2016. FastText is proposed as an extension of Word2Vec that trains models given labeled texts, performs predictions, and evaluates models. It is a hierarchical classifier where labels are represented in a binary tree that

Benim	ben+Pron+Pers+A1sg+Pnon+Gen
de	de+Conj
aklım	akıl+Noun+A3sg+P1sg+Nom
sen**de**	sen+Pron+Pers+A2sg+Pnon+Loc
kaldı	kal+Verb+Pos+Past+A3sg

Table 1: The morphological analysis of a Turkish sentence (My mind also remains with you) with both the clitic and the affix forms of “de”.

facilities much faster model training without loss of accuracy. FastText breaks words into n-grams creating sub-words that are fed to the model to obtain the embeddings of each word. The tri-grams of the word *selam* are *sel*, *ela*, and *lam*. In this way information about patterns within words are captured, which enables out of vocabulary words to be processed.

Word2Vec models generate word embeddings with a two-layer neural network that creates a set of feature vectors for words in a corpus.

2.4 Turkish Language

Turkish is an agglutinative language, where complex words are derived by stringing together morphemes. In agglutinative languages a sequence of affixes are attached to the end of the words. Table 1 shows the morphological analysis of the sentence (using the ITU NLP pipeline (Eryiğit, 2014)): “Benim de aklım sende kaldı.”, which roughly translates to “My mind remains with you too” (a manner of expressing that one’s thoughts are with someone). More literally it translates to “Also, my mind has remained with you.” This sentence includes both forms of “de”, which are shown in bold. The “de” following “Benim” refers to ”also”. The affix “de” within “sende” is locative and means at you (in English this is expressed as with you).

The morphological analysis of Turkish sentences can get very complex. It is rather difficult for non native speakers to learn the ordering of affixes and to distinguish among the clitics. Even native speakers may have trouble distinguishing the intended meaning and will need to clarify the context. These complexities present significant challenges to building language supporting tools for Turkish. Although, machine learning approaches show promise.

3 Related Work

Zemberek is a collection of natural language processing tools for Turkish and is capable of various tasks including morphological analysis, tokenization and sentence boundary detection and basic spell checker. It is also used as the spell checker for LibreOffice. However, it is not capable of detecting the misspelling of the clitic "de/da" as it does not make a semantic analysis on the sentence.(Akın and Akın, 2007)

ITU Turkish Natural Language Processing Pipeline can make syntactic and morphological analysis of raw Turkish sentences, although it is not capable of making a semantic analysis and thus fails to classify and correct spellings of Turkish "de/da" clitic (Eryiğit, 2014).

The spelling correctors for Turkish do not satisfactorily correct misspellings of the “de/da” clitic as they are limited to the morphological analysis of words which is insufficient for accurately classify them. Google, Microsoft Office, and LibreOffice all have different spell checkers for Turkish but none of them present satisfactory results in the case of handling the “de/da” clitics in Turkish. Their accuracy is significantly lower compared to our model as will be detailed in Section 5.

4 Experiments and Results

4.1 Data

To train the model, sentences with both correct and incorrect spellings of the clitic “de/da” are required. For this purpose, incorrect sentences have been generated from the correct sentences from a corpus consisting of approximately 75 million Turkish sentences extracted from various websites, novels and news sites (Yildiz et al., 2016). Since the corpus was extracted from novels and news sites, the sentences are assumed to include only a few or no orthographic errors. Thus, the spellings of the “de/da” cases are considered to be correct when written separately, attached as a locative suffix, or used as a conjunction. Note that some words simply end with “de/da” and these suffixes are not due to locative morphemes (i.e., ‘ziyade’ meaning plentiful). However, such cases are few and considered negligible.

To generate incorrectly spelled forms of “de/da” samples, two simple actions are performed: (1) append the separately written “de/da” to its preceding word and (2) separate the “de/da” suffixes

	Train	Dev	Test
Sentences	15,203	3,729	2,070
Tokens	383,066	94,232	51,226

Table 2: The number of sentences and tokens for the training, development, and test dataset used in training our models.

from the words that contain them. For example, for the sentence “Kedi de gördüm” (meaning “I also saw a cat”), the sentence “Kedide gördüm” (meaning “I saw it at the cat”) is generated by concatenation. Both are syntactically correct sentences but have very different meanings. The sentence “Evde kalıyorum” meaning “I am staying at home” which uses the locative suffix “de/da” correctly, the sentence “Ev de kalıyorum” is generated. The resulting sentence is an incorrectly separated “de/da”, which translates to “I am staying also home”, which doesn’t make sense.

The generated sentences are tagged in a manner like the CoNLL NER tags (Section 2.2). We tag incorrectly spelled terms with “B-ERR” and all others with “O” (other), such as:

Correct sentence	Incorrect sentence
`Onlar O`	`Onlarda B-ERR`
`da O`	`'Sende O`
`'Sende O`	`kalsın O`
`kalsın O`	`, savcılığa O`
`, savcılığa O`	`verirsin O`
`verirsin O`	`'O`
`'O`	`dediler O`
`dediler O`	`. O`
`. O`	

The dataset consisting of sentences whose words are tagged with “B-ERR” and “O” are divided into training, development, and test sets (Table 2).

In addition to the this synthetically constructed dataset, a dataset consisting of 100 Turkish sentences with misspelled forms of “de/da” is formed manually. The sentences in this second dataset is created so that they are syntactically correct but semantically challenging to understand[1].

4.2 Model

A multilayered bidirectional LSTM and CRF based model (Akbik et al., 2018) that uses pretrained embeddings was considered suitable for our problem since it achieved the state-of-the-art results for named entity recognition, part-of-speech tagging and chunking tasks.

4.3 Experimental Setup

The initial task was to train the model with Turkish word embeddings. For this task, GloVe was used with the dimension size of 300 and window size of 15. The pretrained word vectors for Turkish were obtained from the model trained on Common Crawl and Wikipedia using fastText (Grave et al., 2018). The pretrained Word2Vec vectors are for Turkish with dimension size 300 (Güngör and Yıldız, 2017). The models were trained using Continuous Bag of Words (CBOW), with position-weights, dimension size of 300, character n-grams of length 5, and a window size of 5 and 10 negatives.

Parameter optimization was performed to achieve the best F$_1$ scores. During hyperparameter optimization, the training was performed for 10 epochs using fastText embeddings for all possible configurations for the following criteria:

- batch size: [8, 16, 32, 64]
- RNN layer size: [1, 2, 3, 4]
- learning rate: [0.05, 0.1, 0.15, 0.2]
- hidden size: [16, 32, 64, 128, 256]

The hyperparameters with the highest F$_1$ score are: batch size=16, RNN layer size=2, learning rate=0.2, and hidden size=256. These parameter values were used to train models with different word embedding configurations for 150 epochs. All models were trained on a PC with GPU GeForce RTX2080 with 32 GB RAM. A single training took approximately 10 hours to complete.

5 Results and Evaluation

A total of seven different models were trained with the optimal parameters. The embedding types used were GloVe (Pennington et al., 2014), fastText (Grave et al., 2018) and Word2Vec. These embeddings were also combined by concatenating them to form a new embedding with a higher number of dimensions. Furthermore, two baseline models were used for comparison purposes. Baseline model baseline$_1$ considers only the separately written “de/da” as correct, falsely classifying the correctly spelled locative suffix “de/da” as a misspelling. Baseline model baseline$_2$ considers only

[1] Both this and the synthetic dataset is shared at https://github.com/derlem/kanarya

Model			BL		P	R	F_1
G	fT	W	1	2	(%)	(%)	(%)
			+		10.60	25.67	15.00
				+	59.89	74.32	66.33
+					87.09	81.53	84.22
	+				87.05	79.73	83.23
		+			87.67	79.50	83.39
+	+				90.55	81.98	86.05
+		+			89.79	81.83	85.63
	+	+			87.59	80.03	83.64
+	+	+			**91.56**	**82.28**	**86.67**

Table 3: A comparison of the results our model trained with various combinations of the Glove (G), fastText (fT) and Word2Vec(W) methods on a synthetically constructed dataset against two baseline models (BL-1 & BL-2). P, R and $\mathbf{F_1}$ refer to the precision, recall, and $\mathbf{F_1}$ measures.

the suffix form of "de/da" to be correct, falsely classifying the correctly spelled "de/da" conjunction as a misspelling. The results of these models are shown in Table 3.

Figure 1 shows some of the challenging sentences that where spelling errors and were correctly identified using our best model. The erroneous words are shown with a red bounding box. In these examples, the second sentence correctly identifies "çokta" as an error. In Turkish, when "-de/da" is to follow a work that ends with of the letters "p, ç, t, k, s, ş, h, f", "-de/da" becomes "-te/-ta". However, as a grammatical term it is referred to as "de/da" and is the more common case.

Finally, we examined the performance of various configurations of our model with other well-known spellcheckers for the 100 manually curated challenging sentences. Table 4 shows that our models performed significantly better than others. The best model utilizes the Word2Vec embeddings with an accuracy of 71% while the second best accuracy was achieved by Google Docs with 34%.

6 Discussion and Future Work

The work presented in this paper created a state-of-the-art model that achieved a much higher accuracy in detecting the "de/da" misspellings in Turkish when compared to existing spell correctors. Our model currently only addresses the misspelling of the "de/da" clitic. Further work is needed to integrate this work with morphological analysis to yield a more complete spell checker for Turkish.

Maça iyide başlamıştık aslında ama olmadı.

Bu adam öyle aslında çokta kötü bir adam değil.

Ya ders calış yada çık dışarıda oyna.

Sonunda bizde derin öğrenmeye geçtik.

Kalemleri ve kitabı ev de kalmış.

Belkide Galatasaray'ı şampiyonluktan ettik.

Onuda yaptığında gidebilirsin.

Figure 1: The errors caught by our model with the best configuration on challenging sentences.

Recently, much success is being reported regarding the use of BERT (Devlin et al., 2019), which we are currently working on to obtain word embeddings, which we expect to further increase the performance of our model.

The proposed model can be integrated with various platforms, ranging from text editors to social media to messaging platforms. The "de/da" distinctions can be especially difficult for foreigners who are attempting to learn Turkish as a second language. Such spellcheckers could be very useful in assisting learning. We are also working on developing and API and a demo service that make this work more accessible. The scope of access will be limited by the resources we are able to acquire.

7 Conclusions

We developed a deep learning model to detect orthographic errors caused by the misspelling of the clitic "de/da" in Turkish. This model uses various word embeddings to train a model for the named entity recognition task for this clitic. The best model achieved an F_1 score of 86.67% on a synthetically constructed dataset. To our knowledge, this is the state-of-the-art result for spelling correction for the misspellings of "de/da" clitics in Turkish. These results are very encouraging. We intend to extend the model with a similar case as well as make all the resources related to this work accessible as open source.

Abstract

Propaganda of various pressure groups ranging from big economies to ideological blocks is often presented in a form of objective newspaper texts. However, the real objectivity is here shaded with the support of imbalanced views and distorted attitudes by means of various manipulative stylistic techniques.

In the project of Manipulative Propaganda Techniques in the Age of Internet, a new resource for automatic analysis of stylistic mechanisms for influencing the readers' opinion is developed. In its current version, the resource consists of 7,494 newspaper articles from four selected Czech digital news servers annotated for the presence of specific manipulative techniques.

In this paper, we present the current state of the annotations and describe the structure of the dataset in detail. We also offer an evaluation of bag-of-words classification algorithms for the annotated manipulative techniques.

1 Introduction

State and pressure groups propaganda is a very well studied phenomenon from the sociological point of view (Herman and Chomsky, 2012; Zhang, 2013; Paul and Matthews, 2016). With the spread of digital media, the influence of propaganda news grows rapidly (Helmus et al., 2018) and the consequences of public opinion manipulation reach new levels (Woolley and Howard, 2017).

The main way of self-protection against such propaganda influence lies in careful verification of the presented information sources. Nevertheless, psycholinguistic evidence (Fazio et al., 2015) shows that a prevailing opinion often outweighs even direct knowledge. Computational tools that could warn against possible manipulation in the text can thus offer an invaluable help even to an informed reader.

In the following text, we are presenting the first results of a research project aimed at automatic analysis of the *style* of a newspaper text to identify a presence of specific manipulative techniques. In the first phase, a specific tool for expert annotations of selected news from 4 Czech internet media sites was developed (Baisa et al., 2017). This tool has now been used to obtain 7,494 annotated articles with detailed manipulative techniques annotations of texts expressing e.g. blaming, demonizing, relativizing, labelling, or fear mongering. The following Section 2 provides detailed information about the dataset characteristics and content. In Section 3, an evaluation of 10 classification techniques and their results with the benchmark dataset is presented.

2 The Benchmark Dataset

The Propaganda benchmark dataset currently contains data from two successive years. The first part is based on two sets of articles from 2016. The newspaper texts were extracted from four newspaper media domains[1] which were previously scrutinized by annotators as possible sources of pro-Russian propaganda. The downloaded cleaned data were merged with the annotation data stored separately in a SPSS[2] format (converted with the GNU PSPP tool[3]) which is used widely in Social science research. The result is a corpus with metadata (structure attributes) available for full-text

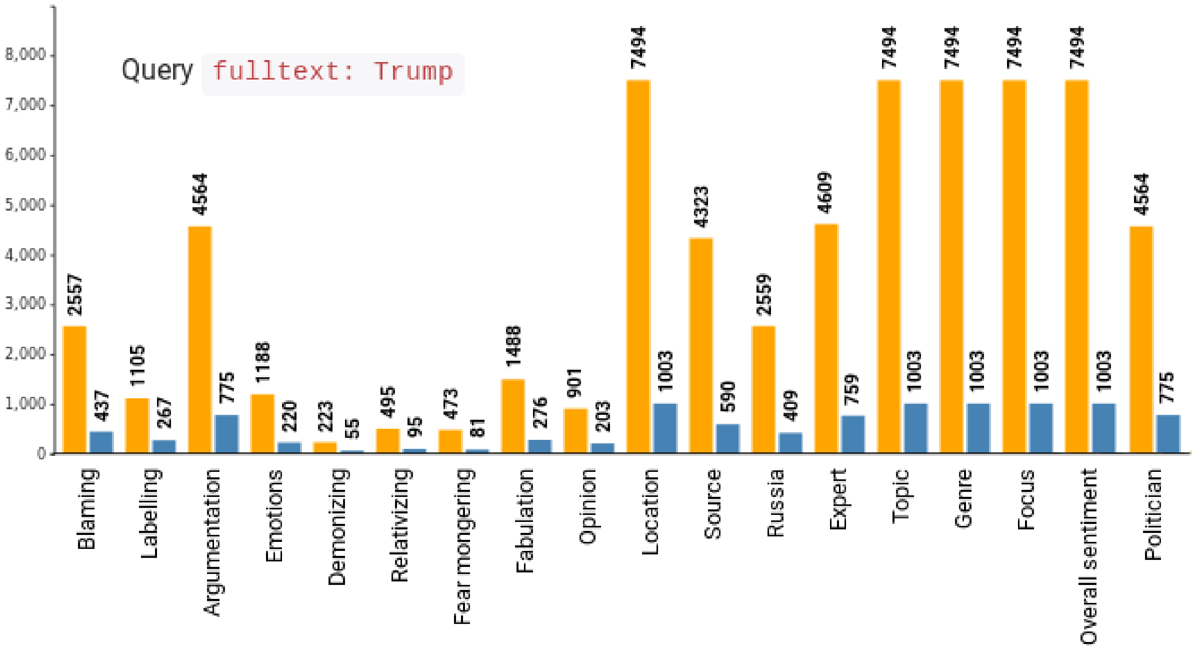

Figure 1: Numbers of articles with significant attribute values (not null, neutral or missing) in the whole collection of 7,494 documents. The first (yellow) columns show numbers for the whole collection and the second (blue) columns show an example of a filtered subset of articles containing the word "Trump".

search in the Sketch Engine corpus manager (Kilgarriff et al., 2014). As far as we know, this is the first corpus of propaganda text annotated for detailed ensemble of manipulative techniques. The full document texts were thus supplemented with the following attributes (see Figure 1 for representation of particular attributes in the dataset):

a) **Blaming**: does the text accuse someone of something?

b) **Labelling**: the text uses specific labels – short and impactful phrases or words – to describe a person or a group.

c) **Argumentation**: does the text present facts or arguments (logical, emotional, etc.) to support the main claim?

d) **Emotions**: What is the main emotion the text is trying to evoke in the reader? Anger, hate, fear.

e) **Demonizing**: is the “enemy” and/or his/her goals or interests presented in the text as being evil?

f) **Relativizing**: are the presented actions of a person, group or party being relativized?

g) **Fear mongering**: is the text trying to appeal to fear, uncertainty or other threat?

h) **Fabulation**: does the text contain unsubstantiated, overstated or otherwise incorrect claims?

i) **Opinion**: does the author of the text present his or hers personal opinion?

j) **Location**: what is the main location the text talks about?

k) **Source**: is the text presented as being based on a specific source?

l) **Russia**: is the topic related to Russia?

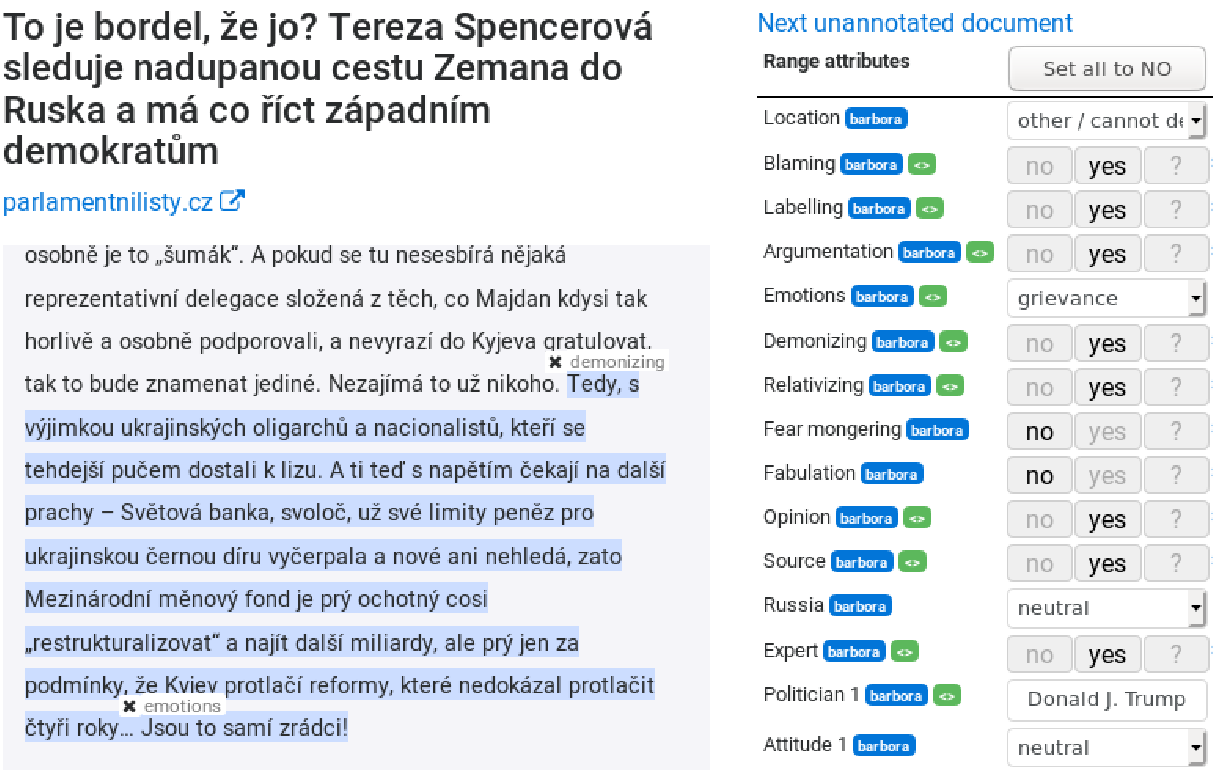
m) **Expert**: is the text or opinion in the text presented as being supported by an expert?

n) **Attitude to a politician**: neutral, negative, positive for up to 3 mentioned politicians.

o) **Topic**: migrant crisis, domestic politics, etc.

p) **Genre**: report, interview, or commentary.

q) **Focus**: foreign, domestic, can’t be determined.



To je bordel, že jo? Tereza Spencerová sleduje nadupanou cestu Zemana do Ruska a má co říct západním demokratům

parlamentnilisty.cz

osobně je to „šumák". A pokud se tu nesesbírá nějaká reprezentativní delegace složená z těch, co Majdan kdysi tak horlivě a osobně podporovali, a nevyrazí do Kyjeva gratulovat, tak to bude znamenat jediné. Nezajímá to už nikoho. Tedy, s výjimkou ukrajinských oligarchů a nacionalistů, kteří se tehdejší pučem dostali k lizu. A ti teď s napětím čekají na další prachy – Světová banka, svoloč, už své limity peněz pro ukrajinskou černou díru vyčerpala a nové ani nehledá, zato Mezinárodní měnový fond je prý ochotný cosi „restrukturalizovat" a najít další miliardy, ale prý jen za podmínky, že Kviev protlačí reformy, které nedokázal protlačit čtyři roky... Jsou to samí zrádci!

Figure 2: An example of (a part of) an annotated article with ranges showing *demonizing* and *grievance* as a value of the *emotions* attribute.

r) **Overall sentiment**: neutral, negative, or positive.

The second part, articles from the same domains published in 2017, has undergone a fine-grained annotation using a specific data processing and annotating tool (Baisa et al., 2017), which requires the annotators not only to specify the respective attribute values but also enrich them with particular phrase examples. The annotators were asked to amend each significant attribute value (not null, neutral or missing) by marking a particular block (or blocks) of text that offer the evidence of the value. The attributes are split into two groups. The attributes a) to n), denoted as *range attributes*, are bound to a sequence of words from the text, the attributes o) to r), i.e. the document attributes, are related to the article as a whole. An example of annotated range attributes can be seen in Figure 2. Unfortunately, due to the complexity of the annotation process, there was only one annotator per document and the inter-annotator agreement could not be decided.

The text of the articles has been extracted from the media server web pages, then tokenized using *unitok* (Michelfeit et al., 2014) and morphologically annotated using *majka* (Šmerk, 2009) and *desamb* (Šmerk, 2010). The dataset thus allows complicated full-text search in the articles. The size of the data (sub)sets is in Table 1.

3 Dataset Evaluation

We have performed the dataset evaluation to express the baseline accuracy of assigning the labels automatically using 10 machine learning classifiers. The classifiers were trained with the 20,000 most frequent lemmata present in the corpus, with the text transformed to a numerical vector format using bag-of-words using TF-IDF weighting.

3.1 Selected Classifiers

For the evaluation, we have chosen a representative subset of classification techniques, which are often employed in bag-of-words tasks for attribute value estimation. The resulting set of classifiers includes:

- `dummy`: a baseline, classifies every instance as the majority class present in the input data.
- `passive_aggressive`: an efficient Perceptron-like classifier (Crammer et al., 2006).
- Two Naive Bayes variants: `bernoulli_nb` assumes that the data is Bernoulli distributed, while `multinomial_nb` assumes a Multinomial distribution (McCallum et al., 1998).
- Three different Support Vector Machine classifiers trained using stochastic gradient descent: `sgd_l1` with L1 regularization, `sgd_l2` with L2 regularization and `sgd_elasticnet` with Elasticnet regularization (Zhang, 2004).
- `ridge` is a regularized linear regression based classifier (Rifkin and Lippert, 2007).
- `random_forest`: An ensemble of decision tree classifiers is built on samples drawn from the training set. The resulting class during the classification is obtained by taking the most common class as assigned by each of the decision trees (Breiman, 2001).
- `nearest_centroid`: computes a per-class mean of examples during training, the classification then assigns class according to the closest mean (McIntyre and Blashfield, 1980).

Table 3: Examples of word sentiment data used in the experiment.

Czech	English	Positive	Negative

přístupný	accessible	0.625	0
zastrčený	inserted	0.125	0
úslužný	obliging	0.75	0

3.2 Evaluation Strategy

The final accuracy scores have been obtained by stratified 3-fold cross validation to evaluate the performance of the classifiers. In the 3-fold cross validation, documents were first grouped by their classes. Each of these classes was then divided into 3 parts. The training set for the investigated classifier then consists of two parts of all groups and the test set consists of the remaining parts of all groups. There are three different ways to select which of the parts will go into the training and the evaluation sets. Each classifier has been evaluated three times, once with each of these ways or folds. The resulting score was computed as the average of the three scores obtained for each of the folds.

Table 4: Classifier prediction accuracy sorted by the weighted F1-score which takes into account imbalanced attribute classes. The resulting accuracy is compared to the baseline accuracy of the majority class.

	best classifier	weighted F1	accuracy	baseline	difference

3.3 Evaluation Metrics

Each trained classifier predicts the class for a document based on its text. By comparing the results to the dataset gold standard data, each of the classifier was evaluated by means of its attribute-related accuracy, precision, recall, and F1 score. The accuracy results are summarized in Table 2 and compared with the `dummy` baseline accuracy in Table 4.

3.4 Correlations of Attributes and Sentiment Coefficients

The set of article attributes contains several items which express sentiment values, either to the article as a whole or to a mentioned politician. We have evaluated the possibility of using the article sentiment analysis to predict the corresponding attribute values for the texts.

The paragraph sentiment analysis results were explicitly expressed as an average score of positivity and negativity of particular words. A list of 6,261 words was prepared as projections of SentiWordNet (Baccianella et al., 2010) scores via the Czech WordNet (Rambousek et al., 2018; Horák et al., 2008) database, see Table 3 for examples. Each paragraph received an average value of *only positive* words, *only negative* words and of their *average score* computed as a difference between word positivity and negativity. The overall document scores were then computed as a maximum positive paragraph score, maximum negative paragraph score and maximum and minimum of the average word score for each paragraph.

Each of the resulting document sentiment scores were evaluated for a correlation[4] with positive and negative values of the selected attributes annotated in the data. The results are presented in Table 5. None of the attributes has proven really strong correlation, but several attributes partly correlate with the maximum negative sentiment of the document. Interestingly, there is no correlation in case of the *emotions* attribute.

4 Conclusion and Future Directions

We have introduced a new benchmark dataset for propaganda manipulative techniques detection in Czech newspaper texts. The dataset contains 7,494 documents annotated for the presence of eight manipulative techniques and 10 document attributes relevant for propaganda detection. The

[4] Computed as Spearman's correlation coefficient with statistical significance.

dataset is currently being expanded with the third part of documents from 2018 and it is planned to be released for public access after this expansion.

We have evaluated the current data with 10 current classification techniques. Regularized linear regression and Support vector machines are able to classify the data with the best accuracies, even though the manipulative techniques need to employ extra features to significantly improve over the baseline.

In the currently running experiments, we are preparing new evaluation of the dataset using detailed stylometric features and distributed semantic representations of the texts.

Abstract

In the last few years, the increasing availability of large corpora spanning several time periods has opened new opportunities for the diachronic analysis of language. This type of analysis can bring to the light not only linguistic phenomena related to the shift of word meanings over time, but it can also be used to study the impact that societal and cultural trends have on this language change. This paper introduces a new resource for performing the diachronic analysis of named entities built upon Wikipedia page revisions. This resource enables the analysis over time of changes in the relations between entities (concepts), surface forms (words), and the contexts surrounding entities and surface forms, by analysing the whole history of Wikipedia internal links. We provide some useful use cases that prove the impact of this resource on diachronic studies and delineate some possible future usage.

1 Introduction

The availability of large corpora spanning different time periods has encouraged researchers to analyse language from a diachronic perspective. Language is dynamic and detecting significant linguistic shifts in the meaning and usage of words is a crucial task for both social and cultural studies and for Natural Language Processing applications. Recent work focusing on the automatic detection of the semantic shift of words has adopted diachronic (or dynamic) word embeddings (Kim et al., 2014; Hamilton et al., 2016b; Kulkarni et al., 2015). This type of work represents words as vectors in a *semantic* space where the proximity between word vectors indicate the existence of a semantic relationship between the terms involved. The diachronic analysis is then performed by building a different semantic space for each period of investigation and aligning vectors belonging to different spaces in order to make them comparable. The variations in the similarity between the word vectors in two different spaces marks possible changes in the context of appearance of that word. This is used as a proxy indicator of change, either cultural, social or semantic, associated with the occurrence of that specific word. This kind of work has generated a variety of resources for the diachronic analysis of word meanings, covering different time periods, languages, and genres.

While the broader area of automatic detection of semantic shift of words is gaining momentum, only little effort has focused on the more specific problem of analysing the semantic shift of named entities. This problem has a huge impact on the correct identification of entities in context, with repercussions on many natural language processing problems, such as entity linking and search, aspect-based sentiment analysis and event detection (Kanhabua and Nørvåg, 2010b; Tahmasebi et al., 2012; Georgescu et al., 2013).

Generally, an entity has a clear referent and what evolves is the context in which it appears or the surface form used to refer to it. In this work, we build a resource that tracks how the surface forms used to link an entity change over time by taking into account the revisions of Wikipedia pages. In doing so, we also extract time-dependent contexts of each mention of a link in Wikipedia

Proceedings of Recent Advances in Natural Language Processing, pages 84–91,
Varna, Bulgaria, Sep 2–4 2019.

pages. The Wikipedia page history, sometimes called revision history or edit history, tracks the order in which changes were made to any editable Wikipedia page. We believe that this corpus can help researchers to design approaches for tracking entities usage over time. This resource can be functional to promote new research for dynamic embeddings of named entities. We propose some preliminary case studies for proving the potentiality of this resource.

The paper is structured as follows: Section 2 reviews the state of the art, while Section 3 describes the methodological aspects of our approach. Section 4 shows some use cases of our resource followed by some final remarks.

2 Related Work

The diachronic analysis of language via word embeddings has been an active area of research during the past decade that has generated many resources for several time periods, languages and genres. Kim et al. (2014) used Google Ngram as a diachronic resource to build word embeddings via Word2Vec on a random sample of the 10 million 5-grams from the English fiction portion of the corpus. The authors made the resource available, but due to space limitations, they released the word embeddings only for the 5-year time period. A similar approach was proposed by Grayson et al. (2016), where Word2Vec embeddings are trained on the Eighteenth-Century Collections Online corpus (ECCO-TCP) by taking into account five twenty-year periods for 150 million words randomly sampled from the "Literature and Language" section of the corpus. Hamilton et al. (2016b) also trained word embeddings on the Google Ngram for detecting semantic changes. The authors analysed four different languages, i.e. English, French, German and Chinese, and created a resource which has been successfully used in subsequent studies (Garg et al., 2017; Hamilton et al., 2016a). A different approach to detect the semantic shift of words was adopted by Kulkarni et al. (2015). The authors adopt a change point detection algorithm on the time series generated by computing the cosine similarity between word embeddings trained on several corpora, such as: Twitter, Amazon reviews, and the Google Book Ngrams. A similar approach is proposed in Basile and McGillivray (2018), in which the Temporal Random Indexing (TRI) is adopted for building a distributed, time-based, word representation for the JISC UK Web Domain Dataset (1996-2013) corpus.

Other research efforts have been directed to release resources and applications for the visual analysis and querying of these diachronic collections. The Google Ngram viewer (Michel et al., 2011) was released as a tool for allowing users to query the Google Ngram corpus, a collection of ngram occurrences spanning several years and languages extracted from the Google Book project. Hellrich and Hahn (2017) proposed a system that allows users to explore different corpora via a diachronic semantic search. They used the Corpus of Historical American English, the Deutsches Textarchiv "German Text Archive", and the Royal Society Corpus, in addition to the Google Books Ngram Corpus.

Research directed toward the specific problem of detecting changes in the context surrounding named entities has attracted limited attention compared to the broader area of automatic detection of the semantic shift of words. Some previous work on named entities focused on problems related to searching (Berberich et al., 2009; Kanhabua and Nørvåg, 2010a; Zhang et al., 2016). Tahmasebi et al. (2012) proposed an interesting approach to identify the evolution of named entities. Berberich et al. (2009) defined a method for query reformulations able to paraphrase the user's information need using terminology prevalent in the past. In this work, the original dataset is enriched with annotated phrases extracted from the text by using Wikipedia page titles. In Kanhabua and Nørvåg (2010a), Wikipedia internal links and redirect pages are exploited for finding synonyms across time by using different snapshot of Wikipedia. The identified synonyms are used for query expansion in order to increase the retrieval effectiveness. In some respects, this approach is similar to ours. However, it does not use page revisions and the relation between concepts, surface forms and contexts. Zhang et al. (2016) described an approach to find *past* similar terms closest to a given *present* term. The goal was to improve the retrieval effectiveness in archives and collections of past documents. In this work, Wikipedia is only functional to the creation of the test set, where only the information about the entity lifetime is used (e.g. the time when the name of a country or a company changed). Regarding named entity evolution, Tahmasebi et al. (2012) proposed a method to capture the evolution of one name into another by using a sliding window of co-occurrence terms. The corpus used for the evaluation is the New York Times Annotated Corpus. Lansdall-Welfare et al. (2017) analysed a collection of historical data spanning 150 years of British articles. The authors focus on historical and cultural changes that are tracked via a quantitative analysis of word frequencies. However, they expand their methodology to a "semantic" level by working on named entities extracted from text. The work proposed in Szymanski (2017) is the first attempt to highlight the potential of diachronic word embeddings for solving analogy tasks involving entities and relationships, although this work does not seek to capture named entities in an explicit way. Moreover, Caputo et al. (2018) applied a method to recognise and linking named entities in the whole New York Times corpus. The Temporal Random Indexing is then applied on the annotated corpus in order to build a semantic vector representation for entities and tracking significant shift in their contexts. An explicit representation of named entities is also provided in (Bianchi et al., 2018) where the authors tackle the problem of incorporating time in the Knowledge Graph embeddings in order to provide a similarity measure between entities that accounts for temporal factors.

3 Methodology

The revision history associated with each Wikipedia page opens the way to different diachronic analyses of the highly interconnected concepts represented by its pages. In Wikipedia, pages are interconnected by internal links manually created by users that consist of a surface form and a target. The target is another Wikipedia page, and can be regarded as a "conceptual" link created by the user between the surface form and a specific concept (the Wikipedia page). The same surface form can link several entities and the same entity can be linked to several surface forms. Moreover, since a surface form occurs in a specific context, we can define the surface context as a window of n words to the left and to the right of the surface form. Each page has multiple revisions created every time a user edits that page, and each revision page is associated with a timestamp, so that it is possible to track the changes over time of the temporal relation existing between the surface form, the target and context. For example, it is possible to track the change over time of different surface forms linking to a specific target or to detect the change in the target context. All these capabilities open several possibilities to the analysis of entities using a diachronic perspective.

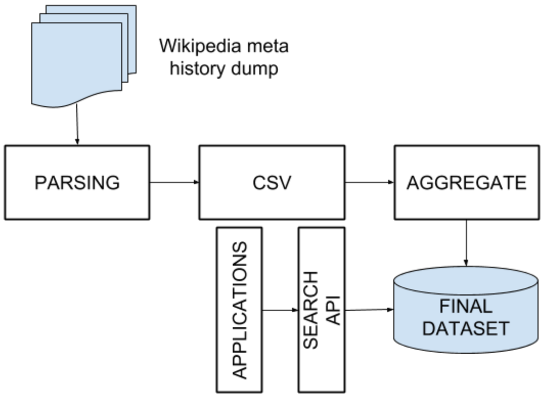

Figure 1: Flowchart of the dataset creation.

Figure 1 depicts the process followed for the creation of our resource. The starting point is the Wikipedia meta history dump which includes all the page revisions in XML format. The dump is composed of several XML files containing the page revisions in Mediawiki syntax. Each XML file is parsed using the DKPro-JWPL API[1], which is able to produce the accurate Abstract Syntax Tree (AST) of each page revision. From the AST, we extract all the internal links that refer to standard[2] Wikipedia pages; each internal link has a surface form and the name of the linked Wikipedia page. In addition, we extract the year from the revision timestamp and the context as the n words around the internal link. The context is processed using the *StandardAnalyzer* provided by the Apache Lucene API[3]. Each extracted internal link is saved in a CSV file as a record consisting of: year, pageId, target, surface form, left context and right context.

An example of a row in a CSV file is reported below:

[1] https://github.com/dkpro/dkpro-jwpl

[2] We remove links to special pages, such as category and user pages.

[3] http://lucene.apache.org/

```
  2003 11057 forge forge forging
term shaping metal use heat
hammer basic smithy contains
sometimes called hearth heating
metals commonly iron steel
malleable temperature
```

The row meaning is that in page *11057* in the year *2003* the target *forge* is linked by the surface form *forge* with the right context *forging, term, ...* and the left context *sometimes, called, ...*.

Since the tuple <*year, surface form, target*> can occur multiple times, we aggregate multiple tuple occurrences in a single record. The aggregation step is performed several times, one time for each dump file plus a final step that aggregates all the records in a single file that represents our final dataset.

In the final file, information is stored as follows:

- A row starting with the sequence *#T* <*TAB*>T_i which identifies the beginning of a sequence of rows in the file that are related to the page (concept) T_i (until a new row starting with *#T* is encountered). T_i represents the Wikipedia page title;
- A sequence of rows containing several values separated by the *tabular* character in the form: year y_k, surface form s_j, the number of time that the surface s_j is used for linking T_i in the year y_k. Then, we build a Bag-of-Word (BoW) from the words occurring in the context, and in the same row we provide the BoW size followed by all the words in the BoW represented as a sequence of pairs <*word, occurrences*>.

A row in the aggregate format is shown in the following example:

```
  #T Apple Computer
2018 Apple Computer 2 30 freedos
1 x 1 supports 1 support 3
officially 1 10 1 s 1 programming
1 9 1 scsi 1 bda 1 2005 1 usb
2 mac 3 announced 2 storage 2
august 1 31 1 ray 2 advanced 1 os
3 its 2 interface 2 blu 2 joined
1 aspi 1 march 1 8.5.1 1 disc 2
mass 2
2018 Apple 1 21 developed 1
computer 1 years 1 independently
1 group 1 computer's 1 1987
1 he 1 while 1 advanced 1
henson 1 associates 1 eric 1
tracking 1 facial 1 technology
1 collaborated 1 six 1 starting 1
worked 1 animation 1
```

The aggregated format shows that the surface form *Apple Computer* was used twice for linking the target *Apple Computer*, while the surface form *Apple* was used only once. The BoW follows each surface form. In the first aggregation step, an aggregated file is created for each segment of the Wikipedia dump, then in the second aggregation step, all the segments are merged in the final dataset.

In this first version of the dataset we do not take into account disambiguation pages and redirects. Managing redirects is a very challenging problem since they are not consistent over dumps.

Relying on this final dataset, we built a search API for easily retrieving all the information related to the target, the surface form and the context according to a specific time period[4].

We exploit the meta history dump dated 1st February 2019; the first Wikipedia pages are dated 2001. The original dump size is about 950GB, the total size of the CSV files is about 30GB, while the final dataset obtained by aggregating data from the CSVs is about 47GB. We set to 10 the dimension of the context window. Since a page can have multiple revisions in the same year, in building our resource we consider only the latest one for each year. It is possible to perform a more fine-grained analysis by taking into account more revisions per year (e.g. a revision for each month). The total number of distinct targets is about 31M, which is larger than the effective number of Wikipedia pages for several reasons: 1) some targets are a redirect to other targets; 2) some pages have been removed or renamed over the years; 3) some targets are a link to a specific section of a page. In this release, we do not take into account these issues, which we plan to tackle in a future release.

The search API can be used for building several applications, such as a RESTful Web Services for remotely querying the data, data analysis for discovering when named entities or surface forms change their usage, and data visualisation.

It is important to underline that the proposed approach is completely unsupervised and language independent since it does not require any NLP pre-

[4] The dataset and the source code are available here https://github.com/pippokill/dae

processing step. Moreover, the proposed methodology is intrinsically multi-language because it is possible to rely on the specific Wikipedia dump of the language under analysis. In addition, it is possible to exploit multi-language Wikipedia links for comparing the evolution of named entities across different languages.

One limit of our approach is the short time frame taken into account since Wikipedia was launched in 2001. However, our approach is incremental and the dataset can grow when new Wikipedia dumps are available. Moreover, the dataset is not only useful for diachronic analysis of entities, but the detection of semantic changes over a short period of time can be exploited to improve the performance of several algorithms, such as entity linking, relation extraction and ontology/knowledge graph population.

4 Use cases

In this section we report some use cases that have emerged from an exploratory analysis of the proposed dataset. We perform the analysis by indexing the 1M most frequent targets extracted from the final dataset. We build an API for querying the dataset by using the Apache Lucene library. Each following subsection reports details about a specific use case.

4.1 Concepts linked by a surface form

The first use case concerns the analysis of the concepts linked by a surface form over time. Table 1 shows the concepts linked by the surface form "Donald Trump". While before 2015 there is only one concept linked by this surface form, since 2016, the concepts related to the presidential campaign have emerged, with the concept "Presidency of Donald Trump" occurring in the first top-5 concepts since 2018. It is important to underline that the first column (2015) reports only one concept since no other concepts are related to the surface form "Donald Trump" in the 2015. This is due to the fact that in this preliminary study we limited our analysis to the 1M most frequent targets and not the whole set of 33M targets. A reverse analysis shows the usage of the surface form "President Trump" to refer to the concept "Donald Trump" since 2017.

4.2 Contexts of a given target

Another interesting analysis concerns the change over time of the contexts of a given target. In this case, it is possible to compute the displacement over time of the target concept by computing the cosine similarity between the context BoWs. For each pair of years, we build a BoW vector for the context of the target concept. Then, we generate a time series by computing the cosine similarity between the BoW of two consecutive years (BoW_{y_i} and $BoW_{y_{i+1}}$). Figure 2 reports the time series generated for the concept "Donald Trump"; we observe a change point corresponding to a drop in similarity between 2015 and 2016.

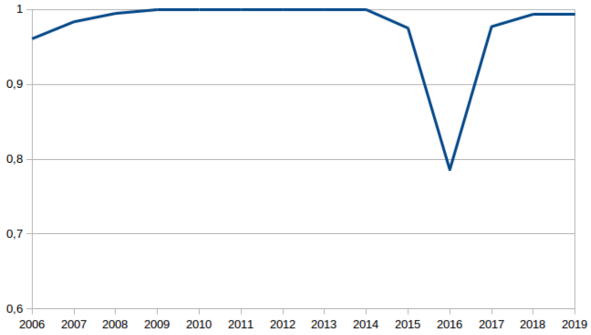

Figure 2: BoW cosine similarity time series for the concept "Donald Trump".

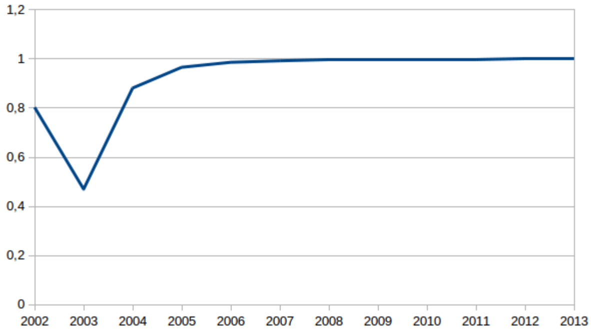

Figure 3: BoW cosine similarity time series for the concept "Arnold Schwarzenegger".

A similar analysis performed for the concept "Arnold Schwarzenegger" shows a change point between 2002-2003 and 2003-2004, as reported in Figure 3. Through the analysis of the most frequent words in the BoWs of the contexts of "Arnold Schwarzenegger" in the period 2002-2004, it emerged that while the most frequent words in 2002 were *film, actor, movie, terminator*, in 2003 new words such as *governor* and *California* related to "Arnold Schwarzenegger" political

2015	2016	2017	2018	2019
Donald Trump	Donald Trump presidential campaign, 2016	Donald Trump	Donald Trump	Donald Trump
	Protests against Donald Trump	Protests against Donald Trump	Protests against Donald Trump	Donald Trump presidential campaign, 2016
	Donald Trump sexual misconduct allegations	Donald Trump presidential campaign, 2016	Donald Trump presidential campaign, 2016	Protests against Donald Trump
	Political positions of Donald Trump	Donald Trump sexual misconduct allegations	Donald Trump sexual misconduct allegations	Donald Trump sexual misconduct allegations
	Stop Trump movement	Donald Trump (Last Week Tonight)	Presidency of Donald Trump	Presidency of Donald Trump

Table 1: Top-5 concepts linked by the surface form "Donald Trump".

activity have started to appear, to become the most frequent words in the BoWs since 2004.

Another interesting use case is the analysis of the BoWs of the targets linked by the same surface form. This analysis may highlight changes in the way common words are used for referring to named entities. For example, analysing the usage of the surface form "tweet", we observe that since 2012 it has been used to refer to the concept "Twitter", while before 2012 it did not refer to any concept.

4.3 Similarity between two entities over time

The last scenario shows the possibility to compute the similarity between two entities over time as the cosine similarity between the target contexts. Figure 4 reports the time series of similarities between three pairs of entities (Apple-Microsoft, Apple-IBM, IBM-Microsoft). It is interesting to observe that the similarity between IBM and Microsoft is higher then the similarity between Apple and the other two entities, although Apple is equally related to both of them.

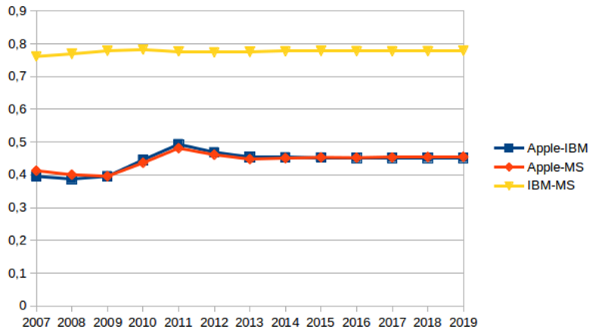

Figure 4: Comparison between pair of entities.

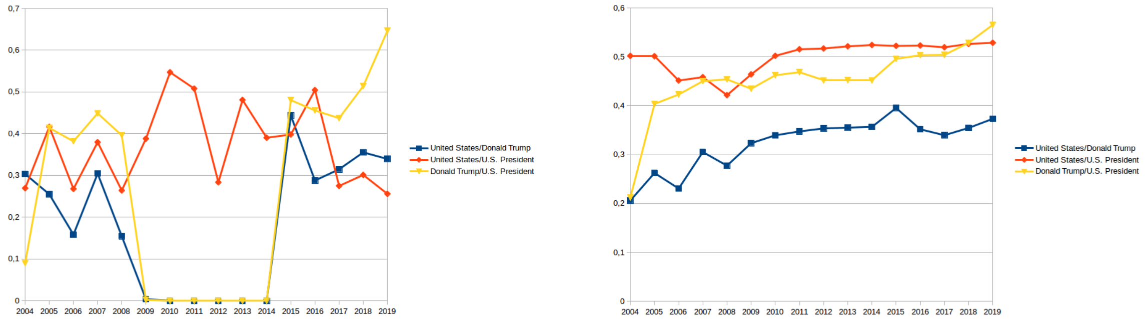
Finally, the plots in Figure 5 show the cosine similarity between the BoWs of two different targets (concepts). Using this approach it is possible to show how the similarity between two targets changes over time. In particular, for each time point we build the BoW of each concept and then we compute the similarity between the BoWs. It is important to point out that the target BoW is built by taking into account the context around each occurrence of the target in the corpus. In this way, if two targets occur in similar contexts their BoWs will be similar. We adopt two strategies:

point-wise: each BoW is built by taking into account only the target occurrences at time t_i;

cumulative: each BoW is built by taking into account all the target occurrences up to time t_i, including time t_i. The idea is to take into account all the previous history of the target and not only the time period under analysis.

Observing the plots in Figure 5, it is possible to note that the similarity between *United States-U.S. President* and *United States-Donald Trump* is constant across time, while we observe an increment in similarity between *U.S. President-Donald Trump* after the year 2018. This increment is clearly evident in the point-wise analysis (Figure 5a), as we expected. It is important to underline that in Figure 5a some points are near zero (2009-2014) this means that the targets do not occur in similar contexts in that periods and indeed the two BoWs share just a few words. Figure 5b show a different trend, since we take into account all the previous target occurrences before the time t_i by exploiting the cumulative approach.

The promising results obtained in this preliminary case study about BoW similarity suggest that it is possible to build effective "time-dependent" embeddings by using our resource.



(a) Plot of the point-wise targets BoW cosine similarity over time.

(b) Plot of the cumulative targets BoW cosine similarity over time.

Figure 5: BoW analysis of pair of targets: plot over time of the cosine similarity between BoWs of two targets with point-wise (a) and cumulative (b) strategy.

5 Conclusions and Future Work

In this paper, we described the construction and utilisation of a new resource built upon Wikipedia page revisions that enables the diachronic analysis of entities. Using the timestamp provided by each revision, we tracked Wikipedia internal links in order to extract the temporal relations between surface forms, contexts, and concepts (Wikipedia pages). We provided some preliminary use cases which show the effectiveness of this resource. These preliminary results show the potentiality of our methodology and open several research scenarios that can be investigated as future work, such as semantic change point detection of entities, entity linking in diachronic collections, event detection, and temporal entity search. The preliminary version of our dataset has some issues that we plan to fix in future versions such as redirects, disambiguation pages and character encoding issues.

Abstract

Building multilingual ontologies is a hard task as ontologies are often data-rich resources. We introduce an approach which allows exploiting structured lexical semantic knowledge for the ontology building. Given a multilingual lexical semantic (non ontological) resource and an ontology model, it allows mining relevant semantic knowledge and make the ontology building and enhancement process faster.

1 Introduction

Nowadays, termino-ontological resources are increasingly rich in terms of data they rely upon. The scientific community works intensively on data acquisition for the ontology building. In particular, the NeOn project[1] has been set up to provide a methodology for the ontology engineering by integrating preexisting knowledge resources into an ontology building process. The NeOn methodology contains a consistent framework for modular ontology building as well as for setting up ontology networks. Here we focus on exploiting Lexical Semantic Networks (LSNs) to enrich an ontology or accompany the ontology building process. We assume that LSNs represent knowledge as it is expressed through the human language whereas ontologies provide a formal description (specification) of a conceptualization (concepts and relationships between those concepts) shared by a community of agents. A concept corresponds to a set of individuals sharing similar characteristics and may or may not be lexicalized. Thus, the ontology labels cannot be polysemous. The strength of ontologies is in their formal consistency. The weaknesses are linked to their coverage, size (as stated in (Raad and Cruz, 2015), ”large ontologies usually cause serious scalability problems”), and human effort needed for their building. The potential of the LSNs is linked to the large amount of explicit semantic information they contain. However, a filtering process is needed to discriminate irrelevant information (polysemy, noise).

2 State of the Art

The opportunity of ontology construction empowered by the use of Natural Language Processing (NLP) techniques and tools has been explored for more than 20 years. Among the achievements, one can distinguish the tools which take into account the difference between the lexical term and the ontology concept (differentiated tools) and those that do not make such distinction. Differentiated tools and methods suggest extracting the terminological units from texts and organizing them as a network using a set of hierarchical and equivalence relation types. Such network guides the ontology expert through the conceptualisation and ontology building process. Such process relies on an intermediary structure, a termino-ontology (for instance, the *Terminae* suite, (Szulman, 2012)). Undifferentiated tools use some statistical information to suggest the can-

[1] http://neon-project.org/nw/About_NeOn.html

didate concepts. They exploit such methods as formal concept analysis (Mondary, 2011) or knowledge based methods (for instance, *TextToOnto*[2]). ”Lexical ontologies” (Abu Helou et al., 2014) are successfully used for ontology building. Numerous approaches targeted at high level ontology or information retrieval ontology based on general knowledge (such as (Marciniak, 2013)) rely on PWN. Others use PWN and domain specific semantic lexicons for forming the concepts (Turcato et al., 2000). Many other ontology learning techniques use distributional semantics to learn lightweight ontologies, for example, (Wong, 2009).

In the framework of corpora based approaches to the ontology building such as described in (Kietz et al., 2000), the idea of *notable (salient, relevant) element* or *relevant piece of knowledge* (RPK) has been introduced. It corresponds either to the frequent terms appearing in a corpus and to the tacit knowledge contained in texts. Such tacit knowledge corresponds to the semantic relationships (subsomption relationship and other specialized relationships). Their presence in texts may take the form of ”indices”. In contrast, the explicit elements may reveal the presence of concepts. The main drawback such definition of RPKs is that it relies on the features defined or recorded for a particular language. In addition, statistical criteria are often preferred and it is difficult to qualify such RPKs from the semantic point of view and in a language independent manner. In this paper, we will detail the experiments we conducted to provide a new definition of the RPKs based on the structured lexical semantic information and describe the way so defined RPKs can be used to help the top down ontology building process.

3 Ressources

In the present section, we will describe the resources we used in our experiments.

The **RezoJDM** (Lafourcade, 2007) is a lexical semantic network (LSN) for French built using crowdsourcing methods and, in particular, games with a purpose (GWAPS) such as JeuxDeMots[3] and additional games . This commons sense network has been built since 2007. It is a directed, typed and weighted graph. At the time of our writing, RezoJDM contains 2.7 millions of terms that are modeled as nodes of the graph and 240 millions of relations (arcs).

The **MLSN** (Bebeshina-Clairet, 2019) is a multilingual LSN (it covers French, English, Spanish, and Russian) with an interlingual pivot built for the cuisine and nutrition domain. This network is inspired by the RezoJDM in terms of its model. Structurally speaking, the MLSN is a directed, typed, and valuated graph. It contains k sub-graphs corresponding to each of the k languages it covers and a specific sub-graph which fulfills the role of the *interlingual pivot*. Similar to the RezoJDM, we call *terms* the nodes of the MLSN and *relations* - its typed, weighed, and directed arcs. The MLSN nodes may correspond to one of the following types : **lexical items** (*garlic*), **interlingual items** (pertaining to the interlingual pivot and also called *covering terms*), **relational items** (i.e. relationship reifications such as *salad[r_has_part]garlic*), and **category items** parts of speech or other morpho-syntactic features (i.e. *Noun:AccusativeCase*).

As it has been difficult to set up the pivot using a multilingual embedding (joining multiple spaces, one per language) as well as to avoid pairwise alignment based on combinatorial criteria, the pivot has been started as a natural one using the English edition of DBNary (Sérasset, 2014). It incrementally evolves to become interlingual. The pivot evolution relies on sense-based alignments between the languages of the MLSN and aims at taking into account the difference of sense ”granularity” in different languages. For example, as *stew*in English can be translated as into French as *pot-au-feu* and *ragoût*. It reflects the conceptualization discrepancy as *ragoût* refers to sauté the ingredients and then add water

[2] https://sourceforge.net/p/texttoonto/wiki/

[3] http://www.jeuxdemots.org

whereas *pot-au-feu* refers to boiling them together in a larger amount of water than used for the *ragoût*. In the MLSN pivot we have the interlingual term corresponding to stew (which covers the English term) with two hyponyms corresponding to 0rench terms. The alignments are progressively obtained through external resources or by inference. Thus it can be considered as a union of word senses lexicalized or identified in the languages covered by the MLSN. . Even though we assume the pivot as being interlingual, it is still close to a natural one. A relation $r \in R$ is a sextuplet $r =< s, t, type, v, l_s, l_t >$ where s and t correspond respectively to the source and the target term of the relation. The relation $type$ is a typical relation type. It may model different features such as taxonomic and part-whole relations (*r_isa, r_hypo, r_has_part, r_matter, r_holo*), possible predicate-argument relations (typical object *r_object*, location *r_location*, instrument *r_instr* of an action), "modifier" relations (typical characteristic *r_carac*, typical manner *r_manner*) and more[4]. The relationship valuation v corresponds to the characteristics of the relation which are its weight, confidence score, and annotation. The relation weight may be negative in order to model noise and keep the information about erroneous relations easy to access programmatically so they could not affect the inference processes. The confidence score is a score attributed to a particular data origin (external resource, inference process). In practice, this feature is an array as different origins may provide the same relation. The confidence information is provided as an argument to the function that maps from some external knowledge resource to the MLSN. In case of relation calculated by an inference process, it corresponds to the precision evaluated on a sample of candidate relations returned by this process. To *annotate* a relation we add a complementary information that allows qualifying this relation. The figure 1 details and exemplifies the annotation scheme.

The labels l_s and l_t correspond to the language (subgraph) labels. At the time of our writing, the MLSN contains 821 781 nodes and 2 231 197 arcs. It covers 4 languages : English, French, Russian, and Spanish.

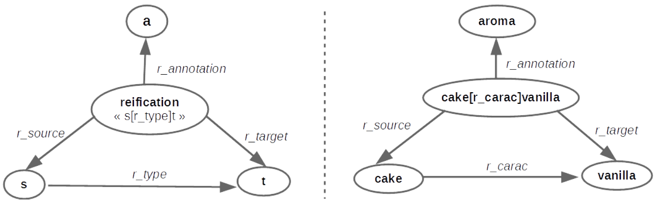

Figure 1: MLSN: relationship annotation scheme.

MIAM (Desprès, 2016)[5] is a modular termino-ontology for the digital cooking. It provides knowledge necessary for the elaboration of general nutritional suggestions. The knowledge model of this ontology gathers expert knowledge on food, food transformation, cooking actions, relevant dishes that reflect french culinary tradition, recipes necessary to cook such dishes. MIAM contains about 7 000 nodes and 30 000 semantic (non subsumption/ontological is-a) relations.

4 Method: Immersion - Projection

4.1 Summing up the Method

Our method is built upon the idea of projecting a model (the MIAM model) onto a multilingual or monolingual LSN (respectively MLSN and Rezo-JDM) in order to extract an intermediary resource that can be used by ontology or domain experts in the scope of information retrieval or validation of the automatically suggested pieces of knowledge.

Our method differs from others by the definition of the RPK and by the use of a non ontological semantically structured resource for ontology building. We define RPK as follows : "a relevant piece of knowledge is either a term or a relation or a semantic structure which is known as qualified and qualifying". *Qualified* refers to the possibility to describe

[4] We also introduced more specific relation types such as *r_entailment*, *r_cause*, *r_telic_role*, *r_incompatible*, *r_before*, *r_after* etc.

[5] http://www-limics.smbh.univ-paris13.fr/ontoMIAM/

the RPK in a discrete way (i.e. by enumerating the typed relations). If the RPK is a term, it needs to have a high in-degree (which reveals its conceptual role as it is used to define other terms of the network). If the RPK is a relation, it needs to be contextualized (through the annotation mechanism represented on the figure 1 or through the constraints put on source and/or target terms of the relation). If the presumed RPM is a graph structure (path, subgraph), it needs to possess a certain number of occurrences in the network. *Qualifying* refers to the possibility to use the candidate RPK for endogenous inference process. If the RPK is a term, it needs to have hypernyms, hyponyms, synonyms among its neighbours. It has to be aligned with other terms pertaining to the other languages of the LSN (if such LSN is multiligual). If the RPK is a relation, it must not be unique (other real or potential[6] relations must exist in the network). If the candidate RPK is a structure, its terms and relations must be qualifying.

Here we detail the experiments that have been conducted on the basis of the MLSN in order to propose "pseudo-class" and "pseudo-property" candidate RPKs to enhance the MIAM ontology and those concerning the enrichment of an ontology draft using the monolingual LSN, RezoJDM (Lafourcade, 2007). These experiments rely on lexical knowledge. Therefore, the resulting RPKs have no pretension to the ontological validity. The decision pertains to the human expert.

4.2 Immersion

The projection of a given ontology model onto a LSN starts by the immersion of such model. The immersion mechanism uses a set of manually defined mapping rules. It is possible to generate them automatically for the ontological resources that exploit standard vocabularies (such as RDFS, SKOS and other machine readable formats). The input of the immersion algorithm is the reference ontology (MIAM) and the set of mapping rules whereas its output is the action of inferring terms and relations in the target LSN (MLSN, RezoJDM).

In their general form, the mapping rules state: "If x and y are respectively domain and range of an Object Property p of the ontology to be immersed and y is a subclass of C, then x has a relation R with y and y has a relation *is-a* with C in the receiving (target) LSN". Such rules have been defined for the multilingual experiment for two reasons. First, for each of the 93 MIAM properties, we determined relevant MLSN semantic relation types (or set of types). Thus, the *Object Property* `aPourProduitInitial` (*hasInitialProduct*) corresponds to the substance and part-whole meronymy (MLSN relations typed *r_has_part* and *r_matter*). Second, we mapped the ontology labels to the MLSN terms by coincidence (3 930 terms; i.e. *poulet basquaise* formally denotes a MIAM concept, a lexical item with the same label already exists in the MLSN) or by composition (4 135 terms, i.e.: *unité mesure capacité* doesn't correspond to any existing MLSN term because it doesn't correspond to any commonly used collocation in French; this label is split and integrated into MLSN with the semantic relations that link its parts.

As part of the monolingual experiment, 115 descriptors have been automatically expressed in French on the basis of their Uniform Resource Identifier (URI) strings. All the terms except one were already present in the RezoJDM network. We exploited the relations typed *r_carac* (typical characteristic) for this experiment. This relation has been annotated using the URIs of the ontology properties `aPourDescripteurBruit` (*hasSoundDescriptor* is immersed as follows: *croûte r_carac* :: *bruit croustillant* ("*croûte* has typical characteristic linked to the noise *croustillant*"[7]). The premises of the mapping rules rely on the contextualization of the LSN relations. Such contextualization is possible when using sets of hypernyms and neighborhood semantic relations of the source and target terms of a

[6] Relations that can be calculated using inference.

[7] *crust* has typical characteristic linked to the sound *crusty*

relation. Meta-information attached to the LSN relations (annotations, weight) may also be used. For instance: *pétrir r_object pâte* ∧ *pétrir r_isa technique de base* ∧ *pâte r_isa préparation*[8]).

As part of the immersion process the ontology labels become LSN terms that can be polysemous.

4.3 Projection

4.3.1 Inference in the LSN Context

In the MLSN context we set up several algorithms to discover relevant pieces of knowledge (RPK) of the types "class/individual" (ci) and "ontology property"(op). To discover the RPK(ci) we compare the neighborhood terms inside an hierarchical chain which goes up to a high level MIAM concept immersed into the LSN. For the RPK(op) we look for (real or possible) MLSN relations similar to the immersed MIAM properties. The inference scheme we use is the abduction scheme. When we have two similar terms (such as cohyponyms) the relations detained by one of them can be proposed for the other. For a term *T*, the abduction implies selecting a set of similar terms (according to some criteria) in order to propose the relations detained by those similar terms to T.

4.3.2 Discovering the RPK(ci)

In MIAM, the **general axioms** concern the disjunction between the MIAM classes which is the basis of the ontology consistence. To translate them in terms of MLSN, we considered the labels of the classes listed in the axioms in order to identify the criteria that could have determined the disjunction. We manually analyzed a subset of the MIAM axioms and came up with the following criteria: *affiliation* (*r_has_part* i.e. a specific label (organic)), *transformation* (*r_carac* i.e. boiled mixture, cubed vegetable), *composition* (*r_matter* i.e. *produit à base de poisson* "fish based product"), *category based distinctions* (*r_hypo* i.e. *volaille type dinde* "turkey type poultry"). This analysis allowed selecting a subset of relation types to consider during the experiment. The RPK(ci) inference includes two steps: validation of the hierarchical chain (figure 2) and RPK(ci) candidate suggestion.

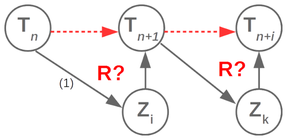

Figure 2: Hierarchy chain validation. T_i are the terms of the hierarchy chain. We check by triangulation their semantic relatedness and use a subset of relations types (such relations are noted R) for that.

We calculated and validated hierarchical chains corresponding to 1 322 top MIAM concepts pertaining to the *Aliment* module. First we obtained 132 213 chains. After filtering them by weight, the set has been reduced to 53 749 chains (40% of the initial set). Still, a certain number of redundancies may exist inside this statistically pre-filtered set since a long chain may include several shorter ones. The logical filtering by triangulation left us with a set containing 9 600 hierarchical chains (18% of the number of statistically filtered chains and 7% of the initial number of candidates).

Hierarchical chain examples after filtering:
(1) "***baguette complète***→*pain complet* →
pain→***ingrédient de recette de cuisine***→*aliment*"
(2) "***angélique***→confiserie→bonbon".
RPK(ci) examples:
truffe chocolat `subClassOf` chocolat
pomme à cidre `subClassOf` pomme
sucre de pomme `subClassOf` confiserie
The analysis and validation of the hierarchical chains corresponds to the important memory load. The complexity of the algorithm depends on the importance of the MIAM concept being processed as well as on the length of the hierarchical chains that are considered. The use of a subset of the semantic relations types available in the MLSN reduces the number of combinations to process. Thus, given

[8] *knead r_object dough* ∧ *knead r_isa basic technique* ∧ *dough r_isa mixture*

that the highest in-degree typed *r_isa* in the French sub-graph of the MLSN is 5 264 (for the term *aliment*) and that the maximum length $l = 9$, the complexity in the worst case would be $O(d_{isa}^{l}$ or $O(5\,264^{9}) = 3,103436942 \times 10^{33}$.

The table 1 introduces the results obtained for the discovery of RPK(ci) related to the top level concept *Aliment* in the French sub-graph of the MLSN. The automatic evaluation of the proposed RPK(ci) would mostly rely on similarity measures. However, the projection step implicitly relies on relatedness and similarity between the LSN terms. Thus, in our future work, the RPK(ci) evaluation will need human expert decisions.

#candidates	#valid	%valid	#new	%new
11 520	11 289	98%	4 741	42%

Table 1: The RPK(ci) discovery.

4.3.3 The RPK(op) Discovery

The RPK(op) discovery seems to be particularly useful in the context of multilingual ontology building or localization of an existing ontology. In our experience, each module of the MIAM ontology has its own hierarchy of properties. While immersing them into the MLSN, these properties have been expressed in terms of semantic relations contextualized using annotations. The choice of the MLSN semantic relation type made for these properties allows us to distinguish the following cases for the MIAM Object Properties (OPs): *composition based* (`aPourProduitInitial`, ”hasInitialProduct”); *related to processes* (`aPourMethodeDeConservation`, ”hasConservationMethod”); *temporal and spatial relation based* (`aPourMoisPrimeur`, ”hasEarlyMonth”); *characteristic based* (`aPourEtat`, ”hasState”); *OPs with a specific sub-graph*[9] (`aPourAlimentAmi`, ”hasFriendlyFoodItem”).

The MIAM ontology we try to enrich counts 21 565 instances of *Object Properties*. Once they are immersed into the MLSN, one could consider that we have the same number of inference rule instances that can be used for the cross-lingual RPK(op) discovery. A naive approach would be setting up a cross-lingual inference mechanism. However, such approach would be error-prone due to the potential alignment and polysemy issues. In addition, as MIAM has been built according to the top-down methodology by a community of domain experts, it contains a variable number of instances per property. The naive approach would reiterate this imbalance.

To refine the RPK(op) discovery, we experimented a rule based approach. First, the validity of the rule for the source language is calculated. Second, structures similar to those specified by the rule are being discovered in the MLSN (in other languages).

The rule has the following form:
`property=aPourEtatPhysique`
(property name)
`src=?s` *(domain, set of terms)*
`reltype=r_carac` *(relation type)*
`tgt=?o`*(range, set of terms)*
`source_isa=aliment`*(src hypernyms)*
`target_isa=etat physique`
(tgt hypernyms)
`annotation=int:physical state`
(meta-information)
`src_feat=OUT/r_pos/int:Noun`
(in and out relations that characterize terms in the source set)
`tgt_feat=OUT/r_pos/int:Adj` *(in and out relations that characterize terms in the target set)*
If a given rule allowed detecting enough structures in the source language (at least, 2 structures), it is considered as a valid one and can generate the qualifying object. Thanks to this object, candidate structures are detected in the other language sub-graphs of the MLSN. The mechanism of RPK(op) discovery reveals the following elements that allowed discovering new pieces of knowledge : **possibly annotated semantic relation** (case of the properties such

[9] A subset of MLSN terms connected through semantic relations.

as `aPresenceLactose`, `aPresenceGluten`); **specific pattern** (defined by rules); **complex structure** for properties related to processes. The results obtained using possibly annotated relations(in particular, *Data Properties*)) are presented in the table 2. the potential improvement is estimated as an increase compared to the initial number of property instances (impr.%).

#DP	#MIAM	#RPK(op)	filt.	+%
aTeneurLipide	0	4 741	3 271	-
aPresenceLactose	2 593	530	408	+16%
aPresenceGluten	289	820	762	+263%

Table 2: The RPK(op) discovery on the basis of simple semantic relations.

Example of the output of the rule-based algorithm: *ru:jarkoje* aPourProduitDiscriminant *podlivka* ("stew hasDiscriminatingProduct sauce") and *en:stew* aPourProduitInitial *en:vegetable (produce)* ("stew hasInitialProduct vegetable"). Our rule-based RPK(op) experiment (given the actual state of the MLSN) yielded the results listed in the table 3.

Fully automated structure-based evaluation such as described in (Fernández et al., 2009) may be chosen to compare to other resources available on the Web such as (Dooley et al., 2018). To address the ontology accuracy, completeness, conciseness, efficiency, consistency, and other features (Raad and Cruz, 2015), a combination of methods is needed. In particular, gold standard ontology, specific tasks and corpora may be used for evaluation. A task-based evaluation such as semantic analysis (Bebeshina-Clairet, 2019), dietary conflict detection from dish titles (Clairet, 2017) have been used for the MLSN. To evaluate the output of the immersion- projection method, we need to organize our triples into a fully structured ontology. This will be one of the priorities of our future work.

4.3.4 Towards the Automatic Suggestion of the RPKs(op)

To extend the RPK discovery experiment, we tried to automatically suggest pseudo ontology properties to be submitted to the domain and ontology human experts. We considered the ontology SensoMIAM[10] for this experiment. This ontology is a MIAM module but we considered it as a "draft" ontology as the sensory aspect modeling is a flourishing research and development area and the SensoMIAM could be improved. We used the monolingual LSN (RezoJDM). The SensoMIAM contains sensory descriptors such as `DescripteurTact` ("TactileDescriptor") = {*astringent, filandreux, ..., nerveux*}; `DescripteurSubstance` ("SubstanceDescriptor")= {*aéré, dense, . . . , épais*}

To calculate the RPK descriptors RPK(desc), we explored the semantics of the source terms of the relations typed *r_carac*. If the set of outgoing relations of such terms connects them to a food item and if they have a set of typical characteristics shared with other terms with an hypernym ≈ "food", the target term of their outgoing relations typed r_carac that is not present in the SensoMIAM can be suggested as a potential RPK(desc). The relation typed *r_carac* is annotated. The process is represented on the figure 3. The experience allowed to suggest the RPK(desc) such as: `DescripteurArome`={*sucré-salé, miellé, . . . , vinaigré*} or `DescripteurTact` = {*écailleux, spongieux,. . . , floconneux*}.

We automatically suggested and semi-automatically validated 342 RPKs(desc). We explored the possibility of suggesting relevant RPKs to human experts. We defined 3 pseudo-properties for testing: *aPourComposantFlaveur* ("hasFlavourComponent"), *aPourComposantToucher* ("hasTouchComponent"), and *aPourComposantAspect* ("hasAspectComponent"). To populate them, we explored the RezoJDM relations typed *r_has_part* and *r_matter* and considered the characteristics that can be shared

by a ”whole” and its ”parts”. We tried to generalize to the ”whole” some of the characteristics of its parts. Automatically suggested toy triples: *veau Orloff* `aPourComposantFlaveur` *lard* from {*gras, viande*} ”veal Prince Orloff has a component that influences its flavour *lard* because they share *fat, meat*”; *gratin* `aPourComposantAspect` *fromage* from {*gratiné, gras, brûlé*} ”gratin has a component that influences its aspect *cheese* as they share characteristics *grilled, fat, burned*”. We automatically suggested 1 709 RPKs(op) for the pseudo-properties we explored. They have been automatically validated by constraining the range of the pseudo-property (it must be related to the terms ”flavour”, ”touch”, and ”aspect”) and by checking the sufficient intersection size between the relation sets typed *r_carac* of the ”whole” and its ”part”.

Conclusion and Perspectives

We described a method that attaches an intermediary resource containing relevant pieces of knowledge harvested from semantically structured resources in different languages to the main building process. The method suits for other domains of knowledge and the amount of work necessary for the immersion process is proportional to the size and to the type of the ontological resource to be enhanced. It is also possible to use such resources as WordNets [11] as the basis for the intermediary resource. Among the difficulties linked to our method appear the differences between formal representation paradigms as well as the availability of well structured and semantically rich resources.

Naive Regularizers for Low-Resource Neural Machine Translation

Abstract

Neural machine translation models have little inductive bias, which can be a disadvantage in low-resource scenarios. They require large volumes of data and often perform poorly when limited data is available. We show that using naive regularization methods, based on sentence length, punctuation and word frequencies, to penalize translations that are very different from the input sentences, consistently improves the translation quality across multiple low-resource languages. We experiment with 12 language pairs, varying the training data size between 17k to 230k sentence pairs. Our best regularizer achieves an average increase of 1.5 BLEU score and 1.0 TER score across all the language pairs. For example, we achieve a BLEU score of 26.70 on the IWSLT15 English–Vietnamese translation task simply by using relative differences in punctuation as a regularizer.

1 Introduction

One of the major challenges when training neural networks is overfitting. Overfitting is what happens when a neural network in part memorizes the training data rather than learning to generalize from it. To prevent this, neural machine translation (NMT) models are typically trained with an L_1 or L_2 penalty, dropout, momentum, or other general-purpose regularizers. General-purpose regularizers and large volumes of training data have enabled us to train flexible, expressive neural machine translation architectures that have provided a new state of the art in machine translation.

For low-resource language pairs, however, where large volumes of training data are *not* available, neural machine translation has come with diminishing returns (Koehn and Knowles, 2017). The general-purpose regularizers do not provide enough inductive bias to enable generalization, it seems. This is an area of active research, and other work has explored multi-task learning (Firat et al., 2016; Dong et al., 2015), zero-shot learning (Johnson et al., 2016), and unsupervised machine translation (Gehring et al., 2017) to resolve the data bottleneck. In this paper, we consider a fully complementary, but much simpler alternative: naive, linguistically motivated regularizers that penalize the output sentences of translation models departing heavily from simple characteristics of the input sentences.

The proposed regularizers are based on three surface properties of sentences: their length (measured as number of tokens), their amount of punctuation (measured as number of punctuation signs), and the frequencies of their words (as measured on external corpora). While there are languages that do not make use of punctuation (e.g., Lao and Thai), in general these three properties are roughly preserved across translations into most languages. If we translate a sentence such as (1), for example:

(1) That dog is a Chinook.

it is relatively safe to assume that a good translation will be short, contain at most one dot, and contain at least one relatively frequent word (for *dog*) and at least one relatively infrequent word (for *Chinook*). This assumption is the main motivation for our work.

Contributions Our contribution is three-fold: (a) We propose three relatively naïve, yet linguistically motivated, regularization methods for machine translation with low-resource languages.

Two of the regularizers are derived directly from the input, without relying on any additional linguistic resources. This makes them adequate for low-resource settings, where the availability of linguistic resources can generally not assumed. Our third regularizer (frequency) only assumes access to unlabeled data. (b) We show that regularizing a standard NMT architecture using naive regularization methods consistently improves machine translation quality across multiple low-resource languages, also compared to using more standard methods such as dropout. We also show that combining these regularizers leads to further improvements. (c) Finally, we present examples and analysis showing *how* the more linguistically motivated regularizers we propose, help low-resource machine translation.

2 Related Work

End-to-end neural machine translation is based on encoder–decoder architectures (Sutskever et al., 2014; Cho et al., 2014; Luong et al., 2015a, 2017), in which a source sentence $x = (x_1, x_2, ..., x_n)$ is encoded into a vector (or a weighted average over a sequence of vectors) $z = (z_1, z_2, ..., z_n)$. The hidden state representing z is then fed to the transducer (also called decoder) which generates translations, noted as $y = (y_1, y_2, ..., y_m)$.

Neural machine translation has achieved state-of-the-art performance for various language pairs (Luong et al., 2015a; Sennrich et al., 2015; Luong and Manning, 2016; Neubig, 2015; Vaswani et al., 2017), especially when trained on large volumes of parallel data, i.e., millions of parallel sentences (also called bi-sentences), humanly translated or validated. Such amounts of training data, however, are difficult to obtain for low-resource languages such as Slovene or Vietnamese, and in their absence, neural machine translation is known to come with diminishing returns, suffering from overfitting (Koehn and Knowles, 2017).

In order to avoid overfitting, NMT models are often trained with L_1 or L_2 regularization, as well as other forms of regularization such as momentum training or dropout (Srivastava et al., 2014; Wang et al., 2015; Miceli Barone et al., 2017). However, these regularization methods are very general and do not carry any language specific information.

On the other hand, it has been shown that transfer learning approaches using out of domain data, such as the European Parliament data[1], to regularize the learning helps improve the translation quality (Miceli Barone et al., 2017). This approach produces good results, but it is not applicable in low-resource settings because it requires large amounts of data in the language of interest. To the best of our knowledge, our work is the first to introduce naive, linguistically motivated regularization methods such as sentence length, punctuation and word frequency.

3 Model Description

3.1 Baseline

In order to show the impact that our regularizers have on the translation quality, we use an off-the-shelf NMT system described by Luong et al. (2017) as our baseline. The model consists of two multi-layer recurrent neural networks (RNNs), one that encodes the source language and one that decodes onto the target language. For the encoder cell, we use a single Long Short-Term Memory (LSTM) layer (Hochreiter and Schmidhuber, 1997) and output the hidden state, which then gets passed to the decoder cell.

We train our models to minimize the cross-entropy loss and back-propagate the loss to update the parameters of our model. We update network weights using Adam optimization (Kingma and Ba, 2014), which calculates the exponential moving average of the gradient and squared gradient, and combines the advantages of AdaGrad and RMSProp. For the purpose of comparison, we set the dropout to 0.2, similar to Luong et al. (2015b).

3.2 Regularized NMT

To apply our new regularizers, we add each regularizer to the loss function during the training of the NMT model (Luong et al., 2015a; Luong and Manning, 2016; Luong et al., 2017). Since we aim to minimize the cross-entropy loss, this means that we favor training instances which have a low penalty from the regularizers (e.g., a small length difference). Importantly, we do *not* use dropout in this scenario, as we want to contrast our naive, but linguistically motivated signals with a traditional, but not linguistically motivated regularization method, i.e., dropout.

Furthermore, we do not explore alternative ways for adding regularizers to the loss function here (other alternatives could be to have a

[1] http://www.statmt.org/europarl/

weighted penalty which is then tuned to find the best penalty and added to the loss function for testing). The main purpose of this work is to study the effect of naive linguistically motivated regularizers and show that they can improve translation quality; we leave it to future work to find the optimal configuration of regularizers that maximizes the overall translation quality.

4 Naive Regularizers

4.1 Length-Based Regularizer

NMT models have shown to suffer "the curse of sentence length", and it has been hypothesized that this is due to a lack of representation at the decoder level (Cho et al., 2014; Pouget-Abadie et al., 2014). Our proposed sentence-length-based regularizer penalizes relative differences between the input and the MT output lengths during the training of the NMT model:

$$\text{reg}_{\text{length}} = |l_0 - l_1| \tag{1}$$

Here, l_0 and l_1 represent the input sentence and the MT output sentence lengths, respectively, as measured by the number of words (not to be confused with L_1 and L_2 regularization methods).

Note that this regularizer is different from the word penalty feature in phrase-based machine translation (Zens and Ney, 2004), which only penalizes the target sentence length. The relative difference between the input and the MT output sentence lengths is also used as a feature in Marie and Fujita (2018).

4.2 Punctuation-Based Regularizer

The punctuation-based regularizer penalizes training instances whenever the amount of punctuation marks in the input sentence differs from the amount in the MT output sentence. It is computed as follows:

$$\text{reg}_{\text{punct}} = |p_0 - p_1| \tag{2}$$

Here, p_0 and p_1 is the total number of punctuation marks in the input and the MT output sentence, respectively.

Unfortunately, the only available methods to generate more efficient NMT models have included data intensive methods such as sentence alignment (Bahdanau et al., 2014). Some very early research done in alignment used simple methodologies such as punctuation-based alignment (Chuang et al., 2004). Our second regularizer is based on this simple idea, as it penalizes training instances where the quantities of punctuation marks differ between input and MT output sentences. Example (2) is taken from the training set of the French–English translation task:

(2) IN *Pas parce qu'ils sont moins bons, pas parce qu'ils sont moins travailleurs.*
REF And it's not because they're less smart, and it's not because they're less diligent.
OUT And . . . .

We note that the punctuation in the French input sentence matches the punctuation of the desired English reference. However, during an early training step, the NMT model translates the input to a sequence containing six times the number of punctuation marks in the input sentence, which is obviously incorrect. Our punctuation regularizer further penalizes examples like this one.

4.3 Frequency-Based Regularizer

Our last regularizer is based on the distribution of word frequencies between the source and the target sentences. Generally speaking, if the source sentence contains an uncommon word, we assume that its translation in the target language is also uncommon. The intuition behind this regularizer is that if the source sentence contains one uncommon word and three common words, then its accurate translation should contain similar word frequencies. The example below is extracted from the English–French translation task:

(3) IN *But now there is a bold new solution to get us out of this mess.*
REF Mais il exist une solution audacieuse pour nous en sortir.
OUT Mais maintenant il y a une solution pour nous en sortir.

The English sentence contains the frequent word *there* and the less frequent word *bold*. The French output sentence is acceptable, but it is not accurate since the English word *bold* (*audacieuse* in the reference translation) was omitted in the output. During training, the frequency regularizer penalizes such cases that have a big divergence between the word frequencies in the input and output sentences.

The purpose of our frequency-based regularizer

Languages	#Words
Czech	1.7M
English	85.57M
French	55.72M
German	35.47M
Russian	2.5M
Slovene	1.45M
Vietnamese	3.5M

Table 1: The size of the Wikipedia dumps (#words) used to calculate word frequencies for each language.

is to calculate how different the MT output sentence is from the source input in terms of vocabulary distribution. For instance, the frequency of using the word *chauve-souris* in French is almost similar to the frequency of using its English translation *bat* in English. The same could be applied for the more frequent words such as *et* in French and its English translation *and*.

We start by computing the frequency vectors $\overrightarrow{v_{\text{in}}}$ and $\overrightarrow{v_{\text{out}}}$, containing the frequency for every word w_i in the input and MT output sentence, respectively:

$$\overrightarrow{v} = \langle f(w_1), \ldots, f(w_n) \rangle \tag{3}$$

To calculate the word frequencies $f(w)$ for each language, we use the Wikipedia database[2] as an external resource. Table 1 contains the size of the datasets (in number of words) used to estimate these. We note that there is considerably more data for English and French than for e.g. Vietnamese (cf. Table. 1); we discuss the effect that this might have on the results in Sec. 6.

We interpret the resulting frequency vectors $\overrightarrow{v}$ as distributions, for which we now calculate the Kullback-Leibler (KL) divergence to obtain our regularization term:

$$\text{reg}_{\text{freq}} = D_{\text{KL}}(\overrightarrow{v_{\text{in}}}, \overrightarrow{v_{\text{out}}}) \tag{4}$$

Essentially, this regularizer penalizes translations if their word frequency distributions diverge too strongly from those of the source sentence.

(4) IN It was a big lady who wore a fur around her neck
REF C'était une dame forte qui portait une fourrure autour du cou
OUT C'était une femme forte portant une fourrure autour du cou

Example (4) shows an input sentence and its MT output, for which we would compute the frequency vectors as follows:

$$\overrightarrow{v_{\text{in}}} = \langle f(\text{'it'}), \quad f(\text{'was'}), \quad \ldots, f(\text{'neck'})\rangle$$
$$\overrightarrow{v_{\text{out}}} = \langle f(\text{'c'était'}), \quad f(\text{'une'}), \quad \ldots, f(\text{'cou'})\rangle$$

Languages	Sentence Pairs

Vietnamese	133,317	1,553	1,268

Table 2: The size of the training data in sentence pairs. To test our proposed models, we experiment by translating to/from English for every non-English language.

5 Experiments

5.1 Data

The purpose of our experiments is to show that signals such as sentence length, punctuation or word frequency help improve the translation quality of a standard neural machine translation architecture. To that effect, we experiment with 12 translation tasks, translating from English to six low-resource languages, and vice versa.

The six languages represent the following language families: Slavic, Romance, Germanic, and Austro-Asian. We further vary the size of the training data to test how our regularization methods affect the quality of the MT output in different setups. Table 2 contains the size of the training, development and test set for every language pair. Note that the training sets vary considerably in size, from 17k sentence pairs for Slovene to almost 233k for French.

The data is from the International Workshop on Spoken Language Translation (IWSLT), except for Russian, Slovene and Vietnamese which are from IWSLT 2015, the data for the remaining translation tasks is from IWSLT 2017 (Cettolo et al., 2012).

[2] https://en.wikipedia.org/wiki/Wikipedia:Database

Preprocessing The purpose of our experiments is to learn how to efficiently translate low-resource languages. For that purpose, we do not use any advanced preprocessing for any of our translation tasks except tokenization where we use the script from the Moses toolkit (Koehn et al., 2007). We also set the maximum sentence length to 70 tokens and the vocabulary size to 50k.

5.2 Training Details

We use the attention-based model described in Luong et al. (2015b). Our model is composed of two LSTM layers each of which has 512-dimensional units and embeddings; we also use a mini-batch size of 128. Adding an attention mechanism in neural machine translation helps to encode relevant parts of the source sentence when learning the model. We propose to add additional regularizers on top of the attention-based model at each translation step.

We have noticed that the convergence highly depends on the language pairs involved. While our baseline model is identical to the NMT model described by Luong et al. (2015b), we deviate from their training procedure by continuing the training until convergence, which for us took 15 epochs instead of the 12 epochs described by the authors. The convergence in our case is measured by the models having no improvements on the development set over five epochs.

Table 3 shows that our baseline is +1.5 BLEU points better than the scores reported by Luong et al. (2015b). On top of that, our length-based and punctuation-based models produce a statistically significant improvement over the baseline (+0.5 BLEU points).

We train all our models automatically until convergence. In Table 4, we report the number of epochs it took to converge by translation task when translating to/from English. We note that except for Czech and Slovene, which converged the quickest, most of the translation tasks took between 15k and 20k steps to converge.

6 Evaluation

In order to show that the naive regularizers which we propose in this paper significantly boost the translation quality, we test the machine translation output using the toolkit MultEval defined in Clark et al. (2011). In this paper, we report the results using three commonly used metrics: the n-gram based metrics BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005), as well as the error-rate based metric TER (Snover et al., 2006). The evaluation metric BLEU (Papineni et al., 2002) is based on n-gram matching between the input and the output, whereas the error-rate based metric TER (Snover et al., 2006) measures how many edits are needed so that the machine translation resembles the man-made reference.

(c) TER

Table 5: Contrasting our three proposed models to the baseline (NMT; Luong et al., 2017) across 12 translation tasks. We evaluate all the models using BLEU, METEOR and TER. The bold values represent the models that show statistically significant improvements over the baseline ($p < 0.001$; Clark et al., 2011). Note that for BLEU and METEOR, higher is better, while for TER, lower is better. All regularization schemes almost consistently lead to improvements, with the punctuation-based regularizer achieving the highest gains.

baseline across almost all language pairs for all models and across all metrics. We obtain statistically significant results for almost all translation tasks for at least one regularization method.

More specifically, the punctuation regularizer outperforms all the other models on all translation tasks except for French–English and English–French. For the latter, we observe that the word frequency regularizer is better than the other systems. This could be explained by the fact that the English vocabulary has many words borrowed from French, which makes the word frequency regularizer a better signal than punctuation or sentence length for this specific task. It also could be due to the fact that both English and French have the largest vocabulary for training the word frequencies (cf. Table 1; English has around 80M words and French has around 50M words, whereas all other languages have much less data).

The most challenging translation tasks are Slovene–English and English–Slovene, especially in terms of error rate. The results show that with 17k sentence pairs as a training set, it becomes more challenging to efficiently learn anything. The results we obtained are between 2 and 5 BLEU points when translating from English. The Slovene output contained many non-translated words. Specifically, this task greatly suffers when using the word frequency regularizer, with an error increase of about 10 TER points from English to Slovene. We do not observe such losses for the Czech–English and English–Czech translation tasks, even though the vocabulary size for estimating the word frequencies is lower for Czech. We hypothesize that this is due to the Czech training set being seven times larger than the Slovene one. We hypothesize that this is due to the fact that for Slovene we only have 17K sentence pairs for the training step; whereas for Czech, we have 122K sentence pairs, which helped control the model compared to Slovene.

One case where the punctuation regularizer succeeds consistently is on the English–German and German–English translation tasks, with an error reduction of about 1 TER point. This reflects the similarity in punctuation between these languages. Although we also observe improvements using the other regularization methods, e.g. the length-based method, these are not statistically significant here as calculated by MultEval (Clark et al., 2011).

Table 3 shows the BLEU scores of seven different systems including the one where we combine our three regularizers on the English–Vietnamese translation task. The combined regularizer does not only produce a statistically significant improvement of almost 1-BLEU point over the attention based baseline, but it also outperforms all the other regularizers achieving a BLEU score of 27.23.

7 Translation Examples

The punctuation regularizer outperforms the baseline in most cases, and all of our regularization methods show statistically significant improvements in at least one language. Below we present examples, extracted from the test data, of how each of the regularization methods affects the output in comparison to the baseline model. The purpose of the examples is to show how each objective function in the learning component affects the performance component.

7.1 Frequency-Based Regularizer

The frequency-based regularization method penalizes cases where the distribution of the target vocabulary greatly differs from the source vocabulary. We have noted a significant improvement for this specific regularizer when translating from French to English and vice-versa. Examples (5) and (6) show how this regularizer is improving the translation output.

(5) IN 90 % de notre temps entourés par l'architecture .
REF That's 90 percent of our time surrounded by architecture .
BASE <unk> percent of our time **via** architecture .
FREQ <unk> percent of our time **surrounded** by architecture .

(6) IN Débloquer ce potentiel est dans **l'intérêt** de chacun d'entre nous .
REF Unlocking this potential is in the **interest** of every single one of us .
BASE <unk> that potential is in all of us .
FREQ <unk> that potential is in the **interest** of all of us .

More precisely, *entourés* in French is almost as frequent as *surrounded* in English, which is a word that our model with frequency-based regularization translates correctly, while the baseline does not. Additionally, in Example (6), our model has a better fluency and adequacy than the baseline since it not only correctly translates *l'intérêt* to *interest*, but also correctly produces *of all* instead of *in all*, as in the baseline output.

7.2 Punctuation-Based Regularizer

The punctuation-based regularization performs best in the German–English and English–German translation tasks. This regularizer penalizes cases where the difference in the number of punctuation between the source and the target sentences is particularly large. As seen in Example (7), simply introducing this bias into a translation model leads to an output which more closely matches the punctuation of the source and target sentences.

(7) IN Und die Antwort , glaube ich , ist ja . [" F = T ∇ S$\mathcal{T}$ "] . Was Sie gerade sehen , ist wahrscheinlich die beste Entsprechung zu $E = mc^2$ für Intelligenz , die ich gesehen habe .
REF And the answer , I believe , is yes . [" F = T ∇ S$\mathcal{T}$ "] What you're seeing is probably the closest equivalent to an $E = mc^2$ for intelligence that I've seen .
BASE And the answer , I think , is yes .
PUNC And the answer , I think , is yes . [**" R = T T <unk> "**] **What you're looking at is probably the best <unk> <unk> <unk> of intelligence that I've seen .**

The baseline MT output completely fails to capture anything from the input except for the first part up to "...is yes." Our punctuation-based model, however, manages to capture most parts of the sentence.

7.3 Length-Based Regularizer

Finally, the length-based regularization method leads to noticeable improvements in the Czech–English and English–Czech translation tasks. Example (8) shows that introducing an input sentence length bias led to an MT output that is much closer to the reference than the baseline. The input sentence consists of 12 tokens (including punctuation), the baseline output consists of 10 tokens, while our length based regularization model preserves the length of 12 tokens.

(8) IN V roce 2009 jsem ztratila někoho , koho jsem velmi milovala .
REF In 2009 , I lost someone I loved very much .
BASE In 2009 , I lost somebody who I loved .
LEN In 2009 , I lost somebody who I loved **very much .**

7.4 General Improvements

The Slovene dataset is our smallest with about 17k sentence pairs for training. Despite the low amount of resources available in Slovene, we found that introducing very naive linguistic biases into our machine translation models actually leads to subtle differences that result in an output closer to the reference, not only lexically, but also semantically. In Example (9), we compare the output of the frequency based system against the baseline for the Slovene to English translation:

(9) IN In kaj potem ?
REF And so , what after that ?
BASE And then **then** ?
FREQ And then **, what** ?

In this particular case, the frequency based regularization model takes care of the translation of the word *what*, and although the word *so* is not translated, the overall meaning of the source is preserved.

(10) IN Imeti moraš otroke , da preživiš .
REF You need to have children to survive .
BASE **Well you have the kids that you need** to educate .
FREQ You **have to have kids** to educate .

Example (10) shows another case of how the output of the frequency-based regularization system actually shows overall improvements in an extremely low-resource language. The output of our system is semantically closer to the reference than the baseline output, up to the word *educate*. In addition, the system preserves a similar length as the source sentence.

(11) IN Mi smo tu na vrhu .
REF We are here on top .
BASE **What** we are at the top .
FREQ We are **here** at the top .

Finally, Example (11) shows a low-resource case where our system manages to make subtle changes in order to reach the correct translation, whereas the baseline system does not.

8 Conclusion

We have shown that using naive regularization methods based on sentence length, punctuation, and word frequency consistently improves the translation quality in twelve low-resource translation tasks. The improvement is consistent across multiple language pairs and is not dependent on the language family. We have reported and discussed examples demonstrating why and how each regularizer is improving the translation quality.

Our proposed approach shows that even naive, but linguistically motivated, regularizers help improve the translation quality when training NMT models. We believe this shows the usefulness of using task-related regularizers for improving neural models, and opens the door for future work to exploit these regularization methods in an even more efficient manner by experimenting with different ways of combining the regularizers with the loss function.

Exploring Graph-Algebraic CCG Combinators for Syntactic-Semantic AMR Parsing

Sebastian Beschke
University of Hamburg, Germany
beschke@informatik.uni-hamburg.de

Abstract

We describe a new approach to semantic parsing based on Combinatory Categorial Grammar (CCG). The grammar's semantic construction operators are defined in terms of a graph algebra, which allows our system to induce a compact CCG lexicon. We introduce an expectation maximisation algorithm which we use to filter our lexicon down to 2500 lexical templates. Our system achieves a semantic triple (Smatch) precision that is competitive with other CCG-based AMR parsing approaches.

1 Introduction

Parsing sentences to formal meaning representations, known as *Semantic Parsing*, is a task at the frontier of Natural Language Understanding. Abstract Meaning Representation (AMR) is a meaning representation language that represents sentence semantics in the form of graphs. Research on AMR parsing systems has been very productive in recent years with many competing approaches.

Current AMR parsers vary regarding the extent to which they rely on a formal grammar. Some of the most successful systems generate AMRs through an end-to-end neural architecture, with no explicit symbolic derivations (Zhang et al., 2019). Other parsers employ transition systems with limited explanatory power (Peng et al., 2018). Constructing grammar-based semantic analyses that can be understood in terms of linguistic theory is a more difficult task than end-to-end AMR parsing because of the additional structural requirements on the output and the algorithmic constraints imposed thereby.

In this paper, we explore how semantic parsers can be built to be *interpretable* and *transparent*. Interpretability means that our system exposes rich symbolic information in the form of CCG derivations. Transparency means that it works with a compact and intuitively plausible lexicon. The lexicon is itself an artifact that can be inspected.

We achieve these goals by equipping CCG with graph-based semantics. Meaning reprentations are constructed through the operations of a simple graph algebra, which effectively constrains the search space for parsing and lexicon induction and makes the available operations and resulting lexical items easy to understand.

Technical contributions of this paper include a modified expectation-maximisation (EM) algorithm to induce compact delexicalised CCG lexica, a technique for training a syntactic-semantic supertagger with incomplete labels, and a hybrid update mechanism for training the linear parsing model.

1.1 Related Work

This work builds upon the concept of graph-algebraic CCG, which has so far been tested only in the context of lexicon induction (Beschke and Menzel, 2018). We extend the lexicon induction process by delexicalisation and EM filtering and demonstrate the first end-to-end parsing system based on graph-algebraic CCG. The idea of applying graph algebras to AMR parsing has also been applied in the context of Interpreted Regular Tree Grammar (Groschwitz et al., 2018). Furthermore, improved definitions of graph-composing CCG combinators have been proposed (Blodgett and Schneider, 2019) to cover a wider range of semantic phenomena.

Other systems that apply CCG to AMR parsing use an encoding of AMR graphs to λ-calculus expressions (Artzi et al., 2015; Misra and Artzi, 2016). One drawback of these systems is that lexicon induction is coupled to the training loop of a

Proceedings of Recent Advances in Natural Language Processing, pages 112–121,
Varna, Bulgaria, Sep 2–4 2019.

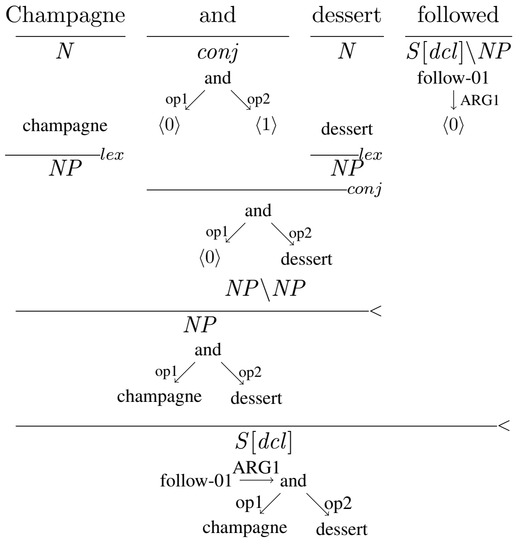

Figure 1: An example graph-algebraic CCG derivation.

parser, which makes it compute-intensive and difficult to manage. We address this issue by performing lexicon induction in a separate step.

Besides AMR parsing, CCG has also been used for joint syntactic-semantic parsing in other contexts (Krishnamurthy and Mitchell, 2014; Lewis et al., 2015).

2 Background

This paper uses Combinatory Categorial Grammar (CCG) to derive Abstract Meaning Representations (AMR) using a graph-algebraic modification of CCG's syntax-semantics interface. These concepts are briefly introduced in this below.

2.1 CCG for Semantic Parsing

Combinatory Categorial Grammar (CCG) describes syntax and semantics as part of the same derivation process (Steedman, 2000). CCG derivations are trees where every node is annotated with both a syntactic and a semantic category. The categories at the leaves of the tree are drawn from a *lexicon*, while categories at the inner nodes result from the application of *combinatory rules* to the child nodes' categories. The syntax-semantics interface in CCG is *transparent*, meaning that the same rule is always applied to syntactic and semantic categories.

In CCG, categories are understood as n-ary *functions*. *Syntactic categories* essentially express the type of the associated semantic category by specifying the types of constituents that can be accepted as arguments, either to the right of the constituent or to the left. This directionality is expressed by forward and backward slashes. E.g., given the atomic syntactic categories S for sentences and NP for noun phrases, the complex category $(S\backslash NP)/NP$ represents a transitive verb, accepting first an NP to the right and then another NP to the left to produce a sentence.

Semantic categories contain building blocks for sentential meaning representations. Traditionally, λ-calculus is used to represent the compositionality of semantic categories, while the object language that is being composed is a logical representation of sentence meaning. This paper deviates from that tradition by using a graph representation for semantic categories which is defined Section 2.3.

2.2 Abstract Meaning Representation

The Abstract Meaning Representation (AMR; Banarescu et al., 2013) is a meaning representation language that underlies much recent work in semantic parsing. In AMR, meaning is annotated on the sentence level in the form of a labeled, directed graph. While the nodes of the graph represent instances of concepts, edges represent roles that these entities play with respect to each other.

2.2.1 Evaluation of AMRs

AMR parsers are usually evaluated with respect to the *Smatch* metric (Cai and Knight, 2013), which measures precision and recall of semantic triples in an AMR graphs with respect to a gold standard graph. The computation of Smatch relies on finding an optimal alignment between the two graphs, which is usually approximated.

2.3 Graph-Algebraic CCG

Graph algebras are an established means to model the derivation of AMRs (Koller, 2015). A modification of CCG that applies graph-algebraic operators to semantic categories has first been presented by Beschke and Menzel (2018). They define a set of semantic operators that apply to *s-graphs*, which contain specially marked *source nodes*, which are consecutively indexed starting from 0. They also define three semantic operators:

- *Application*, which 1) merges the root of an argument graph with the highest-indexed source node of the function graph and 2) merges all source nodes that have the same index.

Combinator	Left Operand	Right Operand		Result
$>$	$X/Y : \bigcirc\!\!\rightarrow \langle 0\rangle$	$Y : \Diamond$	$\Rightarrow$	$X : \bigcirc\!\!\rightarrow\!\Diamond$
$<$	$Y : \Diamond$	$X\backslash Y : \bigcirc\!\!\rightarrow \langle 0\rangle$	$\Rightarrow$	$X : \bigcirc\!\!\rightarrow\!\Diamond$
$\mathbf{B}>$	$X/Y : \bigcirc\!\!\rightarrow \langle 0\rangle$	$Y/Z : \Diamond\!\!\rightarrow \langle 0\rangle$	$\Rightarrow$	$X/Z : \bigcirc\!\!\rightarrow\!\Diamond\!\!\rightarrow \langle 0\rangle$
$\mathbf{B}_{\times}<$	$Y/Z : \Diamond\!\!\rightarrow \langle 0\rangle$	$X\backslash Y : \bigcirc\!\!\rightarrow \langle 0\rangle$	$\Rightarrow$	$X/Z : \bigcirc\!\!\rightarrow\!\Diamond\!\!\rightarrow \langle 0\rangle$
$\mathbf{B}^2>$	$X/Y : \bigcirc\!\!\rightarrow \langle 0\rangle$	$(Y/Z_1)/Z_2 : \Diamond\!\!\rightarrow \langle 0\rangle$ $\searrow \langle 1\rangle$	$\Rightarrow$	$(X/Z_1)/Z_2 : \bigcirc\!\!\rightarrow\!\Diamond\!\!\rightarrow \langle 0\rangle$ $\searrow \langle 1\rangle$
conj	conj : $\mathit{conj} \rightarrow \langle 0\rangle$ $\searrow \langle 1\rangle$	$X : \bigcirc\!\!\rightarrow \langle 0\rangle$	$\Rightarrow$	$X\backslash X$: $\mathit{conj} \rightarrow \langle 1\rangle$ $\searrow \bigcirc\!\!\rightarrow \langle 0\rangle$
rp	$X : \Diamond$	$. : \epsilon$	$\Rightarrow$	X : $\Diamond$
lp	$. : \epsilon$	$X : \Diamond$	$\Rightarrow$	X : $\Diamond$

Table 1: The set of binary combinators used in our system. Circles and diamonds correspond to arbitrary AMR subgraphs. X and Y represent arbitrary syntactic categories. The *conj* node represents any concept corresponding to a conjunction, such as *and* or *contrast*. Edge labels are omitted.
The combinators Forward Application ($>$), Backward Application ($<$), Forward Composition ($\mathbf{B}>$), Backward Crossed Composition ($\mathbf{B}_{\times}<$), and Forward Generalised Composition ($\mathbf{B}^2>$) all use the *Application* semantic operator. The Conjunction (*conj*) combinator uses the *Conjunction* semantic operator, and Left and Right Punctuation (*lp*, *rp*) use *Identity*.

- *Conjunction*, which 1) merges the root of an argument graph with the 1-indexed source node of the conjunction graph, and 2) renames the 0-indexed source node of the conjunction graph so that it becomes the highest-indexed source node in the combined graph (thus becoming accessible for application).

- *Identity*, in which the function graph is empty and the argument graph is returned unchanged.

An overview of the rules as well as how they are applied in the context of CCG derivations is given in Table 1.

An example derivation is given in Figure 2.

3 Lexicon Induction

For parsing with graph algebraic CCG, a lexicon must first be obtained. We achieve this using the *recursive splitting* algorithm by Beschke and Menzel (2018), which uses the following information to induce lexical items from an AMR-annotated sentence:

- The sentence's AMR

- A syntactic CCG parse obtained from a syntax parser

- A set of alignments linking tokens in the sentence to nodes in the meaning representation, obtained from automatic alignment tools

A set of lexical items explaining the sentence can then be obtained by walking down the syntactic parse tree, starting at the root with the full sentential meaning representation. At each binary derivation step, the meaning representation is partitioned into two subgraphs by unmerging nodes as appropriate. Each split is done in such a way that it can be reversed using a graph algebraic combinator and the token-to-node alignments are honored.

For any token, this procedure may generate several or no lexical entries. If the alignments do not uniquely specify how the meaning representation should be divided in a splitting step, all alternatives are explored. Also, splitting may abort at an inner node of the derivation if there is no combinator that satisfies the alignment constraint.

This work adds two steps to the lexicon induction process: the delexicalisation of lexical items, followed by filtering for the most probable derivation for each sentence according to EM estimates.

3.1 Delexicalisation

We achieve generalisation over content words by delexicalising lexical entries. We follow the approach from Kwiatkowski et al. (2011) which divides lexical entries into *templates* and *lexemes*. A template is a graph wherein up to one node has been replaced by a *lex* marker. A lexeme x—y is a pair of a word x and a node label y. For examples of templates and lexemes, see Table 2.

The idea of the delexicalisation algorithm is that a node in the graph which corresponds to the lexical meaning of the lexical entry is replaced by a marker, converting it into a template. Since it is not known in advance which node carries the lexical meaning, we replace every node in turn and add all resulting templates to the lexicon. Every replaced node label is associated with the token currently under consideration and stored as a lexeme.

Not all lexical entries contain a node with lexical meaning, e.g. in the case of function words. Therefore, the original meaning representation is also added to the lexicon as a template along with an empty lexeme.

Special lexemes are also added that map any word to a node labeled by the word's lemma, its surface form in quotes, or any of the propbank frame names associated with its lemma.

This process creates a large amount of superflous template/lexeme pairs. Therefore, the lexicon is subsequently filtered using Expectation Maximisation.

3.2 Expectation Maximisation

Both splitting and delexicalisation generate spurious templates and lexemes. We wish to keep only those that generalise well by being broadly applicable. In contrast, noise introduced during grammar induction should be removed.

This noise manifests itself in spurious derivations for the sentences of the training set. Expectation Maximisation (EM) is applied to identify a single most likely derivation per sentence. Every template and lexeme that in not used in at least one of these derivations is deleted.

We use a variant of the inside-outside algorithm (Baker, 1979) to estimate multinomial distributions P_t for templates and P_l for lexemes. From these, we derive a probability distribution over derivations:

$$P(d) = \prod_{(t,l)\in\textsc{lex}(d)} P_t(t)P_l(l)$$

where $\textsc{lex}(d)$ gives all template-lexeme pairs instantiated by the derivation.

Algorithm 1 Variation of the inside-outside algorithm to estimate parameters over CCG derivations. See Section 3.2 for function definitions.

```
Input: Data set $S$; scoring function $\textsc{Score}^i$
Output: Distributions $P_T^{i+1}$ and $P_L^{i+1}$
$count_T[j] \leftarrow 0$ for $0 \le j < |T|$
$count_L[j] \leftarrow 0$ for $0 \le j < |L|$
for $s \in S$ do
    $chart \leftarrow \textsc{Split}(s)$
    $likelihood \leftarrow \sum_{e\in chart[0,|s|-1]} \textsc{in}^{i+1}(e)$
    for $e \in chart$ do
        $c \leftarrow \frac{\textsc{Score}^i(e)\textsc{out}^{i+1}(e)}{likelihood}$
        for $(t,l) \in \textsc{Delex}(e)$ do
            $count_T[t] \leftarrow count_T[t] + c$
            $count_L[l] \leftarrow count_L[l] + c$
        end for
    end for
end for
$P_T^{i+1}(t) = \frac{count_T[t]}{\sum_{t'\in T} count_T[t']|}$ for $t \in T$
$P_L^{i+1}(l) = \frac{count_L[l]}{\sum_{l'\in L} count_L(l')|}$ for $l \in L$
```

Our inside-outside algorithm operates on *split charts*, which keep track of all derivation nodes created during recursive splitting. A split chart c for a sentence s contains cells $c[i,j]$ with $0 < i \le j, j < |s|$. A cell contains a number of entries e, each of which is associated with a meaning representation $\textsc{MR}(e)$ and a (possibly empty) set of child pairs $(l,r) \in \textsc{Cld}(e)$, which are in turn entries. An entry can also have several parents $e' \in \textsc{Par}(e)$, in which case it also has a neighbour $\textsc{Nb}(e,e')$ for every parent e'.

To compute a probability for an entry, we employ a function $\textsc{Delex}$ which decomposes the entry's meaning representation into all possible template-lexeme pairs.

Inside and outside probabilities for entries are calculated recursively as follows:

$$\textsc{in}^{i+1}(e) = \textsc{Score}^i(e) + \sum_{(l,r)\in\textsc{Cld}(e)} \textsc{in}^{i+1}(l)\cdot\textsc{in}^{i+1}(r)$$

$$\textsc{out}^{i+1}(e) = \sum_{e'\in\textsc{Par}(e)} \textsc{out}^{i+1}(e') \cdot \textsc{in}^{i+1}(\textsc{Nb}(e,e'))$$

where

$$\textsc{Score}^i(e) = \sum_{(t,l)\in\textsc{Delex}(\textsc{MR}(e))} P_T^i(t)P_L^i(l)$$

A given meaning representation $\textsc{MR}(e)$ can be created by either instantiating a lexical entry with probability $\textsc{Score}^i(e)$, or by deriving it using any of its pairs of children (l, r) with probability $\textsc{IN}^i(l)\textsc{IN}^i(r)$. All of these are alternative choices; therefore, the probabilities are summed to make up the inside probability. The outside probability is composed of the entry's parents' outside probabilities and the entry's neighbours' inside probabilities.

Algorithm 3.2 describes how an updated set of parameters is estimated using these calculations.

4 Parsing

Our parser uses a CKY-style chart parsing algorithm to parse sentences to AMR. For each token, template-lexeme pairs are drawn from the lexicon. Recursively, derivation nodes are created according to CCG/AMR rules. All candidate derivation nodes are evaluated with respect to a linear model. A beam search limitation is applied, meaning that only the top n candidates from each chart cell are kept.

The flip side of using a delexicalised lexicon is that every template can now be applied to every token. To limit the number of leaves that have to be considered, we employ a supertagger which predicts the most suitable template for each token. We then limit our search to the most probable templates as predicted by the supertagger.

4.1 Supertagging

For supertagging, we use a single-layer BiLSTM. For inputs, the raw tokens and syntactic CCG categories predicted by a CCG supertagger are used. The model is then trained to predict the template instantiated by each token.

The following preprocessing steps are applied:

- Tokens are embedded using the third layer produced by ELMo (Peters et al., 2018).

- CCG supertags, as well as templates, that occur in less than two sentences are replaced by `UNK`.

To predict supertags on the *dev* and *test* sections, we train the supertagger on the entire *train* section and output the predicted token-wise supertag distributions (clipping at 99% cumulative probability). To obtain supertag predictions on the *train* section, we employ 5-way jackknifing: the data is split into five parts and predictions for each part are obtained by training on the remaining four parts.

During training, the occurrence of the correct label within the top-10 predictions for every token is monitored and training aborted when this measure stops improving (early stopping).

4.1.1 Limited Supervision

The grammar induction process as described in Section 3 attempts to find lexical items for every individual token, but may stop early if no combinatory rule fitting the alignment constraint is available. In this case, no supervision for training the tagger is available at the token level. We overcome this issue by labelling the respective tokens as `UNK` (the same label used for rare templates occurring only once) and masking `UNK` tokens in the loss function.

This allows the tagger to fill in the gaps with reasonable templates that are in the lexicon. However, it also means that not every sentence from the train set can be perfectly parsed any more, because it is possible that its meaning representation cannot be constructed using the induced token-level lexical entries.

5 Training

To drive the parser, we train a linear model over graph algebraic CCG derivations. Since we do not observe derivations in the data, this is an instance of latent variable learning and a supervision signal must be generated. We take a dual approach by combining two weak supervision signals:

1. An oracle is used to heuristically generate silver-standard derivations, which can then be used for training.

2. The derivations found by the parser are evaluated and used for cost-sensitive parameter updates.

5.1 Model

We train a linear model using a structured perceptron algorithm (Collins, 2002) with Adadelta updates (Zeiler, 2012). We use features over paths in the graph as well as the identities of invoked templates, lexemes, and combinators.

Template	Lexeme	Combined
$N:\ lex$	weapons—weapon	$N:$ weapon
$NP/N:\ \langle 0\rangle$	the—∅	$NP/N:\ \langle 0\rangle$
$N/N:\ \langle 0\rangle \xrightarrow{\text{mod}} lex$	nuclear—nucleus	$N/N:\ \langle 0\rangle \xrightarrow{\text{mod}}$ nucleus
$(S\backslash NP)/NP:\ lex \xrightarrow{\text{ARG0}} \langle 0\rangle$ $\xrightarrow{ARG1} \langle 1\rangle$	said—say-01	$(S\backslash NP)/NP:$ say-01 $\xrightarrow{\text{ARG0}} \langle 0\rangle$ $\xrightarrow{ARG1} \langle 1\rangle$
$NP:$ country $\xrightarrow{\text{name}}$ name $\xrightarrow{\text{op1}}$ lex	Iran—"Iran"	$NP:$ country $\xrightarrow{\text{name}}$ name $\xrightarrow{\text{op1}}$ "Iran"

Table 2: Selected templates and lexemes from the induced lexicon. The templates are among the 20 most highly scored according to EM parameters; the lexemes among the top 50.

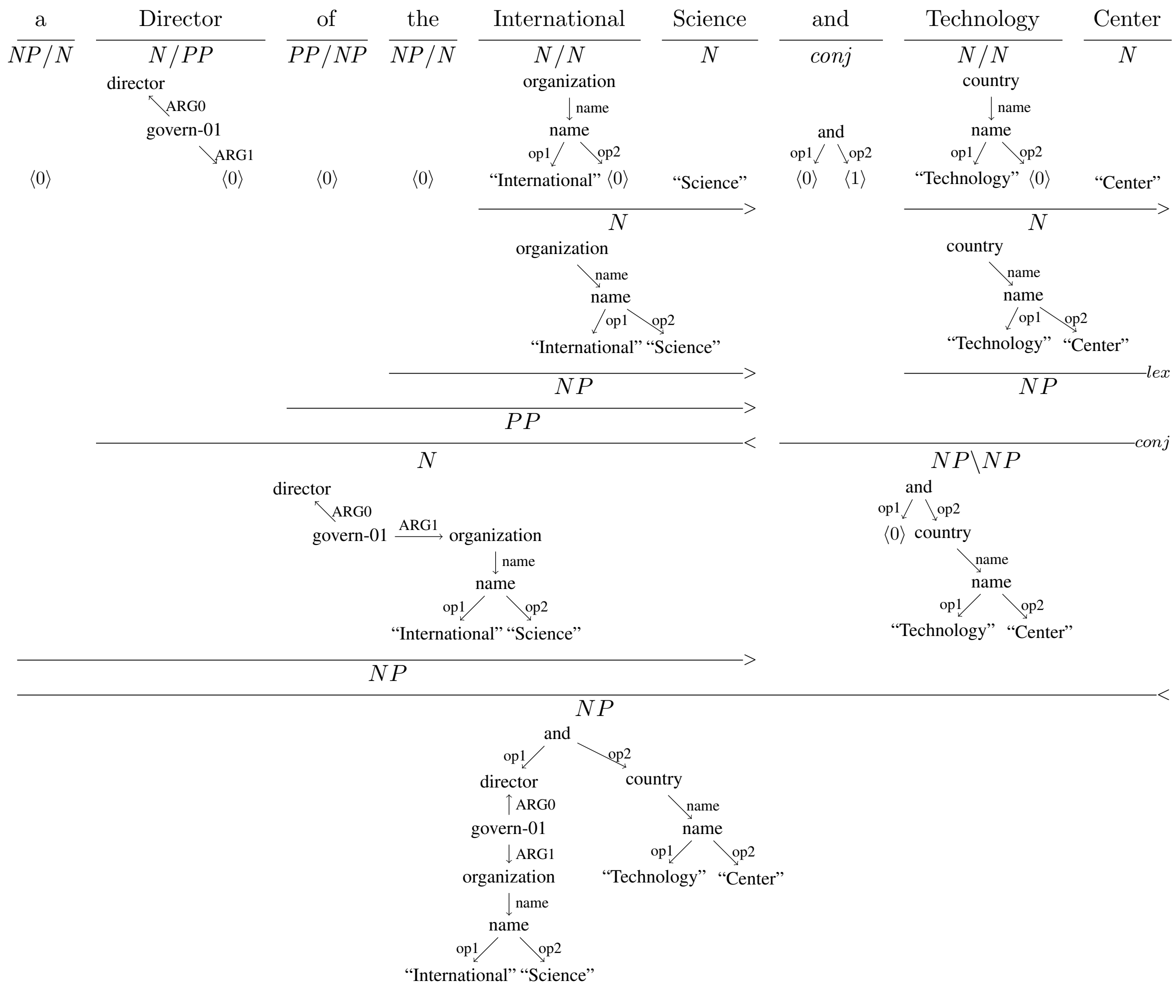

Figure 2: A derivation for a subsequence of PROXY_NYT_ENG_20020406_0118.25, as produced by our parser.

5.2 Oracle Parsing

In latent variable learning in structured prediction settings, the challenge is to obtain an unobserved derivation for a known gold-standard result. In this case, gold-standard sentential AMRs are annotated in the AMR corpus, but they are not related to the sentence by a grammatical derivation.

A common approach to this challenge is *forced decoding* (Artzi et al., 2015): the parser is used to construct derivations which lead to the correct result by pruning all hypotheses from the search space which deviate from the gold-standard AMR. E.g., all AMRs that contain elements not present in the gold-standard could be pruned.

However, as noted in Section 4.1, not every gold-standard AMR can be reconstructed perfectly using the induced lexicon due to the incompleteness of the splitting algorithm, which defies finding correct parses using forced decoding.

Instead, we train the parser using an oracle driven by a heuristic scoring function which scores the correctness and completeness of an intermediate hypothesised AMR. We parse the sentence using CKY with beam search, ranking intermediate results according to the harmonic mean of the following values:

- **Triple precision:** the proportion of node-edge-node triples in the intermediate result that also occur in the gold standard meaning representation.

- **Alignment recall:** the proportion of node labels that are linked by an alignment edge to one of the intermediate result's tokens that also occur in the intermediate result.

This scoring function is designed to rank results in proportion to their deviation from the gold standard, achieving a soft form of pruning.

Having obtained a set of derivations using oracle parsing, we finally re-rank these derivations by their Smatch f1 scores and use the best derivation to perform a parameter update using an early update strategy (Collins and Roark, 2004).

5.3 Cost-Sensitive Update

Another approach to training with weak supervision for structured prediction are cost-sensitive updates. While the gold-standard to update towards is unknown, an evaluation metric is available for the AMR that results from a specific derivation. Cost-sensitive updates let the parser search for complete derivations and enforce a margin between the best derivations in the beam and all the others. We follow Singh-Miller and Collins (2007) by implementing a cost-sensitive perceptron algorithm which weights hypotheses according to their Smatch f1 score.

5.4 Combined Update Strategy

While early updates are efficient, our oracle is imperfect. To allow the parser to improve over oracle parses, we use a cost-sensitive update whenever a parse has been found whose Smatch f1 score surpasses that of the oracle parse.

6 Experimental Setup

We evaluate our parser[1] on the *proxy* section of the AMR 1.0 corpus (LDC2014T12; Knight et al., 2014). This section consists of newswire texts.

Sentences are tokenised and lemmatised using Stanford NLP (Manning et al., 2014). We use EasyCCG to obtain CCG parses and supertags (Lewis and Steedman, 2014). Token-to-AMR alignments are obtained by combining outputs generated by the JAMR aligner (Flanigan et al., 2014) and the ISI aligner (Pourdamghani et al., 2014), as described by Beschke and Menzel (2018).

First, we induce a CCG/AMR lexicon from the entire *proxy-training* section, delexicalise the entries, and filter for the best derivations using EM, as described in Section 3. We perform 100 iterations of EM. Sentences longer than 100 tokens are filtered out. The resulting lexicon contains 15630 templates and 10504 lexemes.

Next, we extract template tag sequences and train our suppertagger on them. First, tags for the training data are predicted using 5-way jackknifing. Then, a model is trained on the entire training section and used to predict tags for the *dev* and *test* sections of the corpus. Since only templates are predicted that occur in at least two training sentences, a set of 2453 templates is used for prediction. The top-10 recall of the annotated supertags is 96.4% on a randomly chosen held-out portion of the training set.

Finally, the induced lexicon as well as the predicted tag sequences are used to parse the *proxy-test* section of the AMR corpus. We use a beam

size of 15 during parsing and 20 for finding oracle derivations (see Section 5.2). Parses whose root categories do not match any of the top-10 derivations produced by EasyCCG are dropped from the parser output[2].

The `smatch` tool[3]is used to calculate Smatch precision, recall, and f1 scores for the parser output.

7 Results

We compare our system to two previous CCG-based AMR parsers (Artzi et al., 2015; Misra and Artzi, 2016), as well as the current state of the art in AMR parsing on this data set (Liu et al., 2018). The results are shown in Table 7. The system introduced in this paper achieves comparable precision to the other CCG-based systems, but lower recall.

This gap is largely, but not completely, explained by sentences that were not parsed at all: when unparsed sentences are excluded from the evaluation, our system achieves a precision of 0.701 and a recall of 0.615[4]. Oracle parsing achieves a Smatch precision of 0.886 and an f1 score of 0.706.

The evaluation set contains 823 sentences in total, of which 170 were not parsed, resulting in a coverage of 79%. Of these sentences, 68 were skipped because they were longer than 40 tokens. The remaining 102 are unparsed because the parser failed to find a complete parse.

7.1 Discussion

The parser output in Figure 5 shows some of the most common errors produced by our parser. Firstly, the sequence *International Science and Technology Center* is not recognised as a contiguous named entity. Additionally, *Technology Center* is misrecognised as a country. Both of these issues can be classified as supertagging errors, as they result from the templates chosen from the lexicon. In this specific case, the supertagger's behaviour could likely be improved by adding named entity features to its input. In general, the supertagging task is challenging, especially in the case of function words, which tend to be highly polysemous.

Additionally, the scopes of *and* and *of* are inverted. This can be interpreted as a weakness of the parsing model, which misjudges the probability of the respective scope assignments. Although one would hope for a semantic parser to improve precisely upon these semantically informed syntactic decisions, this behaviour is perhaps to be expected given that we train a sparse linear model with a relatively small amount of training data. Replacing the linear classifier with a neural model that computes embeddings of graph meanings, such as the architecture proposed by (Misra and Artzi, 2016), could improve the parser's judgment.

8 Conclusion

We have introduced a pipeline for training a CCG parser which jointly models syntax and semantics. A central element of our architecture are efforts to reduce the lexicon size. With 2453 delexicalised templates, our parser uses a relatively small lexicon despite the templates being induced automatically. We employ a semantic construction mechanism that is less powerful with λ-calculus, but still achieve competitive precision.

Future directions in this line of work could include applications that make use of the system's transparency, such as the interactive training of parsers without gold-standard annotations, or the application of external constraints such as contextual knowledge to the parser.

Acknowledgments

The author would like to thank Wolfgang Menzel for discussions and advice, as well as the anonymous reviewers.

[2] This restriction was included because the parser tended to favour interpretations of sentences as *NP* instead of *S*.

[3] `https://github.com/snowblink14/smatch`, revision `ad7e655`

[4] The precision improves when unparsed sentences are excluded because the `smatch` tool does not permit empty AMRs to be specified. Unparsed sentences are therefore represented by single-node placeholder AMRs, which are penalised in terms of precision.

Quasi Bidirectional Encoder Representations from Transformers for Word Sense Disambiguation

Michele Bevilacqua and **Roberto Navigli**
Department of Computer Science
Sapienza University of Rome
{bevilacqua,navigli}@di.uniroma1.it

Abstract

While contextualized embeddings have produced performance breakthroughs in many Natural Language Processing (NLP) tasks, Word Sense Disambiguation (WSD) has not benefited from them yet. In this paper, we introduce QBERT, a Transformer-based architecture for contextualized embeddings which makes use of a co-attentive layer to produce more deeply bidirectional representations, better-fitting for the WSD task. As a result, we are able to train a WSD system that beats the state of the art on the concatenation of all evaluation datasets by over 3 points, also outperforming a comparable model using ELMo.

1 Introduction

Word Sense Disambiguation (WSD) is the task of associating a word in context with the right meaning among a finite set of possible senses (Navigli, 2009). Consider the following sentence, in which SERVED is the target word:

(1) The waiter standing near the counter SERVED the revolutionary cause well.

In WordNet (Fellbaum, 1998), the most used English computational lexicon in NLP, the following two senses are associated (among many others) to the verb *to serve*:

1. ***devotion***: *devote (part of) one's life or efforts to, as of countries, institutions, or ideas*;
2. ***food***: *help to some food; help with some food or drink*;

The WSD system, in this case, would be tasked to associate the target word with the correct meaning – i.e. the *devotion* sense.

Currently the best WSD systems are supervised, i.e. they leverage annotated corpora as training data (Yuan et al., 2016; Vial et al., 2018; Melacci et al., 2018). However, data labeling is a bottleneck for WSD, even more so than in other fields of NLP. Semantic annotation is a costly process, requiring expert annotators (Taghipour and Ng, 2015; Pasini and Navigli, 2017). If we consider that neural networks, the best performing approach in virtually every task in NLP, are particularly data-hungry, it appears unlikely that there will be much progress in WSD unless either more data is available, or less data is needed.

Between the two directions, we believe efforts towards the latter will prove more fruitful, firstly, because of scalability considerations, and secondly, and more importantly, because of the recent growth in the use of transfer learning, as exemplified by contextualized embeddings. Contextualized embeddings have been shown to produce much better results on downstream tasks compared to end-to-end training, even when less data is provided (Peters et al., 2018; Howard and Ruder, 2018; Devlin et al., 2019; He et al., 2018; Akbik et al., 2018). Contextualized embeddings that use words as tokenization units, such as ELMo (Peters et al., 2018), are most suited to WSD. They are usually trained through self-supervised Causal Language Modeling (CLM) (Lample and Conneau, 2019): given a word sequence $w_1, w_2, \ldots, w_n$ the system has to use w_1 to predict w_2, the sequence $w_{1:2}$ to predict w_3 and so on. CLM is inherently unidirectional, as the model must not be able to "peek" at the word it has to predict. Thus to encode the left and the right contexts two separate networks have to be used, even if they often share part of the weights and are jointly trained.

As regards the use of contextualized embeddings in WSD, this is bound to pose a problem.

Consider the sentence (1) above. It features attractors, i.e. words or phrases pushing the sense interpretation in one direction or the other, with the left context providing a strong cue for the *food* sense and the right for the *devotion* sense. In this paper, we propose a modification of the usual CLM architecture for transfer learning that enables us to train a high-performance WSD system. In this context, we make the following contributions:

- we introduce the BiTransformer, a novel Transformer-based (Vaswani et al., 2017) co-attentive layer allowing deeper bidirectionality;
- we introduce QBERT (Quasi Bidirectional Encoder Representations from Transformers), a novel Transformer-based architecture for CLM making use of the BiTransformer;
- we train a WSD model using QBERT contextualized embeddings, outperforming on the standard evaluation datasets both the previously established state of the art (by a large margin) and a comparable model using ELMo;
- we use QBERT to beat ELMo on the recently established Word-in-Context (WiC) task (Pilehvar and Camacho-Collados, 2019).

2 Related Work

Despite the limited availability of training data, the WSD systems offering the best performances are supervised ones. Many of the approaches are still end-to-end, i.e. they only make use of the information learned during the WSD training.

End-to-end WSD Systems In WSD traditional machine learning techniques are still very competitive because they are not as data-hungry as neural networks. The very popular It Makes Sense (IMS) system (Zhong and Ng, 2010), based on Support Vector Machines and hand-crafted features, performs very well when word embeddings are used as additional features (Iacobacci et al., 2016); the classifier by Papandrea et al. (2017) also gets competitive results. The system of Weissenborn et al. (2015) attains very high performances, but only disambiguates nouns. More recently, neural models have been developed (Kagebäck and Salomonsson, 2016; Uslu et al., 2018; Luo et al., 2018). Some of the most successful offer an intuitive framing of WSD as a tagging task (Raganato et al., 2017a; Vial et al., 2018).

Transfer Learning WSD Systems One of the best performing WSD systems (Yuan et al., 2016) employs a semi-supervised neural architecture, whereby a unidirectional LSTM was trained to predict a masked token on huge amounts of unlabeled data (over 100B tokens). The trained LSTM was used to produce contextualized embeddings for tagged tokens in SemCor; then kNN or a more sophisticated label propagation algorithm was used to predict a sense. The size of the training data makes replication difficult – a reimplementation attempt with a smaller corpus led to worse results (Le et al., 2018). A similar approach using ELMo contextualized embeddings has been presented by Peters et al. (2018), but the results were underwhelming. Another attempt at using transfer learning in WSD has been carried out by Melacci et al. (2018). The authors enhanced IMS with context2vec (Melamud et al., 2016), obtaining performance roughly on a par with Yuan et al. (2016).

Contextualized Embeddings Most of the approaches to contextualized embeddings involve CLM pretraining of directional (either attentive or recurrent) networks. Very successful CLM-based models include ELMo, in which two separate directional LSTMs are fed the output of a shared character-based Convolutional Neural Network (CNN) encoder (Peters et al., 2018), and OpenAI GPT, using Transformers instead of LSTMs and a BPE vocabulary (Sennrich et al., 2016) with regular embeddings instead of the CNN encoder (Radford et al., 2018). Another popular approach, Flair, features character-level LSTMs, outputting hidden states at word boundaries (Akbik et al., 2018). As CLM architectures are normally unidirectional, one alternative in order to guarantee a joint encoding of the context is the Masked Language Modeling (MLM) of BERT (Devlin et al., 2019), which, however, requires a variety of tricks at training time.

3 The QBERT Architecture

Similarly to other LM-based approaches to contextualized embeddings (Peters et al., 2018; Radford et al., 2018; Howard and Ruder, 2018; Devlin et al., 2019), the architecture we hereby propose has two main components, which we will refer to

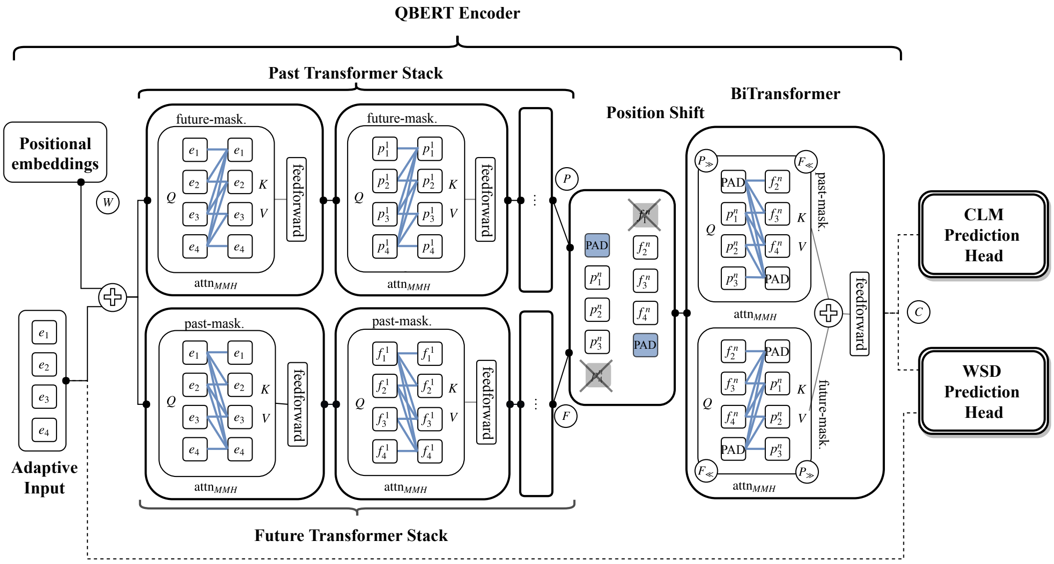

Figure 1: A high-level view of the QBERT architecture.

as Encoder and task-specific Prediction Head. In Figure 1 we show a high-level view of our system. Raw tokens are fed to the encoder, which embeds them into context-independent fixed-length vector representations (the *word embeddings*, W in Figure 1), then uses them to produce context-dependent hidden representations (the *contextualized embeddings*, C), where the context is some subset of the sequence itself. The Prediction Head exploits the vectors produced by the Encoder to perform a task.

3.1 Encoder

As will become clear in what follows, the Encoder of the QBERT architecture is able to compute the hidden representation of a word w_t in a sequence $w_{1:n}$ as a function of the weights and of the whole sequence except w_t itself, i.e. of $w_{1:t-1}$ and $w_{t+1:n}$. To embed tokens, the Encoder uses the Adaptive Input layer (Baevski and Auli, 2018). Sinusoidal positional embeddings are added to the output and passed to two separate stacks of masked Transformers, computing two directional encodings of the sequence, with one (P) having past and present ($w_{1:t}$) information encoded in the present-token hidden vector and the other (F) having present and future ($w_{t:n}$) information instead. Since in the CLM training information about the present token must be hidden from the output layer, we shift and pad the sequences in order to have only the past tokens encoded in the output of the first stack ($P_{\gg}$) and only future tokens encoded in the output of the second ($F_{\ll}$). To combine the shifted sequences we use a novel Transformer layer variant taking them both as input, the BiTransformer, featuring a co-attentive mechanism in which $P_{\gg}$ attends over $F_{\ll}$ and $F_{\ll}$ attends over $P_{\gg}$. The Encoder is trained on CLM using an Adaptive Softmax layer (Grave et al., 2017) as Prediction Head.

3.2 Transformer Variants in QBERT

In the QBERT Encoder we employ three distinct variants of the plain Transformer: the future-masked Transformer, the past-masked Transformer and the BiTransformer. To introduce them we first need to elaborate further into the inner workings of the layer. A vanilla Transformer layer (Vaswani et al., 2017) can be defined as a multi-head self attention submodule followed by a time-wise 2-layer feedforward network, with additional residual connection (He et al., 2016) and layer normalization stabilizing training (Ba et al., 2016).

Core (Self) Attention The intuition behind the attention mechanism is very simple (Bahdanau et al., 2015; Luong et al., 2015). We have a sequence of vectors (the n_q queries Q of dimension d_q) and we want to compute relevance scores against some other sequence of vectors (the n_k keys K of dimension d_k) specific to each couple of vectors q and k. The $n_q \times n_k$ relevance score matrix is then used to compute n_q weighted means of another sequence of vectors (the n_k values V of dimension d_v). So, if we pack Q, K, V into matrices, the mechanism can be distilled into the formula:

$$\text{attn}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}})V \quad (1)$$

where $\sqrt{d_k}$ is a normalization factor meant to prevent the dot products from getting too large. In the case of the *self* attention mechanism Q, K, V stand for the same matrix. In the Transformer (Vaswani et al., 2017), multi-head attention is used, in which n attentions (the heads) are computed in parallel, concatenated and then combined through dot product with a $d_q n \times d_o$ matrix W^o. For each attention head h_i, there are three weight matrices W_i^Q, W_i^K, W_i^V, multiplying respectively Q, K and V. Formally, we define multi-head attention (attn_{MH}) as:

$$\text{attn}_{\text{MH}}(Q, K, V) = \bigoplus_{i=0}^{n}[\text{softmax}(\frac{(QW_i^Q)(KW_i^K)^T}{\sqrt{d_k}})(VW_i^Q)]W^o \quad (2)$$

where $\oplus$ denotes concatenation along the second dimension.

Transformer Masking In the past and future stacks, as well as in the BiTransfomer layer, we employ a masking mechanism on attention to enforce directionality, i.e. to force the relevance scores computed between Q and K to be 0 for tokens following or preceding the current one, as needed. Masking can be implemented by performing an elementwise sum between QK^T and a $n_q \times n_k$ masking matrix M, whose values are set to $-\infty$ if K_i and V_j are to be excluded from the attention computation, else 0. In our architecture we employ two different masking matrices: a future masking-matrix M_f which is set to $-\infty$ when $i < j$ and a past-masking matrix M_p set to $-\infty$ when $i > j$; note that $M_f = M_p^T$. Multihead and masked attention can be combined by simply using the same masking matrix in each attention head. We use M_f in the past Transformer stack and M_p in the future stack, producing, respectively, P and F. To encourage the network to encode comparable representations we tie the weights between layers at the same depth on the past and future stack.

3.2.1 Timestep Shift

Present-token information is still encoded in both P and F. To remove it, we use a simple shifting approach where we detach the nth timestep from P and the first from F and add padding to the opposite sides. This effectively shifts the hidden representation by one place to the left and by one place to the right. We refer to the resulting sequences as, respectively, $P_{\gg}$ and $F_{\ll}$. As a result, the ith position of $P_{\gg}$ encodes information from tokens $w_{1:i-1}$ while $F_{\ll}$ encodes $w_{i+1:n}$. Formally:

$$\begin{aligned} P_{\gg} &= PAD \oplus P_{1:n-1} \\ F_{\ll} &= F_{2:n} \oplus PAD \end{aligned} \quad (3)$$

where $\oplus$ denotes concatenation along the timestep dimension. The padding vector PAD is learned during training. The process is visualized in Figure 1, where tokens are aligned according to their shifted positions.

3.2.2 BiTransformer

To combine $P_{\gg}$ and $F_{\ll}$ we employ the BiTransformer, a novel Transformer layer variant that uses a masked coattentive multihead attention mechanism over two sequences. Masking allows $P_{\gg}$ to attend over $F_{\ll}$ while keeping present-token knowledge hidden from the network, and vice versa. This allows deeper bidirectionality in that the resulting output is not a naive combination of two separate directional representations but rather the result of a whole-sequence attention, albeit computed in a two-step process, where the first step can be arbitrarily deep (the masked Transformer stacks) and the second is always shallow (the BiTransformer). Unfortunately, BiTransformers cannot be stacked as each timestep in the output of the layer encodes information about every token in the sequence but the one it has to predict in CLM, so any further use of attention would make pretraining impossible.

The BiTransformer requires modifications to the first part of the vanilla Transformer intramodule architecture. First, both input sequences are layer normalized separately. We compute a masked multihead attention using the future-masked sequence $P_{\gg}$ as Q, the past-masked sequence $F_{\ll}$ as K and V, using the past-masking matrix M_p. To give an insight into what happens, the position i of the n queries, encoding information about words 1 to $i - 1$, is allowed to look at positions i to n of the keys, encoding words $w_{i+1:n}$, $w_{i+2:n}$ and so on. Then we compute the reverse, using $F_{\ll}$, $P_{\gg}$ and future-masking matrix M_f. This process results in two sequences to which input residuals are added, and then added together via a simple elementwise sum. The rest of the layer works just like a regular Transformer layer. We formally describe this coattentive mechanism as follows:

$$\begin{aligned} P'_{\gg} &= \text{LayerNorm}(P_{\gg}) \\ F'_{\ll} &= \text{LayerNorm}(F_{\ll}) \\ O &= \text{attn}_{MMH}(P'_{\gg}, F'_{\ll}, F'_{\ll}, M_p) + \\ &\quad \text{attn}_{MMH}(F'_{\ll}, P'_{\gg}, P'_{\gg}, M_f) + P_{\gg} + F_{\ll} \end{aligned} \tag{4}$$

O goes through the 2-layer feedforward to produce contextualized embeddings, which are used as input for the task-specific Prediction Heads. We describe them in the relevant paragraphs of Sections 4.1 and 5.

4 Experimental Setup

In what follows we first describe the Encoder architecture hyperparameters and CLM pretraining details (Section 4.1). In Section 4.2 we describe the contextualized embeddings systems we use as comparison in the WSD and Word-in-Context experiments. Finally, we report the setup and results of the experiments in Section 5.

4.1 QBERT Encoder Pretraining

CLM Prediction Head and Hyperparameters To train the QBERT Encoder on CLM we use an Adaptive Softmax (Grave et al., 2017) layer as Prediction Head. Following Baevski and Auli (2018), we tie the weights (Press and Wolf, 2017) of the embedding matrices but not the projective weights. Both Adaptive Input and Adaptive Softmax use a vocabulary of 400k words, with cutoffs set to 35k, 100k, 200k and a shrinking factor of 4. The past and future stacks as well as the BiTransformer feature an input and output size of 512, while the first layer of the internal feedforward projects the input to 2048 dimensions, the same as the base configuration in Vaswani et al. (2017). The masked Transformer stacks are both 5-layer deep.

Training Hyperparameters We train QBERT on the English UMBC corpus (Han et al., 2013), which contains around 3B tokens. In our training loop we feed the input in batches of 5000 tokens, splitting the corpus in sequences of max 100 tokens. We found it beneficial to accumulate the gradient for many training steps, performing an update every 16 batches, resulting in a virtual batch size of 80000 tokens. As an optimizer we employ regular Nesterov-accelerated SGD, with a learning rate that first increases linearly from 10^{-5} to 1 during a warmup phase lasting 2000 updates, and then varies from a maximum of 1 to a minimum of 10^{-5} according to a Cyclical Learning Rate (Smith, 2017) policy with cosine scheme, with a period of 2000 updates. With each cycle, the period is multiplied by 1.5 while both the maximum and minimum values are halved. We train until convergence.

We implement the system and training logic in `pytorch` with the help of the `fairseq` library.

4.2 Comparison Systems

In our experiments we compare QBERT with three different contextualized embeddings systems:

1. Off-the-shelf pretrained **ELMo** (Peters et al., 2018). We employ a model featuring 4096-sized bidirectional LSTMs and 512-sized contextualized embeddings[1], pretrained on the concatenation of a Wikipedia dump and a few English monolingual news corpora[2], for a total of 5.5B tokens.

2. Off-the-shelf pretrained **Flair** (Akbik et al., 2018). We employ the models the project's page[3] refers to as `mix-forward` and `mix-backward`, pretrained on "Web, Wikipedia, Subtitles"[4]. We concatenate their contextualized embeddings.

3. **SBERT** (Shallowly Bidirectional Encoder Representations from Transformers), a baseline featuring the same architecture as QBERT but missing the BiTransformer layer: the outputs of the past and future stacks are simply combined through elementwise sum after the position shift.

We do not include in our comparison the BPE-based systems BERT and GPT (Devlin et al., 2019; Radford et al., 2018) as they use a different tokenization unit, which is not suitable for WSD.

[1] The model implementation and weights are available in the `allennlp` library.

[2] The corpora used are the 2008 to 2012 news crawls, available at `http://data.statmt.org/news-crawl/en/`

[3] `https://github.com/zalandoresearch/flair`

[4] There are no further specifications about the composition of the training corpus.

5 Evaluation tasks

As the first and main experiment we train and evaluate a WSD Transformer classifier (Section 5.1.1) using QBERT and comparison contextualized embeddings. To corroborate the results, as further experiments we evaluate the performance of the contextualized embeddings on the Word-in-Context task (Pilehvar and Camacho-Collados, 2019) (Section 5.2).

5.1 Word Sense Disambiguation

5.1.1 Setup

To perform our WSD experiment we train a simple Transformer-based classifier, which we evaluate on all-words WSD benchmark datasets. We use F1 on the test set as a measure of performance.

Architecture Our Transformer classifier takes as input the w-weighted mean between the word embeddings produced by the Encoder (the Adaptive Input layer in the case of QBERT, the character-level CNN in the case of ELMo) and the contextualized embeddings. We freeze the Encoder and only train w and the weights of the Transformer classifier. As Flair has no word embeddings, we concatenate the outputs of the forward and backward models with GloVe embeddings (Pennington et al., 2014), and substitute the weighted mean with a dense layer projecting the concatenated matrix to the Transformer hidden dimension. The classifier produces a probability distribution over an output vocabulary which includes all the possible synsets plus a special `<untagged>` symbol for words with no associated tag. During training only, we treat monosemous words as tagged. At test time, we predict the synset with the highest probability among those associated with the lemma of the target word. Importantly, we do not employ any Most Frequent Sense backoff strategy.

Hyperparameters All models are trained with Adam for a maximum of 60 epochs. We use a similar learning rate scheduling scheme as in the CLM training, first linearly increasing the value from 10^{-5} to 10^{-3}, then using a cosine CLR scheduler with period 200, maximum learning rate 10^{-3} and minimum learning rate 10^{-4}; with each cycle the maximum and minimum are halved, while the period is doubled.

Training and Test Data For each comparison system we train two WSD classifiers, one using only SemCor as training corpus and the other using the concatenation of SemCor and the corpus of WordNet's Tagged Glosses[5] (WTG). WTG includes 117659 manually disambiguated WordNet synset glosses, with 496776 annotated tokens. We test the performance of the models on the English all-words evaluation datasets from the SensEval and SemEval WSD evaluation campaigns, namely Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Snyder and Palmer, 2004), SemEval-07 (Pradhan et al., 2007), SemEval-13 (Navigli et al., 2013), SemEval-15 (Moro and Navigli, 2015) and their concatenation (ALL). We use SemEval-2015 as our development set, to select the best epoch of the run. We use the version of SemCor and the evaluation datasets included in the WSD framework[6] of Raganato et al. (2017b).

5.1.2 Results

We show in Table 1 and Table 2 the results of the evaluation on all-words WSD of the Prediction Head trained on top of QBERT and the comparison systems. Our best model beats all the previously established results on all evaluation datasets. While the performance of the systems using SBERT and ELMo are also very competitive, in many cases exceeding the state of the art, QBERT consistently outperforms them, achieving one of the largest performance gains in years.

SemCor If we restrict the comparison to models trained on SemCor (Table 1), QBERT beats the state of the art with a margin of 0.7 points on Semeval-07 and 1.5 points on SemEval-13. On our development set, SemEval-15, we get a score 2 points over the state of the art. On Semeval-2 and Senseval-3 our F1 score is in the same ballpark as, respectively, Yuan et al. (2016) and Uslu et al. (2018). QBERT also performs well measured against our comparison systems. SBERT achieves lower performance across the board, but attains overall competitive results on all the datasets. ELMo performs on a par with SBERT on the concatenation of all datasets, but gets better results than QBERT on the development set. Flair, perhaps as a result of its purely character-based nature, is severely outperformed on most datasets.

Table 2: Results of the evaluation on the English datasets of models trained on the concatenation of SemCor and WTG. We use the same notation as in Table 1, employing $\star$ to mark significance against the single model state of the art. Models from Vial et al. (2018), marked by SMP, use a random sample of sentences from SemCor and WTG as development. In the row blocks we report 1) competitor neural networks; 2) the state of the art as the maximum value in the previous rows and in Table 1; 3) QBERT and our comparison systems.

SemCor and WTG When we report in the comparison systems trained on the concatenation of SemCor and WTG (Table 2), QBERT beats the state of the art more consistently and by a larger margin. We reach 1.3 points above the previous state of the art on Senseval-2, 0.4 points on Senseval-3, 2.4 on Semeval-07, 3.8 on Semeval-13 and 4.6 on Semeval-15 (which is however our development set). On the concatenation of all datasets, our margin is of 3 points. Even if we consider the ensemble of 20 models trained on SemCor and WTG by Vial et al. (2018), we get better results on every dataset with the exception of SemEval-07, with a difference of 2.2 points on ALL. With respect to our own comparison systems, QBERT performs better than ELMo, Flair and SBERT in this setting as well. ELMo gets very competitive results compared to the previous state of the art, which it beats on many datasets. Compared to QBERT, however, it gets worse results on almost every dataset, with the single exception of SemEval-13. Flair underperforms also in this setting. SBERT achieves good performances, but still consistently lower than QBERT, except for SemEval-07, which is however a small dataset whose F1 scores show high variance across different training runs.

5.2 Word-in-Context

The Word-in-Context task (WiC) was recently established by Pilehvar and Camacho-Collados (2019). Like WSD, WiC requires identification of a contextually appropriate meaning, but it is framed as a simpler binary classification task: given two contextual occurrences of the same lemma, predict whether the pair shares the same sense. The dataset includes 8320 context pairs, divided between training and development (the test set has not yet been released). By including the same target word in each element of the pair, the dataset is constructed in such a way that context-insensitive word embeddings would not perform better than the random baseline. Thus, the dataset is an ideal evaluation set for assessing the quality of the semantic information encoded in contextualized embeddings.

5.2.1 Setup

Among the baselines offered by Pilehvar and Camacho-Collados (2019), one uses ELMo contextualized embeddings as input to a simple two-layer feed-forward classifier. We replicate the same setting, but using the concatenation of QBERT Encoder word and contextualized embeddings as input instead. Also, as the authors have not yet released the gold keys for the development set and evaluation can only be performed by uploading a prediction file to the Codalab competition page[7], we take $\frac{1}{10}$ of the training instances as our development set, and use the provided development set for testing. We train the system for a max of 40 epochs, submitting the epoch with best accuracy on the development split. WiC's scorer reports the accuracy calculated on the predictions. We implement the same system employing ELMo, Flair (using the concatenation of GloVe and contextualized embeddings) and SBERT as well. Performance is measured by mean accuracy over 5 runs.

5.2.2 Results

In Table 3 we show the results of the evaluation on the WiC development set.

System	Acc. μ	Acc. σ
Elmo (ours)	59.97	1.41
Flair	60.23	0.91
SBERT	60.03	1.13
QBERT	**60.74**	1.22

Table 3: Results of our ELMo, SBERT and QBERT models on the WiC dataset evaluation dataset. We report the mean and standard deviation of the accuracy for 5 runs.

In this setting ELMo performs on a par with SBERT and Flair, while QBERT achieves the best result. Note that the quasi-deeply bidirectional encoding that QBERT can exploit through the BiTransformer might see its effectiveness reduced in this setting since many pairs feature limited context, even as short as 2 or 3 words. Still, the results of the WiC task corroborate those of the all-words WSD, providing evidence that joint encoding is crucial to better performance in word-level semantics.

6 Conclusion

In this paper we showed that the use of contextualized embeddings enables a WSD system to beat the previous state of the art. Moreover, we demonstrated that the use of the BiTransformer coattentive mechanism in the QBERT contextualized embeddings model itself results in even stronger performance. As a result, we attain one of the largest gains in WSD performance in years, with a margin of 3 points over the best reported single model on the concatenation of all datasets, and of 2.2 points over the best ensemble model in the literature. We leave for future work the assessment of whether the gains brought about by the use of the BiTransformer in QBERT carry over to other tasks, helping to bridge the gap between CLM-based and fully bidirectional MLM-based contextualized embeddings. We release the code to train the QBERT Encoder and the WSD classifier, along with pretrained models at https://github.com/mbevila/qbert.

Abstract

In this work, we address the evaluation of distributional semantic models trained on smaller, domain-specific texts, particularly philosophical text. Specifically, we inspect the behaviour of models using a pre-trained background space in learning. We propose a measure of *consistency* which can be used as an evaluation metric when no in-domain gold-standard data is available. This measure simply computes the ability of a model to learn similar embeddings from different parts of some homogeneous data. We show that in spite of being a simple evaluation, consistency actually depends on various combinations of factors, including the nature of the data itself, the model used to train the semantic space, and the frequency of the learned terms, both in the background space and in the in-domain data of interest.

1 Introduction

Distributional semantic (DS) models (Turney and Pantel, 2010; Erk, 2012; Clark, 2015) typically require very large corpora to construct accurate meaning representations of words (Bengio et al., 2003). This big data methodology presents challenges when working with text in a specific domain or a low-resource language. In this paper, we are interested in modeling concepts in philosophical corpora, which are far smaller than a typical web corpus. Instead of training directly on the philosophical in-domain data, which is too sparse for learning, we rely on a pre-trained background semantic space, thus simulating a speaker with some linguistic knowledge coming to a new domain.

Our focus is the evaluation problem encountered when working with domain-specific data. DS models are typically evaluated on gold standard datasets containing word association scores elicited from human subjects (e.g. Bruni et al., 2014; Hill et al., 2015). Beside the limited practical use of such evaluation metrics (e.g. Gladkova and Drozd, 2016), this is not a feasible method for evaluating DS models in low-resource situations. When domain-specific terminology is used and the meaning of words possibly deviate from their most dominant sense, creating regular evaluation resources can require significant time investment from domain experts. Evaluation metrics that do not depend on such resources are valuable. Thus, we introduce the metric of **consistency**, which requires a model to learn similar word embeddings for a given term across similar sources, for example, two halves of a book.

Philosophical texts make a suitable case study for out-of-domain data, as words may have very different meanings in philosophy than in general usage. For example, while a *proposition* is synonymous for *offer* or *proposal* in ordinary language, in philosophy it is, among other things, a bearer of truth-value (McGrath and Frank, 2018). Furthermore, philosophical writing is often precise and terminology tends to be defined or at least discussed in the text, so there should be enough information for modeling meaning even when working with small data, for instance in one or multiple works by a particular philosopher or from a particular philosophical tradition. Last but not least, the field of philosophy could benefit from this type of modeling — although philosophers have not yet made broad use of computational methods (Betti et al., 2019), it has been shown that new insights can be obtained using an information retrieval tool based on a distributional semantic model of digitalized philosophical texts (Ginammi et al., in press).

Using philosophical data, we perform a battery of tests which reveal interesting properties of consistency. We show that in spite of being a simple evaluation, consistency actually depends on various combinations of factors, including the nature of the data itself, the model used to train the semantic space, and the frequency of the learned terms, both in the background space and in the in-domain data of interest. This leads us to conclude that the evaluation of in-domain word embeddings from small data has to be controlled extremely carefully in order not to draw incorrect conclusions from experimental results.

2 Related Work

Learning embeddings for rare words is a very challenging process (Luong et al., 2013). Word2Vec (W2V, Mikolov et al., 2013a)'s skipgram model can learn embeddings from tiny data after modification, as shown by Herbelot and Baroni (2017) when it consists of just a single highly informative definitional sentence. However, philosophical data is typically *small data* rather than tiny data. While tiny data consists of a single definitional sentence, our small data consists of multiple context sentences per term that are not necessarily definitional. Herbelot and Baroni's (2017) Nonce2Vec (N2V) has not been tested on this type of data. W2V has been tested on smaller datasets, but was found to be suboptimal (Asr et al., 2016) and surpassed by SVD models on a 1 million word dataset (Sahlgren and Lenci, 2016).

Different DS evaluations test different aspects of the learned embeddings (i.e. Wang et al., 2019). Most existing methods are however not easily applicable to our task. The typical evaluation of comparing embedding similarities to a gold standard of word similarity scores, such as the SimLex-999 dataset (Hill et al., 2015) cannot be applied, because we are interested in the representation of specific terms: even if these terms are present in the evaluation set, their meaning in the philosophical domain is likely to differ. Manually creating a domain-specific resource requires labor-intensive effort by domain experts, which makes it impractical to port standard datasets to a specific type of corpora. This holds also for other evaluation methods such as analogy scores (Mikolov et al., 2013b), as well as coherence (Schnabel et al., 2015), which is based on the idea that pairs of similar words should be close in semantic space.

Methods where human raters directly respond to output of the model, such as comparative intrinsic evaluation (Schnabel et al., 2015) are interesting, but require domain experts, as well as instructions that elicit the desired type of semantic relation (i.e. similarity). Extrinsic evaluation requires a downstream task that can be evaluated, but in this use case we are interested in the information encoded by the DS model itself. QVEC (Tsvetkov et al., 2015) evaluates by aligning dimensions of a semantic space to linguistic features, but we are interested only in evaluating some vectors rather than an entire space (target term vectors but not the background space vectors), and this approach requires language-specific resources.

Nooralahzadeh et al. (2018) evaluate domain-specific embeddings by building a query inventory for their domain from a glossary containing synonym, antonym and alternative form information. Unfortunately, such structured glossaries are generally not available for specific philosophers. Hellrich and Hahn (2016) test their models for reliability in a study investigating historical English and German texts, another relatively low-resource domain. Their reliability metric involves training three identically parametrized models, and comparing the nearest neighbors of each word in each model using a modified Jaccard coefficient. This metric does not require any language-specific data, but it mainly serves as a test of the impact of the sources of randomness in Word2Vec, and not as a measure of the systematic semantic differences across various data sources.

3 Consistency Metric

We propose **consistency** as a useful metric to evaluate word embeddings in the absence of domain-specific evaluation datasets. We consider a model to be consistent if its output does not vary when its input should not trigger variation (i.e. because it is sampled from the same text). Thus, a model can only be as consistent as the input data it is trained on and it requires the experimenter to compute data consistency in addition to vector space consistency.

To evaluate *data consistency*, we create vectors for target terms in a domain corpus under two conditions: a) random sampling; b) equal split. The 'equal split' condition simply corresponds to splitting the data in the middle, thus obtaining two subcorpora of equal size and in diachronic order. Given a pre-trained background space kept frozen across experiments, the vector representation of a target is generated by simple vector addition over its context words. Therefore, the obtained vector directly represents the context the target term occurs in, and consequently, similar representations (in terms of cosine similarity) mean that the target term is used in a similar way in different parts of a book/corpus, and is thus consistently learnable. Crucially, though, this measure may interact with data size. Kabbach et al. (2019) recently noted a *sum effect* in the additive model, where summed vectors are close to each other. It may be the case that additive model vectors summed over more context data contain more information and may have higher similarity between each other, resulting in higher consistency scores. We test this in Section 6. When randomly sampling, we limit the number of sentences per sample to control for this.

To evaluate *space consistency*, we create identically parametrized models as in Hellrich and Hahn's (2016) reliability metric, but over different parts of the data, with the data being split in the middle, as just described. We consider two ways of comparing two vectors $\vec{a_1}$ and $\vec{a_2}$: by similarity, where a higher cosine similarity indicates more consistency, or by nearest neighbor rank, where a higher rank of $\vec{a_1}$ among the nearest neighbors of $\vec{a_2}$ indicates more consistency. Every vector in the background space, as well as $\vec{a_2}$, is ranked by cosine similarity to $\vec{a_1}$ to compute this rank value.

Although it is more complex than having a single metric, we must consider both rank and similarity simultaneously: rank is a more relative metric and helps to ground the similarity value in the local context of the target term. A vector with 0.8 similarity but lower rank is a worse result than a vector with 0.8 similarity and a high rank, as the low rank means that the vectors are in a dense part of the semantic space and a very high similarity is required to consistently identify which of the neighbouring vectors refers to the same concept. Conversely, a low-similarity, high-rank vector can be a cause for scepticism, as it may have been placed far out from the rest of the semantic space.

We take consistency to be a desirable property of word embeddings at the level of a certain domain. Of course, consistency only measures one specific desirable property of embeddings and should thus not be interpreted as a general quality or accuracy score. But even taken on its own, we will show that it exhibits complex behavior with respect to data, background vectors and term frequency.

4 Task Description

Our overall aim is to obtain consistent embeddings of terms central to the works of Willard Van Orman Quine (1908-2000), an influential 20th century philosopher and logician. As the meaning of terms may differ between authors and even between books by the same author, we need to learn such embeddings from small data, bounded by the occurrences of the term in one particular book.

Quine datasets We build novel datasets based on a corpus of 228 philosophical articles, books and bundles written by Quine, with a focus om two of Quine's books: *A System of Logistic* (Quine, 1934) and *Word & Object* (Quine, 1960). These Quine texts are part of a larger corpus of philosophical texts, which is still being compiled, that are central to the history of scientific ideas (Betti and van den Berg, 2016). We focus on these particular works from the corpus because testing consistency is best done on homogeneous data, and our philosophy domain experts informed us that Quine was a remarkably stable philosopher in his outlook (Betti and Oortwijn, p.c.).

The first book is a formula-heavy logic book, deviating strongly from ordinary language. Such a technical book is particularly likely to be internally consistent. It contains 80,279 tokens after tokenization and manual replacement of formulas with special tokens. The second book is more textual and consists of standard philosophical argumentation. Our domain experts consider it conceptually consistent. It contains 133,240 tokens after tokenization. The full corpus of the 228 Quine articles contains 1.7 million tokens and is pre-processed with NLTK (Bird et al., 2009) for sentence splitting and tokenization. A less common preprocessing step we took was to remove one-character tokens from the texts. These works contain many one-letter variable names, logical symbols and other formal language that a model might otherwise use to position vectors of Quine terminology in particular areas of the semantic space, as these tokens are highly infrequent in the general domain.

To obtain terms that would be relevant to model, we automatically extract terms from the two books' indexes, as the most important terminology is likely to be listed there. We include multi-word terms, and divide the terms into 70%/30% subsets for training and testing, resulting in a 157 / 67 split for *Logistic* and a 184 / 79 split for *Word & Ob-*

ject. The target terms thus differ per book, as each book lists different terms in its index. Instead of this automatic approach to obtaining target terms, an expert-created resource could provide a better set of target terms, if available. If neither this nor a terms glossary or index of terms is available, keyword extraction methods could be used as an alternative way of obtaining terms for evaluation. In cases where the model will not be used for any analysis of domain-specific content downstream, it may be sufficient to randomly select words from the text as target terms.

Next, we derive datasets from this corpus using our two conditions for data consistency: random sampling and equal split. In *random sampling*, for each target term that meets a frequency cutoff of 10, we randomly select five non-overlapping samples of up to 10 random sentences that contain the target term, divided evenly across the samples if the term occurs in fewer than 50 sentences. This gives us the datasets *Quine-WordObject-rnd* (with Word & Object core terms as target terms), *Quine-Logistic-rnd* (with System of Logistic core terms) for our two books of interest, and *Quine-all-rnd* sampled from the full Quine corpus, where we also use the Word & Object core terms as target terms.[1] In the *equal split* condition, we divide a book into two halves at a chapter boundary, and extract all sentences containing index terms that meet a frequency cuf-off of 2 in each half, resulting in the datasets *Quine-WordObject* and *Quine-Logistic*. With random sampling, we intend to capture the basic consistency of the model. With equal split, we aim to capture consistency across potential meaning development throughout the book.[2]

Wikipedia dataset For cross-domain comparison, we apply our method to a 140M word preprocessed Wikipedia snapshot using the same random sampling process. As target terms, we used 300 randomly sampled one-word Wikipedia page titles, following Herbelot and Baroni (2017).

5 Method

Before evaluating whether we have *space consistency*, we must establish to what extent we have *data consistency*, following our argumentation in Section 3. To obtain an embedding for a new target term, we use an additive model over its context words, using as background space ordinary language representations. For the in-domain context, we use a window size of 15, with the window being restricted to the sentence. The background space is based on a Wikipedia snapshot of 1.6*B* words trained with Word2Vec's Gensim implementation with default parameters, and containing 259,376 word vectors in 100 dimensions. For each target term, context words undergo subsampling, which randomly drops higher-frequency words.[3] The vectors of the remaining context words are summed to create a vector for the target term. This additive model was used by Lazaridou et al. (2017) for their textual data, and was shown by Herbelot and Baroni (2017) to work reasonably well on tiny data. We calculate the vectors separately per sample (or book half), yielding comparable term vectors.

Next, we turn to *space consistency*. We use our consistency metric to evaluate two models that are suited to learning embeddings from small data: Nonce2Vec (Herbelot and Baroni, 2017) and an SVD-reduced count-based model over concatenations of our datasets with general-domain data.

The first model, Nonce2Vec, modifies W2V's 'skip-gram' model (Mikolov et al., 2013a) in a way that is inspired by *fast mapping* (Carey and Bartlett, 1978) in humans. Human learners can acquire new words from just a single token and this process of fast mapping appears to build on concepts that are already known (Coutanche and Thompson-Schill, 2014). Nonce2Vec models this through incremental learning, an initial high learning rate, greedy processing, and parameter decay. To simulate the existence of background knowledge, Nonce2Vec maps its novel word vectors into a previously learned semantic space, based on the aforementioned Wikipedia snapshot and the same subsampling procedure. Target term vectors are initialized to their sum vector from the additive model. For each sentence, the model is trained on the target term, only updating the weights for that term and freezing all other network parameters. The learning rate and context window size decay in proportion to the number of times the target term has been seen, and the subsampling rate increases per sentence.

Secondly, we try a count-based approach, creat-

[1] Word & Object touches upon much of Quine's work, so its terminology can be considered representative.

[2] While our datasets are derived from copyrighted works and cannot be shared, we provide replication instructions, term lists and code here: https://bloemj.github.io/quine2vec/

[3] Some promising alternative subsampling methods for tiny data were recently discussed by Kabbach et al. (2019).

Dataset	cos-sim	rank
Quine-WordObject	0.938	1
Quine-Logistic	0.907	22.4
Quine-WordObject-rnd	0.919	1
Quine-Logistic-rnd	0.935	1
Quine-all-rnd	0.953	1
Wiki-rnd	0.927	1.001

Table 1: Consistency metrics on different data sets using the additive model.

n	cos-sim
1	0.794
2	0.837
3	0.905
4	0.923
8	0.956
all	0.987

Table 2: Data consistency for the term *analytical hypotheses* in Word & Object when varying the number of sentences per sample n.

ing vectors over the general-domain and in-domain data at the same time. In this procedure, we concatenate a particular Quine dataset with a 140M word Wikipedia corpus sample, in which the Quine terms are marked with special tokens in order to be trained separately from the same term in the Wikipedia data. We create embeddings from this corpus, applying PPMI weighting and singular value decomposition (SVD) to reduce the models to 100 dimensions, to match the dimensionality of our other models and because factorized count models have been shown to work well on smaller datasets (Sahlgren and Lenci, 2016). We use the *Hyperwords* implementation of Levy et al. (2015), with a window size of 5, and other hyperparameters set to the default values.

In both the above approaches, we can then compute vector space consistency between different vectors learned for the same term over different splits of the data.

6 Consistency of Data

We start by applying the additive model to quantify data consistency on the different datasets described in Section 4. We compute average similarities and nearest neighbor ranks over the vectors of all target terms in a dataset. For the randomly sampled data sets, we have five vectors per term, one from each sample, and compute the metrics over all unique combinations of 2 vectors. For the equal split setting, we compare the term vectors summed over each half of the book.

The additive model produces highly consistent embeddings on the training data: for most terms, the vectors summed over each book half are each other's nearest neighbors in the background space. This trend is also observed for the test sets presented in Table 1, where we observe high consistency for the embeddings from both books.

Using the book halves of System of Logistic (*Quine-Logistic*) gives us a slightly lower data consistency score than random sampling from that book (*Quine-Logistic-rnd*), possibly because the meaning of a term may evolve from the first half to the second half of a book. This suggests some utility of the data consistency measure in quantifying meaning development throughout a text, as long as other factors are controlled for. We also see that the Wikipedia domain data (*Wiki-rnd*) is less consistent than the Quine domain data (*Quine-all-rnd*), which is to be expected as it contains more diverse text.

These results seem to indicate that the additive model provides consistent embeddings. This means that it must be possible to learn consistent embeddings from these datasets, at least up to the consistency values reported here, as the additive model directly represents the contexts that predictive models use for training.

As already mentioned, however, the factor of data size may interfere with consistency. We do observe in Table 1 that the consistency of data sampled across the full Quine corpus is higher. Although we limited our samples to 10 sentences per term, not every core Quine term is used frequently enough to have 5 samples with the maximum size of 10 sentences. Specifically, in the full Quine dataset, 68.6% of terms reach the maximum size, while in the Word & Object dataset, only 32.1% of terms reach it. In the Wiki set, this is 90.9%, showing that its lower consistency is not explained by limited data. To fully control for data size, we would need to use artificial data: if we control for the number of sentences, the number of words and the number of words subsampled still affect data size. As we are mainly interested in the quality of models on our own philosophical corpus, we leave this for future work.

Instead, we test the effect of data size by summing two vectors for the same term over varying numbers of sentences, and computing the consistency between them. Table 2 shows a clear effect of data size: vectors summed over more sentences have higher data consistency. This shows that data consistency should ideally be computed within the constraints of a particular data size, because vectors summed over more context are more informative and thus more consistent.

7 Consistent Spaces

Having established that our data is consistent even with fairly small samples, we proceed to use two small data approaches to place terms consistently in vector space. We start with Nonce2Vec (N2V), which uses the sum vectors from the additive model for initialization and trains only on that vector, as it does not update the vectors in the background space, only that of the target term.

For this experiment, we modified N2V in two ways. Firstly, it now takes multiple sets of input sentences per target term, one from each sample or book half, and trains each term on all sets separately, resulting in multiple term vectors, one over each sample. Secondly, we implemented the consistency metrics described in Section 3 for comparing the different sample vectors and analyzing their position in the background space.

Using N2V's default parameters, we obtain low consistency scores. While N2V was designed for learning from a dataset with one sentence per term, the terms in our dataset occur in more sentences. A likely consequence of this difference, having small data instead of tiny data, is that the default parameters may include a too high learning rate and N2V's parameter decay may be too fast. A learning rate that is too high can result in models with low stability. To adapt to small data, we tune N2V's parameters on the full Quine dataset with the training set of target terms. We performed a grid search following a parameter space containing different learning rates ($[0.1, 0.5, \mathbf{1}, 1.5]$), the number of negative samples ($[1, \mathbf{3}, 5]$), the subsampling rate ($[100, 3000, 5000, \mathbf{10000}, 20000]$), learning rate decay ($[30, \mathbf{70}, 100, 180]$), subsampling rate decay ($[1.0, 1.3, \mathbf{1.9}, 2.5]$) window decay ($[1, 3, \mathbf{5}]$), window size ($[\mathbf{15}]$). Bold values are the best performing values in Herbelot and Baroni (2017) or defaults of N2V. We obtain our best performance with a learning rate of 0.1, 5 negative samples, a learning rate decay of 30 and a subsampling decay factor of 2.5.

We obtain fairly consistent embeddings with these parameters on the test set, as shown in Table 3: the vectors learned from the two book halves in the *Quine-WordObject* and *Quine-Logistic* datasets are often each other's nearest neighbour, with average nearest neighbour ranks of 1.21 and 1.48, respectively. Surprisingly, although this model is initialized using Wikipedia background vectors, that domain (*Wiki-rnd*) fares the worst in terms of consistency, as it does in the additive model. In general, these vector space consistency scores are lower than the data consistency scores we saw before, so there is room for improvement.

Dataset	cos-sim	rank
Quine-WordObject	0.686	1.21
Quine-Logistic	0.748	1.48
Quine-WordObject-rnd	0.695	2.11
Quine-Logistic-rnd	0.743	1
Quine-all-rnd	0.717	1.59
Wiki-rnd	0.589	507.8

Table 3: Consistency metrics on different data sets for the Nonce2Vec-based models.

Dataset	cos-sim
Quine-WordObject-rnd	0.352
Quine-Logistic-rnd	0.436
Quine-all-rnd	0.440
Wiki-rnd	0.321

Table 4: Consistency on different data sets for the SVD models.

We therefore turn to our other approach that is not based on the additive model: the SVD models over the concatenation of in-domain and general-domain data. When concatenating the datasets, we have to ensure that the target terms in our random samples of in-domain data are trained separately from the same term in the general domain and in other samples. We therefore mark them with a different ID for each sample. As before, we compute cosine similarities between these target terms from different samples to measure consistency.

Table 4 shows that the resulting embeddings are not very consistent, with much lower average cosine similarities between the samples that does not reflect the consistency of the data, as indicated by the additive model in Table 1. The consistency of the SVD vectors is also lower than that of the Nonce2Vec vectors from the previous experiment.

One possible explanation for the difficulty that both of these models have in learning from our data is in the bridging of the domain gap between the

Group of terms	similarity
System of Logistic	0.323
Word & Object	0.366
Q-High-freq W-Low-freq	0.735
Q-Low-freq W-Low-freq	0.417
Q-Low-freq W-High-freq	0.109
Q-High-freq W-High-freq	0.078

Table 5: Average similarities between Quine vectors and Wiki vectors in our SVD model. Q = Quine, W = Wiki.

Wikipedia general-domain spaces and the Quine terminology. To quantify the difference between domains, we selected all sentences from the Quine corpus containing 35 target terms and concatenated them with our 140M word Wikipedia sample, as in the previous experiment. These terms were selected to be either high-frequent or low-frequent in the Quine domain and either high-frequent or low-frequent in the general domain. Again, the Quine terms were marked in order to be trained separately from the same term in the Wikipedia domain, and we created a SVD model. In this SVD model, we computed the cosine similarities between each Quine term and its Wikipedia counterpart, and take this to be a measure of domain difference.

Table 5 shows a clear effect of term frequency. We grouped all terms according to two factors: their frequency in the Quine book they were selected for (low, relative frequency[4] < 0.0005 or high, relative frequency > 0.001) and their frequency in the Wikipedia domain (low, RF < 0.000025 or high, RF > 0.00005).[5] We observe that infrequent terms with a dominant philosophical sense such as *stimulus* have more similar vectors in both domains despite their sparsity in both corpora. Generally, terms that are highly frequent in the Quine-domain but have low frequency in the Wikipedia domain are more similar between the two domains (*Q-High-freq W-Low-freq*). To a lesser extent, this is also true for terms that are low-frequent in both domains.

This result indicates that bridging the domain gap should be easier with these philosophical core terms than with frequent Wikipedia terms. The fact that our models are less consistent on Wikipedia data also indicates that the generality of this domain is more relevant than any specific differences with the Quine domain. It must therefore be possible to learn good representations from this data by using background knowledge from the Wikipedia domain, but the models we tested did not reach the level of consistency of the additive model.

Dataset	cos-sim	rank
Quine-WordObject-rnd	0.352	22,947
Quine-Logistic-rnd	0.353	24,513
Quine-all-rnd	0.382	17,262
Wiki-rnd	0.475	2,902

Table 6: Average similarities between learned in-domain term vectors and pretrained general-domain background vector on different data sets for the Nonce2Vec-based models.

For better or for worse, our models do move away from what is in the background space. In our Nonce2Vec experiment on the *Quine-all-rnd* dataset, we also measured the average cosine similarity and nearest neighbour rank of the pretrained Word2Vec term vector from the background space, compared to the vectors we learned for that same term from the in-domain data. These numbers, shown in Table 6, reveal that the model does not stay close to the pre-trained background vectors in order to achieve high consistency, which could be a risk if consistency was used as a learning signal in combination with an invariant initialization. Furthermore, the vectors learned from the Wiki data are closer to the pre-trained vectors than those learned from the Quine data. This is expected of a good model, as there is no domain gap to bridge when training with Wikipedia context sentences into a Wikipedia background space. This also means that the vector representations for terms as used by Quine become more distinct after training, as our philosophy domain experts would expect of a good meaning representation of these in-domain terms.

We must again note that consistency is not the only desirable property of word embeddings. Unfortunately, other properties are more difficult to evaluate on low-resource data. Without a domain-specific evaluation set, we can only explore issues with quality by examining nearest neighbors of vectors that our metric marks as perfectly consistent. We observe both in our results, illustrated by cherry-picked examples from the Nonce2Vec model on the *Quine-WordObject* dataset. Table 7 shows that the nearest neighbours for both book half vectors for the term *talking* (*Word & Object*) look bad. The vectors' nearest neighbours are some

[4] $\frac{F}{C}$ where F is the term frequency and C is the corpus size.

[5] Different thresholds are necessary for the larger corpus.

Term		$\vec{a_1}$ NNs	$\vec{a_2}$ NNs
talking	1	wrongfulness	axiomatically
	2	axiomatically	epiphenomenon
	3	particularized	impredicative
verbs	1	logophoric	logophoric
	2	deverbal	resumptive
	3	adpositions	countability
	4	uninflected	adverbials

Table 7: Qualitative examination of some nearest neighbours of target term vectors computed over book halves 1 and 2 of *Word & Object*.

apparently unrelated words yet they are closest to each other (similarity 0.751). We thus have high consistency, but not a good semantic representation. The word *verb* is an example that does work: all nearest neighbours from the background space are linguistic terms. The two *verbs* vectors are also closest to each other (similarity 0.625).

8 Conclusion

Our results show that it is possible to learn consistent embeddings from small data in the context of a low-resource domain, as such data provides consistent contexts to learn from. Applying an additive model that sums general-domain vectors from a pre-trained background space resulted in similar vectors for the same terms across different contexts from the same domain. The Nonce2Vec model also results in consistent embeddings that are closer to vectors of the same term trained on different context sentences than to vectors of other terms. The summed vectors from the additive model applied to our philosophical small data are highly discriminative, distinguishing the target terms from background terms almost perfectly.

Our results show the benefits of using consistency as an intrinsic evaluation metric for distributional semantic models, particularly for low-resource situations in which no gold standard similarity scores are available. While the metric may appear simple, it proved useful both for evaluating the homogeneity of a dataset and for evaluating the stability of vector spaces generated by a given model. Consistency turns out to depend on various combinations of factors, including the nature of the data itself, the model used to train the semantic space, and the frequency of the learned terms, both in the background space and in the in-domain data of interest.

For the specific purpose of modeling philosophical terminology, consistency helps us assess the quality of embeddings for philosophical terms, which may differ in meaning across a book or an author's work, and for which no gold standard evaluation sets are available. These embeddings can then be used to aid in the examination of large volumes of philosophical text (Ginammi et al., in press). Beyond our use case, the consistency metric is quite broadly applicable — a relevant background semantic space is necessary, but this can be constructed from out-of-domain data.

Like any metric, the consistency metric does not answer all of our questions about the quality of our embeddings. Although the additive model is more consistent than the others, both its dependence on data size and the not-always-great qualitative results show that exploring other models is worthwhile for small data. Further research is required to determine whether the representations produced by the additive model are useful for downstream tasks. Using the knowledge of domain experts in a structured evaluation task would be a good, though resource-intensive, next step. Our metric helps quantify the reliability of a model before investing more resources into evaluation.

Our observation that the consistency metric depends on a variety of other factors shows that consistency is a non-trivial aspect of the evaluation of distributional semantic models that should not be overlooked. In future work, we will apply the consistency metric to evaluate other models, and datasets from other domains.

Acknowledgments

We are grateful to Yvette Oortwijn and Arianna Betti for their input as Quine domain experts. We also thank them as well as Lisa Dondorp, Thijs Ossenkoppele and Maud van Lier for their work on the Quine in Context corpus. We thank Pia Sommerauer for help with the SVD setup, and the UvA e-Ideas group for their fruitful discussion of a draft of this paper. We also thank the anonymous reviewers for their time and valuable comments. This research was supported by VICI grant *e-Ideas* (277-20-007) awarded to Arianna Betti and VENI grant *Reading between the lines* 275-89-029 awarded to Antske Fokkens, both financed by the Dutch Research Council (NWO).

Cross-Domain Training for Goal-Oriented Conversational Agents

Alexandra Bodirlau, Stefania Budulan, Traian Rebedea

Abstract

Goal-Oriented Chatbots in fields such as customer support, providing specific information or general help with bookings or reservations, suffer from low performance partly due to the difficulty of obtaining large domain-specific annotated datasets. Given that the problem is closely related to the domain of the conversational agent and that data belonging to a specific domain is difficult to annotate, there have been some attempts at surpassing these challenges such as unsupervised pre-training or transfer learning between different domains. A more thorough analysis of the transfer learning mechanism is justified by the significant boost of the results demonstrated in the results section. We describe extensive experiments using transfer learning and warm-starting techniques with improvements of more than 5% in relative percentage of success rate in the majority of cases, and up to 10x faster convergence as opposed to training the system without them.

1 Introduction

Goal-Oriented Conversational Agents (GO Chatbots) are seeing increased use to help users to achieve predetermined goals, but they can handle only very simple tasks, such as playing songs, searching information, set alarms or reminders. Building a dialogue agent to fulfill complex tasks remains one of the fundamental challenges for the Natural Language Processing (NLP) community and Artificial Intelligence (AI) in general.

There are two dominant approaches for solving this problem. The first one relies on (fully) supervised learning, e.g. using sequence-to-sequence (Sutskever et al., 2014) models, encoding a user's utterance and its context to decode the answer provided by the chatbot. However, this method does not explicitly allow to locate and make use of specific information such as entity recognition (e.g. a person's workplace) and requires large amounts of data in order to flawlessly extract and process particular pieces of information relevant for the task at hand, usually a mandatory requirement for GO Chatbots.

The second category entails partitioning the dialog system into smaller subsystems, usually implemented and trained separately. An example of such a system (Li et al., 2017) consists of several components: Natural Language Understanding, Dialog Manager, and Natural Language Generation. The Dialog Manager is often implemented with the aid of reinforcement learning (RL) based techniques, for instance using Deep Q-Nets (DQN) (Mnih et al., 2015) and having the main goal of learning the policy on account of which the agent will be able to provide answers.

The first approach is used with more favourable outcomes in the case of open-domain dialogue systems (Serban et al., 2016) than in closed-domain dialogue systems (Peng et al., 2017), because it does not require a method to reward the accomplishment of the task. Instead, the success of the conversation resides in the engagement of the user, measured in the level of coherence and cohesion of the dialog. The second approach better fits learning tasks having less labeled data, where the validity of the answer can be determined through evaluating the task's completion (e.g. making a restaurant reservation). These RL-based dialogue systems have the ability to simulate conversations, thus exploring the unknown dialogue space efficiently.

Currently reduced performance of domain-specific conversational agents in fields such as customer support, providing certain information or general help with reservations etc., is partly due to the difficulty of obtaining large annotated datasets. With each new domain and each new conversation flow introduced by a new task, newly annotated data need to be fed into the system in order to assimilate them and later provide the best answer for different inputs. The efforts for selecting, categorising and annotating the data are substantial, no matter the previous experience or domain-knowledge. This paper analyses the possibility to alleviate the data annotation endeavor through the inter-domain transfer learning technique (Ilievski et al., 2018). Alongside with unsupervised pre-training and others, transfer learning has proven a significant contribution to deliver better results, but it has only been tested with datasets from a small number of domains. We experiment with larger datasets, wider scenarios and we offer a richer understanding of the method, premises and results for overcoming the lack of data.

In this paper, we provide a thorough study on the impact of transfer learning in goal-oriented chatbots, starting from the work presented by (Ilievski et al., 2018). They proposed the possibility to reuse the knowledge gained from a source domain to boost the training and testing performance of a machine learning chatbot model on a different target domain, as described in more detail in the following sections. They identify two cases:

- **domain overlap** - the source and target domains are different, but share a fraction of actions, and
- **domain extension** - the source domain is extended by the target domain.

In both cases, there are common actions that justify the transfer learning between domains instead of independently training models for each of them. This approach has two effects: (1) the success rate of the model obtained with transfer learning is significantly higher than that of the model trained without any prior knowledge, and (2) transfer learning can be an alternative or complementary to warm starting, which also requires labeled data.

The results presented by the aforementioned authors represent a significant improvement for GO Chatbots, but they are obtained with only three domains, with relatively small datasets: Movie Booking, Restaurant Booking, and Tourist Info. In order to train a model for a more complex domain such as customer support, the improvement has to be validated on multiple datasets from different domains. Also, because the cost of annotating data for such a domain is very high, transfer learning methods should be studied for possible improvements that increase the automation of domain-specific conversations with few data.

The rest of the paper is organized as follows. Section 2 presents the related work for Goal Oriented Chatbots. The model used in our experiments is detailed in Section 3 and the datasets in Section 4. The results of our experiments are described in detail and interpreted in Section 5. Finally, future improvements and conclusions are presented in Section 6.

2 Related Work

We have already classified the existing solutions used for building machine learning chatbots in two categories, based on the learning method: supervised learning and reinforcement learning. In this section, we are providing a more in depth analysis of these two alternatives.

Serban et al. (2016) propose a solution for non-goal-driven systems, which uses an encoder-decoder model and word embeddings to generate the response of the agent starting from the utterance of the user as input. The architecture is composed from two RNNs: one for the utterance level, which treats the dialogue as a sequence of utterances, and one at the word level, which processes an utterance as a sequence of words. This model is trained on movie scripts and the dialogues include the speech acts. A detail worth mentioning here is that the pre-training is performed on a large related, but non-dialogue, corpus. The consequence is that the model accomplishes slightly better results compared with an initialization with fixed word embeddings.

Another supervised learning model for chatbots is presented by (Wen et al., 2017). The architecture is significantly more complex, and is divided in several modules. The utterances received from the user are converted into two representations: a probability distribution over the slot-value pairs called the belief state, and an intent representation generated by an intent network. A database operator selects the most probable values in the belief state and makes a query to the database. A policy network takes as input the intent representation, database result, and belief state and returns a representation of the next system action. Finally, a generation network uses the action representation to generate a template sequence, which is filled with actual values from the database. This system is very similar to the one used in the current paper, but the former is trained in a supervised fashion and, therefore, it is possible to fail at finding a good policy due to the shortcomings in dialogue exploration. Firstly, the policy is learned by a network instead of using RL (our case) and, secondly, the $\epsilon - greedy$ policy used in our experiments ensures the exploration of unknown states, instead of relying entirely on seen training data and rigid choices.

A possible solution for the disadvantage of using supervised training in the model presented above is proposed by Su et al. (2016). The architecture is similar, but there is a difference in the policy network training: it receives the current state and predicts the next system action in a supervised fashion in the first phase, followed by a reinforcement learning phase. The purpose of the second phase is to improve the generalization capacity of the policy by a better exploration of the action space using reinforcement learning.

A step forward in solving complex tasks is done by Peng et al. (2017). They introduce a hierarchical deep reinforcement learning architecture for solving composite tasks for travel planning, that are a collection of subtasks such as: book air ticket, reserve hotel room, buy train ticket, etc. This type of tasks are a challenge for RL approaches because of the reward sparsity, the slot constraints between different subtasks and the agent's tendency to switch between different subtasks frequently when conversing with users, which leads to poor user experience. The dialogue manager consists of (1) a top-level dialogue policy that selects subtasks, (2) a low-level dialogue policy that selects the actions in a given subtask, and (3) a global state tracker that supervises the cross-subtask constraints.

Ilievski et al. (2018) use the transfer learning mechanism for chatbots employing neural models to reduce the amount of training data and speed up the learning process for new domains. This can be accomplished with the transfer of the parameters learned in a source domain to a target domain, which has some common actions with the former. In order to apply the transfer, it is necessary to have the same state distribution in both domains, therefore the bots trained on the source domain must be aware of the actions in the target domain. They obtain an improvement of 65% in success rate in the case of domain extension and 20% for domain overlap. This represents a noteworthy result and one of the reasons we chose to study this mechanism in more detail. Another reason is the faster learning resulted from the combination of transfer learning with warm start.

In a more recent paper, Wolf et al. (2019) present the improvement brought by transfer learning in generative tasks such as open-domain dialog generation. A Transformer model (Vaswani et al., 2017) is pre-trained on a large unlabeled dataset, followed by a fine-tuning step in which two loss functions are optimized: (1) a next-utterance classification loss, and (2) a language modeling loss. As a result, the model outperforms the existing systems by a significant margin obtaining 51% absolute improvement in perplexity on the validation dataset.

Given that many works successfully engage unsupervised learning in various manners, there still remains the question: how does unsupervised pre-training work? An answer is formulated by (Erhan et al., 2010) and a possible explanation is that the pre-training guides the learning towards basins of attraction of minima that support better generalization from the training dataset. Therefore, it acts like a regularizer for the supervised fine-tunning phase, when the parameters are restricted to a relatively small space. This assumption is reinforced by the results that show an effectiveness' upgrade of pre-training as the number of units per layer increases, a better generalization performance, but worse training errors, and worse performance than random initialization for small networks, all characteristics of regularization. They also show a growth in the probability of finding a local minima by increasing the depth of a network with random initialization, compared to an unsupervised pre-training.

The most important advantage of pre-training is the possibility of using unlabeled data, which is really helpful given the high costs of data annotation. Therefore, the effect of pre-training with very large datasets observed in the experiments is the most surprising result of the paper (Erhan et al., 2010): the early examples determine the basin of attraction for the remainder of the training and the supervised fine-tuning cannot escape from it. The hypothesis is that those examples induce changes in the magnitude of the weights, which decreases the number of regions accessible to the stochastic gradient descent procedure. This is why, in a large-scale setting, the influence of unsupervised pre-training is still present, in contrast to the classical regularizers, when the effect disappears with more data.

Nevertheless, fine-tuning large pre-trained models is parameter inefficient, because each task requires an entirely new model. A compact and extensible model is needed in order to solve this shortcoming. For this purpose, (Houlsby et al., 2019) introduce adapter-based tuning, which achieves a mean GLUE score of 80.0 on several text classification tasks, compared to 80.4 achieved by full fine-tuning, using 1.3 task-specific parameters in total, compared to 9. This method also facilitates continual learning (training on a sequence of tasks) and multi-task learning (training on simultaneous tasks).

3 Model

The system used in this paper is a *semantic frames* system (Li et al., 2017). It represents the dialogue as a set of slot-value pairs and at each step t, given the user utterance u_t, the agent takes an action a_t, which can be either the final result or a request for a value of an empty slot. The architecture consists of two parts: a **User Simulator** module and a **Dialogue Manager** module.

The purpose of the **User Simulator** is to interact with the Dialogue Manager in order to train a policy for an agent. First, a user goal is chosen randomly from the goals' pool and is unknown for the agent, but it tries to help the user to accomplish it during the dialogue. The goal consists of two types of slots:

- *inform slots* - represent the constraints imposed by the user, hence their values are known (e.g. {movie_name: ”deadpool”, city: ”Madison Heights”, date: ”saturday”, number_of_people: ”5”}).
- *request slots* - represent the values that the agent should provide, hence they enclose unknown values to the user (e.g. {price, start_time, critic_rating}).

Then, the user utterance u_t is generated following the **Agenda-Based** model (Li et al., 2016): the user has an internal state s_u composed of a goal G and an agenda A. The goal consists of constraints C and requests R. At each step t, the user simulator generates the user action $a_{u,t}$ based on the current state $s_{u,t}$ and the last agent action $a_{a,t}$ and updates the current state $s^{'}_{u,t}$.

Natural Language Generation (NLG) is the module that generates natural language text for the user dialogue actions. For better results, a hybrid approach is used, including a model-based NLG and a template-based NLG. The model-based NLG is an LSTM decoder, which takes a dialogue action as input and generates a sentence with slot placeholders. If the sentence can be found in the predefined templates, the template-based NLG is applied for filling the slots, otherwise, the utterance generated by the model-based NLG is used.

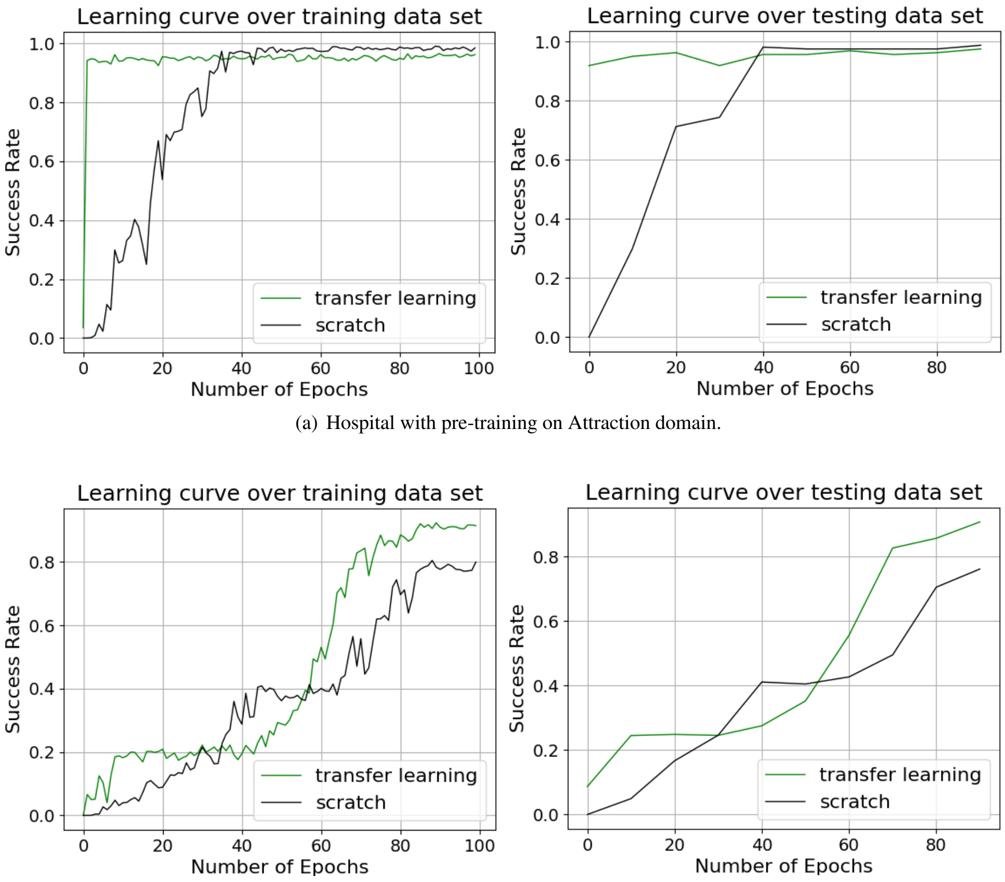
Natural Language Understanding (NLU) is the opposite to the NLG module: it takes as input an utterance and determines the user's *intent* and the set of *slots* associated with it (e.g. {movie_name: ”deadpool”, date: ”saturday”, number_of_people: ”5”}), in order to form a semantic frame. It is implemented with an LSTM and its objective is to maximize the conditional probability of the slots and the intent, given the utterance.

The **Dialogue Management (DM)** includes two submodules: **Dialogue State Tracker** and **Policy Learning** module. The goal of the **Dialogue State Tracker** is to build a representation of the current state for policy learning, using the semantic frame received from the NLU component. It keeps the history of the user utterances, system actions and the query results from the Knowledge Base.

Policy learning module generates the next action of the system a_t according to the policy $\pi = P(a|s)$, given the current state s_t, in order to accomplish the user goal in the smallest number of steps. The state s_t includes the latest user action, the latest agent action, turn information, history dialogue turns and the available database results. A DQN (Mnih et al., 2015) is used to approximate the state-action function $Q(s, a|\Theta)$ and contains the experience replay mechanism.

4 Dataset

In order to study the impact of transfer learning in multiple domains, we choose MultiWOZ



(a) Hospital with pre-training on Attraction domain.

(b) Taxi with pre-training on Train domain.

Figure 1: Small number of extra slots in target domain.

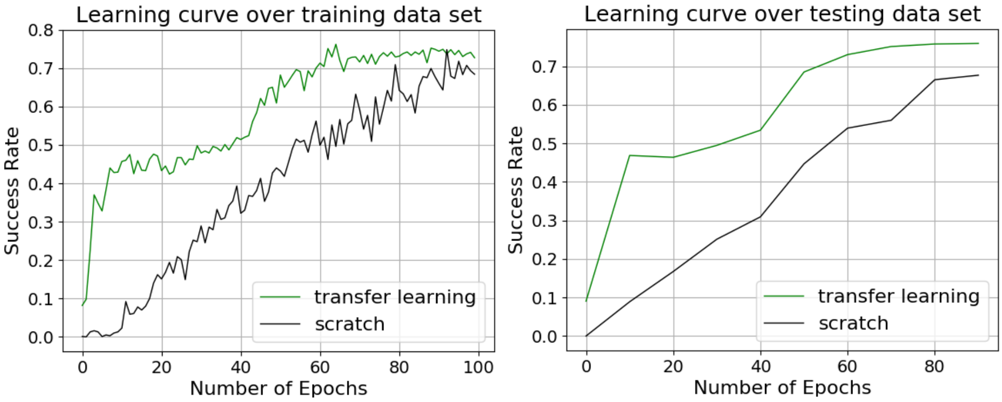
2.0 (Budzianowski et al., 2018), a large-scale multi-domain corpus of natural human-human conversations, collected through the Wizard-of-Oz framework (Kelley, 1984). It contains about 10000 samples from seven domains, with an average of turns per dialogue between 8.9 and 15, depending on the domain. From this dataset, we select the following five domains: **hotel**, **attraction**, **train**, **taxi**, **hospital**, and also keep **movie** and **tourist** domains used by Ilievski et al. (2018). These domains are grouped in source-target pairs according to their common slots, resulting five new opportunities for transfer learning. The total number of slots for source and target domains, respectively, as well as the amount of common slots is presented in Table1. We call *extra source/target slots* the difference between the total domain slots and the common ones.

The goals can be divided into two categories depending on whether they contain request slots or not. In the first case, the user sends a list of inform slots to the agent and the agent should accomplish the task respecting the constraints imposed by the user. In the second case, the user sends a list of request slots besides the list of inform slots, and the agent should accomplish the task and answer to the user's questions.

	Source Domain	Target Domain	Source Slots	Target Slots	Common Slots
1	movie	restaurant	6	9	3
2	restaurant	tourist	9	9	6
3	**hotel**	**attraction**	13	9	5
4	**train**	**taxi**	9	6	4
5	**movie**	**hotel**	17	13	5
6	**tourist**	**hotel**	9	13	6
7	**attraction**	**hospital**	9	4	3

Table 1: Number of slots per domain

This is a noteworthy detail, because it can influence the success rate through the experience accumulated in the warm start phase. In this phase, a fixed-size buffer is filled with experiences from positive-outcome conversations. Thus, the learning process gains a boost when having to self-calibrate based on an experience which will lead



(a) Attraction with pre-training on Hotel domain.

Figure 2: Medium number of extra slots in target domain.

to goal-achievement. We have noticed that the best results are obtained with warm start on no-request goals, following that the agent will manage to achieve request goals during training. As we increased the percentage of request goals in the warm start buffer, the overall success rate decreases and the learning curve becomes less smooth.

The total number of goals per domain is distributed as follows:

- 3000 training and 400 testing user goals in hotel, train and attraction;
- 2000 training and 200 testing user goals in taxi datasets;
- 80 training and 15 testing user goals in hospital dataset.

5 Experiments

The experiments are executed on overlapping domains, with the setup from (Ilievski et al., 2018) and running each experiment 10 times, with $n_{epochs} = 100$ epochs. The second set of experiments mimic testing on extension domain by restricting the slots in the source domain to the common ones. The warm start technique with experience replay buffer is used for both *transfer learning* and *scratch* agent (the same version, but without transfer learning), and the experience buffer is flushed when the agent reaches, for the first time, a success rate of 0.3. We also keep the maximal number of allowed turns per dialogue $n_{max\_turns} = 20$ in most experiments, except in the case of attraction domain with pre-training on hotel. In this situation, the number of turns is too small compared with the number of slots from the hotel domain, and the agent trained on the source domain is not able to learn. Consequently, we increased n_{max_turns} to 40 turns.

5.1 Different Domains

The first set of experiments aims to analyze the convergence for the agent with and without transfer learning on new domains. We group the experiments in three categories, according to the number of extra slots in the target domain, as follows: 1. small number of extra slots (less than 2 slots); 2. medium number of extra slots (between 3 and 6 slots); and 3. big number of extra slots (greater than 6 slots). We are interested in the improvement transfer learning brings to the success rate and the convergence pace.

Figure 1 presents the learning curve for the target domains with a small number of extra slots. For hospital domain with pre-training on attraction, both agents converge to a success rate greater than 95%, but the agent with transfer learning converges in a few epochs (<5), while the scratch agent needs 40 epochs to reach similar accuracy values. In the case of taxi domain with pre-training on train domain, the improvement of transfer learning is 15% for train dataset and 19% for test dataset. In absolute terms, the success rate increases from 80% to 91% for train dataset and from 76% to 91% on test dataset.

For the attraction domain with pre-training on hotel, presented in Figure 2, the model obtained with transfer learning has a success rate 7% higher than that of the scratch model on train dataset. This denotes an increase from 68% to 73% in absolute terms. For test dataset, transfer learning improves the success rate from 68% to 76% or with 12% in relative terms.

The last category registers the lowest overall success rate for both agents and we consider that these results stem from the large number of extra slots in the target domain. The learning curves are illustrated in Figure 3 and the success rate is similar for train and test datasets. Hotel domain with pre-training on movie has a success rate of 27% with transfer learning and 8.5% without transfer learning, with an improvement of 217%. While the same domain with tourist as source domain of transfer learning, registers a relative boost of 737%, from 4.3% to 36%.

5.2 Same Domains, Different Number of Slots

The second set of experiments targets the evolution of the success rate according to the number of extra slots, both in the source and target domain. The selected experiment evaluates the hotel domain with pre-training on tourist dataset, given they each have large number of slots with few common ones (see Table1). We keep the setup for the other parameters and only change the number of extra slots in one domain, while the other remains constant.

	Source Slots	Target Slots	Scratch Score	TL Score	Scratch Epochs	TL Epochs
1	6	6	0.81	0.88	100	40
2	7	6	0.81	0.86	100	70
3	8	6	0.81	0.84	100	70
4	9	6	0.77	0.83	100	50
5	6	9	0.55	0.72	100	100
6	7	9	0.57	0.63	100	100
7	8	9	0.54	0.70	80	100
8	9	9	0.56	0.70	100	100

Table 2: Source Slots number influence

The final success rate on the test dataset for constant slots in target domain is summarized in Table 2. When the target contains only the common slots, we observe a decrease of the success rate with less than 2% with each extra slot added in the source domain, for the model trained with transfer learning. However, it is still by 6.6% greater than the success rate of the agent trained with any other prior knowledge. An interesting fact is that the same test with the common slots plus three extra slots in target domain has the effect of diminishing the success rate by an average of 15% compared with the previous situation. At the same time, the improvement over the scratch agent is equal to 24%.

	Source Slots	Target Slots	Scratch Score	TL Score	Scratch Epochs	TL Epochs
1	6	6	0.81	0.88	100	40
2	6	7	0.75	0.85	90	40
3	6	8	0.63	0.79	70	100
4	6	9	0.55	0.72	100	100
5	6	10	0.53	0.59	100	100
6	6	11	0.09	0.52	100	90
7	6	12	0.01	0.44	90	100
8	6	13	0.0	0.39	10	100
9	9	6	0.77	0.83	100	50
10	9	7	0.71	0.82	90	100
11	9	8	0.65	0.76	100	100
12	9	9	0.56	0.70	100	100
13	9	10	0.54	0.59	100	100
14	9	11	0.11	0.52	100	100
15	9	12	0.04	0.42	90	100
16	9	13	0.04	0.36	100	60

Table 3: Target Slots number influence

As expected, the number of extra slots in target domain has a bigger influence over the final results. Therefore, the relative average decrease of the success rate for the agent with transfer learning is 9.5% for each extra slot, while the source domain contains only common slots. Another three slots added to the source dataset generates an average decrease of 3.6%, relative to the previous test. In comparison with the scratch agent, the improvement increases from 79% in the first case, to 274% in the latter.

6 Conclusions

In this paper, we study the factors that influence the success of transfer learning approach in Reinforcement Learning-based Goal-Oriented Chatbots and demonstrate the results on five new cases of overlapping domains. We found that a big number of different slots between the source domain and the target domain leads to a smaller success rate. Even so, the transfer learning mechanism brings a betterment of over 79% over the agent trained with no prior knowledge.

The outcomes encourage the use of transfer learning with warm start on various cases of overlapping and extending source and target domains. However, the optimal selection in terms of hyperparameters of the system, such as the number of epochs or the number of maximum turns in a conversation, need to be determined for each particular scenario. They are, after all, directly influenced by the amount of data and its characteristics: number of slots, types and distribution of goals, and the degree of overlapping between source and target slots.

Further work involves developing wider experiment scenarios for hierarchical deep reinforce-

(b) Hotel with pre-training on Tourist domain.

Figure 3: Big number of extra slots in target domain.

ment learning system and introducing the transfer learning approach into this architecture when the sub-tasks share slots. Moreover, we can imagine other transfer learning setups such as sharing subtasks as the learnt common part, instead of slots, from one composite task to another. All these attempts have the objective of gaining more context information and better performance with less annotated data, which is onerous to obtain.

Abstract

We present a novel and effective technique for performing text coherence tasks while facilitating deeper insights into the data. Despite obtaining ever-increasing task performance, modern deep-learning approaches to NLP tasks often only provide users with the final network decision and no additional understanding of the data. In this work, we show that a new type of sentence embedding learned through self-supervision can be applied effectively to text coherence tasks while serving as a window through which deeper understanding of the data can be obtained. To produce these sentence embeddings, we train a recurrent neural network to take individual sentences and predict their location in a document in the form of a distribution over locations. We demonstrate that these embeddings, combined with simple visual heuristics, can be used to achieve performance competitive with state-of-the-art on multiple text coherence tasks, outperforming more complex and specialized approaches. Additionally, we demonstrate that these embeddings can provide insights useful to writers for improving writing quality and informing document structuring, and assisting readers in summarizing and locating information.

1 Introduction

A goal of much of NLP research is to create tools that not only assist in completing tasks, but help gain insights into the text being analyzed. This is especially true of text coherence tasks, as users are likely to wonder where efforts should be focused to improve writing or understand how text should be reorganized for improved coherence. By improving coherence, a text becomes easier to read and understand (Lapata and Barzilay, 2005), and in this work we particularly focus on measuring coherence in terms of sentence ordering.

Figure 1: This paper abstract is analyzed by our sentence position model trained on academic abstracts. The sentence encodings (predicted position distributions) are shown below each sentence, where white is low probability and red is high. Position quantiles are ordered from left to right. The first sentence, for example, is typical of the first sentence of abstracts as reflected in the high first-quantile value. For two text coherence tasks, we show the how the sentence encodings can easily be used to solve them. The black dots indicate the weighted average predicted position for each sentence.

Many recent approaches to NLP tasks make use of end-to-end neural approaches which exhibit ever-increasing performance, but provide little value to end-users beyond a classification or regression value (Gong et al., 2016; Logeswaran et al., 2018; Cui et al., 2018). This leaves open the question of whether we can achieve good performance on NLP tasks while simultaneously providing users with easily obtainable insights into the data. This is precisely what the work in this paper aims to do in the context of coherence analysis, by providing a tool with which users can quickly and visually gain insight into structural information about a text. To accomplish this, we rely on the surprising importance of sentence location in many areas of natural language processing. If a sentence does not appear to belong where it is located, it decreases the coherence and readability of the text (Lapata and Barzilay, 2005). If a sentence is located at the beginning of a document or news article, it is very likely to be a part of a high quality extractive summary (See et al., 2017). The location of a sentence in a scientific abstract is also an informative indicator of its rhetorical purpose (Teufel et al., 1999). It thus follows that the knowledge of where a sentence should be located in a text is valuable.

Tasks requiring knowledge of sentence position – both relative to neighboring sentences and globally – appear in text coherence modelling, with two important tasks being order discrimination (is a sequence of sentences in the correct order?) and sentence ordering (re-order a set of unordered sentences). Traditional methods in this area make use of manual feature engineering and established theory behind coherence (Lapata and Barzilay, 2005; Barzilay and Lapata, 2008; Grosz et al., 1995). Modern deep-learning based approaches to these tasks tend to revolve around taking raw words and directly predicting local (Li and Hovy, 2014; Chen et al., 2016) or global (Cui et al., 2017; Li and Jurafsky, 2017) coherence scores or directly output a coherent sentence ordering (Gong et al., 2016; Logeswaran et al., 2018; Cui et al., 2018). While new deep-learning based approaches in text coherence continue to achieve ever-increasing performance, their value in real-world applications is undermined by the lack of actionable insights made available to users.

In this paper, we introduce a self-supervised approach for learning sentence embeddings which can be used effectively for text coherence tasks (Section 3) while also facilitating deeper understanding of the data (Section 4). Figure 1 provides a taste of this, displaying the sentence embeddings for the abstract of this paper. The self-supervision task we employ is that of predicting the location of a sentence in a document given only the raw text. By training a neural network on this task, it is forced to learn how the location of a sentence in a structured text is related to its syntax and semantics. As a neural model, we use a bidirectional recurrent neural network, and train it to take sentences and predict a discrete distribution over possible locations in the source text. We demonstrate the effectiveness of predicted position distributions as an accurate way to assess document coherence by performing order discrimination and sentence reordering of scientific abstracts. We also demonstrate a few types of insights that these embeddings make available to users that the predicted location of a sentence in a news article can be used to formulate an effective heuristic for extractive document summarization – outperforming existing heuristic methods.

The primary contributions of this work are thus:

1. We propose a novel self-supervised approach to learn sentence embeddings which works by learning to map sentences to a distribution over positions in a document (Section 2.2).

2. We describe how these sentence embeddings can be applied to established coherence tasks using simple algorithms amenable to visual approximation (Section 2.3).

3. We demonstrate that these embeddings are competitive at solving text coherence tasks (Section 3) while quickly providing access to further insights into texts (Section 4).

2 Predicted Position Distributions

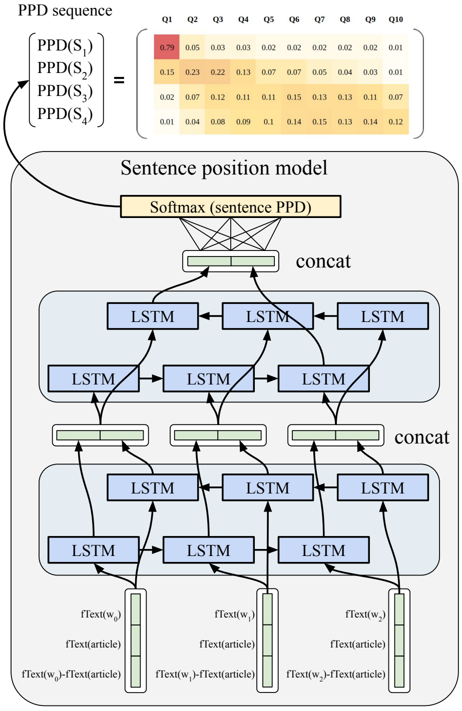
2.1 Overview

By training a machine learning model to predict the location of a sentence in a body of text (conditioned upon features not trivially indicative of position), we obtain a sentence position model such that sentences predicted to be at a particular location possess properties typical of sentences found at that position. For example, if a sentence is predicted to be at the beginning of a news article, it should resemble an introductory sentence.

In the remainder of this section we describe our neural sentence position model and then discuss how it can be applied to text coherence tasks.

2.2 Neural Position Model

The purpose of the position model is to produce sentence embeddings by predicting the position in



Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8	Q9	Q10
0.79	0.05	0.03	0.03	0.02	0.02	0.02	0.02	0.02	0.01

Figure 2: Illustration of the sentence position model, consisting of stacked BiLSTMs. Sentences from a text are individually fed into the model to produce a PPD sequence. In this diagram we see a word sequence of length three fed into the model, which will output a single row in the PPD sequence.

a text of a given sentence. Training this model requires no manual labeling, needing only samples of text from the target domain. By discovering patterns in this data, the model produces sentence embeddings suitable for a variety of coherence-related NLP tasks.

2.2.1 Model Architecture

To implement the position model, we use stacked bi-directional LSTMs (Schuster and Paliwal, 1997) followed by a softmax output layer. Instead of predicting a single continuous value for the position of a sentence as the fraction of the way through a document, we frame sentence position prediction as a classification problem.

Framing the position prediction task as classification was initially motivated by the poor performance of regression models; since the task of position prediction is quite difficult, we observed that regression models would consistently make predictions very close to 0.5 (middle of the document), thus not providing much useful information. To convert the task to a classification problem, we aim to determine what quantile of the document a sentence resides in. Notationally, we will refer to the number of quantiles as Q. We can interpret the class probabilities behind a prediction as a discrete distribution over positions for a sentence, providing us with a predicted position distribution (PPD). When $Q = 2$ for example, we are predicting whether a sentence is in the first or last half of a document. When $Q = 4$, we are predicting which quarter of the document it is in. In Figure 2 is a visualization of the neural architecture which produces PPDs of $Q = 10$.

2.2.2 Features Used

The sentence position model receives an input sentence as a sequence of word encodings and outputs a single vector of dimension Q. Sentences are fed into the BiLSTM one at a time as a sequence of word encodings, where the encoding for each word consists of the concatenation of: (1) a pretrained word embedding, (2) the average of the pretrained word embedding for the entire document (which is constant for all words in a document), and (3) the difference of the first two components (although this information is learnable given the first two components, we found during early experimentation that it confers a small performance improvement). In addition to our own observations, the document-wide average component was also shown in (Logeswaran et al., 2018) to improve performance at sentence ordering, a task similar to sentence location prediction. For the pretrained word embeddings, we use 300 dimensional fastText embeddings[1], shown to have excellent cross-task performance (Joulin et al., 2016). In Figure 2, the notation $ftxt(token)$ represents converting a textual token (word or document) to its fastText embedding. The embedding for a document is the average of the embeddings for all words in it.

The features composing the sentence embeddings fed into the position model must be chosen carefully so that the order of the sentences does not directly affect the embeddings (i.e. the sentence embeddings should be the same whether the sentence ordering is permuted or not). This is because we want the predicted sentence positions to be independent of the true sentence position, and not every sentence embedding technique provides

[1] Available online at `https://fasttext.cc/docs/en/english-vectors.html`. We used the `wiki-news-300d-1M` vectors.

this. As a simple example, if we include the true location of a sentence in a text as a feature when training the position model, then instead of learning the connection between sentence meaning and position, the mapping would trivially exploit the known sentence position to perfectly predict the sentence quantile position. This would not allow us to observe where the sentence *seems* it should be located.

2.3 Application to Coherence Tasks

For the tasks of both sentence ordering and calculating coherence, PPDs can be combined with simple visually intuitive heuristics, as demonstrated in Figure 3.

Figure 3: A visualization of our NLP algorithms utilizing PPDs applied to a news article. To reorder sentences, we calculate average weighted positions (identified with black circles) to induce an ordering. Coherence is calculated with the Kendall's rank correlation coefficient between the true and induced ranking. We also show how PPDs can be used to perform summarization, as we will explore further in Section 4.

2.3.1 Sentence Ordering

To induce a new ordering on a sequence of sentences, S, we simply sort the sentence by their weighted average predicted quantile, $\hat{\mathcal{Q}}(s \in S)$, defined by:

$$\hat{\mathcal{Q}}(s) = \sum_{i=1}^{Q} i \times PPD(s)_i, \tag{1}$$

where $PPD(s)$ is the Q-dimensional predicted position distribution/sentence embedding for the sentence s.

2.3.2 Calculating coherence

To calculate the coherence of a text, we employ the following simple algorithm on top of the PPDs: use the Kendall's tau coefficient between the sentence ordering induced by the weighted average predicted sentence positions and the true sentence positions:

$$coh = \tau((\hat{\mathcal{Q}}(s), \text{ for } s = S_1, ..., S_{|S|}), (1, ..., |S|)). \tag{2}$$

3 Experiments

In this section, we evaluate our PPD-based approaches on two coherence tasks and demonstrate that only minimal performance is given up by our approach to providing more insightful sentence embeddings.

Task	Dataset	Q	Epochs	Layer dropouts	Layer widths
Order Discrim.	Accident	5	10	(0.4, 0.2)	(256, 256)
	Earthquake	10	5	(0.4, 0.2)	(256, 64)
Reordering	NeurIPS	15	20	(0.5, 0.25)	(256, 256)

Table 1: The neural sentence position model hyperparameters used in our coherence experiments. The following settings are used across all tasks: batch size of 32, sentence trimming/padding to a length of 25 words, the vocabulary is set to the 1000 most frequent words in the associated training set. The Adamax optimizer is used (Kingma and Ba, 2014) with default parameters supplied by Keras (Chollet et al., 2015).

Order discrimination setup. For order discrimination, we use the Accidents and Earthquakes datasets from (Barzilay and Lapata, 2008) which consists of aviation accident reports and news articles related to earthquakes respectively. The task is to determine which of a permuted

	Order discrimination		Reordering	
Model	**Accident**	**Earthquake**	**Acc**	τ
Random	50	50	15.6	0
Entiry Grid	90.4	87.2	20.1	0.09
Window network	-	-	41.7	0.59
LSTM_PtrNet	93.7	99.5	50.9	0.67
RNN Decoder	-	-	48.2	0.67
Varient-LSTM+PtrNet	94.4	99.7	51.6	**0.72**
ATTOrderNet	**96.2**	**99.8**	**56.1**	**0.72**
PPDs	94.4	99.3	54.9	**0.72**

Table 2: Results on the order discrimination and sentence reordering coherence tasks. Our approach trades only a small decrease in performance for improved utility of the sentence embeddings over other approaches, achieving close to or the same as the state-of-the-art.

ordering of the sentences and the original ordering is the most coherent (in the original order), for twenty such permutations. Since these datasets only contain training and testing partitions, we follow (Li and Hovy, 2014) and perform 10-fold cross-validation for hyperparameter tuning. Performance is measured with the accuracy with which the permuted sentences are identified. For example, the Entity Grid baseline in Table 2 gets 90.4% accuracy because given a shuffled report and original report, it correctly classifies them 90.4% of the time.

Sentence ordering setup. For sentence ordering, we use past NeurIPS abstracts to compare with previous works. While our validation and test partitions are nearly identical to those from (Logeswaran et al., 2018), we use a publicly available dataset[2] which is missing the years 2005, 2006, and 2007 from the training set ((Logeswaran et al., 2018) collected data from 2005 - 2013). Abstracts from 2014 are used for validation, and 2015 is used for testing. To measure performance, we report both reordered sentence position accuracy as well as Kendall's rank correlation coefficient. For example, the Random baseline correctly predicts the index of sentences 15.6% of the time, but there is no correlation between the predicted ordering and true ordering, so $\tau = 0$.

Training and tuning. Hyperparameter tuning for both tasks is done with a random search, choosing the hyperparameter set with the best validation score averaged across the 10 folds for order discrimination dataset and for three trials for the sentence reordering task. The final hyperparameters chosen are in Table 1.

Baselines. We compare our results against a random baseline, the traditional Entity Grid approach from (Barzilay and Lapata, 2008), Window network (Li and Hovy, 2014), LSTM+PtrNet (Gong et al., 2016), RNN Decoder and Varient-LSTM+PtrNet from (Logeswaran et al., 2018), and the most recent state-of-the art ATTOrderNet (Cui et al., 2018).

Results. Results for both coherence tasks are collected in Table 2. For the order discrimination task, we find that on both datasets, our PPD-based approach only slightly underperforms ATTOrderNet (Cui et al., 2018), with performance similar to the LSTM+PtrNet approaches (Gong et al., 2016; Logeswaran et al., 2018). On the more difficult sentence reordering task, our approach exhibits performance closer to the state-of-the-art, achieving the same ranking correlation and only slightly lower positional accuracy. Given that the publicly available training set for the reordering task is slightly smaller than that used in previous work, it is possible that more data would allow our approach to achieve even better performance. In the next section we will discuss the real-world value offered by our approach that is largely missing from existing approaches.

4 Actionable Insights

A primary benefit of applying PPDs to coherence-related tasks is the ability to gain deeper insights into the data. In this section, we will demon-

Figure 4: The PPDs for a CNN article. (full text available at http://web.archive.org/web/20150801040019id_/http://www.cnn.com/2015/03/13/us/tulane-bacteria-exposure/). The dashed line shows the weighted average predicted sentence positions.

strate the following in particular: (1) how PPDs can quickly be used to understand how the coherence of a text may be improved, (2) how the existence of multiple coherence subsections may be identified, and (3) how PPDs can allow users to locate specific types of information without reading a single word, a specific case of which is extractive summarization. For demonstrations, we will use the news article presented in Figure 4.

4.1 Improving Coherence

For a writer to improve their work, understanding the incoherence present is important. Observing the PPD sequence for the article in Figure 4 makes it easy to spot areas of potential incoherence: they occur where consecutive PPDs are significantly different (from sentences 1 to 2, 6 to 7, and 10 to 11). In this case, the writer may determine that sentence 2 is perhaps not as introductory as it should be. The predicted incoherence between sentences 10 and 11 is more interesting, and as we will see next, the writer may realize that this incoherence may be okay to retain.

4.2 Identifying Subsections

In Figure 4, we see rough progressions of introductory-type sentences to conclusory-type sentences between sentences 1 and 10 and sentences 11 and 15. This may indicate that the article is actually composed of two coherent subsections, which means that the incoherence between sentences 10 and 11 is expected and natural. By being able to understand where subsections may occur in a document, a writer can make informed decisions on where to split a long text into more coherent chunks or paragraphs. Knowing where approximate borders between ideas in a document exist may also help readers skim the document to find desired information more quickly, as further discussed in the next subsection.

4.3 Locating Information and Summarization

When reading a new article, readers well-versed in the subject of the article may want to skip high-level introductory comments and jump straight to the details. For those unfamiliar with the content or triaging many articles, this introductory information is important to determine the subject matter. Using PPDs, locating these types of information quickly should be easy for readers, even when the document has multiple potential subsections. In Figure 4, sentences 1 and 11 likely contain introductory information (since the probability of occurring in the first quantiles is highest), the most conclusory-type information is in sentence 10, and lower-level details are likely spread among the remaining sentences.

Locating sentences with the high-level details of a document is reminiscent of the task of extractive summarization, where significant research has been performed (Nenkova et al., 2011; Nenkova and McKeown, 2012). It is thus natural to ask how well a simple PPD-based approach performs

Model (lead baseline source)	ROUGE-1	ROUGE-2	ROUGE-L
Lead-3 (Nallapati et al., 2017)	39.2	15.7	35.5

Table 3: ROUGE scores on the CNN/DailyMail summarization task. Our PPD-based heuristic outperforms the suite of established heuristic summarizers. However, the higher performance of the deep-learning models demonstrates that training explicitly for summarization is beneficial.

at summarization. To answer this question, the summarization algorithm we will use is: select the n sentences with the highest $PPD(s \in S)_0$ value, where S is the article being extractively summarized down to n sentences. For the article in Figure 4, sentences 1, 11, and 3 would be chosen since they have the highest first-quantile probabilities. This heuristic is conceptually similar to the Lead heuristic, where sentences that actually occur at the start of the document are chosen to be in the summary. Despite its simplicity, the Lead heuristic often achieves near state-of-the-art results (See et al., 2017).

We experiment on the non-anonymized CNN/DailyMail dataset (Hermann et al., 2015) and evaluate with full-length ROUGE-1, -2, and -L F1 scores (Lin and Hovy, 2003). For the neural position model, we choose four promising sets of hyperparameters identified during the hyperparameter search for the sentence ordering task in Section 3 and train each sentence position model on 10K of the 277K training articles (which provides our sentence position model with over 270K sentences to train on). Test results are reported for the model with the highest validation score. The final hyperparameters chosen for this sentence location model are: Q = 10, epochs = 10, layer dropouts = (0.4, 0.2), layer widths = (512, 64).

We compare our PPD-based approach to other heuristic approaches[3]. For completeness, we also include results of deep-learning based approaches and their associated Lead baselines evaluated using full-length ROUGE scores on the non-anonymized CNN/DailyMail dataset.

Table 3 contains the the comparison between our PPD-based summarizer and several established heuristic summarizers. We observe that our model has ROUGE scores superior to the other heuristic approaches by a margin of approximately 2 points for ROUGE-1 and -L and 1 point for ROUGE-2. In contrast, the deep-learning approaches trained explicitly for summarization achieve even higher scores, suggesting that there is more to a good summary than the sentences simply being introductory-like.

5 Related Work

Extensive research has been done on text coherence, motivated by downstream utility of coherence models. In addition to the applications we demonstrate in Section 4, established applications include determining the readability of a text (coherent texts are easier to read) (Barzilay and Lapata, 2008), refinement of multi-document summaries (Barzilay and Elhadad, 2002), and essay scoring (Farag et al., 2018).

Traditional methods to coherence modelling utilize established theory and handcrafted linguistic features (Grosz et al., 1995; Lapata, 2003). The Entity Grid model (Lapata and Barzilay, 2005; Barzilay and Lapata, 2008) is an influential traditional approach which works by first constructing a sentence × discourse entities (noun phrases) occurrence matrix, keeping track of the syntactic role of each entity in each sentence. Sentence transition probabilities are then calculated using this representation and used as a feature vector as in-

[3] Implementations provided by Sumy library, available at https://pypi.python.org/pypi/sumy.

put to a SVM classifier trained to rank sentences on coherence.

Newer methods utilizing neural networks and deep learning can be grouped together by whether they indirectly or directly produce an ordering given an unordered set of sentences.

Indirect ordering. Approaches in the indirect case include Window network (Li and Hovy, 2014), Pairwise Ranking Model (Chen et al., 2016), the deep coherence model from (Cui et al., 2017), and the discriminative model from (Li and Jurafsky, 2017). These approaches are trained to take a set of sentences (anywhere from two (Chen et al., 2016) or three (Li and Hovy, 2014) to the whole text (Cui et al., 2017; Li and Jurafsky, 2017)) and predict whether the component sentences are already in a coherent order. A final ordering of sentences is constructed by maximizing coherence of sentence subsequences.

Direct ordering. Approaches in the direct case include (Gong et al., 2016; Logeswaran et al., 2018; Cui et al., 2018). These model are trained to take a set of sentences, encode them using some technique, and with a recurrent neural network decoder, output the order in which the sentences would coherently occur.

Models in these two groups all use similar high-level architectures: a recurrent or convolutional sentence encoder, an optional paragraph encoder, and then either predicting coherence from that encoding or iteratively reconstructing the ordering of the sentences. The PPD-based approaches described in Section 2 take a novel route of directly predicting location information of each sentence. Our approaches are thus similar to the direct approaches in that position information is directly obtained (here, in the PPDs), however the position information produced by our model is much more rich than simply the index of the sentence in the new ordering. With the set of indirect ordering approaches, our model approach to coherence modelling shares the property that induction of an ordering upon the sentences is only done after examining all of the sentence embeddings and explicitly arranging them in the most coherent fashion.

6 Conclusions

The ability to facilitate deeper understanding of texts is an important, but recently ignored, property for coherence modelling approaches. In an effort to improve this situation, we present a self-supervised approach to learning sentence embeddings, which we call PPDs, that rely on the connection between the meaning of a sentence and its location in a text. We implement the new sentence embedding technique with a recurrent neural network trained to map a sentence to a discrete distribution indicating where in the text the sentence is likely located. These PPDs have the useful property that a high probability in a given quantile indicates that the sentence is typical of sentences that would occur at the corresponding location in the text.

We demonstrate how these PPDs can be applied to coherence tasks with algorithms simple enough such that they can be visually performed by users while achieving near state-of-the-art, outperforming more complex and specialized systems. We also demonstrate how PPDs can be used to obtain various insights into data, including how to go about improving the writing, how to identify potential subsections, and how to locate specific types of information, such as introductory or summary information. As a proof-of-concept, we additionally show that despite PPDs not being designed for the task, they can be used to create a heuristic summarizer which outperforms comparable heuristic summarizers.

In future work, it would be valuable to evaluate our approach on texts from a wider array of domains and with different sources of incoherence. In particular, examining raw texts identified by humans as lacking coherence could be performed, to determine how well our model correlates with human judgment. Exploring how the algorithms utilizing PPDs may be refined for improved performance on the wide variety of coherence-related tasks may also prove fruitful. We are also interested in examining how PPDs may assist with other NLP tasks such as text generation or author identification.

Abstract

This paper presents experiments in risk factors analysis based on clinical texts enhanced with Linked Open Data (LOD). The idea is to determine whether a patient has risk factors for a specific disease analyzing only his/her outpatient records. A semantic graph of "meta-knowledge" about a disease of interest is constructed, with integrated multilingual terms (labels) of symptoms, risk factors etc. coming from Wikidata, PubMed, Wikipedia and MESH, and linked to clinical records of individual patients via ICD–10 codes. Then a predictive model is trained to foretell whether patients are at risk to develop the disease of interest. The testing was done using outpatient records from a nation-wide repository available for the period 2011-2016. The results show improvement of the overall performance of all tested algorithms (kNN, Naïve Bayes, Tree, Logistic regression, ANN), when the clinical texts are enriched with LOD resources.

1 Motivation

Recently, with the improving quality of Natural Language Processing (NLP), it is increasingly recognized as the most useful tool to extract clinical information from the free text of scientific medical publications and clinical records. In this way NLP becomes an instrument supporting biomedical research and new application scenarios are sought to reveal patterns and dependencies expressed by medical texts. Open-source NLP software appears, tailored to clinical text, and this increases NLP dissemination and acceptance. The construction of language resources for biomedical NLP goes in parallel to technology development. The large variety of medical terminology systems is continuously transformed and integrated into standardized, structured repositories of Linked Open Data[1]; de-identified data sets of electronic health records (EHRs) are made available as open resources[2]. Current hype in open linked data and collective efforts for their generation allow to benefit from the multilingual versions of some encyclopedic datasets like Wikidata and Wikipedia. Still there is a lack of NLP tools and linguistic resources with sufficient quality for processing medical texts in languages other than English but the interest to process such texts increases too.

Our goal is to determine whether a patient has risk factors for a specified disease, according to the information in his/her outpatient record. We suggest to enrich patient-related clinical narratives with additional information sources in order to enable a deeper investigation of dependencies between diseases and risk factors. In general it is difficult to predict the risk of a certain disease from the text of a clinical record only. Patient history contains numerous facts that are documented within a series of records but most often the medical expert reads them in isolation. In addition, many symptoms might signal various diseases. We propose to construct semantic graphs of "meta-knowledge" about diseases of interest, to integrate there multilingual terms (labels) of symptoms, risk factors etc., and to link clinical records of individual patients to this construction with the hope to discover new hints and interrelations that are not contained in the primary documents.

In the experiments presented here, patient records in Bulgarian language are enhanced with

[1] https://lod-cloud.net/

[2] E.g. at BioPortal https://bioportal.bioontology.org/ and at DBMI Data Portal https://portal.dbmi.hms.harvard.edu/

semantic information provided by medical ontologies and other resources in English, like scientific publications and encyclopedic data. Several data mining experiments were run on datasets containing outpatient records of diabetic patients in Bulgarian linked to encyclopedic extracts and Life Sciences LOD in English. The results show that LOD infuse some relations that are not found by standard text mining techniques of clinical narratives, and thus enable the discovery of associations hinting to further risk factors for diabetes mellitus.

2 Related Work

Mining of inter-related collections of clinical texts and LOD is still rare. On the one hand, with hundreds of open biomedical ontologies and numerous biomedical datasets made available as LOD, there is a salient opportunity to integrate clinical and biomedical data to better interpret patient-related texts and to uncover associations of biomedical interest. On the other hand, such mining experiments require significant efforts to make clinical data interoperable with standardized health terminologies, biomedical ontologies and growing LOD repositories. One of the earliest papers in this direction is (Pathak et al., 2013) which describes how patient EHRs data at Mayo Clinic are represented as Resource Description Framework (RDF) in order to identify potential drug-drug interactions for widely prescribed cardiovascular and gastroenterology drugs. Some drug-drug interactions of interest were identified which suggest lack of consensus on practice guidelines and recommendations. The authors of (Odgers and Dumontier, 2015) describe how they transformed a de-identified version of the STRIDE[3] EHRs into a semantic clinical data warehouse containing among others annotated clinical notes. They showed the feasibility of using semantic web technologies to directly exploit existing biomedical ontologies and LOD. As far as NLP is concerned, an open-source tool (NegEx) is used in the EHR transformation to recognize negated terms. The integrated search in EHR data and LOD is not yet considered as a popular trend in the secondary use of clinical narratives (Meystre et al., 2017) and is still an emerging direction of research mostly due to the complex data preparation.

Information Extraction (IE) refers to the automatic extraction of concepts, entities and events as well as their relations and associated attributes from free text. A recent review of clinical IE applications (Wang et al., 2018) notes the increasing interest to NLP but lists only 25 IE systems which were used multiple times, outside the labs where they were created. Isolated attempts exist to apply IE in the context of EHR processing in frameworks for semantic search, for instance SemEHR deployed to identify contextualized mentions of biomedical concepts within EHRs in a number of UK hospitals (Wu et al., 2018). We mention the following research prototypes as experimental developments, based on some sort of IE: (Shi et al., 2017) reports about a system extracting textual medical knowledge from heterogeneous sources in order to integrate it into knowledge graphs; (Hassanpour and Langlotz, 2016) describes a machine learning system that annotates radiology reports and extracts concepts according to a model covering most clinically significant contents in radiology; (Jackson et al., 2018) presents the information extraction and retrieval architecture CogStack, deployed in the King's College Hospital. CogStack has functionality to transform records into de-identified text documents and applies generic clinical IE pipelines to derive additional structured data from free texts.

Most of the successful systems listed above work for clinical narratives in English. All major resources, ontologies and terminology classifications like UMLS[4] and MESH[5] are available in English. The comprehensive ontology SNOMED CT[6] was developed initially in English and then translated to other languages. Progress in biomedical NLP for languages other than English will catalyze the development of tools in the respective languages and will enable access to medical data presented in a variety of languages (Névéol et al., 2018). In Europe, the European commission supports the development of multilingual platforms like SEMCARE which performs queries on unstructured medical data in English, German, and Dutch (López-García et al., 2016).

Using Big Data (nowadays - millions of EHRs) to advance medical research and health care prac-

[3] Stanford Translational Research Integrated Database Environment including a repository for EHR data, https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2815452/

[5] https://meshb.nlm.nih.gov/search

[6] http://www.snomed.org/

tices is now on the rise (Kessel and Combs, 2016). Core NLP components are already embedded in general clinical platforms similar to CogStack (Jackson et al., 2018). Development of high quality corpora and terminology is a key factor for NLP progress in smaller languages. Here we employ English terminology in data mining tasks concerning EHRs in Bulgarian language.

3 Materials

The datasets used in this study are a blend between LOD and clinical texts in Bulgarian language that belong to the Repository underpinning the Bulgarian Diabetes Register.

The Register was automatically generated in 2015 from 260 million pseudonymized outpatient records (ORs) provided by the National Health Insurance Fund (NHIF) for the period 2011–2014 for more than 5 million citizens yearly, more than 7 million citizens in total (Boytcheva et al., 2017). Updated twice with data about 2015 and 2016, today the Register is maintained by the University Specialized Hospital for Active Treatment of Diabetes (USHATE) - Medical University Sofia. At present the Repository of ORs, which underpins the Register, contains about 262 million records. These are reimbursement requests submitted by General Practitioners and Specialists from Ambulatory Care after every contact with a patient. The average number of patients with Diabetes Mellitus Type 2 (T2DM) per year is about 450,000.

In the primary database, from where we extract our datasets, the ORs are stored as semi-structured files with predefined XML-format. Administrative information is structured: visit date and time; pseudonymized personal data and visit-related information, demographic data etc. All diagnoses are given by ICD–10[7] codes and location names are specified in Bulgarian according to a standard nomenclature. However much information is provided as free text: anamnesis (case history, previous treatments, often family history, risk factors), patient status (summary of patient state, height, weight, body-mass index, blood pressure etc.), clinical tests (values of clinical examinations and lab data listed in arbitrary order) as well as prescribed treatment (codes of drugs reimbursed by NHIF, free text descriptions of other drugs).

To enhance clinical information with semantic data related to diagnoses, risk factors and symptoms, the following open datasets are selected:

- Wikidata[8] - contains multilingual encyclopedic information. Wikidata is a trusted resource, providing multilingual terminologies, their association with MESH codes, and complex relations between diagnoses, risk factors, and symptoms. Currently Wikidata contains descriptions of 5,227 items included in ICD–10 and 10,517 descriptions of items included in ICD–10–CT. The main problem is that many duplicated entities exist. For instance, for ICD–10 code I20 there are two items "angina pectoris (Q180762)" and "ischaemic heart disease (Q1444550)". Using SPARQL[9] queries, from Wikidata we collect for a given diagnosis all risk factors related to it as well as the associated MESH codes. From the list of risk factors that is originally in English we produce also a list in Bulgarian for the corresponding terms.

- PubMed[10] – the largest collection of scientific publications in the area of biomedicine and life sciences. From Pubmed we automatically extract publication abstracts and related MESH terms via advanced queries[11] through API. The search is limited to 10,000 abstracts in order to keep balance between the amounts of clinical narratives and texts of scientific publications.

- Wikipedia – from Wikipedia we extract automatically Wikipedia pages' summaries for a specified query via MediaWiki RESTful web service API[12]. The information in Wikipedia is encyclopedic and more broader, thus the semantic information there is too vague and shallow, in contrast to PubMed abstracts.

- MESH ontology – this ontology is chosen because both Pubmed publications and Wikidata contain references to it. In addition a mapping between MESH and SNOMED CT is available.

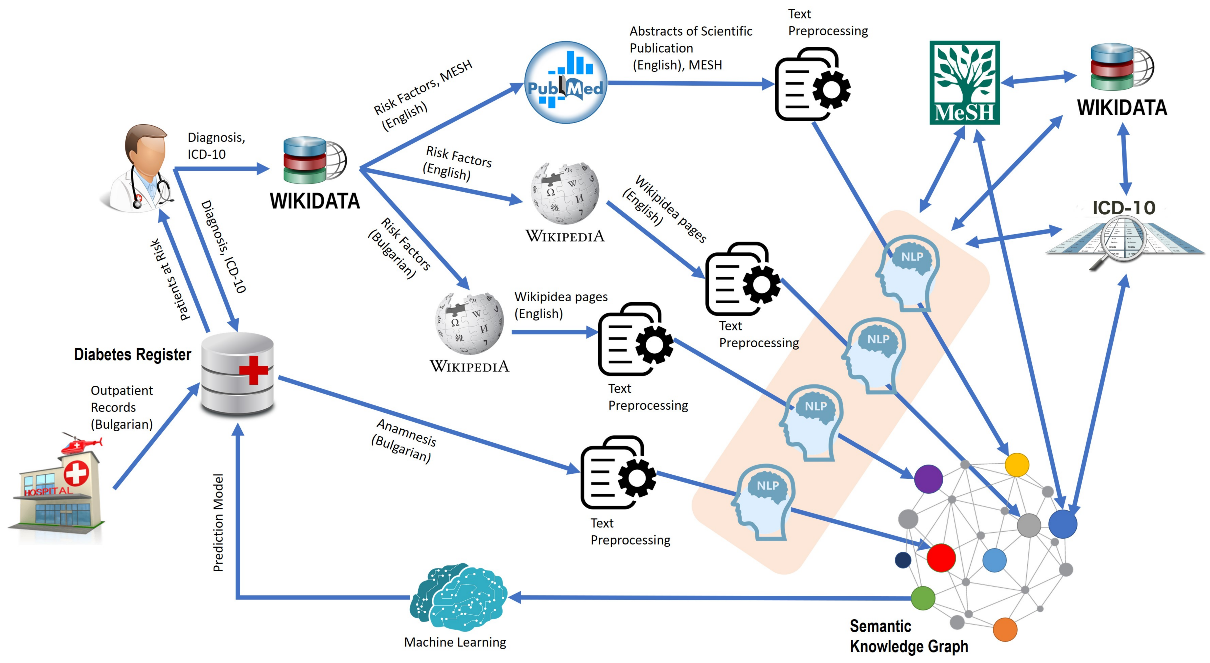

Figure 1: Pipeline for identification of patients at risk

4 Methods

The proposed method for risk factors identification is based on LOD and benefits from mapping multilingual data and using their vocabularies.

The data flow diagram is shown on Fig. 1. The process starts with selection of a diagnosis D, according to ICD–10 or ICD–10–CD by a medical expert who is looking for patients at risk in the Diabetes Register. The next step is to extract corresponding risk factors and symptoms for D in English $RE = \{re_1, re_2, ..., re_n\}$ from Wikidata, their equivalent terms in Bulgarian $RB = \{rb_1, rb_2, ..., rb_n\}$ and the MESH codes $M = \{m_1, m_2, ..., m_n\}$.

For each term re_i in English and its corresponding rb_i in Bulgarian, summaries of the respective Wikipedia pages are extracted automatically.

For each Mesh code m_i of risk factor r_i are extracted up to 10,000 abstracts of Pubmed publications and their annotations with MESH codes. For Pubmed the advanced search is done using an automatically generated query in the form:

```
(D/pc [majr] OR D/di [majr] OR
   D/ep [majr] D [mh]) AND
( re1 [mh] OR ...  OR ren [mh])
```

where the MeSH qualifiers for subheadings are: "pc" refers to "prevention and control"; "di" means "diagnosis"; "ep" is "epidemiology", "mh" - MeSH heading, and "majr" - to search MeSH heading that is a major topic of an article.

From the Bulgarian Diabetes Register a dataset is excerpted for patients with the diagnosis D. For those with recent D onset, ORs for previous periods are collected (only within 2011–2016).

4.1 Text Pre-Processing

The main transformations are done stepwise:

- tokenization - for Bulgarian language we used the UDPipe tokenizer[13].
- convertion of all words to lower case;
- removal of all punctuation marks;
- removal of all numbers;
- application of a stemmer and lemmatizer - for Bulgarian the UDPipe lemmatizer, for English Porter Stemmer (Porter, 2006);
- filtering stopwords - both for Bulgarian[14] and English;
- application of text vectorization based on TFIDF.

[14] http://bultreebank.org/wp-content/uploads/2017/04/BTB-StopWordList.zip

4.2 Semantic Model

Semantic Knowledge Graphs are used recently as powerful representation of entities and relations between them (Paulheim, 2017). Often knowledge graphs are generated automatically from semi-structured resources or from the documents underpinning various ontologies, through terms/words they contain, by a combination of linguistic and statistical methods (Grainger et al., 2016).

In our experiment, all data are interlinked in a Semantic Knowledge graph via MESH codes and ICD–10 codes. Wikidata is the mediator between all resources providing cross-lingual ontology information and mapping between MESH and ICD-10 codes. Term mappings from MeSH to ICD-10 are 1,535 and to ICD-10-CM are 2,127. In addition Wikidata provides multilingual vocabulary for symptoms and diseases, and Pubmed publications are annotated by Mesh codes.

For each symptom and risk factor, related to the selected diagnosis D, the system identifies the most significant words related to D from the Wikipedia and Pubmed datasets respectively, using p-value as a measure for their significance. The knowledge graph is enriched with relations between these terms. The main relation between clinical texts and other resources is based on ICD-10 codes and some symptoms and risk factors that are presented in the anamnesis section of ORs.

4.3 Predictive Model

Two types of clinical texts are used as training datasets - for patients that have the diagnosis D, and for patients that do not have D. After text preprocessing, semantic hashing of all clinical texts in both datasets is done for predefined size of the hash. Two predictive models are applied:

- Based on the ORs information only
- Based on the ORs information enhanced with semantic data for symptoms and risk factors. In this case the vector space is extended; not only the dimensions of semantic hash vectors are used, but also additional dimensions for all symptoms, risk factors and the most significant terms related to them.

Several machine learning techniques were used to train the predictive model, including Naïve Bayes (NB) (McCallum et al., 1998), kNN, Tree, Logistic Regression and Artificial Neural Networks. (Dreiseitl and Ohno-Machado, 2002).

5 Experiments and Results

The diagnosis with ICD–10 code I20 "Ischaemic heart disease" is chosen for experiments because the Diabetes Register contains a plenty of clinical descriptions about this case. Patients with T2DM are at higher risk for developing I20 which is one of the T2DM complications. Sets of symptoms and risk factors for I20, both in Bulgarian and English, and English MeSH codes are automatically extracted by Wikidata queries. Seven symptoms are extracted: angina pectoris, nausea, dyspnea, lightheadedness, unstable angina, neck pain, fatigue. Only for three of them there are labels in Bulgarian, and for five of them there are MESH codes. In addition, there are 18 risk factors and for 11 of them labels in Bulgarian exist. Multiple MeSH codes are associated to some risk factors but there diagnoses without associated MeSH code. The final cardinality of the generated term set is $|RE| = 24$, $|RB| = 14$ and $|M| = 34$.

The Wikipedia API extracts 87 documents for a query with the RB terms in Bulgarian and we limit the set to the top 5 related documents. They contain 14,600 tokens from 3,627 types. Although only the top 5 most related documents are taken into consideration, some of the extracted Wikipedia pages are not directly related to the symptoms and risk factors, as they discuss e.g. herbs and medications for treatment. But some very related symptoms are included: for example for "nausea" the Wikipedia page about "vomiting" is extracted, and for "smoking" pages about "tobacco" and "pipe" are found. In addition, some barely related pages are extracted – mainly about some famous people, who suffer from the diseases in question and have related symptoms. Unfortunately the information in Wikipedia categories "Medical conditions" and "Diseases" for Bulgarian is too limited. For "Medical conditions" there are only 41 pages, and for many diseases the articles in the Bulgarian Wikipedia are stubs or some pages are not tagged in the respective categories.

For the query with RE terms 146 documents are identified that contain 40,099 tokens from 3,803 types. The extracted Wikipedia pages in English are also sometimes noisy and unrelated mainly due to the ambiguity e.g. pages about "Nausea(novel)" and "Nausea(band)", or "Insomnia (2002 film)" are extracted too. Other pages, indirectly related to the risk factors, contain information about Health organizations for treatment of the respective diseases, about diagnostic procedures, medication for the treatment etc.

Using the Pubmed advanced search, the generated query with RE terms identified 67,103 related scientific papers, from which we retrieved a subset of 2,000 abstracts only. The MeSH headings only contain 104,363 tokens from 2,509 types. Both MeSH heading and Pubmed abstracts contain 546,772 tokens from 12,684 types.

Despite the imperfection of all texts extracted from Wikipedia and PubMed, the most significant terms related to the predefined subsets of symptoms and risk factors are sound and correct. Their identification is based on bag–of–words and calculation of p-value ($p \leq 0.01$) and False Discovery Rate ($FD \leq 0.2$). For example, for тютюнопушене (tobacco smoking) the following words are identified as relevant: тютюнопушене (tobacco smoking), дим (smoke), пушене (smoking), тютюнев (tobacco), практикувам (practice), пристрастяване (addiction), пушач (smoker), цигара (cigar). These words were selected among 3,588 words in the text of related Wikipedia pages in Bulgarian. From those words 754 were filtered as relevant, and the final selection contain 9 words as most significant.

Two subsets of ORs (Anamnesis section) are extracted from the Repository behind the Diabetes Register: $S1$ for 36,580 patients with diagnosis I20 and $S2$ for 86,000 patients without diagnosis I20. All clinical texts are preprocessed. The total number of tokens in $S1$ and $S2$ is 123,258 from 25,086 types. For experiments are used kNN (5 neighbours, Mahalanobis metric), Tree (Pruning: at least 2 instances in leaves, at least 5 instances in internal nodes, maximum depth 100; Stop splitting when majority reaches 95%), Neural Network (30 hidden layers, Rectified Linear Activation Function (ReLu) (Nair and Hinton, 2010), stochastic gradient-based optimizer Adam (Kingma and Ba, 2014)), $\alpha = 0.0004$, Max iterations 200, replicable training) , NB and Logistic Regression (Ridge L2). The baseline results of the prediction model based on ORs only are presented in Table 1.

The results of prediction models trained with enhanced LOD data (Table 2) show improvement of the overall performance of all algorithms on this task, especially NB and Logistic Regression, when the clinical texts are enriched with additional information provided by open data resources and medical terminologies.

Model	F1	P	R
kNN	0.796	0.795	0.801
Tree	0.778	0.776	0.783
Neural Network	0.705	0.713	0.735
NB	0.588	0.615	0.701
Logistic Regression	0.581	0.640	0.703

Table 1: Baseline: Performance of employed ML algorithm using semantic hashing over ORs only.

Model	F1	P	R
kNN	0.819	0.752	0.899
Tree	0.893	0.858	0.932
Neural Network	0.743	0.746	0.760
NB	0.823	0.704	0.989
Logistic Regression	0.825	0.703	0.999

Table 2: Performance of employed ML algorithm using semantic hashing of ORs enhanced with semantic model data.

6 Conclusion and Further Work

The proposed approach shows how clinical texts can be enhanced with additional information about the diseases, their symptoms and risk factors. The experimental results show promising improvement of the risk factors prediction accuracy. Still there is a problem with Latin medical terminology that is often used in the Bulgarian clinical texts. Another issue is the imperfection of the additional terms provided by the LOD resources, due to many ambiguous terms included there. As future work we plan to apply word sense disambiguation to the texts extracted from open resources and more precise methods for constructing the relations in the semantic knowledge graphs. As future work we are planning to do deep analysis of the individual contribution of each new term added to the clinical texts. Another direction for future work is to use some transfer learning methods like UMLfit (Howard and Ruder, 2018), BERT (Devlin et al., 2018) and XLnet (Yang et al., 2019) to train models for word embedding on clinical texts in Bulgarian.

Acknowledgments

This research is partially funded by the Bulgarian Ministry of Education and Science, grant DO1-200/2018 ’Electronic health care in Bulgaria’ (e-Zdrave) and the Bulgarian National Science Fund, grant DN-02/4-2016 ’Specialized Data Mining Methods Based on Semantic Attributes’ (IZIDA). Parallel Sentence Retrieval From Comparable Corpora for Biomedical Text Simplification

natalia.grabar@univ-lille.fr

Abstract

Parallel sentences provide semantically similar information which can vary on a given dimension, such as language or register. Parallel sentences with register variation (like expert and non-expert documents) can be exploited for the automatic text simplification. The aim of automatic text simplification is to better access and understand a given information. In the biomedical field, simplification may permit patients to understand medical and health texts. Yet, there is currently no such available resources. We propose to exploit comparable corpora which are distinguished by their registers (specialized and simplified versions) to detect and align parallel sentences. These corpora are in French and are related to the biomedical area. Manually created reference data show 0.76 inter-annotator agreement. Our purpose is to state whether a given pair of specialized and simplified sentences is parallel and can be aligned or not. We treat this task as binary classification (alignment/non-alignment). We perform experiments with a controlled ratio of imbalance and on the highly unbalanced real data. Our results show that the method we present here can be used to automatically generate a corpus of parallel sentences from our comparable corpus.

1 Introduction

Parallel sentences provide semantically similar information which can vary on a given dimension. Typically, parallel sentences are collected in two languages and correspond to mutual translations. In the general language, the Europarl (Koehn, 2005) corpus provides such sentences in several pairs of languages. Yet, the dimension on which the parallelism is positioned can come from other levels, such as expert and non-expert register of language. The following pair of sentences (first in expert and second in non-expert languages) illustrates this:

- *Drugs that inhibit the peristalsis are contraindicated in that situation*
- *In that case, do not take drugs intended for blocking or slowing down the intestinal transit*

Pairs of parallel sentences provide useful information on lexicon used, syntactic structures, stylistic features, etc., as well as the correspondences between the languages or registers. Hence, pairs built from different languages are widely used in machine translation, while pairs differentiated by the register of language can be used for the text simplification. The purpose of text simplification is to provide simplified versions of texts, in order to remove or replace difficult words or information. Simplification can be concerned with different linguistic aspects, such as lexicon, syntax, semantics, pragmatics and even document structure.

Automatic text simplification can be used as a preprocessing step for NLP applications or for producing suitable versions of texts for humans. In this second case, simplified documents are typically created for children (Vu et al., 2014), for people with low literacy or foreigners (Paetzold and Specia, 2016), for people with mental or neurodegenerative disorders (Chen et al., 2016), or for laypeople who face specialized documents (Leroy et al., 2013). Our work is related to the creation of simplified medical documents for laypeople, such as patients and their relatives. It has indeed been noticed that medical and health documents contain information that is difficult to understand by patients and their relatives, mainly because of the presence of technical and specialized terms and notions. This situation has a negative effect on the healthcare process (AMA, 1999; Mcgray, 2005; Rudd, 2013). Hence, helping patients to better understand medical and health information is an important issue, which motivates our work.

In order to perform biomedical text simplification, we propose to collect parallel sentences, which align difficult and simple information, as they provide crucial and necessary indicators for automatic systems for text simplification. Indeed, such pairs of sentences contain cues on transformations which are suitable for the simplification, such as lexical substitutes and syntactic modifications. Yet, this kind of resources is seldom available, especially in languages other than English. As a matter of fact, it is easier to access comparable corpora: they cover the same topics but are differentiated by their registers (documents created for medical professionals and documents created for patients). More precisely, we can exploit an existing monolingual comparable corpus with medical documents in French (Grabar and Cardon, 2018). The purpose of our work is to detect and align parallel sentences from this comparable corpus. We also propose to test what is the impact of imbalance on categorization results: imbalance of categories is indeed the natural characteristics in textual data.

The existing work on searching parallel sentences in monolingual comparable corpora indicates that the main difficulty is that such sentences may show low lexical overlap but be nevertheless parallel. Recently, this task gained in popularity in general-language domain thanks to the semantic text similarity (STS) initiative. Dedicated *SemEval* competitions have been proposed for several years (Agirre et al., 2013, 2015, 2016). The objective, for a given pair of sentences, is to predict whether they are semantically similar and to assign a similarity score going from 0 (independent semantics) to 5 (semantic equivalence). This task is usually explored in general-language corpora (Coster and Kauchak, 2011; Hwang et al., 2015; Kajiwara and Komachi, 2016; Brunato et al., 2016). Among the exploited methods, we can notice:

- lexicon-based methods which rely on similarity of subwords or words from the processed texts or on machine translation (Madnani et al., 2012). The features exploited can be: lexical overlap, sentence length, string edition distance, numbers, named entities, the longest common substring (Clough et al., 2002; Zhang and Patrick, 2005; Qiu et al., 2006; Nelken and Shieber, 2006; Zhu et al., 2010);

- knowledge-based methods which exploit external resources, such as WordNet (Miller et al., 1993) or PPDB (Ganitkevitch et al., 2013). The features exploited can be: overlap with external resources, distance between the synsets, intersection of synsets, semantic similarity of resource graphs, presence of synonyms, hyperonyms or antonyms (Mihalcea et al., 2006; Fernando and Stevenson, 2008; Lai and Hockenmaier, 2014);

- syntax-based methods which exploit the syntactic modelling of sentences. The features often exploited are: syntactic categories, syntactic overlap, syntactic dependencies and constituents, predicat-argument relations, edition distance between syntactic trees (Wan et al., 2006; Severyn et al., 2013; Tai et al., 2015; Tsubaki et al., 2016);

- corpus-based methods which exploit distributional methods, latent semantic analysis (LSA), topics modelling, word embeddings, etc. (Barzilay and Elhadad, 2003; Guo and Diab, 2012; Zhao et al., 2014; Kiros et al., 2015; He et al., 2015; Mueller and Thyagarajan, 2016).

There has been work for detection of paraphrases in French comparable biomedical corpora (Deléger and Zweigenbaum, 2009), but there is no work on building a corpus for text simplification in the biomedical domain. Our work is positioned in this area.

In what follows, we first present the linguistic material used, and the methods proposed. We then present and discuss the results obtained, and conclude with directions of future work.

2 Method

We use the CLEAR comparable medical corpus (Grabar and Cardon, 2018) available online[1] which contains three comparable sub-corpora in French. Documents within these sub-corpora are contrasted by the degree of technicality of the information they contain with typically specialized

[1] http://natalia.grabar.free.fr/resources.php#clear

and simplified versions of a given text. These corpora cover three genres: drug information, summaries of scientific articles, and encyclopedia articles. We also exploit a reference dataset with sentences manually aligned by two annotators.

2.1 Comparable Corpora

Table 1 indicates the size of the comparable corpus in French: number of documents, number of words (occurrences and lemmas) in specialized and simplified versions. This information is detailed for each sub-corpus: drug information (*Drugs*), summaries of scientific articles (*Scient.*), and encyclopedia articles (*Encyc.*).

The *Drugs* corpus contains drug information such as provided to health professionals and patients. Indeed, two distinct sets of documents exist, each of which contains common and specific information. This corpus is built from the public drug database[2] of the French Health ministry. Specialized versions of documents provide more word occurrences than simplified versions.

The *Scientific* corpus contains summaries of meta-reviews of high evidence health-related articles, such as proposed by the Cochrane collaboration (Sackett et al., 1996). These reviews have been first intended for health professionals but recently the collaborators started to create simplified versions of the reviews (*Plain language summary*) so that they can be read and understood by the whole population. This corpus has been built from the online library of the Cochrane collaboration[3]. Here again, specialized version of summaries is larger than the simplified version, although the difference is not very important.

The *Encyclopedia* corpus contains encyclopedia articles from Wikipedia[4] and Vikidia[5]. Wikipedia articles are considered as technical texts while Vikidia articles are considered as their simplified versions (they are created for children from 8 to 13 year old). Similarly to the works done in English, we associate Vikidia with Simple Wikipedia[6]. Only articles indexed in the medical portal are exploited in this work. From Table 1, we can see that specialized versions (from Wikipedia) are also longer than simplified versions.

Those three corpora have different degrees of parallelism: Wikipedia and Vikidia articles are written independently from each other, drug information documents are related to the same drugs but the types of information presented for experts and laypeople vary, while simplified summaries from the *Scientific* corpus are created starting from the expert summaries.

2.2 Reference Data

The reference data with aligned sentence pairs, which associate technical and simplified contents, are created manually. We have randomly selected 2x14 *Encyclopedia* articles, 2x12 *Drugs* documents, and 2x13 *Scientific* summaries. The sentence alignment is done by two annotators following these guidelines:

1. exclude identical sentences or sentences with only punctuation and stopword difference ;

2. include sentence pairs with morphological variations (e.g. *Ne pas dépasser la posologie recommandée.* and *Ne dépassez pas la posologie recommandée.* – both examples can be translated by *Do not take more than the recommended dose.*);

3. exclude sentence pairs with overlapping semantics, when each sentence brings own content, in addition to the common semantics;

4. include sentence pairs in which one sentence is included in the other, which enables many-to-one matching (e.g. *C'est un organe fait de tissus membraneux et musculaires, d'environ 10 à 15 mm de long, qui pend à la partie moyenne du voile du palais.* and *Elle est constituée d' un tissu membraneux et musculaire.* – *It is an organ made of membranous and muscular tissues, approximately 10 to 15 mm long, that hangs from the medium part of the soft palate.* and *It is made of a membranous and muscular tissue.*);

5. include sentence pairs with equivalent semantics – other than semantic intersection and inclusion (e.g. *Les médicaments inhibant le péristaltisme sont contre-indiqués dans cette situation.* and *Dans ce cas, ne prenez pas de médicaments destinés à bloquer ou ralentir le transit intestinal.* – *Drugs that inhibit peristalsis are contraindicated in*

Table 2: Size of the reference data with consensual alignment of sentences. Column headers: number of documents, sentences and word occurrences for each subset, alignment rate

that situation. and *In that case, do not take drugs intended for blocking or slowing down the intestinal transit.*).

The judgement on semantic closeness may vary according to the annotators. For this reason, the alignments provided by each annotator undergo consensus discussions. This alignment process provides a set of 663 aligned sentence pairs. The inter-annotator agreement is 0.76 (Cohen, 1960). It is computed within the two sets of sentences proposed for alignment by the two annotators.

Table 2 shows the details of the manually aligned set of sentences. Because the three corpora vary in their capacity to provide parallel sentences, we compute their *alignment rate*. The alignment rate for a given corpus is the number of sentences that are part of an aligned pair relative to the total number of sentences. As expected, only a tiny fraction of all possible pairs corresponds to aligned sentences. We can observe that the *Scientific* corpus is the most parallel with the highest alignment rate of sentences, while the two other corpora (*Drugs* and *Encylopedia*) contain proportionally less parallel sentences. Sentences from simplified documents in the *Scientific* and *drugs* corpora are longer than sentences from specialized documents because they often add explanations for technical notions, like in this example: *We considered studies involving bulking agents (a fibre supplement), antispasmodics (smooth muscle relaxants) or antidepressants (drugs used to treat depression that can also change pain perceptions) that used outcome measures including improvement of abdominal pain, global assessment (overall relief of IBS symptoms) or symptom score.* In the *Encylopedia* corpus such notions are replaced by simpler words, or removed. Finally, in all corpora, we observe frequent substitutions by synonyms, like {*nutrition*, *food*}, {*enteral*, *directly in the stomach*}, or {*hypersensitivity*, *allergy*}. Notice that with such substitutions, lexical similarity between sentences is reduced.

The documents are pre-processed. They are segmented into sentences using strong punctuation (*i.e.* *.?!;:*). We removed, from each subcorpus, the sentences that are found in at least half of the documents of a given corpus. Those sentences are typically legal notices, section titles, and remainders from the conversion of the HTML versions of the documents. The lines that contain no alphabetic characters have also been removed. That reduces the total number of possible pairs for each document pair approximately from 940,000 to 590,000.

2.3 Automatic Detection and Alignment of Parallel Sentences

Automatic detection and alignment of parallel sentences is the main step of our work. The unity processed is a pair of sentences. The objective is to categorize the pairs of sentences in one of the two categories:

- alignment: the sentences are parallel and can be aligned;
- non-alignment: the sentences are non-parallel and cannot be aligned.

The reference data provide 663 positive examples (parallel sentence pairs). In order to perform the automatic categorization, we also need negative examples, which are obtained by randomly pairing all sentences from all the document pairs except the sentence pairs that are already found to be parallel. Approximately 590,000 non-parallel sentences pairs are created in this way. That high degree of imbalance is the main challenge in our work and we address it in the experimental design (sec 2.4).

For the automatic alignment of parallel sentences, we first use a binary classification model that relies on the random forests algorithm (Breiman, 2001). The implementation we use is the one that is available in scikit-learn (Pedregosa et al., 2011). Our goal is to propose features that can work on textual data in different languages and registers. We use several features which are mainly lexicon-based and corpus-based, so that they can be easily applied to textual data in other corpora, speacialized areas and languages or transposed on them. The features are computed on word forms (occurrences). The features are the following:

1. *Number of common non-stopwords*. This feature permits to compute the basic lexical overlap between specialized and simplified versions of sentences (Barzilay and Elhadad, 2003). It concentrates on non-lexical content of sentences;

2. *Percentage of words from one sentence included in the other sentence, computed in both directions*. This features represents possible lexical and semantic inclusion relations between the sentences;

3. *Sentence length difference between specialized and simplified sentences*. This feature assumes that simplification may imply stable association with the sentence length;

4. *Average length difference in words between specialized and simplified sentences*. This feature is similar to the previous one but takes into account average difference in sentence length;

5. *Total number of common bigrams and trigrams*. This feature is computed on character ngrams. The assumption is that, at the sub-word level, some sequences of characters may be meaningful for the alignment of sentences if they are shared by them;

6. *Word-based similarity measure exploits three scores (cosine, Dice and Jaccard)*. This feature provides a more sophisticated indication on word overlap between two sentences. Weight assigned to each word is set to 1;

7. *Character-based minimal edit distance* (Levenshtein, 1966). This is a classical acception of edit distance. It takes into account basic edit operations (insertion, deletion and substitution) at the level of characters. The cost of each operation is set to 1;

8. *Word-based minimal edit distance* (Levenshtein, 1966). This feature is computed with words as units within sentence. It takes into account the same three edit operations with the same cost set to 1. This feature permits to compute the cost of lexical transformation of one sentence into another;

9. *WAVG*. This features uses word embeddings. The word vectors of each sentence are averaged, and the similarity score is calculated by comparing the two resulting sentence vectors (Stajner et al., 2018);

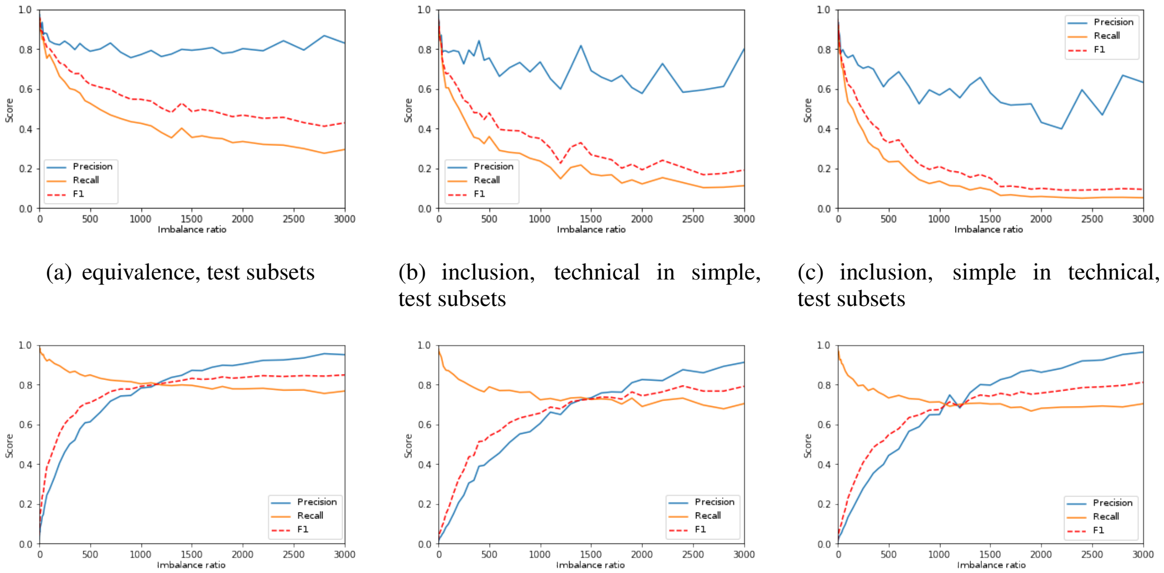
10. *CWASA*. This feature is the continuous word alignment-based similarity analysis, as described in (Franco-Salvador et al., 2016).

For the last two features, we trained the embeddings on the CLEAR corpus using word2vec (Mikolov et al., 2013), and the scores are computed using the CATS tool (Stajner et al., 2018).

2.4 Experimental Design

The set with manually aligned pairs is divided into three subsets:

- *equivalence*: 238 pairs with equivalent semantics,
- *tech in simp*: 237 pairs with inclusion where the content of technical sentence is fully included in simplified sentence, and simplified sentence provides additional content,
- *simp in tech*: 112 pairs with inclusion where the content of simplified sentence is fully included in technical sentence, and technical sentence provides additional content.



(a) equivalence, test subsets

(b) inclusion, technical in simple, test subsets

(c) inclusion, simple in technical, test subsets

(d) equivalence, real data

(e) inclusion, technical in simple, real data

(f) inclusion, simple in technical, real data

Figure 1: Precision, Recall and F-1 for the various experiments and subsets

For each subset, we perform two sets of experiments:

1. We train and test the model with balanced data (we randomly select as many non-aligned pairs as aligned pairs), and then we progressively increase the number of non-aligned pairs until we reach a ratio of 3000:1, which is close to the real data (∼4000:1).

2. Then, for each ratio, we apply the obtained model to the whole dataset and evaluate the results. Note that the training data is included in the whole dataset, we proceed this way because of the low volume of available data.

As there is some degree of variability coming with the subset of non-aligned pairs that are randomly selected for the imbalance ratio, every single one of those experiments has been performed fifty times: the results that are presented correspond to the mean values over the fifty runs.

2.5 Evaluation

For evaluating the results, in each experiment we divide the indicated datasets in two parts: two thirds for training and one third for testing. The metrics we use are Recall, Precision and F1 scores. As we are primarily focused on detection of the aligned pairs, we only report scores for that class. Another reason to exclude the negative class and the global score from the observations is that when the data are imbalanced (negative class is growing progressively), misclassifying the positive data has little influence over the global scores, which thus always appear to be high (metrics above 0.99).

Finally, we apply the best model for equivalent pairs on another 30 randomly selected documents and evaluate the output.

3 Presentation and Discussion of Results

We present the results in Figure 1: The x axis represents the growing of imbalance (the first position is 1 and corresponds to balanced data), while the y axis represents the values of Precision, Recall and F-measure. The results for the three subsets are presented: equivalence (Figures 1(a) and 1(d)), inclusion of technical sentence in simple sentence (Figures 1(b) and 1(e)), and inclusion of simple sentence in technical sentence (Figures 1(c) and 1(f)). Besides, Figures 1(a), 1(b) and 1(c) present the results obtained by training and testing the model on the dataset with the same imbalance ratio (first set of experiments described in section 2.4). As for Figures 1(d), 1(e) and 1(f), they present the results obtained by the models mentioned above that are applied on the whole set of manually annotated data (second set of experiments described in section 2.4).

	equivalence	simp. in tech.	tech. in simp.	intersection	false positives
nb. of pairs	56	10	4	9	1
ratio	70%	12.5%	5%	11.25%	1.25%

Table 3: Breakdown by pair types of the output of the model trained on equivalent pairs with an imbalance ratio of 1200:1 and applied to 30 randomly chosen pairs of documents

The most visible conclusion we can draw from those experiments is that equivalent pairs (Figures 1(a) and 1(d)) are easier to classify than inclusion pairs (the rest of the Figures). Values of both, Precision and Recall, are higher on the equivalence dataset at different imbalance points. For instance, with training on the equally balanced dataset (position 1 on Figure 1(a)), the scores for Precision (0.98) and Recall (0.95) are higher than the scores obtained by the technical in simple dataset (0.96 Precision and 0.94 Recall) and the simple in technical dataset (0.95 Precision and 0.93 Recall) at the same point. For the application to the real data, for ratio 1200:1 – the point where Precision and Recall meet for equivalent pairs, see Figure 1(d) – we obtain 0.81 Precision and 0.81 Recall. At that same ratio, for the technical in simple pairs the scores are 0.65 Precision and 0.73 Recall, and for the simple in technical pairs Precision is 0.73 and Recall is 0.70. This result is positive because the equivalence dataset usually provides the main and the most complete information on transformations required for the simplification. As for the inclusion relations, they cover a large variety of situations which do not necessarily correspond to the searched information. This is illustrated by the unstability of the curves in Figures 1(b) and 1(c), whereas they are smooth in Figure 1(a). The negative examples subset seems to have a quite high influence on the results, which indicates that it is more difficult to draw a clear separation between positive and negative examples. We need to design additional processing steps to be able to classify those pairs in a more efficient way.

We can also observe from Figures 1(a), 1(b) and 1(c) that the use of balanced data provides very high results, both for Precision and Recall, which are very close to the reference data (> 0.90 performance). This is true for the three subsets tested (equivalence and inclusions). These good results in an artifical setting cannot be applied to the real dataset, as is indicated by the starting point in Figures 1(d), 1(e) and 1(f). Yet, the imbalance has greater effect on the inclusion datasets, while again the equivalence dataset resists better. An interesting fact is that, when the model is learned on a substantial degree of imbalance, the Precision score is high when that model is applied to the real data, which has a ratio of about 4,000:1. This is interesting because it shows that the model is particularly good at discriminating counter-examples. The recall value is also high, but since two thirds of the real data examples have been used for training, that good score should be considered cautiously. We are planning to evaluate the models on a separate set of manually annotated documents. This is still a good result, as during the tests that we performed with other classification algorithms, the models did not successfully recognize the examples they had seen during training.

For further evaluation, we randomly selected 30 pairs of documents to evaluate the performances of the models. We used the model that was trained at a ratio of 1200:1 on equivalent pairs. In terms of precision, the model shows 98.75% on all the sentence pairs aligned (80 sentence pairs), including equivalence, inclusions and intersection. Table 3 shows the breakdown of this output in terms of pair types: 70% (56 pairs) are equivalent pairs, 29% (23 pairs) are examples of inclusion (10 simple in technical, 4 technical in simple) and intersection (9), and one pair contains two unrelated sentences. Those results show that we have a model that can be used to automatically generate a parallel corpus with reduced noise, from highly imbalanced comparable corpus, for text simplification purposes.

4 Conclusion and Future Work

We addressed the task of detection and alignment of parallel sentences from a monolingual comparable French corpus. The comparable aspect is on the technicality axis, as the corpus contrasts technical and simplified versions of information on the same subjects. We use the CLEAR corpus, that is related to the biomedical area.

Several experiments were performed. We divide the task in three subtasks – equivalent pairs, and inclusion on both directions – and make observations on the effect of imbalance during training on the performance on the real data. We show that increasing the imbalance during training increases the Precision of the model while still maintaining a stable value for Recall. We also find that the task is easier to perform on sentence pairs that have the same meaning, than on sentence pairs where one is included in the other.

We will use that model to generate a corpus of parallel sentences in order to work on the development of methods for biomedical text simplification in French. We will also perform experiments on the general language. Another task we will explore addresses the question on how that model performs with the cross-lingual transfer of descriptors and models.

Abstract

The ability to produce high-quality publishable material is critical to academic success but many Post-Graduate students struggle to learn to do so. While recent years have seen an increase in tools designed to provide feedback on aspects of writing, one aspect that has so far been neglected is the *Related Work* section of academic research papers. To address this, we have trained a supervised classifier on a corpus of 94 *Related Work* sections and evaluated it against a manually annotated gold standard. The classifier uses novel features pertaining to citation types and co-reference, along with patterns found from studying *Related Works*. We show that these novel features contribute to classifier performance with performance being favourable compared to other similar works that classify author intentions and consider feedback for academic writing.

1 Introduction

Argument structures are key in allowing an author to construct a persuasive message that realizes the author's intention. The automatic identification of such intentions has been shown to be a valuable resource in areas such as summarising information (Teufel and Moens, 2002; Cohan and Goharian, 2015), and understanding citation function and sentiment (Teufel et al., 2006; Jurgens et al., 2018). Recent years have seen more academic writing tools focused on content that use an understanding of expected author intentions to assist in feedback. This is an important resource for Post-Graduate (PG) students who struggle to gain the necessary skills in academic writing that are critical to their success (Aitchison et al., 2012; Paltridge and Starfield, 2007). Automating understanding of author intentions is challenging as research articles, whilst classed in their own genre, are known to differ in content and linguistic style across disciplines (Hyland, 2008).

Despite these challenges, previous work using author intentions has been successful in automating writing feedback though largely focused on the Abstract (Feltrim et al., 2006) or the Introduction (Cotos and Pendar, 2016; Abel, 2018). One reason for this focus on a single section of a research paper is that each section has its own purpose, which encourages different linguistic practices. Existing tools may concentrate on the Introduction due to formative work done by Swales (1990). Swales was one of the first to recognise these intentions in academic writing calling them *rhetoric intentions*. Swales showed how linguistic patterns in the Introduction could be matched to intentions, such as *establishing a territory* or *defining the problem*.

One section of academic papers that has not yet been explored for automated content feedback is the *Related Work* section. One particular challenge students have when learning to write is to find and project their own viewpoint (Kamler and Thomson, 2006). Often their lack of experience and confidence in projecting their own voice amongst established scholars results in students making bland statements about others' work. Such bland statements in the *Related Work* section do nothing more than provide a list of work with no real critical commentary or attempt to relate it to the author's own work. We address this gap of content feedback for *Related Work* by building a model of author intentions that one expects to find in *Related Work*.

We show how the labels of an annotated corpus for author intention, designed for writer feedback in *Related Work*, can be identified reliably. We build on existing methods for feature representation of author intentions and show that the novel features we introduce contribute significantly to the classifier performance, improving on performance of existing writer feedback tools.

2 Related Work

Automating Author Intentions – Previous models of author intentions in research articles have been successfully automated. One of the first and widely used is Teufel (1999) who proposed Argument Zoning (AZ) which labels sentences with zones representing the rhetoric purpose (author intent) within the global context of a document e.g. background, aim or conclusion. Further work has applied this schema to biology papers (Mizuta and Collier, 2004), with a modified, finer grained approach applied to papers on chemistry (Teufel et al., 2009). Liakata et al. (2012) took a different approach to labelling author intentions, studying the conceptual structure of biology articles treating the article as an investigation. Fisas et al. (2015) develop a schema based on both Liakata and Teufel's work to represent scientific concepts that appear in computer graphics articles. These works have successfully identified author intentions, but they differ from our work by seeking intentions in a global context across a whole article. For example, AZ was developed to support summarisation and information access. The author intentions that these activities would be associated with are rarely found in a *Related Work* section and are unlikely to be helpful in writing feedback for this section. They are nevertheless useful in supporting writing feedback on Abstracts and summaries of PhDs (Feltrim et al., 2006).

Related Work does have in common with other sections the fact that it should contain citations. Understanding the motivations or function of a citation can help determine an author intention (Teufel et al., 2006). Work on citation function has been an area of research for several decades (Weinstock, 1971; Oppenheim and Renn, 1978; Teufel et al., 2006; Angrosh et al., 2012), with more recent work considering how this recognition can be automated. Jurgens et al. (2018) investigates the framing of citations and how this can be used to study the evolution of a field. Teufel et al. (2006) work on automated recognition of citation function and show a strong relationship between function and sentiment. One work that specifically looks at context identification of sentences in *Related Work* is (Angrosh et al., 2010). This work focuses on sentences in terms of their ability to support intelligent information retrieval in digital library services. While aspects of this work and the previous works on citation function are relevant, what is missing is the need to identify where an author talks about their own work in context to other work, showing why it is different or how it fills a gap. As discussed in the Introduction, one of the problems with poor writing in *Related Work* is bland statements that provide lists of citations. Cited works should be ones that have implications for the author's work (Maxwell, 2006). To provide such feedback, we must capture this context in addition to citation function.

Recognising Author Intentions – Specific phrasing has been shown to function in structuring discourse by guiding readers through a text (Hyland, 2012) and can be found to align to sections, such as the Introduction or Results. Most previous work in automating author intentions have utilised these patterns as part of their feature set. The early work of Teufel (1999) (in the domain of computational linguistics) uses cue phrases and lexical patterns that involve parts of speech and citation markers as features. Jurgens et al. (2018) shows how applying bootstrapping to Tuefel's lexicon improves citation function recognition.

Verbs have been shown to have a role in understanding citation function by determining rhetorical and semantic levels. Verbs used to report can show positive and negative aspects of evaluation in cited works and differentiate between intentions e.g in Angrosh et al. (2010) they use reporting verbs that describe (examine, propose), refer to an outcome (develop, show) or show a strength (improve). Citation forms (Swales, 1990) of integral and non-integral have been shown to be a contributing feature to author intention recognition, with studies of novice writers showing that they use a limited range of citation types (Thompson and Tribble, 2001). Our approach also uses linguistic patterns, verb types and citation types to support building our feature set, and we do this within one domain, computational linguistics (cf. Section 4).

Automated Assessment of Writing – Existing, academic writing tools have focused on identifying author intentions, such as those described by Swales (1990), that can be found in an Introduction (Cotos and Pendar, 2016; Anthony and

V. Lashkia, 2003; Abel, 2018). The Criterion online writing service, focuses on automated persuasive essay evaluation and uses recognition of discourse elements based on aspects such as supporting ideas, introductions and conclusion (Burstein et al., 2003, 2004). Several other works have focused on identifying argument components and relations and how these relate to essay scores (Ghosh et al., 2016; Song et al., 2014). Recognizing argument components in this case focuses on premises and claims largely based on the Toulmin model of argumentation (Toulmin, 2003) which is a different approach to ours. In addition, all this work focuses on feedback for persuasive essays which will differ in linguistic practices found in scientific papers and from the author intention structure of a *Related Work*. Overall, whilst aspects may be relevant in general, these methods would not facilitate the kind of content feedback that would help a writer with *Related Work*.

3 Author Intentions to Support Feedback

3.1 Annotation Schema for Data

The need for annotated data is something that previous methods have in common, each using an annotation schema that supports the intentions they seek. It is known that annotation schemas benefit from being task-orientated (Guo et al., 2010). We use an annotation schema developed to recognise author intentions in *Related Work* sections and provide authors with useful feedback (Casey et al., 2019). This schema uses qualities that should be present in *Related Work* sections, following (Kamler and Thomson, 2006). Qualities group into four areas: **Background** – helps the author locate their work in the field, demonstrating they understand their field and its history through indicating seminal works and relevant research fields; **Cited works** – in addition to generally identifying the field, the author should demonstrate specifically (i) which works are most pertinent to their work, (ii) how these works have influenced them and (iii) if and how the current works build on or use these methods; **Gap** – make clear what the gap is and what has specifically not been addressed; **Contribution** – having exposed the gap, the author should identify their contribution. This schema tries to isolate neutral citations that provide mere description, compared to those that highlight gaps or problems, along with identifying where an author talks about their own work and how this relates to the cited work or background in general. The sentence label schema we use can be found in Table 1, and we indicate which of the qualities each label falls into.

3.2 Annotated Dataset

The annotated dataset in (Casey et al., 2019) is composed of papers from the ACL anthology (Bird et al., 2008) that have been pre-annotated for citations and co-reference to the author's own work by (Schäfer et al., 2012). We use 94 papers with *Related Work* sections after removing one due to OCR issues. All papers were conference papers 6-8 pages in length. The authors report annotator agreement, based on Cohen Kappa (Cohen, 1960) at 0.77, which increased to 0.85 following a round of discussion.

3.3 Challenges and Changes to the Schema to Support Automation

Previous works have largely been based on annotating at a sentence level but some works have considered a smaller discourse unit such as (Shatkay et al., 2008). This smaller discourse unit does allow for instances where an author may encode two intentions in one sentence. The data we use is labelled on a sentence basis. The authors in (Casey et al., 2019) acknowledge that this may not be satisfactory as some sentences could be multi-labelled, such as where an author highlights a gap then state their contribution. Just as this is challenging for an annotator to label, it may be more so for an automated classifier.

From the annotated data, some categories were rare and were collapsed into more frequent categories. The distinction these rare labels offered was not necessary. In particular, the two labels that denoted the author said something positive about a citation/field were merged into the appropriate cited/field evaluation categories. We merged the two categories (author's work builds on/adapts/uses X, and author's work is similar to X) into one category. Finally, comparison of two cited works was merged to cited work description. Table 2 shows the distribution of the labels in the 94 *Related Work* sections. We abbreviate some of the labels from the original schema.

Quality	Label	Description
Background	BG-NE	Description of the state of the field, describing/listing known methods or common knowledge. No evidence i.e. citation is not included
	BG-EP	As above but evidence provided i.e.citation included
	BG-EV	Positive, shortcoming, problem or gap in the field
Cited Works	CW-D	Describes cited work, this could be specific details, or very high level details or nothing more than a reference for further information
	A-CW-U	Author's work uses/builds/similar to a cited work
	CW-EV	Positive, shortcoming, problem or gap about the cited work
Gap and Contribution	A-D	Author describes their work with no linguistic marking to other's work or being different
	A-GAP	Author specifically says they address a gap or highlights the novelty of their work
	A-CW-D	Author's highlights how their work is different to cited work
	TXT	Sentence provides information about what will be discussed in the next section

4 Methods

4.1 Classifiers

All models are trained using LibSVM (Chang and Lin, 2011) with a linear kernel and default settings. SVM's are known to be robust to over-fitting, and perform well in document classification tasks when features are sparse and the set of them is large. SVM does not assume statistical independence, making it a more suitable method when features may be overlapping or interdependent. Initially, we experimented with decision trees. However, when we tested multiple iterations for reliability, both Random Forest (Breiman, 2001) and C4.5 (Sumner et al., 2005) were not only consistently lower in performance (12%) but rare categories showed large variation (15%) between iterations and in some instances labels would not classify. We believe this was due to feature overlap and the problem previously discussed with some labels being multi-class. Due to the unreliability of its performance, we did not pursue the decision tree approach further.

4.2 Features

Features were motivated by other works that classify author intention and citation function, and were extracted on a sentence basis. We use a vector of sentence features as the input to our classifier. The following list summarises the features used in this work.

- **Structural** Positional information, such as relative sentence position, has been useful for identifying background sentences, as these are more likely to occur in an Introduction or *Related Work* than a Results section (Teufel, 1999; Jurgens et al., 2018; Liakata et al., 2012). We do not include relative sentence position but instead use a binary indicator for paragraph start and end sentence, manually added from the original PDF. This is similar to the feature in (Teufel and Moens, 2002) of paragraph structure. We expect this to work like a sentence relative position, as many background statements will come at the start of paragraphs, and towards the end of paragraphs authors will be more likely to relate their own work.

- **Citations Type Features** Authorial and parenthetical citations (Swales, 1990) have been shown to be useful in determining author intention. We build a parser to identify three types of citation: (i) those that form part of the syntax of the sentence (authorial); (ii) those that refer to the name of a system or known algorithm; and (iii) those that provide supporting evidence, found in parenthetical with no syntax e.g **in (Smith, 1990)** although in parenthesis would be of type (i). This slightly differing approach we believe will help to discriminate between background sentences with citation evidence and citation description sentences. We also take a count of type 1 and 2 citations and a separate count of type 3 citations.

- **N-grams** Work based on a much larger corpus than ours show that n-grams contribute significantly to the performance of their classifier. Liakata et al. (2012) show a 40% contribution and Cotos and Pendar (2016) work is mainly based on n-gram features of 650 Introductions. While our corpus is much smaller (Related Work from 94 articles), we nevertheless include binary values for bigrams and trigrams occurring with a frequency of ≥5. We do not remove stop words.

- **Co-referencing Features** Often discussion about a work or the author's work will be carried out over several sentences. The later sentences can have co-references to the original citation such as *'this paper' 'this model'* However, as Teufel (1999) shows, determining what she calls agents (e.g US_AGENT - 'our paper'), these co-reference phrases can be ambiguous. For example does *'this paper'* mean the previously cited paper or it is referencing the author's work. We take a different approach and use the annotations in our corpus for (i) references to the authors own work, (ii) cited work. In addition, we manually mark co-reference to multiple works in background sentences e.g *'previous work has been done in the area of ..'* and co-reference to previously cited work e.g. *'these previously mentioned works above'*

- **Verb Features** We use part of speech (POS) tags to identify verbs, treating the six possible VB tags (VB, VBD, VBG, VPN, VBP, VBZ) as binary features of being present or not in a sentence. Having substituted the co-references, described above, in a sentence we then parse for dependency extracting subject and object verb pairs in every sentence.

- **Linguistic Patterns** Teufel (1999) makes available a list of patterns containing cue phrases/words, lexical categories, constrained by PoS tags, developed on computational linguistic literature. Like (Jurgens et al., 2018) we use this list and adapt it manually using patterns we observe in *Related Work*. For example, one aspect we consider is contrasts that occur at the beginning of a sentence and those that happen mid sentence, creating lexical expressions to capture these. We also produce finer grained lexicon patterns for discourse connectives as these are indicative of a continuation sentence. Within those patterns we include citation types and co-references as described above.

- **Sentiment** We use our adapted version of Teufel's list to identify positive and negative words (e.g *advantageous* - positive adjective, *inaccurate* - negative adjective). In addition, we use the 82 polar phrases found in (Athar, 2014). We parse each sentence and count the positive and negative words.

- **Counts** Counts of sentence words, nouns, adverbs, discourse connectives.

- **Subject** We assign a sentence subject label before assigning a sentence label to decide if the sentence is about a citation, background or field information, author's work, or a combination of author's work and cited work. This subject feature is based on rules of sentence and previous sentence features e.g our finer grained approach to discourse connectives in conjunction with co-reference markers help us to understand subject.

5 Experimental Setup and Evaluation

5.1 Baseline

We provide two baselines, one with n-gram features only and one with all features based on the majority class.

5.2 Evaluation

Our work is similar to other automated classifications but not directly comparable as schemas and experimental settings differ. Our results are more comparable to the works of (Teufel, 1999; Jurgens et al., 2018; Teufel and Kan, 2011) as we use the same pattern list from (Teufel, 1999) as a starting point. These works use Naive Bayes, Random Forest and Maximum Entropy as classifier methods. We report their published Macro F1 scores, range of F1 scores for labels and the number of labels in the schema for comparison (Table

Features	Prec	Recall	F1	Acc%
ALL	.69 (.005)	.7 (.004)	.7 (.005)	70 (.48)
Cotos(2016)	.686	.549	.61	72.9%
Teufel(2011)	.478	.376	.4142	66.8%

Table 3: Classifier Performance, Mean scores after 10 iterations, Variance in brackets

System	Macro F1/Range	Label No.
(Teufel and Kan, 2011)	0.41 (0.19-0.81)	8
(Jurgens et al., 2018)	0.53	6
(Teufel, 1999)	0.68 (0.28-0.86)	12
(Cotos and Pendar, 2016)	0.61 (0.36-0.85)	17
Our Work

- no novel feat	0.54 (.15-.87)	
Baseline		
Ngram(B,T)	0.39 (.02-.68)	
Majority	0.57 (-)	

Table 4: Classifier Comparison, * significant 0.01

4). Also included is the work of (Cotos and Pendar, 2016) which focuses on writer feedback for Introductions. This is a much larger corpus using 650 annotated Introductions but fewer features, focusing on unigram and trigrams. However, it also uses SVM for classification. Where available, we also report Precision, Recall and Accuracy from these works to compare against our best performing model in Table 3.

Reliability of our model is important to ensure consistent results. Therefore, in addition to 10-fold cross validation, we carry out 10 iterations of the All features model, reporting on mean precision, recall, F1, Accuracy and variance in Table 3. None of our iterations produced significantly different results, demonstrating reliability and low variation. Significance, where noted, is tested with corrected t-test, p <0.01, (Nadeau and Bengio, 1999).

We also look at the features in our model and how they influence the label F1 scores with leave one out (LOO), which highlights the performance decrease when a single feature is omitted and single features (SF), which highlights the contribution of a single feature to performance. Looking at individual label features is important as having just one label perform poorly, such as being able to recognise an author gap sentence or where an author says how their work is different, will impact our goal of giving writer feedback.

6 Results

6.1 Classifier Performance

We compare our results to those mentioned in Section 5, Table 4. Comparing F1 scores overall, we outperform the other systems by a reasonable margin. In addition, the range of F1 scores for our labels are also similar to other systems. We outperform the work of Cotos and Pendar (2016), who looks at classification for Introduction feedback, despite their work being based on a bigger annotated corpus. We significantly outperform both our baselines of n-grams and majority class. We rerun our classification (no novel feat) removing the manual additions we added to the original pattern list of Teufel (1999), removing co-references and subject labels. This results in lower performance, significant (p <0.01) than our all features and our majority baseline.

6.2 Feature Contribution

Here we examine feature contributions by single feature and leave one out cross validation runs (Table 5). For each category, we highlight the lowest score in bold, which corresponds to the feature being left out. We place in brackets any scores higher than the All features model.

More frequently occurring categories, cited work description (CW-D), background sentences with and without evidence (BG-NE, BG-EP) are more robust to feature omissions. Features are not independent, so many of the patterns cover the n-gram features which may be why leaving out n-grams has less impact than expected. In the lower part of the table, n-grams as a single feature contributes most to labels TEXT and CW-DESC. Compared to other works that have used n-grams, our size is much smaller at <3000, whereas Liakata et al. (2012) used ∼42000 and Cotos and Pendar (2016) had ∼27000. It would be expected in a much larger corpus that n-grams will contribute more as a feature.

The removal of the paragraph start and end markers makes relatively little difference, with the exception of the author gap category (A-GAP): Being a rare category, this addition although small is important. Sentiment contributes in a small way to performance but particularly in the evaluation labels (BG-EV, CW-EV) as expected. Surprisingly, sentiment contributes to the text label. However, within text-labelled sentences, both these counts are zero, which may explain why it con-

Table 5: F-Measures for Features and Labels,10 cross validation

tributes here. Neither of our evaluations labels (BG-EV, CW-EV) perform as well as expected. These two labels are merged from the annotation schema, positive and shortcoming/problem into one evaluation label. These original labels are both quite different linguistically and we speculate that this might prove difficult for the classifier.

Total citation counts and counts of adverbs, words, nouns and discourse connectives seem to actually make the performance of the classifier worse on many of the labels, although not significantly so. There is an overlap in total citation counts with the count of our citation types perhaps indicating this feature could be omitted.

We note that the features we add to the pattern list, dependencies and subject label show very close to performance of the All features model. We observe better performance on the rare label author gap (A-GAP) with just these features alone.

Most categories are negatively impacted by the removal of the subject label with the exception of author uses/build/similar to cited work (A-CW-U) and authors work differs from cited work (A-CW-D). As a single feature we see that subject is important to the classifier performance and contributes to several of the labels - background with no evidence (BG-NE), cited work description (CW-D), author description (A-D) and author and cited work differ (A-CW-D). Leaving out subject label was the only feature to cause a drop in classifier performance that was significant. In Table 6 and Table 7 experiments from using a gold subject label and using a history feature of previous label are presented. History label was previously shown by (Liakata et al., 2012) to contribute to sentence classification. Our gold subject label was determined from the annotated label. We see that determining this label accurately has an almost 15% increase in the performance of our classifier and an increase in F1 score for all label categories. Including a previous label also increases the classifier performance, but this increase was not significant.

7 Discussion and Conclusions

We use a manually annotated data-set designed for support of writer feedback of a *Related Work* section and show that we can outperform existing similar methods. We describe our feature set, proposing some novel features such as co-reference specific to *Related Works*, citation types and include these in our adapted pattern set. We show the introduction of our features over and above the original pattern features (Teufel, 1999) was a contributing factor to the performance of our classifier. This highlights the importance of understanding the author intentions of interest and looking for patterns that are specific to these. This major contribution of patterns though is also a limitation in that this is built on a study of patterns that occur within the computational linguistic domain and how it would perform in another domain remains to be investigated. Recent work of (Asadi et al., 2019) show that using WordNet roots for Nouns, e.g where nouns are taken to their more general form (e.g., *mm* and *cm* become *quantity*, is a useful feature for author intention identification. The application of WordNet is one possible

Table 7: Classifier Performance, Mean scores after 10 iterations

avenue that may assist in transitioning our pattern list to another domain.

In future work, we intend to investigate augmenting our pattern set further. Jurgens et al. (2018) implement a bootstrapping pattern that identifies over four times the manually curated patterns, identifying new patterns that apply in a citing sentence, the preceding or following sentence. Bootstrapping to expand seed cue phrases based on rhetorical relations (Abdalla and Teufel, 2006) has also been successful. Incorporating more information from a preceding or following sentence we believe could help classify sentences where there is no linguistic clue as to the subject e.g. those that carry on describing a cited work but their is no co-reference to signal the subject. Understanding sentence subject is important, currently it contributes to the classifier performance but we show an almost 15% increase in performance that could occur using a gold sentence subject label. Having a way to improve our current implementation of sentence subject assignment would be beneficial.

Our overall intention for this work is to support writer feedback and so we intend to investigate how well our current level of automatic recognition of author intentions can support feedback and how useful this is to novice writers.

Abstract

In this paper we study the performance of several text vectorization algorithms on a diverse collection of 73 publicly available datasets. Traditional sparse vectorizers like Tf-Idf and Feature Hashing have been systematically compared with the latest state of the art neural word embeddings like Word2Vec, GloVe, FastText and character embeddings like ELMo, Flair. We have carried out an extensive analysis of the performance of these vectorizers across different dimensions like classification metrics (.i.e. precision, recall, accuracy), dataset-size, and imbalanced data (in terms of the distribution of the number of class labels).

Our experiments reveal that the sparse vectorizers beat the neural word and character embedding models on 61 of the 73 datasets by an average margin of 3-5% (in terms of macro f1 score) and this performance is consistent across the different dimensions of comparison.

1 Introduction

The use of text vectorization for NLP applications has its roots in information retrieval and allied fields for measuring semantic similarity as enshrined by Jones (1972). Traditional methods for converting text into a fixed length vector include a bag of words representation (Zelling, 1954), where each word in the vocabulary is represented by a unique index, Tf-Idf builds upon this by weighting the frequency of each word by the inverse count of its document occurrence thereby mitigating the noise induced by Zipfian distribution of words in natural language. These vector space models are often referred to as sparse discrete representations owing to the large number of zeros that predominate their vector representations. Building on this foundation, research direction was aimed at generating continuous distributional semantics of text using factorization of word co-occurrence matrix as evinced in Latent Semantic Analysis (Dumais et. al, 1988, 2004). These SVD (Singular Value Decomposition) based approaches form the precursors of modern topic modeling (Blei et. al, 2003, 2002). Feature hashing often referred to as the hashing trick (analogy to the kernel trick) involves using a non-cryptographic hash function to convert text (i.e. word tokens) to a corresponding numerical representation, these representations are made to be uniformly distributed by including a secondary hashing function which alters the sign bit of the output of the first hashing function. These have been shown to have provable error bounds (Weinberger et al, 2009) and have been previously used for collaborative spam filtering and large scale multi-task learning (Attenberg et al, 2009, Weinberger et al, 2009).

The use of the word neural word embeddings was first coined by the authors (Bengio et al, 2003) in their landmark paper which showed the efficacy of using hidden layer representations for measuring semantic similarity between words. Building upon this, it was further demonstrated by (Collobert et al, 2011) that unsupervised pre-training of word vectors preserved their syntactic and semantic similarities which lead to state of the art results on many downstream tasks. But it wasn't until introduction of Word2Vec (Mikolov et. al, 2013) that neural word embeddings became mainstream, this in a sense opened the flood gates of research into these models. GloVe (Pennington et. al, 2014) uses a log-bilinear regression model that combines the advantages of the two major model families in the literature - global matrix factorization and local context window methods. Enriching word vectors with subword information has proven to be effective as can be seen in fastText(Bojanowski et.al, 2017). Recent embedding models like ELMo

Proceedings of Recent Advances in Natural Language Processing, pages 188–197,
Varna, Bulgaria, Sep 2–4 2019.

(Peters et. al, 2018) use masked language modeling and textual entailment tasks to generate context-sensitive character-level representations. In the same vein, Flair embeddings (Akbik et. al, 2018) leverage the internal states of a trained character language model to produce a novel type of word embedding which the authors allude to as contextual string embedding. Moving from individual word representations to document and phrase level representation, we observe a less spectacular retinue of research work. Notable among these are Skip-Thought (Kiros et al, 2015) and InferSent (Conneau et al, 2017). Recently proposed Universal Sentence Encoder (Cer et. al, 2018) which uses multi-task transfer learning based on the transformer architecture (Vaswani et. al, 2017) to deliver promising results on several natural language inference tasks.

In light of these prolific advances made in the field of text vectorization, it becomes necessary to evaluate the different algorithms on downstream tasks and juxtapose their performance with the traditional non-neural counterparts. Existing evaluations (Baroni et. al, 2014) have only focused on the semantic aspect of these representations while ignoring tasks like text classification. Even when comparisons are made on benchmarks similar to the GLUE benchmark (Wang et. al, 2018), they are almost always made with state of art deep neural network based classifiers, the non-neural classifiers like Random Forests, SVMs and GradientBoosting are left out. To the best of our knowledge there is no existing research which comprehensively evaluates the performance of modern text vectorizers on text classification tasks, it is this research gap which we want to bridge in the present study. The main contributions of the paper are the following – 1. We have collected, curated and standardized a set of 73 different datasets which cover all aspects of text classification in particular and language modeling in general. 2. We have extensively analyzed the performance of neural vectorizers like Word2Vec, GloVe, FastText, ELMo and Flair on these datasets across many dimensions like dataset-size, class imbalance, classification metrics and juxtaposed it with their count-based non-neural alternatives like Feature Hashing and Tf-Idf. 3. We have also reported results on the performance of traditional ML classifiers, since our main aim is to study the efficacy of vectorization algorithms we haven't included any neural network based classifiers in the present study. 4. Our benchmark contains 73 datasets in comparison to GLUE which has only 10, thereby making it more diverse and challenging. Finally, we have made our source code[++], datasets[**] (including train and test splits), result files and all other necessary information publicly available so that, researchers can reproduce our results and further the progress in the field. While not central to the study we have also carried out an interpretation analysis on the predictions of these vectorizers by using model agnostic, locally interpretable explanations (Riberio et. al, 2016), the results are not included in the paper, however interested readers are encouraged to refer to Appendix A for more details.

The paper is organized as follows – Section 1 introduces the paper and gives an overview of the prior research work. Section-2 provides details of our datasets and the models used. Section-3 elucidates the approach we have taken for our experiments. Section-4 presents the results of our experiments, including an extensive analysis. Section-5 concludes the paper and provides useful future research directions.

2 Data & Model Details

We have collected the datasets from a variety of online sites like Kaggle, Crowdflower (now known as FigureEight), DataTurks, UCI repository and others. They have been grouped into 8 categories for ease of analysis, these are – emotion, sentiment, reviews, medical, general classification, news, spam-fake-hate-ironic and other. The general classification category set includes things like gender classification, website categorization weather and disaster detection from tweets etc. The other category set includes a set of language tasks like natural language inference, duplicate question detection, objectivity-subjectivity analysis which have been recast in a classification framework to promote uniformity. Details about the metadata of each category is present in table 1. All the end tasks are different text categorizations ranging from classification of sentiments, emotions, news articles, reviews, gender, hate speech detection etc. All the datasets have been standardized in a common format, this format contains only two fields one for the text data other for the class label. Refer to Appendix B for necessary details about the data standardization process. As can be inferred from table 1, all the categories contain more than a

Table 1: Details of datasets on a category basis

million sentences on an average. Out of the 73 datasets 17 contain more than 50K data samples, 39 contain less than 10K data points and 17 contain between 10K to 50K rows. On a per category basis we observe that the general classification category contains the greatest number of datasets whose size is greater than 50K, while the sentiment category contains the maximum concentration of datasets of size less than 10K. To get an insight into the distribution of the number of rows per category refer to the box and whisker plot in figure 1, the y-axis contains the number of rows on a logarithmic scale (base 10).

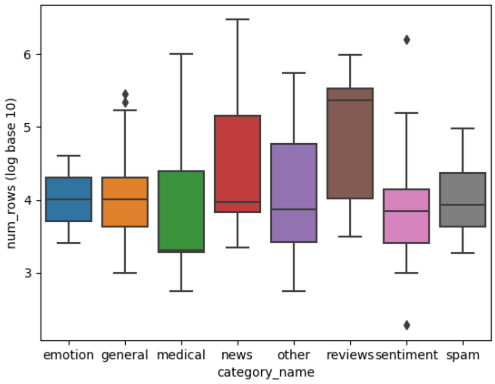

Figure 1: Box plot of distribution of rows per category

The neural embedding models have been pre-trained** in the following way - the Word2Vec model (of dimension 300) and has been trained on Google News Corpus (100 billion words). For greater ease of comparison both the GloVe and fastText models have a dimension of 300 and have been trained on the Common Crawl Corpus (640 billion words). The ELMo embedding has also been trained on Google News Corpus and as for the Flair embeddings we have used the original model provided by the authors which has been trained on English Wikipedia text. To provide a level-ground of comparison with the neural counterparts both the Tf-Idf and Feature Hashing vectorizers have a dimension of 300. For the hashing vectorizer, a variant of Murmurhash3(Appleby, 2015) has been used to project the word tokens in a lower dimensional embedding space.

3 Approach

A systematic and comprehensive comparison of the vectorizers entails evaluating them across several dimensions, reporting the results using relevant metrics and then interpreting the results. The dimensions considered in the present study are the following – 1. Dataset-size, we consider 3 mutually exclusive and exhaustive ranges: less than 10K, greater than 50K and between 10K and 50K, these ranges have been chosen because they provide the most coverage across the selected datasets. For each of these ranges we analyze the performance on a per category basis. 2. Imbalance measure as reflected in the distribution of number of class labels (using equation 1).

$$Imbalance = \sum_{\forall\, n1,n2} \frac{|n1-n2|}{n1+n2} \qquad (1)$$

In equation 1, n1 and n2 are the number of samples belonging to classes C_i and C_j. For a given dataset containing N different classes we find the ratio of the absolute difference of the number of data-points in the two classes to the total number of data points in the two classes, we calculate this for all pairs of classes. For a perfectly balanced dataset this value will be zero, higher the value more will be the imbalance measure, there is no upper bound on the value. For the imbalance measure we calculate the terciles and divide the datasets into three parts based on the interval of these tercile values they are – [0, 1.03), [1.03, 4.46), [4.46, ∞], where ∞ denotes the max value across all the datasets.

As mentioned in section 1, we have only considered non-neural classifiers as our main aim is to study the performance of vectorizers. The classifiers included in the present study are Random Forests, GradientBoost, AdaBoost, SVM (Linear Kernel) and Logistic Regression. These have been included because they represent a healthy mix of both bagging and boosting approaches along with linear models. For each dataset we measure its performance across all combinations of vectorizers and classifiers.

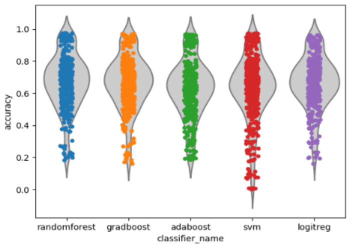

Figure 4: Classifier accuracy (global)

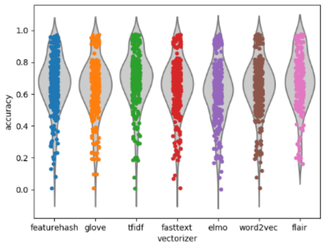

Figure 5: Vectorizer accuracy (global)

4 Experiments & Results

All the experiments have been performed on a 32 GB Intel i7 processor, with a clock rate of 3.40 GHz. Since all the embedding models have been pre-trained, using a dedicated GPU doesn't result in a significant speedup, as we have noticed an increase of only 1.5x - 2x while using a Nvidia GTX Geforce 1080 Ti, 11 GB graphics processor. The total training time for all combinations of datasets, vectorizers and classifiers is more than 3 weeks.

We have carried out basic pre-processing of the text data like – case normalization, stopword removal, punctuation and special character removal followed by word tokenization, though it will be interesting to see the effects of more sophisticated pre-processing like lemmatization on the results. The hyperparameter settings of all the classifiers have been set to default values as used in the scikit-learn library except for number of trees in the Random Forest model which has been set to 51. Figures 2 and 3 provide a global view of the macro f1 score of the vectorizers and classifiers averaged across all the datasets. For a given vectorizer we have calculated the mean performance metric (precision, recall, accuracy) across all classifiers and datasets. As can be inferred from figure 2, tf-idf and feature hashing consistently outperform their heavy weight neural counterparts, among the neural vectorizers flair embeddings demonstrate competitive performance on almost all datasets. The violin plots shown in figures 4 and 5 elucidate the performance of the classifiers and vectorizers (based on accuracy) under the same conditions as figures 2 and 3. We can observe the same trends in these figures as we have previously seen in figures 2, 3. With respect to classifiers, Random Forests, Gradient Boost and Logistic Regression are always among the top performing trio. Apart from this, we have also seen that our results[*] conform to widely established trends like the negative correlation between the increase in number of classes and classifier performance metrics, we will expand upon this more in the section on analyzing performance metrics based on class imbalance.

4.1 For Size Less Than 10K

Tables 2 and 5, illustrate the performance of vectorizers and classifiers for all datasets whose size is less than 10K. The results have been grouped on a per category basis, in the category column the number inside the brackets denotes the number of datasets which fall into that category for the given dataset size range. The mean values of Precision Recall and Accuracy have been juxtaposed by following the notation Pr./Rec./Acc. We notice a wide variance in the performance metrics across the categories especially for reviews and emotion. The reason for this is that the emotion category has a dataset which has 18 classes while only containing 2524 samples, same is the case for reviews which has a dataset containing 41 classes. It is this small sample size and sparse data problem which reflects in the suboptimal performance of the vectorizers and classifiers. The number of class labels for all the other datasets in this size range lies between 2-5. Again, we observe that, tf-idf and feature hash come out on top consistently beating the neural counterparts (except for Flair) by a margin of 10% (in terms of accuracy). On the classifier front again Random Forests, Gradient Boost and Logistic Regression edge out SVMs and AdaBoost. In context of the vectorizers we would like to make a case for feature hashing, extolling its many virtues which include – low computational footprint, the absence of a fixed vocabulary, theoretical error bounds and competitive performance, which serve to make it an ideal candidate for establishing strong baselines.

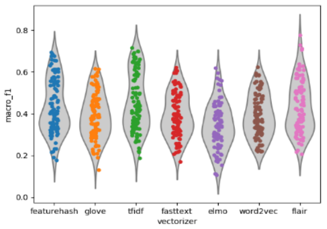

Figure 8: Performance (f1-score) for imbalance range [1.03, 4.46)

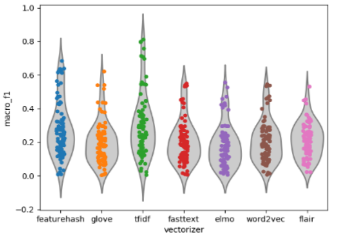

Figure 9: Performance (f1-score) for imbalance range [4.46, ∞)

4.2 For Size Between 10K – 50K

Tables 3 and 6 provide an overview of the performance metrics of the vectorizers and classifiers under the same conditions as tables 2 and 5 the only difference is that the range of datasets is between 10K and 50K, since Medical and Other categories have no datasets in this range, they haven't been included in the tables. The trends observed here are consistent with the ones we have observed in section 4.1. The average number of class labels in this range is less than 10 for all categories except for news, which has a dataset containing 75 classes and emotion where the number of class labels is 13 for a given dataset.

4.3 For Size Greater Than 50K

Tables 4 and 7 illustrate the performance metrics for 17 datasets whose size is greater than 50K, the emotion category is missing because it has no datasets in this range. The presence of a dataset with 27995 class labels in the general classification category skews the results and leads to the observed performance metrics, same is the case for news which has a dataset containing 756 classes. For all the experiments we have used a train-test split of 80-20, the seed used for random split is kept same so the results will be consistent while reproducing. Again, the trends noticed here are faithful to the observed trends in section 4.1 and 4.2. Here we would briefly like to mention that our intention is not to undermine the spectacular advances of deep learning and state of the art results it has produced in NLP, we are aware of the fact that only deep models are capable of scaling in performance with the increase in data-size, however it might seem like an overkill in situations where simpler models do an equally good job. Refer to figure 6 (dataset used is of a news classification task), for a case where a neural embedding (Flair) beats every other non-neural and neural counterpart (in terms of accuracy). Figure 7 also illustrates an accuracy heatmap where the results are more in tune with the general trends of the study, the dataset used here is one of agreement-disagreement between sentence pairs.

4.4 Metrics Under Class Imbalance

Tables 8, 9 and10 demonstrate the performance of the vectorizers across the three selected strata of imbalance measure. Tf-Idf and Feature Hash shines in all three cases. As a general trend we have noticed that the accuracy of the vectorizers increase when the text is more verbose (i.e. news) in comparison to limited character content. (i.e. tweets). Flair embeddings show a competitive performance (when the imbalance measure is less than 4.46), sometimes even outperforming the sparse vectorizers, as per the results aggregated it is clearly our neural vectorizer of choice. The violin plots in figures 8 and 9, illustrate the performance of the vectorizers (macro f1 score averaged across all datasets and classifiers) under different ranges of class imbalance (as calculated using equation 1). In all these cases feature hashing has the highest median performance as can inferred from the greatest density of points in the center. The tf-idf vectorizer has the highest variance in its performance because of a skew in class distribution, which in turn skews the performance of this count-based vectorizer. Word2Vec, FastText and GloVe have almost similar performance.

5 Conclusion & Future Work

"*Neural Embedding models are not a silver bullet*", it is in this spirit that we have carried out the present study and reported the results. The analysis presented here might serve as a starting point for researchers new to this field, who might be overwhelmed by the plethora of alternate text vectorizers available. It will also serve as a strong baseline for future research direction in the domain of text classification. In the future we would like to use neural classifiers (CNNs and RNNs) in place of traditional ones presently used, so that we can provide a complete picture of classifier performance across the entire spectrum. Fine-tuning models like ELMo, ULMFit (Howard and Ruder, 2018) and observing the change in results will be an interesting line of future work. Additionally, we would also like to explore other embedding models like BERT (Devlin et. al, 2018) and CoVe (McCann et.al, 2017).

Abstract

We present ARAP-Tweet 2.0, a corpus of 5 million dialectal Arabic tweets and 50 million words of about 3000 Twitter users from 17 Arab countries. Compared to the first version, the new corpus has significant improvements in terms of the data volume and the annotation quality. It is fully balanced with respect to dialect, gender, and three age groups: under 25 years, between 25 and 34, and 35 years and above. This paper describes the process of creating the corpus starting from gathering the dialectal phrases to find the users, to annotating their accounts and retrieving their tweets. We also report on the evaluation of the annotation quality using the inter-annotator agreement measures which were applied to the whole corpus and not just a subset. The obtained results were substantial with average Cohens Kappa values of 0.99, 0.92, and 0.88 for the annotation of gender, dialect, and age respectively. We also discuss some challenges encountered when developing this corpus.

1 Introduction

As the popularity of natural language processing (NLP) based tools increases, there is a rising need for language resources such as annotated corpora to develop NLP tools. In this regard, Arabic lags behind other languages due to several reasons. First, Arabic is complex at various levels of linguistic representation (phonology, orthography, morphology, and syntax). Even though native Arabic speakers prefer using Modern Standard Arabic (MSA) for official communications, we are witnessing with the popularity of social media a rise in the use of dialectal Arabic for informal online interactions such as those found in blogs, forums, chats, tweets, posts, etc. (Mubarak and Darwish, 2014; Bouamor et al., 2018).

The content written by the users in social media sites can reveal some characteristics and attributes about them, which is the main focus of author profiling research. However, the lack of Arabic language resources limits that research on author profiling for the Arabic language in particular dialectal Arabic.

We present in this paper ARAP-Tweet 2.0, which is a large-scale manually-annotated multi-dialectal Arabic corpus. A first version of this corpus was presented in (Zaghouani and Charfi, 2018a,b) and it was extended significantly in terms of data volume, number of users, and annotation quality. ARAP-Tweet 2.0 covers dialects from 17 Arab countries and 15 regions. The number of users per region is 198, including a total of about 3000 users and approximately 5 million tweets. All users' accounts were manually annotated with respect to the dialect, gender, and age. Thereby, we distinguished three age groups: under 25 years, between 25 years and 34 years, and 35 years and above. Moreover, significant effort was put in checking and improving the annotation quality.

The rest of this paper is organized as follows. Section 2 presents related work and Section 3 describes the methodology used in creating and annotating our corpus. Section 4 reports on the verification of the annotation as well as the evaluation. Section 5 discusses some challenges that we encountered when developing this corpus. Finally, Section 6 concludes the paper and outlines possible directions for future work.

Varna, Bulgaria, Sep 2–4 2019.

2 Related Work

Most research on Arabic NLP has focused on Modern Standard Arabic (MSA) (Habash, 2010). There are many parallel and monolingual annotated data collections with syntactic and semantic information such as the different iterations of Penn Arabic Probanks (Palmer et al., 2008; Zaghouani et al., 2010, 2012) and treebanks (Maamouri et al., 2010). Based on such resources, various tools were developed for syntactic parsing and morphological analysis (Habash, 2010).

Even though there are relatively many resources for MSA, Dialectal Arabic (DA) lags behind in terms of available resources. There have been some limited efforts toward creating resources for the most popular dialects such as the Egyptian and Levantine dialects which were presented in (Habash et al., 2013; Diab and Habash, 2007; Pasha et al., 2014). For example, Habash et al. created resources for morphological analysis of Egyptian dialect (Habash et al., 2013). For their work on machine translation, Zbib et al. (2012) created Levantine-English and Egyptian-English parallel corpora using crowd sourcing. Khalifa et al. (2018) created a morphologically annotated data corpus of Emirati Dialect.

Khalifa et al. (2016) created a corpus of 100M words covering various Arabic dialects. Other related projects worth to be mentioned are: the Egyptian Arabic Treebank (Maamouri et al., 2014); the Levantine Arabic Treebank (Maamouri et al., 2006), The Curras Palestinian Arabic annotated corpus with more than 70,000 words of various genres (Jarrar et al., 2014).

Furthermore, AlShargi et al. (2016) created a Yemeni (Sanaa Dialect) dataset and also a Moroccan Arabic corpus, while Al-Twairesh et al. (2018) built SUAR, a Najdi Arabic corpus annotated with the morphological analyzer MADAMIRA (Pasha et al., 2014). Finally, Voss et al. (2014) presented a Moroccan Arabic corpus annotated for code-switching (French, Berber and Morrocan Arabic).

Moreover, there have been some efforts towards creating Dialectal Arabic corpora by either translating existing corpora to dialects or by crowd sourcing annotation for data collected through various sources such as microblogs (e.g., Twitter). Along these lines, DART was developed as a Twitter based data set of dialectal Arabic covering five Arabic dialects: Egyptian, Levantine, Gulf, and Iraqi (Alsarsour et al., 2018). The annotation of this corpus was done through crowd sourcing. Bouamor et al. (2014) presented a multi-dialectal parallel corpus with 2,000 sentences translated to MSA, Tunisian, Jordanian, Palestinian and Syrian Arabic. Later on, MADAR was developed as a Multi-dialectal large scale corpus that provides parallel translation for 25 Arabic city dialects (Bouamor et al., 2018). All these efforts on creating Dialectal Arabic corpora either targeted some specific dialects only or did not provide the necessary annotation for author profiling such as annotation about age and gender.

3 Methodology

In the following, we report on the methodology and process followed for the creation, annotation, and validation of our corpus.

3.1 Corpus Overview

Twitter is an increasingly popular social media platform among the Arabic speaking people who tend to frequently use their Arabic dialects when sharing their stories and opinions. Therefore, we focused on Twitter to collect the data for our corpus. ARAP-Tweet 2.0 was developed in the context of the ARAP research project[1] and it includes about 5.3 million Arabic tweets of approximately 3000 users from the following 15 Arabic speaking regions: Qatar, Kuwait, United Arab Emirate (UAE), Kingdom of Saudi Arabia (KSA), Oman, Yemen, Iraq, Tunisia, Algeria, Libya, Morocco, Lebanon-Syria, Palestine-Jordan, Egypt, and Sudan. To the best of our knowledge, there is no other corpus that covers as many Arab regions as ours. For every region, we collected the tweets of 198 users that were equally-balanced over gender and three age groups: under 25, 25 until 34, and 35 and up. Compared to the first version of our corpus (Zaghouani and Charfi, 2018a) the number of users per region doubled in this second version.

3.2 Users

We used Twitter as our source for finding the users. In the beginning, we got a number of accounts by the geographical location of tweets and by searching on Twitter using specific words. We collected the users who posted tweets in a specific geographical location as defined in the tweet's object. As this information was not available for all

[1] arap.qatar.cmu.edu

tweets, we searched for users who had tweets that include some unique words, which are specific to a certain Arab region. Table 1 shows some of these unique words from every region covered by our corpus along with a tweet example for each word.

After that, we found further accounts using the followers of the initially identified users. Once the users were found, we hired experienced annotators to manually annotate their age, gender, and dialect. The annotators followed well-defined annotation guidelines, which are based on an extended version of the guidelines published in (Zaghouani and Charfi, 2018b). We continuously monitored the annotators' work and updated the guidelines when needed. For each region, we retrieved the tweets of the users from their Twitter profiles. The selected users had to have at least 100 Arabic tweets and at most 3200 tweets. Moreover, the tweets had to be the original tweets, which means that we did not include retweets in our corpus. The average number of words per tweet is 10.

3.3 Annotation

In the following, we report on the annotation of the users with respect to gender, age and dialect.

3.3.1 Gender Annotation

The gender was manually annotated for users and the number of users is balanced with respect to the gender across all regions, which means that we have 99 male users and 99 female users for each region. The annotation was done based on guidelines and criteria that were used to distinguish male and female users. For every user, the annotator determined the gender by analyzing the username, profile picture, and indicative words. The annotator checked the username if it is denoting a male or female name. Some users put their real photos in their Twitter profile, which also helped in determining their gender. In some cases, the username and the profile picture did not give sufficient information to identify their gender. Therefore, the annotators were looking for some indicative words in the user' s tweets. For example, the adjectives that describe feminine in Arabic usually end with ـة *(Taa' Marbootah)*. Therefore, finding words that end with the Arabic letter Taa' Marbootah such as بردانة *(Feeling cold)*, نعسانة *(Feeling sleepy)*, or جعانة *(Feeling hungry)* in the tweets of a user indicates that the writer is a female. However, if the writer is a male, the adjectives used in his tweets would not have that letter. The annotators used this Arabic rule to determine the user's gender when it was not possible to do so using the username or the profile photo. It is noteworthy that users for which the gender could not determined were not included in the corpus and were replaced by other users for which the gender could be determined as explained above.

3.3.2 Age Annotation

We annotated the age of the selected Twitter users using three age groups: under 25, 25 until 34, and 35 and above. In many cases, we were able to find the exact ages whereas in some other cases we were able to determine the correct age group without the exact age. The annotators went through the following steps to determine the age of a user:

Getting the exact age: Several Twitter users include their birth year as a part of their usernames. For example, in the username *Omda1981m* the birth year is most likely 1981, which indicates that this user is 38 years old. Some other users put their date of birth in their Twitter biography or in their other social media accounts such as Facebook, Instagram, or LinkedIn. Other users put their exact age in some of their tweets and we were able to search for those tweets using some relevant keywords in different languages as shown in Table 2.

Getting the estimated age: There were several cases in which we were not able to determine the exact age even after following the abovementioned steps. In these cases, we opted to determine the approximate ages, so that we could annotate the user with the correct age group. This was done by searching for the user on other social media networks such as LinkedIn and Facebook. We often found either their exact ages or other age related hints such as the year of their graduation from university, which helped us in making an educated guess towards the user's age. Furthermore, as a last resort for some few users, two annotators guessed the age separately using the Twitter photo. Then, we used Microsoft's online tool[2] that predicts the age by analyzing the facial features of a user through machine learning. Only users were included for which the age group guessed by Microsoft's age determination tool.

3.3.3 Dialect Annotation

As mentioned above, we selected the users for our corpus by searching for tweets with dialect spe-

[2] www.how-old.net

Region	Unique Word	User's Tweet
Lebanon-Syria	هيدا	عملت غوغل و **هيدا** يلي طلع معي
Tunisia	برشا	ذقت أنواع كسكسي متاع **برشا** دول يبقى الألذ والافضل التونسي
Iraq	اهوايه	اي والله صحيح **اهوايه** اكو هيجي نماذج مع الاسف
KSA	**جحفله**	صدقوني الموضوع فيه إنّ وفيه **جحفله**
Palestine-Jordan	هاظ	طبعاً **هاظ** اشي مفروغ منه
Qatar	احاتي	انا لعبتي **احاتي** الدراسة بس ما ادرس
Kuwait	طنطل	عاد انتي دلو مفروض تكونين **طنطل** شفيكم يا جماعه
Sudan	زول	تاني ما هعمل ريتويت لي اي **زول**
UAE	مايو ب	تسلمين يالوافيه يا راعيه الذوق يالراقيه دوم راعيه **مايوب**
Yemen	معادبش	يعني معقوله **معادبش** ولا شي كملوها السرق
Morocco	دابا	كنت ديما كنتسائل أش كاين فالكتاب **دابا** لقيت الجواب الشافي
Algeria	زاوش	كنا انا وخويا وولد عمي نصيدو **زاوش** ونسلخوه ونديروه مشوي
Libya	شهدره	عليش **شهدره** اسمي في ريبلي
Egypt	دلوقتي	سيبوني **دلوقتي** انا كويس
Oman	شقبه	انزين عادي م خسرانه بطلعي **شقبه** صدقيني

Table 1: Examples of unique words from each dialectal region with tweets that include these words.

Indicative word	Language	Tweet Example
(My birthday) ميلادي	Arabic	اكتوبر ١٩٩٠ عيد **ميلادي**
(My age) عمري	Arabic	الليله اخر يوم لي وأنا **عمري** ٢٢
(Year) سنة	Arabic	بكون ٢٣ **سنة** ان شاء الله في مونديال ٢٠٢٢
Turn	English	Hey Sosoo I will **turn** 20 in few days
(Years) Ans	French	16 **ans**?? J'ai 35 ans ma chérie

Table 2: Examples of keywords from different languages used to determine the users age.

cific words and then retrieving the users of those tweets and their followers. In addition, once we retrieved the user's tweets, the annotator(s) manually went through them and checked that at least half of the tweets are in the user's respective dialect. When the users' tweets were not mostly in their originally identified dialect, the annotators were instructed to replace them with other users from the same dialect, the same gender, and the same age group.

3.4 Tweets Retrieval

Twitter offers an Application Programming Interface (API) that allows developers to interact with Twitter's web services. We used the Python programming language with the *tweepy.py*[3] library to interact with the Twitter API and retrieve each user's timeline (tweets). Due to restrictions by Twitter, we were only allowed to retrieve at most 3,200 of the users most recent Tweets. The number of tweets of every user in our corpus ranges from a required minimum of 100 tweets to a maximum of 3,200 tweets. After collecting the maximum possible number of tweets for each user, we filtered them. Specifically, we removed the non-Arabic tweets, retweets, and short tweets that contain less than 3 words. Eventually, we kept only the Twitter accounts who had at least 100 original users tweets that are in Arabic and that have

[3] http://docs.tweepy.org/en/v3.5.0/index.html

three words at least. At the end of this process, we were able to have a well-balanced multi-dialect corpus of 198 users for 15 regions spanning 17 Arab countries. The corpus is equally-balanced with respect to gender and age.

4 Verification and Evaluation

Our main objective was to produce a multi-dialectal corpus of tweets with a very good quality of annotation so that it can be used to promote Arabic NLP research including research on author profiling. This is a major improvement compared to the previous version of the corpus. To ensure a good quality annotation, we performed two rounds of annotation for each Arab region, which means that each region was annotated by two different annotators. Next, we report on the verification and evaluation process for the annotation of dialect, age, and gender. Moreover, we present the evaluation results for each annotation category.

4.1 Verification of Dialect Annotation

The annotation was done by experienced Arab annotators who were asked to go through each file of retrieved users tweets and check the dialect used in these tweets. This step was necessary to verify the overall dialect of all tweets for every user, and not only the last tweets in a users timeline. Based on this dialect verification, we did the following:

Removing the users who post tweets in multiple dialects: many Arab users do not live in their original countries, and consequently, their dialects are affected by the dialects of the countries they live in. We opted to drop such users from our corpus and we replaced them by users from the same gender and age group and which used one dialect only.

Removing the users who have many tweets in MSA: some Arab users post few tweets in their own dialects, and they write their tweets mostly in MSA. After checking all retrieved tweets of a given user, we included in our corpus only those who have more than half of their tweets written in their dialect.

4.2 Verification of Age and Gender Annotation

Although the age was determined manually, the corpus included initially some users for which neither the exact age nor the age group could be determined with high confidence. These cases occurred for example when the age of the user was determined mainly by using their Twitter profile photo.

Moreover, the annotators found initially some difficulties with determining the gender for some users for instance when the profile did not include a real name nor a profile photo. For the latter cases, the accounts were replaced by accounts from the same gender and age group for which the age could be determined with higher confidence. For all accounts, a second round of annotation was performed by a different annotator. At the end of this phase, we were able to have two annotations from different contributors for each user account. Eventually, variations were checked and resolved by a member of the research team together with the annotators by reviewing and discussing the provided justifications for a certain annotation of age, gender, or dialect.

4.3 Annotation Evaluation

In order to evaluate the quality of the annotation, we used the inter-annotator agreement measures. We were able to have two rounds of annotation by different annotators for each user and this applies for the gender, dialect and age group for the whole corpus unlike in the previous version (Zaghouani and Charfi, 2018a) in which the inter-annotator agreement was based on a 10 % subset of the corpus data.

We measured the inter-annotator agreement using Cohens Kappa, which is a statistical measure of the degree of agreement for a data point (gender, dialect, and age in our case), that was labeled by two annotators, over what would be expected by chance. We obtained substantial results for the agreement with average Kappa values of **0.99**, **0.92**, and **0.88** respectively for the annotation of gender, dialect, and age. The exact Kappa values per region are shown in Table 3.

5 Challenges

In the following, we report on some challenges that we faced when developing this corpus:

First, we encountered some difficulties in finding user accounts for some age groups for certain regions. This was the case for Sudani, Iraqi, and Gulf females whose age is 35 or above. For some Arab regions, female Twitter users tend to hide their real name and also avoid putting their photos on social media because of the local cul-

Region	**Gender**	**Age**	**Dialect**
Lebanon-Syria	1	0.924	1
Tunisia	1	0.742	1
Iraq	1	0.696	0.9
Saudi Arabia	1	0.856	0.9
Palestine-Jordan	0.989	0.856	0.9
Qatar	0.969	0.901	0.9
Kuwait	0.979	0.886	0.9
Sudan	1	0.734	0.8
UAE	0.979	0.848	0.8
Yemen	1	0.984	1
Morocco	1	0.954	0.9
Algeria	0.959	0.931	0.9
Libya	0.989	0.924	1
Egypt	1	0.969	1
Oman	0.989	0.931	0.9
Overall	0.99	0.88	0.92

Table 3: Kappa values per region for gender, age, and dialect annotation.

ture and norms. This was an issue for us as we sometimes depend on the Twitter profile photos to guess the age especially if the username is not a real name. Second, we notice that older Arabs often write in Modern Standard Arabic (MSA) on social media, and this made the task of finding dialect users above 35 years much harder. Third, we faced an issue with Maghrebi users who often tweet in French more than Arabic.

To address these issues, we put more effort into the user selection and we replaced any users who did not fulfill the criteria explained above.

Fourth, we noticed that some users use more than one Arabic dialect to write their tweets on Twitter. For example, in Arab regions with high immigration rates such as Gulf countries, the dialect of the residents is sometimes affected by the language of their host country. Consequently, these users tweet in multiple dialects and they might mix dialects even in one same tweet. Other users had similar issues because their parents come from different Arab countries. To address this issues, all tweets were manually reviewed and users tweeting in two dialects or more were replaced by mono-dialectal users.

Fifth, we worked on regions sequentially, i.e., we selected a large set of accounts from Twitter for one region, annotated them, and then retrieved their tweets. Then, we worked on the next region. As a result, when we retrieved again the users or their tweets we noticed that some profiles were either made private or even closed. In such cases, we were no longer able to access the users profile and tweets. We addressed this problem by periodically checking the users' accounts and replacing any accounts that were deactivated or made private.

6 Conclusion

We presented in this paper a significantly improved version of a large-scale manually-annotated and fine-grained multi-dialectal corpus of Arabic tweets, which is compsed of 5 millions dialectal Arabic tweets of about 3000 Twitter users from 17 Arab countries. To the best of our knowledge, our corpus is the most comprehensive dialectal corpus in terms of coverage for so many Arab dialects and the data volume. Moreover, our corpus is balanced with respect to dialect, gender, and age. The corpus was annotated manually based on well-defined annotation guidelines and it was fully evaluated using the inter-annotation agreement measures.

The corpus was already and it can further be used to promote research on Arabic NLP including author profiling (Rosso et al., 2018), authorship attribution, dialect identification, sentiment analysis in dialectal Arabic, and bots detection in dialectal Arabic.

Acknowledgments

We thank our dedicated annotators: Hoda Ibrahim, Safaa Ellaham, Syrine Guediche for their hard work on the corpus annotation. This publication was made possible by NPRP 9-175-1-033 from the Qatar National Research Fund (a member of Qatar Foundation). Abstract

In Natural Language Generation (NLG) systems, personalization strategies - i.e., the use of information about a target author to generate text that (more) closely resembles human-produced language - have long been applied to improve results. The present work addresses one such strategy - namely, the use of Big Five personality information about the target author - applied to the case of abstractive text summarization using neural sequence-to-sequence models. Initial results suggest that having access to personality information does lead to more accurate (or human-like) text summaries, and paves the way for more robust systems of this kind.

1 Introduction

Computational approaches to text summarization may be divided into two general categories: abstractive and extractive summarization. Extractive summarization consists of selecting relevant pieces of text to compose a subset of the original sentences, whereas the more complex abstractive summarization involves interpreting the input text and rewriting its main ideas in a new, shorter version. Both strategies may be modelled as a machine learning problem by making use of unsupervised (Ren et al., 2017), graph-based and neural methods (Wan and Yang, 2006; Cao et al., 2015), among others. The present work focuses on the issue of neural abstractive summarization, addressing the issue of personalized text generation in systems of this kind.

Text-generating systems may in principle produce always the same fixed output from a given input representation. In order to generate more natural (or 'human-like') output, however, systems of this kind will often implement a range of stylistic variation strategies. Among these, the use of computational models of *human personality* has emerged as a popular alternative, and it is commonly associated with the rise of the Big Five model of human personality (Goldberg, 1990) in many related fields.

The Big Five model is based on the assumption that differences in personality are reflected in natural language use, and comprises five fundamental dimensions of personality: *Extraversion*, *Agreeableness*, *Conscientiousness*, *Neuroticism*, and *Openness to experience*. Given its linguistic motivation, the Big Five personality traits have been addressed in a wide range of studies in both natural language understanding and generation alike. Thus, for instance, the work in Mairesse and Walker (2007) introduces PERSONAGE, a fully-functional NLG system that produces restaurant recommendations. PERSONAGE and many of its subsequent extensions support multiple stylistic variations that are controlled by personality information provided as an input.

The use of personality information for text summarization, by contrast, seems to be far less common, and we are not aware of any existing work that addresses the issue of personality-dependent neural text summarization. Based on these observations, this paper introduces a personality-dependent text summarization model that makes use of a corpus of source and summary text pairs labelled with personality information about their authors. In doing so, our goal is to use personality information to generate summaries that more closely resemble those produced by humans.

The rest of this paper is structured as follows. Section 2 discusses the issues of sequence-to-sequence learning and attention mechanism for text summarization. These are the basis of our current work described in Section 3. Section 4

Proceedings of Recent Advances in Natural Language Processing, pages 205–212,
Varna, Bulgaria, Sep 2–4 2019.

reports two experiments comparing the proposed models against a number of alternatives, and Section 5 presents final remarks and future work.

2 Background

Due to the capacity of neural language generation models to learn and automatically induce representations from text (Rush et al., 2015; Nallapati et al., 2016; Mikolov et al., 2013), neural abstractive summarization has attracted a great deal of attention in the field. Architectures of this kind may not only produce high-quality summaries, but may also embed external information easily (See et al., 2017). Accordingly, these models have achieved significant results, at least in terms of intrinsic evaluation measures such as BLEU (Papineni et al., 2002) or ROUGE (Lin and Hovy, 2003), when comparing to extractive approaches (Celikyilmaz et al., 2018).

2.1 Sequence-to-sequence Learning

Neural text summarization models are often grounded on a particular kind of neural network, the sequence-to sequence architecture (Sutskever et al., 2014a; Cho et al., 2014). In models of this kind, input text is modelled as a sequence of representations carrying any contextual information from end to end in the generation process. More formally, a sequence-to-sequence model is defined in Goodfellow et al. (2016) as a neural network that directly models the conditional probability $p(y|x)$ of a source sequence, $x_1, ..., x_n$, to a target sequence, $y_1, ..., y_m$[1].

A basic form of sequence-to-sequence model consists of two main components: (i) an encoder that computes a representation s for each source sequence; and (ii) a decoder that generates one target token at a time, decomposing the conditional probability as follows:

$$p(y|x) = \sum_{j=1}^{m}(y_j|y_{<j}, s)$$

A common strategy for learning sequence representations is by making use of Recurrent Neural Networks (RNN) (Rumelhart et al., 1986). According to Hochreiter and Schmidhuber (1997), a RNN generalizes the concept of feed-forward neural network to sequences. Given a temporal sequence of inputs $(x_1, ..., x_t)$, the standard RNN computes a sequence of outputs $(y_1, ..., y_t)$ mapped onto sequences using the following equation (Sundermeyer et al., 2012):

$$h_t = sigmoid(W^{hx}x_t + W^{hh}h_{t-1})$$
$$y_t = W^{yh}h_t$$

A simple strategy for general sequence learning is to map the input sequence to a fixed-sized vector using a RNN, and then map the vector to the target sequence by using a second RNN. This may in principle be successful, but long term dependencies may make the training of the two networks difficult (Bengio et al., 1994; Hochreiter, 1998). As an alternative, Long Short-Term Memory (LSTM) networks (Hochreiter and Schmidhuber, 1997), and their simplification known as Gated Recurrent Unit (GRU) (Cho et al., 2014) are known to learn problems with long range temporal dependencies, and may therefore succeed in this setting.

The goal of a LSTM/GRU network is to estimate the conditional probability $p(y|x)$, where $(x_1, ..., x_{t'})$ is an input sequence and $(y_1, ..., y_t)$ is its corresponding output sequence whose length t' may differ from t (Cho et al., 2014). The conditional probability is computed by first obtaining the fixed dimensional representation v of the input sequence $(x_1, ..., x_{t'})$ given by the last hidden state of the network, and by computing the probability of $(y_1, ..., y_t)$ with a standard LSTM/GRU formulation in which the initial hidden state is set to the representation v of $(x_1, ..., x_{t'})$. Finally, each $p(y_j|s, y_1, ..., y_{j-1})$ distribution is represented with a softmax over all the words in the vocabulary.

GRUs are distinct from LSTMs in that a GRU architecture contains only a single unit to control when the current states 'forgets' a piece of information (Goodfellow et al., 2016). Due to this simplification, GRUs can directly access all hidden states without bearing the price of a memory state (Cho et al., 2014).

GRU architectures model sequences as causal relationships through the input sequence by examining left-to-right relationships only (Goodfellow et al., 2016). However, many sequence classification problems may require predicting an output that depends (bidirectionally) on the entire input sequence, that is, from left to right and also from right to left. This is the case, for instance, of a large number of common NLP applications that

[1] Sentences are assumed to start with a special 'start-of-sentence' token $< bos >$ and end with an 'end-of-sequence' token $< eos >$.

need to pay regard to contextual dependency when modelling phrases and sentences.

Bidirectional GRUs (Bi-GRUs) are applied to a wide range of tasks to scan and learn both left-to-right and right-to-left dependencies, which can capture complementary types of information from its inputs. The left and right hidden representations produced by GRUs can be linearly combined (θ) to form a final representation (Goodfellow et al., 2016): $h_t = h_t^{\leftarrow} \ \theta \ h_t^{\rightarrow}$.

2.2 Attention Mechanism

Sequence-to-sequence architectures have been successfully applied to a wide range of tasks, including machine translation and natural text generation (Cho et al., 2014; Sutskever et al., 2014a) and, accordingly, have been subject to a great deal of extensions and improvements. Among these, the use of more context-aware sequence generation methods (Cho et al., 2014) and the use of attention mechanism to score and select words that best describe the intended output are discussed below.

In natural language generation, attention models as introduced in Cho et al. (2014) and Sutskever et al. (2014a) are intended to generalize the text generation task so as to handle sequence pairs with different sizes of inputs and outputs. This approach, subsequently called sequence-to-sequence with attention mechanism, applies a mapping strategy from a variable-length sentence to another variable-length sentence. This mapping strategy is a scoring system over the contextual information from the input sequence (Cho et al., 2014), making a set of attention weights.

Attention-based models (Sutskever et al., 2014b; Luong et al., 2015) are sequence-to-sequence networks that employ an encoder to represent the text utterance and an attention-based decoder that generates the response, one token at a time. More specifically, neural text summarization can be viewed as a sequence-to-sequence problem (Sutskever et al., 2014a), where a sequence of input language tokens $x = x_1, ..., x_m$ describing the input text are mapped onto a sequence of output language tokens $y_1, ..., y_n$ describing the target text output. The encoder is a GRU unit (Cho et al., 2014) that converts $x_, ..., x_m$ into a sequence of context-sensitive embeddings $b_1, ..., b_m$. A general-attention decoder generates output tokens one at a time. At each time step j, the decoder generates y_j based on the current hidden state s_j, and then updates the hidden state s_{j+1} based on s_j and y_j. Formally, the attention decoder is defined by original equation proposed in Cho et al. (2014):

$$s_1 = tanh(W^{(s)} b_m)$$
$$p(y_j = w|x, y_{1:j-1}) \ \alpha \ exp(U[s_j, c_j])$$
$$s_{j+1} = GRU([\phi^{(out)}(y_j), c_j], s_j)$$

where $i \ \epsilon \ \{1, ..., m\}$, $j \ \epsilon \ \{1, ..., m\}$ and the context vector c_j, is the result of general attention (Luong et al., 2015). The matrices $W^{(s)}$, $W^{(\alpha)}$, U and the embedding function $\phi^{(out)}$ are decoder parameters.

3 Current Work

Our basic model is generally inspired from the architecture in Cho et al. (2014), with an added personality embedding layer. As in many other sequence-to-sequence models with attention, our model takes as an input a sentence, and produces as an output a set of words that summarizes the given input. The actual rendering of this output as structured text is presently not addressed.

The proposed architecture is illustrated in Figure 1, which is adapted from Cho et al. (2014), and further discussed below.

In this example, $B \ B \ B \ B$ represent the input sequence from the target sequence $Z \ X$, and C is the personality embedding representation. The five main components of the architecture are as follows.

(A) a bidirectional GRU that maps words to personality types

(B) a word embedding layer

(C) a personality embedding layer

(D) an attention mechanism

(E) a bidirectional GRU that outputs word encodings

The input bidirectional GRU (A) produces a word-to-personality compositional representation of each word. This serves two main purposes: combining the composite sequences of words and personality information, and combining attention weights over sequences in our decoder model.

The word embeddings layer (B) produces a typical word-level representation of each input word. In the present work, we make use of both random

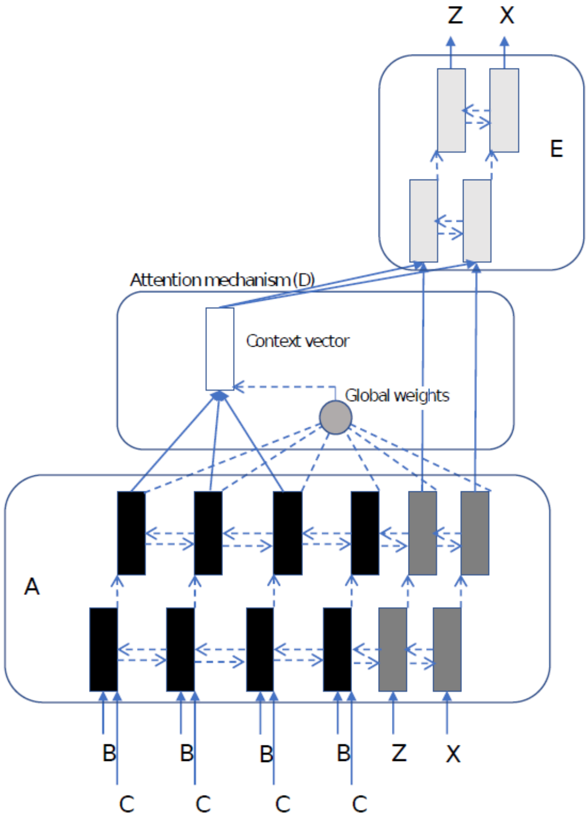

Figure 1: Model architecture

and pre-trained word embeddings. The latter are Skip-gram 300 word embeddings taken from Hartmann et al. (2017).

Word embeddings are complemented with induced personality embeddings (C) for each target author. The role of this layer is twofold. First, it is intended to learn the probability $P(Y|X, personality)$, that is, the $personality$ representation of each author for each word in the vocabulary. Second, this layer is also intended to decide which profile value should be selected (from the corpus gold standard annotation) in order to generate a summary.

The attention mechanism (D) attempts to learn a general representation from the most important parts of the input text at each time step. To this end, the experiments described in the next section will consider two score function alternatives: general attention and dot product.

Finally, the output bidirectional GRU (E) combines the attention weight representations, and produces a final encoding for each word. A loss function describe the overall generation probability, and it is intended to optimize the above parameters. This function is described as follows.

$$\ell_1(\theta, D(c), D(x,y))$$

$$= - \sum_{(X,Y)\ \epsilon\ D^c \cup D^{pr}} logP(Y|X, < k_i, v_i >)$$

$$= - \sum_{(X,Y)\ \epsilon\ D^c} logP^{fr}(Y|X)$$

The first term of the function is the negative log likelihood of observing $D^{(c)}$ and the second term for $D^{(pr)}$. $D^{(pr)}$ consists of pairs where a summary is related to a profile key and its response match to the summary, and $D^{(c)}$ has only general text-summary pairs. $< k_i, v_i >$ is the personality representation. The decoder P^{fr} does not have shared parameters. A simple epoch-based training strategy using gradient descendent is performed.

4 Evaluation

We envisaged two experiments on neural text summarization based on the model described in the previous section. The first experiment aims to assess whether a general or a dot product attention mechanism is more suitable to the task. The second experiment focuses on our main research question, that is, on whether the use of personality information does improve summarization results.

As in many (or most) sequence-to-sequence approaches to text generation, our work focuses on the selection of text segments to compose an abstract summary, but it does not address the actual rendering of the final output text, which would normally require additional post-processing. Each of the two experiments is discussed in turn in the following sections, but first we describe the dataset taken as their basis.

4.1 Data

We make use of the text and caption portions of the b5 corpus in Ramos et al. (2018), called *b5-text* and *b5-caption*. The corpus conveys 1510 multi- and single-sentence image description pairs, all of which labelled with Big Five personality information about their authors. Table 1 summarizes the corpus descriptive statistics.

The corpus was elicited from a crowd sourcing task in which participants were requested to provide both long and short descriptions for 10 stimulus images taken from GAPED, a database of images classified by valence and normative significance designed to elicit various reactions (Dan-

Table 1: Corpus descriptive statistics.

Data	Words	Average	Types	Average
text	84463	559.4	37210	246.4
caption	4896	32.4	4121	27.3

Figure 2: Stimulus image from *GAPED* (Dan-Glauser and Scherer, 2011).

Glauser and Scherer, 2011). From a set of 10 selected images with valence degrees in the 3 to 54 range, participants were first instructed to describe everything that they could see in the scene (e.g., as if helping a visually-impaired person to understand the picture) and, subsequently, were requested to summarize it in a single sentence (similar to a picture caption.)

An example of stimulus image is illustrated in Figure 2. We notice however that in the present work we only consider the text elicited from these images, and not the images themselves.

Based on scenes as in Figure 2, the following is a possible long description (translated from the Portuguese original text) of the kind found in the corpus.

> '*A black baby, about one year old. He's in a cradle. He is dressed in a dirty blue blouse, on a pink sheet, without a pillow. A blue blanket is next to the baby. It seems that he has not taken a shower for a while.*'

A single-sentence summary for the same scene (and which would have been written by the same participant in the data collection task) may be represented as the following example.

> '*A sad-looking baby.*'

In the experiments described in the next sections, texts were pre-processed by removing punctuation and numerical symbols. In addition to that, the first data split performed for the purpose of cross-validation is shown in Table 2.

Table 2: Data split

Split	Samples
Train	1358
Validation	152
Total	1510

4.2 Experiment 1: Basic Neural Summarization with Attention Mechanism

In Encoder-Decoder Recurrent Neural Networks, the global attention mechanism may be seen as a model-inferred context vector computed as a weighted average of all inputs by making use of a score function. The choice of score function may have a great impact on the overall performance of the model, and for that reason in what follows we examine two alternatives: using the dot product over the context vectors of the source, and using the learned representation over the context states.

To this end, our first experiment evaluates our basic summarization model (cf. the previous section) in two versions, namely, using general and dot product attention mechanisms. Both of these models, hereby called *sDot* and *sGen*, will make use of encoder/decoder randomized word embedding of size 300, and two encoder/decoder hidden units of size 600.

Both models were trained using Adam optimization with mini batches of size 128. The initial learning rate was set to 0.0001 with a gradient clipping based on the norm of the values. We also applied different learning rates for the decoder module, set to five times the learning rate of the encoder. In order to reduce over-fitting, a 0.5 drop-out regularization was applied to both embedding layers.

Model optimization was performed by using gradient descendent with masked loss, and by applying early stopping when the BLEU scores over the evaluation dataset did not increase for 20 epochs. Except for the embedding layer, all other

Table 3: 10-fold cross validation BLEU scores for text summarization using dot product (sDot) and general (sGen) attention. the best result is highlighted.

Model	BLEU
sGen	**13.88**
sDot	13.63

parameters were initialized by sampling from a uniform distribution $U(-sqrt(3/n), sqrt(3/n))$, where n is the parameter dimension.

We performed 10-fold cross-validation over our corpus data, and we compared the output summaries produced by both models using BLEU[2]. Results are presented in Table 3.

From these results, we notice that the attention mechanism based on the general function in *sGen* outperforms the use of dot function in *sDot*. Although the difference is small, the use of a generalized network to learn how to align the contextual information is superior to simply concatenating contextual information obtained from the global weights. Based on these results, the general attention strategy will be our choice for the next experiment.

4.3 Experiment 2: Personality-dependent Summarization

Our second and main experiment assesses the use of personality information in text summarization. To this end, two models are considered: the full personality-aware model presented in Section 3, hereby called *sPers*, and a simplified baseline version of the same architecture without access to personality information, hereby called *sBase*. In doing so, our goal is to show that summaries produced by *sPers* resemble the human-made texts (as seen in the corpus) more closely than those produced by *sBase*.

Both *sPers* and *sBase* make use of pre-trained skip-gram 300 word embeddings for the Brazilian Portuguese language taken from Hartmann et al. (2017). Both models also make use of encoder/decoder randomized word embedding of size 300, and two encoder/decoder hidden units of size 600 with general attention.

Table 4: 10-fold cross validation BLEU scores for text summarization with (sPers) and without (sBase) personality information. The best result is highlighted.

Model	BLEU
sBase	14.21
sPers	**14.58**

All optimization, training and other basic procedures are the same as in the previous experiment. Results are presented in Table 3.

We notice that personality-dependent summarization as provided by *sPers* outperforms standard summarization (i.e., with no access to personality information) as provided by *sBase*. Although the difference is once again small (which may be explained by the limited size of our dataset), this outcome offers support to our main research hypothesis by illustrating that the use of author personality information may improve summarization accuracy.

4.4 Selected Examples

As a means to illustrate the kinds of output that may be produced by our models, Table 5 presents a number of examples taken from the original corpus summaries, and the corresponding summaries obtained from the same input by making use of the *sBase* baseline and by the personality-dependent *sPers* models. For ease of illustration, the examples are informally grouped into three error categories (small, moderate and large) according to the distance between the corpus summaries and their *sPers* counterparts, and are presented in both original (Portuguese) and translated (English) forms.

5 Final Remarks

This paper addressed the use of Big Five personality information about the target author to generate personalized summaries in neural sequence-to-sequence text summarization. The model - consisting of two bidirectional GRUs, word embeddings and attention mechanism - was evaluated in two versions, namely, with and without an additional personality embedding layer. Initial results suggest that having access to personality information does lead to more accurate (or human-like) text summaries.

The use of personality information is of course only one among many possible personalization

[2] We are aware that, although popular in machine translation and text generation, BLEU may not be the ideal metrics for the present task (Liu et al., 2011; Song et al., 2013), and that it may not co-relate well with, e.g., human judgments (Reiter and Belz, 2009).

Table 5: Selected examples taken from the corpus, baseline (sBase) and personality-dependent (sPers) summarization models, grouped by distance (small, moderate or large) between sPers and the expected (corpus) summary in original Portuguese (Pt) and translated English (En).

Error	Model	Summary (Pt)	Summary (En)
small	corpus	*homem na cerca*	*man by fence*
	sBase	*homem idoso*	*elderly man*
	sPers	*homem na cerca*	*man by fence*
moderate	corpus	*pessoas pedindo ajuda*	*people asking for help*
	sBase	*pessoas esperando*	*people waiting*
	sPers	*pessoas aguardam atendimento*	*people waiting for help*
large	corpus	*menino com um balde de terra*	*boy with a bucket full of soil*
	sBase	*crianca com balde*	*child with bucket*
	sPers	*crianca com balde de terra*	*child with bucket full of soil*

strategies for text summarization. In particular, we notice that the increasing availability of text corpora labelled with author demographics in general (e.g., gender, age, education information etc.) may in principle support a broad range of speaker-dependent summarization models. Thus, as future work we intend to extend the current approach along these lines, and provide additional summarization strategies that may represent more significant gains over the standard, fixed-output summarization approach.

Abstract

Lack of labelled data in the target domain for training is a common problem in domain adaptation. To overcome this problem, we propose a novel unsupervised domain adaptation method that combines projection and self-training based approaches. Using the labelled data from the source domain, we first learn a projection that maximises the distance among the nearest neighbours with opposite labels in the source domain. Next, we project the source domain labelled data using the learnt projection and train a classifier for the target class prediction. We then use the trained classifier to predict pseudo labels for the target domain unlabelled data. Finally, we learn a projection for the target domain as we did for the source domain using the pseudo-labelled target domain data, where we maximise the distance between nearest neighbours having opposite pseudo labels. Experiments on a standard benchmark dataset for domain adaptation show that the proposed method consistently outperforms numerous baselines and returns competitive results comparable to that of SOTA including self-training, tri-training, and neural adaptations.

1 Introduction

A machine learning model trained using data from one domain (source domain) might not necessarily perform well on a different (target) domain when their distributions are different. Domain adaptation (DA) considers the problem of adapting a machine learning model such as a classifier that is trained using a source domain to a target domain. In particular, in Unsupervised Domain Adaptation (UDA) (Blitzer et al., 2006, 2007; Pan et al., 2010) we do not assume the availability of any labelled instances from the target domain but a set of labelled instances from the source domain and unlabelled instances from both source and the target domains.

Two main approaches for UDA can be identified from prior work: **projection-based** and **self-training**.

Projection[1]-based methods for UDA learn an embedding space where the distribution of features in the source and the target domains become closer to each other than they were in the original feature spaces (Blitzer et al., 2006). For this purpose, the union of the source and target feature spaces is split into domain-independent (often referred to as *pivots*) and domain-specific features using heuristics such as mutual information or frequency of a feature in a domain. A projection is then learnt between those two feature spaces and used to adapt a classifier trained from the source domain labelled data. For example, methods based on different approaches such as graph-decomposition *spectral feature alignment* (Pan et al., 2010) or autoencoders (Louizos et al., 2015) have been proposed for this purpose.

Self-training (Yarowsky, 1995; Abney, 2007) is a technique to iteratively increase a set of labelled instances by training a classifier using current labelled instances and applying the trained classifier to predict pseudo-labels for unlabelled instances. High confident predictions are then appended to the current labelled dataset, thereby increasing the number of labelled instances. The process is iterated until no additional pseudo-labelled instances can be found. Self-training provides a direct solution to the lack of labelled data in the target do-

[1] we consider the terms *project* and *embed* as synonymous in this paper

Proceedings of Recent Advances in Natural Language Processing, pages 213–222,
Varna, Bulgaria, Sep 2–4 2019.

main in UDA (McClosky et al., 2006; Reichart and Rappoport, 2007; Drury et al., 2011). Specifically, the source domain's labelled instances are used to initialise the self-training process and during subsequent iterations labels are inferred for the target domain's unlabelled instances, which can be used to train a classifier for the task of interest.

So far in UDA projection-learning and self-trained approaches have been explored separately. An interesting research question we ask and answer positively in this paper is whether *can we improve the performance of projection-based methods in UDA using self-training?* In particular, recent work on UDA (Morerio et al., 2018) has shown that minimising the entropy of a classifier on its predictions in the source and target domains is equivalent to learning a projection space that maximises the correlation between source and target instances. Motivated by these developments, we propose **Self-Adapt**, a method that combines the complementary strengths of projection-based methods and self-training methods for UDA.

Our proposed method consists of three steps.

- First, using labelled instances from the source domain we learn a projection ($\mathcal{S}_{\text{prj}}$) that maximises the distance between each source domain labelled instance and its nearest neighbours with opposite labels. Intuitively, this process will learn a projected feature space in the source domain where the margin between the opposite labelled nearest neighbours is maximised, thereby minimising the risk of misclassifications. We project the source domain's labelled instances using $\mathcal{S}_{\text{prj}}$ for the purpose of training a classifier for predicting the target task labels such as positive/negative sentiment in cross-domain sentiment classification or part-of-speech tags in cross-domain part-of-speech tagging.
- Second, we use the classifier trained in the previous step to assign pseudo labels for the (unlabelled) target domain instances. Different strategies can be used for this label inference process such as selecting instances with the highest classifier confidence as in self-training or checking the agreement among multiple classifier as in tri-training.
- Third, we use the pseudo-labelled target domain instances to learn a projection for the target domain ($\mathcal{T}_{\text{prj}}$) following the same procedure used to learn $\mathcal{S}_{\text{prj}}$. Specifically, we learn a projected feature space in the target domain where the margin between the opposite pseudo-labelled nearest neighbours is maximised. We project labelled instances in the source domain and pseudo-labelled instances in the target domain respectively using $\mathcal{S}_{\text{prj}}$ and $\mathcal{T}_{\text{prj}}$, and use those projected instances to learn a classifier for the target task.

As an evaluation task, we perform cross-domain sentiment classification on the Amazon multi-domain sentiment dataset (Blitzer et al., 2007). Although most prior work on UDA have used this dataset as a standard evaluation benchmark, the evaluations have been limited to the four domains *books*, *dvds*, *electronic appliances* and *kitchen appliances*. We too report performances on those four domains for the ease of comparison against prior work. However, to reliably estimate the generalisability of the proposed method, we perform an additional extensive evaluation using 16 other domains included in the original version of the Amazon multi-domain sentiment dataset.

Results from the cross-domain sentiment classification reveal several interesting facts. A baseline that uses $\mathcal{S}_{\text{prj}}$ alone would still outperform a baseline that uses a classifier trained using only the source domain's labelled instances on the target domain test instances, without performing any adaptations. This result shows that it is useful to consider the label distribution available in the source domain to learn a projection even though it might be different to that in the target domain.

On the other hand, training a classifier using the pseudo-labelled target domain instances alone, without learning $\mathcal{T}_{\text{prj}}$ further improves performance. This result shows that pseudo labels inferred for the target domain unlabelled instances can be used to overcome the issue of lack of labelled instances in the target domain.

Moreover, if we further use the pseudo-labelled instances to learn $\mathcal{T}_{\text{prj}}$, then we see a significant improvement of performance across all domain pairs, suggesting that UDA can benefit from both projection learning and self-training.

These experimental results support our claim that it is beneficial to combine projection-based and self-training-based UDA approaches. Moreover, our proposed method outperforms all self-training based domain adaptation methods such as tri-training (Zhou and Li, 2005; Søgaard, 2010) and is competitive against neural domain adaptation methods (Louizos et al., 2015; Ganin et al., 2016; Saito et al., 2017; Ruder and Plank, 2018).

2 Related Work

Self-training (Yarowsky, 1995) has been adapted to various cross-domain NLP tasks such as document classification (Raina et al., 2007), POS tagging (McClosky et al., 2006; Reichart and Rappoport, 2007) and sentiment classification (Drury et al., 2011). Although different variants of self-training algorithms have been proposed (Abney, 2007; Yu and Kübler, 2011) a common recipe can be recognised involving the following three steps: (a) Initialise the training dataset, $\mathcal{L} = \mathcal{S}_L$, to the labelled data in the source domain, and train a classifier for the target task using $\mathcal{L}$, (b) apply the classifier trained in step (a) to the unlabelled data in the target domain $\mathcal{T}_U$, and append the most confident predictions as identified by the classifier (e.g. higher than a pre-defined confidence threshold τ) to the labelled dataset $\mathcal{L}$, (c) repeat the two steps (a) and (b) until we cannot append additional high confidence predictions to $\mathcal{L}$.

Another popular approach for inferring labels for the target domain is co-training (Blum and Mitchell, 1998), where the availability of multiple views of the feature space is assumed. In the simplest case where there are two views available for the instances, a separate classifier is trained using the source domain's labelled instances that involve features from a particular view only. Next, the two classifiers are used to predict pseudo labels for the target domain unlabelled instances. If the two classifiers agree on the label for a particular unlabelled instances, then that label is assigned to that instance. Co-training has been applied to UDA (Yu and Kübler, 2011; Chen et al., 2011), where the feature spaces in the source and target domains were considered as the multiple views. The performance of co-training will depend on the complementarity of the information captured by the different feature spaces. Therefore, it is an important to carefully design multiple feature spaces when performing UDA. In contrast, our proposed method does not require such multiple views and does not require training multiple classifiers for the purpose of assigning pseudo labels for the target domain unlabelled instances, which makes the proposed method easy to implement.

Tri-training (Zhou and Li, 2005) relaxes the requirement of co-training for the feature spaces to be sufficient and redundant views. Specifically, in tri-training, as the name implies three separate classifiers are trained using bootstrapped subsets of instances sampled from the labelled instances. If at least two out of the three classifiers agree upon a label for an unlabelled instance, that label is then assigned to the unlabelled instance. Søgaard (2010) proposed a variation of tri-training (i.e. tri-training with diversification) that diversifies the sampling process and reduces the number of additional instances, where they require exactly two out of the three classifiers to agree upon a label and the third classifier to disagree. It has been shown that the classic tri-training algorithm when applied to UDA acts as a strong baseline that outperforms even more complex SoTA neural adaptation methods (Ruder and Plank, 2018). As later shown in our experiments, the proposed **Self-Adapt** method consistently outperforms self-training, tri-training and tri-training with diversification across most of the domain pairs considered.

Projection-based approaches for UDA learn a (possibly lower-dimensional) projection where the difference between the source and target feature spaces is reduced. For example, Structural Correspondence Learning (SCL) (Blitzer et al., 2006, 2007) learns a projection using a set of domain invariant common features called *pivots*. Different strategies have been proposed in the literature for finding pivots for different tasks such as the frequency of a feature in a domain for cross-domain POS tagging (Blitzer et al., 2006; Cui et al., 2017a), mutual information (Blitzer et al., 2007) and pointwise mutual information (Bollegala et al., 2011, 2015) for cross-domain sentiment classification. Cui et al. (2017b) proposed a method for learning the appropriateness of a feature as a pivot (*pivothood*) from the data during training, without requiring any heuristics. Although we use projections in the proposed method, unlike prior work on projection-based UDA, we *do not* require splitting the feature space into domain independent and domain specific features. Moreover, we learn two separate projections for each of the source and target domain, which gives us more flexibility to address the domain-specific constrains in the learnt projections.

Neural adaptation methods have recently reported SoTA for UDA. Louizos et al. (2015) proposed a Variational Fair Autoencoder (VFAE) to learn an invariant representation for a domain.

They used Maximum Mean Discrepancy (MMD) (Gretton et al., 2006) for further promoting the invariant projected feature space. Ganin et al. (2016) proposed Domain Adversarial Neural Network (DANN) to learn features that combine the discriminative power of a classifier and the domain-invariance of the projection space to simultaneously learn adaptable and discriminative projections. Saito et al. (2017) proposed a deep tri-training method with three neural networks, two for pseudo labelling the target unlabelled data and another one for learning discriminator using the inferred pseudo labels for the target domain. Ruder and Plank (2018) proposed Multi-task Tri-training (MT-Tri) based on tri-training and Bi-LSTM. They show that tri-training is a competitive baseline and rivals more complex neural adaptation methods. Although MT-Tri does not outperform SoTA on cross-domain sentiment classification tasks, their proposal reduces the time and space complexity required by the classical tri-training.

As stated above, our proposed method **Self-Adapt**, differs from the prior work discussed above in that it (a) does not require pivots, (b) does not require multiple feature views, (c) learns two different projections for the source and target domains and (d) combines a projection and a self-training step in a non-iterative manner to improve the performance in UDA.

3 Self-Adaptation (Self-Adapt)

In UDA, we are given a set of positively ($\mathcal{S}_L^+$) and negatively ($\mathcal{S}_L^-$) labelled instances for a source domain $\mathcal{S}$ ($\mathcal{S}_L = \mathcal{S}_L^+ \cup \mathcal{S}_L^-$), and sets of unlabelled instances $\mathcal{S}_U$ and $\mathcal{T}_U$ respectively for the source and target domain $\mathcal{T}$. Given a dataset $\mathcal{D}$, we are required to learn a classifier $f(\boldsymbol{x}, y; \mathcal{D})$ that returns the probability of a test instance $\boldsymbol{x}$ taking a label y. For simplicity, we consider the pairwise adaptation from a single source to single target, and binary ($y \in \{-1, 1\}$) classification as the target task. However, self-adapt can be easily extended to multi-domain and multi-class UDA.

We represent an instance (document/review) x by a bag-of-n-gram (BonG) embedding (Arora et al., 2018), where we add the pre-trained d-dimensional word embeddings $\boldsymbol{w} \in \mathbb{R}^d$ for the words $w \in x$ to create a d-dimensional feature vector $\boldsymbol{x} \in \mathbb{R}^d$ representing x. Self-adapt consists of three steps: (a) learning a source projection using $\mathcal{S}_L$ (Section 3.1), (b) pseudo labelling $\mathcal{T}_U$ using a classifier trained on the projected $\mathcal{S}_L$ (Section 3.2); (c) learning a target projection using the pseudo-labelled target instances, and then learning a classifier f for the target task (Section 3.3).

3.1 Source Projection Learning ($\mathcal{S}_{\text{prj}}$)

In UDA, the adaptation task does not vary between the source and target domains. Therefore, we can use $\mathcal{S}_L$ to learn a projection for the source domain $\mathcal{S}_{\text{prj}}$ where the separation between an instance $x \in \mathcal{S}_L$ and its opposite-labelled nearest neighbours is maximised. Specifically, for an instance x we represent the set of k of its nearest neighbours $\text{NN}(\boldsymbol{x}, \mathcal{D}, k)$ selected from a set $\mathcal{D}$ by a vector $\phi(\boldsymbol{x}, \mathcal{D}, k)$ as the sum of the word embeddings of the neighbours given by (1).

$$\phi(\boldsymbol{x}, \mathcal{D}, k) = \sum_{u \in \text{NN}(\boldsymbol{x}, \mathcal{D}, k)} \theta(x, u)\boldsymbol{u}. \qquad (1)$$

Here, the weight $\theta(x, u)$ is computed using the cosine similarity between $\boldsymbol{u}$ and $\boldsymbol{x}$, and is normalised s.t. $\sum_{u \in \text{NN}(\boldsymbol{x}, \mathcal{D}, k)} \theta(x, u) = 1$. Other similarity measures can also be used instead of cosine, for example, Euclidean distance (Van Asch and Daelemans, 2016). Then, $\mathcal{S}_{\text{prj}}$ is defined by the projection matrices $\mathbf{A}_+ \in \mathbb{R}^{d \times d}$ and $\mathbf{A}_- \in \mathbb{R}^{d \times d}$ and is learnt by maximising the objective O_L given by (2).

$$\begin{aligned} O_L(\mathbf{A}_+, \mathbf{A}_-) = & \sum_{\boldsymbol{x} \in \mathcal{S}_L^+} \left|\left|\mathbf{A}_+\boldsymbol{x} - \mathbf{A}_-\phi(\boldsymbol{x}, \mathcal{S}_L^-, k)\right|\right|_2^2 \\ & + \sum_{\boldsymbol{x} \in \mathcal{S}_L^-} \left|\left|\mathbf{A}_-\boldsymbol{x} - \mathbf{A}_+\phi(\boldsymbol{x}, \mathcal{S}_L^+, k)\right|\right|_2^2 \qquad (2) \end{aligned}$$

We initialise $\mathbf{A}_+$ and $\mathbf{A}_-$ to the identify matrix $\mathbf{I} \in \mathbb{R}^{d \times d}$ and apply Adam (Kingma and Ba, 2014) to find their optimal values denoted respectively by $\mathbf{A}_+^*$ and $\mathbf{A}_-^*$. Finally, we project $\mathcal{S}_L$ using the learnt $\mathcal{S}_{\text{prj}}$ to obtain a projected set of source domain labelled instances $\mathcal{S}_L^* = \mathbf{A}_+^* \circ \mathcal{S}_L^+ \cup \mathbf{A}_-^* \circ \mathcal{S}_L^-$. Here, we use the notation $\mathbf{A} \circ \mathcal{D} = \{\mathbf{A}\boldsymbol{x} | \boldsymbol{x} \in \mathcal{D}\}$ to indicate the application of a projection matrix $\mathbf{A} \in \mathbb{R}^{d \times d}$ on elements $\boldsymbol{x} \in \mathbb{R}^d$ in a dataset $\mathcal{D}$.

3.2 Pseudo Label Generation (PL)

In UDA, we do not have labelled data for the target domain. To overcome this issue, inspired by prior work on self-training approaches to UDA, we train a classifier $f(\boldsymbol{x}, y; \mathcal{S}_L^*)$ on $\mathcal{S}_L^*$ first and then use this classifier to assign pseudo labels for the target domain's unlabelled data $\mathcal{T}_U$, if the classifier

Algorithm 1 Pseudo Label Generation

```
Input: source domain positively labelled data $\mathcal{S}_L^+$,
       source domain negatively labelled data $\mathcal{S}_L^-$,
       source domain positive transformation matrix $\mathbf{A}_+$,
       source domain negative transformation matrix $\mathbf{A}_-$,
       target domain unlabelled data $\mathcal{T}_U$,
       a set of target classes $Y = \{+1, -1\}$,
       classification confidence threshold $\tau$.
Output: target domain pseudo-labelled data $\mathcal{T}'_L$
  $\mathcal{S}_L^* \leftarrow \mathbf{A}_+^* \mathcal{S}_L^+ \cup \mathbf{A}_-^* \mathcal{S}_L^-$
  $\mathcal{T}'_L \leftarrow \emptyset$
  for $\boldsymbol{x} \in \mathcal{T}_U$ do
    $y \in Y$, $p(t = y|\boldsymbol{x}) = f(\boldsymbol{x}, y; \mathcal{S}_L^*)$ {probability of $\boldsymbol{x}$ belongs to class $y$}
    if $p(t = y|\boldsymbol{x})) > \tau$ then
      $\mathcal{T}'_L \leftarrow \mathcal{T}'_L \cup \{(\boldsymbol{x}, y)\}$
    end if
  end for
  return $\mathcal{T}'_L$
```

is more confident than a pre-defined threshold τ. Algorithm 1 returns a pseudo-labelled dataset $\mathcal{T}'_L$ for the target domain. According to the classical self-training (Yarowsky, 1995; Abney, 2007), $\mathcal{T}'_L$ will be appended to $\mathcal{S}_L^*$ and the classifier is retrained on this extended labelled dataset. The process is repeated until no further unlabelled instances can be assigned labels with confidence higher than τ. However, in our preliminary experiments, we found that this process does not improve the performance in UDA beyond the first iteration. Therefore, we limit the number of iterations to one as shown in Algorithm 1. Doing so also speeds up the training process over classical self-training, which retrains the classifier and iterates.

3.3 Target Projection Learning ($\mathcal{T}_{\text{prj}}$)

Armed with the pseudo-labelled data generated via Algorithm 1, we can now learn a projection for the target domain, $\mathcal{T}_{\text{prj}}$, following the same procedure we proposed for learning $\mathcal{S}_{\text{prj}}$ in Section 3.1. Specifically, $\mathcal{T}_{\text{prj}}$ is defined by the two target-domain projection matrices $\mathbf{B}_+ \in \mathbb{R}^{d \times d}$ and $\mathbf{B}_- \in \mathbb{R}^{d \times d}$ that maximises the distance between each pseudo-labelled target instance x and its k opposite labelled nearest neighbours selected from positively ($\mathcal{T}_L'^+$) and negatively ($\mathcal{T}_L'^-$) pseudo-labelled instances. The objective O'_L for this optimisation problem is given by (3).

$$O'_L(\mathbf{B}_+, \mathbf{B}_-) = \sum_{\boldsymbol{x} \in \mathcal{T}_L'^+} \left|\left|\mathbf{B}_+\boldsymbol{x} - \mathbf{B}_-\phi(\boldsymbol{x}, \mathcal{T}_L'^-, k)\right|\right|_2^2 + \sum_{\boldsymbol{x} \in \mathcal{T}_L'^-} \left|\left|\mathbf{B}_-\boldsymbol{x} - \mathbf{B}_+\phi(\boldsymbol{x}, \mathcal{T}_L'^+, k)\right|\right|_2^2 \quad (3)$$

Likewise with $\mathcal{S}_{\text{prj}}$, $\mathbf{B}_+$ and $\mathbf{B}_-$ are initialised to the identify matrix $\mathbf{I} \in \mathbb{R}^{d \times d}$, and Adam is used to find their minimisers denoted respectively by $\mathbf{B}_+^*$ and $\mathbf{B}_-^*$. We project the target domain pseudo-labelled data using $\mathcal{T}_{\text{prj}}$ to obtain $\mathcal{T}_L'^* = \mathbf{B}_+^* \circ \mathcal{T}_L'^+ \cup \mathbf{B}_-^* \circ \mathcal{T}_L'^-$. Finally, we train a classifier $f(\boldsymbol{x}, y; \mathcal{S}_L^* \cup \mathcal{T}_L'^*)$ for the target task using both source and target projected labelled instances $\mathcal{S}_L^* \cup \mathcal{T}_L'^*$. Any binary classifier can be used for this purpose. In our experiments, we use ℓ_2 regularised logistic regression following prior work in UDA (Blitzer et al., 2006; Pan et al., 2010; Bollegala et al., 2013). Moreover, by using a simple linear classifier, we can decouple the projection learning step from the target classification task, thereby more directly evaluate the performance of the former.

4 Experiments

Our proposed method *does not* assume any information about the target task and can be in principle applied for any domain adaptation task. We use cross-domain sentiment classification as an evaluation task in this paper because it has been used extensively in prior work on UDA, thereby enabling us to directly compare the performance of our proposed method against previously proposed UDA methods. In particular, we use the Amazon multi-domain sentiment dataset, originally created by Blitzer et al. (2007), as a benchmark dataset in our experiments. This dataset includes Amazon Product Reviews from four categories: Books (**B**), DVDs (**D**), Electronic Appliances (**E**) and Kitchen Appliances (**K**). Considering each category as a domain[2], we can generate $\binom{4}{2} = 12$ pair-wise adaptation tasks involving a single source and a single target domain.

An Amazon product review is assigned 1-5 star rating and product reviews with 4 or 5 stars are labelled as positive, whereas 1 or 2 star reviews

[2] Multiple reviews might exist for the same product within the same domain. Products are not shared across domains.

are labelled as negative. 3 star reviews are ignored because of their ambiguity. In addition to the labelled reviews, the Amazon multi-domain dataset contains a large number of unlabelled reviews for each domain. We use the official balanced train and test dataset splits, which has 800 (pos), 800 (neg) training instances and 200 (pos), 200 (neg) test instances for each domain. We name this dataset as the Multi-domain Adaptation Dataset (**MAD**).

One issue that is often raised with **MAD** is that it contains only four domains. In order to robustly evaluate the performance of an UDA method we must evaluate on multiple domains. Therefore, in addition to **MAD**, we also evaluate on an extended dataset that contains 16 domains. We name this dataset as the Extended Multi-domain Adaptation Dataset (**EMAD**). The reviews for the 16 domains contained in **EMAD** were also collected by Blitzer et al. (2007), but were not used in the evaluations. The same star-based procedure used in **MAD** is used to label the reviews in **EMAD**. We randomly select 20% of the available labelled reviews as test data and construct a balanced training dataset from the rest of the labelled reviews (i.e. for each domain we have equal number of positive and negative labelled instances in the train datasets). Likewise in **MAD**, we generate $\binom{16}{2} = 240$ pair-wise domain adaptation tasks from **EMAD**.

We train an ℓ_2 regularised logistic regression as the target (sentiment) classifier, in which we tune the regularisation coefficient using validation data. We randomly select 10% from the target domain labelled data, which is separate from the train or test data. We tune regularisation coefficient in $[0.001, 0.01, 0.1, 1]$. We use 300 dimensional pre-trained GloVe word embeddings (Pennington et al., 2014) to create BonG embeddings for uni and bigrams. We found that a maximum of 100 epochs to be sufficient to reach convergence in all projection learning tasks for all domains. The source code implementation of **self-adapt** will be made publicly available upon paper acceptance.

4.1 Effect of Projection Learning and Pseudo-Labelling

Our proposed method consists of 3 main steps as described in Section 3: source projection learning, pseudo labelling and target projection learning. Using **MAD**, in Table 1, we compare the relative effectiveness of these three steps towards the overall performance in UDA using $k = 1$ for all the steps. Specifically, we consider the following baselines.

NA: No-adaptation. Learn a classifier from $\mathcal{S}_L$ and simply use it to classify sentiment on target domain test instances, without performing any domain adaptation.

$\mathcal{S}_{\text{prj}}$: Learn a source projection $\mathcal{S}_{\text{prj}}$ and apply it to project $\mathcal{S}_L$ to obtain $\mathcal{S}_L^* = \mathbf{A}_+^* \circ \mathcal{S}_L^+ \cup \mathbf{A}_-^* \circ \mathcal{S}_L^-$. Train a sentiment classifier using $\mathcal{S}_L^*$ and use it to classify target domain test instances.

$\mathcal{S}_{\text{prj}}$ +PL: Use the classifier trained using $\mathcal{S}_L^*$ on target domain unlabelled data to create a pseudo-labelled dataset $\mathcal{T}'_L$. Train a sentiment classifier on $\mathcal{S}_L^* \cup \mathcal{T}'_L$ and use it to classify target domain test instances.

$\mathcal{S}_{\text{prj}}$ +$\mathcal{T}_{\text{prj}}$: This is the proposed method including all three steps. A target projection $\mathcal{T}_{\text{prj}}$ is learnt using $\mathcal{T}'_L$ and is applied to obtain $\mathcal{T}'^*_L = \mathbf{B}_+^* \circ \mathcal{T}'^+_L \cup \mathbf{B}_-^* \circ \mathcal{T}'^-_L$. Finally, a sentiment classifier is trained using $\mathcal{S}_L^* \cup \mathcal{T}'^*_L$ and used to classify target domain test instances.

With all methods, we keep $k = 1$ in the nearest neighbour feature representation in (1) for the ease of comparisons. Confidence threshold τ is tuned in the range $[0.5, 0.9]$ using cross-validation. From Table 1 we see that $\mathcal{S}_{\text{prj}}$ consistently outperforms **NA**, showing that even without using any information from the target domain, it is still useful to learn source domain projections that discriminates instances with opposite labels. When we perform pseudo labelling on top of source projection learning ($\mathcal{S}_{\text{prj}}$ **+PL**) we see a slight but consistent improvement in all domain-pairs. However, when we use the pseudo labelled instances to learn a target projection ($\mathcal{S}_{\text{prj}}$ +$\mathcal{T}_{\text{prj}}$) we obtain the best performance in all domain-pairs. Moreover, the obtained results are significantly better under the stricter $p < 0.001$ level over the **NA** baseline in 7 out of 12 domain-pairs.

Table 3 shows the classification accuracy for the **EMAD**. Due to the limited availability of space, we show the average classification accuracy for adapting to the same target domain instead of showing all 240 domain-pairs for **EMAD**. Likewise in **MAD**, we see in **EMAD** we obtain the best results when we use both source and target projections. Interestingly, we see that the proposed method adapting well even to the domains

Table 1: Target domain test data classification accuracy for the different steps in the proposed method ($k = 1$). $\mathcal{S} - \mathcal{T}$ denotes adapting from a source $\mathcal{S}$ to a target $\mathcal{T}$ domain. The best result for each domain-pair is bolded. Statistically significant improvements over **NA** according to the binomial exact test are shown by "*" and "**" respectively at $p = 0.01$ and $p = 0.001$ levels.

with smaller numbers of unlabelled data such as **gourmet_food** (168 labelled and 267 unlabelled train instances). This is encouraging because it shows that the proposed method can overcome the lack of labelled instances via pseudo labelling and projection learning.

4.2 Comparisons against Self-Training

Ruder and Plank (2018) evaluated classical general-purpose semi-supervised learning methods proposed for inducing pseudo labels for unlabelled instances using a seed set of labelled instances in the context of UDA. They found that tri-training to outperform more complex neural SoTA UDA methods. Considering the fact that **Self-Adapt** is performing pseudo-labelling, similar to other self-training methods, it is interesting to see how well it compares against classical self-training methods for inducing labels (Yarowsky, 1995; Abney, 2007; Zhou and Li, 2005; Søgaard, 2010) when applied to UDA. Specifically, we consider the classical self-training (Yarowsky, 1995; Abney, 2007) (**Self**), Tri-training (Zhou and Li, 2005) (**Tri**) and Tri-training with diversification (Søgaard, 2010) (**Tri-D**). For each of those methods, we use the labelled data in the source domain as seeds and induce labels for the unlabelled data in the target domain. Table 2 reports the results on **MAD**.

We re-implement the classical self-training methods considered by Ruder and Plank (2018) and evaluated them against the proposed self-adapt on the same datasets, feature representations and settings to conduct a fair comparison. All classical self-training methods were trained using the source domain labelled instances $\mathcal{S}_L$ as seed data. As discussed in Section 3.2, similar to **Self-Adapt**, we observed that the performance did not significantly increase beyond the first iteration for any of the classical self-training methods in UDA. Consequently, we compare all classical self-training methods for their peak performance, obtained after the first iteration. We tune the confidence threshold τ for each method using validation data and found the optimal value of τ to fall in the range $[0.6, 0.9]$. k is a hyperparameter selected using validation dataset for **Self-Adapt** in comparison.

Experimental results on **MAD** and **EMAD** are shown respectively in Tables 2 and 4. From those Tables, we see that **Self-Adapt** for most of the domain pairs performs similarly or slightly worse than **NA**. Although **Tri** and **Tri-D** outperform **NA** on all cases, we found that those two methods are highly sensitive to the seed instances used to initialise the pseudo-labelling process. We find the proposed **Self-Adapt** to outperform all classical self-training based methods in 11 out of 12 domain pairs in **MAD** and in all 16 target domains in **EMAD**, showing a strong and robust improvement over classical self-training methods. This result shows that by combining source and target domain projections with self-training, we can obtain superior performance in UDA in comparison to using classical self-training methods alone.

ric Tri-training (Saito et al., 2017) (**Asy-Tri**), and Multi-task Tri-training (Ruder and Plank, 2018) (**MT-Tri**). We select these methods as they are the current SoTA for UDA on **MAD**, and report the results from the original publications in Table 5.

Although only in 3 out of 12 domain-pairs **Self-Adapt** is obtaining the best performance, the difference of performance between **DANN** and **Self-Adapt** is not statistically significant. Although **MT-Tri** is outperforming **Self-Adapt** in 8 domain-pairs, it is noteworthy that **MT-Tri** is using a larger feature space than that of **Self-Adapt**. Specifically, **MT-Tri** is using 5000 dimensional tf-idf weighted unigram and bigram vectors for representing reviews, whereas we **Self-Adapt** uses a 300 dimensional BonG representation computed using pre-trained GloVe vectors. Moreover, prior work on neural UDA have not used the entire unlabelled datasets and have sampled a smaller subset due to computational feasibility. For example, **MT-Tri** uses only 2000 unlabelled instances for each domain despite the fact that the original unlabelled datasets contain much larger numbers of reviews. This is not only a waste of available data but it is also non-obvious as how to subsample unlabelled data for training. Our preliminary experiments revealed that the performance of neural UDA methods to be sensitive to the unlabelled datasets used.[3] On the other hand, **Self-Adapt** does not require sub-sampling of unlabelled data and uses all the available unlabelled data for UDA. During the pseudo-labelling step, **Self-Adapt** automatically selects a subset of unlabelled target instances that are determined to be confident by the classifier more than a pre-defined threshold τ. The ability to operate on a lower-dimensional feature space and obviating the need to subsample unlabelled data are properties of the proposed method that are attractive when applying UDA methods on large datasets and across multiple domains.

5 Conclusions

We proposed **Self-Adapt**, an UDA method that combines projection learning and self-training. Our experimental results on two datasets for cross-domain sentiment classification show that projection learning and self-training have complementary strengths and jointly contribute to improve UDA performance. In future, we plan to apply **Self-Adapt** to other UDA tasks in NLP such as cross-domain POS tagging and NER.

[3] Unfortunately, the source code for MT-Tri was not available for us to run this method with the same set of features and unlabelled dataset that we used. Therefore, we report the results from the original publication.

Abstract

In this work, we propose to address the detection of negation and speculation, and of their scope, in French biomedical documents. It has been indeed observed that they play an important role and provide crucial clues for other NLP applications. Our methods are based on CRFs and BiLSTM. We reach up to 97.21 % and 91.30 % F-measure for the detection of negation and speculation cues, respectively, using CRFs. For the computing of scope, we reach up to 90.81 % and 86.73 % F-measure on negation and speculation, respectively, using BiLSTM-CRF fed with word embeddings.

1 INTRODUCTION

The detection of speculation and negation in texts has become one of the unavoidable pre-requisites in many information extraction tasks. Both are common in language and provide information on factuality and polarity of facts, which is particularly important for the biomedical field (Elkin et al., 2005b; Denny and Peterson, 2007; Gindl et al., 2008; Chapman et al., 2001). Indeed, negation and speculation provide there crucial information for detecting patient's present, speculated or absent pathologies and co-morbidities, detecting whether a particular medication has been, may have been, or has not been prescribed or taken, defining the certainty of diagnosis, etc. In order to efficiently identify speculation and negation instances, it is first necessary to identify their cues, i.e., words (or morphological units) that express speculation and negation, and then their scopes, i.e., tokens within the sentence which are affected by the negation or speculation. In this paper, we present two French datasets annotated with negation and speculation cues and their scope. We also propose machine learning and deep learning based systems to tackle the automatic detection of cues and scopes that achieve high performance.

2 EXPRESSION of NEGATION and SPECULATION

In French, the expression of negation and speculation have some specifics that are described below.

2.1 NEGATION

The negation cues may consist of one word or prefix, or of multiple words. Moreover, negation can be expressed via a large panel of cues which can be morphological (*an, in, im, ir, dis*), lexical (*absence de*(absence of), *à l'exception de*(excepting)), and grammatical (*non, ne...pas, ni...ni*). In the following examples, we present sentences with instances of negation (the cues are underlined).

1. *En alternative des traitements locaux (chirurgie, radiothérapie, radiofréquence, cryoablation) peuvent être indiqués mais ils ne sont pas* ***toujours*** *faisables.* *(Alternatively, local treatments (surgery, radiotherapy, radiofrequency, cryoablation) may be indicated but are not* ***always*** *feasible.)*

2. *Il n'existe* ***toujours*** *pas aujourd'hui de consensus quant à une définition précise de ce phénomène hétérogène ou des modalités de sa prise en charge.* *(There is* ***still*** *no consensus today on a precise definition of this heterogeneous phenomenon or the modalities of its management.)*

3. *il n'y a pas de traitement curateur de la maladie* ***en dehors de*** *l'allogreffe de moelle.* *(there is no curative treatment for this disease* ***apart from*** *bone-marrow homograft)*

4. *Lymphome non hodgkinien à cellules B matures récidivant/réfractaire.* *(Relapsed/refractory mature B-cell non-Hodgkin's lymphoma.)*

Proceedings of Recent Advances in Natural Language Processing, pages 223–232,
Varna, Bulgaria, Sep 2–4 2019.

5. *Elle n'est soulagée que par la marche et doit donc écouter la télévision en faisant les cent* ***pas*** *dans son salon. (She is only relieved by walking and must therefore listen to the TV pacing in her living room.)*

Examples (1-2) show the possible effect of frequency adverbs, here *toujours (always)*. In the first sentence *traitements locaux (chirurgie, radiothérapie, radiofréquence, cryoablation)*, the content would be negated without *toujours(always)*. In the second sentence, with or without *toujours*, the meaning of the sentence does not change, therefore, the scope of the negation remains the same.

Example (3) shows how the preposition *en dehors de(apart from)*, can stop the scope of negation. Many other prepositions such as *à part*, *à l'exception de* or *excepté*, with more or less the same meaning than *en dehors de (apart from)*, would have the same effect on the negation scope. However, these prepositions can also play the role of negation by themselves.

Examples (4) show that cues can also be included in medical concepts such as ***non*** *hodgkinien (non-Hodgkin's)*. In our work, we chose to label *hodgkinien* as part of the negation scope.

Finally, example (5) shows the context in which the ambiguous word *pas*, meaning both *no/not* and *footstep*, has the non-negation meaning. In this example, ***pas*** is part of the idiomatic expression ***faire les cent pas*** *(pacing, walking around)*. Another ambiguity is related to the adverb ***plus*** meaning either ***more*** or, in conjunction with ***ne***, ***no more***.

2.2 SPECULATION

The expression of speculation can be even more complex than negation. Indeed, speculation can be triggered by many specific sequences of words. We describe several of them below.

1. *En effet, l'arrêt du traitement antituberculeux en soi pourrait* ***permettre un rétablissement de la fonction normale des héptocytes*** *en éliminant la source de l'atteinte hépatique. (Indeed, stopping TB treatment per se could restore normal hepatocyte function by eliminating the source of liver damage.)*

2. ***Le bénéfice de l'association lénalomide + R-CHOP au rapport par rapport au R-CHOP*** *reste à démontrer. (The benefit of the combination of lenalomide + R-CHOP compared with R-CHOP remains to be demonstrated.)*

3. *Elle aurait* ***eu la pose à 2 reprises d'un dispositif intrautérin*** *(DIU). (She would have had the pose of an intrauterine device (IUD) twice.)*

Example (1) shows a typical occurrence of *pourrait (could)*. As in English, where *can, could, may, etc.* express speculation, in French, *pouvoir* can occur in many forms.

Example (2) shows the effect of *reste à (remains to)* combined with an infinitive verb, here *démontrer*. Other infinitive verbs, such as *expliquer (to explain)* or *vérifier (to verify)*, associated with *reste à* trigger speculation.

Example (3) shows how the conditional tense triggers speculation. In English, *would* triggers speculation in this case, which is simpler to detect. Indeed, in French, the conditional tense is expressed via suffixes (*-ais, -ais, -ait, -ions, -iez, -aient*), which makes the detection harder, especially for supervised learning techniques.

3 RELATED WORK

We present several corpora and methods that have been proposed in the existing work to tackle the tasks of speculation and negation detection.

3.1 DATA

In the recent years, several specialized corpora in English have been annotated with speculation and negation, which has resulted in models for their automatic detection. These corpora can be divided into two categories: (1) corpora annotated with cues and scopes, such as Bioscope (Vincze et al., 2008) or **SEM-2012*, and (2) corpora focusing on concepts and named entities, such as I2B2 and Mipacq. We briefly describe these corpora. The Bioscope corpus (Vincze et al., 2008) contains reports of radiological examinations, scientific articles, and abstracts from biomedical articles. Each sentence and each negation and speculation cue/scope pair receives unique identifier. The *SEM-2012 corpus (Morante and Blanco, 2012) consists of a Sherlock Holmes novel and three other short stories written by Sir Arthur Conan Doyle. It contains 5,520 sentences, among which 1,227 sentences are negated. Each occurrence of the negation, the cue and its scope are annotated, as well as the focus of the negation if relevant. In this corpus, cues and scopes can be discontinuous. The I2B2/VA-2010 challenge (Uzuner et al., 2011) featured several tasks using US clinical records. One task aimed the detection of statements and of their scope. Medical concepts had to be associated with the corresponding statement: *present*, *absent*, *possible*, *conditional*, *hypothetical* or *not associated with the patient*. Mipacq (Albright et al., 2013) is another corpus with clinical data in English annotated with syntactic and semantic labels. Each detected UMLS entity has two attribute locations: *negation* (*true* or *false*) and *status* (*none*, *possible*, *HistoryOf* or *FamilyHistoryOf*).

3.2 EXPERT SYSTEMS

Among the rule based systems dedicated to the negation detection, *NegEx* (Chapman et al., 2001) pioneered the area. It uses regular expressions to detect the cues and to identify medical terms in their scope. It was later adapted to various languages including French (Deléger and Grouin, 2012). *ConText* (Harkema et al., 2009), derived from *NegEx*, covers more objectives: negation, temporality, and the subject concerned by this information in the clinical texts. It has been adapted to French (Abdaoui et al., 2017). In another work, medical concepts may receive additional labels (positive, negative or uncertain) Elkin et al. (2005a). Özgür and Radev (2009); Øvrelid et al. (2010); Kilicoglu and Bergler (2010) exploit lexical, grammatical and syntactic information to detect speculation and its scope. ScopeFinder (Apostolova et al., 2011) detects the scope of negation and speculation with rules built automatically from BioScope (lexico-syntactic patterns extraction). *NegBio* (Peng et al., 2018) detects both negation and speculation in radiology reports with rules based on universal dependency graphs.

3.3 SUPERVISED LEARNING

To our knowledge, Light et al. (2004) is the first work to include supervised learning for speculation detection. It relies on SVM to select speculative sentences in MEDLINE abstracts. Tang et al. (2010) proposes a cascade method based on CRF and SVM classifiers to detect speculation cues and another CRF classifier to identify their scopes. Velldal et al. (2012) proposes a SVM-based cue detection system, trained on simple n-grams features computed on the local lexical context (words and lemmas). This system offers a hybrid detection of the scope, which combines expert rules, operating on syntactic dependency trees, with a ranking SVM that learns a discriminative ranking function over nodes in constituent trees. It was further improved by Read et al. (2012) and is used as a fall-back by Packard et al. (2014) when the main MRS (minimal recursion semantics) Crawler cannot parse the sentence. Qian et al. (2016) addresses the scope detection with an approach based on a convolutional neural network which extracts features from various syntactic paths between the cues and the candidate tokens in constituency and dependency parsed trees. Fancellu et al. (2016) uses neural networks to solve the problem of negation scope detection. One approach uses Feed-forward neural network, while the other, which appears to be more efficient for the task, uses a bidirectional Long Short-Term Memory (BiLSTM) neural network. Given the results from the latter approach, it inspired our work.

	French clin. trials	French clin. cases
Documents	–	200
Sentences	6,547	3,811
Tokens	150,084	87,487
Vocabulary (types)	7,880	10,500
Negative sentences	1,025	804
Speculative sentences	630	226

Table 1: Statistics on the two French corpora

4 FRENCH MEDICAL CORPORA

We manually annotated two corpora from the biomedical field. Table 1 presents some statistics on these corpora: the number of words, the variety of the vocabulary, the number of sentences, the number of negative sentences with one or more negations. The Inter Annotator Agreement (IAA) on negation annotation is high (Cohen's κ=0.8461).

4.1 ESSAI: FRENCH CORPUS with CLINICAL TRIALS

One corpus contains clinical trial protocols in French. They were mainly obtained from the National Cancer Institute registry[1]. The typical protocol consists of two parts: the summary of the trial, which indicates the purpose of the trial and the methods applied; and a detailed description of the trial with the inclusion and exclusion criteria.

Form	Lemma	POS	Cue	scope
Pas	pas	ADV	pas	_
de	de	PRP	_	de
dyspnée	dyspnée	NOM	_	dyspnée
.	.	SENT	_	_

Table 2: Excerpt from the CAS corpus. The columns contain linguistic (lemmas, POS-tag) and reference (cue, scope) information.

4.2 CAS: FRENCH CORPUS with CLINICAL CASES

This corpus contains clinical cases published in scientific literature and training material. They are published in different journals from French-speaking countries (France, Belgium, Switzerland, Canada, African countries, tropical countries) and are related to various medical specialties (cardiology, urology, oncology...). The purpose of clinical cases is to describe clinical situations of patients. Hence, their content is close to the content of clinical narratives (description of diagnoses, treatments or procedures, evolution, family history, expected audience, etc.). In clinical cases, the negation is frequently used for describing the patient signs, symptoms, and diagnosis. Speculation is present as well but less frequently.

4.3 ANNOTATION LAYERS

These two corpora are Part-of-Speech tagged and lemmatized with TreeTagger (Schmid, 1994). For the creation of the reference data necessary for machine learning, both corpora were annotated manually to mark up negation and speculation cues and their scope. However, the 200 annotated clinical cases did not include enough examples of speculation for a machine learning models to train properly. Therefore, speculation detection is either trained and tested with ESSAI alone or with ESSAI and CAS. Table 2 presents an annotated sentence from CAS: *No dyspnea.*. The corpora also includes two additional columns (sentence number and token position).

5 METHODOLOGY

As indicated on Figure 1, our methods rely on specifically trained word vectors and supervised learning techniques (BiLSTM and CRF). The objective is to classify each word as being part or not of the negation/speculation cue and/or scope.

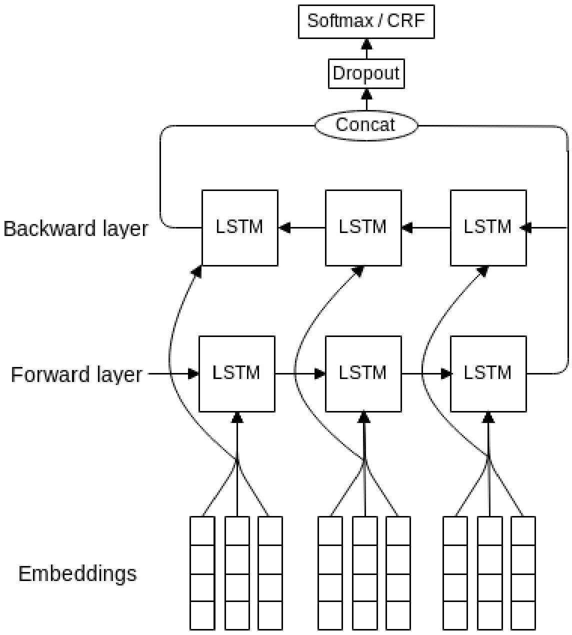

Figure 1: Our bidirectional RNN uses LSTM cells with either a softmax or CRF output layer. Features are either words/lemmas/PoS for cue detection or words/PoS/Cue information for scope detection.

5.1 WORD VECTOR REPRESENTATIONS

In the recent years, several models have been introduced to generate vector representations of words helping machine learning approaches to better capture their semantics. The models used in the negation/speculation detection task are the following ones.

word2vec (Mikolov et al., 2013) is a predictive model to learn word embeddings from plain text. The embeddings can be calculated using two model architectures: the continuous bag-of-words (CBOW) and *Skip-Gram* (SG) models. In this work, we use use the SG model; it treats each context-target pair as new observation, which is suitable for large datasets.

fastText (Bojanowski et al., 2017) addresses the Word2vec's main issue: the words, which do not occur in the vocabulary, cannot be represented. Hence, this algorithm uses subword information: each word is represented as a bag of all possible character n-grams it contains. The word is padded using a set of unique symbols which helps singling out prefixes and suffixes. The full sequence is added to the bag of n-grams as well. The vector now denotes every char n-gram and the word vector is the sum of its char n-gram vectors. Since the char n-gram representations across words are often shared, rare words can also get reliable representations.

These two word embedding models are trained using the *Skip-Gram* algorithm, 100 dimensions, a window of 5 words before and after each word, a minimum count of five occurrences for each word and negative sampling. The training data are composed of the French Wikipedia articles and biomedical data. The latter includes the ESSAI and CAS corpora, the French Medical Corpus from CRTT[2] and the Corpus QUAERO Médical du français[3] (Névéol et al., 2014). These models are trained using the Gensim[4] (Rehurek and Sojka, 2010) python library.

5.2 RECURRENT NEURAL NETWORK

Recurrent neural network takes into account the previously seen data in addition to the currently seen data. This is implemented with loops in the architecture of the network, which allows the information to persist in memory. Among the RNNs, long short-term memory networks (LSTM) (Hochreiter and Schmidhuber, 1997) are the most efficient for the learning of long-term dependencies and are therefore more suitable to solve the problem of discontinuous scope, which is typical for the negation. LSTM cells are also more efficient at retaining useful information during backpropagation.

We use a bidirectional LSTM, which operates forward and backward on the sentence, to detect cues and scopes. The backward pass is relevant for the scope detection because the scope may be before or after the cue. Prediction is computed by either a *softmax* or a CRF (suitable for the sequence labeling) output layer. We use embeddings of dimension $k = 100$ and a dimensionality of the output space of 400 units per layer (backward/forward) with 0.5 dropout. 50 epochs achieve the highest F_1 score on the validation sets.

5.3 CONDITIONAL RANDOM FIELDS

Conditional random fields (CRFs) (Lafferty et al., 2001) are statistical methods used to label word sequences. By training a model on appropriate features and labels to be predicted, the CRFs generally obtain good results with much lower training time than neural networks.

We performed the gradient descent using the L-BFGS (Limited-memory BFGS) method with 0.1 L1 penalty and 0.01 L2 penalty. We only experiment with CRFs for the cue detection task, in comparison with BiLSTM-CRF.

5.4 EVALUATING LABELING SYSTEMS

We use standard evaluation measures: precision P, recall R, and F_1 score. The scope detection is evaluated in two ways: (1) on individual scope tokens which is the standard evaluation, and (2) on exact scopes to assess more strictly how efficient our models are. For the latter, we use the available evaluation script[5]. Each corpus is randomly segmented into the training set (80%, 20% for validation), and the test set (20%).

6 CUE DETECTION

The speculation and negation cue detection is the first step of the task. To tackle this problem, we experiment with two supervised learning approaches. First, we train a CRF using several features (words, lemmas and POS-tags) with empirically defined window over features. Our second approach uses a BiLSTM with a CRF output layer, which is trained on the same features. We did not use any pre-trained embeddings for this task.

Table 3 presents the results obtained with our approaches on the ESSAI and CAS corpora. We can see that cue detection shows high evaluation values: 93.92 to 97.21 F-measure for negation cues, and 86.88 to 91.30 F-measure for speculation cues. Although there is little room for improvement on negation cue detection, indeed 10k-fold cross-validation with our CRF reaches more than 95 F-measure on both corpora, speculation cue detection would benefit from more training examples. Indeed, the potential number of cues and the numerous contexts in which they appear and do or do not express speculation makes them harder to detect and will require more annotated examples. For both negation and speculation cue detection, our CRF is slightly more efficient than the BiLSTM-CRF when the CAS corpus is involved, which indicates that the CAS corpus contains less complex examples than ESSAI.

7 SCOPE DETECTION

In all the scope detection experiments proposed, we only train the neural networks on nega-

Table 5: Cross-corpora Precision, Recall and F$_1$-score for the scope detection task (bold: best scores).

tive/speculative sentences. The base system takes as input an instance $I(w, c, t)$, where each word is represented by: w vector (*word-embedding*), c vector (*cue-embedding*), indicating if the word is a cue or not, t vector (*POS-tag-embedding*). Preliminary tests showed that adding lemmas as features only decreases the F-measure. For each system, we use the same empirically defined hyperparameters given before. During training, embeddings weights are updated.

Table 4 indicate the results obtained for the scope detection task. One can see that it is easier to predict the scope of negation cues (up to 90.81 F-measure) than of speculation cues (up to 86.73 F-measure). Results show that using pre-trained embeddings improves F-measures for exact scope detection by up to 6 points for both negation and speculation. Moreover, the CRF output layer either outperforms the *softmax* layer or reaches an equivalent F-measure for exact scope detection. In another experiment, we trained the models on one corpus and tested them on the other (Table 5): the models trained on ESSAI are more efficient, and the negation and speculation structures are more stable in the CAS corpus. However, even though CAS (speculation) was only trained on 226 examples, the model still shows decent results in scope tokens detection.

7.1 ERROR ANALYSIS

An analysis of the results makes it possible to isolate frequent types of errors. In the following examples, the speculation and negation cues are underlined, the scope is between brackets, while the segments in bold correspond to predictions errors.

7.1.1 NEGATION

In the first example, the prediction fails at labeling ***rénale*** *(renal)*. In the majority of cases in the reference data, the scopes associated to the cue ***sans*** often only include one token, which may be causing this error that impacts recall:

- GOLD: *Le patient sortira du service de réanimation guéri et sans [insuffisance rénale] après huit jours de prise en charge et cinq séances d'hémodialyse.*
- PRED: *Le patient sortira du service de réanimation guéri et sans [insuffisance]* ***rénale*** *après huit jours de prise en charge et cinq séances d'hémodialyse.*

  (The patient will be discharged from the intensive care unit without renal failure after eight days of management and five hemodialysis sessions.)

The second example illustrates the error that impacts precision. Here, the model wrongly predicts that all tokens in the sentence are within the scope. In the reference data, the cue ***aucun*** *(any, no)* often occurs at the beginning of sentences, and in sentences with many instances of negation. The model, mostly trained on this kind of examples, may try to reproduce these structures which causes bad prediction in some cases.

- GOLD: *Les colorations spéciales (PAS, coloration de Ziehl-Neelsen, coloration de Grocott) ne [mettaient en évidence] aucun [agent pathogène].*
- PRED: ***[Les colorations spéciales (PAS, coloration de Ziehl-Neelsen, coloration de Grocott]*** *) ne [mettaient en évidence] aucun [agent pathogène].*

  (Special stains (PAS, Ziehl-Neelsen stain, Grocott stain) showed no pathogens.)

In the third example, the error impacts both precision and recall. In this example, we have two instances of negation with the same cues: ***n...pas***. Usually, its scope follows, however, in the first instance it precedes. As we do not have many examples of this kind to train on, the model fails to correctly label the sequence. In the second negation instance, the scope may be shorter than usual, which impacts precision.

- GOLD: *[Le retrait du matériel d'ostéosynthèse incriminé] n'[est] pas [systématique], ce qui explique qu'il n'[ait] pas [été proposé] à notre patient asymptomatique.*
- PRED: ***Le retrait du matériel d'ostéosynthèse incriminé*** *n'[est] pas [systématique], ce qui explique qu'il n'[ait] pas [été proposé* ***à notre patient asymptomatique*** *].*

  (The removal of the implicated osteosynthesis material is not systematic, which explains why it has not been proposed to our asymptomatic patient.)

7.1.2 SPECULATION

In the first example, the scope of the speculation has been predicted up to the end of the preposition while in the reference data, the scope covers the verbal group. This typically impacts precision.

- GOLD: *Ce médicament n'a pas la toxicité de la chimiothérapie, mais entraine une disparition des lymphocytes B normaux pendant plusieurs mois, ce qui pourrait [favoriser la survenue d'infections graves] car ces lymphocytes participent à la défense immunitaire.*
- PRED: *Ce médicament n'a pas la toxicité de la chimiothérapie, mais entraine une disparition des lymphocytes B normaux pendant plusieurs mois, ce qui pourrait [favoriser la survenue d'infections graves* ***car ces lymphocytes participent à la défense immunitaire****]*

  (This drug does not have the toxicity of chemotherapy, but causes the disappearance of normal B lymphocytes for several months, which could increase the occurrence of serious infections because these lymphocytes participate in the immune defense.)

However, most of our errors impact recall, like in the following example.

- GOLD: *Elles possèdent les caractéristiques de la tumeur et pourraient [permettre à l'avenir de faire le diagnostic de tumeur sans biopsie ainsi que de suivre l'évolution de la tumeur traitée], les CTC disparaissant quand le traitement fonctionne.*
- PRED: *Elles possèdent les caractéristiques de la tumeur et pourraient [permettre à l'avenir de faire le diagnostic de tumeur]* ***sans biopsie ainsi que de suivre l'évolution de la tumeur traitée****, les CTC disparaissant quand le traitement fonctionne.*

  (It has the characteristics of the tumor and could in the future be used to diagnose the tumor without biopsy and to follow-up the evolution of the treated tumor, the CTC disappearing when the treatment is efficient.)

Several examples show errors where both precision and recall are impacted. Usually, the reason is that they are rare cases in our corpora where the scope is reversed. For instance, in the example below, most of the scope of *devrait* precedes it, while in the reference data, its scope follows this cue.

- GOLD: *L'objectif de cet essai est d'évaluer [la diminution des complications postopératoires de l'oesophagectomie qui] devrait [être obtenue] en réalisant une partie de l'intervention sous coelioscopie, chez des patients ayant un cancer de l'oesophage résécable.*
- PRED: *L'objectif de cet essai est d'évaluer la diminution des complications postopératoires de l'oesophagectomie qui devrait [être obtenue* ***en réalisant une partie de l'intervention sous coelioscopie****], chez des patients ayant un cancer de l'oesophage résécable.*

  (The objective of this trial is to evaluate the decrease in postoperative complications of esophagectomy that should be achieved by performing part of the procedure under laparoscopy, for patients with resectable esophageal cancer.)

8 CONCLUSION and FUTURE WORK

The interest for the automatic detection of speculation and negation in English with supervised machine learning has increased in the recent years. Yet, the lack of data for other languages and for specialized domains hampers the further development of such approaches. In our work, we presented new bodies of biomedical data in French annotated with negation and speculation (cues and their scope). Prior to the dissemination to the research community, the French clinical trial protocols corpus will be finalized through the integration of new data and the computation of the inter-annotator agreement. The French CAS corpus will be distributed as more clinical cases are manually annotated, as we need more speculative sentences to train supervised learning models on this dataset. Another contribution of our work is the study of different types of word vector representations and recurrent neural networks for the detection of negation and speculation. There has not been much work of this type on French corpora, especially for the biomedical domain which contains specific negation and speculation phenomena. We showed that a *CRF* layer yields better performance than *softmax* on exact scope match. Finally, the models have been applied in a cross-corpus context. Besides, we plan to improve our neural network performance by providing richer feature. In particular, recent embedding techniques, such as BERT or ELMO (Devlin et al., 2018; Peters et al., 2018) may provide more accurate representation of the sentences. Moreover, in order to provide more accurate features, we plan to move from TreeTagger, which makes a substantial number of mistakes on our datasets, to a POS tagger/lemmatizer dedicated to French biomedical texts. Syntactic parsing of sentences may also provide useful features for the detection of scope.

Abstract

We describe work consisting in porting various morphological resources to the OntoLex-Lemon model. A main objective of this work is to offer a uniform representation of different morphological data sets in order to be able to compare and interlink multilingual resources and to cross-check and interlink or merge the content of morphological resources of one and the same language. The results of our work will be published on the Linguistic Linked Open Data cloud.

1 Introduction

A significant number of linguistic resources have been published on the Linguistic Linked Open Data cloud (LLOD),[1] and projects like ELEXIS[2] and Prêt-à-LLOD[3] are contributing to its further extension. But we notice that only very few, if any, specific morphological resources are included in the LLOD cloud. Available morphology information is mostly contained in lexical or dictionary entries. Our aim is to make also specialized morphological resources available in this cloud. With this step we want to support the interlinking of such resources with other types of linguistic data, in a multilingual fashion, extending work described in (Gromann and Declerck, 2019), which is linking synsets of the Princeton WordNet (PWN) (Fellbaum, 1998) that are associated with plural forms to full lexical descriptions.

A first step of our current work consisted in mapping the MMorph[4] set of multilingual morphological resources to the OntoLex-Lemon model.[5]

In the next sections, we first describe briefly the Linguistic Linked Open Data cloud, and one of its salient component, the OntoLex-Lemon model. Following this summary, we describe the (multilingual) morphological resources we selected for mapping to OntoLex-Lemon. We present the result of such mappings and conclude with a description of the next steps of our work, aiming at supporting the cross-lingual comparison of morphological resources, and the cross-checking, correcting and merging of different morphological resources for one and the same language.

2 The Linguistic Linked Open Data Cloud

The LLOD initiative had its inception in 2012 at a workshop co-located with the 34th Annual Conference of the German Linguistic Society (DGfS). The workshop was organized by members of the Open Knowledge Foundation,[6] and the contributions to this workshop are available in (Chiarcos et al., 2012). The workshop has been a point of focal activity for several research and infrastructure projects, as well as for the "Ontology Lexica" W3C Community Group.[7] Those developments are described in (McCrae et al., 2016). A major result of those activities is the development of the OntoLex-Lemon model, which is described in more details in Section 3.

We adopted OntoLex-Lemon for the representation of morphological resources, as this model was shown to be able to represent both classical lexicographic description (McCrae et al., 2017) and lex-

ical semantics networks, like WordNet (McCrae et al., 2014), to which we want to link full morphological descriptions.

3 OntoLex-Lemon

The OntoLex-Lemon model was originally developed with the aim to provide a rich linguistic grounding for ontologies, meaning that the natural language expressions used in the description of ontology elements are equipped with an extensive linguistic description.[8] This rich linguistic grounding includes the representation of morphological and syntactic properties of lexical entries as well as the syntax-semantics interface, i.e. the meaning of these lexical entries with respect to an ontology or to specialized vocabularies.

The main organizing unit for those linguistic descriptions is the lexical entry, which enables the representation of morphological patterns for each entry (a MWE, a word or an affix). The connection of a lexical entry to an ontological entity is marked mainly by the `denotes` property or is mediated by the `LexicalSense` or the `LexicalConcept` properties, as this is represented in Figure 1, which displays the core module of the model.

OntoLex-Lemon builds on and extends the *lemon* model (McCrae et al., 2012b). A major difference is that OntoLex-Lemon includes an explicit way to encode conceptual hierarchies, using the SKOS standard.[9] As can be seen in Figure 1, lexical entries can be linked, via the `ontolex:evokes` property, to such SKOS concepts, which can represent WordNet synsets. This structure is paralleling the relation between lexical entries and ontological resources, which is implemented either directly by the `ontolex:reference` property or mediated by the instances of the `ontolex:LexicalSense` class.

More recent developments of the model have been described in (McCrae et al., 2017). Currently two extension modules are being discussed: a lexicographic and a morphology module.[10] Our work can also be seen as preparing the field for a detailed representation of morphological components of lexical data by first porting morphological resources to the core module of OntoLex-Lemon, displayed in 1, before applying the representation guidelines of the morphology extension module, which is not yet in a stable and final state.

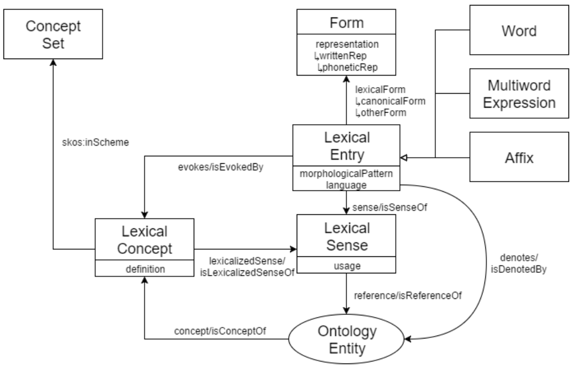

Figure 1: The core module of OntoLex-Lemon: Ontology Lexicon Interface. Graphic taken from `https://www.w3.org/2016/05/ontolex/`.

4 The Morphological Resources

We considered two types of morphological data sets. One is an updated version of the multilingual MMorph resource (Petitpierre and Russell, 1995), covering 5 languages. And we also mapped two monolingual data sets, one for German and one for Italian. We will use those additional data sets for the comparison, cross-checking and merging of monolingual morphological resources, using the uniform representation of the data in OntoLex-Lemon.

4.1 MMorph

MMorph was originally developed by ISSCO at University of Geneva in the past MULTEXT project.[11] For our purposes, we used the extended MMorph version developed at DFKI LT Lab (*MMorph3*). This version includes huge morphological resources for English, French, German, Italian and Spanish.

We choose this resource as it provides already in its original format a largely unified representation of the morphological data in the different lan-

[8] See (McCrae et al., 2012a), (Cimiano et al., 2016) and also `https://www.w3.org/community/ontolex/wiki/Final_Model_Specification`.

[9] SKOS stands for "Simple Knowledge Organization System". SKOS provides "a model for expressing the basic structure and content of concept schemes such as thesauri, classification schemes, subject heading lists, taxonomies, folksonomies, and other similar types of controlled vocabulary" (https://www.w3.org/TR/skos-primer/)

[10] See respectively `https://www.w3.org/community/ontolex/wiki/Lexicography` and `https://www.w3.org/community/ontolex/wiki/Morphology`.

[11] See `https://www.issco.unige.ch/en/research/projects/MULTEXT.html` for more details on the resulting `MMorph 2.3.4` version.

guages, with only few differences across the distinct sources.

Very generally, the MMorph tool relates a word to a morphosyntactic description (MSD) containing free-definable attribute and values. The MMorph lexicon used to realize such MSD consists of a set of lexical entries and structural rules. For example, the following rule creates in English a noun plural concatenating the singular form and the noun suffix “s” (Petitpierre and Russell, 1995):

```
"s" noun_suffix[number=plur]

noun[number=plur gender=$gen]
    <- noun[number=sing gender=$gen]
       noun_suffix[number=plur]
```

Note how the rule ensures that the gender does not change in the plural form. Further *adjustment rules* are defined to catch the orthographic features of a specific language (e.g. *box+s* = *boxes* in English).

The MMorph lexica can be dumped to full form lists for the usage in further programs:

Listing 1: The MMorph entry for the German noun “Aachener” (*inhabitant of Aachen*)

```
"aachener" = "aachener" Noun[gender=masc
    number=singular case=nom|dat|acc]
"aachener" = "aachener" Noun[gender=masc
    number=plural case=nom|gen|acc]
"aachenern" = "aachener" Noun[gender=masc
    number=plural case=dat]
"aacheners" = "aachener" Noun[gender=masc
    number=singular case=gen]
```

As the reader can observe in Listing 1, the nominal entries are completed by appropriate features describing *case*, *gender*, and *number*. Multiple values of a feature are expressed by “|”. The user can freely define language- and word class-specific features (e.g. *clitics* for verbal entries or *rection* of prepositions). As the example above demonstrates, the dumped lexica are ideally suited for the mapping into the OntoLex-Lemon format, as they present their data in a well structured fashion.

Our German version of MMorph contains over 2.630.000 full-forms. Compared to the original version, it has specifically improved the coverage of compounds.

To transform the MMorph data into OntoLex-Lemon we used a Python script including the `rdflib` module[12], which supports the generation of RDF-graphs in `rdf:xml`, `turtle` syntax and other relevant formats.

In Listing 2 we show the resulting OntoLex-Lemon representation of the German noun “Aachener”.

Listing 2: The OntoLex-Lemon entry for *Aachener*

```
:lex_aachener a ontolex:LexicalEntry ;
   lexinfo:gender lexinfo:masculine ;
   lexinfo:partOfSpeech lexinfo:noun ;
   ontolex:canonicalForm :form_aachener ;
   ontolex:otherForm
      :form_aachener_dat_plural ,
      :form_aachener_gen_singular ,
      :form_aachener_nom-gen-acc_plural .

:form_aachener a ontolex:Form ;
   lexinfo:case lexinfo:accusative ,
      lexinfo:dative ,
      lexinfo:nominative ;
   lexinfo:number lexinfo:singular ;
   ontolex:writtenRep "Aachener"@de .

:form_aachener_dat_plural a
      ontolex:Form ;
   lexinfo:case lexinfo:dative ;
   lexinfo:number lexinfo:plural ;
   ontolex:writtenRep "Aachenern"@de .

:form_aachener_gen_singular a
      ontolex:Form ;
   lexinfo:case lexinfo:genitive ;
   lexinfo:number lexinfo:singular ;
   ontolex:writtenRep "Aacheners"@de .

:form_aachener_nom-gen-acc_plural a
      ontolex:Form ;
   lexinfo:case lexinfo:accusative ,
      lexinfo:genitive ,
      lexinfo:nominative ;
   lexinfo:number lexinfo:plural ;
   ontolex:writtenRep "Aachener"@de .
```

The reader can observe how the relations between a lemma (an instance of the class `LexicalEntry`) and its different morphological forms (instances of the class `Form`) is made explicit by the use of named properties. Another feature of our work is the re-use of established vocabularies, for example the LexInfo vocabulary[13] to represent the morpho-syntactic features.

In Listing 3, we show examples of the resulting data for the lemma “cura” in Spanish.

Listing 3: The OntoLex-Lemon entry for *cura*

```
:lex_cura_1 a ontolex:LexicalEntry ;
    lexinfo:gender lexinfo:feminine ;
    lexinfo:partOfSpeech lexinfo:noun ;
    ontolex:canonicalForm :form_cura ;
    ontolex:otherForm :form_cura_plural .
```

[12] See `https://github.com/RDFLib/rdflib` for more details.

[13] See `https://lexinfo.net/` and (Cimiano et al., 2011) for more details

```
:lex_cura_2 a ontolex:LexicalEntry ;
    lexinfo:gender lexinfo:masculine ;
    lexinfo:partOfSpeech lexinfo:noun ;
    ontolex:canonicalForm :form_cura ;
    ontolex:otherForm :form_cura_plural .

:form_cura a ontolex:Form ;
    lexinfo:number lexinfo:singular ;
    ontolex:writtenRep "cura"@es .

:form_cura_plural a ontolex:Form ;
    lexinfo:number lexinfo:plural ;
    ontolex:writtenRep "curas"@es .
```

As the reader can observe, we have two lexical entries for the entry "cura", as this is suggested by the lexicographic module of Ontolex-Lemon.[14] "Cura" in feminine means *cure* or *healing*, while in masculine it refers to a *cure*. But one can also propose a unique entry for "cura" and add in each of the associated senses a usage restriction indicating the gender of the corresponding `ontolex:Form`.

The reader can also see the harmonized representation of morphological resources across languages (here German and Spanish). This is an important feature that will allow to link various lemmas (or senses) from different languages to a unique reference point in external information sources, like WordNet(s)[15] or knowledge Graphs, like DBpedia[16] or Wikidata[17].

The transformation of nominal entries from MMorph to the OntoLex-Lemon format resulted in 67778 instances of the class `LexicalEntry` for German, 17313 for Spanish, 21085 for Italian, 29959 for English and 13525 for French. The English nominal data in OntoLex-Lemon include 59108 instances of the class `Form`, while the German data consists of 224449 such forms. This largely depends on the maintenance state of the original resources, but gives nevertheless a good idea on the difference of morphological variations in the distinct languages.

4.2 Two Monolingual Resources

Other data sets we are considering are "Morph-it!"[18] for Italian and the "DE_morph_dict data"[19].

An entry in Morph-it! has the form displayed in Listing 4:

Listing 4: The Morph-it! entry for "abbassamento" (*lowering* or *reduction*)

```
abbassamento    abbassamento    NOUN–M:s
abbassamenti    abbassamento    NOUN–M:p
```

The corresponding OntoLex-Lemon encoding is displayed in Listing 5. While this representation looks much more complex than the original Morph-it! one, it represents the relations in an explicit and declarative way and at the same time it gives a full "autonomy" to the form variants, which are now represented as instances of the class `ontolex:Form` and equipped with an URI, so that they can be accessed independently of their corresponding headword.

Listing 5: The OntoLex-Lemon representation for "abbassamento" (*lowering* or *reduction*)

```
:lex_abbassamento a
        ontolex:LexicalEntry;
   lexinfo:gender lexinfo:masculine ;
   lexinfo:partOfSpeech lexinfo:noun ;
   ontolex:canonicalForm
:form_abbassamento ;
   ontolex:otherForm
     :form_abbassamento_m_p .

:form_abbassamento a ontolex:Form ;
   lexinfo:number lexinfo:singular ;
   ontolex:writtenRep "abbassamento"@it.

:form_abbassamento_m_p a ontolex:Form ;
   lexinfo:number lexinfo:plural ;
   ontolex:writtenRep "abbassamenti"@it.
```

In Listing 6 below, we display an original entry of the DE_morph_dict resource, in this example the word "Abgang" (*departure*, *leaving*, *dispatch*, etc.). The reader can immediately see the difference to the Italian entry in Listing 4, as in German there are four cases and three genders, a fact which leads to a high number of morphological form variants. Also this entry is including obsolete forms of the word, which is adding an additional line in the original encoding.

[14] See the discussion on this case at `https://www.w3.org/community/ontolex/wiki/Lexicography`.

[15] Concerning the linking to WordNets, we started linking the French, Italian and Spanish morphological data to their counterparts in the Open Multilingual WordNet initiative. See `http://compling.hss.ntu.edu.sg/omw/` and (Bond and Paik, 2012) for more details

[16] `https://wiki.dbpedia.org/`

[17] `https://www.wikidata.org/wiki/Wikidata:Main_Page`

[18] `https://docs.sslmit.unibo.it/doku.php?id=resources:morph-it`. See also (Zanchetta and Baroni, 2005)).

[19] `https://github.com/DuyguA/german-morph-dictionaries`. See also for this resource the companion morphological analyser in (Altinok, 2018)).

Listing 6: The DE_morph_dict entry for “Abgang” (*departure* or *leaving* etc)

```
Abgang
Abgang NN,masc,acc,sing
Abgang NN,masc,nom,sing
Abgang NN,masc,dat,sing
Abgange
Abgang NN,masc,dat, ing,old
Abganges
Abgang NN,masc,gen,sing
Abgangs
Abgang NN,masc,gen,sing
Abgänge
Abgang NN,masc,nom,plu
Abgang NN,masc,acc,plu
Abgang NN,masc,gen,plu
Abgängen
Abgang NN,masc,dat,plu
```

The mapping of this entry to OntoLex-Lemon results in a representation that is by now familiar, and which is given in Listing 7.

Listing 7: The OntoLex-Lemon representation for “Abgang” (*departure* or *leaving* etc)

```
:lex_abgang a ontolex:LexicalEntry ;
    lexinfo:gender lexinfo:masculine ;
    lexinfo:partOfSpeech lexinfo:noun ;
    ontolex:canonicalForm :form_abgang ;
    ontolex:otherForm
        :form_abgang_dat_plu ,
        :form_abgang_dat_sing ,
        :form_abgang_gen_sing ,
        :form_abgang_nom-gen-acc_plu .

:form_abgang a ontolex:Form ;
    lexinfo:case lexinfo:accusative ,
        lexinfo:dative ,
        lexinfo:nominative ;
    lexinfo:number lexinfo:singular ;
    ontolex:writtenRep "Abgang"@de .

:form_abgang_dat_plu a ontolex:Form ;
    lexinfo:case lexinfo:dative ;
    lexinfo:number lexinfo:plural ;
    ontolex:writtenRep "Abgängen"@de .

(etc.)
```

With those resources represented in OntoLex-Lemon, which are duplicating the German and Italian resources we have already from MMorph, we aim at discovering possible inconsistencies or similarities within resources for one language, which could lead to both a improvement and a merging of the original resources.

We are in a sense extending a former experiment on automatically merging Italian morphological resources in the context of a finite automata environment, and which is described in (Declerck et al., 2012). The new work is not only a multilingual extension, but is aiming at a broad interoperability of morphological resources by using a defacto standard developed by a W3C Community Group and publishing the results in an accessible subset of the Linked Data cloud.

5 Conclusion

We described our current work consisting in porting a number of (multilingual) morphological resources to OntoLex-Lemon, in order to harmonize those and to support their interlinking, cross-checking, but also their linking with other data source in the Linguistic Linked Open Data, as for examples WordNets, or with data sets included in knowledge graphs, like DBpedia or Wikidata.

As a final goal of our work, we see the possibility to interlink or merge those morphological resources in the Linguistic Linked Open Data cloud.

Acknowledgments

Work presented in this paper has been supported in part by the H2020 project “Prêt-à-LLOD” with Grant Agreement number 825182. Contributions by Thierry Declerck are also supported in part by the H2020 project “ELEXIS” with Grant Agreement number 731015.

Dependency-Based Self-Attention for Transformer NMT

Hiroyuki Deguchi, Akihiro Tamura, Takashi Ninomiya
Ehime University
{deguchi@ai., tamura@, ninomiya@}cs.ehime-u.ac.jp

Abstract

In this paper, we propose a new Transformer neural machine translation (NMT) model that incorporates dependency relations into self-attention on both source and target sides, dependency-based self-attention. The dependency-based self-attention is trained to attend to the modifiee for each token under constraints based on the dependency relations, inspired by linguistically-informed self-attention (LISA). While LISA was originally designed for Transformer encoder for semantic role labeling, this paper extends LISA to Transformer NMT by masking future information on words in the decoder-side dependency-based self-attention. Additionally, our dependency-based self-attention operates at subword units created by byte pair encoding. Experiments demonstrate that our model achieved a 1.0 point gain in BLEU over the baseline model on the WAT'18 Asian Scientific Paper Excerpt Corpus Japanese-to-English translation task.

1 Introduction

In the field of machine translation (MT), the Transformer model (Vaswani et al., 2017) has outperformed recurrent neural network (RNN)-based models (Sutskever et al., 2014) and convolutional neural network (CNN)-based models (Gehring et al., 2017) on many translation tasks, and thus has garnered attention from MT researchers. The Transformer model computes the strength of a relationship between two words in a sentence by means of a self-attention mechanism, which has contributed to the performance improvement in not only MT but also various NLP tasks such as language modeling and semantic role labeling (SRL).

The performance of MT, including statistical machine translation and RNN-based neural machine translation (NMT), has been improved by incorporating sentence structures (Lin, 2004; Chen et al., 2017; Eriguchi et al., 2017; Wu et al., 2018). In addition, Strubell et al. (2018) have improved a Transformer-based SRL model by incorporating dependency structures of sentences into self-attention, which is called linguistically-informed self-attention (LISA). In LISA, one attention head of a multi-head self-attention is trained with constraints based on dependency relations to attend to syntactic parents for each token.

In the present work, we aim to improve translation performance by utilizing dependency relations in Transformer NMT. To this end, we propose a Transformer NMT model that incorporates dependency relations into self-attention on both source and target sides. Specifically, in training, a part of self-attention is learned with constraints based on dependency relations of source or target sentences to attend to a modifiee for each token, and, in decoding, the proposed model translates a sentence in consideration of dependency relations in both the source and target sides, which are captured by our self-attention mechanisms. Hereafter, the proposed self-attention is called dependency-based self-attention. Note that the dependency-based self-attention is inspired by LISA, but the straightforward adaptation of LISA, which is proposed for Transformer encoder, does not work well for NMT because a target sentence is not fully revealed in inference. Therefore, the proposed model masks future information on words in the decoder-side dependency-based self-attention to prevent from attending to unpredicted subsequent tokens.

Recent NMT models treat a sentence as a sub-

word sequence rather than a word sequence to address the translation of out-of-vocabulary words (Sennrich et al., 2016). Therefore, we extend dependency-based self-attention to operate at subword units created by byte pair encoding (BPE) rather than word-units.

Our experiments demonstrate that the proposed Transformer NMT model performs 1.0 BLEU points higher than the baseline Transformer NMT model, which does not incorporate dependency structures, on the WAT'18 Asian Scientific Paper Excerpt Corpus (ASPEC) Japanese-to-English translation task. The experiments also demonstrate the effectiveness of each of our proposals, namely, encoder-side dependency-based self-attention, decoder-side dependency-based self-attention, and extension for BPE.

2 Transformer NMT

We provide here an overview of the Transformer NMT model (Vaswani et al., 2017), which is the basis of our proposed model. The outline of the Transformer NMT model is shown in Fig. 1.

The Transformer NMT model is an encoder-decoder model that has a self-attention mechanism. The encoder maps an input sequence of symbol representations (i.e., a source sentence) $X = (x_1, x_2, \ldots, x_{n_{enc}})^T$ to an intermediate vector. Then, the decoder generates an output sequence (i.e., a target sentence) $Y = (y_1, y_2, \ldots, y_{n_{dec}})^T$, given the intermediate vector. The encoder and the decoder are composed of a stack of J_e encoder layers and of J_d decoder layers, respectively.

Because the Transformer model does not include recurrent or convolutional structures, it encodes word positional information as sinusoidal positional encodings:

$$P_{(pos,2i)} = sin(pos/10000^{2i/d}), \tag{1}$$
$$P_{(pos,2i+1)} = cos(pos/10000^{2i/d}), \tag{2}$$

where pos is the position, i is the dimension, and d is the dimension of the intermediate representation. At the first layers of the encoder and decoder, the positional encodings calculated by Equations (1) and (2) are added to the input embeddings.

The j-th encoder layer's output $S_{enc}^{(j)}$ is generated by a self-attention layer $SelfAttn()$ and a position-wise fully connected feed forward network layer $FFN()$ as follows:

$$H_{enc}^{(j)} = LN(S_{enc}^{(j-1)} + SelfAttn(S_{enc}^{(j-1)})), \tag{3}$$
$$S_{enc}^{(j)} = LN(H_{enc}^{(j)} + FFN(H_{enc}^{(j)})), \tag{4}$$

where $S_{enc}^{(0)}$ is the input of the encoder, $H_{enc}^{(j)}$ is the output of the j-th encoder's self-attention, and $LN()$ is layer normalization (Lei Ba et al., 2016). The j-th decoder layer's output $S_{dec}^{(j)}$ is generated by an encoder-decoder attention layer $EncDecAttn()$ in addition to the two sublayers of the encoder (i.e., $SelfAttn()$ and $FFN()$) as follows:

$$H_{dec}^{(j)} = LN(S_{dec}^{(j-1)} + SelfAttn(S_{dec}^{(j-1)})), \tag{5}$$
$$G_{dec}^{(j)} = LN(H_{dec}^{(j)} + EncDecAttn(H_{dec}^{(j)})), \tag{6}$$
$$S_{dec}^{(j)} = LN(G_{dec}^{(j)} + FFN(H_{dec}^{(j)})), \tag{7}$$

where $S_{dec}^{(0)}$ is the input of the decoder, $H_{dec}^{(j)}$ is the output of the j-th decoder's self-attention, and $G_{dec}^{(j)}$ is the output of the j-th decoder's encoder-decoder attention.

The last decoder layer's output $S_{dec}^{(J_d)}$ is linearly mapped to a V-dimensional matrix, where V is the output vocabulary size. Then, the output sequence Y is generated based on $P(Y \mid X)$, which is calculated by applying the softmax function to the V-dimensional matrix.

Self-attention computes the strength of the relationship between two words in the same sentence (i.e., between two source words or between two target words), and encoder-decoder attention computes the strength of the relationship between a source word and a target word.

Both the self-attention and encoder-decoder attention are implemented with multi-head attention, which projects the embedding space into n_{head} subspaces of the $d_{head} = d/n_{head}$ dimension and calculates attention in each subspace. In the j-th layer's self-attention, the previous layer's output $S^{(j-1)} \in \mathbb{R}^{n \times d}$ is linearly mapped to three d_{head}-dimensional subspaces, $Q_h^{(j)}$, $K_h^{(j)}$, and $V_h^{(j)}$, using parameter matrices $W_h^{Q^{(j)}} \in \mathbb{R}^{d \times d_{head}}$, $W_h^{K^{(j)}} \in \mathbb{R}^{d \times d_{head}}$, and $W_h^{V^{(j)}} \in \mathbb{R}^{d \times d_{head}}$, where n is the length of the input sequence and $1 \leq h \leq n_{head}$[1]. In the j-th decoder layer's encoder-decoder attention, the previous layer's output $S_{dec}^{(j-1)}$ is mapped to $Q_h^{(j)}$, and the last encoder layer's output $S_{enc}^{(J_e)}$ is mapped to $K_h^{(j)}$ and $V_h^{(j)}$.

Then, an attention weight matrix, where each value represents the strength of the relationship between two words, is calculated on each subspace as follows:

$$A_h^{(j)} = softmax(d_{head}^{-0.5} Q_h^{(j)} K_h^{(j)^T}). \tag{8}$$

By multiplying $A_h^{(j)}$ and $V_h^{(j)}$, a weighted representation matrix $M_h^{(j)}$ is obtained:

$$M_h^{(j)} = A_h^{(j)} V_h^{(j)}. \tag{9}$$

$M_h^{(j)}$ in self-attention includes the strengths of the relationships with all words in the same sentence for each source or target word, and $M_h^{(j)}$ in encoder-decoder attention includes the strengths of the relationships with all source words for each target word.

Finally, the concatenation of all $M_h^{(j)}$ (i.e., $M_{1,2,\ldots,n_{head}}^{(j)}$) is mapped to a d-dimensional matrix $M^{(j)}$ as follows:

$$M^{(j)} = W^{M^{(j)}}[M_1^{(j)}; \ldots; M_{n_{head}}^{(j)}], \tag{10}$$

where $W^{M^{(j)}} \in \mathbb{R}^{d \times d}$ is a parameter matrix.

Note that, in training, the decoder's self-attention masks future words so as to ensure that the attentions of a target word do not rely on unpredicted words in inference.

3 Proposed Method

Figure 2 shows the outline of the proposed model. The proposed model incorporates dependency relations into self-attention on both source and target sides, *dependency-based self-attention*. In particular, it parses the dependency structures of source sentences and target sentences by one attention head of the p_e-th encoder layer's multi-head self-attention and one of the p_d-th decoder layer's multi-head self-attention, respectively, and translates a sentence based on the source-side and target-side dependency structures. We use the deep bi-affine parser (Dozat and Manning, 2016) as a model for dependency parsing in the dependency-based self-attention according to LISA. There are two inherent differences between LISA and our dependency-based self-attention: (i) our decoder-side dependency-based self-attention masks future information on words, and (ii) our dependency-based self-attention operates at subword units created by byte pair encoding rather than word-units.

Figure 2: Proposed model.

3.1 Dependency-Based Self-Attention

The dependency-based self-attention parses dependency structures by extending the multi-head self-attention of the p-th layer of the encoder or decoder[2]. First, the p-th self-attention layer maps the previous layer's output $S^{(p-1)}$ of d-dimension to d_{head}-dimensional subspaces of multi-head at-

[1] $S^{(j)}$ indicates $S_{enc}^{(j)}$ for the encoder and $S_{dec}^{(j)}$ for the decoder.

[2] p indicates p_e for the encoder and p_j for the decoder.

tention as follows:

$$Q_{parse} = S^{(p-1)} W^{Q_{parse}}, \tag{11}$$

$$K_{parse} = S^{(p-1)} W^{K_{parse}}, \tag{12}$$

$$V_{parse} = S^{(p-1)} W^{V_{parse}}, \tag{13}$$

where $W^{Q_{parse}}$, $W^{K_{parse}}$, and $W^{V_{parse}}$ are $d \times d_{head}$ weight matrices. Next, an attention weight matrix A_{parse}, where each value indicates the dependency relationship between two words, is calculated by using the bi-affine operation as follows:

$$A_{parse} = softmax(Q_{parse} U^{(1)} K_{parse}^{T} + Q_{parse} U^{(2)}), \tag{14}$$

where $U^{(1)} \in \mathbb{R}^{d_{head} \times d_{head}}$, $U^{(2)} = \overbrace{(\mathbf{u} \ldots \mathbf{u})}^{n}$, and $\mathbf{u} \in \mathbb{R}^{d_{head}}$ are the parameters. In A_{parse}, the probability of token q being the head of token t (i.e., t modifying q) is modeled as $A_{parse}[t, q]$:

$$P(q = head(t) \mid X) = A_{parse}[t, q], \tag{15}$$

where X is a source sentence or a target sentence, and the root token is defined as having a self-loop (i.e., $q = head(t) = ROOT$). Then, a weighted representation matrix M_{parse}, which includes dependency relationships in the source sentence or target sentence, is obtained by multiplying A_{parse} and V_{parse}:

$$M_{parse} = A_{parse} V_{parse}. \tag{16}$$

Finally, after one attention head (e.g., $M^{(p)}_{n_{head}}$) is replaced with M_{parse}, the concatenation of all $M^{(p)}_h$ (i.e., M_{parse} and $M^{(p)}_{1,2,\ldots,n_{head-1}}$) is mapped to a d-dimensional matrix $M^{(p)}$ like the conventional multi-head attention:

$$M^{(p)} = W^{M^{(p)}} [M_{parse}; M^{(p)}_1; \ldots; M^{(p)}_{n_{head}-1}], \tag{17}$$

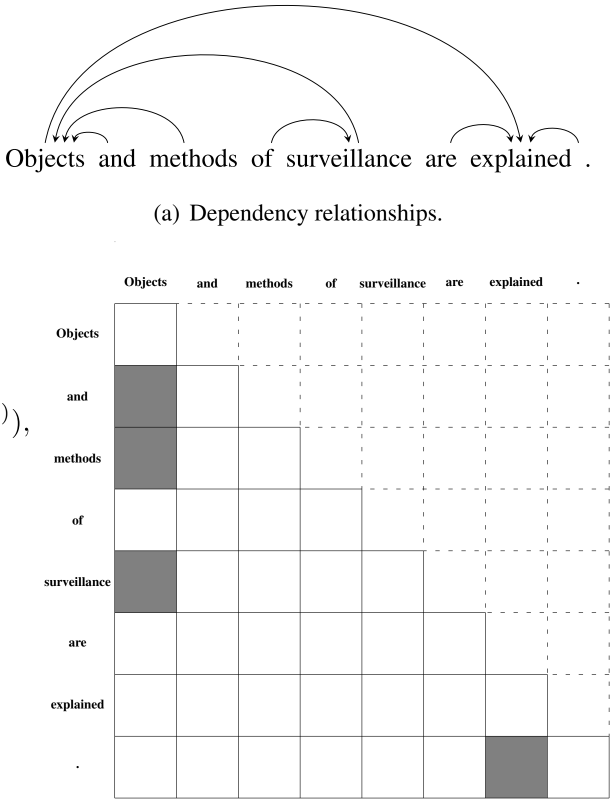
where $W^{M^{(p)}} \in \mathbb{R}^{d \times d}$ is a parameter matrix.

As can be seen in Equation (17), in the dependency-based self-attention, dependency relations are identified by one attention head M_{parse} of the p-th layer's multi-head attention.

3.2 Objective Function

Our model learns translation and dependency parsing at the same time by minimizing the following objective function:

$$e^{tokens} + \lambda_{enc} e^{parse}_{enc} + \lambda_{dec} e^{parse}_{dec}, \tag{18}$$



(a) Dependency relationships.

(b) Attention matrix representing supervisions.

Figure 3: Decoder side masked dependency-based self-attention.

where e^{tokens} is the error of translation, and e^{parse}_{enc} and e^{parse}_{dec} are the errors of dependency parsing in the encoder and the decoder, respectively. $\lambda_{enc} > 0$ and $\lambda_{dec} > 0$ are hyper-parameters to control the influence of dependency parsing errors in the encoder and the decoder, respectively. e^{tokens} is calculated by label smoothed cross entropy (Szegedy et al., 2016), and e^{parse}_{enc} and e^{parse}_{dec} are calculated by cross entropy.

Note that, in the training of the decoder-side dependency-based self-attention, future information is masked to prevent attending to unpredicted tokens in inference. An example of training data for the decoder-side dependency-based self-attention is provided in Figure 3, where (a) is an example of dependency structures[3] and (b) shows the attention matrix representing the supervisions from (a). In (b), a dark cell indicates a dependency relation and a dotted cell means a masked

[3] In this paper, an arrow is drawn from a modifier to its modifiee. For example, the arrow drawn from "Objects" to "explained" indicates that "Objects" modifies "explained" (i.e., "explained" = $head$("Objects")).

element. As shown, future information on each word is masked. For example, the dependency relation from "are" to "explained" is masked.

3.3 Subword Dependency-Based Self-Attention

Recent NMT models have improved the translation performance by treating a sentence as a subword sequence rather than a word sequence. Therefore, we extend dependency-based self-attention to work for subword sequences. In our subword dependency-based self-attention, a sentence is divided into a subword sequence by BPE (Sennrich et al., 2016). When a word is divided into multiple subwords, the modifiee (i.e., the head) of the rightmost subword is set to the modifiee of the original word and the modifiee of each subword other than the rightmost one is set to the right adjacent subword.

Figure 4 shows an example of subword-level dependency relations, where "@@" is a subword segmentation symbol. "Fingerprint" is divided into the three subwords: "Fing@@", "er@@", and "print". When the head of the word "Fingerprint" is "input" in the original word-level sentence, the heads of the three subwords are determined as follows: "er@@" = head("Fing@@"), "print" = head("er@@"), and "input" = head("print").

4 Experiments

4.1 Experiment Settings

In our experiments, we compared the proposed model with a conventional Transformer NMT model, which does not incorporate dependency structures, to confirm the effectiveness of the proposed model. We stacked six layers for each encoder and decoder and set $n_{head} = 8$ and $d = 512$. For the proposed model, we incorporated dependency-based self-attention into the fourth layer in both the encoder and the decoder (i.e., $p_e = p_d = 4$).

We evaluated translation performance on the WAT'18 ASPEC (Nakazawa et al., 2016) Japanese-to-English translation task. We tokenized each Japanese sentence with $KyTea$ (Neubig et al., 2011) and preprocessed according to the recommendations from WAT'18[4]. We used the vocabulary of 100K subword tokens based on BPE for both languages and used the first 1.5 million translation pairs as the training data. In the training, long sentences with over 250 subword-tokens were filtered out. Table 1 shows the statistics of our experiment data.

We used Japanese dependency structures generated by EDA[5] and English dependency structures generated by Stanford Dependencies[6] in the training of the source-side dependency-based self-attention and the target-side dependency-based self-attention, respectively. Note that Stanford Dependencies and EDA are not used in the testing.

4.2 Training Details

We trained each model using Adam (Kingma and Ba, 2014), where the learning rate and hyperparameter settings are set following Vaswani et al. (2017). For the objective function, we set ϵ_{ls} (Szegedy et al., 2016) in label smoothing to 0.1 and both the hyperparameters λ_{enc} and λ_{dec} to 1.0. We set the mini-batch size to 224 and the number of epochs to 20. We chose the model that achieved the best BLEU score on the development set and evaluated the sentences generated from the test set using beam search with a beam size of 4 and length penalty $\alpha = 0.6$ (Wu et al., 2016).

4.3 Experiment Results

Table 2 lists the experiment results. Translation performance is measured by BLEU (Papineni et al., 2002). In Table 2, DBSA denotes our dependency-based self-attention. As shown, our proposed model

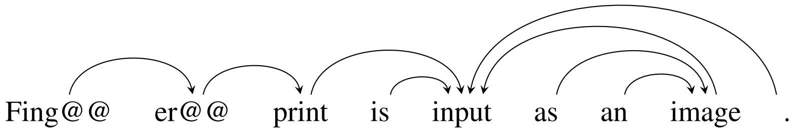

Figure 4: Subword-level dependency relationships.

Model	BPE	BLEU
Trans.	w/o	26.39
Trans.	w/	27.29
Trans. + DBSA(Enc) + DBSA(Dec)	w/o	26.62
Trans. + DBSA(Enc) + DBSA(Dec)	w/	**28.29**

Table 3: Effectiveness of subword.

"Trans.+DBSA(Enc)+DBSA(Dec)" performed significantly better than the baseline model "Trans.", which demonstrates the effectiveness of our dependency-based self-attention. Table 2 also shows that using either the encoder-side dependency-based self-attention or the decoder-side dependency-based self-attention improves translation performance, and using them in combination achieves further improvements.

5 Discussion

To determine the effectiveness of our extension to utilize subwords, we evaluated the models without BPE, where each sentence is treated as a word sequence. In the models without BPE, words that appeared fewer than five times in the training data were replaced with the special token "<UNK>". Table 3 lists the results. As shown, BPE improves the performance of both the baseline and the proposed model, which demonstrates the effectiveness of the subword dependency-based self-attention. Table 3 also shows that the proposed model outperforms the baseline model when BPE is not used. This strengthens the usefulness of our dependency-based self-attention.

6 Related Work

NMT models have been improved by incorporating source-side dependency relations (Chen et al., 2017), or target-side dependency relations (Eriguchi et al., 2017), or both (Wu et al., 2018).

Chen et al. (2017) have proposed SDRNMT, which computes dependency-based context vectors from source-side dependency trees by CNN and then uses the representations in the encoder of an RNN-based NMT model.

Eriguchi et al. (2017) have proposed NMT+RNNG, which combines the RNN-based dependency parser, RNNG (Dyer et al., 2016), and the decoder of an RNN-based NMT model.

Wu et al. (2018) have proposed a syntax-aware encoder, which encodes two extra sequences linearized from source-side dependency trees in addition to word sequences, and have incorporated Action RNN, which implements a shift-reduce transition-based dependency parsing by predicting action sequences, into the decoder. Their method has been applied to an RNN-based NMT model and a Transformer NMT model.

As far as we know, except for Wu et al. (2018), existing dependency-based NMT models have been based on RNN-based NMT. Although Wu et al. (2018) used dependency relations in Transformer NMT, they did not modify the Transformer model itself. In contrast, we have improved a Transformer NMT model to explicitly incorporate dependency relations (i.e., dependency-based self-attention). In addition, while Wu et al. (2018) need a parser for constructing source-side dependency structures in inference, our proposed method does not require an external parser in inference because the learned dependency-based self-attention of the encoder finds dependency relations.

7 Conclusion

In this paper, we have proposed a method to incorporate dependency relations on both source and target sides into Transformer NMT through dependency-based self-attention. Our decoder-side dependency-based self-attention masks future information to avoid conflicts between training and inference. In addition, our dependency-based self-attention is extended to work well for subword sequences. Experimental results showed that the proposed model achieved a 1.0 point gain in BLEU over the baseline Transformer model on the WAT'18 ASPEC Japanese-English translation task. In future work, we will explore the effectiveness of our proposed method for language pairs other than Japanese-to-English.

Abstract

Online media aim for reaching ever bigger audience and for attracting ever longer attention span. This competition creates an environment that rewards sensational, fake, and toxic news. To help limit their spread and impact, we propose and develop a news toxicity detector that can recognize various types of toxic content. While previous research primarily focused on English, here we target Bulgarian. We created a new dataset by crawling a website that for five years has been collecting Bulgarian news articles that were manually categorized into eight toxicity groups. Then we trained a multi-class classifier with nine categories: eight toxic and one non-toxic. We experimented with different representations based on ElMo, BERT, and XLM, as well as with a variety of domain-specific features. Due to the small size of our dataset, we created a separate model for each feature type, and we ultimately combined these models into a meta-classifier. The evaluation results show an accuracy of 59.0% and a macro-F1 score of 39.7%, which represent sizable improvements over the majority-class baseline (Acc=30.3%, macro-F1=5.2%).

1 Introduction

The number of online news sources has grown dramatically in recent years, and so has the amount of news that has been bombarding users on a daily basis, especially in social media. As people have limited time to spend reading news, capturing people's attention is getting ever harder. Media have to use various techniques to get their readers back such as bigger advertisement and better services. Alternatively, it turns out that an easy way to attract people's attention is to use some toxicity in the articles, as people are intrigued by the unusual. Thus, our aim here is to try to detect articles that can harm, give false impressions, or deceive the readers. Such articles can use some of the following techniques:

- *Sensationalism*: overexposing insignificant or ordinary events by manipulating the main point of an article;
- *Fake news*: news that sound right, but totally misinterpret facts such as statistical data, locations, or dates, with the conscious aim of proving something wrong.
- *Conspiracy theories*: information that usually gives a lot of detail, but does not offer officially confirmed evidence or scientific research to back the claims that are being made. This is typically centered around political, or strange scientific phenomena.
- *Hate speech*: specifically targeting a person or a social group to brutalize them or to bully over the rate of normal conversation, to directly hurt or to manipulate them.

Given the proliferation of toxic news online, there have been many efforts to create tools and mechanisms to counteract their effect and spread. Such tools should help preserve and improve the reading integrity. Solving this problem is not a trivial task, and it requires a lot of effort by trained domain experts. Yet, there are limitations in how much it is possible to handle manually in a short period of time (and time is very critical as toxic content spreads fast). Thus, an attractive alternative is to use machine learning and natural language processing to automate the process of toxic news detection.

While most previous research has focused almost exclusively on English, here we target Bulgarian. In particular, we built a dataset for our experiments based on the knowledge base of *Media Scan*, which has catalogued and characterized many of the Bulgarian online media in the past five years. If a medium published a toxic news, this was recorded and the article, as well as the medium, got labelled accordingly. The analyzed media vary from digital newspapers, to media groups and blogs. For some articles there is detailed explanation with examples about why they were labelled like that. In some cases, the *Media Scan* website describes attempts to contact the authors of an article asking for clarification about some questionable facts that are being reported.

Here we use this information by performing multi-class classification over the *toxicity* labels: *fake news*, *sensations*, *hate speech*, *conspiracies*, *anti-democratic*, *pro-authoritarian*, *defamation*, *delusion*. Note that we allow multiple of these labels simultaneously. We further add a *non-toxic* label for articles that represent good news.

2 Related Work

The proliferation of false information has attracted a lot of research interest recently. This includes challenging the truthiness of news (Brill, 2001; Hardalov et al., 2016; Potthast et al., 2018), of news sources (Baly et al., 2018a, 2019; Dinkov et al., 2019), and of social media posts (Canini et al., 2011; Castillo et al., 2011), as well as studying credibility, influence, bias, and propaganda (Ba et al., 2016; Chen et al., 2013; Mihaylov et al., 2015a; Kulkarni et al., 2018; Baly et al., 2018a; Mihaylov et al., 2018; Barrón-Cedeño et al., 2019; Da San Martino et al., 2019; Zhang et al., 2019). Research was facilitated by shared tasks such as the SemEval 2017 and 2019 tasks on Rumor Detection (Derczynski et al., 2017; Gorrell et al., 2019), the CLEF 2018 and 2019 Check-That! labs (Nakov et al., 2018; Elsayed et al., 2019b,a), which featured tasks on automatic identification (Atanasova et al., 2018, 2019) and verification (Barrón-Cedeño et al., 2018; Hasanain et al., 2019) of claims in political debates, the FEVER 2018 and 2019 task on Fact Extraction and VERification (Thorne et al., 2018), and the SemEval 2019 task on Fact-Checking in Community Question Answering Forums (Mihaylova et al., 2019), among others.

The interested reader can learn more about "fake news" from the overview by Shu et al. (2017), which adopted a data mining perspective and focused on social media. Another recent survey (Thorne and Vlachos, 2018) took a fact-checking perspective on "fake news" and related problems. Yet another survey was performed by Li et al. (2016), and it covered truth discovery in general. Moreover, there were two recent articles in *Science*: Lazer et al. (2018) offered a general overview and discussion on the science of "fake news", while Vosoughi et al. (2018) focused on the proliferation of true and false news online.

The veracity of information has been studied at different levels: (*i*) claim (e.g., *fact-checking*), (*ii*) article (e.g., *"fake news" detection*), (*iii*) user (e.g., *hunting for trolls*), and (*iv*) medium (e.g., *source reliability estimation*). Our primary interest here is at the article-level.

2.1 Fact-Checking

At the claim-level, fact-checking and rumor detection have been primarily addressed using information extracted from social media, i.e., based on how users comment on the target claim (Canini et al., 2011; Castillo et al., 2011; Ma et al., 2016, 2017; Dungs et al., 2018; Kochkina et al., 2018). The Web has also been used as a source of information (Mukherjee and Weikum, 2015; Popat et al., 2016, 2017; Karadzhov et al., 2017b; Mihaylova et al., 2018; Baly et al., 2018b; Zlatkova et al., 2019).

In both cases, the most important information sources are *stance* (does a tweet or a news article agree or disagree with the claim?), and *source reliability* (do we trust the user who posted the tweet or the medium that published the news article?). Other important sources are linguistic expression, meta information, and temporal dynamics.

2.2 Stance Detection

Stance detection has been addressed as a task in its own right, where models have been developed based on data from the Fake News Challenge (Riedel et al., 2017; Thorne et al., 2017; Mohtarami et al., 2018; Hanselowski et al., 2018), or from SemEval-2017 Task 8 (Derczynski et al., 2017; Dungs et al., 2018). It has also been studied for other languages such as Arabic (Darwish et al., 2017b; Baly et al., 2018b; Mohtarami et al., 2019).

2.3 Source Reliability Estimation

Unlike stance detection, the problem of source reliability remains largely under-explored. In the case of social media, it concerns modeling the user[1] who posted a particular message/tweet, while in the case of the Web, it is about the trustworthiness of the source (the URL domain, the medium).

The source reliability of news media has often been estimated automatically based on the general stance of the target medium with respect to known manually fact-checked claims, without access to gold labels about the overall medium-level factuality of reporting (Mukherjee and Weikum, 2015; Popat et al., 2016, 2017, 2018). The assumption is that reliable media agree with true claims and disagree with false ones, while for unreliable media it is mostly the other way around. The trustworthiness of Web sources has also been studied from a Data Analytics perspective. For instance, Dong et al. (2015) proposed that a trustworthy source is one that contains very few false facts.

Note that estimating the reliability of a source is important not only when fact-checking a claim (Popat et al., 2017; Nguyen et al., 2018), but such reliability scores can be used as an important prior when addressing article-level factuality tasks such as "fake news" and click-bait detection (Brill, 2001; Hardalov et al., 2016; Karadzhov et al., 2017a; De Sarkar et al., 2018; Pérez-Rosas et al., 2018).

2.4 "Fake News" Detection

Most work on "fake news" detection has relied on medium-level labels, which were then assumed to hold for all articles from that source.

Horne and Adali (2017) analyzed three small datasets ranging from a couple of hundred to a few thousand articles from a couple of dozen sources, comparing (*i*) real news vs. (*ii*) "fake news" vs. (*iii*) satire, and found that the latter two have a lot in common across a number of dimensions. They designed a rich set of features that analyze the text of a news article, modeling its complexity, style, and psychological characteristics. They found that "fake news" pack a lot of information in the title (as the focus is on users who do not read beyond the title), and use shorter, simpler, and repetitive content in the body (as writing fake information takes a lot of effort). Thus, they argued that the title and the body should be analyzed separately.

In follow-up work, Horne et al. (2018b) created a large-scale dataset covering 136K articles from 92 sources from `opensources.co`, which they characterize based on 130 features from seven categories: structural, sentiment, engagement, topic-dependent, complexity, bias, and morality. We use this set of features when analyzing news articles.

In yet another follow-up work, Horne et al. (2018a) trained a classifier to predict whether a given news article is coming from a reliable or from an unreliable ("*fake news*" or *conspiracy*)[2] source. Note that they assumed that all news from a given website would share the same reliability class. Such an assumption is fine for training (distant supervision), but it is problematic for testing, where manual documents-level labels are needed.

Potthast et al. (2018) used 1,627 articles from nine sources, whose factuality has been manually verified by professional journalists from BuzzFeed. They applied stylometric analysis, which was originally designed for authorship verification, to predict factuality (fake vs. real).

Rashkin et al. (2017) focused on the language used by "fake news" and compared the prevalence of several features in articles coming from trusted sources vs. hoaxes vs. satire vs. propaganda. However, their linguistic analysis and their automatic classification were at the article level and they only covered eight news media sources.

2.5 Work for Bulgarian

We are aware of only one piece of previous work for Bulgarian that targets toxicity. In particular, (Karadzhov et al., 2017a) built a fake news and click-bait detector for Bulgarian based on data from a hackaton.

While most of the above research has focused on isolated and specific task (such as trustworthiness, fake news, fact-checking), here we try to create a holistic approach by exploring several toxic and non-toxic labels simultaneously.

[1] User modeling in social media and news community forums has focused on finding malicious users such as opinion manipulation *trolls*, paid (Mihaylov et al., 2015b) or just perceived (Mihaylov et al., 2015a; Mihaylov and Nakov, 2016; Mihaylov et al., 2018; Mihaylova et al., 2018), *sockpuppets* (Maity et al., 2017), *Internet water army* (Chen et al., 2013), and *seminar users* (Darwish et al., 2017a).

[2] We show in parentheses, the labels from `opensources.co` that are used to define a category.

Characteristic	Value
Toxic articles	221
Non-toxic articles	96
Media	164
Average title length (chars)	70.47
Average title length (words)	11.08
Average text length (chars)	3,613.70
Average text length (words)	556.83
Average text length (sentences)	31.64

Table 1: Statistics about the dataset.

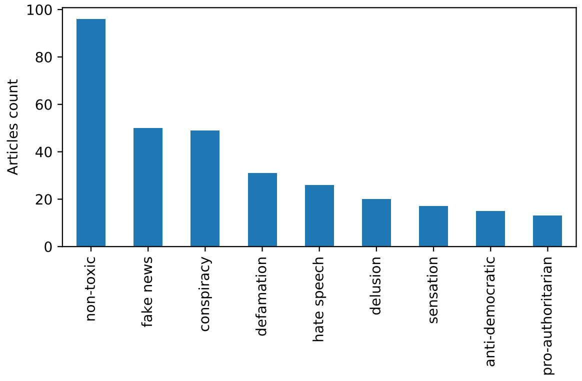

Figure 1: Label distribution in the dataset.

3 Data

We used *Media Scan*[3] as a source of toxicity labels for Bulgarian media Web sites. The site contains information about 700 media, and 150 of them are associated with at least one toxic article. Many of these toxic articles are removed after the respective media have been contacted and informed about the problems with these articles. Naturally, the author of *Media Scan* wanted to preserve the original form of the evaluated article, and thus had a link to a PDF copy in case the original HTML page was not accessible. We only crawled the HTML for articles that have not been changed or removed at the time we created the dataset.

For each Web page with a toxic label, we ran a mechanical crawler to obtain its contents. This was not very reliable as each individual medium site has its own structure, while the crawler expected more or less semantic and valid HTML to be able to process it. Thus, we manually verified the data, fixed any issues we could find and added any missing information. We ended up with a little over 200 articles with some kind of toxicity.

In addition to this dataset of only toxic articles, we added some “non-toxic” articles, fetched from media without toxicity examples in Media Scan: we added a total of 96 articles from 25 media.

Table 1 shows statistics about the dataset, and Figure 1 shows the distribution of the labels.

4 Method

We used a feature-rich classifier based on logistic regression and a neural network.

For each article, we extracted its title and its body. We further extracted some meta information about the corresponding news medium. As some NLP resources are only available or are better for English, we translated the articles to English, by using Google Translate API, so that we can extract features from them as explained in subsections 4.2, 4.6, 4.7, and 4.8.

4.1 LSA

We trained a Latent Semantic Analysis (LSA) model on our data. We first built TF.IDF vectors for the title and the body. Then, we applied singular value decomposition (SVD) to generate vectors of 15 dimensions for the titles and of 200 dimensions for the article bodies.

4.2 BERT

We used BERT (Devlin et al., 2019) for sentence representation, which has achieved very strong results on eleven natural language processing tasks including GLUE, MultiNLI, and SQuAD. Since then, it was used to improve over the state of the art for a number of NLP tasks. The original model was trained on English Wikipedia articles (2500M words). Due to the model complexity and to its size, it is hard to find enough data that represents a specific domain for a specific language.

We used BERT-as-a-service, which generates a vector of 768 numerical values for a given text. In its original form, this is a sentence representation tool, but we used it to generate text over the first 512 tokens of our article’s title or text. We used the multilingual cased pretrained model[4]. We experimented with all possible pooling strategies for representing the article title and its body, and we eventually chose the following pooling strategies: *REDUCE_MAX* for the title and *CLS_TOKEN* for the text of the article.

[3] http://mediascan.gadjokov.com

[4] http://github.com/google-research/bert#pre-trained-models

4.3 Stylometric Features

For the title and the body of each article, we calculate the following features:

- *avg_word_length_title*: average length of the word in the article title;
- *avg_word_length_text*: average length of the words in the article body
- *word_count_title*: number of words in the article title;
- *word_count_text*: number of words in the article body;
- *char_count_title*: number of characters in the article title;
- *char_count_text*: number of characters in the article body;
- *spec_char_count_title*: number of specific (non-alpha-numeric) characters in the article title;
- *spec_char_count_text*: number of specific (non-alpha-numeric) characters in the article body;
- *upper_char_count_title*: number of uppercase characters in the article title;
- *upper_char_count_text*: number of uppercase characters in the article body;
- *upper_word_count_title*: number of words starting with an uppercase character in the article title;
- *upper_word_count_text*: number of words starting with an uppercase character in the article body;
- *sentence_count_text*: number of sentences in the article;
- *avg_sentence_length_char_text*: average length of the sentences in the article body, in terms of characters;
- *avg_sentence_length_word_text*: average length of the sentences in the article body, in terms of words;

4.4 Media Features

We further extracted binary and numerical features characterizing the medium the article came from:

- *editor*: its value is 1 if the target medium has a designated chief editor, and it is 0 otherwise;
- *responsible_person*: its value is 1 if the target medium has a responsible person, and it is 0 otherwise;
- *bg_server*: its value is 1 if the target medium's location is in Bulgaria, and it is 0 otherwise;
- *popularity*: reciprocal value of the target medium's rank the Web traffic analysis platform Alexa[5];
- *domain_person*: its value is 1 if the target medium has a designated owner, and it is 0 otherwise;
- *days_existing*: number of days between when the medium was created and 01.01.2019. As this value is quite large, we take the logarithm thereof. For example, a medium created on Januarty 1, 2005 would have 5,113 days of existence, which would correspond to 3.70 as this feature's value.

4.5 XLM

We further used cross-lingual representations from the Facebook's XLM model (Lample and Conneau, 2019), which creates cross-lingual representations based on the Transformer, similarly to BERT. This model is pretrained for 15 languages including Bulgarian and English. We use their pretrained models, which were fine-tuned for Cross-lingual Natural Language Interence (XNLI) tasks. This yielded a 1024-demnsional representation for the title, and another one for the article body.

4.6 Universal Sentence Encoder

We also extracted representation using Google's Universal Sentence Encoder, or USE, (Cer et al., 2018). We used the pretrained model from TF Hub[6]. As the model is only available for English, we used the translations of the news articles. We passed the model the first 300 tokens for each title or body to generate 512-dimensional vectors.

[5] http://www.alexa.com/

[6] http://tfhub.dev/google/universal-sentence-encoder/2

4.7 ElMo

Next, we use deep contextualized word representations from ElMo, which uses generative bidirectional language model pre-training (Peters et al., 2018). The model yields 1024-dimensional representation, which we generate separately for the article title and for its body.

4.8 NELA Features

Finally, we use features from the NELA toolkit (Horne et al., 2018a), which were previously shown useful for detecting fake news, political bias, etc. The toolkit implements 129 features, which we extract separately for the article title and for its body:

- **Structure**: POS tags, linguistic features (function words, pronouns, etc.), and features for clickbait title classification from (Chakraborty et al., 2016);
- **Sentiment**: sentiment scores using lexicons (Recasens et al., 2013; Mitchell et al., 2013) and full systems (Hutto and Gilbert, 2014);
- **Topic**: lexicon features to differentiate between science topics and personal concerns;
- **Complexity**: type-token ratio, readability, number of cognitive process words (identifying discrepancy, insight, certainty, etc.);
- **Bias**: features modeling bias (Recasens et al., 2013; Mukherjee and Weikum, 2015) and subjectivity (Horne et al., 2017);
- **Morality**: features based on the Moral Foundation Theory (Graham et al., 2009) and lexicons (Lin et al., 2018)

A summary of all features is shown in Table 2.

Feature Group	Title	Body
BERT	768	768
ElMO	1,024	1,024
LSA	15	200
NELA	129	129
Stylometry	19	6
USE	512	512
XLM	1,024	1,024
Media	6	

Table 2: Summary of our features.

5 Experiments and Evaluation

5.1 Experimental Setup

We used logistic regression as our main classification method. As we have a small dataset, we performed 5-fold cross-validation. For evaluation, we used accuracy and macro-average F_1 score. The results are presented in Table 3.

Our baseline approach is based on selecting the most frequent class, i.e., *non-toxic*, which covers 30.30% of the dataset (see Table 1).

5.2 Individual Models

We evaluated a total of 14 setups for feature combination. Four of them represent features generated from the original article's title and body as well as a combination thereof. The next four setups present feature sets generated from the English translation as well as a combination thereof. The final section of Table 3 shows three setups that are somewhat language-independent: meta media, all features combined together as well as a meta classifier. We tuned the logistic regression for each individual experimental setup, using an additional internal cross-validation for the training part of each experiment in the 5-fold cross-validation. In total, 15,000 additional experiments have been conducted to complete the fine-tuning.

We can see in Table 3 that the BERT features (setups 2, 9) perform well both for English and for Bulgarian. The feature combinations (setups 6, 11, 13) do not yield good results as this increases the number of features, while the number of training examples remains limited. Using only the right 6 meta features about the target medium yields 12% improvement over the baseline. Interestingly, LSA turns out to be the best text representation model.

5.3 Meta Classifier

Next we tried a meta classifier. For this purpose, we extracted the posterior probabilities of the individual classifiers in Table 3 (2-5, 7-10, 12). Then, we trained a logistic classifier on these posteriors (we made sure that we do not leak information about the labels when training the meta classifier).

We can see in Table 3 that the meta classifier yielded the best results, outperforming all of the individual models, and achieving 3.5% absolute gain in terms of accuracy.

Language	N	Feature Set	Dimension	Accuracy	F1-macro
-	1	Baseline	-	30.30	05.17
BG	2	BERT(title), BERT(text)	1,536	47.69	32.58
	3	XLM(title), XLM(text)	2,048	38.50	24.58
	4	Styl(title), Styl(text)	15	31.89	08.51
	5	LSA(title), LSA(text)	215	55.59	42.11
	6	Bulgarian combined	3,824	39.43	24.38
EN	7	USE(title), USE(text)	1,024	53.70	40.68
	8	NELA(title), NELA(text)	258	36.36	23.04
	9	BERT(title), BERT(text)	1,536	52.05	39.78

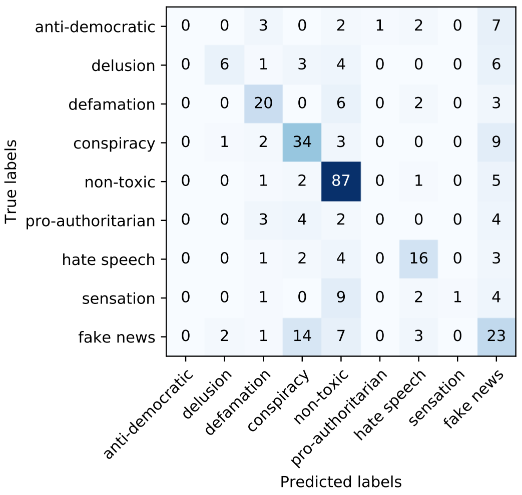
	13	All combined	8,694	38.16	26.04
	14	**Meta classifier**	**153**	**59.06**	**39.70**

Table 3: Evaluation results.



True labels \ Predicted labels	anti-democratic	delusion	defamation	conspiracy	non-toxic	pro-authoritarian	hate speech	sensation	fake news
anti-democratic	0	0	3	0	2	1	2	0	7
delusion	0	6	1	3	4	0	0	0	6
defamation	0	0	20	0	6	0	2	0	3
conspiracy	0	1	2	34	3	0	0	0	9
non-toxic	0	0	1	2	87	0	1	0	5
pro-authoritarian	0	0	3	4	2	0	0	0	4
hate speech	0	0	1	2	4	0	16	0	3
sensation	0	0	1	0	9	0	2	1	4
fake news	0	2	1	14	7	0	3	0	23

Figure 2: Confusion matrix.

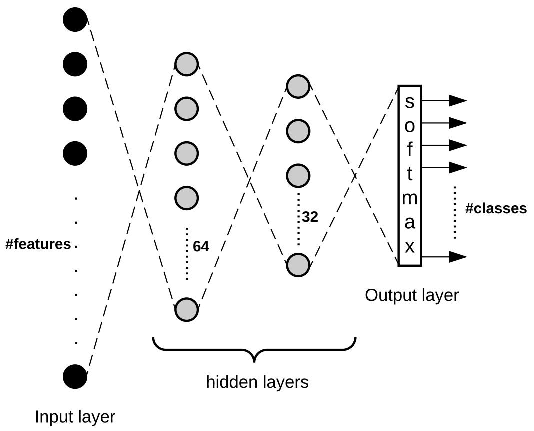


Figure 3: Our neural network.

5.4 Analysis

Figure 2 shows a confusion matrix over the entire dataset for the best model in Table 3, namely experiment 14. We can see that the model works best for the biggest *non-toxic* class. A decent chunk of *fake news* samples are misclassified as *conspiracy* as those two classes are the second and the third largest ones. For three of the labels, there are hardly any predictions; these are the smallest classes, and three of them combined cover less than 18% of the dataset.

5.5 What Did Not Work

Oversampling We evaluated all models from Table 3 but with oversampling the small classes. We tried simple random oversampling as well as the more complex SMOTE (Chawla et al., 2002) model. None of these techniques yielded improvements.

Neural Network We also tried a feed forward neural network with two hidden densely connected layers, with 64 nodes (ReLU activation) and 32 nodes (Tanh activation), and a dropout rate of 0.35 for each of them; see Figure 3. We used Adam for optimization, and we tried various parameter values, but we could not get improvements, possibly due to the small size of our dataset.

6 Discussion

Below we compare the performance of the models when working with Bulgarian vs. English resources, and we further discuss issues related to the small size of our dataset.

6.1 Language-Related Issues

The first part of the feature comparison in Table 3 is between English and Bulgarian, and it is interesting to compare them. The first comparison is between the BERT features. Even though we used a pre-trained BERT model, with same pooling techniques there is close to 4.5% absolute improvement when using the English translation. This is probably due to the English BERT being trained on more data as the English Wikipedia is much bigger for English: 5.7M English articles vs. just 250K Bulgarian articles.

Another notable comparison is between the types of models. Two of the Bulgarian feature sets are created via local models (experiments 4 and 5), while all of the English experiments are from transfer-learning. We can see that LSA (experiment 5) is the best feature set, and one can argue that this is to be expected. On such a small dataset in a non-English language, it is hard to represent the text with pre-trained models. Nevertheless, we can see that a combination between only pre-trained models (experiment 11) performs better compared to fusion between local and transfer-learning models (experiment 6).

6.2 Data Size Issues

There are several aspects of the above experiments where we can observe the negative effect of having insufficient data. First, in experiments 6, 11, 12 in Table 3, we can see that the combination of features performs worse in each language group compared to single feature types.

Another place where we felt we had insufficient data was in the neural network experiments, where we had many more parameters to train than in the simple logistic regression.

A related problem is that of class imbalance: we have seen in Section 5.4 above that the smallest classes were effectively ignored even by our best classifier. We can see in Figure 1 that those three classes have less than 60 articles combined, while the "non-toxic" only had 96 articles.

7 Conclusion and Future Work

We have presented experiments in detecting the toxicity of news articles. While previous research was mostly limited to English, here we focused on Bulgarian. We created a new dataset by crawling a website that has been collecting Bulgarian news articles and manually categorized them in eight toxicity groups. We then trained a multi-class classifier with nine categories: eight toxic and one non-toxic. We experimented with a variety of representations based on ElMo, BERT, xand XLM. We further used a variety of domain-specific features, which we eventually combined in a meta classifier. The evaluation results show an accuracy of 59.0% and a macro-F1 score of 39.7%, which represent sizable improvements over the majority-class baseline (Acc=30.3%, macro-F1=5.2%).

In future work, we plan to extend and also to balance the dataset. This can be achieved by either exploring another source for articles using the methodology of *Media Scan*, or by processing the unstructured PDF article, which we ignored in the present study. We also plan to explore new information sources. From a technical point of view, we would like to improve the neural network architecture as well as the oversampling techniques (with possible combination with undersampling).

Data and Code We are releasing all of the code for our experiments in a public repository that can be found in GitHub[7] with explanations about how to reproduce our environment. In that repository, we further release the full dataset together with the generated features, all the textual data, all the translations and all the meta data about the articles.

Acknowledgements

This research is part of the Tanbih project,[8] which aims to limit the effect of "fake news", propaganda and media bias by making users aware of what they are reading. The project is developed in collaboration between the Qatar Computing Research Institute (QCRI), HBKU and the MIT Computer Science and Artificial Intelligence Laboratory (CSAIL).

This research is also partially supported by Project UNITe BG05M2OP001-1.001-0004 funded by the OP "Science and Education for Smart Growth" and the EU via the ESI Funds.

De-Identification of Emails:
Pseudonymizing Privacy-Sensitive Data in a German Email Corpus

Abstract

We deal with the pseudonymization of those stretches of text in emails that might allow to identify real individual persons. This task is decomposed into two steps. First, named entities carrying privacy-sensitive information (e.g., names of persons, locations, phone numbers or dates) are identified, and, second, these privacy-bearing entities are replaced by synthetically generated surrogates (e.g., a person originally named *'John Doe'* is renamed as *'Bill Powers'*). We describe a system architecture for surrogate generation and evaluate our approach on CODEALLTAG, a German email corpus.

1 Introduction

With the advent and rapidly increasing adoption of electronic interaction platforms, the communication patterns of modern societies have changed fundamentally. We observe an unprecedented upsurge of digitally transmitted private communication and exploding volumes of so-called user-generated contents (UGC). As a major characteristic of these new communication habits, a sender's individual email, post, comment, tweet is distributed to an often (very) large number of addressees—the recipients of an email, other bloggers, friends or followers in social media platforms, etc.. Hence, hitherto private communication becomes intentionally public.

Responding to these changes, digital (social) media communication has become a focus of research in NLP. Yet there seems to be a lack of awareness among NLP researchers that the exploitation of natural language data from such electronic communication channels, whether for commercial, administrative or academic purposes, has to comply with binding legal regulations (Wilson et al., 2016). Dependent on each country's law system, different rules for privacy protection in raw text data are enforced (cf., e.g., two recent analyses for the US (Mulligan et al., 2019) and the EU (Hoofnagle et al., 2019)). Even privacy-breach incidents in a legal grey zone can be harmful for the actors involved (including NLP researchers).

This is evidenced dramatically in the so-called AOL search data leak.[1] In August of 2006, American Online (AOL) made a large query log collection freely accessible on the Internet for a limited time. The data were extracted over three months from their search engine to support academic research. The collection represented 650k users issuing 20 million queries *without* any significant anonymization. The result of this release, among others, was the disclosure of private information for a number of AOL users. The most troubling aspect of the data leak was the ease by which single unique individuals could be pinpointed in the logs. Even ignoring the existence of social security, drive license, and credit card numbers, the *New York Times* demonstrated the ability to determine the identity of a real user.[2] The outline of this incident and counter-measures against this privacy crash are reported by Adar (2007) from which we adopted the case description as well.

Despite this specific case, query logs from search engines might still be at the lower end of the vulnerability chain for data privacy, while UGC bundled in freely distributed corpora is clearly at its higher end, since clear names of persons, locations, etc. are dispersed all over such documents.

[1] Briefly described in https://en.wikipedia.org/wiki/AOL_search_data_leak, last accessed on July 24, 2019.

[2] https://www.nytimes.com/2006/08/09/technology/09aol.html, last accessed July 24, 2019.

Surprisingly, despite its high relevance for NLP operating on UGC, the topic of data privacy has long been neglected by the mainstream of NLP research. While it has always been of utmost importance for medical, i.e., clinical, NLP (Meystre, 2015), it has received almost no attention in NLP's non-medical camp for a long time (for two early exceptions, cf. Rock (2001); Medlock (2006)).

This naïve perspective is beginning to change these days with the ever-growing importance of social media documents for text analytics. However, there are currently no systematic actions taken to hide personally sensitive information from down-stream applications when dealing with chat, blog, SMS or email raw data. Since this attitude also faces legal implications, a quest for the protection of individual data privacy has been raised and, in the meantime, finds active response in the most recent work of the NLP community (Li et al., 2018; Coavoux et al., 2018).

We distinguish two basic approaches to eliminate privacy-bearing data from raw text data. The first one, *anonymization*, identifies instances of relevant privacy categories (e.g., person names or dates) and replaces sensitive strings by some artificial code (e.g., *'xxx'*). This blinding approach might be appropriate to eliminate privacy-bearing data in the medical world, but it is inappropriate for most NLP applications since crucial discriminative information and contextual clues will be erased by such a scrubbing procedure.

The second approach, *pseudonymization*, preserves such valuable information by replacing privacy-bearing text strings with randomly chosen alternative synthetic instances from the same privacy type (e.g., the person name *'Suzanne Walker'* is mapped to *'Caroline Snyder'*). As a common denominator, the term *de-identification* subsumes both, anonymization and pseudonymization.

The focus of this paper will be on pseudonymization and more precisely on the methods needed to produce realistic synthetic replacements, a process often also referred to as *surrogate generation*. We start with a discussion of related work in Section 2 and then introduce the semantic types we consider as relevant carriers of personal information in emails in Section 3. Next, we provide an overview of the email corpus our experiments are based on in Section 4, including manual annotation efforts. In Section 5, we turn to the process of surrogate generation, with focus on German language data. Since surrogate generation constitutes a highly constrained case of language generation, in Section 6 we describe the results of an evaluation study to assess the naturalness of these replacements with native speakers of German, as well as the performance of a recognizer for privacy-relevant text stretches on original and already pseudonymized data.

2 Related Work

The main thrust of work on de-identification has been performed for clinical NLP.[3] Most influential for progress in this field have been two challenge competitions within the context of the I2B2 (Informatics for Integrating Biology & the Bedside) initiative[4] which focused on 18 different types of Protected Health Information (PHI) categories as required by US legislation (HIPAA).[5] The first of these challenge tasks was launched in 2006 for 889 hospital discharge summaries, with a total of 19,498 PHI instances of person-identifying verbal expressions (Uzuner et al., 2007). The second was run in 2014 and addressed an even broader set of PHI categories (Stubbs et al., 2015a). In summary, the best system performances peaked in the high 90s (F_1 score) using classical machine learning methods, Conditional Random Fields (CRFs) in particular, and hand-written rules, or a mixture of both. As a successor to I2B2, the CEGS-NGRID Shared Tasks and Workshop on Challenges in NLP for Clinical Data created a corpus of 1,000 manually de-identified psychiatric evaluation records (Stubbs et al., 2017). Interestingly, for the automatic de-identification task performance values dropped significantly down to 79.85 F_1 for the best-performing system indicating an only modest potential for domain and text genre portability (moving from discharge summaries to psychiatric evaluation records).

Recently, the deep learning wave has also hit the (clinical) de-identification community. For this task, bidirectional Long-Short Term Memory Networks (Bi-LSTMs) became quite popular as evidenced by the work of Dernoncourt et al. (2017)

[3] Note that we have to distinguish between data protection in structured data contained in (clinical) information systems, (for which k-anonymity (Sweeney, 2002) is a well-known model to minimize a person's re-identification risk) and pseudonym-based textual variant generation for unstructured verbal data we here focus on.

[4] https://www.i2b2.org/

[5] https://www.hhs.gov/hipaa/for-professionals/privacy/index.html

who achieve an F_1 score of 97.85 on the I2B2 2014 dataset, or Liu et al. (2017) who report performance figures ranging from 95.11% over 96.98% up to 98.28% micro F_1 score under increasingly sloppier matching criteria on the same dataset.

Note that these challenges were focusing on the *recognition* of privacy-relevant text stretches textual but did not incorporate pseudonymization, a more complex task (Stubbs et al., 2015b). Carrell et al. (2013) deal with the latter challenge within the context of the 'Hiding In Plain Sight' approach where the detected privacy-bearing identifiers are replaced with realistic synthetic surrogates in order to collectively render the few 'leaked' identifiers difficult to distinguish from the synthetic surrogates—a major advantage for pseudonymization over anonymization. Targeting English medical texts SCRUB (Sweeney, 1996) is one of the first surrogate generation systems followed by work from Uzuner et al. (2007), Yeniterzi et al. (2010), Deléger et al. (2014), Stubbs et al. (2015b) and Stubbs and Uzuner (2015). Similar procedures have been proposed for Swedish (Alfalahi et al., 2012) and Danish (Pantazos et al., 2011) clinical corpora, yet not for German ones.

Work outside the clinical domain is rare. While we found no work dealing with the anonymization or even pseudonymization of emails and Twitter-style social media data,[6] anonymizing SMSes is a topic of active research. Patel et al. (2013) introduce a system capable of anonymizing SMS (Short Message Service) communication. Their study builds on 90,000 authentic French text messages and uses dictionaries as well as decision trees as machine learning technique. Their evaluation task is, however, very coarse-grained—select those SMSes from a test corpus of 23,055 messages that either have or have not to be anonymized. There is no breakdown to PHI-like categories known from the medical domain.

Treurniet et al. (2012) were taking care of privacy-relevant data for a Dutch SMS corpus (52,913 messages, in total) in much more detail. They automatically anonymized all occurrrences of dates, times, decimal amounts, and numbers with more than one digit (telephone numbers, bank accounts, etc.), e-mail addresses, URLs, and IP addresses. All sensitive information was replaced with corresponding semantic placeholder codes of the encountered semantic *type* (e.g., each specific email address was replaced by the type symbol `EMAIL`), not by an alternative semantic *token*, i.e., a pseudonym. The same strategy was also chosen by Chen and Kan (2013) for their SMS corpus that contains more than 71,000 messages, focusing on English and Mandarin. However, neither are the methods of automatic anonymization described in detail, nor are performance figures of this process reported in both papers (Chen and Kan (2013) only mention the use of regular expressions for the anonymization process).

In conclusion, pseudonymization has to the best of our knowledge only been seriously applied to medical documents, up until now. Hence, our investigation opens this study field for the first time ever to non-medical applications of pseudonymization. Such de-identified corpora can then easily be distributed via public sites and so might stimulate further NLP research.

3 Named Entities for De-Identification

Perhaps the most relevant source and starting point for determining types of personally identifying information pieces in written documents is a catalogue of *Personal Health Information* (PHI) items that has been derived from the *Health Information Privacy Act* (HIPAA) which is binding law in the US. PHI enumerates altogether 18 privacy-sensitive items organized into eight main categories (Stubbs and Uzuner, 2015):

- *Name* includes the names of patients, doctors and user names,
- *Profession* of persons mentioned,
- *Location* includes rooms, clinical departments, hospital names, names of organizations, street names, city names, state names, names of countries, ZIPs, etc.,
- *Age* of persons,
- *Date* expressions,
- *Communication* data, e.g., phone or fax numbers, email addresses, URLs, IP addresses,
- all sorts of *IDs* such as Social Security number, medical record number, health plan number, account number, license number, vehicle ID, device ID, biometric ID, etc.,
- any *Other* form of personally sensitive data.

While some types of categories from above are generally useful also for non-medical anonymization procedures, others are quite domain-specific,

[6] Lüngen et al. (2017) report on *manual* anonymization efforts for German chat data.

because they are intrinsically attached to the clinical domain (such as the names of patients, doctors or nurses, the names of hospitals and their departments, or various forms of IDs, e.g., health insurance numbers). Hence, we adapted this list for email documents while, at the same time, we tried to avoid over-fitting to this text genre.

We, finally, came up with the category set depicted in Figure 1 which we stipulate to universally account for all types of emails, irrespective of any particular natural language and email (header) encoding. The categories are organized in a concise hierarchy whose top level categories are *SocialActor (ACTOR)*, *Date (DATE)*, *FormalIdentifier (FID)*, *Location (LOC)*, and *Address (ADD)*. We anticipate that this hierarchy can be further refined and accomodated to other text genres as well.

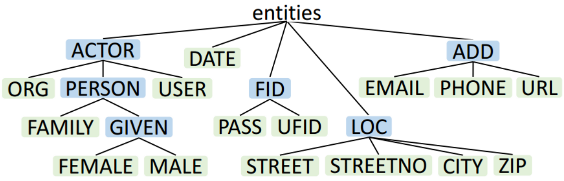

Figure 1: Hierarchy of privacy-bearing entity types (pis) relevant for emails (leaves in green)

The category of *SocialActor* can be further divided into *Organization (ORG)*, which includes all types of legal actors such as companies, brands, institutions and agencies, etc., human *Persons (PERSON)*, with subtypes *FamilyName (FAMILY)*, also including initials and credentials, and *GivenName (GIVEN)*, with another split into two subcategories, namely *FemaleName (FEMALE)* and *MaleName (MALE)*, both including nicknames and initials. Finally, *UserName (USER)* covers all kinds of invented user names for IT systems and platforms.

Date (DATE) includes all sorts of date descriptions, such as date of birth, marriage, or death, starting and ending dates of contracts, etc.

The category of *FormalIdentifier (FID)* includes *Password (PASS)* as user-provided supplementary artificial name for all kinds of technical appliances, and *UniqueFormalIdentifier (UFID)* to capture persons (students, customers, employees, members of social security systems (SSN), authors (ORCHID), etc.), computer systems (IP addresses), or other artifacts (e.g., IBANs, DOIs).

The *Location* (LOC) category subsumes *StreetName (STREET)*, *StreetNumber (STREETNO)*, *ZipCode (ZIP)*, and *CityName (CITY)* which stands for villages, towns, cities, larger metropolitan areas (e.g., *'Larger Manchester'*) and regions smaller than a state (e.g., *'Bay Area'*); it also includes derivations of these names (e g., *'Roman'*).

Finally, *Address (ADD)* encompasses *EmailAddress (EMAIL)*, *PhoneNumber (PHONE)*, including fax numbers, and *URL (URL)*, as well as other forms of domain names.

Unlike some approaches from the field of clinical NLP (Stubbs et al., 2015b), we did not take ages or professions into account, because our use case is not that sensible and ages or professions probably are mentioned far more often in clinical reports than in emails. Furthermore, unspecific dates like *'Christmas'* or *'next week'* and geographical information such as landmarks, rivers or lakes were not tagged for de-identification since their contribution to possible re-identification is fairly limited due to their generality.

4 Email Corpus and Entity Annotation

Our experiments are based on 1,390 German emails from the CODE ALLTAG$_{S+d}$ corpus (Krieg-Holz et al., 2016), which were collected on the basis of voluntary email donation. The donors have provided their explicit consent that, *after de-identification*, their emails may be made publically available. Sharing the corpus would create lots of opportunities for NLP research, since public access to private emails is generally forbidden.[7]

For the manual annotation campaign,[8] we set up a team of three annotators who tagged equally sized parts of the corpus, according to the privacy-bearing (pi) categories described in Section 3 (Figure 1). Annotation was performed on entity level. Therefore, we did not have to care about token boundaries in the surrogate generation step and, thus, no special handling for compounds and multi-token entities is required.

In order to measure the inter-annotator agreement (IAA), the annotators worked on 50 identical emails randomly selected from the corpus within the same annotation phase as the entire corpus.

[7] One of the rare exceptions is the ENRON corpus (Klimt and Yang, 2004) whose non-anonymized contents was released for open inspection by order of US judges in the course of the destruction of the Enron company as a consequence of criminal financial transactions of the Enron management. For yet another example, cf. the *Avocado Research Email Collection*, available from LDC2015T03.

[8] We used BRAT (`http://brat.nlplab.org/`) for annotation (Stenetorp et al., 2012).

Table 1 shows Cohen's Kappa (Cohen, 1960) as a measure for IAA for the pairs of annotators calculated on the entities represented by the BIO annotation scheme.[9] Hence, not only the token label itself but also matching starting and ending points of an entity are taken into account, as well. The agreement is quite high, especially between annotator 1 and 3.

A1 - A2	A2 - A3	A3 - A1
0.925	0.933	0.958

Table 1: Cohen's Kappa for BIO tags on CODE ALLTAG$_{S+d}$

Based on these 50 emails the annotators also examined and discussed differences of their annotations and decided on the gold standard by majority vote, which we applied for further evaluation in order to measure precision (Prec), recall (Rec) and F$_1$ score (F$_1$). Table 2 shows the outcomes regarding BIO tags per annotator and the overall result calculated over the joint annotations of the annotators. We took the averages from the outcomes of the single categories weighted by the number of true instances for each label.

	Prec	Rec	F$_1$
A1	98.06	95.63	96.72
A2	87.67	77.92	80.36
A3	94.14	84.79	86.82
A1+A2+A3	93.37	86.11	88.66

Table 2: Weighted average of precision, recall and F$_1$ score with respect to the gold standard for BIO tags of CODE ALLTAG$_{S+d}$

An error analysis revealed that, besides mostly accidental errors, a higher disagreement on tagging ORGs (due to overlap or confusion with city or product names and rather generic organizations)[10] and an uncertainty regarding DATEs could be observed. The latter problem was solved by the decision to treat all dates as *pi* regardless of their specificity. As a consequence, one annotator worked through the entire corpus to re-tag each DATE and, if necessary, also re-tag ORGs according to the findings of the error analysis. The outcome of this overhaul constituted the final gold standard annotations of CODE ALLTAG$_{S+d}$ for the de-identification task.

5 Surrogate Generation

Once *pi*-relevant named entities have been recognized they undergo a replacement process where original identifiers are substituted by synthetic, though natural, surrogates. For this step, we distinguish language-independent criteria from those which are intrinsically language-specific. Only the latter have to be re-specified for languages other than German.

5.1 Language-Independent Criteria

Personal information belonging to the categories ADD (EMAIL, PHONE or fax number, URL), FID (PASSword, UFID), USER name and ZIP code are relatively simple to replace. Each digit of the string is substituted with a randomly generated alternative digit, each alphabetic character is replaced with a randomly generated alternative letter of the same case and alphabet. Other characters like '*@*' or punctuation marks are left as is. For URLs, we also keep the subdomain *'www'* and commonly used URL schemes like *'http'*, *'https'*, *'ftp'*, *'file'* and *'mailto'*. In contrast to Stubbs et al. (2015b) we did not implement any other restrictions for the selection of characters. As a consequence, the resulting surrogates may have an unrealistic appearance.

To maintain temporal ordering in the document we generate a time shift separately for each text to make re-identification difficult, if not impossible. We shifted the dates by a random interval between 365 days forward or backward. As we try to keep the original language-dependent formats, the user has to determine the formats to be generated.

In order to maintain coreferences between *pi* entities, we replace multiple occurrences of an entity by the same surrogate. To account for different spellings of names regarding lower and upper case we treat different possibilities of combinations, the original spelling, lower case, upper case and a normalized format which is language-specific. We decided not to consider misspellings, because checking for slightly different names, e.g., employing the Levenshtein distance, could also lead to coreference breaks since quite a few names differ only in one letter (like *'Lena'* and *'Lina'*).

[9] 'B' preceding a token's tag stands for the Beginning of an entity, 'I' for its continuation (Inside), and 'O' for any stretch of text not belonging to an entity (Outside).

[10] Stubbs and Uzuner (2015) also report confusions of organizations with other subcategories from their location class (department, hospital) and Stubbs et al. (2017) witness an uncertainty for tagging quasi-generic organizations.

For resolving initials and abbreviations of GIVEN, FAMILY and CITY names, we adopt the approach by Stubbs et al. (2015b) and use letter-to-letter mappings generated for each document. This means that each name of the respective category starting with a certain character is replaced with a name with its first letter corresponding to the mapping of this character or in case of initials and abbreviations with the mapping solely. For example *'Gandalf'* and *'Gimli'* would be substituted by names starting with the same character like *'Bilbo'* and *'Boromir'*. Hence, an initial *'G.'*, will also be replaced with *'B.'*; it does not have to be disambiguated and assigned to any of the previously occurring names (a task left to a coreference resolution module we currently do not provide).

We also try to account for frequency distributions of GIVEN, FAMILY, CITY, ORG and STREET names by constraining these random letter-to-letter-mappings to map first letters to letters with a similar frequency. In this way, mappings of very common first letters, such as *'A'* in case of German first names, to rare ones, like *'X'*, can be avoided. This approach still allows rare substitutes for common names. However, we circumvent the problem of adding ambiguity to the text, if we only have few names starting with *'X'* (Stubbs et al. (2015b) also mentioned but did not implement this idea). As we map distributions in quite a rough way, we do not think that this could cause a leak of information of the original text, but distributional mappings are optional and the user may choose the granularity and distribution in his or her own module or language extension.

5.2 Language-Dependent Criteria for German

Since the categories DATE, STREET, CITY, GIVEN and FAMILY name, and ORG are affected by language-specific influences we implemented a German language module for these named entity types. In contrast to other surrogate generation systems we know of, our solution takes inflection into account (relying on the NLP tool SPACY (Honnibal and Montani, 2017)).

Dates. The formats we handle include typical combinations of day, month and year according to German formatting style (e.g., days precede months), yet also account for different spellings (e.g., *'01.06.2019'* or *'1.6.19'*). Days, months, and years occurring in isolation are processed as well. If a month is given in letter format, it is substituted with an alternative month name trying to keep differences between standard varieties (e.g., *'Januar'* (standard German) vs. *'Jänner'* (Austrian German) for *'January'*) and also preserve abbreviations (e.g., *'Jan.'*).

Street names. For names of streets, we recognize the abbreviations *'S|-str(.)'* (for *'Straße'* (street)) and *'P|-pl(.)'* (for *'Platz'* (place)) for look-up and coreference. We do not handle inflections of street names like *'Ligusterweg(e)s'* (genitive) because, in emails, street names most often are part of an address and thus lack inflection.

The list of surrogates is built from large repositories of German street names[11] jointly with Austrian ones from different provinces[12] that do not contain special characters or are composed of more than two terms (e.g., *'Albert-Einstein-Straße'*). Furthermore, we restricted them to contain only names with standard street suffixes (*'-straße'*, *'-weg'*, *'-platz'*, etc.), because we had to get rid of village names that do not have any named streets (such as with *'Wegscheid 15'*).

Given Names and Family Names. Common German proper nouns are singular and do not change number. (Duden, 2009, p. 191) Hence, our system does not process any plural forms of forenames or surnames (which rarely may occur), yet handles the genitive singular case. Therefore, our system is also capable of resolving coreferences between uninflected and inflected genitive forms.

To acquire suitable look-up dictionaries we extracted female and male names with their associated nicknames from a list of first names.[13] These lists are restricted to more or less common forenames in German-speaking countries except for names with rare first letters, where we included less frequent names, too. An alternative list of German surnames[14] is frequency-independent, thus includes also lots of uncommon names.

City names. For the CITY category, the genitive singular case is handled too. While person names and city, town or village names are mostly

[11] http://www.datendieter.de/item/Liste_von_deutschen_Strassennamen_.csv

[12] http://www.statistik.at/strasse/suchmaske.jsp

[13] ftp://ftp.heise.de/pub/ct/listings/0717-182.zip

[14] http://www.namenforschung.net/fileadmin/user_upload/dfa/Inhaltsverzeichnisse_etc/Index_Band_I-V_Gesamt_Stand_September_2016.pdf

used without determiner, a few German names for regions (e.g., *'die Steiermark'*, *'das Drautal'*) always require a determiner (Duden, 2009, pp. 299ff.). These names can be of every gender and also pluralia tantum, whereas city, town or village names are neuter and singularia tantum (Duden, 2009, pp. 160f.). Unfortunately, we currently do not dispose of repositories for gender- and number-specific CITY names large enough, so we rather tolerate possible mistakes than a potential information leakage.

In contrast to person names, we consider derivations of locations and implemented rules for signifying inhabitants (*'die Klagenfurterin'*) and adjectivized toponyms ending on *'-(i)sch/-erisch/-er'* (*'kärntnerisch'* (carinthian), *'Wiener Dialekt'* (Viennese dialect)). We check for coreferences using Levenshtein distance on previously seen CITYs. To catch lemmata occurring later we form appropriate candidates in a rule-based manner together with a lexicon look-up. For naming inhabitants, we only treat the standard forms ending on *'-er'* such as *'Wiener'* (Viennese) and do not care about non-standard names like *'Hesse'* (Hessian).

The generation of derivations from the substitute lemma is restricted to the most common cases. We produce derivatives by concatenating the lemma and *'-er'* or *'-r'*, if the lemma ends with *'-e'*. For adjectivized forms ending with *'-isch/-sch/-erisch'* that often allow a variation of these suffixes (Duden, 2016, p. 685) we decided on generating derivatives with *'-erisch'* (e.g., *'Wienerisch'* (Viennese)). Our system produces the inflectional forms for derivations by copying the original inflectional suffix to the generated form.

To maintain local national information we employed separate lists of location names for the three major German-speaking countries[15] on which we perform a dictionary look-up to determine which country the location name is from. Admittedly, this approach fails, if the place is either not mentioned or occurs in multiple countries. For substitution, we provide cleaner lists containing only villages, towns and cities for Germany,[16] Austria,[17] and Switzerland.[18]

Organizations. Similarly, we consider the genitive case for organizations. As the same company or institution in a document might be denoted by different name forms, such as its full name (*'Stadtwerke GmbH'*), with or without the corporate form (*'Stadtwerke'*) or an acronym (*'STW'*), with respect to coreference chains a more sophisticated solution is required. For now, we only check for names without a list of corporate forms. The substitution is performed with a list of German company names,[19] restricted to names not containing any GIVEN or FAMILY name. Due to gender variability and the lack of a list of institutions, we here added fictional acronyms and randomly generated letter combinations.

5.3 System Architecture

Our system for surrogate generation (see Figure 2) accepts any type of text, not only emails, but requires BRAT annotations of pi-relevant entities as described in Section 3. It allows for an easy adaptation to languages other than German, since the base module of the surrogate generation system can implement a language module for alternative languages, too. While language-independent categories (Section 5.1) do not need any further consideration, this language module has to provide allowed date formats and lists with language- and category-appropriate substitutes for the language-dependent classes (Section 5.2). Furthermore, frequency mappings of first letters may be specified in order to take distributions of names with respect

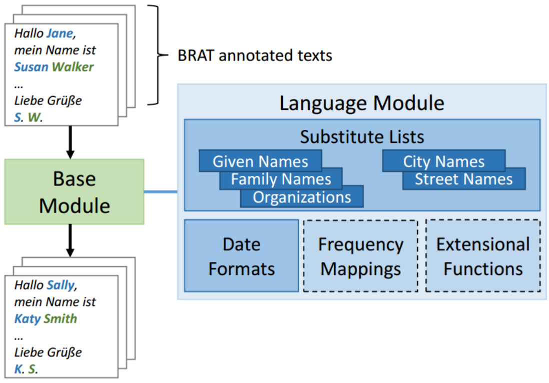

Figure 2: Schematic system architecture and surrogate generation workflow; dashed parts optional

to their first letters into account. If a use case requires a special treatment of a category, extensional functions have to be defined, e.g., for inflection generation. Otherwise, the base system replaces the entities with default entries in the substitute lists, i.e., generally (non-inflected) lemmata.

6 Evaluation of Pseudonymization

6.1 Grammaticality and Acceptability Tests

In a first round of evaluations, we wanted to test whether the surrogates we had generated were well-formed in terms of grammaticality and semantically 'natural' in terms of acceptability. For privacy reasons, we refrained from explicitly evaluating whether coreference relations were preserved, because it is difficult to keep track of them without the original wording.

First, the pseudonymized emails were scored on both evaluation dimensions on a scale from 1 (worst) to 5 (best) in packages of about 30 emails by different annotators. Each email was annotated only once. While *grammaticality* refers to the agreement in number, gender and case between the generated surrogate and the sentence constituents the surrogate is embedded in, a surrogate is *acceptable* if it semantically fits into the surrounding context so that a reasonable semantic interpretation can be made. For example, *'We bought the car at Amici Pizza Express'* is considered as semantically inacceptable because cars normally cannot be bought at a pizzeria. In contrast common names replaced with rare ones (e.g., *'Paris'* with a small village name) are regarded as acceptable.

For the evaluation, the manually tagged 1,390 German-language emails of CODE ALLTAG$_{S+d}$ underwent the surrogate generation process twice to be sure not to reveal any original pi items to the annotators. The automatically generated output was checked manually, also substituting phrases not covered by our categories, such as course names (the corpus contains lots of university related emails donated by our students). After that it was fed again to the surrogate generation system.

With 4.90 for grammaticality and 4.73 for semantic acceptability the results are pretty sound. The lower outcome for semantic acceptability is mostly due to the surrogates for the ORG category. Occasionally, rather odd combination like *'Serial Knitters, IT solutions'* (for *'Institute for XX, YY-University'*) and substitutes with a different, inaccurate function were found.

6.2 Frequency Analysis

As Deléger et al. (2014) remark, large frequency imbalances between corpora may influence the performance of machine learning systems. Therefore, we also assessed frequency imbalances between different corpora: The original non-pseudonymized CODE ALLTAG$_{S+d}$ corpus with hand-annotated pi entities (referred to as ORIG), the pseudonymized[20] form of the original corpus (PSEUD) and pseudonymized[20] CODE ALLTAG$_{S+d}$ with automatically recognized pi entities (PSEUDPIR). For the latter, we retrieved the pi entities by training a model on $9/10$ of ORIG and applying it to the unseen part on ten different folds. We used a system for recognizing privacy-bearing information (PIR) based on NEURONER (Dernoncourt et al., 2017; Lee et al., 2016), with slight modifications of its neural network architecture from our side.

Table 3 shows that the number of tokens declines for both pseudonymized corpora compared to the original corpus. Taking a closer look, the category discrepancy almost entirely results from the category ORG and, to a much lesser extent though, also from STREET and CITY names. We conclude that our substitution dictionaries obviously contain shorter names, i.e., entities consisting of fewer tokens. Contrasting ORIG and the automatically annotated PSEUDPIR, we witness an increase of pi entities. For one thing, this can be explained by taking the tokens of one entity separately and thus splitting one single entity into multiple ones, which is also reflected in the smaller difference between the number of tokens. As this phenomenon especially occurs with URLs and PHONE or fax numbers (these categories are substituted randomly) it has no effect on surrogate generation. Again, ORGanizations play a major role here, because the PIR system achieves the worst results for this category.

	ORIG	PSEUD	PSEUDPIR
# token	151,229	150,166	150,425
# types[21]	21,159	22,320	22,455
# pi entities	8,866	8,866	9,427
# pi tokens	12,649	11,586	11,865

Table 3: Quantitative breakdown of the corpora used for evaluation; "#" stands for frequency count

[20] Processed by the surrogate generation system without any further reworking.

6.3 Automatic Recognition Performance

Further, we followed Yeniterzi et al. (2010) and Deléger et al. (2014) and tested the performance of the PIR system on the three corpora. Like Yeniterzi et al. (2010), we also found better results for training and testing on the PSEUD corpus than on ORIG,[22] while the performance difference decreases for PSEUDPIR and ORIG (see Table 4). Among others, this may be a consequence of the frequency imbalance, because the pseudonymized data contain fewer tokens especially those related to the hard to recognize ORGanizations.

Corpus	Prec	Rec	F_1	p-value
ORIG	83.02	82.26	82.52	
PSEUD	86.15	86.24	86.07	0.007
PSEUDPIR	82.26	85.79	83.86	0.063

Table 4: Results of the PIR system on different corpora (10-fold cross validation); significance difference (p-value) with respect to ORIG (paired t-test)

For training and testing on different corpora, we eliminated the emails found in the test set from the train set in a 10-fold cross-validation manner, even if they were pseudonymized in one of the datasets to avoid any overlap. Again, similar to Yeniterzi et al. (2010), training on ORIG and testing on PSEUD yields significantly better results than the other way round (see Table 5). Also the F_1 score plunges deeply when training on PSEUDPIR and testing on ORIG compared to ORIG and testing on PSEUDPIR.

If we subsume the language-independent categories, because they are randomized and treated similarly in surrogate generation, we get comparable outcomes for all experiments with the PIR system with an F_1 score around 90.00. In contrast, language-dependent categories, with the exception of DATEs, which accomplish equivalent results for nearly all experiments, too, consistently perform worse compared to training and testing on the same corpus, especially regarding ORGanizations, CITYs and STREETs. As the results in Table 3 reveal, the amount of word types is higher in the pseudonymized corpora; hence, they are more diverse. Further, they may contain rarer names. Both phenomena potentially lead to a decrease of performance on these data sets when trained on the ORIG corpus. Regarding the drop of the reverse experiment the fewer occurrences of 'I'-tags (from the BIO format) have an impact, too.

<table>
<tr><th>Train|Test</th><th>Prec</th><th>Rec</th><th>F_1</th><th>p</th></tr>
<tr><td>ORIG|PSEUD</td><td>77.97</td><td>73.12</td><td>74.93</td><td></td></tr>
<tr><td>PSEUD|ORIG</td><td>70.25</td><td>61.32</td><td>64.57</td><td>0.0</td></tr>
<tr><td>ORIG|PSEUDPIR</td><td>85.23</td><td>75.21</td><td>78.39</td><td></td></tr>
<tr><td>PSEUDPIR|ORIG</td><td>67.31</td><td>63.21</td><td>63.88</td><td>0.0</td></tr>
</table>

Table 5: Results of the PIR system trained on Train and tested on Test (10-fold cross validation without overlap); significance difference (p-value) over reverse setting (paired t-test)

In contrast to Yeniterzi et al. (2010) and our results, Deléger et al. (2014) report a smaller performance difference between training on original and testing on pseudonymized data and vice versa. This is probably due to the fact that they replaced pi entities with different entities of the same category taken from the same original corpus, thus almost retaining the original personal information. This approach bears the potential of causing a leak of personal information due to categories with limited occurrences.

7 Conclusion

In this paper, we moved the de-identification problem out of the medical domain (cf. also our work in this field described in Kolditz et al. (2019)) into the realm of user-generated content, emails in our use case. In particular, we focused on the surrogate generation step of that task, i.e., substituting named entities bearing privacy-relevant information by synthetic, yet mostly natural surrogates.

Our main contributions are the specification of a language-independent type hierarchy composed of named entities that carry privacy-relevant information, and the realization of the first German non-medical surrogate generation pipeline. It is composed of a language-dependent part for German input and a language-independent one which can readily be reused for languages other than German, without any changes.

We also ran a series of experiments on emails from the German-language CODE ALLTAG$_{S+d}$ corpus. In this evaluation of our surrogate generation system, we found high scores for the grammaticality and acceptability of the automatically

[21] Types of tokens excluding punctuation and stop words.

[22] When the k-fold splits are performed on sentences rather than on emails the results get notably better achieving 86.24 F_1 score for ORIG. But for reasons of comparability between non-pseudonymized and pseudonymized corpora we had to split on emails.

generated surrogates. A frequency analysis of different variants of CODE ALLTAG$_{S+d}$ revealed a quantitative imbalance between the original corpus, the pseudonymized one, and a de-identified variant that was built using an automatic recognizer for privacy-relevant named entities. Experiments on these three corpora further exposed differences in recognition performance already discussed in the literature.

Our future work will focus on a more adequate treatment of German derivational morphology and coreferences rooted in varying spellings. The main methodological desideratum concerns the investigation of ways to deal with organizations with different functions in order to improve semantic acceptability. Last but not least, we will have to demonstrate that the results from the small-scale corpus we currently dealt with (CODE ALLTAG$_{S+d}$) will scale up to much larger document collections (e.g., CODE ALLTAG$_{XL}$ as described in Krieg-Holz et al. (2016)).

Acknowledgments

We want to thank our RANLP reviewers for pointing out improvements of the original submission. These hints were gratefully acknowledged and incorporated in the final version of the paper.

This work was funded by the Austrian HRSM project *Kompetenznetzwerk Digitale Edition* (KONDE).

Abstract

This paper introduces a new approach to estimating the text document complexity. Common readability indices are based on average length of sentences and words. In contrast to these methods, we propose to count the number of rare words occurring abnormally often in the document. We use the reference corpus of texts and the quantile approach in order to determine what words are rare, and what frequencies are abnormal. We construct a general text complexity model, which can be adjusted for the specific task, and introduce two special models. The experimental design is based on a set of thematically similar pairs of Wikipedia articles, labeled using crowdsourcing. The experiments demonstrate the competitiveness of the proposed approach.

1 Introduction

Automated text complexity measurement tools have been proposed in order to help teachers to select textbooks that correspond to the students' comprehension level and publishers to explore whether their articles are readable. Thus, plenty of readability indexes were developed. Measures like *Automated Readability Index* (Senter and Smith, 1967), *Flesch-Kincaid readability tests* (Flesh, 1951), SMOG index (McLaughlin, 1969), Gunning fog (Gunning, 1952) and etc. use heuristics based on simple statistics such as total number of words, mean number of words per sentence, total number of sentences or even number of syllables to evaluate how complex given text is. By combining these statistics with different weighting factors, readability indexes assign the given document a *complexity score*, which is, in most cases, the approximate representation of the US grade level needed to comprehend the text. For instance, an Automated Readability Index (ARI) has the following form for the document d:

$$ARI(d) = 4.71 \times \frac{c}{w} + 0.5 \times \frac{w}{s} - 21.43 \quad (1)$$

where c refers to the total number of letters in the document d, w is the total number of words and s denotes the total number of sentences in d.

Since readability indexes rely on a few basic factors, precise assessment requires aggregation of many scores. Thus, Coh-Metrix-PORT tool (Aluisio et al., 2010) includes more than 50 different indexes for Portuguese language. The tool is based on Coh-Metrix (Graesser et al., 2004) principles to estimate complexity and cohesion not only for explicit text, but for the mental representation of the document.

Readability indexes are interpretable and easy to implement. However, the great number of constants tuned specifically for the English language texts, lack of the semantics consideration and tailoring to the US grade level system restrains the number of possible applications.

As for the non-English languages, several lexical and morphological features for Italian to solve text simplification problem were presented (Brunato et al., 2015), supervised approach in readability estimations was introduced (vor der Brck et al., 2008) and the complexity estimations for legal documents in Russian were explored (Dzmitryieva, 2017).

In this paper we introduce a new approach to gauge the complexity of the documents based on their lexical features. Our research is motivated by information retrieval applications such as exploratory search for learning or editorial purposes (Marchionini, 2006; White and Roth, 2009; Palagi et al., 2017). In the exploratory search, the user needs a hint which of the found documents to read first, gradually moving from simple to more complex documents. Reading order optimization is an alternative way to content consumption that departs from the typical ranked lists of documents based on their relevance (Koutrika et al., 2015). The more specific terms document contains, and the more rare they are, the more complex the document is. To formalize this consideration, we estimate the complexity of each term in the document and then aggregate them to get the complete document complexity score. We use Wikipedia as a *reference collection* of moderately complex texts in order to determine what term frequencies are abnormal.

In section 2 we describe quantile approach to estimate the single term complexity. We present highly flexible general model in section 3 and models in subsections 3.1 and 3.2. The way of evaluating the proposed methods is introduced in section 4 and the experiments result are provided in section 5.

2 Single Term Complexity Estimation

Reference collection: Let D denote a reference collection. Let document $d \in D$ consist of terms $t_1, t_2, \dots t_{n_d}$, where n_d refers to the length of document d. Each term can be either a single word or a key phrase.

Quantile approach: In general case each term can occur in different complexity states, which may depend on a position in text or context surrounding the term. Each complexity state of the term t_i standing in position i is described with a *term complexity score* $c(t_i)$. Consider a complexity scores empirical distribution for each term over the reference collection. Assume that term t_i is *in complex state* if its complexity $c(t_i)$ in current text position i is greater than γ-quantile $C_\gamma(t_i)$ of the distribution over $c(t_i)$, where γ is a hyperparameter, responsible for the complexity level. Therefore, when estimating complexity score of the document, we count $c(t_i)$ only for terms t_i which are in the complex state, defined by the γ parameter.

For instance, $c(t_i)$ can be a constant, which means all terms have identical complexity, or can be set equal to 0 if it occurs in the reference collection and 1 otherwise. In this case, we count new terms (for the reference collection) as complex and all other terms as simple.

3 General Document Complexity Model

Document d complexity $W(d)$ can be calculated by aggregating complexity scores of terms that form d. In this paper we propose a weighed sum over the complex terms to be the aggregate function.

$$W(d) = \sum_{i=1}^{n_d} w(t_i)[c(t_i) > C_\gamma(t_i)] \qquad (2)$$

where $[\,]$ refers to the Iverson notation (i.e. $[true] = 1, [false] = 0$).

By defining weights $w(t_i)$ and complexity scores $c(t_i)$ for all terms t_i specialize the complexity model.

Some examples of interpretable weights $w(t_i)$ are presented in Table 1.

$w(t_i)$	**Meaning of** $w(t_i)$
1	number of complex terms
$1/n_d \times 100\%$	complex terms percentage
$c(t_i)$	total complexity
$c(t_i)/n_d$	mean complexity
$c(t_i) - C_\gamma(t_i)$	excessive complexity
$(c(t_i) - C_\gamma(t_i))/n_d$	mean excessive complexity

Table 1: Weights $w(t_i)$ examples.

3.1 Distance-Based Complexity Model

The following model relies on the assumption, proposed in (Birkin, 2007). Consider an arbitrary document d which is the sequence of terms $t_1, t_2, \dots t_{n_d}$. Let $r(t_i)$ be a distance in terms to the previous occurrence of the same term t_i in document d. Formally,

$$r(t_i) = \min_{1 \le j < i} \{i - j \mid t_i = t_j\}. \qquad (3)$$

If i is the first occurrence of term t_i in document d, it means that $r(t_i)$ is undefined. In such cases we take $r(t_i)$ equal to n_d. Hence, for terms with the only occurrence in d complexity scores are the greatest.

If term t does not appear in the reference collection, we set C_γ equal to $-\infty$, therefore counting it as a constantly complex term.

Assume that term t in the position i is more complex than the same term in the position j if $r(t_i) > r(t_j)$. Consider there are no separators between documents in the reference collection, so it becomes a single document d_{all}. Thus, it is possible to count distributions of $r(t)$ of each unique term t in d_{all} and corresponding γ-quantiles $C_\gamma(t)$ of these distributions.

For the document d, which complexity we try to estimate, we calculate $r_d(t_i)$ values for all terms $t_i \in d$.

We define mean distance $r_{d,i}(t_i)$ for term t_i in i-th position in the document d as

$$\bar{r}_{d,i}(t_i) = \frac{\sum_{j=1}^{i} r_d(t_i)[t_i = t_j]}{\sum_{j=1}^{i}[t_i = t_j]} \tag{4}$$

which aggregates all occurrences of the term t_i from the document start.

Finally $c(t_i)$ has the form:

$$c(t_i) = \bar{r}(t_i) - \bar{r}_{d,i}(t_i) \tag{5}$$

where $\bar{r}(t_i)$ is the mean distance of the reference collection scores $r(t_i)$ for the term t_i.

Intuitively, this means, that term is more complex if it occurs less in reference collection and occurs more in document d.

Figures 1 and 2 show distributions of distances $r(t)$ for the simple term 'algebra' and the complex term 'nlp', calculated over the reference collection containing 1.5M documents of the Russian Wikipedia. For the 'algebra' term most occurrences are relatively close to each other, whether 'nlp' occurrences have fairly greater distance scores.

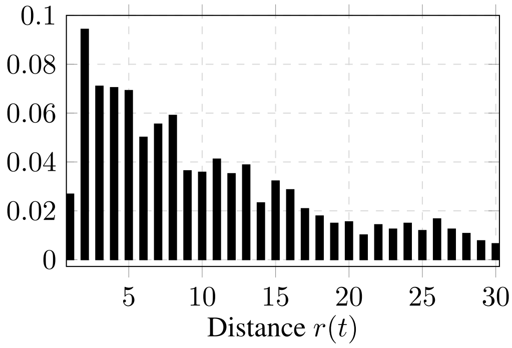

Figure 1: Distribution of distances $r(t)$, calculated over the complete Wikipedia dataset for the word 'algebra'.

So, using the formula for $c(t_i)$ as above and choosing weights $w(t_i)$ we get the distance-based complexity model.

3.2 Counter-Based Complexity Model

The second model presented in this paper is based on the assumption that each term has an independent fixed complexity in the whole language. Thus, in this section we consider not the complexity distribution of a single term, but the general complexity distribution over all terms in the language. Hence, each term t is assigned the only

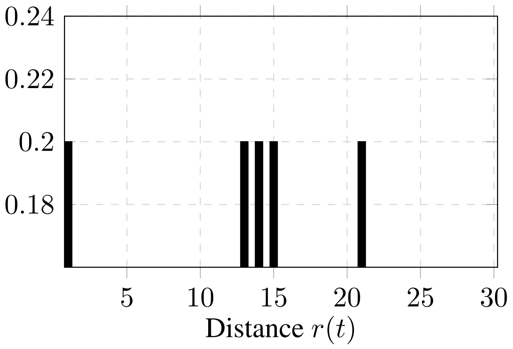

Figure 2: Distribution of distances $r(t)$, calculated over the complete Wikipedia dataset for the word 'nlp'.

complexity score $c(t)$ and the γ-quantile we count is now a constant C_γ.

Hence, the model has the following form:

$$W(d) = \sum_{i=1}^{n_d} w(t_i) \left[\frac{1}{count(t_i)} > C_\gamma\right] \tag{6}$$

where $w(t_i)$ corresponds to the term weights introduced before.

Assume the term t_1 is more complex than the term t_2 if number of occurrences in the reference collection of the term t_1 is lesser than the number of occurrences of the term t_2.

Let $count(t)$ denote number of occurrences of the term t in the reference collection. Thus, the complexity score function can be defined as

$$c(t) = \frac{1}{count(t)} \tag{7}$$

so the assumption above is satisfied.

For each term t we calculate counters $count(t)$ and complexity scores $c(t)$ over the reference collection. Having the distribution of $c(t)$, we obtain γ-quantiles C_γ. The described distribution for the Russian Wikipedia reference collection is shown on Figure 3.

Thus, we have defined $c(t)$ for all terms possible and the distribution necessary to count the C_γ. By varying weights $w(t_i)$ described in section 3, we obtain the counter-based model for the complexity estimation.

4 Quality Metric

To measure the quality of proposed algorithms, we asked assessors to label 10K pairs of Russian Wikipedia articles. Assessors were asked to carefully read both articles and to choose which was

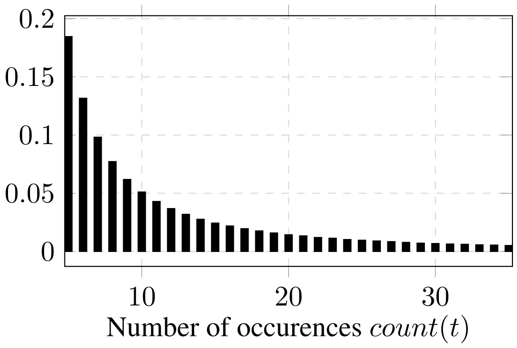

Figure 3: Distribution of $count(t)$, calculated over complete Wikipedia articles dataset.

more difficult to comprehend. If person cannot determine which document is more complex, then he was asked to choose 'documents are equal' option. If documents in the given pair are from different scientific domains, then we ask assessor to choose 'invalid pair' option.

Documents were chosen from math, physics, chemistry and programming areas. Clustering was performed using the topic modeling technique (Hofmann, 1999). BigARTM open-source library was used to perform the clustering (Vorontsov et al., 2015). Pairs were formed so that both documents belong to a single topic and their lengths are almost identical. Examples of document pairs to assess are introduced in Table 2.

Document 1	**Document 2**	**Result**
Matrix	Tensor	RIGHT
Neural network	Linear regression	LEFT
Electric charge	Molecule	EQUAL
Mac OS X	Convex Hull	INVALID

Table 2: Examples of labeled document pairs.

Each pair was labeled twice in order to avoid human factor mistakes. We assume that the pair was labeled correctly if labels were not controversial, i.e. first assessor labeled the first document as more complex, while second assessor chose the second document. If one or both grades were 'documents are equal' then we assume the pair to be correctly labeled.

8K pairs out of 10K were labeled correctly and were used to compare for the different versions of algorithms. For each we calculated the accuracy score, which is the rate of correctly chosen document in the pair.

5 Experiments

Two types of experiments were done. In first case we used full Russian Wikipedia articles dataset (1.5M documents) as a reference collection. In second type we used only Wikipedia articles from the math domain. To do that, we built a topic model using ARTM (Additive Regularization of Topic Models) technique (Vorontsov and Potapenko, 2015), which clusters documents into monothematic groups.

5.1 Complete Wikipedia Dataset

Preprocessing: All Wikipedia articles were lemmatized (i.e. reduced to normal form). In this experiment we assume term to be either a single word or a bigram (i.e. two words combination). To extract them, RAKE algorithm (Rose et al., 2010) was used. Hence, each document in the collection was turned into the sequence of such terms.

Reference collection: Preprocessed Wikipedia articles were used as a reference collection. $r(t)$ for every term position and $count(t)$ for every unique term were counted.

Documents to estimate complexity on: We used the labeled pairs described in Section 4 to evaluate the models. Accuracy was used as a quality metric.

Models to evaluate: Models introduced in 3.1 and 3.2 with different $w(t_i)$ parameters were tested. We took ARI and Flesch-Kincaid readability test as benchmarks.

The results of the experiments are introduced in Table 3. Also we tested how the bigrams extraction affects final quality with fixed weight function $w(t) = c(t)/n_d$. The results are given in Table 4.

Model	$w(t)$	**Accuracy**
ARI	-	**46%**
Flesch-Kincaid	-	**57%**
Distance-based	$c(t)$	**68%**
Distance-based	$c(t)/n_d$	**71%**
Counter-based	$c(t)$	**77%**
Counter-based	$c(t)/n_d$	**81%**

Table 3: Results of experiment 1 with different weight function.

Results show that both distance- and counter-based approaches work twice as well as readability indexes. Counter-based model with $w(t) = c(t)/n_d$ weights show the best results.

Model	Terms	Accuracy
Distance-based	Words	**63%**
Distance-based	Words+Bigrams	**71%**
Counter-based	Words+Bigrams	**74%**
Counter-based	Bigrams	**81%**

Table 4: Results of experiments 1 with terms differently defined.

5.2 Single Topic Wikipedia Dataset

In experiment 2 we shortened the reference collection to include only documents from specific topic.

ARTM model: To divide documents into single-topic clusters, topic modeling is used. Topic Models are unsupervised machine learning models and perform soft clustering (i.e. assign each document a distribution over topics). The set of such vectors for all documents form a matrix, which is usually denoted by Θ. *ARTM model* was trained on the preprocessed Wikipedia dataset. ARTM features dozens of various types of regularizers and allows to treat modalities (i.e. types of terms) differently.

In this specific experiment we used regularizers to sparse Θ matrix and make each topic distribution over terms more different. Words and bigrams (i.e. pairs of words) modalities were used with weights 1 and 5 respectively. Using this model, we detect the most likely topic for each document.

Experiment setup: In the following experiment we chose math and physics documents to be the reference collection. Documents were preprocessed in the same way as they were in the previous experiment. We also divided labeled pairs into same single-topic groups to test models configured with different reference collections on various single-topic groups of labeled pairs.

Math collection included 200K documents in reference collection and 3.5K labeled pairs, while for the physics collection it was 250K documents in reference collection and 1.5K labels. The results are shown in Table 5 and Table 6.

As it can be seen from results, using tailored reference collection improves the score. Indeed, that solves terms ambiguity problem and eliminates terms unrelated to the topic from the reference collection, so they are treated complex in the estimating document, which is fairly logical.

Model	$w(t)$	Accuracy
ARI	-	**41%**
Flesch-Kincaid	-	**49%**
Distance-based	$c(t)$	**55%**
Distance-based	$c(t)/n_d$	**61%**
Counter-based	$c(t)$	**79%**
Counter-based	$c(t)/n_d$	**84%**

Table 5: Results of experiment 2 on math collection of Wikipedia articles with different weights.

Model	$w(t)$	Accuracy
ARI	-	**52%**
Flesch-Kincaid	-	**58%**
Distance-based	$c(t)$	**65%**
Distance-based	$c(t)/n_d$	**63%**
Counter-based	$c(t)$	**82%**
Counter-based	$c(t)/n_d$	**81%**

Table 6: Results of experiment 2 on physics collection of Wikipedia articles with different weights.

6 Conclusions

We have presented an approach to estimating text complexity based on lexical features. Document complexity is an aggregation of terms' complexities. Introduced general model is highly flexible, it can be adjusted by tuning weights $w(t)$ and choosing proper reference collection.

Complexity score can only be count with respect to the reference collection. Reference collection can be a large set of documents on different topics or just contain single-topic texts.

The proposed complexity measures are used in AITHEA exploratory search system (http://aithea.com/exploratory-search) for ranking search results in complexity-based reading order.

Abstract

The massive amount of multi-formatted information available on the Web necessitates the design of software systems that leverage this information to obtain knowledge that is valid and useful. The main challenge is to discover relevant information and continuously update, enrich and integrate knowledge from various sources of structured and unstructured data. This paper presents the Learning Engine Through Ontologies (LETO) framework, an architecture for the continuous and incremental discovery of knowledge from multiple sources of unstructured and structured data. We justify the main design decision behind LETO's architecture and evaluate the framework's feasibility using the Internet Movie Data Base (IMDB) and Twitter as a practical application.

1 Introduction

In recent years, research in machine learning, knowledge discovery, data mining and natural language processing, among others, have produced many approaches and techniques to deal with the large amount of information available on the Internet to carry out a variety of tasks, such as, for example building search (Brin and Page, 1998) and recommendation systems (Davidson et al., 2010) that could be used to improve business, health-care and political decisions (Ferrucci et al., 2013).

The purpose of our proposal is to present LETO: Learning Engine Through Ontologies, a framework to automatically and gradually extract knowledge from different sources (both structured and unstructured), building internal representations that can be adapted to and integrated in multiple domains. The current state of LETO's implementation is a computational prototype that illustrates the different components of its architecture and demonstrate its feasibility. Inspired by the different processes that occur during human learning, we design the framework's architecture as a learning pipeline that gradually builds more complex knowledge.

In a simplified view, the human learning process can be modeled as a continuous loop that transforms sensorial data into knowledge (see Figure 1) (Gross, 2015). Humans collect information about the environment through senses, where the human brain attempts to detect relations between individual signals to form a more structured representation of reality. By relating as many signals as possible, humans build a much richer semantic representation of the environment, which is unconsciously filtered storing only the most relevant part. In order to achieve this, the brain is able to access to stored experiences about what has been important before, and what is already known. This feedback loop also evaluates previously known facts, and modifies them at the light of new experiences. In time, humans not only learn new facts, but also learn better ways of learning.

The challenge of building computational knowledge discovery systems is an active research problem in the field of artificial intelligence, specifically in emerging areas such as ontology learning (Cimiano et al., 2009) and learning by reading (Barker et al., 2007). Modern systems employ a combination of knowledge-based techniques (i.e., using rules handcrafted by domain experts (Chandrasekaran, 1986)) and statistical approaches (i.e., based on pattern recognition with statistical and probabilistic models (Kevin, 2012)).

Given the large amount of information available online, several knowledge discovery systems fo-

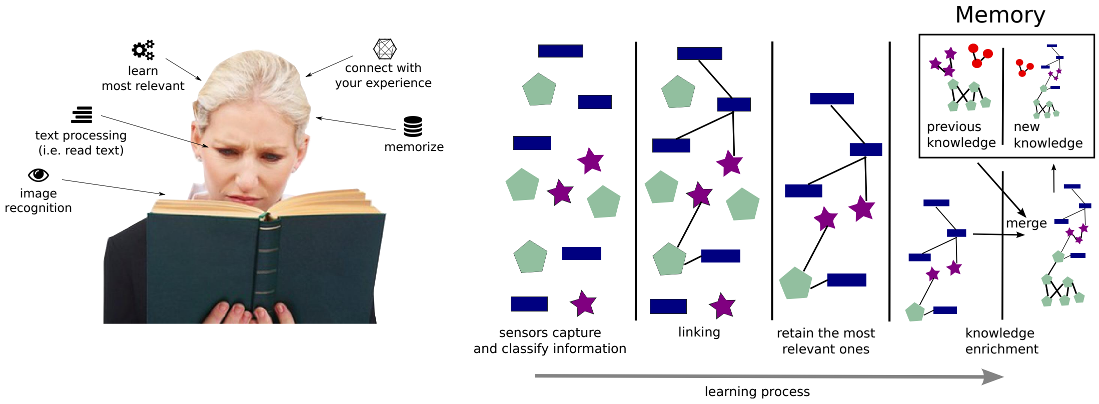

Figure 1: Simplified representation of the human learning process.

cus on extracting knowledge and exploiting the semi-structured format of web resources , e.g, ARTEQUAKT (Alani et al., 2003), SOBA (Buitelaar et al., 2006) and WEB->KB (Craven et al., 2000). In order to extract relevant knowledge from natural language text, NLP techniques have been introduced in systems such as OPTIMA (Kim et al., 2008) and ISODLE (Weber and Buitelaar, 2006). Natural language features can be used to build rule-based systems (e.g., OntoLT (Buitelaar and Sintek, 2004)) or systems based on statistical or probabilistic models trained on NLP corpora, such as LEILA (Suchanek et al., 2006) or Text2Onto (Cimiano and Völker, 2005). Some systems address the issue of inferring more abstract knowledge from the extracted facts, often using unsupervised techniques to discover inherent structures. Relevant examples of this approach are OntoGain (Drymonas et al., 2010), ASIUM (Faure and Poibeau, 2000) and BOEMIE (Castano et al., 2007).

Most of the mentioned systems focus on one iteration of the extraction process. However, more recent approaches, like NELL (Mitchell et al., 2018), attempt to learn continuously from a stream of web data, and increase over time both the amount and the quality of the knowledge discovered.

One of the main characteristics of LETO, in contrast to similar proposals in the literature (such as NELL (Mitchell et al., 2018) or BOEMIE (Petasis et al., 2011)), is the explicit management of separated pieces of knowledge. By isolating the knowledge for different domains, it is possible to apply different techniques and/or parameters as appropriate. Besides, this allows the temporal existence of contradictions or unreliable information that can be crosschecked in the future.

The rest of the paper is organized as follows to facilitate a detailed description of our proposal: Section 2 describes the proposed architecture of a general framework for knowledge discovery. In Section 3 we present an application of LETO to a specific knowledge discovery problem combining Twitter and IMDB. Finally, in Section 4 we present the main conclusions of the research and outline possible future works.

2 Learning Engine Through Ontologies (LETO)

In this section we present LETO, a general architecture for a framework designed to discover relevant knowledge from a variety of data sources, both structured and unstructured.

The LETO framework is divided into 6 modules, which are interrelated. Each module has a specific responsibility defining the inputs and outputs that establish the intercommunication among the rest of the modules within the framework. Figure 2 shows a general overview of the framework.

As shown in Figure 2 the top layer (Data Sources) represents the sources of data that serve as input for the framework. The middle layer contains the Main Modules, which perform the processing of the input data to extract and discover the relevant knowledge latent in this data. Figure 2 also shows the subprocesses that occur inside each module. The main modules always communicate with each other by sharing ontologies. The following sections 2.1, 2.2 and 2.3 explain in detail the inner workings of the main modules. The bottom layer (Backend) contains modules used by the rest of framework:

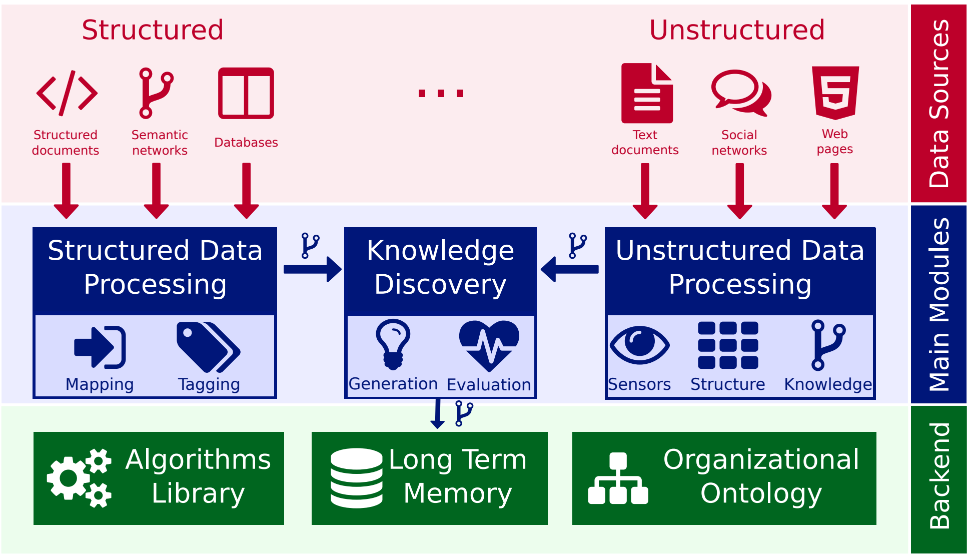

Figure 2: Overview of the architecture of LETO.

Algorithms Library: Contains different algorithms and mathematical models for solving specific problems, along with associated metadata.

Long Term Memory: Contains all the knowledge accumulated by the other modules, in the form of individual ontologies with metadata that describes their content.

Organizational Ontology: An internal representation of the framework's components in an ontological format which enables the automatic construction of the user interface.

2.1 Structured Data Processing

This module is responsible for processing structured data. Sources for structured data are available online in different formats. Among the different types of structures for representing information, such as relational databases, concept maps, knowledge graphs, and others, LETO proposes the use of ontologies for their semantic richness. Ontologies were chosen because they are more expressive than other DTO (Data Transfer Object) formats.

The general pipeline that this module performs can be thought of as a classic Extract, Transform and Load process (ETL) (Vassiliadis, 2009; Hermida et al., 2012). Afterwards, the normalized and tagged block of knowledge (stored as an ontology) is handled to the knowledge processing module, for further refinement and storage. Figure 3 shows an schema of this module. This module performs two main tasks:

Mapping: Since there are many different structured formats, the first stage of this module is to convert any of these representations into a standard representation for internal use, in the form of an ontology, using a mapping process (Choi et al., 2006; Y. An and Mylopoulos, 2006; Noy and Musen, 2003). The current implementation infers classes and relations from CSV or TSV input files using a rule-based approach, and outputs and ontology in OWL format.

Tagging: This step attaches several tags, such as source, domain, topic and reliability to the mapped ontology. This tags can be either inferred automatically (e.g., the domain and reliability) or provided by the user (e.g., the source). The current implementation requires a manual input by a domain expert.

2.2 Unstructured Data Processing

The sources for unstructured data are extremely varied in format and computational representation. Text is one of the most common forms for storing and communicating human knowledge, but pictures, sound files, and videos are also interesting and increasingly popular forms of communication. Also, in contrast with structured sources, there is a lot of variety in the level of reliability and completeness of unstructured sources.

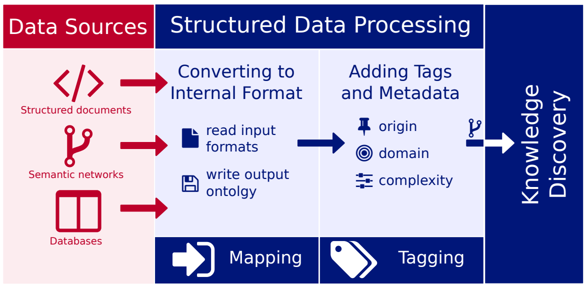

Figure 3: A schema of the Structured Data Module, and a representation of the processes that occur in each of the two main tasks performed by this module.

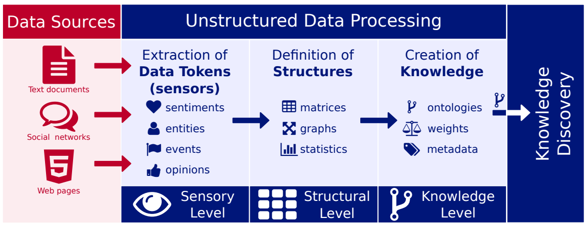

Figure 4: A schema of the three stages of the Unstructured Data Module and its relation with the rest of the framework.

Besides these factors, contrary to structured sources, there is no predefined structure of concepts and relations inside a block of unstructured data. Hence, the module for processing unstructured data is designed as a pipeline through which simple concepts are processed and transformed into more complex ones. Figure 4 shows a schema of this module, as well as an example of the type of processes that occur inside and their relation with each other. The module is organized in a three-levels pipeline as follows:

Sensory Level: Contains a number of processing units called "sensors", which extract different chunks of data. Among the implemented sensors, LETO includes named entity recognition) (Gattani et al., 2013), sentiment analysis (Montoyo et al., 2012), and detection of subject-actions-target triplets (Estevez-Velarde et al., 2018). In general, each of these sensors performs a specific analysis and produces a stream of *data tokens* of a particular type. Each of these data tokens represents a single unit of semantic information, for instance, the existence of a particular entity, or the association between an entity and an event, and are not interrelated.

Structural Level: The data tokens extracted from the original source are processed as a group to find an underlying structure. Techniques implemented in this stage include Latent Semantic Analysis (LSA) (Hofmann, 2017), Principal Components Analysis (PCA) (Guo et al., 2002), Word Embeddings (Turian et al., 2010) and clustering techniques. The output of this stage is either a graph, a correlation matrix, or some statistical description that represents the underlying structure of the data tokens that were previously extracted.

Knowledge Level: The structured information that was previously built is analyzed to refine, remove noise, and extract the relevant pieces of knowledge, based on clustering techniques. This allows synthesizing the knowledge discovered so far according to the context defined by the relations between the semantic units extracted in the previous stage. The output of this stage is always an ontology, which is then passed to the Knowledge Discovery Module for further integration with the stored knowledge. The resulting ontology then becomes part of the stored knowledge of the framework, which is iteratively refined, corrected and enhanced with new knowledge extracted from different sources.

2.3 Knowledge Discovery

The knowledge discovery module receives the output from unstructured data processing and structured data processing, always in the form of an ontology. Each of these ontologies represents a collection of knowledge assets from a particular domain or a general domain. Some of them may overlap, containing the same knowledge facts, even if labeled as different entities or relations. Others may have contradictions or inconsistencies, either within themselves or with one another, see Figure 5. For this purpose, this module performs two main tasks:

Generation: The generation of knowledge involves two processes, namely the merging of ontologies (Noy et al., 2000; Noy and Musen, 2003), and the generation of new (or more general-domain) ontologies from other ontologies (Aussenac-Gilles and Jacques, 2006; Blomqvist, 2009). Merging ontologies requires this module be able to undertake a matching among entities, relations and instances in two or more ontologies that are deemed similar (Shvaiko and Euzenat, 2013).

Evaluation: After the new ontology is created, this step provides quality evaluation metrics that assert the reliability, completeness or soundness of the new knowledge. These metrics are based on comparing the new ontology with the existing knowledge.

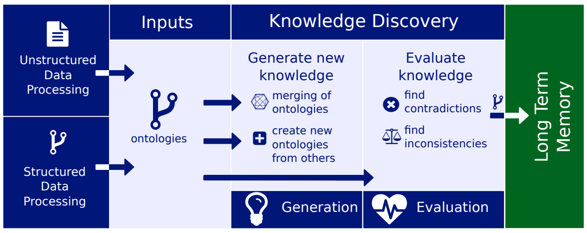

Figure 5: A schema of the architecture of Knowledge Discovery Module, showing the internal tasks performed and its relations with the rest of the framework.

3 Application of LETO to Knowledge Discovery

This section shows the use of the LETO system through a practical scenario that involves the processing of both unstructured and structured data sources. This application illustrates the types of processes (i.e. processing of both unstructured and structured data sources) that our framework performs. We select the Internet Movie Database (IMDB) that contains information about films and actors. We aim to enrich this knowledge with opinions expressed in social networks. Opinions can be extracted from a specific Twitter *hashtag* feed (i.e., `#Oscars`). Figure 6 shows a schematic representation of the whole process.

The first step consist of obtaining the IMDB data (in CSV format) and mapping it to an OWL ontology. Data from IMDB was obtained in tab-separated files, processed by LETO's generic mapping pipeline which infers class names and relation names from the CSV structure. This results in a total of 4,807,262 film instances and 8,427,043 person instances, related by 27,044,985 tuples in 12 different relation types. After the mapping process, the resulting ontology is tagged with relevant metadata. In this case, the domain is **Cinema**, and a high confidence can be assigned since this source is known to be of high quality. These steps are represented in the figure with the numbers *1a* and *1b* and performed in LETO using the *Structured Data Processing* module (see Fig. 3).

The next step involves the processing of a continuous stream of Twitter messages (*2a*). These are obtained through the standard Twitter query API, filtering with the hashtag `#Oscars`, which returned 3375 messages that span a period of 2 weeks. Using standard NLP techniques, each tweet is processed to obtain named entities (Nadeau and Sekine, 2007) and an opinion label (Pang et al., 2008; Liu, 2012) (*2b*). The entity sensor was implemented using spaCy (Honnibal and Montani, 2017), which returned 524 unique PERSON instances, from a total of 1961 PERSON mentions. The document level emotion sensor was implemented through the use of the SAM[1] project (Fernández et al., 2015). An example output of the entity sensor is shown in Figure 7. Similar interfaces are available in LETO for interacting with all the components of the framework, but are not shown for space restrictions.

Afterwards, the different mentions of the same entities across multiple tweets are matched together (*2c*). The least relevant mentions (e.g., those with very few appearances) are filtered out (*2d*). through the clustering technique Affinity Propagation (Pedregosa et al., 2011). Finally, the filtered entities with their associated opinions (*2e*) are tagged and stored in an ontology (*2f*). These steps are performed using components from the *Unstructured Data Processing* module.

After the processing of both structured and unstructured data is completed (*3a*), both sources are selected for a knowledge integration process (*3b*). An ontology mapping technique (Choi et al., 2006) is applied, which maps relevant instances of the IMDB ontologies to their corresponding mentions in the tweets (*3c*). The result of this mapping process is an ontology in the same format as IMDB, but with additional aggregated opinion labels for each instance (of those found in Twitter). This enriched knowledge is tagged (*e3*) and stored for future use. These steps are performed using components from the *Knowledge Discovery* module. The resulting ontology can be visualized in LETO, as shown in Figure 9. This visualization tool shows both the classes and instances, enabling an interactive exploration of the ontology.

Figure 8: Main UI of LETO, specifically the Task Management view.

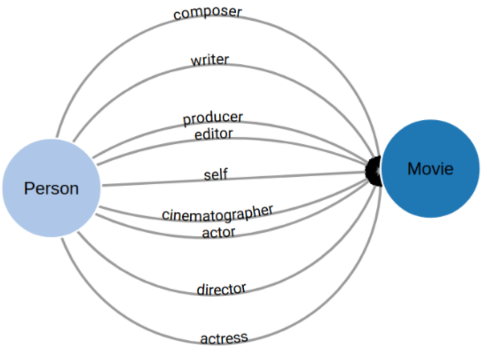

Figure 9: Visualizing the structure of the IMDB ontology in LETO.

The knowledge generation process involved matching Twitter PERSON instances with IMDB instances and attaching an average of the emotions found in each mention of the corresponding instance. A total of 212 instances were matched, which indicates a 40.45% of accuracy for the Twitter entity extractor. A manual review of the 542 recognized instances was performed, to evaluate the reasons for the mistakes. All entities appearing in Twitter where searched in Google and the first result was used as ground truth. Table 1 summarizes these results.

The current implementation of LETO provides an interactive application where researchers can apply the different algorithms and techniques implemented in each module, both interactively (i.e., using a single input example) or in batch mode.

Metric	Value	Percent
Correct matches	212	**40.45**
Correct mismatch	19	**3.62**
Matching error	118	22.52
Extraction error	165	31.48
Knowledge error	10	1.91
Context missing	2	0.38
Total errors	293	55.92

Table 1: Summary of results of the knowledge discovery process.

LETO supports multiple processes running in parallel, and provides tools for running and monitor long-term processes that can take hours or days. Figure 8 shows a overall view of LETO's main user interface, specifically the view for task management.

4 Conclusion and Future Works

In this research work, the aim was to design and implement a framework for automatic knowledge discovery from different data sources. We considered the discovery of knowledge from structured and unstructured sources of information. This framework has been designed as a modular set of components that perform specific tasks and communicate with each other. An open-source prototype implementation of LETO is currently available[2], which already contains several of the main components. In future lines of development, we will pursue the implementation of more var-

[2] https://github.com/knowledge-learning/leto

ied sensors, and more complex mechanisms for knowledge integration (e.g., ontology merging and mapping processes). Another line for future research is related to context mismatch and recognition, specifically in the *Unsupervised Processing Module*. This process is necessary for accurately matching portions of unstructured text to sections of an already stored ontology. We will also focus on extending the automation processes currently available in LETO.

Acknowledgments

This research has been supported by a Carolina Foundation grant in agreement with University of Alicante and University of Havana. Moreover, it has also been partially funded by both aforementioned universities, the Generalitat Valenciana and the Spanish Government through the projects SIIA (PROMETEU/2018/089), LIVINGLANG (RTI2018-094653-B-C22) and INTEGER (RTI2018-094649-B-I00).

Abstract

In this paper, we report on the extrinsic evaluation of an automatic sentence simplification method with respect to two NLP tasks: semantic role labelling (SRL) and information extraction (IE). The paper begins with our observation of challenges in the intrinsic evaluation of sentence simplification systems, which motivates the use of extrinsic evaluation of these systems with respect to other NLP tasks. We describe the two NLP systems and the test data used in the extrinsic evaluation, and present arguments and evidence motivating the integration of a sentence simplification step as a means of improving the accuracy of these systems. Our evaluation reveals that their performance is improved by the simplification step: the SRL system is better able to assign semantic roles to the majority of the arguments of verbs and the IE system is better able to identify fillers for all IE template slots.

1 Introduction

Sentence simplification is one aspect of text simplification, which is concerned with the conversion of texts into a more accessible form. In many cases, text simplification is performed to facilitate subsequent human or machine text processing. This may include processing for human reading comprehension (Canning, 2002; Scarton et al., 2017; Orăsan et al., 2018) or for NLP tasks such as dependency parsing (Jelínek, 2014), information extraction (Jonnalagadda et al., 2009; Evans, 2011; Peng et al., 2012), semantic role labelling (Vickrey and Koller, 2008), and multidocument summarisation (Blake et al., 2007; Siddharthan et al., 2004).

In previous research, Caplan and Waters (1999) noted a correlation between sentence comprehension difficulty for human readers and the numbers of propositions expressed in the sentences being read.[1] Evans and Orăsan (2019) presented an iterative rule-based approach to sentence simplification which is intended to reduce the per sentence propositional density of input texts by converting sentences which contain compound clauses and complex NPs[2] into sequences of simpler sentences.

Evaluation of text simplification systems is difficult, especially when such evaluations need to be conducted repeatedly for development purposes and cost is a critical factor. In general, the choice of evaluation method depends on the purpose of the simplification task. Various types of evaluation are currently used, but these are problematic. In previous work, evaluation of sentence simplification systems (including Evans and Orăsan's (2019) system, which is extrinsically evaluated in our current paper) has relied on one or more of three main approaches: the use of overlap metrics such as Levenshtein distance (Levenshtein, 1966), BLEU score (Papineni et al., 2002) and SARI (Xu et al., 2016) to compare system output with human simplified texts (e.g. Wubben et al., 2012; Glavas and Stajner, 2013; Vu et al., 2014); automated assessments of the readability of system output (Wubben et al., 2012; Glavas and Stajner, 2013; Vu et al., 2014); and surveys of human opinions about the grammaticality, readability, and meanings of system output (Angrosh et al., 2014; Wubben et al., 2012; Feblowitz and Kauchak, 2013). In previous work, researchers have also used methods such as

[1] Propositions are atomic statements that express simple factual claims (Jay, 2003). They are considered the basic units involved in the understanding and retention of text (Kintsch and Welsch, 1991).

[2] NPs which contain finite nominally bound relative clauses.

eye tracking (Klerke et al., 2015; Timm, 2018), and reading comprehension testing (Orăsan et al., 2018) to evaluate text simplification systems.

There are several challenges in these approaches to evaluation. The development of gold standards in text simplification is problematic because they are difficult to produce and numerous variant simplifications are acceptable. As a result, existing metrics may not accurately reflect the usefulness of the simplification system being evaluated. Even when there are detailed guidelines for the simplification task, there is still likely to be a variety of means by which a human might simplify a text to produce a reference simplification. Further, due to the difficulty of the human simplification task, it may be that evaluation measures such as BLEU and SARI are unable to exploit a sufficiently large set of reference simplifications.

Evaluation of text simplification methods using automatic readability metrics is problematic because the extent to which all but a handful of readability metrics correlate with human reading comprehension is uncertain. Evaluation via opinion surveys of readers is difficult because participants may have varying expectations about the upper and lower limits of sentence complexity, making responses to Likert items unreliable. Participants also vary in terms of linguistic ability and personal background knowledge. These variables, which affect reading behaviour and may affect responses to opinion surveys, are difficult to control.

When using methods such as eye tracking to evaluate text simplification, previous work has shown that differences in reading behaviour depend on participants' reading goals (Yeari et al., 2015). This variable is usually controlled by asking participants to respond to text-related opinion surveys or multiple choice reading comprehension questions. One adverse effect of this is that these evaluations may be of limited validity when considering the usefulness of system output for other purposes. While we may learn whether a sentence simplification method improves participants' performance in answering short reading comprehension questions, it is not clear whether similar benefits would be obtained in terms of readers' abilities to be entertained by the text or to understand it well enough to be able to summarise it for friends.

Given that text simplification is usually made for a particular purpose, the evaluation method should offer insights into the suitability of the text simplification system for this purpose. Extrinsic evaluation offers the possibility of meeting this requirement. Text simplification has also been claimed to improve automatic text processing (e.g. Vickrey and Koller, 2008; Evans, 2011; Hasler et al., 2017), though the evidence for this has been fairly limited. In this paper, we explore whether syntactic simplification can facilitate two NLP tasks: semantic role labelling (SRL) and information extraction (IE).

In Section 2 of this paper, we present an overview of previous related work. In Section 3, we present an overview of Evans and Orăsan's (2019) method for sentence simplification, which is the simplification method used in our current paper. In Section 4, we present each of the extrinsic evaluation experiments based on SRL (Section 4.1) and IE (Section 4.2). Each of these sections describes the task, the test data used, the NLP system whose output is used for extrinsic evaluation of the sentence simplification system, our motivation for considering that accuracy of the NLP system may be improved via a preprocessing step in which sentence simplification is performed, the evaluation method, our results, and a discussion of the results. In Section 5, we draw conclusions and consider directions for future work.

2 Related Work

Chandrasekar and Srinivas (1997) hypothesised that approaches to sentence simplification may evoke improvements in subsequent text processing tasks. In previous work, researchers have sought to determine whether or not a preprocessing step based on text simplification can facilitate subsequent natural language processing. In the current paper, our concern is to investigate the impact of a system simplifying sentences which contain compound clauses. Hogan (2007) and Collins (1999) observed that, for dependency parsers, dependencies involving coordination are identified with by far the worst accuracy of any dependency type (F_1-*score* $\approx 61\%$). This is one factor motivating our research in this direction.

Sentence simplification has also been applied as a preprocessing step in neural machine translation and hierarchical machine translation (Hasler et al., 2017). In their approach, the approach to sentence simplification was sentence compression. One contribution of our current paper is an investigation of the use of an information preserving approach to sentence simplification as a preprocessing step in the NLP applications.

Vickrey and Koller (2008) applied their sentence simplification method to improve performance on the CoNLL-2005 shared task on SRL.[3] For sentence simplification, their method exploits full syntactic parsing with a set of 154 parse tree transformations and a machine learning component to determine which transformation operations to apply to an input sentence. They find that a SRL system based on a syntactic analysis of automatically simplified versions of input sentences outperforms a strong baseline. In their evaluation, Vickrey and Koller (2008) focus on the overall performance of their SRL system rather than on the particular contribution made by the sentence simplification method. As noted earlier, in our current paper, we isolate sentence simplification as a preprocessing step and investigate its impact on subsequent NLP tasks.

3 Sentence Simplification System

Evans and Orăsan (2019) presented an iterative rule-based method for sentence simplification based on a shallow syntactic analysis step. Their system transforms input sentences containing compound clauses and complex NPs into sequences of simpler sentences that do not contain these types of syntactic complexity.

The first stage of sentence simplification is a shallow syntactic analysis step which tags textual markers of syntactic complexity, referred to as *signs*, with information about the syntactic constituents that they coordinate or of which they are boundaries. The signs of syntactic complexity are a set of conjunctions, complementisers, wh-words, punctuation marks, and bigrams consisting of a punctuation mark followed by a lexical sign. In the analysis step, syntactic constituents are not identified. It is only the signs which are tagged. The automatic sign tagger was developed by Dornescu et al. (2013). In their scheme, clause coordinators are tagged CEV[4] while the left boundaries of subordinate clauses are tagged SSEV.[5]

After shallow syntactic analysis of the sentence, an iterative algorithm is applied to sentences containing compound clauses and complex NPs. The algorithm (Algorithm 1) integrates a sentence transformation function which implements the transformation schemes listed in Table 1.

```
   Input: Sentence $s_0$, containing at least one
          sign of syntactic complexity of class $c$,
          where $c \in \{$CEV, SSEV$\}$.
   Output: The set of sentences $A$ derived from
           $s_0$, that have reduced propositional
           density.
1  The empty stack $W$;
2  $O \leftarrow \emptyset$;
3  $push(s_0, W)$;
4  while $isEmpty(W)$ is $false$ do
5      $pop(s_i, W)$;
6      if $s_i$ contains a sign of syntactic
         complexity of class c (specified in Input)
         then
7          $s_{i_1}, s_{i_2} \leftarrow transform_c(s_i)$;
8          $push(s_{i_1}, W)$;
9          $push(s_{i_2}, W)$;
10     else
11         $O \leftarrow O \cup \{s_i\}$
12     end
13 end
```

Algorithm 1: Sentence simplification algorithm

In its original implementation, the *transform* function (line 7 of Algorithm 1) included 28 sentence simplification rules to implement one transformation scheme simplifying compound clauses and 125 rules implementing three transformation schemes simplifying sentences which contain complex NPs. Evaluation of the method revealed that simplification of sentences containing complex NPs was significantly less reliable than simplification of sentences containing compound clauses. For this reason, in the extrinsic evaluations presented in this paper, we deactivated the rules simplifying sentences that contain complex NPs. Each of the remaining implemented rules includes a rule activation pattern which, when detected in the input sentence, triggers an associated transformation operation. Table 1 presents the transformation scheme used to simplify compound clauses and an example of the sentence transformation that it makes. Input sentences are transformed if they match any of the rule activation patterns, which are expressed in terms of particular words, parts of speech, and tagged signs of syntactic complexity. Each application of a rule transforms a single input sentence into two sim-

pler sentences which are added to the working set (stack W in Algorithm 1).

The iterative nature of the algorithm enables it to convert complex sentences containing multiple signs of syntactic complexity such as (1) into the sequence of simple sentences (2).

(1) Kattab, of Eccles, Greater Manchester, was required to use diluted chloroform water in the remedy, but the pharmacy only kept concentrated chloroform, which is 20 times stronger.

(2) a. Kattab, of Eccles, Greater Manchester, was required to use diluted chloroform water in the remedy.
b. The pharmacy only kept concentrated chloroform.
c. Concentrated chloroform is 20 times stronger.

4 Experimental Setup

We evaluated the sentence simplification method extrinsically via two NLP applications. In each case, the application was treated as a black box. We compared performance of the system when processing input in its original form and in an automatically simplified form generated by the simplification method. As noted in Section 3, our approach to sentence simplification is syntactic rather than lexical. As they are based to some extent on exact string matching, the experiments described in this paper would be unsuitable for evaluation of lexical simplification systems.

4.1 Semantic Role Labelling

Semantic role labelling (SRL) is the task of automatically detecting the different arguments of predicates expressed in input sentences. We evaluated a system performing SRL in accordance with the Propbank formalism. In this scheme, an "individual verb's semantic arguments are numbered, beginning with zero. For a particular verb, [A0] is generally the argument exhibiting features of a Prototypical Agent (Dowty, 1991), while [A1] is a Prototypical Patient or Theme. No consistent generalizations can be made across verbs for the higher-numbered arguments"[6] (Palmer et al., 2005). The scheme includes semantic roles for "general, adjunct-like arguments" providing information on the verb's cause [AMCAU], direction [AMDIR], discourse relations [AMDIS], location [AMLOC], manner [AMMNR], modal function[7] [AMMOD], negation [AMNEG], purpose [AMPNC], and time [AMTMP], among others. For extrinsic evaluation of the sentence simplification method, we focused on verbal predicates[8], their arguments, and the nine listed adjunct-like argument types.

Table 2 provides an example of SRL to analyse sentence (3).

(3) When Disney offered to pay Mr. Steinberg a premium for his shares, the New York investor didn't demand the company also pay a premium to other shareholders.

The table contains a row of information about the semantic roles associated with each of the four main verbs occurring in the sentence. For example, it encodes information about the agent (*the New York investor*), patient or theme (*the company also pay a premium to other shareholders*), time (*When Disney offered to pay Mr. Steinberg a premium for his shares*), and negation (*n't*) of the verb *demand*.

Test Data. No suitable test data exist to evaluate a SRL system as a means of extrinsically evaluating the sentence simplification method. Although annotated data from the CONLL-2004/5[9] shared tasks on SRL are available, this test data is available only for the original versions of input sentences and not for simplified versions which may be generated using sentence simplification systems. Given that it is difficult to map verbs,

Table 2: *Example of semantic role labelling of Sentence (3)*

their arguments, and the semantic labels of these arguments from sentences in their original form to groups of sentences in their automatically generated simplifications, we developed a new set of test data for this purpose. We used a 7270-token collection of news articles from the METER corpus (Gaizauskas et al., 2001) to derive a new manually annotated data set. The original version of this dataset contains 265 sentences while the automatically simplified one contains 470 sentences.

NLP System. We made our extrinsic evaluation of the sentence simplification method using *Senna* (Collobert et al., 2011), a SRL system which tags predicates and their arguments in accordance with the formalism used in *Propbank*

Motivation. In our previous work (Evans and Orăsan, 2019), we used six metrics to assess the readability of the original and simplified versions of texts which include those that we use as test data for the SRL task. We found that the automatically simplified news texts have a lower propositional density (0.483 vs. 0.505) and reading grade level (5.4 vs. 10.3) and greater syntactic simplicity (89.07 vs. 46.81) and temporal consistency, assessed in terms of tense and aspect (30.15 vs. 27.76) than the original news texts. We determined the scores for these readability metrics using the CPIDR tool (Covington, 2012)[10] and the Coh-Matrix Web Tool (McNamara et al., 2014). As a task dependent on accurate syntactic parsing, we would expect that automatic SRL would be more accurate when processing the simplified versions of the input texts.

Evaluation Method. We applied Senna to the original and automatically simplified versions of the test data. Table 3 contains an example of the semantic roles labelled in one of the test sentences that we used. In this table, arguments identified more accurately in simplified sentences are underlined. For cases in which the SRL performed by Senna differed when processing the original and automatically simplified versions of input sentences, we manually inspected the two analyses, and recorded the number of cases for which SRL of the original sentence was superior to that of the simplified sentence, and vice versa. The inspection was made by a single annotator. In future work, we will seek to employ additional annotators for this task.

Results. Our manual evaluation of output from Senna revealed that 86.39% (1707) of the arguments identified in the two versions of the texts were identical. Of the remaining arguments, 5.31% (105) of those correctly identified in the original versions of the texts were not identified in the simplified versions, while 8.29% (164) of the arguments correctly identified in the simplified versions of the texts were not identified in the original versions. Of the 269 arguments identified in only one of the versions of the texts, 60.97% were arguments identified more accurately in the simplified version, while 39.03% were arguments identified more accurately in the original versions of the texts.

Table 4 shows the number of semantic roles labelled more accurately, by type, when Senna processes the original (*Orig*) and the automatically simplified (*Simp*) versions of news articles. To illustrate, when processing the original versions of the news texts, Senna correctly identifies the agents (arguments with semantic role label A0) of 14 verbs that it did not identify when process-

Table 4: *Positive differences in numbers of true positives obtained for semantic role labelling of original and simplified versions of input texts*

ing the automatically simplified versions of those texts. Conversely, when processing the automatically simplified versions, Senna correctly identified the agents of 23 verbs that it did not identify when processing the original versions.

Discussion. Overall, while there are advantages to performing SRL on each version of input texts, the greatest improvement in performance arises from processing the automatically simplified versions. A larger-scale evaluation is necessary but this observation constitutes some evidence that the sentence simplification method facilitates the NLP task of SRL.

4.2 Information Extraction

Information extraction (IE) is the automatic identification of selected types of entities, relations, or events in free text (Grishman, 2005). In this paper, we are concerned with IE from vignettes which provide brief clinical descriptions of hypothetical patients.

The discourse structure of these vignettes consists of six elements: *basic information* (patient's gender, profession, ethnicity, and health status); *chief complaint* (the main concern motivating the patient to seek medical intervention); *history* (a narrative description of the patient's social, family, and medical history); *vital signs* (a description of the patient's pulse and respiration rates, blood pressure, and temperature); *physical examination* (a narrative description of clinical findings observed in the patient); and *diagnostic study and laboratory study* (the results of several different types of clinical test carried out on the patient).

Each element in the discourse structure is represented by a template encoding related information. For example, the template for physical examinations holds information on each clinical finding/symptom (FINDING) observed in the examination, information on the technique used to elicit that finding (TECHNIQUE), the bodily location to which the technique was applied (LOCATION), the body system that the finding pertains to (SYSTEM), and any qualifying information about the finding (QUALIFIER). In this article, we focus on automatic extraction of information pertaining to physical examinations. The goal of the IE system is to identify the phrases used in the clinical vignette that denote findings and related concepts and add them to its database entry for the vignette.

Test Data. Our test data comprises a set of 286 clinical vignettes and completed IE templates, encoding information about TECHNIQUES, LOCATIONs, SYSTEMs, and QUALIFIERs, associated with the 719 FINDINGs that they contain. This test data was developed in the context of an earlier project and is based on clinical vignettes owned by the National Board of Medical Examiners.[11]

NLP System. For the experiments described in this paper, we used a simple IE system in which input texts are tokenised and part of speech tagged, domain-specific gazetteers are used to identify references to medical concepts and a simple set of finite state transducers (FSTs) is used to group adjacent references to concepts into multiword terms. The gazetteers and FSTs were developed in previous work presented by Evans (2011).

After tagging references to clinical concepts in the vignettes, IE is performed using a small number of simple rules. To summarize, vignettes are processed by considering each sentence in turn. Every mention of a clinical FINDING or SYMPTOM is taken as the basis for a new IE template. The first tagged TECHNIQUE, SYSTEM, and LOCATION within the sentence containing the focal SYMPTOM or FINDING is considered to be related to it.[12] QUALIFIERS (e.g. *bilateral* or *peripheral*) are extracted in the same way, except in sentences containing the word *no*. In these cases, the QUALIFIER related to the FINDING is identified as *none*.

The sentences in the test data were simplified using the method presented in Section 3. We then ran the IE system in two settings. In the first (IE_{ORIG}), it processed the original collection of vignettes. In the second (IE_{SIMP}), it processed the automatically simplified vignettes which contain a reduced number of compound clauses.

Motivation. An analysis of the readability of the original and simplified versions of the clinical vignettes did not provide a strong indication that the automatic sentence simplification method would improve the accuracy of the IE system. The 286 original clinical vignettes in the test data have a mean propositional density of 0.4826 ideas per word and 5.499 ideas per sentence. The values of these metrics for the simplified versions of the vignettes are 0.4803 ideas per word and 5.269 ideas per sentence, respectively. Although they are of the correct polarity, these differences are not statistically significant ($p = 0.5327$ and $p = 0.1407$, respectively). However, previous work in sentence simplification for IE (Jonnalagadda et al., 2009; Evans, 2011; Peng et al., 2012; Niklaus et al., 2016) has demonstrated that automatic sentence simplification can improve the accuracy of IE systems. This motivated us to evaluate the impact of the automatic sentence simplification method in this task.

Evaluation Method. For the IE task, our evaluation metric is based on F_1-score averaged over all slots in the IE templates and all templates in the test data. Identification of true positives is based on exact matching of system-identified slot fillers with those in the manually completed IE templates in our test data.

Results. The accuracy scores obtained by each variant of the IE system are presented in Table 5. Inspection of this table reveals that FINDINGs and all related concepts are identified more accurately in the simplified versions of the input texts.

Sentence (4) and its automatically simplified variant (5) provide an example of the difference in performance obtained by the two systems. In these examples, identified FINDINGs are italicised and associated concepts are underlined. Multiword terms appear in square brackets.

(4) She has $\underline{\text{truncal}}_{LOC}$ *obesity* and $\underline{\text{pigmented}}_{QUAL}$ $\underline{\text{abdominal}}_{LOC}$ *striae*.

(5) a. She has $\underline{\text{truncal}}_{LOC}$ [*obesity striae*].
b. She has $\underline{\text{pigmented}}_{QUAL}$ $\underline{\text{abdominal}}_{LOC}$ *striae*.

In (5-a), the FINDING *obesity* is not tagged correctly because the SYMPTOM *striae* is erroneously grouped with *obesity* to form a new FINDING, *obesity striae* which does not match the FINDING listed in the gold standard. By contrast, LOCATIONS in (5) are identified with greater accu-

[11] https://www.nbme.org/. Last accessed 31st May 2019.

[12] Versions of the system in which the closest tagged concept was extracted in each case, rather than the first, were significantly less accurate in both cases (overall accuracy of 0.6542 for IE from the original vignettes, and 0.6567 for IE from vignettes automatically simplified using the system described in Section 3). See Table 5 for results obtained using the superior IE system.

	IE$_{ORIG}$		IE$_{SIMP}$		
Template slot	Acc	95% CI	Acc	95% CI	Best Performer
FINDING	0.8819	[0.847, 0.914]	0.8861	[0.853, 0.917]	0.5486
TECHNIQUE	0.8514	[0.814, 0.886]	0.8903	[0.858, 0.922]	0.9344
SYSTEM	0.8097	[0.769, 0.850]	0.8431	[0.806, 0.881]	0.873
QUALIFIER	0.7431	[0.697, 0.786]	0.7708	[0.728, 0.814]	0.794
LOCATION	0.8431	[0.806, 0.881]	0.8611	[0.825, 0.894]	0.735
All	0.8258	[0.808, 0.843]	0.8503	[0.834, 0.867]	0.976

Table 5: *Performance of the IE systems processing our test data.*

racy than those in (4) because IE$_{ORIG}$ erroneously extracts the same LOCATION (*truncal*) for both FINDINGs in (4).

We applied a bootstrapping method to obtain confidence intervals for accuracy of extraction of each of the IE template slots. For this purpose, 50% of the the output of each system was randomly sampled in each of 100 000 evaluations. The confidence intervals are presented in the *95% CI* columns of Table 5. The figures in the *Best Performer* column of this table indicate the proportion of evaluations for which the IE_{SIMP} system was more accurate than the IE_{ORIG} system. Differences in the accuracy of IE were found to be statistically significant in all cases, using McNemar's test ($p < 0.00078$), with the exception of differences when extracting FINDINGs ($p = 0.6766$).

Discussion. Chinchor (1992) notes that assessment of the statistical significance of differences in accuracy between different IE systems is challenging. In our evaluation experiment, Dos Santos et al. (2018) framed the comparison between IE$_{ORIG}$ and IE$_{SIMP}$ using a binomial regression model. Given that such models apply only when the variables being considered are independent, dos Santos et al. (2018) included a latent variable in the analysis to represent the effect of the text on the performance of the two systems (the two evaluations are not independent because both systems process the same text). They showed that the odds ratio of agreement between IE$_{SIMP}$ and the gold standard is 1.5 times greater than that between IE$_{ORIG}$ and the gold standard. For all slots in the IE template, the probability of agreement between IE$_{ORIG}$ and the gold standard is 0.937. The probability of agreement between IE$_{SIMP}$ and the gold standard is 0.957. This difference is statistically significant. They conclude that IE$_{ORIG}$ and IE$_{SIMP}$ differ in their performance on the information extraction task. The probability of agreement with our gold standard is greater for IE$_{SIMP}$ than for IE$_{ORIG}$, although the probability of agreement is already large for IE$_{ORIG}$. This evaluation indicates that the automatic sentence simplification method facilitates IE.

5 Conclusions

As a result of various difficulties identified in current approaches to intrinsic evaluation of sentence simplification methods, we performed an extrinsic evaluation of one information-preserving sentence simplification method via three NLP tasks. We found that the sentence simplification step brings improvements to the performance of IE and SRL systems. In a third experiment, not described here due to space restrictions, we evaluated the sentence simplification method extrinsically with respect to a multidocument summarisation task using MEAD (Radev et al., 2006) to summarise clusters of documents developed for Task 2 of DUC-2004.[13] We found that the simplification step had no impact on this task. As a result, although the findings reported in our current paper seem promising, it is difficult to know the extent to which they are applicable to other NLP tasks or to tasks which differ only with respect to the test data used. This is one issue that we are interested in exploring in future work. Another is a test of whether extrinsic evaluation methods sensitive to information about the types of changes made in the simplification step would perform better than the black box methods used in the current paper.

[13] Information about the DUC conferences is accessible from https://www-nlpir.nist.gov/projects/duc/index.html (last accessed 22nd August 2018). Guidelines about the tasks presented in DUC-2004 are available at https://www-nlpir.nist.gov/projects/duc/guidelines/2004.html (last accessed 22nd August 2018).

Abstract

We introduce OlloBot, an Arabic conversational agent that assists physicians and supports patients with the care process. It doesn't replace the physicians, instead provides health tracking and support and assists physicians with the care delivery through a conversation medium. The current model comprises healthy diet, physical activity, mental health, in addition to food logging. Not only OlloBot tracks user daily food, it also offers useful tips for healthier living. We will discuss the design, development and testing of OlloBot, and highlight the findings and limitations arose from the testing.

1 Introduction

According to World Health Organisation (WHO), poor diet and physical inactivity have tremendous implications on individuals health (Michie et al., 2009; Hard et al., 2012). Healthy diet helps protect against malnutrition in all its forms, as well as noncommunicable diseases (NCDs) (Michie et al., 2009). Middle eastern countries are among the mostly affected nations by poor diet and physical inactivity and its effect on cardiovascular diseases (Organization et al., 2010, 2012). According to WHO report, total deaths caused by NCDs are among the highest in countries such as, Saudi Arabia, Iraq, Qatar, and Bahrain (See Table-1). This is an evident for a global risk and there is a need for nationwide approach to help mitigate or prevent this escalation.

By 2025, AI systems could be involved in everything from population health management, to virtual assistants capable of answering specific patient queries. Overall, AI has the potential to improve outcomes by 30 to 40 percent while cutting treatment costs by as much as 50 percent (Koh et al., 2011). Conversational agents, an example of AI powered systems can communicate with users through an intelligent conversation using a natural language, they can aid doctors in enhancing productivity and enabling them to respond to patients quickly. For example, doctors could interact with a diet chatbot to recommend the appropriate food to their patients. Patients could also engage with this chatbot to get instant information about their dietary choices.

The NCDs and Middle East (WHO)	
Countries	% of total deaths by NCDs
Saudi Arabia	*Cardiovascular diseases = 46%*
Qatar	*Cardiovascular diseases = 24%*
Iraq	*Cardiovascular diseases = 33%*
Bahrain	*Cardiovascular diseases = 26%*

Table 1: Middle East Countries and NCD Burden.

Currently, some ways to use healthcare chatbots include: scheduling doctor appointments based on the severity of the symptoms, monitoring the health status and notifying a human nurse immediately if the parameters are out of control, helping home-care assistants stay informed about patients evolution. However, current health conversational agents are mature for English language but still in their infancy for specific demographics and languages. For example, Hebrew and Arabic are far more complex languages for conversational agents. To ensure timely health information delivery to Arabic users, the patient should be able to tell the bot what symptoms they are experiencing and receive medical advice. However, this is not possible with current approaches, since they merely focus on generic approaches. Hence, in this research we highlight the role of chatbots to provide health services to individuals with language barriers. The approach targets demographics who are not bilingual and can speak only Arabic language. This is important, since from Table-1 we see the burden of NCDs in Arabic speaking countries. We propose OlloBot, an Arabic conversational agent able to converse with users and handle daily tasks about diet, physical activity, mental wellness and coping. The bot can also track users daily food and keep a record of their daily dietary habits. To our knowledge, few studies exists on conversational agents that supports Arabic language, able to flexibly converse and handle dialogues. However, no study exists that have considered the health benefit achievable with language specific conversational agents. Few platforms provide support to Arabic language technology to build interactive and intelligent conversational agents. This might be due to the complexity of the language and the resource scarcity available to support it. Our approach relies on IBM Watson Conversation API (IBM bluemix)[1] to handle the dialogue structure and Telegram Bot Platform to build the chatbot. We tested OlloBot with 43 Arabic speaking users and presented the findings in this paper.

2 Background Research

Although cognitive behavioral therapeutic (CBT) apps have demonstrated efficacy, still they are characterized by low adherence rate (Fitzpatrick et al., 2017). Conversational agents, on the other hand, may offer a convenient and engaging alternative of giving support at any time. A work by Graf et al., (Graf et al., 2015) built a chatbot that assimilates into daily routines. The bot communicates with user and gathers nutrition data. Keeping interaction with the bot final is a good design practice, however building a great dialogue flow is also essential to ensure smooth user interaction. This includes the way the bot handles several user interactions and requests. Zaghouani et al., (Zaghouani et al., 2015) presented a correction annotation guidelines to create a manually corrected nonnative (L2) Arabic corpus. The work extends a large scale Arabic corpus and its manual corrections to include manually corrected non-native Arabic learner essays. The approach uses annotated corpus to develop components for automatic detection and correction of language error to help standard Arabic learners and improve the quality of Arabic text produced. Chatbots could be used as language learning tools, to access information, to visualise the context of a corpus and to give answers to specific questions (Abu Shawar, 2005). A work by Shawar et al., (Abu Shawar, 2005) built a general language chatbot that supported different language among which is Arabic and English. The study also used different corpora structure, such as dialogue, monologue and structured text to build the dialogue model.

A work by Ali et al., (Ali and Habash, 2016) presented BOTTA, an Arabic dialect chatbot that communicates with users using the Egyptian Arabic dialect. Another work by Shawar et al., (Shawar and Atwell, 2009) described a technique to access Arabic information using chatbot with natural language processing (NLP) tools. The bot provides responses to capture the logical ontology of a given domain using a set of pattern-template matching rules. The literature shows no studies considering conversational agent as assistive tool for Arabic speakers. Which could provide instant access to health information and data, and assist physicians in providing a follow up to the patients. Conversational agents are great in handling repetitive tasks which consumes most of the healthcare providers time. Sundermeyer et al., (Sundermeyer et al., 2014) build a two translation recurrent neural models. The first one is a word-based approach using word alignments, while the second presents phrase-based translation models that are more consistent with phrase-based decoding. The models are capable of improving strong baselines in BOLT task for Arabic to English.

3 OlloBot Architecture

To provide the required level of Natural Language Understanding (NLU), we built the Arabic dialogue states on IBM Watson Conversation[2], which defines the conversation flow and dialogue states. The platform provides Artificial Intelligence support to catch different user intents and entities. The OlloBot starts with the user sending a message to the bot (OlloBot) running on Telegram Bot Platform[3]. The application provides the user with the topics they can chat about, then based on user selection the bot forwards the request to IBM Watson Conversation cloud. The conversation slots takes user input and provides them with

[1] https://www.ibm.com/cloud-computing/bluemix/it

[2] https://www.ibm.com/watson/services/conversation/

[3] https://telegram.org/blog/bot-revolution

relevant answer after checking their intent, entity and condition of the conversion. The logical parts of the dialogue are handled by a Node.js wrapper to handle unmatched dialogues by the dialogue flow (Figure-1 illustrates the high-level architectural view of OlloBot).

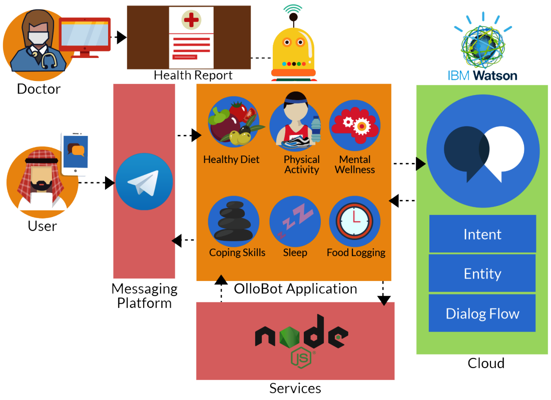

Figure 1: OlloBot High-level Architecture.

The bot detects patterns in user phrasing and correlates them with the intents defined. For example, conversing about users daily meal and asking users to enter their breakfast, they can either provide a list of food items or send an emojis as a list. The bot can extract the intend from each item or emoji and build a list of food items. In principle, this induces the system to recognize food items inserted by users. The need for conversational agents rises due to the on-demand 24/7 access to care. However, with millions of people globally who struggle with poor diet, poor exercise, anxiety and depression, there isn't enough healthcare provider or psychologists to provide the necessary care. Moreover, in some parts, there is limited technological services supporting native languages and sometimes services are practically nonexistent. Due to the associated cost for care, providing conversational agents as a novel technology that is cost effective, efficient and targets the right demographics is essential. OlloBot bridges these gaps and provides Arabic users with a quick and accessible health services. The bot converses about diet, exercise, emotion and provide coping skills. It can also ask the user to log their daily food and gather data about their preferred style of diet and exercise day, exercise, sleep. The fact that OlloBot is supported by Watson and easily accessible by many users makes it able to support many users at the same time.

The chatbot gathers users interaction data, and performance indicators from their interaction. These data are saved in a database in the form of accessible reports by the caregivers. OlloBot acts as a health assistants, meaning that it offers help and support rather than treatment.

3.1 User Intents

The intents refers to what the users want from the bot or what's the objective behind a user's input. For instance, the user intents hi, hello, hi OlloBot are translated to the intent "Greetings", whereas the intents food logging, daily food, logging data...etc are all translated into "Food Logging". We carefully sketched the dialogue scope the bot covers and those that it does not (see Table-2 for a list of user intents). The dialog flow structure was designed in collaboration with a healthcare clinic. After defining the flows for key intents, we defined the bot responses or follow up, once the task is performed. When the user starts a conversation, the bot can either track user dialogue or leave it at resolution and reset. The bot can switch between intends, based on user input. Since the interaction medium is conversational, users can switch intents on the chatbot. For example, while the bot waits for the user to provide relevant information about their physical activity, the user can ask the bot to insert their breakfast. OlloBot switches between the topics given in the above table, by detecting user intent from the conversation. To accurately handle this switching, we designed additional flows represented by conditions. Although this adds flexibility to the interaction, however, it can also create additional cognitive load.

User Intents	
Greetings	*Coping Skills*
Diet and nutrition	*Daily meals Logging*
Mood	*Jokes*
Physical activity	*Conditions*
Anything else	*Farewells*

Table 2: The User Intents

The next bot response depends on what the user will say or choose from the buttons. For example, after the user provides their daily food logging, the bot can move on and ask them about their suitable time to be notified again. Users can come back to the chatbot at a later time, with no recollection of the task they were trying to accomplish, therefore tracking the dialogue flow is essential to offer a more flexible conversation to the users. Finally, to handle fallbacks where the bot has no clue about the respond, we designed the “anything else” intent, to handle unhandled intents.

3.2 Health Report

The chatbot application provides a health report generated by users interaction with the chatbot. This report contains user activity data, their overall interaction with the application and indications about their overall health. The health measure is mainly about their diet, exercise and stress pattern. All these data are structurally generated by the chatbot and saved into the database. These data can then be accessed by the caregiver to obtain relevant user specific data.

3.3 Entities

Entities are the pieces of valuable information hidden in users input. They’re important keywords extracted from a sentence. For example, in the utterance “I want to talk about physical activity”, the word “physical activity” is detected as an entity, and hence the bot switches to the physical activity topic. Entities focus on defining the topic the user is talking about. This is important to provide the right respond to user questions. We defined a big range of entities to build our dialogue model. These entities represented the four main topics and the daily food logging. In Table-3 we provide the entities listed to structure the dialogue flow.

Topic Entities	
Topics	*Meal times*
Daily times	*Weekly times*
Quantity	*Food*
Numbers	*Sport*

Table 3: The Topic Entities

The above table lists the “Topics” entity, namely diet, physical activity, mood, and coping that the bot converses about. The topics entity also covers users daily food logging. Other entities include the “Meal times” which defines the meal periods per day that includes: breakfast, lunch, snacks and dinner. The “Daily times” refers to the periods of the day, namely morning, noon, afternoon, evening and night. Whereas, “Weekly times” entity includes the period of the day, namely yesterday, today and tomorrow. The “Quantity” entity refers to the quantity measurements the user might mention in the conversation (i.e., kg, g, tea spoon, bread loaf), whereas the “Numbers” entity refers to the countable number the user might mention. We have also defined a comprehensive list of common Arabic food items and included them in the “Food” entity. Finally, we defined a list of any kind of sports in the “Sport” entity. The entity list was accompanied by a list of synonym to add flexibility for the entity detection. This is important to detect user intents and sentiments from their conversation. While there has been a lot of research on sentiment analysis in English, the amount of research and datasets for Arabic language is still limited. A work by Alayba et al., (Alayba et al., 2017) built a sentiment analysis dataset in Arabic from Twitter data. The study applied machine learning algorithms (i.e., Naive Bayes, Support Vector Machine and Logistic Regression) for the analysis. Another work by Ismail et al., (Ismail and Ahmad, 2004) proposed a new type of recurrent neural network architecture for speech recognition and Backpropagation Through Time (BPTT) learning algorithm to observe differences in alphabet “alif” until “ya”.

3.4 Dialogue Engine

The dialogue structure was designed for each of healthy diet, physical activity, and mental wellness topics by referencing the Cognitive-behavioural therapy (CBT) (Rothbaum et al., 2000). We based the chatbot dialogue on techniques suggested by the CBT.

The dialogue was then developed on IBM Watson Conversation, where we listed each of the intents and entities and built the dialogue structure and flow. The tasks were intentionally built to be simple to interact with, so to decrease the time and amount of physical and mental efforts needed, and increase user’s ability. For example, when asked to log their food, users can either write the list or send an emoji of the food item. Moreover, button replies were provided to further simplify the data logging. Simplifying food tracking process will increase users ability and decrease the learning curve associated to health tracking. This is because interaction with the bot shouldn’t be only conversational, since some interactions are better with Graphical UI and others with Conversational UI.

3.4.1 Healthy Diet

Around 2 billion people are overweight, but many are ready to change (Van Itallie, 1985). However, according to studies (Mann et al., 2007) temporary fixes to old habits makes people to regain their weight. OlloBot acts as an interactive AI-powered diet tracking bot that converses with individuals in a friendly way directly through the Telegram messaging application. The goal is to give instant advices with each meal eaten and help improve the eating habits on the go. Once the conversation is executed, OlloBot starts conversing about user's diet and asks them questions about their eating habits and highlights the values associated with healthy diet. For example, OlloBot stresses the fact that following a diet rich in vegetables and fruits helps decrease escalation into overweight, obesity or even chronic conditions, and the detrimental effects associated otherwise.

3.4.2 Physical Activity

Studies (Cooney et al., 2014; Mead et al., 2009; Artal et al., 1998; Byrne and Byrne, 1993) have shown that exercise can treat mild to moderate depression as effectively as antidepressant medication and with no associated side-effects. Our conversational agent chats with users about their physical activity and daily energy level, and can provide personalized plans and keep track of workout progress by storing relevant user inputs. Whether the user wants to stay fit, loose weight, or get toned, OlloBot can later provide an efficient and consistent workout plan while keeping track of the progress. Although the bot is not considered as a tool to loose weight through exercise, but rather a supportive tool to help individuals track their exercise and improve in on the go, making users conscious about their health habits also makes them more likely to set aside time for physical activities in the future.

3.4.3 Mental Wellness

Mental health refers to our overall psychological well-being. This includes the way we feel about ourselves, the quality of our relationships and the ability to manage our feeling. OlloBot chats with users about mental health and asks them questions about their stress, sleep and other measures relevant to their mental wellbeing. There exists several mental health chatbots that provide support at different stages of mental illness. For example, X2AI[4] created a set of chatbots for mental health applications. Their flagship AI, Tess, helps patients in tandem with their doctors by providing resources on cognitive-behavioral therapy, medication side effects, and questionnaire automation. Woebot[5] is a mood tracking chatbot with personality. Backed by scientific research, Woebot can help reduce depression, share CBT resources, and learn from conversations over time. Finally, Joy[6] uses a chatbot approach to mental health. She offers options for both individuals and therapists.

3.4.4 Coping Skills

Being mentally or emotionally healthy is more than being free of depression, anxiety, or other psychological issues. Rather than the absence of mental illness, mental health refers to the presence of positive characteristics. With OlloBot, we handle this by providing coping skills and mindfulness support through clever motivational quotes, relevant workout suggestions mixed with some health facts to help users understand the benefit of health and wellness. The bot provides the uses with tips about coping with stress, diet, exercise, sleep, and mindfulness. The quotes and suggestions are all based on best recommendations provided by the World Health Organisation (WHO) (Michie et al., 2009). Coping skills are important, since finding a moment to take a few deep breaths and quiet your mind is a great way to relieve stress and improve your overall health.

3.4.5 Daily Food Logging

While many food-logging tools are already on the market, most are either too complicated or boring for the average individual. OlloBot keeps a food diary, tracks calories, and provides basic nutritional tips based on user's eating habits. We wanted to make the food logging process simpler, more engaging, and more informative for the users. The bot tracks user meals, by asking them to insert each meal items. This helps to know more about users diet. With the NLP capabilities offered by IBM Watson Conversation, the bot supports any food combinations. The user can even log their food by sending emojis of the food items. Once the food logging is done, the bot asks the user about their preferred time to recheck with them. OlloBot is in its early stages, due to the time

Figure 2: Daily Food Logging Conversation with OlloBot.

required to build and integrate new features, then validate it through testing with real users. We understand that existing food logging apps are now far ahead of us in terms of calorie tracking, precision, and various interface features. However, we aim to close this gap and simplify the food tracking/logging and feedback providing process in the future (see Figure-2 for the daily food logging with OlloBot).

4 OlloBot Platform

The dialogue flow in OlloBot were handled with IBM Watson Conversation, whereas the logical part of the dialogue were handled with a Node.js implementation. Our choice of IBM Watson was due to its language support, to our knowledge it was the only conversational agent dialogue building platform that supports Arabic. We deployed the bot on Telegram Bot Platform and built the components to handle user requests and responses. We used various UI elements made available by Telegram and integrated them into our dialogue model.

5 OlloBot - USE Questionnaire

After building and integrating OlloBot with Telegram Bot Platform, we conducted a user experiment with 43 Arabic speaking users. The dialogue and various questions the bot asks were all based on a WHO questionnaire we extracted about health and wellbeing (Kessler and Üstün, 2004; Parslow and Jorm, 2000; , WHO et al.(2017; Organization et al., 2006). After testing the chatbot, we performed a survey analysis to test various aspects of the bot. The questionnaire is based on a standard framework, namely USE Questionnaire (Lund, 2001) to measure the usability of the chatbot. The framework tests four items of usability within a product. It consists of 30 questions to test the usefulness, easy of use, ease of learning and satisfaction with the application. The questionnaires are organised in a scale of 1 - 5, where 1 is *“strongly disagree”* and 5 is *“strongly agree”*. We describe the experiment settings and results in the following sections.

5.1 Participants Demographics

The user demographics consisted of both male (n=26) and female (n=17) participants with an age range of 20 - 65 years old for both gender. We checked the participants familiarity with tracking devices (e.g., any diet, sleep, physical activity, or mood tracking application) and chatbot applications (see Table-4 for the results). There was no significant differences in both cases with either tracking devices (e.g., wearable, sensor, or mobile applications) or chatbot applications. The majority of participants have shown no familiarity with tracking devices (n=26) and chatbot applications (n=27). We provided additional questions at the end of the survey to evaluate their overall experience with the chatbot. A reimbursement of 5€was given to all participants in the form of Amazon coupon.

5.2 Experiment

We distributed the chatbot to all the Arabic speaking participants recruited from Iraq. After carrying out the experiment for 1 week, we collected data

Gender	Female	*17*
	Male	*26*
Age	Mean	*29.8*
	Std. Dev	*9.28*
Tracking devices familiar	No	*26*
	Yes	*17*
Chatbot familiar	No	*27*
	Yes	*16*

Table 4: Participants Demographics.

through questionnaire to test the four main points relevant to the usability of OlloBot.

5.2.1 Usefulness

This item helps to test how useful the participants perceived the application. The usefulness includes measuring whether the bot helps the user to be more effective and productive and enhance their control over their daily life activities. For example, *"I believe is effective to track my health"* evaluates whether the user thinks the bot is effective in tracking their health.

Dimensions	**Mean**	**Std. Dev.**	**t value (df=42)**	**p value**
Usefulness	*3.381*	*0.373*	*6.695*	*p <.01*
Ease Of Use	*3.626*	*0.3944*	*10.405*	*p <.01*
Learning	*3.942*	*0.5341*	*11.564*	*p <.01*
Satisfaction	*3.505*	*0.3667*	*9.031*	*p <.01*

Table 5: The Results from the USE Questionnaire.

5.2.2 Ease of Use

This point helps understand the ease of use aspect. It measures easiness, simplicity and user friendliness of the application (chatbot). This point also measures the steps and effort required to achieve the goal set and whether its easy to recover from mistakes. For example, to measure the effort required for each step, we asked users to provide their scale for *"It requires the fewest steps possible to accomplish what I want to do with it"*. We performed a descriptive statistics about the four items checked in the overall experience (see Table-6). Figure-3 below lists each of the overall bot reliability (Figure-3a), and the participants overall experience (Figure-3b, Figure-3c and Figure-3d).

5.2.3 Ease of Learning

This point measures the learnability of the tool. We measure whether its quick to learn and easy to remember each time. For example, the question *"I quickly became skilful with it"* checks for how quickly a skill is learned using the chatbot.

5.2.4 Satisfaction

This step checks for user's overall satisfaction with the chatbot. It checked whether the users are satisfied and would recommend the tool to others and how entertaining they perceived it. For example, the question *"I would recommend it to a friend or family member"* checks whether the user would recommend the bot to their relatives or friends.

We performed descriptive statistics on the results and reported them in Table-5. One Sample t test showed that averages for all four scales were statistically significantly different from the middle value (value = 3, see Table-5). Further analyses were performed considering gender, familiarity with tracking technology, and familiarity with chatbot as between factors. No differences among the four usability dimensions were observed between male and female participants, and no differences emerged between participants who frequently use or not use tracking devices. A significant difference for the "ease of learning" scale was observed when comparing participants who were familiar in interacting with chatbot application and participants who were not. The latter group reported lower scores for learnability compared to the former group (t(41)= -2.46, p <.01).

5.2.5 Overall Experience

This part evaluated the overall experience with OlloBot and is not part of the USE questionnaire. We tested user satisfaction with the reliability of OlloBot, their overall experience with the bot from different perspectives (see Table-7 for the experience comparison). We have checked whether users like chatbots or rather use a mobile application. Finally, we considered the list of most positive and negative aspects the users mentioned during the survey. In addition, we asked the users about the features they would like to see/use in feature versions of OlloBot.

6 Discussion

This work was the first to evaluate the application of NLP powered health tools into language and context scarce domains. The work involved initial design phase, which involved researchers and health experts in the context of healthy lifestyle

promotion. Involving the health expert was necessary to guarantee the real context applicability of the application. The dialog structure was built in collaboration with a dietitian who described the steps necessary when building a dialog with a patient. We then applied this design paradigm into our dialog engine. The existing work has several limitations worth mentioning. Since most of the research work was carried out in Italy in collaboration with Spain, the dietitian involved in designing the dialog was a native Italian. Yet, the guidance obtained from the expert was translated into Arabic language and integrated into the Watson dialog engine. We also acknowledge that the size of the participants and the period of experiments, although provide good indications, are not enough to conclude any long-term effect. Future work will consider building a standalone dialog model and including a larger user samples and over an extended period.

7 Conclusion

Chatbots can be a trustworthy assistant, like a caring nurse, which provides registration services and patient follow up. Medical practices can rely on chatbots to capture leads and provide 24/7 support to existing patients, answering their simple, repetitive questions using a pre-designed answers. It will not offer a diagnosis, but it can remind patients to take their drugs or help them check for an unusual side effect. Most users showed interest towards social intelligence of the bot. Hence, tone and empathy matters, people can be turned off if the experience is too robot-like or casual, so we should opted for a polite tone. In summary, chatbots offer a great user experience to patients by just chatting with the bot to get relevant answers to their queries. Future work will integrate OlloBot into a health coaching system and make it specific to support Arabic speaking, diabetic patients.

Developing the Old Tibetan Treebank

Abstract

This paper presents a full procedure for the development of a segmented, POS-tagged and chunk-parsed corpus of Old Tibetan. As an extremely low-resource language, Old Tibetan poses non-trivial problems in every step towards the development of a searchable treebank. We demonstrate, however, that a carefully developed, semi-supervised method of optimising and extending existing tools for Classical Tibetan, as well as creating specific ones for Old Tibetan, can address these issues. We thus also present the very first Tibetan Treebank in a variety of formats to facilitate research in the fields of NLP, historical linguistics and Tibetan Studies.

1 Introduction

In historical linguistics, there are currently two types of morpho-syntactically annotated corpora or 'Treebanks', one based on constituency parses, the other on dependency parses. The former includes pioneering work in the Penn-Helsinki tradition, resulting in the Old and Middle English (Taylor and Kroch, 1994), Icelandic (IcePaHC) (Rögnvaldsson et al., 2012) and Portuguese (Tycho Brahe) (Galves, 2018) treebanks. The latter represents syntactic structure in the form of dependencies and is often used for applied NLP tasks and early Indo-European languages, e.g. the PROIEL Treebank family (Eckhoff et al., 2018). In this paper we present a constituency-based treebank for an under-resourced language: Old Tibetan (see Green et al. (2012) and El-Haj et al. (2015) for similar examples of creating under-resourced treebanks).

Old Tibetan is an extremely under-resourced and under-researched language from an NLP point of view. We chose to focus our attention on the Old Tibetan corpus (7-11th c.) since it consists of a small collection of documents compared to the vast amounts of translated and original Classical Tibetan texts. Nonetheless, the Old Tibetan corpus is still heterogeneous enough to represent natural language. The majority of Old Tibetan texts (known to date; new inscriptions and texts are still being discovered) has now been digitised in one way or another (images, OCR and/or transcribed) and annotating this data is fundamental for the understanding of diachronic and synchronic issues in Tibeto-Burman languages. As the first attempt to create a Tibetan Treebank, developing a segmented, POS-tagged and chunk-parsed corpus of Old Tibetan provides new opportunities in Tibetan scholarly history, literature and linguistics.

Old Tibetan was the language spoken in the Yarlung Valley from where the Tibetan empire started its initial expansion. Writing was mainly introduced to facilitate administrative tasks, and the earliest Old Tibetan texts represent the most detailed sources for the history of early Tibet (Hill, 2010). The earliest currently available, securely datable Old Tibetan document dates to ca. 763 CE. However, the digital resources for Old Tibetan are inadequate (problematic transcriptions, transliterations and no digitised secondary resources such as dictionaries, etc.).

The core of the Old Tibetan corpus is available as plain e-texts (without segmentation or any kind of annotation) on the Old Tibetan Documents Online (OTDO) website.[1] We first focus on the Old Tibetan *Annals* (5.9k tokens)

[1] http://otdo.aa.tufs.ac.jp/

Proceedings of Recent Advances in Natural Language Processing, pages 304–312,
Varna, Bulgaria, Sep 2–4 2019.

and Old Tibetan *Chronicles*, since these are the best sources that we have at our disposal in terms of length and linguistic variety (many other Old Tibetan text are short inscriptions or more fragmentary). The Old Tibetan *Annals* are Tibet's earliest extant history. The Old Tibetan *Chronicle*, written in the early 9th century, is more narrative and includes historical accounts and songs related to the Yarlung dynasty and the Tibetan empire.

In this paper we present our annotation procedure that addresses all issues of pre-processing, segmentation, POS tagging and parsing in detail. Our semi-supervised method, resulting in the first Old Tibetan Treebank, can furthermore serve as an example of how to overcome challenges of low-resource and under-researched languages in general.

2 The Annotation Procedure

Since Old Tibetan is an extremely under-resourced language the procedure to develop an annotated corpus needs to be developed with great care. Additional steps are necessary at each of the normal stages, from pre-processing to POS tagging and parsing and finally post-processing. In the pre-processing stage, for example, the normalisation is not a trivial task because of a range of issues with the Tibetan script and the way it is digitised, in either Unicode or a variety of transliteration formats. In addition to solving these script issues, our core solution is to transform our Old Tibetan texts through a 'conversion/normalisation process' with a Constraint Grammar (Cg3) to a form of Tibetan that is closer to Classical Tibetan, for which at least some NLP tools are available.

Before we can move on to the annotation stage, we need to solve a further non-trivial issue of finding word and sentence boundaries. Since there are no Gold Standards or training data available for Old Tibetan, we resort to the little material and tools available for Classical Tibetan and then do a rigorous error analysis checking specific Old Tibetan features that we know differ from Classical Tibetan. Our annotation method is thus supervised in various ways to overcome the obstacles building a treebank of an extremely low-resourced language like Old Tibetan.

3 Pre-Processing

The Old Tibetan texts we work with to start this corpus are already transcribed from the original manuscripts or digitised images. For the present paper we thus only address the issues concerning encoding of transcriptions and transliterations and the issues of tokenising a language without word or sentence boundaries.

3.1 Transliteration Issues

One of the first challenges we encountered in creating the Old Tibetan corpus was the conversion from Tibetan Unicode script (see Hill 2012) to the Wylie transliteration system. There are few reliable tools available and in addition, we have to take the peculiar orthographic features of Old Tibetan into consideration. The Tibetan Unicode script for the Old Tibetan documents was obtained from a modified version of the Wylie transliteration system that is used for the Old Tibetan Documents Online (OTDO) website, through the BDRC conversion tool.[2]

However, this tool only partially addresses the issue, because we also want to transform Old Tibetan into a form of Tibetan that looks more similar to Classical Tibetan in terms of orthography. Therefore, the Wylie transliteration used by the OTDO website had to be modified. As an example the reverse 'i' vowel mark, ྀ - called *gigu* - is transliterated with 'I' on the OTDO website. We substituted 'I' with 'i', which is the standard Wylie transliteration for this character, as shown in (1):

(1) *rgyal po'I* > *rgyal po'i* 'of the king'

3.2 Normalisation

The Old Tibetan script furthermore presents a set of features that need to be 'normalised' or converted to a form that looks like Classical Tibetan. We therefore created a set of rules translated into the Constraint Grammar (Cg3) formalism. Most of the Cg3 rules used to normalise Old Tibetan are simple replacement rules. For example, In Old Tibetan there are many instances of the

[2] https://www.tbrc.org/

above-mentioned reverse *gigu* such as ཀྱྀ *kyI*. These two forms of *gigu*, ྀ and ི are phonetically indistinguishable and mark no difference in Classical Tibetan. The Cg3 `SUBSTITUTE` rule to normalise the reverse *gigu* is:

```
SUBSTITUTE (``([[\^{ }<]*)\u0F80(.*)"r)
(“$1ྀ$2v) TARGET (σ)
```

Two additional problems encountered in the normalisation of Old Tibetan are represented by the alternation between aspirated and unaspirated voiceless consonants and the difficulty of splitting merged syllables. This aspiration, however, was probably not phonemic in Old Tibetan (Hill, 2007, 471). Therefore, a set of string replacement rules in the Cg3 formalism was created to normalise and convert these instances to their equivalent reading in Classical Tibetan.

Furthermore in Classical Tibetan, syllables are separated by a punctuation marker called *tsheg*: ་. In Old Tibetan texts, syllable margins are not so clear and syllables are often merged together with the following case marker or converb, e.g. Old Tibetan བཀུམོ *bkumo* > Clas. Tib. བཀུམ་མོ *bkum mo* ‘kill, destroy’:

(2) བཀུམོ > བཀུམ་མོ

These types of merged syllables were also converted to their classical forms, using a set of three regular expressions in the Cg3 formalism through the rule `SPLITCOHORT`. Considering the complexity of the Tibetan syllable, in order to generate the rules, we took the maximum number of its constituents into account (in terms of vowels and consonants) as well as their order.

Generic Rule:

```
([^aeiouI\s]+[aeiouI][^aeiouI\s]*)
([^aeiouI\s'])([aeiouI][^aeiouI\s']*)
> $1$2 $2$3
```

Cg3 rule:

```
SPLITCOHORT (
  "<$1>"v "$1$3 "v
  "<$3$4>"v "$3$4"v
)("<(.{2,6})(([^\\u0FB2\\u0FB1])
([\\u0F7C\\u0F7A\\u0F74\\u0F72\\u0F80]
 ?))>"r)(NOT 0 (split) or (genitive)
 or (diphthongs));
```

Through these conversions and normalisations, we could apply existing tools for Classical Tibetan to our Old Tibetan corpus to avoid manually creating our treebank from scratch completely. The full Cg3 grammar is discussed in detail in our forthcoming research.

3.3 Segmenting Sentences

Segmenting sentences is necessary since there are no obvious sentence boundaries in Old Tibetan. The Tibetan scripts does have a punctuation marker that sometimes (but not always) indicates meaningful phrases, a so-called *shad*, ། or double *shad*, །།. Since without any further annotation, there is no way of knowing where sentences begin or end, we used the single and double *shad* as sentence boundaries and automatically inserted utterance boundaries indicators (`<utt>`) after every instance. This greatly facilitates subsequent annotation tasks that depend on sentence boundaries, such as POS tagging and chunkparsing.

3.4 Tokenisation

The Tibetan script furthermore does not indicate word boundaries. Tokenisation is therefore a tremendous issue, not only for scholars of Tibetan (who often disagree on what the word boundaries should be), but even more so for any Tibetan NLP tasks. The Classical Tibetan script does have a way of indicating syllable boundaries though, by using the above-mentioned *tsheg* marker ་, e.g. བྲག་མར transliterated *brag mar* ‘Dagmar’ with spaces between every syllable according to the conventions of the Wylie transliteration.

For Classical Tibetan, Meelen and Hill (2017) addressed this tokenisation issue by recasting it as a classification task with a memory-based tagger (Daelemans et al., 2003) giving ‘beginning’, ‘middle’ or ‘end’ labels to every syllable (automatically split based on the aforementioned *tsheg* and *shad* markers. With our supervised learning method first normalising and then converting our Old Tibetan corpus to a form of Tibetan that is much closer to Classical Tibetan, we were able to use this existing segmentation tool for Classical Tibetan and extend and modify them after manually correcting part of our Old Tibetan data.

4 POS Tagging

Since there was no Old Tibetan POS-tagged Gold Standard either, here too we started from the Classical Tibetan training data[3] and tagging method developed by Meelen and Hill (2017). We tested a number of ways to get and improve results for the Old Tibetan corpus, e.g. developing a new, reduced tag set, changing scripts (Unicode vs. Wylie) as well as generating new taggers, based on the manually corrected Old Tibetan only and, finally, adding the manually corrected Old Tibetan to the existing Classical Tibetan Gold Standard.

4.1 Small vs Large Tag Set

The tag set used for the Classical Tibetan Gold Standard, developed by Garrett et al. (2014) is with 79 morpho-syntactic tags rather large. This causes major issues for the out-of-vocabulary items, especially for languages without insightful morphological suffixes like Tibetan. For this first attempt of developing an Old Tibetan Treebank, we therefore decided to reduce the amount of tags to a small and simplified version of the standard Universal Dependency POS set, consisting of 15 tags only (De Marneffe et al., 2014). We transformed the existing Classical Tibetan training data, which is our Gold Standard, in the following way: `interj > INTJ`, `punc > PUNCT`, `n.prop > PROPN`, `skt, dunno > X`, `adj, num.ord > ADJ`, `n.v.cop, v.cop, v.cop.neg > AUX`, `n.count, n.mass, n.rel > NOUN`, `num.card, numeral > NUM`, `cl.focus, cv.fin, cv.imp, cv.ques, neg > PART`, `p.indef, p.interrog, p.pers, p.refl > PRON`, `d.dem, d.det, d.emph, d.indef, d.plural, d.tsam > DET`, and, finally, all verb remaining verb forms in all tenses `> VERB`, all remaining converbs `> SCONJ`, all post-positional case markers `> ADP` and all adverbs `> ADV`. A 10-fold cross-validation with the exact same parameter settings of the memory-based tagger[4] on the $>318k$ Classical Tibetan Gold Standard, yielded better results compared to those of the large tag set reported by (Meelen and Hill, 2017) (increase from 95.0% to 96.3% in Global Accuracy; Known Words increased from 96.8% to 97.8%; Unknown Words from 53.4% to 59.7%).

All tags with a very low number of tokens in the out-of-vocabulary set (ranging from $n = 1$-92) have a Precision and Recall close or equal to zero. These items are always very short (one or two characters only), which makes predicting the tag for new items in this category an almost impossible task for the tagger. With the newly trained small tag set tagger, we tagged the Old Tibetan *Annals* and manually corrected the first $3.5k$ tokens as a start. We then evaluated the tagger again with another 10-fold cross-validation, first on this small Old Tibetan corpus and then again adding this manually corrected Old Tibetan data to the existing Classical Tibetan Gold Standard. This yielded a better Global Accuracy for the combination of Old and Classical Tibetan (96.1%) compared to Old Tibetan alone (92.8%). However, the results for Unknown Words are significantly lower (decrease from 71.1% to 58.5%).

Since these two new Gold Standards differ significantly in size it is impossible to do a fair comparison until we manually correct more Old Tibetan. It is clear, however, that despite our efforts to normalise and convert the Old Tibetan into a form of the language that looks more like Classical Tibetan, it is still making a difference, shown in the lower accuracy (by more than 10%) of unknown words for this combined training data. Without adding the Classical Tibetan training data, however, the vocabulary list that the memory-based tagger builds would simply be too small to get any good results on unseen data. Despite the 10-fold cross-validation, the relatively high scores for the Old Tibetan corpus only are misleading, because of the small size of the corpus. Until we have more manually corrected Old Tibetan data, we therefore proceed with the Classical Tibetan Gold Standard and add an extra stage of error correction, see Section 6.

[3] `http://github.com/tibetan-nlp/soas-corpus/`

[4] These settings for Classical Tibetan are: `-p dwdwfWaw -P psssdwdwdwFawaw -M 1100 -n 5 -% 8 -O+vS -FColumns -G K: -a0 -k1 U: -a0 -mM -k17 -dIL.`

4.2 Unicode vs Wylie Transliteration

The above-mentioned taggers were trained and tested on Tibetan script in Unicode. The Unicode Tibetan script contains a lot of so-called 'stacked' characters that are centred before, above and below one single root letter. A typical example is བསྒྲུབས་ , which is transliterated in the official Wylie system as *bsgrubs* 'achieved'. In Tibetan Unicode, the order of these stacked characters can differ depending on the exact combinations of consonants and vowels. This varying order often yields unexpected problems when processing Tibetan Unicode text as our NLP algorithms do not recognise variants of the same order in the same word as the same type. This then increases the number of types and thus reduces the overall accuracy. For this reason, we converted the Classical Tibetan Gold Standard from Tibetan Unicode script to Wylie transcription as well. Some examples of Tibetan Unicode with Wylie transliterations are: བཅོམ་ལྡན་འདས་ *bcom-ldan-'das* 'Blessed One', ཤཱཀྱ་སེང་གེ་ *shAkya-seng-ge* 'Buddha', ཕྱག་ *phyag* 'arm, prostration'.

In a 10-fold cross-validation of the Classical Tibetan Gold Standard, this conversion to Wylie yields slightly better results. Global Accuracy was 95.0% for Tibetan Unicode vs. 96.5% for Wylie. We observed a major improvement in Unknown Words in particular from 53.4% in the Tibetan Unicode to 62.2% in the Wylie transliteration. Since the results with the Wylie transliteration are slightly better, especially for unknown, out-of-vocabulary items, converting all Unicode Tibetan to Wylie transliteration would appear to be a logical way forward. However, in practice, Unicode Tibetan script is far more widely used within the Tibetan community. To make the corpus more accessible, but also to get support from members of this community who are willing to correct segmentation and any further type of linguistic annotation, a Unicode Tibetan version is indispensable. It is therefore important to develop segmenters, taggers and parsers that work well for both, or develop tools that can automatically convert the Tibetan text (but not any type of annotation also in roman script) back from its Wylie transliteration to Unicode Tibetan script.

4.3 Memory-Based vs Neural-Network Tagging

Finally, we tested a BiLSTM-CNN-CRF tagger[5] to see if it would yield better results than the memory-based tagger. We chose this neural-network tagger, because it processes both word- and character-level representations automatically, using a combination of a bidirectional Long-Short-Term-Memory (LSTM), a Convolutional Neural-Network (CNN) and a Conditional Random Field (CRF). Although this tagger requires no pre-processing of the data or any further feature engineering, the results are better when the system can use word vectors for the specific language. Since the current number of manually corrected tokens in Old Tibetan is too small to train any neural-network-based tool, we again resorted to using Classical Tibetan instead. For Classical Tibetan, we used FastText[6] to create word embeddings with the aim of improving the results of the tagger with word vectors based on a large amount of Tibetan data digitised by the BDRC[7] and annotated by Meelen and Hill 2017: the Annotated Corpus of Classical Tibetan (ACTib) (version 1, (Meelen et al., 2017)). We then divided the above-mentioned $>318k$ token Classical Tibetan Gold Standard in training, test and developments sets (80/10/10), trained a tagger with these word embeddings and evaluated the results on the held-out test set. With its default settings,[8] this BiLSTM-CNN-CRF tagger yielded a result of 95.8% Global Accuracy (F1 score).[9]

These results are slightly better than those of the memory-based tagger (95% Global Accuracy). They are reasonable, but could be improved in a number of ways. Furthermore, at present they cannot easily be reproduced for our small corpus of the Old Tibetan *Annals* written in a very different style and genre.

[5] See `https://github.com/achernodub/targer` and Chernodub et al. (2019).

[6] `https://fasttext.cc/`

[7] `https://www.tbrc.org/`

[8] Batch size = 10; 100 epochs; dropout ration = 0.5 with the Bi-RNN-CNN-CRF model.

[9] Although it is not common practice (anymore) for POS tagging evaluations, we calculated the F1 instead of normal accuracy to make it directly comparable to the results presented by (Meelen and Hill, 2017). Actual accuracies are slightly higher than the Global Accuracies presented here.

These initial neural-network results thus look promising, but need further extension and refinement. In forthcoming work we address these issues by optimising the parameters, improving the segmentation and, with that, creating better word embeddings (Hill et al., ming).

4.4 Summary of POS Tagging

The below table summarises the results of our tests and evaluations discussed in the previous sections. There are some differences between the small and the larger tag sets and between the Unicode Tibetan script and the Wylie transliteration, with the smaller tag sets and the Wylie transliteration getting better results. The neural network tagger performs best overall with the larger tag set. With the smaller tag set, the Wylie transliteration is best for the smaller tag set.

	Global Accuracy
Clas. Tib. (318*k*; 15 tags)	96.3%
Old Tib. (3.5*k*; 15 tags)	92.8%
Old & Clas. (321.5*k*; 15 tags)	96.1%
Wylie translit. (318*k*; 15 tags)	96.5%
Unicode Tib. (318*k*; 79 tags)	95.0%
Wylie translit. (318*k*; 79 tags)	94.7%
NN-tagger (318*k*; 79 tags)	95.8%

5 Chunk-Parsing

To facilitate further future research, we also developed a 'hierarchical chunk-parse' of our Old Tibetan corpus. This is a detailed, but rather shallow parse that aims to be as theory-neutral as possible. Constituents are combined into phrases where necessary and uncontroversial, in a hierarchical fashion, e.g. nouns can combine with adjectives and determiners into a Determiner Phrase (DP), which can then combine with a post-positional case marker into a Pre/Postpositional Phrase (PP).

With the small tag set, all case markers are automatically converted into adpositions. This includes the 'Agentive Case' (`case.agn`) that is used to indicate the subject of transitive verbs. If instead we keep this agentive case marker, our small tag set will be extended, but since this marker is highly consistent in spelling, its Precision, Recall and f-score are extremely high (98%, 100% and 99% respectively for n=5627 in the Wylie transliteration evaluation of Classical Tibetan discussed above). The advantage of keeping the agentive case marker tag is that for many transitive sentences at least, we will be able to automatically detect the subject of the clause. Since Old Tibetan was a pro-drop language (i.e. pronouns need not necessarily be overtly expressed, see Tournadre 2010, 101), it is not always possible to detect non-marked subjects of verbs automatically, so a certain amount of manual correction is still always necessary. Similarly, keeping the genitive case markers (གྱི་ ཀྱི་ འི་/`case.gen`, see Tournadre and Dorje 2003, 102) has the advantage of getting much better automatically chunk-parsed results for complex nominals.

We used the NLTK chunk-parser[10] to combine tagged tokens into phrases. Semi-hierarchical structures were created by carefully formulating all phrase formation rules in the correct order, e.g. adjectival phrases (`ADJP`) before noun phrases (`NP`) and determiner phrases (`DP`) before pre/postpositional phrases (`PP`). A set of sample rules developed to generate a RegEx grammar for Old Tibetan looks like this:

```
ADJP: {<ADJ><ADJ>?}
NP: {<NOUN|PROPN>}
NUMP: {<NUM><NUM>?}
DP: {<DET>?<NP>?<ADJP|NUMP>?<DET>}
DP: {<NP><ADJP|NUMP><ADJP|NUMP>?}
DP: {<NP|DP><case.gen><NP|DP>}
SbjNP: {<NP|DP><case.agn>}
PP: {<DP|NP><ADP>}
VP: {<VERB|AUX>?<VERB|AUX>}
ADVP: {<ADV><ADV>?}
```

Some sample results are shown in (3) and (4):

(3) (S(SbjNP(NP ད་རྒྱལ་མང་པོ་རྗེ/PROPN) ས་/case.agn)
(PP (NP ཞིང་/NOUN) གྱི་/ADP)
(NP ཕྱིང་རིལ་/NOUN) (VP བགྱིས/VERB))
da rgyal mang po rje-s zhing gyi phying ril bgyis
'Dargyal Mangporje carried out a 'felt roll tax'.'

(4) (S(PP(DP(NP ཞང་ཞུང་ཡུལ་/PROPN) གྱི་/case.gen)
(NP མངན་/NOUN)) དུ་/ADP)
(NP སྤུག་གྱིམ་རྩན་རྨ་ཆུང་/PROPN) (VP བཅུག/V)

zhang zhung yul gyi mngan du spug gyim rtsan rma chung bcug

[10] http://www.nltk.org

'[He] installed Spug Gyimrtsan Rmachung as the fiscal governor of the land of Zhang-zhung.'

By exploiting the language's standard head-final word order, we can create subordinate clauses for phrases with nominalised verbs ending in subordinate conjunctions. Similarly, we can create relative clauses for nominalised verbs followed by the genitive, which functions as a relative marker linking the following word to the preceding relative clause.[11] The results require only minimal manual correction and are sufficiently theory-neutral to facilitate morpho-syntactic research within a variety of frameworks. The bracket notation is formatted according to the standard `.psd` guidelines and converted to `.psdx` (a TEI XML version of `.psd`) so that they can be queried by CorpusSearch,[12] CorpusStudio[13] or any other plain text or XML-based way of querying syntactic data. These semi-hierarchical structures are not only useful for historical syntacticians interested in comparing basic phrasal structure in different languages, but they are also invaluable for students and scholars of Tibetan to get a good insight into how the grammar of the language has changed over time. Finally, this semi-hierarchical phrasal structure serves as a great starting point for further Old Tibetan NLP challenges, such as creating more meaningful word embeddings and developing tools for keyphrase extraction, document clustering and topic modelling.[14]

6 Post-Processing

Throughout this paper we have shown how automatic NLP tools for Classical Tibetan can be optimised and extended in order to get as much use out of them for Old Tibetan. In this final section we present the results of a thorough error analysis. Suggestions for semi-automatic and rule-based corrections center around Old Tibetan, though some could be extended to the Classical Tibetan data as well.

6.1 Correction & Error Analysis

For the segmentation stage clear errors are instances of case markers and converbs that are still attached to the tokens they modify, but these markers should each receive their own tag. Because of their consistent orthography, they can often easily be split from their preceding token to facilitate POS tagging and parsing. In addition, these homophonous forms could be checked after POS tagging: their tag should be a converb following a verb, but a case marker following a noun. Similarly, a simple dictionary look-up script could 'check' whether the forms proposed by the segmenter actually exist. In order to make this latter loop-up task work well, however, we first need to collate and convert Old and/or Classical dictionaries into a reliable and searchable format.

6.1.1 Specific Old Tibetan Errors

We have detected a number of specific Old Tibetan errors as well. In example (5), for instance, we can identify some regular mistakes. Adverbial expressions like དགུན *dgun* 'in winter', དབྱརད *dbyard* 'in summer', have been tagged as nouns in many instances, so we can search for these and other recurring adverbial expressions and replace their incorrect nominal tags.

(5) བཙནཔོ་ དབྱརད་ སྤེལ་ ན་ བཞུགས ཤིང་
`NOUN ADV PROPN ADP VERB SCONJ`
"In summer, the emperor stayed in Spel."

Furthermore, converbs (functioning like subordinate conjunctions, `SCONJ`) like the ཤིང *shing* 'and, while' have often been tagged as particles instead of subordinate conjunctions, which again, can be automatically replaced.

The large amount of proper nouns in historical texts such as the Old Tibetan *Annals*, however, create a real challenge for our tools. For now, most of the time these tags (and segmentation) had to be corrected manually. For example, the following sentence was originally segmented and tagged as follows:

(6) བྲག་མ ར་ ན་ བཞུགས །
`NOUN ADP ADP VERB PUNCT`
Lit: 'cliff into/for in stayed'

The correct analysis here instead should combine the ར *-r*, which was originally tagged as an

[11] See Meelen and Roux (fc) for further examples of semi-automatic syntactic annotation.

[12] `corpussearch.sourceforge.net/index.html`

[13] `https://dev.clarin.nl/node/4239`

[14] After finishing all manual corrections at the end of the year, the entire annotated corpus and tools will be made available through Github.

adposition (ADP) with the preceding noun བྲག་མ *brag ma* ‘cliff’, resulting in the proper noun of the place called ‘Dagmar’:[15]

(7) བྲག་མར་ ན་ བཞུགས །
PROPN ADP VERB PUNCT
“[he] resided in Dagmar”

This correction, as many others occurring with proper nouns, cannot be done automatically since the error patterns are not regular. Sometimes *Dagmar*, a toponym, is tagged correctly as a proper noun, however, *dagma* + *r* ‘into a cliff’ is also a possible segmentation, in which case the correct POS tags would be NOUN + ADP. Since the Tibetan script does not identify capital letters, it is difficult for any NLP tool to make the right decision in these cases. It would also be difficult to look up ambiguous forms like these in a comprehensive, searchable Old Tibetan proper noun lexicon (which we are currently developing), as the alternative reading is still possible. This issue is exacerbated by the fact that Tibetan proper nouns are almost exclusively also normal nouns, mainly referring to natural phenomena, e.g. *Nyima* ‘sun, Nyima’.

6.2 De-Normalisation

Since in the pre-processing stage we converted and normalised our Old Tibetan to ‘Classical Tibetan’ orthography, in the post-processing stage we need to reverse the Cg3 normalization rules and apply them to the normalised text. This task is straightforward since the Cg3 normalisation grammar has been created with this de-normalisation process in mind. Through selecting and deselecting the OT and σ tags respectively, we converted our Old Tibetan corpus back to its original form after annotation.

7 Conclusion

Developing this Old Tibetan Treebank is a challenging case study of applying NLP tools to extremely low-resourced languages. We overcame many obstacles by first converting/normalising the Old Tibetan to a form of Tibetan that is orthographically much more similar to Classical Tibetan, so that the few extant tools for Classical Tibetan could be tested. We then optimised and extended these tools in various ways and finally developed a chunk-parser to create the first Old Tibetan Treebank as an indispensable tool for philologists, linguist, but also for scholars in Tibetan studies and the Tibetan communities, as it facilitates the development of good Tibetan dictionaries and other Tibetan NLP tools.

Abstract

In the context of text summarization, texts in the legal domain have peculiarities related to their length and to their specialized vocabulary. Recent neural network-based approaches can achieve high-quality scores for text summarization. However, these approaches have been used mostly for generating very short abstracts for news articles. Thus, their applicability to the legal domain remains an open issue. In this work, we experimented with ten extractive and four abstractive models in a real dataset of legal rulings. These models were compared with an extractive baseline based on heuristics to select the most relevant parts of the text. Our results show that abstractive approaches significantly outperform extractive methods in terms of ROUGE scores.

1 Introduction

Text summarization is the task of producing a condensed representation of an input text, keeping the most relevant information. A summary should be concise, fluent, and contains paraphrased versions of the input text with a reduced length.

There are two approaches to text summarization. The first, known as *extractive*, works by selecting entire sentences directly from the source text. This has been the most widely used solution for a number of years (Luhn, 1958; Edmundson, 1969; Erkan and Radev, 2004a; Mihalcea and Tarau, 2004). Extractive methods typically work by simply (i) scoring phrases or sentences to determine the most relevant; and (ii) selecting the top scoring sentences to compose the summary. Often, the sentences are arranged in the same order of occurrence in the original text in an attempt to preserve the ideas and meanings of the sentences. The scoring function should capture how well the selected sentences represent the text and cover the topics present in the text. The lack of connectives may cause the impression that the generated summary does not have a logical flow.

The second approach, known as *abstractive*, aims to extract the main concepts or ideas from the text and generate a new condensed version different from the original. In this case, the model must learn how to write sentences in a logical flow. Using this approach, it is possible to paraphrase the original and use words that did not occur in the source. This is much more similar to the way a human would create a summary. Most recent research has focused on this approach.

With the increasing availability of data, the need for summarization is felt in many areas. This is especially true in the legal area as the texts are usually lengthy. Law operators are expected to keep updated with important information ranging from news, jurisprudence changes, and rulings from many courts.

This important information amounts to huge volumes of data which cannot be processed by humans. Each ruling from the Brazilian Supreme Court typically has more than 2,000 tokens on average. Hence, it is necessary to focus on the essential portions of each topic and extract just the information that is necessary, leaving the details aside. With that in mind, Courts usually provide extracts, with about 200 tokens on average, of their most important decisions summarizing the main topics discussed and the final outcomes. This provides an easier way to find relevant information without needing to read the whole texts.

Currently, these legal summaries are generated by humans, in a process that is time-consuming and expensive. Human summarizers need to have a good knowledge of the subject to extract the

Proceedings of Recent Advances in Natural Language Processing, pages 313–322,
Varna, Bulgaria, Sep 2–4 2019.

main topics that should appear in the summary. Another important issue with manually created summaries is the lack of standardization. Each specialist from each Court has their own writing style. A standardized way of writing is desirable as it would provide more homogeneous summaries. For these reasons, the use of abstractive approaches is especially appealing in this area.

The summarization of legal texts differs remarkably from mainstream work in text summarization, which is mostly devoted to summarizing news articles, headlines or tweets. Legal texts are generally lengthier and typically contain complex vocabulary and expressions. Also, the order of the words in some expressions can make a big difference in their meaning, *e.g.,"denied an appeal that had accepted"* is very different from *"accepted an appeal that had denied"*.

In this paper, we investigate the suitability of extractive and abstractive approaches in summarizing legal rulings. Given that the vast majority of works in this area focused solely on news datasets, we believe that testing summarization on a new domain is important given the different nature of the input documents. Fourteen approaches were tested over a real dataset containing 10K rulings from the Brazilian Supreme Court (Feijó and Moreira, 2018). Thus, another contribution is using a language that is not typically included in summarization experiments.

The remainder of this paper is organized as follows. Section 2 discusses text representations and introduces the problem of out of vocabulary tokens. Section 3 revises recent works on abstractive summarization. Section 4 describes the dataset and how it was prepared to be used in the experiments. Section 5 presents a simple heuristic-based extractive summarizer that we proposed to serve as a baseline. Sections 6 and 7 describes the algorithms and models that were investigated here. Section 8 discusses our results and findings. Finally, Section 9 concludes this paper and points out possibilities for future work.

2 Text Representation

Representing texts using a sequence of words is useful for exchanging information between humans. However, when using neural models, we need to convert the text into numbers that could be used as input into the neural network.

The usual way of generating a text representation is to split the text and generate a vocabulary from the training data keeping the most frequent tokens. Even considering that the vocabulary would be extracted from a single language, if we consider that texts have upper and lower case characters, numbers, dates, *etc.* the vocabulary usually becomes quite large, frequently with hundreds of thousands of different tokens.

A large vocabulary is a problem because the output layer of the neural network must have its size. This means that the probability of choosing the correct output diminishes as the vocabulary increases. Also, even if infrequent tokens are represented in the vocabulary, its infrequent use would not be sufficient for the model to learn when to use it correctly.

One approach to deal with the size of the vocabulary is to convert all characters to lowercase and replace numbers and dates with zero representations. With these modifications, the vocabulary becomes smaller, but the model will become less capable of generating outputs in the same way as humans would.

Even with the text simplifications, the problem with out of vocabulary words (OOV) remains because not all possible words will be represented. So, it is usual to represent any token that is not present in the vocabulary by a reserved OOV token. This token would be used for uncommon names, dates, and numbers.

Another approach is to use one token per character. This greatly reduces the vocabulary size only using lower and upper case characters, numbers, and symbols. Although the vocabulary is smaller, probably not more than few hundred tokens, it would require each word to be represented by several tokens, leading to very long document. This is problematic because the model will require a large memory to be able to generate the summary without repeating already generated tokens.

The alternative to mitigate the disadvantages of these two approaches is to use *sub-word units as the token representation* (Schuster and Nakajima, 2012; Chitnis and DeNero, 2015; Sennrich et al., 2015; Kudo, 2018). The idea is that a token would represent a common pattern seen in the training data rather than words or characters. This operates with a fixed vocabulary size and assigns a token for the most common patterns found. With this method, the OOV problem is reduced as one word now can be represented by a combination of sub-words. The problem of longer sequences is also addressed because a token now can represent several characters.

3 Related Work

Neural Networks are models capable of learning very complex functions. In the last few years, there has been significant interest in applying them for natural language tasks such as automatic translation and summarization.

One of the first issues that needs to be addressed is that Neural Networks require that both inputs and outputs have a fixed a length, and that is not the case when dealing with text, because each document (or sentence) can have a different length. In order to overcome this limitation, Sutskever et al. (2014) introduced a general end-to-end approach capable of representing sequence-to-sequence models using LSTM (Long Short-Term Memory) cells. Nevertheless, both input and output must still have fixed lengths large enough to fit. The network is trained to output the end-of-sentence (EOS) token when the output is large enough. With this approach, both source input and generated sequence may logically have different lengths and do not require any type of alignment between input and output.

Bahdanau et al. (2014) proposed a model for learning to align the input with the generated output. They realized that the approach for encoding the whole text before starting to decode requires that the whole idea is represented by just one vector. So, they proposed to use auxiliary vectors to represent the alignment of the input in relation to the generated output. Their approach significantly improved the quality of the generated outputs and became known as Attention vectors.

Following the same ideas, Luong et al. (2015) explored different versions for the attention mechanism. They also noticed that as the length of the input increases, the attention vector has a lot more difficulty in learning the weights. So they evaluated the impact of using a local attention mechanism to look just for a smaller portion of the source at each time step.

The attention mechanism works well for short texts, but struggles to focus on relevant information when applied to long documents, common in the legal domain.

Neural Machine Translation (NMT) is a sequence-to-sequence task that is similar to summarization in the sense that both require some text comprehension before an output can be generated. When translating, a model does not have an exact alignment for each word read in the source to the word generated in the output. This happens because a source word may be represented by more (or fewer) words in the translation. Also, the order of the tokens can be different.

Wu et al. (2016) describe the architecture used for the Google Neural Machine Translation (GNMT) system. In that work, they used a LSTM network with 8 encoders and 8 decoders using attention and residual connections. In the beam search, they used length-normalization and applied a coverage penalty to favor an output that is able to cover more words from the source sequence.

Vaswani et al. (2017) improved the GNMT system replacing entirely the recurrence and convolutions by an attention-based model known as Transformer. The model is quite complex and relies on many training variables, but it has the advantage of allowing more parallel computation. With this modification, the model is able to use many GPUs and train a lot faster.

See et al. (2017) addressed two common problems found in the application of RNNs in the context of summarization. First, the problem of rare words that were not present in the vocabulary was solved by having hybrid pointer networks that are capable of using the source word as output when the attention weight is high enough. The second problem is using a coverage vector that represents the weighted sum of the attention vectors. Then, to increase coverage, their model is trained to penalize every time the attention vectors are high in the same regions, encouraging the model to better distribute the attention over the source input.

In our work, the problem of rare words has been diminished using sub-word encoding, as discussed in Section 2. The coverage mechanism, proposed to deal with repetition problem, is complex to train. It is used after the training to condition the decoder to avoid generating attention vector using the same positions that were already used. Paulus et al. (2017) proposed trigram avoidance during the beam search. This approach is much simpler and easy to apply but does not really fix the problem, as it still will happen, it only masks its effects for the evaluation.

There is a growing interest in using reinforcement learning approaches (Paulus et al., 2017; Li et al., 2018; Celikyilmaz et al., 2018) to improve summarization performance. In general, reinforcement learning is employed when an non-differentiable operation is being used. These methods have the disadvantage of being hard to tune and generally slow to converge.

Chen and Bansal (2018) proposed a method for using both extracting and abstracting approaches. Their idea was to select salient sentences and rewrite them abstractively. Reinforcement learning was used to combine these two neural networks. Their idea seems to be a good approach for working with long documents. Although, they did not report results for long documents datasets. We intend to further explore the application of this technique to long documents in the legal domain.

4 Materials and Methods

Our summarization experiment in the legal area uses rulings written in Portuguese. There are some peculiarities when using a language different from English, *e.g.,* we need to check if the standard summarization evaluation (designed for English) can be directly applied.

4.1 Dataset

The dataset used in our experiments is RulingBR (Feijó and Moreira, 2018). It contains about 10K rulings from the Brazilian Supreme Court. These rulings were taken by a group of judges – the individual decision from each judge is known as their "vote", the final decision is made by the majority of the votes. Each ruling has four sections: (*i*) the *ementa*, which represents the summary; (*ii*) the *acórdão*, which has the final decision taken by the majority; (*iii*) the *relatório*, which is an extensive description reporting the request and the actions taken so far; and (*iv*) the *voto*, which contains the individual votes from all judges.

The dataset was randomly split into training, validation, and test sets. Training takes up 60% of the instances (6,373), whereas validation and test have 20% of the instances each (2,125). On average, each document has about 2,500 tokens.

We use the *ementa* as the human-generated ground truth summary. The other three sections together compose the input text, which is submitted to the summarization systems. On average, the *ementa* has a little less than 10% of the size of the source input.

4.2 Official Rouge Script

The standard evaluation metric for text summarization is called Recall-Oriented Understudy for Gisting Evaluation (ROUGE). The general idea of this metric is to count the number overlapping units between one or more reference summaries and the machine-generated summary. It is expected, that a high-quality summary should use the same words found in the reference summaries and preferably in the same order.

The results reported here include Precision, Recall, and F-measure for ROUGE-1, ROUGE-2, and ROUGE-L metrics. A confidence of 95% was adopted. We used the official ROUGE (Lin, 2004) 1.5.5 script in our experiments. Most parameters were set to their default values. The `pyrouge` package, which is a wrapper to the official script, was used to provide the required output text (in HTML) and the configuration file. The only change was to remove the call to the English Porter Stemmer, since our texts are in Portuguese.

4.3 Text Preprocessing

The official Rouge script treats any non-ASCII characters as word separators. Thus, we transformed all accented characters to their base form, *i.e.,* diacritics were removed. In addition, we changed all text to lowercase and isolated the standard punctuation symbols from the alphabetic characters to avoid them being interpreted as part of some word.

4.4 Vocabulary

Portuguese has a rich vocabulary, with words having lots of variant forms. Verbs, specially, can have dozens of different suffixes corresponding to the diverse conjugations. In the legal domain, it is common to reference existing laws, specific dates, and names. Thus, it is very unlikely that the vocabulary generated during training will contain all possible words that are present in the test set. To deal with problem of OOV words, we used the SentencePiece package (Google/SentencePiece, 2019), which implements the sub-word units with unigram representation. The combination of pieces is used to generate words even when they are not present in the training set.

5 A Simple Extractive Summarization Baseline

When generating summaries, the source input length and the desired summary length are required. Ideally, these two lengths should be automatically determined by the algorithm, but that is not how these standard extractive approaches work. In order to establish these lengths, we defined a heuristic-based baseline extractive method.

5.1 Heuristic for Sentence Selection

Through empirical observation, we found that the *relatório* (report) section from the source text usually contains most of the information that is typically present in the reference summary. So, after removing some boilerplate text that is usually present at the beginning of the documents, we extract a sequence of words until the desired summary length is reached.

5.2 Target Length

In the RulingBR dataset, the mean length for the test set is 190 tokens, with a minimum of 20 and maximum of 1,909 tokens. This represents a wide range of summary lengths. Since every summary generated by our baseline needed to have the same length, we experimented truncating the reference summaries at different points to observe the effect over the mean length of the test set.

Table 1 shows the effect of imposing length limits to reduce the standard deviation in favor of a more predictable summary length. The dilemma here is to balance between a lower limit and lower standard deviation (but risking losing important information) with a higher limit and higher deviation (but with a large error associated).

Another concern that arises when deciding about the target length is the fact that the summaries will be evaluated using the ROUGE metric. ROUGE relies both on the Precision and on the Recall. Shorter summaries are expected to have higher precision, while longer summaries tend to have higher recall. Our F-score results assign the same weight to precision and recall. Table 2 shows that truncating the source length has little effect over the F-measure of the ROUGE scores. In order to make a fair comparison between the algorithms, we aimed at generating summaries of similar lengths.

Limit	Mean	Min	Max	Std Dev
No	190	20	1,909	179.46
600	180	20	600	131.89
450	173	20	450	112.02
300	158	20	300	82.37
150	120	20	120	36.85

Table 1: Lengths of the reference summaries that compose our Test Set.

5.3 Source Length

Abstractive summarization models require a fixed size input. Different lengths will require padding, which in turn will have a negative impact on training. We used truncated parts of sections *relatório* and *voto* as they concentrate most of the important information. Table 2 shows the results of our experiment using *relatório* and *voto* with lengths of 150, 300, 450, or 600 tokens and trying to find summaries with this same length.

Because lengthier summaries would require more memory and would lead to a broader range of lengths, we adopted the 300+300 tokens as the input length limit in our experiments (*i.e.,* the input text is a concatenation of the 300 first tokens from *relatório* and the 300 first tokens from *voto*).

As shown in Table 1, truncating the target length to 300 tokens leads to summaries of 158 tokens on average. This will be used as the desired summary length.

6 Extractive Approaches

The ten extractive approaches used in our experiments are described in this section. We used the implementations provided by Sumy (Belica, 2018) and an improved version of TextRank provided by Gensim (Řehůřek and Sojka, 2010).

6.1 Luhn

Proposed by Luhn (1958), the seminal method for determining the importance of a sentence is calculated using Term Frequency (TF) and Inverse Document Frequency (IDF). Significant words are selected among the most frequent words found in the document. Then, the highest scoring sentences are selected to be part of the summary.

When calculating word frequencies, Luhn algorithm proposes a simple stemmer by matching words using their prefixes. A match happens when the number of non-matching letters is less than six.

Length	R1-F	R1-P	R1-R	R2-F	R2-P	R2-R	RL-F	RL-P	RL-R
600+600	33.99	33.46	**43.16**	**12.20**	12.34	**15.59**	19.44	19.10	**25.36**
450+450	34.07	34.40	41.32	12.06	**12.50**	14.72	19.48	19.64	24.24
300+300	**34.47**	**34.84**	40.25	12.08	12.43	14.19	19.74	19.88	23.58
150+150	**34.47**	34.32	37.46	11.88	11.84	13.01	**20.49**	**20.29**	22.61

Table 2: ROUGE scores for different source lengths. The results show that the F-measure is reasonably stable across different lengths.

This technique may be language specific, thus it is possible that a stemmer specificaly designed for the target language would have a different behavior. Here, we use the standard implementation as provided by the Sumy without stemming or stopword removal.

6.2 LexRank

This is a stochastic graph-based method for computing the relative importance of sentences (Erkan and Radev, 2004b). It assumes that the main idea of a text is often paraphrased. As a consequence, finding similar sentences would be the same as finding the important sentences. Also, the central sentence of a cluster would indicate that this sentence is the most similar among them and would probably capture more information.

6.3 TextRank

This is a graph-based ranking model of deciding the importance of a vertex within a graph (Mihalcea and Tarau, 2004). The basic idea is to have some form of votes every time one vertex is similar to another. The highest voted vertex would be the most important. Gensim uses a modified version (Barrios et al., 2016) in which the BM25 similarity function is used in place of just the number of common tokens as adopted by the original TextRank. Thus, TextRank appears twice in our results as we used both the Gensim and the Sumy implementations.

6.4 SumBasic

This algorithm is based on the fact that words present in the summary tend to be the most frequent in the text (Nenkova and Vanderwende, 2005). It computes the probability distribution over the words appearing in the input. Then the sentences containing the highest probability words are selected and for each word in these sentences, update their probabilities until the desired length is reached.

6.5 KLSum

Kullback-Leibler (KL) is a way to compare two probability distributions. It also computes the probability distribution of words in the text. Then, the problem of finding the summary can be stated as finding a set of summary sentences which the probability distribution closely matches the document distribution (Haghighi and Vanderwende, 2009).

6.6 LSA

The summarization using Latent Semantic Analysis (LSA) (Steinberger and Jezek, 2004; Gong and Liu, 2001) is done by constructing a sparse *token x sentences* matrix, applying Singular Value Decomposition (SVD), selecting the singular vector will retrieve the scores for each token, then selecting sentences with highest normalized scores.

6.7 Random

This is another baseline summarizer in which random scores are assigned to the sentences. The highest scoring sentences are selected to the summary.

7 Abstractive Approaches

We experimented with Neural Network models using the `OpenNMT-tf` package (Klein et al., 2017). The models evaluated here were NMTSmall, NMTMedium, Transformer, and TransformerAAN.

NMTSmall and NMTMedium are standard Recurrent Neural Network models. They use an encoder-decoder architecture. The decoder employs Luong et al. (2015) style attention model over the input. The network is trained to learn when to stop generating the summary. This is done appending an End-of-Document token to the instances during training. When the network generates this token, the output is truncated at this point. The model uses a beam search of size four when decoding, and it is configured to ignore outputs that were shorter than the minimum length.

Both NMT and Transformer models use word embedder of size 512. Each model was evaluated until its training loss was no longer diminishing. We report ROUGE results with minimum decoding lengths of 100 and 120 tokens. Recall that we are using SentencePiece and each decoded word may be represented by more than one token. So, the generated output may contain fewer words than this minimum length. In all reported results, we show the mean length of the output considering generated tokens separated by spaces.

Two NMT configurations were used. NMT-Small uses 2-layers, unidirectional LSTM with 512 units, and it has converged in 15,000 steps. NMTMedium uses 4-layers, bidirectional LSTM, with 512 units and it has converged in 26,000 steps. Transformer model uses the configuration as originally proposed by Vaswani et al. (2017). TransformerAAN uses cumulative average attention network in the decoder as described in (Zhang et al., 2018). The objective is to reduce the required training and inference time.

8 Results and Discussion

The performance of the extractive algorithms shown in Table 3 was disappointing. With the exception of SumBasic, all other algorithms have performed worse than our simple Baseline by at least 0.6 points in ROUGE-L. In some cases, the performances were not far from the random baseline. A possible explanation for such poor results is the limitation of this approach of generating summaries using only complete sentences that were present in the source text. Looking at the generated summaries, most of them have selected just one very long sentence while others used a few random disconnected sentences.

Our experiments varying the lengths of the input method (Table 2) have shown that even with larger source inputs, which could contain more tokens that should be present in the output, the performance was decreasing.

The baseline results provided by Feijó and Moreira (2018) for the extractive methods ranged between 11 and 16 points in terms of ROUGE-L. Those results cannot be directly compared to the results in our experiments because they had removed stopwords and they reported results for the entire dataset. Since in this paper, we require a training phase for the neural network models, ROUGE results are reported only for the test set.

One advantage of extractive algorithms is that they do not require prior training, and they can be applied directly over the test data. On the other hand, after the time-consuming training, the abstractive approaches can create the summary a lot faster.

Table 4 shows reasonably good results for both NMT and Transformer models. There was a small advantage for the standard Transformer model when compared to its modified version with the Average Attention Network. They both have reached very similar results and have converged in about 40K steps.

Since the Transformer model has many variables, it requires a lot of memory to run. So, the batches need to be smaller. As a consequence, it needed more steps to converge. Despite that, we observed that it trains faster than standard RNNs. As we are using a concurrent environment, our measures of the time taken for training were not accurate, so we could not report them.

Summarization results in other datasets are not directly comparable to our results. Still, they may serve as reference. Zhang et al. (2019) reports that the current state-of-the-art for the CNN/Daily Mail dataset (Nallapati et al., 2016) reaches scores of ROUGE-1 41.71, ROUGE-2 19.49 and ROUGE-L 38.79.

The summaries generated by the abstractive approaches were promising. They look similar to those produced by humans. In most generated summaries, the main topic was correctly captured by the summarizer. Nevertheless, as shown in Figure 1 there are still some cases in which the summarizer barely captured any meaning of the text, generating summaries that had almost no relation with the expected output. In these cases, the extractive approach would probably have done better. In other cases, the general meaning was correctly captured, but the output had repeating expressions. We believe this may have been caused by the minimum length restriction.

Legal operators rely on summaries to their jobs, since it is impossible to read the full contents of each decision to find precedents for their cases. Missing or referring to an incorrect precedent may cause the petition to be denied and the case would be lost. Thus, considering the results seen so far, neither approach delivers results that could safely

Algorithm	R1-F	R1-P	R1-R	R2-F	R2-P	R2-R	RL-F	RL-P	RL-R

9 Conclusion

This work presented a comparative investigation of ten extractive and four abstractive methods for text summarization using Portuguese language applied to the legal area. The data used here consist of a real-world legal domain dataset containing 10K rulings from the Brazilian Supreme Court. The results show that extractive methods provided weak performance being unable to generate useful summaries. On the other hand, abstractive models provided much better results, with summaries that were very similar to those produced by humans. However, they also presented severe problems with repeating expressions and the introduction of subjects that were not present in the source documents. We intend to further investigate the causes of the factual errors and address this problem in future work.

Entropy as a Proxy for Gap Complexity in Open Cloze Tests

Mariano Felice **Paula Buttery**

Abstract

This paper presents a pilot study of entropy as a measure of gap complexity in open cloze tests aimed at learners of English. Entropy is used to quantify the information content in each gap, which can be used to estimate complexity. Our study shows that average gap entropy correlates positively with proficiency levels while individual gap entropy can capture contextual complexity. To the best of our knowledge, this is the first unsupervised information-theoretical approach to evaluating the quality of cloze tests.

1 Introduction

Fill-in-the-gap or *cloze* test exercises are common means of assessing grammar and vocabulary in the realm of English as a Foreign Language (EFL). The most common example is the *multiple choice question*, which presents the student with a gapped sentence and a set of possible answers from which the right one is to be selected. These are referred to as *closed* cloze questions, since the answer is limited to the alternatives given. On the contrary, *open* cloze questions do not provide predefined options, so the student must produce an answer from scratch.

Generating these exercises is a laborious process, since they must be carefully designed to ensure they test the desired learning objective and do not confuse or present trivial questions to the student. For this reason, choosing the optimal locations in a sentence to insert the gaps and defining a suitable set of answer options becomes crucial, especially when exercises are generated automatically.

In this paper, we focus on open cloze tests and show how entropy can be used to assess the complexity of each gap in the text. Entropy is shown to provide insights into the expected difficulty of the question and correlate directly with the target proficiency level of the exercises. Exploiting this information should thus facilitate the automatic generation of more reliable open cloze exercises.

2 Related Work

Work on automated cloze test generation has mostly focused on multiple choice questions and distractor selection (Mitkov and Ha, 2003; Sumita et al., 2005; Brown et al., 2005; Lee and Seneff, 2007; Lin et al., 2007; Smith et al., 2010; Sakaguchi et al., 2013). Conversely, there has been little work on open cloze tests. Pino et al. (2008) describes a strategy to generate open cloze questions using example sentences from a learners' dictionary. Sentences are chosen based on four linguistic criteria: (grammatical) complexity, well-defined context (collocations), grammaticality and length. Further work improved on this method by providing hints for the gapped words (Pino and Eskenazi, 2009).

Malafeev (2014) developed an open source system to emulate open cloze tests in Cambridge English exams based on the most frequent gapped words. Expert EFL instructors found the generated gaps to be useful in most cases and had difficulty differentiating automated exercises from authentic exams. More recently, Marrese-Taylor et al. (2018) trained sequence labelling and classification models to decide where to insert gaps in open cloze exercises. The models achieved around 90% accuracy/F_1 when evaluated on manually created exercises.

While the quality of the generated gaps has traditionally been judged by human experts (Pino et al., 2008; Malafeev, 2014) or estimated from student responses (Sumita et al., 2005; Brown et al., 2005; Skory and Eskenazi, 2010; Beinborn et al., 2014; Susanti et al., 2016), systems should ideally predict the quality of the gaps during the generation process. In this regard, Skory and Eskenazi (2010) observe that Shannon's information theory (Shannon, 1948) could be used to estimate the reading difficulty of answers to a gap based on their probability of occurrence. Thus, for the sentence *"She drives a nice ______"*, the word "car" would be the most likely answer (lowest readability level) while words such as "taxi", "tank" and "ambulance" would be at increasingly higher levels.

Research on predicting the difficulty of cloze tests is also directly relevant to this work. Beinborn et al. (2014) built models to predict the difficulty of C-tests (i.e. gaps with half of the required word removed) at the gap and test level and later extended their approach to cover closed cloze tests (Beinborn et al., 2015; Beinborn, 2016). More recently, Pandarova et al. (2019) presented a difficulty prediction model for cued gap-fill exercises aimed at practising English verb tenses while Lee et al. (2019) investigated how difficulty predictions could be manipulated to adapt tests to a target proficiency level. Unlike our work, however, all these approaches are supervised and not applied to open cloze tests.

3 Entropy

In this paper, we build on the assumption that the complexity of a gap is correlated to the number of possible answers determined by the surrounding context and the likelihood of each answer. As noted by Pino et al. (2008), high-quality open cloze questions should sufficiently narrow the context of each gap in order to avoid multiple valid answers, which would make the exercise too broad in scope and therefore ineffective. We thus assume that gaps with more restricted context eliciting very specific answers should be more useful than broad gaps with very general answers, so the less "branching" that a gap allows, the better.

This property can be modelled by *entropy*, which quantifies the amount of information conveyed by an event. Intuitively, entropy can be considered a measure of disorder, uncertainty or surprise. If the probability of an event is very high, entropy will be low (i.e. there is less surprise about what will happen) while events with low probabilities will lead to higher entropy. Shannon's entropy, a common formulation to measure the number of bytes needed to encode information, is shown in Equation 1, where $P(x_i)$ stands for the probability of event x_i, i.e. the probability that each word in the vocabulary occurs in the evaluated context.

$$H(X) = -\sum_{i=1}^{n} P(x_i) \log_2 P(x_i) \qquad (1)$$

In this work, we use entropy to assign a score to each gap based on the number of valid words that could fill in the slot given the surrounding context. As a result, gaps with many possible answers will yield higher entropy than those with fewer answers.

4 Experiments

We followed Malafeev's (2014) approach and used open cloze tests from Cambridge English examinations as our gold standard data, since they are manually created by experts in the field of EFL testing. We collected the sample open cloze tests for KET, FCE, CAE and CPE exams that are featured in their respective online handbooks[1] (one per exam together with their answers). These exams correspond respectively to levels A2, B2, C1 and C2 in the Common European Framework of Reference for Languages (CEFR). An open cloze test is not included in the PET (B1) exam, which is why it has not been included in our experiments.

For each exam, we restored the original text by using the answers provided (using the first alternative if there were many) and created 10 different variations of the open cloze tests by inserting gaps randomly throughout the text. We created the same number of gaps as in the original tests.

For each original and automatically generated test, we compute entropy per gap using a 5-gram language model trained on the 1 Billion Word WMT 2011 News Crawl corpus[2] using KenLM (Heafield, 2011). We use the language model bidirectionally, taking 3 words to the left and right of each gap to predict the probability of the next and previous words respectively. Since we obtain a probability for all the words in our vocabulary ($>$ 82,200 words) given the left and right context individually, we multiply the probabilities for each word to get a unified "bidirectional" probability (see Figure 1). Given that this can lead to infinitesimal probabilities that can affect computa-

tion, we use only the top 100 most probable words when computing entropy for each gap.

4.1 Results

Table 1 shows information about our gold standard tests, including CEFR levels, number of gaps and average gap entropy. The average gap entropy correlates positively with CEFR levels, suggesting that entropy increases with proficiency levels.

We then computed the average gap entropy for each of the 10 automatically generated tests per exam and compared them to the gold standard. Results are shown in Table 2.

Unlike the handcrafted gold standard, the automatically generated tests were produced randomly by a machine with no knowledge of test design so we would expect automatic gaps to be often inserted in inconvenient locations within the text, yielding lower quality tests. This hypothesis is verified by looking at the average gap entropy for the automatic tests, which is much higher than for the gold standard in the majority of cases (77.5%). This supports our intuition that entropy can be used to discriminate between good and bad gaps and, consequently, between good and bad tests.

We noticed that automatically generated tests for CPE tend to have lower entropy than the gold standard, contradicting our assumption in principle. However, we do not believe that these lower values indicate better tests but rather that they deviate from the expected difficulty for this proficiency level. In fact, we would expect high-quality tests to have average gap entropy around that of the gold standard tests, not too far below or over this reference value. Based on this premise, better automated tests can be constructed by controlling the entropy of gaps in the text, in line with previous work by Lee et al. (2019).

Exam	**CEFR level**	**Number of gaps**	**Avg. gap entropy**
KET	A2	11	1.29 ± 0.69
FCE	B2	9	2.33 ± 1.28
CAE	C1	9	2.69 ± 1.22
CPE	C2	9	5.16 ± 3.38

Table 1: Characterisation of our gold standard data.

4.2 Analysis

We looked at the gaps with the lowest and highest entropy to analyse how these values relate to the surrounding contexts. Table 3 shows the gaps in our gold standard tests with the lowest and highest entropy.

First, we found that gaps with the lowest entropy correspond mostly to exams at low CEFR levels while those with the highest entropy correspond to the highest CEFR level. This confirms our initial finding that entropy correlates directly with proficiency levels.

Second, we observed that gaps with low entropy are very restricted in context and built around very simple grammatical structures or vocabulary, making it easy to figure out the answers. On the other hand, gaps with high entropy are part of more complex grammatical structures and require longer context or understanding in order to be solved. This explains why our language model is unable to estimate the right answers for complex gaps, leading to higher entropy.

Finally, we investigated the correlation between entropy and the number of valid answers per gap. Pearson correlation for gaps in our gold standard tests is reported in Table 4. Contrary to our intuition, there is no consistent relationship between entropy and the number of valid answers per gap in our gold standard: KET shows negative correlation while CPE shows moderate positive correlation. We hypothesise that this is due to a limitation of the language model used in this preliminary study, which is unable to estimate the right word probabilities for gaps in complex contexts for the reasons described above. Using a more sophisticated language model should ameliorate this problem.

In any case, the values of entropy computed with our current model seem to capture the complexity of the gaps in context, which serves as a measure of difficulty. This, combined with the positive correlation with CEFR levels, makes en-

Exam	Average gap entropy per test

tropy a suitable unsupervised evaluation measure for gaps in open cloze tests and encourages future work beyond this pilot study.

5 Conclusion and Future Work

This work investigated the use of entropy as an evaluation measure for gaps in open cloze EFL tests. Our study revealed that the average gap entropy of a test correlates positively with proficiency levels, so easier tests will contain gaps with lower entropy. A comparison between randomly generated tests and the handcrafted gold standard tests showed that the former had much higher entropy in general, confirming our intuition that generating random gaps is not optimal and that entropy can be used to discriminate between good and bad tests.

We also investigated the correlation between entropy and the number of valid answers per gap but results showed no consistent relationship, most likely due to the limitations of the n-gram language model used in this preliminary work. However, entropy was found to be a suitable proxy for gap complexity, which can be used to control the automatic generation of open cloze tests. Future work will address the limitations in this pilot study and investigate entropy on a larger sample.

Song Lyrics Summarization Inspired by Audio Thumbnailing

{firstname.lastname}@inria.fr

Abstract

Given the peculiar structure of songs, applying generic text summarization methods to lyrics can lead to the generation of highly redundant and incoherent text. In this paper, we propose to enhance state-of-the-art text summarization approaches with a method inspired by audio thumbnailing. Instead of searching for the thumbnail clues in the audio of the song, we identify equivalent clues in the lyrics. We then show how these summaries that take into account the audio nature of the lyrics outperform the generic methods according to both an automatic evaluation and human judgments.

1 Introduction

Automatic text summarization is the task of producing a concise and fluent summary while preserving key information content and overall meaning of a text (Allahyari et al., 2017). Numerous approaches have been developed to address this task and applied widely in various domains including news articles (Cheng and Lapata, 2016), scientific papers (Mei and Zhai, 2008), web content as blogs (Hu et al., 2007), customer reviews (Pecar, 2018) and social media messages (He and Duan, 2018). Just as we may need to summarize a story, we may also need to summarize song lyrics, for instance to produce adequate snippets for a search engine dedicated to an online song collection or for music digital libraries. From a linguistic point of view however, lyrics are a very peculiar genre of document and generic summarization methods may not be appropriate when the input for summarization comes from a specific domain or type of genre as songs are (Nenkova et al., 2011). Compared to news documents, for instance, lyrics have a very different structure. Given the repeating forms, peculiar structure (e.g. the segmentation into verse, chorus, etc.) and other unique characteristics of song lyrics, we need the summarization algorithms to take advantage of these additional elements to more accurately identify relevant information in song lyrics. But just as such characteristics enable the exploration of new approaches, other characteristics make the application of summarization algorithms very challenging, as the presence of repeated lines, the discourse structure that strongly depends on the interrelation of music and words in the melody composition, the heterogeneity of musical genres each featuring peculiar styles and wording (Brackett, 1995), and simply the fact that not all songs tell a story.

In this direction, this paper focuses on the following research questions: *What is the impact of the context in summarizing song lyrics?*. This question is broken down into two sub questions: 1) *How do generic text summarization methods perform over lyrics?* and 2) *Can such peculiar context be leveraged to identify relevant sentences to improve song text summarization?* To answer our research questions, we experiment with generic unsupervised state-of-the-art text summarization methods (i.e. TextRank, and a topic distribution based method) to perform lyrics summarization, and show that adding contextual information helps such models to produce better summaries. Specifically, we enhance text summarization approaches with a method inspired by audio thumbnailing techniques, that leverages the repetitive structure of song texts to improve summaries. We show how summaries that take into account the audio nature of the lyrics outperform the generic methods according to both an automatic evaluation over 50k lyrics, and judgments of 26 human subjects.

In the following, Section 2 reports on related work. Section 3 presents the lyrics summarization task and the proposed methods. Sections 4 and 5 report on the experiments and on the evaluation, respectively. Section 6 concludes the paper.

Varna, Bulgaria, Sep 2–4 2019.

2 Summarization Methods

This section reports on the related work on both text and audio summarization methods.

2.1 Text Summarization

In the literature, there are two different families of approaches for automatic text summarization: extraction and abstraction (Allahyari et al., 2017). *Extractive summarization methods* identify important elements of the text and generate them verbatim (they depend only on extraction of sentences or words from the original text). In contrast, *abstractive summarization methods* interpret and examine the text to generate a new shorter text that conveys the most critical information from the original text. Even though summaries created by humans are usually not extractive, most of the summarization research has focused on extractive methods. Purely extractive summaries often give better results (Nallapati et al., 2016), due to the fact that latter methods cope with more complex problems such as semantic representation, inference and natural language generation. Existing abstractive summarizers often rely on an extractive pre-processing component to produce the abstract of the text (Berg-Kirkpatrick et al., 2011; Knight and Marcu, 2000). Consequently, in this paper we focus on extractive summarization methods, also given the fact that lyrics *i)* strongly use figurative language which makes abstractive summarization even more challenging; and *ii)* the choice of the words by the composer may also have an importance for capturing the style of the song.

In the following, we focus on *unsupervised* methods for text summarization, the ones targeted in our study (no available gold-standard of human-produced summaries of song texts exists). Most methods have in common the process for summary generation: given a text, the importance of each sentence of that text is determined. Then, the sentences with highest importance are selected to form a summary. The ways different summarizers determine the importance of each sentence may differ: *Statistics-based summarizers* extract indicator features from each sentence, e.g. (Fattah and Ren, 2009) use among others the sentence position and length and named entities as features. *Topic-based summarizers* aim to represent each sentence by its underlying topics. For instance, (Hennig, 2009) apply Probabilistic Latent Semantic Analysis, while Latent Dirichlet Allocation is used in (Arora and Ravindran, 2008) to model each sentence's distribution over latent topics. Another type of summarization methods is *graph-based summarizers*. Three of the most popular graph-based summarizers are TextRank (Mihalcea and Tarau, 2004), LexRank (Erkan and Radev, 2004), and (Parveen et al., 2015). These methods work by constructing a graph whose nodes are sentences and whose graph edge weights are sentence similarities. Then, the sentences that are central to the graph are found by computing the PageRank (Page et al., 1999). Contrarily to all previously described methods, systems using *supervised machine learning* form another type of summarizers. For instance, (Fattah, 2014) treats extractive summarization as a binary classification task, where they extract indicator features from sentences of gold summaries and learn to detect the sentences that should be included in a summary.

Context-Specific Summarization. If specific knowledge about the application scenario or the domain of the summarized text is available, generic summarization methods can be adapted to take into account the prior information. In query-based summarization (Otterbacher et al., 2005; Wang et al., 2016), the user's query is taken into account when generating a summary. Summarization of a scientific paper can be improved by considering the citations of it, as in (Delort et al., 2003). However, to the best of our knowledge no summarization methods have been proposed for the domain of song texts. In this paper we present a summarization method that uses prior knowledge about the text it summarizes to help generic summarizers generate better summaries.

Evaluation Criteria and Methods. Summaries should *i)* contain the most important information from input documents, *ii)* not contain redundant information, *iii)* be readable, hence they should be grammatical and coherent (Parveen and Strube, 2015). While a multitude of methods to identify important sentences has been described above, several approaches aim to make summaries less redundant and more coherent. The simplest way to evaluate summaries is to let humans assess the quality, but this is extremely expensive. The factors that humans must consider when giving scores to each candidate summary are grammaticality, non redundancy, integration of most important pieces of information, structure and coherence

(Saggion and Poibeau, 2013). The more common way is to let humans generate possibly multiple summaries for a text and then automatically assess how close a machine-made summary is to the human gold summaries computing ROUGE scores (Lin, 2004), which boils down to measuring n-gram overlaps between gold summaries and automatic summary. More recently there have been attempts to rate summaries automatically without the need for gold summaries (Nenkova et al., 2011). The key idea is that a summary should be similar to the original text in regard to characteristic criteria as the word distribution. (Mackie et al., 2014) find that topic words are a suitable metric to automatically evaluate micro blog summaries.

2.2 Audio Summarization

Lyrics are texts that accompany music. Therefore, it is worthwhile to see if methods in audio summarization can be transferred to lyrics summarization. In audio summarization the goal is to find the most representative parts in a song, in Pop songs those are usually the chorus and the bridge, in instrumental music the main theme. The task of creating short audio summaries is also known as audio thumbnailing (Bartsch and Wakefield, 2005; Chai and Vercoe, 2003; Levy et al., 2006), as the goal is to produce a short representation of the music that fits onto a thumbnail, but still covers the most representative parts of it. In a recent approach of audio thumbnailing (Jiang and Müller, 2015), the authors generate a *Double Thumbnail* from a musical piece by finding the two most representative parts in it. For this, they search for candidate musical segments in an a priori unsegmented song. Candidate musical segments are defined as sequences of music that more or less exactly repeat themselves. The representativeness of each candidate segment to the whole piece is then estimated by their fitness metric. They define the fitness of a segment as a trade-off between how exactly a part is repeated and how much of the whole piece is covered by all repetitions of that segment. Then, the audio segments along with their fitness allow them to create an audio double thumbnail consisting of the two fittest audio segments.

3 Lyrics Summarization

Song texts are arranged in segments and lines. For instance the song text depicted in Figure 1 consists of 8 segments and 38 lines. Given a song text S consisting of n lines of text, $S = (x_1, ..., x_n)$, we define the task of *extractive lyrics summarization* as the task of producing a concise summary sum of the song text, consisting of a subset of the original text lines: $sum(S) \subseteq S$, where usually $|sum(S)| << |S|$. We define the goal of a summary as to preserve key information and the overall meaning of a song text. To address this task, we apply the following methods from the literature: the popular graph-based summarizer TextRank; an adaptation of a topic-based method (TopSum). Moreover, we introduce a method inspired by audio thumbnailing (which we dub Lyrics Thumbnail) which aims at creating a summary from the most representative parts of the original song text. While for TextRank we rely on the off-the-shelf implementation of (Barrios et al., 2016), in the following we describe the other two methods.

3.1 TopSum

We implement a simple topic-based summarization model that aims to construct a summary whose topic distribution is as similar as possible to that of the original text. Following (Kleedorfer et al., 2008), we train a topic model by factorizing a tf-idf-weighted term-document matrix of a song text corpus (see Section 4.2) using non-negative matrix factorization into a term-topic and a topic-document matrix. Given the learnt term-topic matrix, we compute a topic vector t for each new document (song text). In order to treat t as a (pseudo-) probability distribution over latent topics t_i, we normalize t by applying $\lambda t.t/\sum_{t_i \in t} t_i$ to it. Given the distributions over latent topics for each song text, we then incrementally construct a summary by greedily adding one line from the original text at a time (same mechanism as in KLSum algorithm in (Haghighi and Vanderwende, 2009)); that line x^* of the original text that minimizes the distance between the topic distribution t_S of the original text S and the topic distribution of the incremental summary $sum(S)$:

$$x^* = \underset{x \in (S \setminus sum(S))}{\text{argmin}} \{W(t_S,\ t_{sum(S)+x})\}$$

W is the Wasserstein distance (Villani, 2008) and is used to measure the distance between two probability distributions (an alternative to Jensen-Shannon divergence (Louis and Nenkova, 2013)).

Figure 1: Song text of "Let's start a band" by Amy MacDonald along with two example summaries.

3.2 Lyrics Thumbnail

Inspired by (Jiang and Müller, 2015), we transfer their fitness measure for audio segments to compute the fitness of lyrics segments. Analog to an audio thumbnail, we define a Lyrics Thumbnail as the most representative and repetitive part of the song text. Consequently, it usually consists of (a part of) the chorus. In our corpus the segments are annotated (as double line breaks in the lyrics), so unlike in audio thumbnailing, we do not have to induce segments, but rather measure their fitness. In the following, we describe the fitness measure for lyrics segments and how we use this to produce a summary of the lyrics.

Lyrics Fitness Given a segmented song text $S = (S_1, ..., S_m)$ consisting of text segments S_i, where each S_i consists of $|S_i|$ text lines, we cluster the S_i into partitions of similar segments. For instance, the lyrics in Figure 1 consists of 8 segments and 38 lines and the cluster of chorus consists of $\{S_5, S_6, S_7\}$. The fitness Fit of the segment cluster $C \subseteq S$ is defined through the precision pr of the cluster and the coverage co of the cluster. pr describes how similar the segments in C are to each other while co is the relative amount of lyrics lines covered by C:

$$pr(C) = (\sum_{\substack{S_i,S_j \in C \\ i<j}} 1)^{-1} \cdot \sum_{\substack{S_i,S_j \in C \\ i<j}} sim(S_i, S_j)$$

$$co(C) = (\sum_{S_i \in S} |S_i|)^{-1} \cdot \sum_{S_i \in C} |S_i|$$

where sim is a normalized similarity measure between text segments. Fit is the harmonic mean between pr and co. The fitness of a segment S_i is defined as the fitness of the cluster to which S_i belongs:

$$\forall S_i \in C : Fit(S_i) = Fit(C) = 2\frac{pr(C) \cdot co(C)}{pr(C) + co(C)}$$

For lyrics segments without repetition the fitness is defined as zero. Based on the fitness Fit for segments, we define a fitness measure for a text line x. This allows us to compute the fitness of arbitrary summaries (with no or unknown segmentation). If the text line x occurs $f_i(x)$ times in text segment S_i, then its line fitness fit is defined as:

$$fit(x) = (\sum_{S_i \in S} f_i(x))^{-1} \cdot \sum_{S_i \in S} f_i(x) \cdot Fit(S_i)$$

Fitness-Based Summary Analog to (Jiang and Müller, 2015)'s audio thumbnails, we create fitness-based summaries for a song text. A *Lyrics Double Thumbnail* consists of two segments: one from the fittest segment cluster (usually the chorus), and one from the second fittest segment cluster (usually the bridge).[1] If the second fittest cluster has a fitness of 0, we generate a *Lyrics Single Thumbnail* solely from the fittest cluster (usually the chorus). If the thumbnail generated has a length of k lines and we want to produce a summary of $p < k$ lines, we select the p lines in the middle of the thumbnail following (Chai and Vercoe, 2003)'s "Section-transition Strategy" that

[1] We pick the first occurring representative of the segment cluster. Which segment to pick from the cluster is a potential question for future work.

they find to capture the “hook” of the music more likely.[2]

4 Experimental Setting

We now describe the WASABI dataset of song lyrics (Section 4.1), and the tested configurations of the summarization methods (Section 4.2).

4.1 Dataset

From the WASABI corpus (Meseguer-Brocal et al., 2017) we select a subset of 190k unique song texts with available genre information. As the corpus has spurious genres (416 different ones), we focus on the 10 most frequent ones in order to evaluate our methods dependent on the genre. We add 2 additional genres from the underrepresented Rap field (Southern Hip Hop and Gangsta Rap). The dataset contains 95k song lyrics.

To define the length of $sum(S)$ (see Section 3), we rely on (Bartsch and Wakefield, 2005) that recommend to create audio thumbnails of the median length of the chorus on the whole corpus. We therefore estimate the median chorus length on our corpus by computing a Lyrics Single Thumbnail on each text, and we find the median chorus length to be 4 lines. Hence, we decide to generate summaries of such length for all lyrics and all summarization models to exclude the length bias in the methods comparison[3]. As the length of the lyrics thumbnail is lower-bounded by the length of the chorus in the song text, we keep only those lyrics with an estimated chorus length of at least 4. The final corpus of 12 genres consists of 50k lyrics with the following genre distribution: Rock: 8.4k, Country: 8.3k, Alternative Rock: 6.6k, Pop: 6.9k, R&B: 5.2k, Indie Rock: 4.4k, Hip Hop: 4.2k, Hard Rock: 2.4k, Punk Rock: 2k, Folk: 1.7k, Southern Hip Hop: 281, Gangsta Rap: 185.

4.2 Models and Configurations

We create summaries using the three summarization methods described in Section 3, i.e. a graph-based (TextRank), a topic-based (TopSum), and fitness-based (Lyrics Thumbnail) method, plus two additional combined models (described below). While the Lyrics Thumbnail is generated from the full segment structure of the lyrics including its duplicate lines, all other models are fed with unique text lines as input (i.e. rendundant lines are deleted). This is done to produce less redundant summaries, given that for instance, TextRank scores each duplicate line the same, hence it may create summaries with all identical lines. TopSum can suffer from a similar shortcoming: if there is a duplicate line close to the ideal topic distribution, adding that line again will let the incremental summary under construction stay close to the ideal topic distribution. All models were instructed to produce summaries of 4 lines, as this is the estimated median chorus length in our corpus (see Section 4.1). The summary lines were arranged in the same order they appear in the original text.[4] We use the TextRank implementation[5] of (Barrios et al., 2016) without removing stop words (lyrics lines in input can be quite short, therefore we avoid losing all content of the line if removing stop words). The topic model for TopSum is built using non-negative matrix factorization with scikit-learn[6] (Pedregosa et al., 2011) for 30 topics on the full corpus of 190k lyrics.[7] For the topical distance, we only consider the distance between the 3 most relevant topics in the original text, following the intuition that one song text usually covers only a small amount of topics. The Lyrics Thumbnail is computed using String-based distance between text segments to facilitate clustering. This similarity has been shown in (Watanabe et al., 2016) to indicate segment borders successfully. In our implementation, segments are clustered using the DBSCAN (Ester et al., 1996) algorithm.[8] We also produce two summaries by combining TextRank + TopSum and TextRank + TopSum + Lyrics Thumbnail, to test if summaries can benefit from the complementary perspectives the three different summarization methods take.

Model Combination For any lyrics line, we can obtain a score from each of the applied methods. TextRank provides a score for each line, TopSum provides a distance between the topic distributions of an incremental summary and the original text, and fit provides the fitness of each line. We treat our summarization methods as blackboxes and use a simple method to combine the scores the different methods provide for each line. Given the

[2] They also experiment with other methods to create a thumbnail, such as section initial or section ending.

[3] We leave the study of other measures to estimate the summary length to future work.

[4] In case of repeated parts, the first position of each line was used as original position.

[5] https://github.com/summanlp/textrank

[6] https://scikit-learn.org

[7] loss=’kullback-leibler’

[8] eps=0.3, min_samples=2

original text separated into lines $S = (x_1, ..., x_n)$, a summary is constructed by greedily adding one line x^* at a time to the incremental summary $sum(S) \subseteq S$ such that the sum of normalized ranks of all scores is minimal:

$$x^* = \text{argmin} \bigcup_x \{\sum_A \text{R}_\text{A}(x)\}$$

Here $x \in (S \setminus sum(S))$ and $A \in \{\text{TextRank}, \text{TopSum}, \text{fit}\}$. The normalized rank $\text{R}_\text{A}(x)$ of the score that method A assigns to line x is computed as follows: first, the highest scores[9] are assigned rank 0, the second highest scores get rank 1, and so forth. Then the ranks are linearly scaled to the [0,1] interval, so each sum of ranks $\sum_A \text{R}_\text{A}(x)$ is in [0,3].

Model Nomenclature For abbreviation, we call the TextRank model henceforth M_r, the TopSum model M_s, the fitness-based summarizer M_f, model combinations M_{rs} and M_{rsf}, respectively.

5 Evaluation

We evaluate the quality of the produced lyrics summary both soliciting human judgments on the goodness and utility of a given summary (Section 5.1), and through an automatic evaluation of the summarization methods (Section 5.2) to provide a comprehensive evaluation.

5.1 Human Evaluation

We performed human evaluation of the different summarization methods introduced before by asking participants to rate the different summaries presented to them by specifying their agreement / disagreement according to the following standard criteria (Parveen and Strube, 2015):

Informativeness: The summary contains the main points of the original song text.

Non-redundancy: The summary does not contain duplicate or redundant information.

Coherence: The summary is fluent to read and grammatically correct.

Plus one additional criterion coming from our definition of the lyrics summarization task:

Meaning: The summary preserves the meaning of the original song text.

An experimental psychologist expert in Human Computer Interaction advised us in defining the questionnaire and setting up the experiment. 26 participants - 12 nationalities, 18 men, 8 women, aged from 21 to 59 - were taking a questionnaire (Google Forms), consisting of rating 30 items with respect to the criteria defined before on a Likert scale from 1 (low) to 5 (high). Each participant was presented with 5 different summaries - each produced by one of the previously described summarization models - for 6 different song texts. Participants were given example ratings for the different criteria in order to familiarize them with the procedure. Then, for each song text, the original song text along with its 5 summaries were presented in random order and had to be rated according to the above criteria. For the criterion of Meaning, we asked participants to give a short explanation in free text for their score. The selected 6 song texts[10] have a minimum and a median chorus length of 4 lines and are from different genres, i.e. Pop/Rock (4), Folk (1) and Rap (1), similar to our corpus genre distribution. Song texts were selected from different lengths (18-63 lines), genders of singer (3 male, 3 female), topics (family, life, drugs, relationship, depression), and mood (depressive, angry, hopeful, optimistic, energetic). The artist name and song title were not shown to the participants.

Results Figure 2 shows the ratings obtained for each criterion. We examine the significant differences between the models performances by performing a paired two-tailed t-test. The significance levels are: $0.05^*, 0.01^{**}, 0.001^{***}$, and $n.s.$ First, Informativeness and Meaning are rated higher** for the combined model M_{rs} compared to the single models M_r and M_s. Combining all three models improves the summaries further: both for Informativeness and Meaning the model M_{rsf} is rated higher*** than M_{rs}. Further, summaries created by M_{rsf} are rated higher*** in Coherence than summaries from any other model - except from M_f ($n.s.$ difference). Summaries are rated on the same level ($n.s.$ differences) for Non-redundancy in all but the M_r and M_f summaries, which are perceived as lower*** in Non-redundancy than all others. Note, how the model M_{rsf} is more stable than all others by exhibiting lower standard deviations in all criteria except

[9] In the case of topical distance, a "higher score" means a lower value.

[10] "Pills N Potions" by Nicki Minaj, "Hurt" by Nine Inch Nails, "Real to me" by Brian McFadden, "Somebody That I Used To Know" by Gotye, "Receive" by Alanis Morissette, "Let's Start A Band" by Amy MacDonald

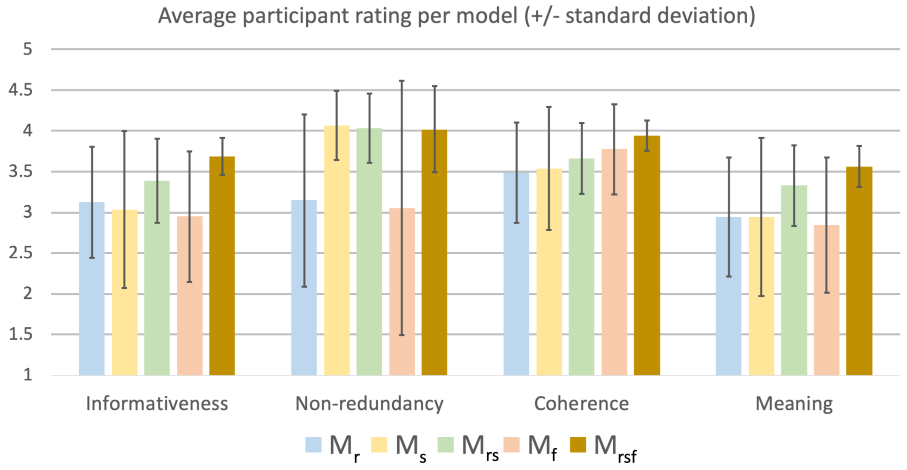

Figure 2: Human ratings per summarization model in terms of average and standard deviation.

Non-redundancy. The criteria Informativeness and Meaning are highly correlated (Pearson correlation coefficient 0.84). Correlations between other criteria range between 0.29 and 0.51.

Overall, leveraging the Lyrics Fitness in a song text summary improves summary quality. Especially with respect to the criteria that, we believe, indicate the summary quality the most - Informativeness and Meaning - the M_{rsf} method is significantly better performing and more consistent.

Figure 1 shows an example song text and example summaries from the experiment. Summary 1 is generated by M_f and consists of the chorus. Summary 2 is made by the method M_{rsf} and has relevant parts of the verses and the chorus, and was rated much higher in Informativeness and Meaning. We analyzed the free text written by the participants to comment on the Meaning criterion, but no relevant additional information was provided (the participants mainly summarized their ratings).

5.2 Automatic Evaluation

We computed four different indicators of summary quality on the dataset of 50k songs described in Section 4.1. Three of the criteria use the similarity between probability distributions P, Q, which means we compute the Wasserstein distance between P and Q (cf. Section 3.1) and apply $\lambda x.\ x^{-1}$ to it.[11] The criteria are:

Distributional Semantics: similarity between the word distributions of original and summary, cf. (Louis and Nenkova, 2013). We give results relative to the similarity of the best performing model (=100%).

Topical: similarity between the topic distributions of original and summary. Restricted to the 3 most relevant topics of the original song text. We give results relative to the similarity of the best performing model (=100%).

Coherence: average similarity between word distributions in consecutive sentences of the summary, cf. (ShafieiBavani et al., 2018). We give results relative to the coherence of the original song text (=100%).

Lyrics fitness: average line-based fitness fit (cf. Section 3) of the lines in the summary. We give results relative to the Lyrics fitness of the original song text (=100%).

Results When evaluating each of the 12 genres, we found two clusters of genres to behave very similarly. Therefore, we report the results for these two groups: the *Rap* genre cluster contains Hip Hop, Southern Hip Hop, and Gangsta Rap. The *Rock / Pop* cluster contains the 9 other genres. Results of the different automatic evaluation metrics are shown in Table 1. Distributional Semantics metrics have previously been shown (Louis and Nenkova, 2013; ShafieiBavani et al., 2018) to highly correlate with user responsiveness judgments. We would expect correlations of this metric with Informativeness or Meaning criteria therefore, as those criteria are closest to responsiveness, but we have found no large differences between the different models for this criterion. The summaries of the M_s model have the highest similarity to the original text and the M_f have the lowest similarity of 90%. The difference between the highest and lowest values are low.

For the Topical similarity, the results are mostly

[11] This works as we always deal with distances > 0.

Evaluation criterion	Genre	M_r	M_s	M_{rs}	M_f	M_{rsf}	original text
Distributional Semantics [%]	Rock / Pop	92	100	97	90	93	n/a
	Rap	94	100	99	86	92	
	$\sum$	92	100	98	90	93	
Topical [%]	Rock / Pop	44	100	76	41	64	n/a
	Rap	58	100	80	48	66	
	$\sum$	46	**100**	77	42	**64**	
Coherence [%]	Rock / Pop	110	95	99	99	100	100
	Rap	112	115	112	107	107	
	$\sum$	110	97	101	100	101	
Lyrics fitness [%]	Rock / Pop	71	53	63	201	183	100
	Rap	0	0	0	309	249	
	$\sum$	62	47	55	**214**	**191**	

Table 1: Automatic evaluation results for the 5 summarization models and 2 genre clusters. Distributional Semantics and Topical are relative to the best model (=100%), Coherence and Fitness to the original text (=100%).

in the same order as the Distributional Semantics ones, but with much larger differences. While the M_s model reaches the highest similarity, this is a self-fulfilling prophecy, as summaries of M_s were generated with the objective of maximizing topical similarity. The other two models that incorporate M_s (M_{rs} and M_{rsf}), show a much higher topical similarity to the original text than M_r and M_f.

Coherence is rated best in M_r with 110%. All other models show a coherence close to that of the original text - between 97% and 101%. We believe that the increased coherence of M_r is not linguistically founded, but merely algorithmic. M_r produces summaries of the most central sentences in a text. The centrality is using the concept of sentence similarity. Therefore, M_r implicitly optimizes for the automatic evaluation metric of coherence, based on similar consecutive sentences. Sentence similarity seems to be insufficient to predict human judgments of coherence in this case.

As might be expected, methods explicitly incorporating the Lyrics fitness produce summaries with a fitness much higher than the original text - 214% for the M_f and 191% for the M_{rsf} model. The methods not incorporating fitness produce summaries with much lower fitness than the original - M_r 62%, M_s 47%, and M_{rs} 55%. In the Rap genre this fitness is even zero, i.e. summaries (in median) contain no part of the chorus.

Overall, no single automatic evaluation criterion was able to explain the judgments of our human participants. However, considering Topical similarity and fitness together gives us a hint. The model M_f has high fitness (214%), but low Topical similarity (42%). The M_s model has the highest Topical similarity (100%), but low fitness (47%). M_{rsf} might be preferred by humans as it strikes a balance between Topical similarity (64%) and fitness (191%). Hence, M_{rsf} succeeds in capturing lines from the most relevant parts of the lyrics, such as the chorus, while jointly representing the important topics of the song text.

6 Conclusion

In this paper we have defined and addressed the task of lyrics summarization. We have applied both generic unsupervised text summarization methods (TextRank and a topic-based method we called TopSum), and a method inspired by audio thumbnailing on 50k lyrics from the WASABI corpus. We have carried out an automatic evaluation on the produced summaries computing standard metrics in text summarization, and a human evaluation with 26 participants, showing that using a fitness measure transferred from the musicology literature, we can amend generic text summarization algorithms and produce better summaries.

In future work, we will model the importance of a line given the segment to avoid cutting off important parts of the chorus, as we sometimes observed. Moreover, we plan to address the challenging task of abstractive summarization over song lyrics, with the goal of creating a summary of song texts in prose-style - more similar to what humans would do, using their own words.

Comparing Automated Methods to Detect Explicit Content in Song Lyrics

Michael Fell, Elena Cabrio, Michele Corazza, Fabien Gandon
Université Côte d'Azur, CNRS, Inria, I3S, France
{firstname.lastname}@inria.fr

Abstract

The Parental Advisory Label (PAL) is a warning label that is placed on audio recordings in recognition of profanity or inappropriate references, with the intention of alerting parents of material potentially unsuitable for children. Since 2015, digital providers – such as iTunes, Spotify, Amazon Music and Deezer – also follow PAL guidelines and tag such tracks as "explicit". Nowadays, such labelling is carried out mainly manually on voluntary basis, with the drawbacks of being time consuming and therefore costly, error prone and partly a subjective task. In this paper, we compare automated methods ranging from dictionary-based lookup to state-of-the-art deep neural networks to automatically detect explicit contents in English lyrics. We show that more complex models perform only slightly better on this task, and relying on a qualitative analysis of the data, we discuss the inherent hardness and subjectivity of the task.

1 Introduction

All content is not always appropriate for all ages and music is no exception. Content industries have been actively searching for means to help adults determine what is and is not appropriate for children. In USA, in 1985, the Recording Industry Association of America (RIAA) introduced the Parental Advisory label (PAL) in order to alert parents of content unsuitable for children because of profanity or inappropriate references[1]. PAL is "a notice to consumers that recordings identified by this mark may contain strong language or depictions of violence, sex or substance abuse"[2] and that parental discretion is advised. In UK, the British Phonographic Industry (BPI) adds to this list "racist, homophobic, misogynistic or other discriminatory language or behavior; or dangerous or criminal behavior"[3].

In the case of a song, the explicit logo is applied when the lyrics or content of a song matches one of these criteria, raising the problem of detecting and labelling explicit songs in a scalable way.

Within the Natural Language Processing (NLP) community, there have been several efforts to deal with the problem of online abusive language detection, since the computational analysis of language can be used to quickly identify offenses and ease the removal of abusive messages. Several workshops (Park and Fung, 2017; Fišer et al., 2018) and evaluation campaigns (Fersini et al., 2018; Bosco et al., 2018; Wiegand et al., 2018) have been recently organized to discuss existing approaches to abusive language detection, propose shared tasks and foster the development of benchmarks for system evaluation. These have led to the creation of a number of datasets for abusive language detection in different languages, that have been shared within the NLP research community. The SemEval 2019 tasks HatEval (Basile et al., 2019) and OffensEval (Zampieri et al., 2019) have aimed at the multilingual detection of hate speech against women or immigrants and the categorization of hate speech, respectively.

In this direction, and given the similarity with the abusive language detection task, this paper addresses the problem of explicit content detection in song lyrics as a binary classification task: a song can be labelled either as explicit or clean (=not explicit). To this end, we first compare a range of classification methods for the task of explicit lyrics detection, from dictionary lookup to deep neural networks. We then attempt the comparison to the

[1] Parental Advisory https://en.wikipedia.org/wiki/Parental_Advisory

[2] RIAA PAL https://www.riaa.com/resources-learning/pal-standards/

[3] BPI Parent Advisory https://www.bpi.co.uk/media/1047/parental-advisory-guidelines.pdf

available related works and shed light on the inherent hardness and subjectivity of the task at hand.

The paper is organized as follows: in Section 2 we survey the state of the art in explicit lyrics detection. In Sections 3 and 4 we introduce the classification methods we apply, and the comparative experimentation. Conclusions end the paper.

NOTE: This paper contains examples of language which may be offensive to some readers. They do not represent the views of the authors.

2 Related Work

Only a few works on the problem of explicit lyrics detection exist. (Bergelid, 2018) consider a dataset of English lyrics (see Table 1, B18) to which they apply classical machine learning algorithms such as Support Vector Machine (SVM) and Random Forest (RF). As features they extract either (i) tf-idf weighted bag-of-word (BOW) representations of each song text or (ii) represent the lyrics with paragraph vectors (Le and Mikolov, 2014). The explicit labels are obtained from Soundtrack Your Brand [4]. They find the RF with tf-idf BOW to perform best, especially in combination with a random undersampling strategy to the highly imbalanced dataset. They also experiment with adding lyrics metadata to the feature set, such as the artist name, the release year, the music energy level, and the valence/positiveness of a song. This results in marginal improvements for some of their models.

(Chin et al., 2018) apply explicit lyrics detection to Korean song texts. They also use tf-idf weighted BOW as lyrics representation and aggregate multiple decision trees via boosting and bagging to classify the lyrics for explicit content. On their corpus (see Figure 1, C18) they report 78% F_1 using the bagging method. Note, that bagging with decision trees is similar to the Random Forest method used by (Bergelid, 2018). Interestingly, they also report a baseline for dictionary lookup, i.e. given a profanity dictionary the song text is classified as explicit if and only if one of its words occurs in the profanity dictionary. With such a baseline they obtain 61% F_1.

More recently, (Kim and Mun, 2019) proposed a method to create explicit words dictionaries automatically by weighting a vocabulary according to all words' frequencies in the explicit class vs. the clean class, accordingly. For instance the word "fuck" is typical for explicit lyrics and atypical for clean lyrics. They compare different methods to generate such a lexicon. The achieved performances using solely dictionary lookup range from 49% F_1 for a man-made dictionary to 75.6% F_1 when using relative class frequencies. Note, that the latter performance is achieved with a dictionary of only 25 words. They work with a corpus of Korean lyrics (see Figure 1, K19). Unlike previous work, they apply a recursive neural network, resulting in 76.6% F_1, slightly higher than the simple dictionary lookup. They find performance to increase to 78.1% when combining the vector representation of the RNN with a one-hot vector indicating for each profane word from the dictionary if the lyric contains it. They argue to use the RNN to find such cases where the expliciteness arises from the context and not from a dictionary check. However, no examples of finding this phenomenon are presented.

3 Methods for Explicit Lyrics Detection

In this work, we compare a range of classification methods for the task of explicit lyrics detection. Common to all methods is that they classify a full song into one of two mutually exclusive classes - explicit or clean (=not explicit). This means, the decision if a song text is explicit is taken globally. We assess the performance of different classification methods ranging from simple dictionary lookup / lexicon checking to general purpose deep learning language understanding models. We try to identify contextual effects by applying a method that outputs the "importance" for each word (see Section 3.4).

3.1 Dictionary-Based Methods

The most straightforward way to implement an automated explicit content detection method, is checking against a dictionary of explicit words. The dictionary can be man-made or automatically created from example explicit and clean lyrics. Then, a classifier uses this dictionary to predict the class of an unseen song text.

3.1.1 Dictionary Creation

It is possible to use handcrafted dictionaries such as Noswearing [5]. Performance using an automatically created lexicon has previously been shown (Kim and Mun, 2019) to improve over the manually created dictionary. We therefore consider only

[4] https://www.soundtrackyourbrand.com

[5] https://www.noswearing.com/

the case of the machine-made dictionary in this work. We generate a dictionary of words that are indicative of explicit lyrics. We define the importance I of a word w for explicit lyrics by the frequency $f(w, ex)$ of w in explicit lyrics compared to its frequency $f(w, cl)$ in clean lyrics:

$$I(w) = f(w, ex)/f(w, cl)$$

We filter out unique and too common words and restrict the number of terms to 1,000 to avoid overreliance on terms that are very corpus specific. The dictionary D_n of the n words most important for explicit lyrics, is now straightforwardly defined as containing the n words with the highest I score.

3.1.2 Dictionary Lookup

Given a dictionary D_n, this method simply checks if a song text S contains any of the explicit terms defined in D_n. Then, S is classified as explicit iff it contains at least one explicit term from D_n.

3.1.3 Dictionary Regression

This method uses BOW made from D_n as the feature set of a classifier. We used a logistic regression, but RF or SVM have been used alike in (Bergelid, 2018).

3.2 Tf-idf BOW Regression

Similar to the Dictionary Regression, but the BOW contains the whole vocabulary of a training sample instead of only the explicit terms. The word features are weighted with the well-known tf-idf weighting scheme.

3.3 Transformer Language Model

Recently, approaches based on self-attention (Vaswani et al., 2017) have been proposed and have proven effective for natural language understanding tasks. These models are structured as an encoder-decoder, and they are trained on unsupervised tasks (such as masked language modelling) in order to learn dense representations of sentences or documents. These models differ from more traditional recurrent neural networks in different aspects. In particular, while recurrent models can process sequences (in NLP, typically word embeddings) in order, transformers use a joint model of the right and left context of each word in order to encode an entire sequence or document. Additionally, transformers are typically less computationally expensive than recurrent models, especially when trained on a GPU accelerator.

One of the most successful transformer-based models proposed in the last few years is BERT (Devlin et al., 2018). This model is composed of multiple transformers connected by residual connections. Pre-trained models are provided by the authors, and they are used in our work to perform explicit language detection in lyrics, without retraining the full model.

3.4 Textual Deconvolution Saliency

We use the Textual Deconvolution Saliency (TDS) model of (Vanni et al., 2018), which is a Convolutional Neural Network (CNN) for text classification. It is a simple model containing an embedding layer for word representations, a convolutional layer with max pooling and two fully connected layers. The interesting part about this model is that they manage to reverse the convolution. Given the learned feature map (the output of the convolution before max pooling) of the CNN, they upsample it to obtain a 3-dimensional sample with dimensions (#words, embedding size, #filters). The TDS for each word is now defined as the sum along the embedding axes of the output of the deconvolution. The TDS represents the importance of each word of the input with respect to the learned feature maps. We use this model with the goal to find local explanations for the global decision of the classification as explicit or clean. Such explanations can arise from contexts or phrases that the model assigns a high importance.

4 Experimental Setting and Evaluation

We compare the different methods as introduced in the previous section to the task of explicit lyrics detection. We attempt a comparison to the related work as well, although due to different datasets comparing the reported scores directly is problematic. We finally analyze the classification qualitatively with examples, and demonstrate the intrinsic hardness and subjectivity of the explicit lyrics detection task.

Abbreviations used: to refer to related works in Table 1 and 3, we use the following abbreviations. B18 stands for (Bergelid, 2018), C18 is (Chin et al., 2018), K19 means (Kim and Mun, 2019), while Ours is this work.

4.1 Dataset

The WASABI database (Meseguer-Brocal et al., 2017) contains song-wise labels for explicit lyrics,

Work	*total*	*explicit*	*ratio*	*language*
B18	25,441	3,310	13.0%	English
C18	27,695	1,024	3.7%	Korean
K19	70,077	7,468	10.7%	Korean
WAS	179,391	17,808	9.9%	English

Table 1: Overview of our dataset WAS (# songs) and comparison to the related works.

such as explicit, unknown, no advice available, or clean (=not explicit). These labels are provided by the music streaming service Deezer [6]. We selected a subset of English song texts from the corpus which are tagged as either explicit or clean. We filtered out duplicate lyrics and such that contain less than 10 tokens. Finally, our dataset (WAS) comprises of 179k lyrics, with a ratio of explicit lyrics of 9.9%. The details and comparison with related works datasets are depicted in Table 1.

For training any of the models described in the previous section, we once randomly split the data into training-development-test sets with the common 60%-20%-20% ratio. We tuned the hyperparameters of the different classification algorithms on the development set to then test with the best performing parameters on the test set. As evaluation metrics we use precision (*P*), recall (*R*), and f-score (F_1). Unless stated otherwise, the scores are macro-averaged over the two possible classes.

4.2 Hyperparameters

For the dictionary-based methods, we found the ideal dictionary size to be 32 words for the lookup and 128 words for the regression. The Tf-idf BOW regression performed best when the full vocabulary of unigrams and bigrams was used. We used the sklearn implementation of logistic regression with the class weighting scheme 'balanced' to account for the class imbalance in the dataset. We used TDS with max sequence length 512 and dropout probability 50%. As is the default with TDS, corpus-specific word vectors were trained using Word2Vec (Mikolov et al., 2013) with dimensionality 128. The BERT model comes pretrained and no further pre-training was performed. We used the smaller of the two published models. BERT then was finetuned to our task using max sequence length 256 and batch size 16, otherwise default parameters for text classification task learning.

4.3 Results

Overall, the results of the different classification methods we tried are all close to each other. The simple dictionary lookup with 32 words performs comparably to the deep neural network with 110M parameters (BERT base model). As baseline, we include the majority class classifier that always predicts the clean class. Furthermore, all related works show similar tendencies of performance on their respective datasets. The results of all the different methods we applied are depicted in Table 2 and described in the following.

The majority class classifier delivers a performance of 47.4% F_1, which is the only outlier in the sense that this is far below any other model. The dictionary lookup with a vocabulary of the 32 most indicative explicit words obtains a balanced performance as precision and recall are close to each other, the overall performance is 77.3% F_1. The dictionary regression performs somewhat better in terms of f-score (78.5% F_1), achieving this with the highest overall recall of 81.5%, but it has lower precision. The tf-idf BOW regression performs very similarly to the dictionary regression. This proves that a limited number of words influences the overall performance of the models, and that they do not need to consider the whole vocabulary, just the most offensive words. The increased vocabulary of 929k unigrams and bigrams is gigantic compared to the explicit words dictionary (32 words). As most of these n-grams may be noise to the classifier, this could explain the slight decrease in performance over the dictionary regression. Finally, the neural-network-based methods behave a bit differently: the BERT language model is clearly better in precision (84.4%) over all other models - the second best is TDS with 81.2%. However, BERT performs the worst in recall with only 73.7%. The overall performance of BERT is average with 77.7% F_1. Finally, TDS performs best in terms of 79.6% F_1. We tested if TDS outperforming BERT was due to TDS using domain-specific word vectors trained on our corpus (BERT is trained on books and Wikipedia). This was not the case as TDS performed almost identically, when using generic word vectors (GloVe, 200d): 80.4% *P*, 78.7% *R*, 79.5% F_1.

A closer look at the classification performance shows that the F_1 scores for the minority class (explicit lyrics) is highest with TDS (63%) and lowest with the dictionary lookup (58.9%). The majority

K19	Man-made Dictionary	49.0
K19	Dictionary Lookup	75.6
Ours	Tf-idf BOW Regression	78.0
C18	Tf-idf BOW	78.0
C18	Tf-idf BOW+	80.0
B18	Tf-idf BOW	67.5
B18	Tf-idf BOW+	82.6
Ours	TDS Deconvolution	79.6
Ours	BERT Language Model	77.7
K19	HAN	76.7
K19	HAN + Dictionary	78.1

Table 3: Performances of dictionary-based methods (top), tf-idf BOW models (middle) and deep models (below). Note that different works use different datasets. Ours always uses the WAS dataset. Values in percent.

class (clean lyrics) on the other hand is best detected by BERT (96.3% F_1) and worst with the tf-idf BOW (95.1% F_1).

We attempt a comparison of the different approaches used in the different related works as well as ours. While the scores achieved (see Table 3) are not strictly comparable, we can see clear tendencies. According to K19, a man-made dictionary is inferior to an automatically generated one. This is supported by the man-made lexicon in C18 performing subpar to their tf-idf BOW. An appropriate lexicon of explicit terms, on the other hand, can compete with a tf-idf BOW model, as we showed with both the dictionary lookup and the regression performance. This is further supported by the generated dictionary of K19 which competes with the deep HAN model. Optimizations to the standard tf-idf BOW models are marked with the + sign. Restricting the POS tags to more likely ones found in explicit terms (C18) improves performance slighly. Using random undersampling to fight the imbalanced class problem (B18) increases performance drastically, however makes the problem somewhat different from the imbalanced problem. The final takeaway is that deep models do not necessarily outperform shallow models. Neither HAN, TDS, nor BERT deliver much higher scores than the dictionary-based or the BOW method.

4.4 Qualitative Analysis

In this section we analyze examples of explicit content lyrics and point to the inherent hardness and subjectivity in classifying and even labelling such data.

4.4.1 Explicitness in Context?

The highest difference in model performance we measured between the deep TDS model (79.6% F_1) and the dictionary lookup (77.3% F_1). We analyzed why the TDS method performed better than the dictionary lookup by inspecting those examples that (i) were explicit, (ii) were tagged as clean by the dictionary lookup, and (iii) were detected as explicit by TDS with high confidence. [7]

From the 13 examples analyzed, we found three main phenomena: (1) Four texts contained explicit terms that were not contained in the dictionary of explicit terms. Words such as *f**kin', motherf**kers* were too rare to be included in the generated lexicon and other words like *fucking, cunt, cum, shit* were not uniquely contained in explicit lyrics. The reason why this is the case can be traced back to problems in the annotations or the fact that these words are relatively frequently used in lyrics. (2) Five texts whose explicitness arises in context rather than on a word level. Examples with violent context found were "organization with horns of satan performs the ancient rituals" or "bombin on mc's, crushin crews with ease". There were also instances of sexual content such as "give it to him down in the parking lot in the backseat, in the backseat of the car". Note that the words {give, it, to, him} in isolation do not belong to an explicit terms list and the sexuality arises from the context. Similarly in "(turn the lights on) so i can see that ass work". Also here, putting "ass" in an explicit terms dictionary is tempting but may not be ideal,

[7] The last layer of TDS outputs probabilities for the input text being explicit or clean. We looked at examples where the explicit class was predicted with at least 80% probability.

as its meaning is not necessarily explicit. (3) Four texts appeared to have been mislabelled since no explicitness could be found. We found for three of them that the album the song is contained in is tagged as explicit. In cases as these, inheriting the label from the album is wrong, but it seems this is exactly what had happened here. In one Raggae lyric, in particular, we found no explicit content, so we suspect the song was mislabelled.

Since we found some annotation to be problematic, we will discuss difficulties that arise from annotating explicitness in lyrics.

4.4.2 How Hard is this Task?

As stated in the introduction, the explicit label is voluntary and we will argue that it is also somewhat subjective in its nature. There are lyrics which are not tagged as explicit although they have profanity in them. Consider for example the song *Bitch* by Meredith Brooks. While it already contains profanity in the title, it does not carry the explicit label and one can argue that in the context of the song, the term "bitch" is used as a contrastive term and to raise attention to the struggle the songwriter sees in her life, torn between potentially conflicting expectations of society ("I'm a little bit of everything - All rolled into one - I'm a bitch, I'm a lover - I'm a child, I'm a mother - I'm a sinner, I'm a saint - I do not feel ashamed").

Another example is *Check Your Head* by Buckcherry where it says "Ooh and you still bitch about your payments" where "bitch" is used as a verb and one can argue that the acceptance in this verb form is higher than in the noun form. A similar case where the part of speech influences the perceived level of profanity is *Hail Hail Rock 'n' Roll* by Discipline. It contains the line "the band starts to play loud as fuck".

We encounter a different kind of problem when dealing with substance abuse or other drug-related content. It is evident that the legal status of the substances mentioned plays a major role in how such content is labelled. This is further complicated by the fact that legislation about substances can vary wildly between different countries. The labels applied to this content are not culture-invariant, and furthermore changes in the societal view can lead to labels that are not relevant anymore. This, like other examples, shows why the labels applied to lyrics are subject to change in different cultures and time periods.

Another aspect that is very sensitive to time periods and cultures comes from words themselves: an inoffensive word can become offensive in slang or common language. One such example can be found in Johnny Cash's *The Christmas Guest*: "When the cock was crowing the night away - The Lord appeared in a dream to me". Here, cock means male chicken, as opposed to the offensive meaning that is now arguably more common.

We finally want to raise attention to the problem of genre confounding. We found that the genre *Hip Hop* contributed by far the most to all explicit lyrics - 33% of all *Hip Hop* lyrics. Since only about 5% of the whole corpus are tagged as *Hip Hop*, this genre is highly overrepresented. This raises the question in how far our task is confounded with genre classification. When inspecting the explicit terms dictionaries we have created, we clearly see that genre bias reflected. The dictionary of 32 terms that we used for the dictionary lookup method consists approximately half of terms that are quite specific to the Rap genre, such as glock, gat, clip (gun-related), thug, beef, gangsta, pimp, blunt (crime and drugs). Finally, the terms holla, homie, and rapper are arguably no causes for explicit lyrics, but highly correlated with explicit content lyrics. Biasing an explicit lyrics detection model away from genres is an interesting future direction of work.

5 Conclusion

Classifying song lyrics as explicit or clean is an inherently hard task to accomplish since what is considered offensive strongly depends on cultural aspects that can change over time. We showed that shallow models solely based on a dictionary of profane words achieve a performance comparable to deep neural networks. We argued that even the hand-labelling is highly subjective, making it problematic to automatically detect if a song text should be tagged as explicit or clean.

We propose as a possible simplification and objectification to study the local detection of explicit content. If we present an authority a report on found trigger words, found contextual sexual content, and alike, they can come to their own subjective conclusion about the final label of the text.

Linguistic Classification:
Dealing Jointly with Irrelevance and Inconsistency

Abstract

In this paper we present new methods for language classification which put to good use both syntax and fuzzy tools, and are capable of dealing with irrelevant linguistic features (i.e. features which should not contribute to the classification) and even inconsistent features (which do not make sense for specific languages). We introduce a metric distance, based on the generalized Steinhaus transform, which allows one to deal jointly with irrelevance and inconsistency. To evaluate our methods, we test them on a syntactic data set, due to the linguist G. Longobardi and his school. We obtain phylogenetic trees which sometimes outperform the ones obtained by Atkinson and Gray (Gray and Atkinson, 2003; Bouckaert et al., 2012).

1 Introduction

According to Ethnologue (Eth, 2018), there are around 7000 living natural languages in the world, and one of the most interesting topics (not only in the academic field, but also in the general public) is their classification. While the comparative method was the main method of classifying natural languages until the 90s, the last decades brought an increasing number of computational approaches for estimating the historical evolution of languages and their relationships. Most of the computational historical linguistics approaches rely on the use of lexical items. In contrast, very few of them take into account syntactic aspects. Moreover, fuzzy tools and information theory were employed quite sparsely in language classification tasks (Ciobanu et al., 2018), in spite the inherent fuzzy nature of the natural language data.

This paper is based on previous work on fuzzy string distances and linguistic classification started in (Franzoi and Sgarro, 2017a,b; Franzoi, 2017), and inspired by the path-breaking ideas put forward back in 1967 (Muljačić, 1967) by the Croat linguist Ž., Muljačić. The technical tool which will be used in this paper is the *general Steinhaus transform*, or *biotope transform*, applied to crisp strings which are however affected by irrelevance and inconsistency, as happens with data due to the linguist G. Longobardi and his school. Fuzziness in linguistics has been seldomly treated (Franzoi and Sgarro, 2017a,b; Dinu et al., 2018), as compared to crisp approaches.

In his 1967 paper Muljačić, even if only rather implicitly, had introduced what appears to us as a natural *fuzzy* generalization of crisp Hamming distances between binary strings of fixed length n, and this only two years after Zadeh's seminal work (Zadeh, 1965): the aim was showing that Dalmatic, now an extinct language, is a bridge between the Western group of Romance languages and the Eastern group, mainly Romanian. The situation is the following: Romance languages $L, \Lambda, \ldots$ are each described by means of n features, which can be present or absent, and so are encoded by string $s(L) = \underline{x} = x_i \ldots x_n$, where x_i is the truth value of the proposition *feature i is present in language L*; however, presence/absence is sometimes only vaguely defined and so each $x = x_i$ is rather a truth value $x \in [0,1]$ in a multi-valued logic as is fuzzy logic; $x = x_i$ is *crisp* only when either $x = 0 =$ false $=$ absent or $x = 1 =$ true $=$ present, else x is *strictly fuzzy*. So, the mathematical objects one deals with are *strings* $\underline{x}, \underline{y}, \ldots$ of length n, each of the n components being a real number in the interval $[0,1]$, and moreover *distances* between such objects, since the classifications are all distance-based. In what follows, rather than Muljačić distance, we need string distances obtained by use of the *Steinhaus transform*, cf. (Dinu et al., 2018), and the *generalized Steinhaus transform*; they are all *metric* distances, in particular they verify the triangle equality. Unlike the case of Muljačić distances, which span the interval $[0, n]$, these distances are *normalized* to the interval $[0, 1]$. Steinhaus transforms allow one to deal with *irrelevance* and *inconsistency* in linguistics, as we already argued in (Dinu et al., 2018), and not only with vagueness, or fuzziness, as in Muljačić case, cf. (Muljačić, 1967; Franzoi and Sgarro, 2017a); the reason to use the *generalized* Steinhaus transform, as we do here, is that it allows one to deal *jointly* with both irrelevance and inconsistency.

Based on arguments defended by the linguist G. Longobardi and his school, cf. (Bortolussi et al., 2011; Longobardi et al., 2016, 2013, 2015), if a feature i has a low truth value in two languages L and Λ, then that feature is scarcely relevant: in fact, in the practice of linguistics the values 0 and 1 have a very *asymmetric* use, and the fact that languages L and Λ both have zero in a position i means that such an irrelevant feature i should *not* really contribute to the distance between the two languages. Technically, one should move from Hamming distances to (normalized) Jaccard distances. To achieve the goal, the convenient tool we have used was the *Steinhaus transform*, cf. (Dinu et al., 2018), which is known to preserve metricity and which is general enough so as to amply cover also the fuzzy situation: one starts from a distance like Muljačić distance $d_M(\underline{x}, \underline{y})$, and obtains its Steinhaus transform, in this case a *fuzzy Jaccard distance* $d_J(\underline{x}, \underline{y})$ for fuzzy strings $\underline{x}$ and $\underline{y}$; starting from the usual *crisp* Hamming distance the transform gives the usual *crisp* Jaccard distance.

In general, to apply a Steinhaus transformation one needs a *pivot string*, which in the Jaccard case is the all-0 string $\underline{z} = \underline{0} = (0, \ldots, 0)$. In the transform, actually, any other string $\underline{z}$ might be used, cf. (Dinu et al., 2018), as we do here so as to cover the case of *logical inconsistency*, as appears in the data due to G. Longobardi: his school is involved in an ambitious and innovative project on language classification based on *syntax*, cf. (Bortolussi et al., 2011; Longobardi et al., 2016); languages are represented through yes-no strings of length 53, each string position corresponding to a syntactic feature which can be present or absent. In his notation Longobardi uses + if a feature is present, - if it is absent, 0 if it is undefined; in our case, cf. Tables 1, 2, we write 1 if a feature is present, 0 if it is absent, * if it is undefined. Actually, due to a complex network of logical implications which constrain features, some positions might be undefined (logically inconsistent). For example, in Longobardi's classification, feature 34 is defined if and only if feature 8 is set to + and either feature 9 is set to + or feature 18 is not set to + (or both); otherwise it will be "neutralized" (*inconsistent*)[1]. This property does not hold true for Ptg (Portuguese), OE (Old English) and Ice (Icelandic).
All this establishes an extremely complex network of logical dependencies in Longobardi's data, and makes it necessary, if one wants to cover also this new intriguing facet, to suitably generalize crisp Hamming distances, or crisp Jaccard distances, respectively: in Longobardi's approach, cf. (Bortolussi et al., 2011; Longobardi et al., 2016, 2013, 2015), the two distances for ternary strings one defines and uses are quite useful, but unfortunately they violate the triangle property, and so are not metric. In this paper we propose one *metric* alternative based on the generalized Steinhaus transform (or generalized biotope transform): the star $*$ will be replaced by the totally ambiguous truth value $\frac{1}{2}$, and the pivot strings in the transform will be given by the set compound by the all-$\frac{1}{2}$ string, i.e. the totally ambiguous string $\underline{z} = \left(\frac{1}{2}, \ldots, \frac{1}{2}\right)$ (which stands for inconsistency) and all-0 string $\underline{z} = (0, \ldots, 0)$, i.e. the totally false string, which

[1] Feature 34 stands for *checking possessives*: it opposes languages like French, wherein possessives occur without any visible article (*mon livre* vs. *le mon livre*), to those like Italian, in which a visible determiner is possible and normally required instead (*il mio libro* vs. *mio libro*). This feature seems to conceptually and typologically depend on full grammaticalization of definiteness (feature 8). Also, it is relevant only in languages with strong Person in D (feature 9) or without strong article (feature 18), because otherwise the language would have GenS with determiner-like function, cf. (Longobardi et al., 2013). Feature 8 asks if a language generalizes the overt marking of definiteness to all relevant cases. Feature 9 (*Strong Person*) defines whether attraction to the D area of referential nominal material (e.g. proper names) is overt (e.g. Romance) or not (e.g. English). Feature 18 (*Strong Article*) is presence of an indefinite article, i.e. of an obligatory marker on singular indefinite count argument nominals, distinct from those used for definite and mass indefinite, cf. (Longobardi et al., 2013).

stands for irrelevance. The idea is to play down not only the contribution of 0's and $\frac{1}{2}$'s separately, as we have done in (Dinu et al., 2018), but rather the contribution of both 0's and $\frac{1}{2}$'s *jointly*. It will turn out that in this case, which is not genuinely fuzzy, rather than to Muljačić distances, the generalized Steinhaus transform had been better applied to the usual *taxicab distance* (Manhattan distance, Minkowski distance), re-found when the standard fuzzy logical operators of *min* and *max* for conjunctions and disjunctions are replaced by Łukasiewicz T-norms and T-conorms, cf. (Franzoi and Sgarro, 2017b; Dinu et al., 2018).

The paper is divided as follow: in Section 2 we shortly re-take both fuzzy Hamming distances, or Muljačić distances, and taxicab distances stressing how the latter relate to Łukasiewicz T-norms; in Section 3 we introduce Steinhaus transform and we apply it to taxi-cab or Łukasiewicz distances; in Section 4 we introduce the general Steinhaus transform to deal with irrelevance and inconsistency *jointly* and we comment on our linguistic results; in Section 5 we sum up our results.

2 Fuzzy Hamming Distances vs. Łukasiewicz or Taxicab Distances

We need some notations and definitions: we set $x \wedge y \doteq \min[x, y]$, $x \vee y \doteq \max[x, y]$ and $\overline{x} \doteq 1 - x$; these are the truth values of conjunction AND, disjunction OR and negation NOT, w.r. to propositions with truth values x and y in *standard fuzzy logic*, a relevant form of multi-valued logic; $x \in [0, 1]$. Define the *fuzziness* of the truth value x to be $f(x) \doteq x \wedge (1 - x)$. For the truth values x and y in $[0, 1]$ we say that x and y are *consonant* if either $x \vee y \leq \frac{1}{2}$ or $x \wedge y \geq \frac{1}{2}$, else they are *dissonant*; let $\mathcal{D}$ and $\mathcal{C}$ denote the set of dissonant and consonant positions i, respectively. We define the following distance for strings $\underline{x}, \underline{y} \in [0, 1]^n$:

$$d_M(\underline{x}, \underline{y}) \doteq \sum_{i \in \mathcal{D}} [1 - [f(x_i) \vee f(y_i)]] + \sum_{i \in \mathcal{C}} [f(x_i) \vee f(y_i)] \quad (1)$$

This expression stresses the link with *crisp* Hamming distances for binary strings $\in \{0, 1\}^n$, but its meaning is better understood due to the following fact: each of the n *additive* terms summed is the truth value of the statement:

[(feature f_i is present in L and absent in Λ) or (feature f_i is absent in L and present in Λ)]

since, as soon proved, cf. e.g. (Franzoi and Sgarro, 2017a), for two truth values x and y one has $(x \wedge \overline{y}) \vee (\overline{x} \wedge y)$ equal to $f(x_i) \vee f(y_i)$ or to $1 - [f(x_i) \vee f(y_i)]$ according whether there is consonance or dissonance. This distance, called henceforth Muljačić distance (and called *Sgarro distance* in (Deza and Deza, 2009), cf. also (Sgarro, 1977)) is simply a natural generalization of crisp Hamming distances to a fuzzy setting. As for alternative logical operators for conjunctions and disjunctions (different T-norms and T-conorms, for which cf. e.g. (Dubois et al., 2000)), they have been discussed in (Franzoi and Sgarro, 2017b). From a metric point of view, the only attractive choice, beside fuzzy Hamming distances, turned out to be Łukasiewicz T-norms for conjunctions and the corresponding T-conorms for disjunctions:

$$x \top y \doteq (x + y - 1) \vee 0, \quad x \bot y \doteq (x + y) \wedge 1$$

One soon checks that in this case, rather curiously, $(x \top \overline{y}) \bot (\overline{x} \top y)$ turns out to be simply $|x - y|$, and so the string distance one obtains is nothing else but the very well-known taxicab distance $d_T(\underline{x}, \underline{y}) = \sum_i |x_i - y_i|$, which in our context, when it is applied to fuzzy strings of length n, might be also legitimately called *Łukasiewicz distance*.

If we consider the fuzziness $f(x) \doteq d(x, x)$ of a logical value x and if we use the Muljačić distance, then we get $f_M(x) = x \wedge (1 - x)$; if we use instead the Łukasiewicz distance, then the fuzziness is always 0.

However, if we consider another equally legitimate definition of fuzziness, namely "ambiguity - crispness", which can be formalized as $\frac{1}{2} - d\left(x, \frac{1}{2}\right)$, then if we use the Muljačić distance the new fuzziness is 0, but if we use the Łukasiewicz distance it is $f_T(x) = \frac{1}{2} - d_T\left(x, \frac{1}{2}\right) = x \wedge (1 - x)$: the result of the competition Muljačić distance vs. Łukasiewicz distance turns out to be a tie. In the next Section we explain why, with Longobardi's data, we decided to resort to taxicab distances.

The distance in (1) is a *fuzzy metric distance*, cf. (Sgarro, 1977; Franzoi and Sgarro, 2017a), from which a standard metric distance is soon obtained by imposing that self-distances $d_M(\underline{x}, \underline{y})$ should be 0, while, unless $\underline{x}$ is crisp (i.e. belong to $\{0, 1\}^n$, the set of the 2^n binary strings of length n), the value given by (1) would be strictly positive.

As for taxicab or Łukasiewicz distances, the self-distance $d_T(\underline{x},\underline{y})$ is always zero even when the argument $\underline{x}$ is not crisp, a possibly unpleasant fact in a fuzzy context (but not in ours), as argued in (Franzoi and Sgarro, 2017b).

3 Steinhaus Transforms

In the general situation, one has objects $x, y, \ldots$, not necessarily strings, a *metric* distance $d(x,y)$ between objects, and a special object z called the "*pivot*-object". The Steinhaus transform, cf. (Deza and Deza, 2009), itself proven to be a metric distance, is:

$$\mathcal{S}_d(x,y) \doteq \frac{2d(x,y)}{d(x,y)+d(x,z)+d(y,z)}$$

set equal to zero when $x = y = z$.

In our case the objects are strings and *pivots* $\underline{z}$ will always be *constant* strings $\underline{z} = (z, \ldots, z)$, $z_i = z$, $\forall i, z \in [0,1]$.

If one starts with the crisp Hamming distance, one obtains the usual crisp Jaccard distance (distances from the pivot are then Hamming *weights*); starting with the more general fuzzy Hamming distance, or Muljačić distance, one has an appropriate Jaccard-like generalization, which weighs only "little" a position where both x and y are "almost 0", and which accounts for irrelevance in itself, but not for inconsistency, as instead we need.

If the term $d_M(\underline{x},\underline{z})$ is equal to the *fuzzy Hamming weight* $w(\underline{x}) \doteq \sum_i x_i$ for $\underline{z} = \underline{0}$, it is equal to $\frac{n}{2}$ independent of $\underline{x}$ when $\underline{z} = \frac{1}{2}$, a constant pivot string which we shall need to deal with inconsistency. The fact that $d_M(\underline{x},\underline{z})$ with $\underline{z} = \frac{1}{2}$ is independent of $\underline{x}$ is a serious drawback, indeed. This is why in the case of Longobardi's data, we have applied the Steinhaus transform, rather than to the fuzzy Hamming distance or Muljačić distance, directly to the taxicab distance or Łukasiewicz distance $d_T(\underline{x},\underline{y})$. In this case, in the denominator of the corresponding Steinhaus transform, the fuzzy Hamming weight $w(\underline{x})$ is replaced by $d_T(\underline{x},\underline{z}) = \sum_i \left| x_i - \frac{1}{2} \right|$. In the next Section, more ambitiously, we shall deal *jointly* with both irrelevance and inconsistency.

4 Dealing with Irrelevance and Inconsistency

In (Franzoi and Sgarro, 2017a,b; Franzoi, 2017; Dinu et al., 2018) one has presented new methods for language classification, testing them on data sets due to Muljačić and Longobardi. So far we have dealt separately with irrelevance and inconsistency, but a question arises spontaneously: can we consider jointly both irrelevance and inconsistency? Does a mathematical tool which takes into account both of them exist? The answer is yes and the tool we are looking for is the *generalized Steinhaus transform* or *generalized biotope transform*, cf. (Deza and Deza, 2009).

Prompted by arguments defended by G. Longobardi and his school, cf. (Bortolussi et al., 2011; Longobardi et al., 2016, 2013, 2015), the novelty of this section is that, since in the language classifications features can be irrelevant or inconsistent, we want to consider both aspects together.

As we said above the idea is to play down not only the contribution of 0's, as in the case of irrelevance, but also the contribution of the $\frac{1}{2}$-positions. Unlike ours, Longobardi's non-metric distance gets rid of irrelevant and inconsistent positions in quite a drastic way, possibly a serious draw-back, as we comment in our Conclusions.

The generalized Steinhaus transform, or generalized biotope transform, is:

$$\mathcal{S}_d(x,y) = \frac{2d(x,y)}{d(x,y) + \inf_{z \in M}(d(x,z)+d(y,z))} \tag{2}$$

where M is the set of pivots we are considering, cf. (Deza and Deza, 2009).

We tackle Longobardi's data (or rather to a sample of his languages, since the data he and his school are providing are steadily improving and extending), data which are not really fuzzy, even if we have decided to "simulate" logical inconsistency by *total fuzziness*. In this case the number of features is 53, and the languages are: Sic = Sicilian, Cal = Calabrese as spoken in South Italy, It = Italian, Sal = Salentin as spoken in Salento, South Italy, Sp = Spanish, Fr = French, Ptg = Portuguese, Rm = Romanian, Lat = Latin, ClG = Classical Attic Greek, NTG = New Testament Greek, BoG = Bova Greek as spoken in the village of Bova, Italy, Gri = Grico, a variant of Greek spoken in South Italy, Grk = Greek, Got = Gothic, OE = Old English, E = English, D = German, Da = Danish, Ice = Icelandic, Nor = Norwegian, Blg = Bulgarian, SC = Serbo Croatian, Slo = Slovenian, Po = Polish, Rus = Russian, Ir = Gaelic, Wel = Welsh, Far = Farsi, Ma = Marathi, Hi = Hindi, Ar = Arabic, Heb = Hebrew or 'ivrit, Hu = Hungarian, Finn = Finnish, StB = Standard Basque, WB = Western

Basque, Wo = Wolof as spoken mainly in Senegal. For comparison reasons, we have selected a part of Longobardi's data set compound by 38 languages; taking $M = \left\{\underline{0}, \underline{\frac{1}{2}}\right\}$ in (2), the UPGMA tree we obtain is given in the following figure:

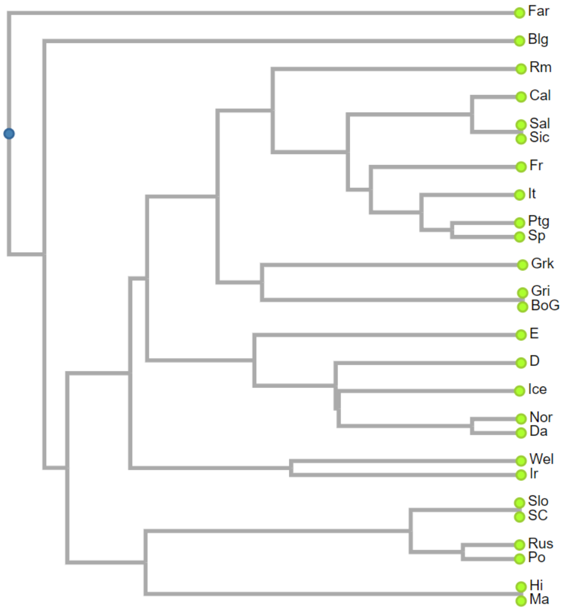

Figure 1: Generalized Steinhaus transform with taxi-cab distance and Longobardi's data

while the Longobardi's original tree is the following one:

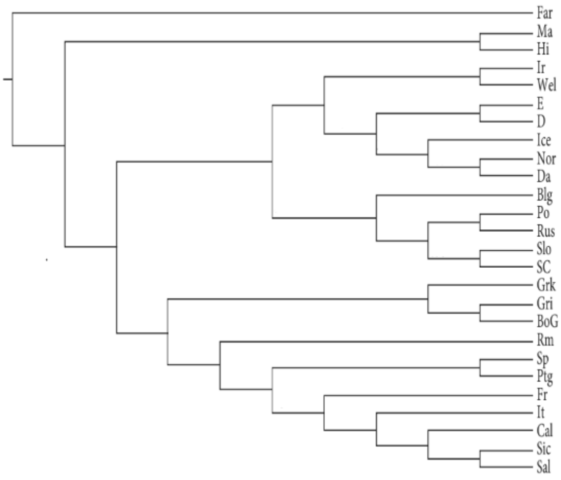

Figure 2: Longobardi's classification tree

We can observe that the Romance languages are grouped together. However there are some differences between the two trees: in our tree (Fig. 1) the big Romance languages (i.e. Italian, Spanish, Portuguese and French) are grouped together and Italian is more integrated with the Ibero-Romance languages (i.e. Portuguese ans Spanish), which are clustered together like in the standard language classifications. The three Italian dialects (i.e. Salentine, Sicilian and Calabrese) are external to this cluster in our case in Fig. 1, while in the original Longobardi's tree (Fig. 2) they are integrated with Italian and then the entire group is linked with French and after with the Ibero-Romance group. In both trees the Romanian is grouped with Romance languages, but is the most exterior with the languages from this group. In both trees the Celtic languages Gaelic (Ir) and Welsh (Wel) and Germanic languages are grouped together, but in the Longobardi's tree in Fig. 2 the Celtic group is more integrated with the Germanic group. There are two main differences between the two trees: the first one is that in Longobardi's tree in Fig. 2 Bulgarian is grouped with Slavic languages; the second one is the moving of the entire Slavic group from a closet proximity with the Germanic group (in the Longobardi's tree) to a more distance linkage with them in our case.

Our classification compares with the one obtained by Longobardi's school with these data, cf. comments in the Conclusion, where we argue why our distance is quite promising for the new and ambitious data Longobardi's school are now providing. Actually, our distance compares rather well also with the classification obtained by Q. D. Atkinson and R. D. Gray, cf. (Gray and Atkinson, 2003; Bouckaert et al., 2012).

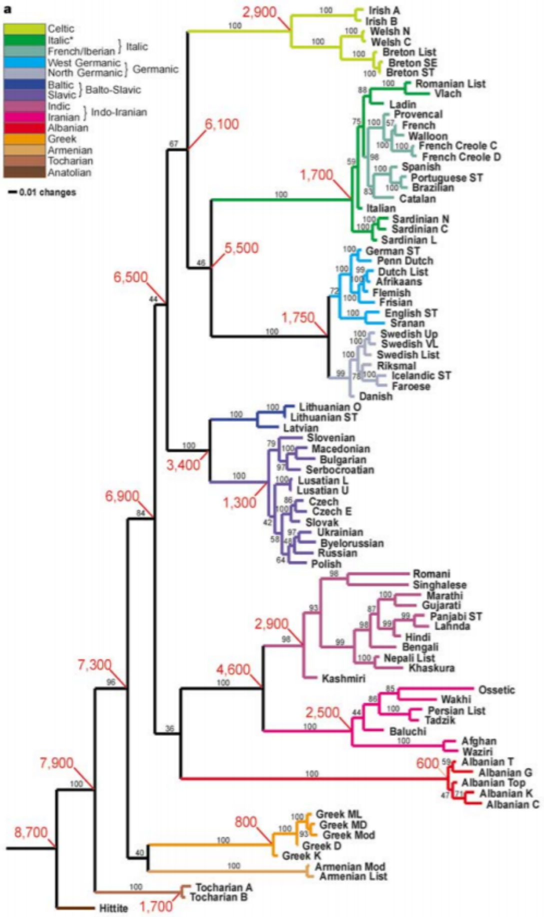

Figure 3: Q. D. Atkinson and R. D. Gray classification tree, cf. (Gray and Atkinson, 2003; Bouckaert et al., 2012)

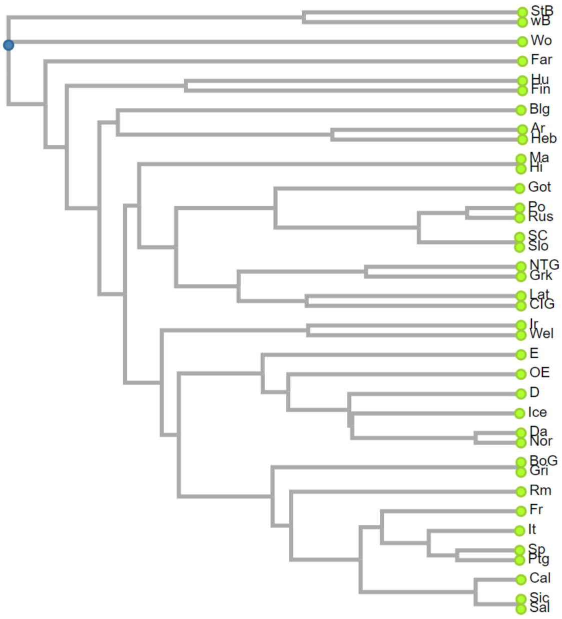

Figure 4: Classification obtained with the generalized Steinhaus transform applied to the taxi-cab distance with Longobardi's data

First of all for the classification we have used Longobardi's dataset, while Atkinson and Gray have used their own dataset. If we look to Marathi and Hindi we can notice that they are grouped together in both trees; also Polish, Russian, Serbo Croatian and Slovenian are grouped together in both trees; the same is for New Testament Greek, Greek and Classical Attic Greek. Also the Celtic languages (i.e. Gaelic and Welsh) and Germanic languages are grouped together. Our misclassification of Bulgarian is not that worring, since Longobardi covers only the syntax of the noun, and the Bulgarian noun is well-known to behave in quite a non-Slavic way, due possibly to its Balcanian substratum.

5 Conclusions

In this paper we have investigated the language classification problem by using original tools inspired by fuzzy logic. In the literature fuzzy tools and information theory have been used only quite sparsely. We have exhibited a metric distance which allows one to deal jointly with both irrelevance and inconsistency, and which is based on the generalized Steinhaus transform. Our classification compares quite well both with the one obtained by Longobardi and the one obtained by Atkinson and Gray. The merits of our metric proposal should not be underestimated, as we now comment. In more recent datasets, Longobardi and his school introduce families and macrofamilies which are quite apart. Now, think of two languages L and Λ such that the following occurs (and this does occur with "remote" languages): in most position i at least one of the two languages has a star signalling non-definition of the corresponding features. Since such positions are totally ignored by Longobardi's non-metric distance, the value obtained for the distance relies on a handful of positions only, and it is no surprise that the two languages end up being poorly classified, a sourse of worry, indeed. Now, our metric distances are not that drastic, and so might be used as a sort of companion to Longobardi's non-metric distances, useful when the latter have a low significance due to the fact that only few features "survive".
We are confident that the fuzzy ideas and methods discussed in this paper and in (Franzoi and Sgarro, 2017a; Franzoi, 2017; Dinu et al., 2018) will prove to be useful not only in linguistic classification and linguistic phylogeny, but also outside

linguistic, first of all in coding theory cf. (Franzoi and Sgarro, 2017a), or even in bioinformatics. Irrelevance and inconsistency appear to be features which are dealt with quite sparsely, if ever, outside Longobardi's school; actually, these flexible features might prove to be quite useful not only in linguistic classification phylogeny, cf. (Franzoi and Sgarro, 2017a,b), but also in the investigation of the history of texts. So far, we are just providing technical tools to be used in Longobardi's research, which, in its turn, is methodically matched with the *current state of the art*, cf. (Bortolussi et al., 2011; Longobardi et al., 2016, 2013, 2015; Longobardi, 2017; Kazakov et al., 2017).

Corpus Lexicography in a Wider Context

Chen Gafni
Bar-Ilan University
chen.gafni@gmail.com

Abstract

This paper describes a set of tools that offers comprehensive solutions for corpus lexicography. The tools perform a range of tasks, including construction of corpus lexicon, integrating information from external dictionaries, internal analysis of the lexicon, and lexical analysis of the corpus. The set of tools is particularly useful for creating dictionaries for under-resourced languages. The tools are integrated in a general-purpose software that includes additional tools for various research tasks, such as linguistic development analysis. Equipped with a user-friendly interface, the described system can be easily incorporated in research in a variety of fields.

1 Introduction

Corpus lexicography, a key component in modern dictionary compilation, has become increasingly powerful and efficient due to the development of various tools such as Word Sketch (Kilgarriff and Tugwell, 2002) and TickBox Lexicography (Kilgarriff et al., 2010). While corpus lexicography deserves further development in its own right, it is worthwhile considering it as an integral part of wider scientific missions. This paper describes several tools for corpus lexicography, whose design takes into consideration their contribution to linguistic research. The tools are integrated in a general-purpose linguistic software, where they can be readily applied in language acquisition studies, psycholinguistics, and other fields of research.

2 Preliminaries

The described system is implemented in the *Child Phonology Analyzer* software (CPA; Gafni, 2015)[1], which was built in MS Excel due to its popularity and user-friendly interface.[2] Nevertheless, the concepts behind the system are general and can be implemented in various environments. The software can analyze corpora stored in various file formats, including Excel and plain-text files, as well as several special formats used in linguistic research: Praat's TextGrids, CHAT transcription files, EAF annotation files, and XML schema for TalkBank data. The software converts analyzed corpora into Excel format and adds all analysis products to the Excel file.

2.1 Organizing the Data

The described tools ("macros") require that the corpus text be stored in a vector format. The text can be converted to a vector format using CPA's "Data preparation" macro with the "Corpus tokenization" option, which segments the text into words.

Segmentation is performed on the basis of blank spaces and additional word-dividing characters, which can be defined in CPA's "Word dividers" table (Figure 1). There are two types of word dividers, which can be used for separating words even at the absence of a blank space: *punctuation* marks (e.g., comma) are deleted during segmentation, while *final letters* are not (final letters are special letter forms appearing only at word endings. See some examples from Hebrew in Figure 1).

[1] Website: https://chengafni.wordpress.com/cpa/

[2] The code is written in Visual Basic for Applications for MS Excel and is available under the GNU General Public License. A version of this system for LibreOffice Calc is planned to appear in the future in order to free it from dependency on proprietary software.

2.2 Longitudinal and Multi-Level Corpora

The system was designed especially for analyzing longitudinal data from language acquisition studies. Such corpora typically list utterances made by a child alongside the hypothesized intended target utterances (a corpus containing such paired utterances is a *multi-level* corpus). The age of the child is also recorded for each utterance for the purpose of developmental analysis (Figure 2). Corpus tokenization (see above) processes all the above-mentioned information. This further allows analyzing both the input (target) and output (production) lexicons of the child from a developmental perspective.

2.3 Multi-Speaker Corpora

CPA can also handle corpora that contain data from multiple sources ("speakers"), stored in a single or multiple spreadsheets. The sources can be different texts, cross-sectional data from several children (Figure 3), parallel data from elicitation experiments, etc. During corpus tokenization, the data from each speaker is labelled accordingly. This allows building a separate lexicon for each speaker for the purpose of comparative analysis.

3 Constructing Corpus Lexicon

The "Construct lexicon" macro takes as input a corpus in vector format and lists the different item types in the vector including the number of occurrences of each item ("Count"). For multi-level corpora, this analysis can be done separately for target and output levels. For multi-speaker corpora, the macro constructs separate lexicons for each speaker. In addition, the macro constructs a general lexicon based on the lexicons of individual speakers (this is done separately for target and output levels). For developmental data, the macro also records the age in which the item is first attempted (for target lexicon) or produced (for output lexicon) and the spreadsheet row index containing the first attempt (Figure 4).

For items containing explicit morphological boundaries (e.g., # in *ha#kelev* 'the.dog' (Hebrew)), the macro creates a list of potential affixes based on word fragments separated by morpheme boundary markers (naturally, the initial list contains both true grammatical affixes and lexical stems). The list of affixes can be used later for analyzing the properties of polymorphemic words in the lexicon.

Figure 4: A lexicon for a developmental corpus

4 Importing Lexical Information

The corpus lexicon can be turned into a dictionary by adding information describing the various items. The descriptive information is stored in separate columns in the lexicon spreadsheet. Each such column represents some lexical property (e.g., part-of-speech, grammatical gender). In the absence of external dictionaries, the lexical information needs to be added manually. However, if there is an available resource for the particular language, the “Import dictionary” macro can import the lexical information from the external resource.

This macro receives as input the corpus lexicon and an external dictionary in a table format. The macro copies information from the external dictionary to the lexicon for every lexicon entry found in the dictionary. The macro can be used for importing information about lexical words (Figure 5), as well as grammatical affixes (Figure 6).

The macro was specially designed to handle lexical entries containing explicit morphological boundaries. For such lexical entries (e.g., *le#ˈkof* ‘to.monkey’ (Hebrew)), the macro first searches the full entry in the words dictionary. If not found, the macro then searches the individual morphemes. If a morpheme is found in the dictionary (e.g., *kof*), the macro imports the information for that entry to the corpus lexicon (Figure 7).

When importing information from an affix dictionary, the macro can use the external list of affixes to remove irrelevant entries from the corpus affixes lexicon (i.e., stems included in the affixes lexicon during its construction).

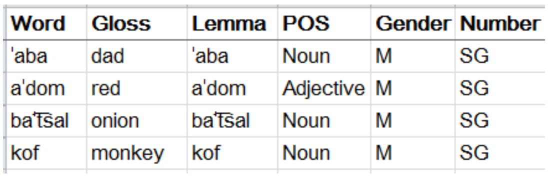
An affixes dictionary is constructed in a similar way to a words dictionary; it contains a list of affixes with additional columns providing information about these affixes. However, the additional fields have a functional role: they specify how the affix modifies the properties of affixed words. This information can be used for modifying polymorphemic entries in the lexicon (see 5.1).

5 Analyzing the Lexicon

5.1 Morphological Analysis

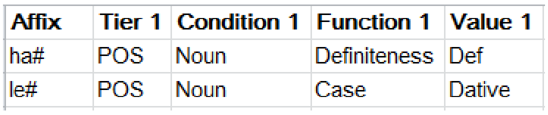
If the corpus lexicon contains polymorphemic words with explicit marking of morphological boundaries, and an affixes dictionary is available (see 4), the “Morphological analysis” macro can import information from the affixes dictionary to the corpus lexicon.

Each entry in the affixes dictionary should have the following fields (Figure 6): (a) Tier: a name of a field in the words lexicon. For example, a “POS” value in the tier field (stands for “Part-of-speech”) indicates that the affix applies to lexical items in a specific lexical category. (b) Condition: a possible value of the lexical field specified in the tier field. For example, a condition value “Noun” indicates that the affix applies to nouns. (c) Function: the name of the lexical field modified by the affix. For example, a value of “Definiteness” indicates that the affix specifies the definiteness value of the hosting word. (d) Value: the value assigned to the lexical field specified in the “Function” field. For example, a value of “Def” indicates that the affix marks the hosting word as being definite.



Word	Gloss	Lemma	POS	Gender	Number
ˈaba	dad	ˈaba	Noun	M	SG
aˈdom	red	aˈdom	Adjective	M	SG
baˈt͡sal	onion	baˈt͡sal	Noun	M	SG
kof	monkey	kof	Noun	M	SG

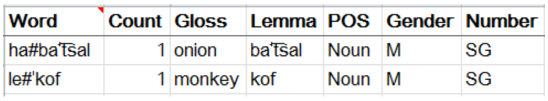
Figure 5: An external words dictionary



Affix	Tier 1	Condition 1	Function 1	Value 1
ha#	POS	Noun	Definiteness	Def
le#	POS	Noun	Case	Dative

Figure 6: An external affixes dictionary

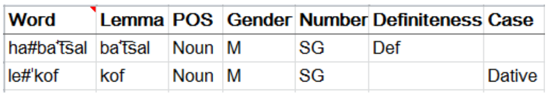
For each affix in the affixes dictionary, it is possible to define multiple feature quadruplets (e.g., “Tier 1”, “Condition 1”, …, “Tier 2”, “Condition 2”, etc.). This option is useful for handling affixes that can affect multiple word classes (e.g., nouns and adjectives) or have multiple functions (e.g., express possession and mark tense).



Word	Count	Gloss	Lemma	POS	Gender	Number
ha#baˈt͡sal	1	onion	baˈt͡sal	Noun	M	SG
le#ˈkof	1	monkey	kof	Noun	M	SG

Figure 7: Imported lexical information based on the stems of prefixed words

The “Morphological analysis” macro finds lexical entries containing affixes and modifies their properties according to the details of the affix. If an affix modifies a lexical field not defined in the lexicon, the macro adds that field to the lexicon (Figure 8).

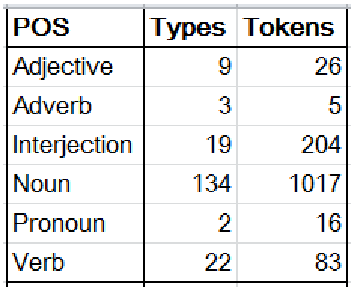


Word	Lemma	POS	Gender	Number	Definiteness	Case
ha#baˈt͡sal	baˈt͡sal	Noun	M	SG	Def	
le#ˈkof	kof	Noun	M	SG		Dative

Figure 8: Lexical entries of prefixed words after morphological analysis

5.2 Lexicon Summary

This macro generates a summary table of the lexicon. The summary table includes a list for each lexical field (e.g., “POS”) that specifies the various values of the field (e.g., “Noun”, “Verb”). For each value, the list indicates the number of corpus tokens and types. The number of types is the number of items in the lexicon with the relevant value (e.g., the number of noun types), and the number of corpus tokens is calculated from the “Count” field in the lexicon (Figure 9).



POS	Types	Tokens
Adjective	9	26
Adverb	3	5
Interjection	19	204
Noun	134	1017
Pronoun	2	16
Verb	22	83

Figure 9: Lexicon summary by part-of-speech

6 Integrating Lexicons

Efficient integration of information is essential for compiling a dictionary based on data from multiple resources. The “Merge worksheets” macro is a general utility macro that integrates the contents of multiple spreadsheets in a file. Thus, it requires lexicons generated from different corpora to be stored in one file (this can be done either manually or automatically with the “Merge workbooks” CPA macro).

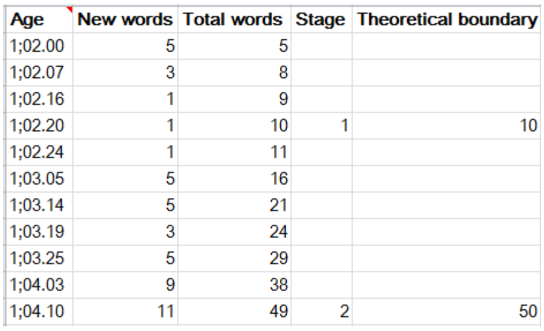
The “Merge worksheets” macro has several operation modes, one of which is designed specifically to integrate lexicon tables. The macro receives as input any number of spreadsheets. It creates a single lexicon[3] containing information from all input lexicons. The merged lexicon contains the union of lexical fields in all input lexicons (i.e., a lexical field will be included in the merged lexicon if it appears at least in one input lexicon).

The entries in the merged lexicon are sorted alphabetically. If a lexical entry appears in multiple input lexicons, the duplicate entries are merged. The merged entry summarizes token counts from the contributing corpora (e.g., if an item appears 10 times in one corpus and 20 times in another corpus, the merged lexicon will record 30 tokens for that item). In addition, the merged entry will contain the lexical properties collected from all contributing entries. In case of conflicting inputs (e.g., an item is classified as a noun in one lexicon and as a verb in another), the merged entry will indicate all possible values for that property (e.g., Noun / Verb). The merging macro can also add labels indicating the source(s) (i.e., the name of the input lexicon) of each entry.

7 Lexical Development

Assessing the size of the child’s lexicon is an important part of longitudinal language acquisition studies, from both theoretical and clinical perspectives. In particular, there is evidence that aspects of grammatical development are tightly correlated with vocabulary size (Bates and Goodman, 1997).

The “Lexical development” macro analyzes lexical growth in corpora that record the age of production of every utterance. Using the age of first attempt to produce target words (see 3), the macro divides the child’s lexicon into stages of lexical development (Figure 10). The first stage is marked by the acquisition of the first 10 words, the second by a total lexicon size of 50 words, and then an additional 50 words for every subsequent stage (Adam and Bat-El, 2009).

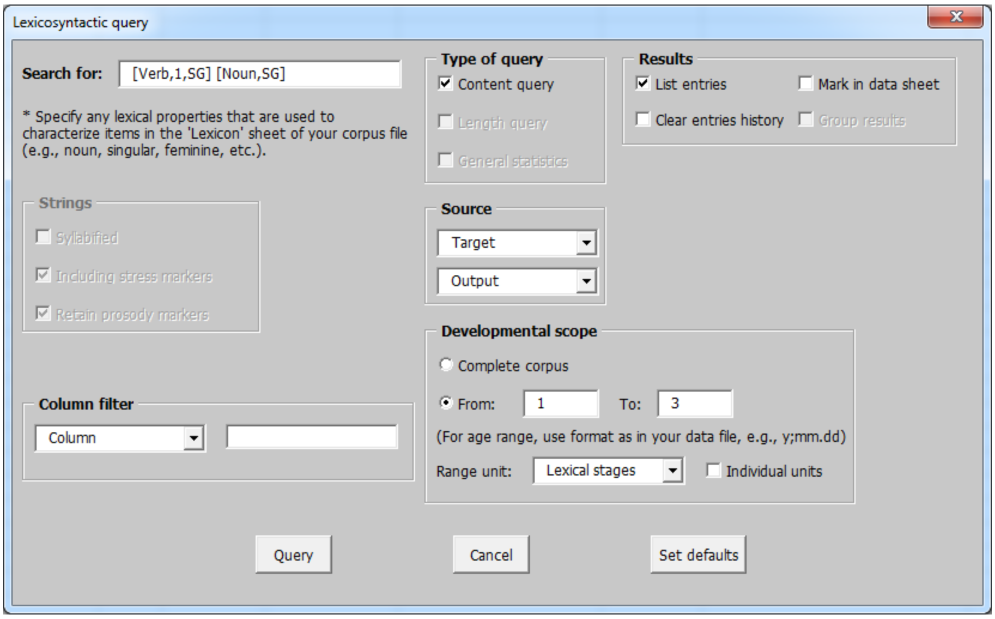


Age	New words	Total words	Stage	Theoretical boundary
1;02.00	5	5		
1;02.07	3	8		
1;02.16	1	9		
1;02.20	1	10	1	10
1;02.24	1	11		
1;03.05	5	16		
1;03.14	5	21		
1;03.19	3	24		
1;03.25	5	29		
1;04.03	9	38		
1;04.10	11	49	2	50

Figure 10: Lexical development

Stages of lexical development are aligned with recording sessions, such that if a theoretical stage boundary is reached in mid-session, the actual boundary will be assigned either to that session or to the preceding session (whichever is closer). For

[3] Due to software limitations, the maximal number of entries in a single lexicon (or a lexicon generated by merging a number of lexicons) is 1,048,575. When this limit is exceeded, CPA splits the lexicon over multiple spreadsheets.



Lexicosyntactic query

Search for: [Verb,1,SG] [Noun,SG]

* Specify any lexical properties that are used to characterize items in the 'Lexicon' sheet of your corpus file (e.g., noun, singular, feminine, etc.).

Type of query
- ☑ Content query
- □ Length query
- □ General statistics

Results
- ☑ List entries
- □ Mark in data sheet
- □ Clear entries history

- ● From: 1 To: 3

(For age range, use format as in your data file, e.g., y;mm.dd)

Range unit: Lexical stages □ Individual units

Column filter
- Column

Figure 11: Lexicosyntactic query form

example, if the child has reached 49 cumulative target types at the end of session 1 and 58 cumulative target types at the end of session 2, the theoretical landmark of 50 words will be assigned to session 1. If the lexicon grows rapidly, such that more than one theoretical stage is passed in a single session, the macro will “skip” intermediate stages and assign only the last stage to that session. For example, if the size of the lexicon jumps from 100 words (stage 3) to 200 words (stage 5) in a single session, that session will be marked as the end point of stage 5, skipping stage 4. The macro also provides a more fine-grained account, indicating the number of new words added to the lexicon in every session and the total lexicon size after every session.

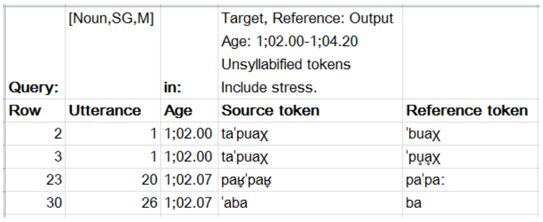
By default, lexical development is calculated based on the full list of lexical entries. However, this list is organized by word form (types), such that words that are interrelated via inflectional morphology (e.g., *cat–cats*) are listed as separate entries. Relying on plain surface forms can result in over-estimation of lexicon size. This can be avoided by analyzing lexical development by lemma/lexeme. When this option is chosen, the macro analyzes the lemma field of the lexicon rather than the word field. The lemma field indicates the lemma of each lexical entry (e.g., the lemma of *cat* and *cats* is *cat*). The lemma information can be supplied manually or imported from an external dictionary (see 4). When a lexical entry has no lemma specified, the surface form of the entry will be taken as the lemma.

8 Lexical Queries

Once lexical properties are specified in the lexicon, this information can be used to analyze the corpus. CPA has a set of macros that can extract linguistic information from the corpus on various levels of analysis, via a user-friendly query form (Figure 11). One of these macros, “Lexicosyntactic query”, queries the corpus at the word and utterance levels. Specifically, “Content Lexicosyntactic queries” can find occurrences of lexical properties and sequences of lexical properties in the corpus. For example, the query [Verb] [Noun] will find all instances of verbs followed by nouns in the corpus. Similarly, the query [Verb,1,SG] [Noun,SG] will find all instances of verbs conjugated in the first person singular followed by singular nouns.

The scope of queries can be constrained by age or stage of lexical development. Thus, for example, it is possible to get all verbs attempted by a child at a given age/lexical stage or range of ages/lexical stages. This option allows for investigation of lexical development at a more fine-grained level.

Queries over single-item sequences (e.g., [Verb,SG]) calculate the number of tokens and types and can also return a list of items that matched the query (Figure 12). Queries over multi-item sequences (e.g., [Verb] [Noun]) do not return



Query:	[Noun,SG,M]	in:	Target, Reference: Output Age: 1;02.00-1;04.20 Unsyllabified tokens Include stress.	
Row	**Utterance**	**Age**	**Source token**	**Reference token**
2	1	1;02.00	taˈpuaχ	ˈbuaχ
3	1	1;02.00	taˈpuaχ	ˈpu̥ḁχ
23	20	1;02.07	paʁ̥ˈpaʁ̥	paˈpaː
30	26	1;02.07	ˈaba	ba

Figure 12: Corpus instances of singular masculine nouns (source) paired with the corresponding forms produced by an infant (reference).

specific items, but rather a list of indices of rows in the corpus where such sequences are found.

In addition to lexicosyntactic queries, CPA has similar query macros for analyzing the phonological properties of corpora. These queries, too, can be correlated with lexical development. Additional, more advanced macros can be used to combine queries on different levels of analysis. This allows, for example, to study the interaction between phonological and lexical development.

9 Discussion

The described set of tools can help creating resources for under-resourced languages. For example, it was used for creating a lexicon with corpus frequency data for Hebrew (Gafni, 2019), and it is currently being used in an ongoing longitudinal study of phonological development in twins. In addition to building a lexicon for each participating child and assessing lexical development, the system can assist in improving the quality of the transcribed data.

Given that the transcribed data can contain many errors (typos, misperceptions), it is important to have it validated. Since the amount of transcribed data can be enormous (tens of thousands of tokens) and the transcription task is very time-consuming, it is impractical to have every token transcribed by multiple transcribers. One possibility to check data quality is to have a random subset of the corpus (e.g., 10% of the tokens) be transcribed by more than one transcriber, and calculate inter-transcriber reliability. However, such an approach can help detecting problems in a limited part of the corpus. The tools described in this paper offer a more systematic approach to quality check of transcribed data. In this lexicon-based approach, one goes over the entries in the automatically generated corpus lexicon and looks for suspicious entries. For the lexicon of target words, this mainly involves looking for non-existing words, which likely resulted from typos. For the lexicon of produced forms (output lexicon), quality check mainly involves examining tokens with unusual structure that deviates from the phonology of the ambient language. Thus, in the proposed approach, one estimates the potential of lexical entries to contain errors, and then focuses on suspicious forms. This is more effective than examining corpus subsets randomly.

The described tools can be integrated in any task involving corpus analysis. For example, the CPA software includes an n-gram frequency calculator, which can calculate corpus-weighted mean n-gram frequencies over a list of strings (in this context, n-gram refers to a sequence of letters or phones within words). This is useful for creating controlled sets of stimuli for psycholinguistic experiments.

Finally, it should be acknowledged that there is some overlap between the described system and other existing systems. Well-established systems such as Sketch Engine (Kilgarriff et al., 2014) provide powerful solutions for corpus lexicography, and the CLAN program (MacWhinney, 2000) can be used for studying lexical development.

Compared to these programs, CPA is currently limited in areas such as collocation analysis and POS tagging. On the other hand, CPA has some advantages over these programs. Its unique built-in lexical development tool allows for more comprehensive study of language development, and its querying system allows for combined lexical and phonological corpus analysis. The user-friendly interface enhances user experience and saves the need to learn complex query syntax, as used by the CLAN program. In addition, CPA is distributed as an Excel file. This means that Excel users can perform the various analysis tasks in the natural environment of the data, without the need to install (or purchase) additional software.

To conclude, this paper views corpus lexicography in a wide context of linguistic research. Accordingly, the described tools are integrated in a single, user-friendly system designed to support any task requiring corpus analysis. Future improvements to the current system will include the addition of standard lexicographic functions, such as collocation analysis and morphological analysis that does not require overt marking.

A Universal System for Automatic Text-to-Phonetics Conversion

Chen Gafni
Bar-Ilan University
chen.gafni@gmail.com

Abstract

This paper describes an automatic text-to-phonetics conversion system. The system was constructed to primarily serve as a research tool. It is implemented in a general-purpose linguistic software, which allows it to be incorporated in a multifaceted linguistic research in essentially any language. The system currently relies on two mechanisms to generate phonetic transcriptions from texts: (i) importing ready-made phonetic word forms from external dictionaries, and (ii) automatic generation of phonetic word forms based on a set of deterministic linguistic rules. The current paper describes the proposed system and its potential application to linguistic research.

1 Introduction

There are currently many commercial and academic works dealing with automatic conversion of text to phonetics (G2P). Existing solutions are based on some combination of language-specific phonetic dictionaries, corpus-based statistical models (e.g., Hidden Markov Models), deterministic models based on linguistic rules, and machine learning techniques (see review in Tomer, 2012). Importantly, most available tools are closed-source, support only a limited number of languages, and are often available only for commercial use (e.g., Baytukalov, 2019).

The current paper describes a new, open-source system that generates phonetic transcriptions from texts. Its design allows it to apply, in principle, to any language. At present, the system relies on two mechanisms to generate the transcriptions: (i) importing ready-made phonetic word forms from external dictionaries, and (ii) automatic generation of phonetic word forms based on a set of deterministic linguistic rules. The following sections describe the transcription mechanisms and additional relevant tools.

2 Preliminaries

The described system is implemented in the *Child Phonology Analyzer* software (CPA; Gafni, 2015)[1], which was built in MS Excel due to its popularity and user-friendly interface.[2] Nevertheless, the concepts behind the system are general and can be implemented in various environments. The following subsections describe the general organization of the system and guidelines for working with the data.

2.1 Tables

The system uses a set of tables of definitions and rules to guide its operation. The tables are stored in separate spreadsheets in the CPA file and can be edited according to the properties of the language in question. Moreover, variants of these tables can be stored in separate files and imported by the system when needed. This feature allows users to maintain sets of definitions and rules for multiple languages.[3]

2.2 Organizing the Data

The transcription procedures ("macros") operate on a vector of words. Thus, the input text should be converted into a vector format prior to running the transcription macros. This can be done using the "Corpus tokenization" option of CPA's "Data

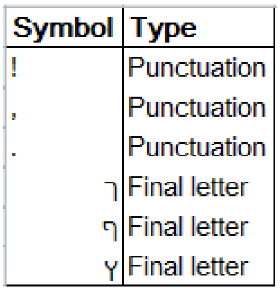
[1] Website: https://chengafni.wordpress.com/cpa/

[2] The code is written in Visual Basic for Applications for MS Excel and is available under the GNU General Public License. A version of this system for LibreOffice Calc is planned to appear in the future in order to free it from dependency on proprietary software.

[3] The system is accompanied by an external resource containing proposed sets of rules for several languages.

preparation” macro, which segments the text into words.

Segmentation is performed on the basis of blank spaces and additional word-dividing characters, which can be defined in CPA’s “Word dividers” table (Figure 1). There are two types of word dividers, which can be used for separating words even at the absence of a blank space: *punctuation* marks (e.g., comma) are deleted during segmentation, while *final letters* are not (final letters are special letter forms appearing only at word endings. See some examples from Hebrew in Figure 1). Once the text is transformed into a vector format, transcription can be performed. One of CPA tools (“Reconstruct corpus”) can then be used to recombine the phonetic word forms according to the structure of the original text.



Symbol	Type
!	Punctuation
,	Punctuation
.	Punctuation
ך	Final letter
ף	Final letter
ץ	Final letter

Figure 1: Word dividing symbols

3 Phonetic Dictionaries

For languages with irregular spelling or high proportion of homographs, such as English, Hebrew, and Arabic, automatic phonetic transcription requires a source of ready-made phonetic forms (i.e., a phonetic dictionary) for irregular and ambiguous words. CPA has a built-in macro that can import such ready-made forms. The macro receives as input a vector of written words to-be-transcribed and a phonetic dictionary – a table of written word forms and corresponding phonetic forms. The macro matches phonetic forms from the dictionary to written words in the vector. For words that are not found in the phonetic dictionary, transcription needs to be generated, either manually or with the automatic linguistic model (see next section). However, once the additional phonetic word forms are supplied, CPA can add them to the phonetic dictionary for future use.

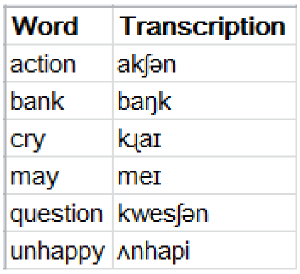
4 The Linguistic Model

For languages with some degree of regular mapping between spelling and sound, phonetic transcription of text can be generated automatically on the basis of deterministic rules. This section describes a multi-stage model of automatic phonetic transcription, guided by linguistic principles. Underlying this model is the assumption that, for any regular orthographic system, phonetic transcription rules can be defined in terms of a small set of general operations. The general operations themselves are hard-coded in the software, but an unlimited number of language-specific rules can be defined on the basis of these operations. This flexible method allows the system to produce automatic phonetic transcription for every language that has, at least partly, regular orthography.

The proposed model has four components, which will be described in the following subsections. The components operate independently of one another, but they should be applied in the order in which they are listed. The first component alone produces sufficient results for most purposes. If needed, the additional three components can be used, together, for fine-tuning.

4.1 Pre-Prosody Transcription

This component takes as input the vector of words to-be-transcribed, a table of pre-prosody transcription rules (Table 1), and a table containing sets of symbols and strings, called “phono-orthographic groups” (Table 2).[4] The pre-prosody transcription[5] applies the transcription rules in successive order to the list of words. Entities



Word	Transcription
action	akʃən
bank	baŋk
cry	kɻaɪ
may	meɪ
question	kwesʃən
unhappy	ʌnhapi

Figure 2: Transcribed words

[4] The tables of rules are generated manually, in principle. CPA has a set of editable tables that contain proposed rules for several languages (see also 2.1).

[5] The term ‘pre-prosody’ indicates that the transcription rules applied by this component disregard the prosodic properties of the word, including syllable structure and stress pattern.

	Target	**Output**	**Type**	**Preceding environment**	**Following environment**
1	ph	f			
2	c				k
3	ay	eɪ		#?	#
4	[cg]	[sj]			[Front_vowel]
5	[Consonant][Consonant]	[Consonant]	Degemination		
6	◌ّ		Lengthening		
7	[V_diac][C_diac]	[C_diac][V_diac]	Metathesis		

Table 1: Pre-prosody transcription rules

defined in the table of phono-orthographic groups may be called by transcription rules. The output of the process is a vector of phonetic forms corresponding to the written words (Figure 2).

The table of pre-prosody transcription rules has five fields (Table 1): (1) Target: the input to the rule, i.e., the string to be converted. All rules must have a value for the target string. The other fields are optional. (2) Output: the string replacing the target; if left empty, the target string will be deleted. (3) Type: the type of operation to be performed by the rule; if left empty, simple substitution will be performed (see below for other types of rules). (4) Preceding environment, and (5) Following environment: these fields are used for formulating context-sensitive rules. When either field is not empty, the transcription rule will apply only to words in which the target string is preceded by the 'preceding environment string' and/or followed by the 'following environment string'.

Substitution rules can be used for simple grapheme-to-phoneme conversions, which can be either context-free or context-sensitive. For example, rule 1 in Table 1 is a context-free substitution of *ph* by *f* in words such as *phone* (/foʊn/). Rule 2 in Table 1 is an example for context-sensitive rule – deleting *c* before *k* in words such as *back* (/bæk/).

Substitution rules may include wildcards to define more general entities. Three types of wildcards are defined in the software: a question mark (?) stands for any single character in the target, output or environment strings; an asterisk (*) stands for any number of successive characters; and, a hash sign (#) represents word boundaries. Wildcards can be used for defining phonological and morphological words patterns. For example, rule 3 in Table 1 captures the pronunciation of *ay* at the end of three-letter English words, such as *bay* (/beɪ/). The question mark in this rule indicates that the rule applies to *ay* sequences preceded by a single character. The hash signs suggest that the rule applies only when word boundaries are present at both edges.

Group	**Members**
cg	c,g
sj	s,ʤ
Front_vowel	e,i,y
Consonant	b,d,f,g,l,m,n,p,r,s,t,z
C_diac	◌ּ,◌ׂ,◌ׁ,'
V_diac	◌ְ,◌ֱ,◌ֹ,◌ָ,◌ַ,◌ֶ,◌ֵ,◌ִ

Table 2: Phono-orthographic groups

Rules can also be generalized by the inclusion of phono-orthographic groups, defined in a separate table. Each entry in the table of phono-orthographic groups has two fields (Table 2): the name of the group, and its members. For example, the term *Front_vowel* can be used for grouping *e*, *i*, and *y*.

Transcription rules can include phono-orthographic groups by enclosing the name of the group between brackets (e.g., [Front_vowel]). When a group is embedded in a transcription rule, the algorithm converts the compact rule into a set of simple rules, each applying to a different member of the group. For example, rule 4 in Table 1 uses groups to capture the pronunciation of *c* and *g* before front vowels (/s/ in *cent* /sent/ and /ʤ/ in *gene* /ʤiːn/, respectively). This single, compact rule stands for six simple rules: c→s/_e, c→s/_i, c→s/_y, g→ʤ/_e, g→ʤ/_i, g→ʤ/_y (where the formula A→B/_X is read: A becomes B before X).

In addition to substitution rules, several types of special operations can be used by specifying the name of the operation in the 'Type' field in the table of rules. Three types of operations are defined in the software: *degemination*, *lengthening*, and *metathesis*.

Degemination is used for collapsing a sequence of two identical phones when pronounced as a single, short sound. For example, rule 5 in Table 1 collapses sequences of identical consonants (e.g., *mm* is pronounced as a single *m* in *hammer*).

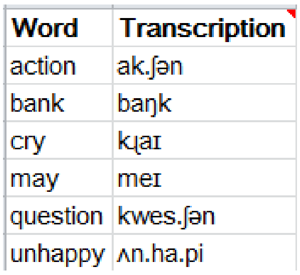
Lengthening realizes the function of diacritical marks of lengthening/gemination. For example, rule 6 in Table 1 realizes the function of the Arabic Shaddah (e.g., the letter م is pronounced /m/ in its plain form, but as /mm/ when modified by a Shaddah, i.e.,مّ).

Finally, *metathesis* switches the order of elements in sequences of two phono-orthographic groups (i.e., if the target contains a member of group 1 followed by a member of group 2, they are switched in the output). For example, in pointed Hebrew scripts, diacritics are used for indicating vowels as well as for modifying the phonetic value of consonants. A single letter can host both consonant and vowel diacritics (the C_diac and V_diac groups in Table 2, respectively). Thus, the string בַּ, pronounced /ba/, is composed of the letter ב (representing the consonants /b/ and /v/), a consonant diacritic ◌ּ (specifying the consonant /b/), and a vowel diacritic ◌ַ (representing the vowel /a/). Although the order in which these diacritics are attached to the letter does not affect the visual form of the text, it is important for the purpose of phonetic transcription – consonant diacritics must be attached before vowel diacritics. For example, the string בַּ can be formed by combining the three elements in two ways: ב+◌ּ+◌ַ, or ב+◌ַ+◌ּ. However, only the first order reflects the phonological structure of the string. A rule of metathesis can be defined to switch the order in sequences of vowel diacritics + consonant diacritic to guarantee correct ordering (rule 7 in Table 1).

After performing the pre-prosody transcription, certain modifications might be needed due to phonological processes related to prosodic structure. This post-prosody transcription (see 4.4) requires that the phonetic forms be parsed into syllables and have stress markers assigned to them. These components are described below.

4.2 Syllabification

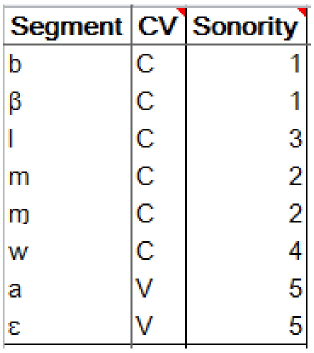
This component takes as input a vector of phonetic word forms, a list of binary parameters and parameter weights, and a phonetic table. The output is a vector of syllabified phonetic word forms (Figure 3). The basic sites of syllable boundaries are around local sonority minima (e.g., the boldfaced consonants in fæ**m**ə**l**i ‘family’ → fæ.**m**ə.**l**i).



Word	Transcription
action	ak.ʃən
bank	baŋk
cry	kɹaɪ
may	meɪ
question	kwes.ʃən
unhappy	ʌn.ha.pi

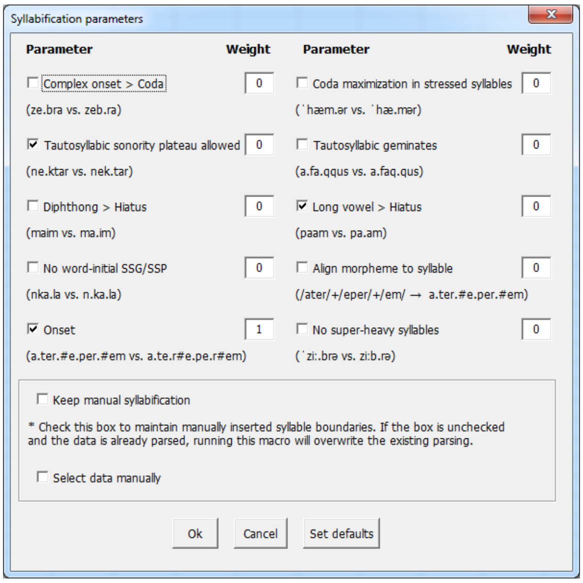
Figure 3: Syllabified phonetic word forms

In order to determine sites of sonority minimum, the syllabification procedure converts the phonetic word forms into strings of sonority levels. Sonority levels are non-negative integers specified for each phone in the phonetic table of CPA (Figure 4). For example, if fricatives, nasals, liquids, and vowels have sonority levels of 1, 2, 3, and 5, respectively, the sonority-level representation of *fæməli* will be 152535. In this representation, 2 and 3 are local sonority minima (Sonority minima at word edges are ignored).



Segment	CV	Sonority
b	C	1
β	C	1
l	C	3
m	C	2
m	C	2
w	C	4
a	V	5
ɛ	V	5

Figure 4: The phonetic table



Syllabification parameters

Parameter	Weight	Parameter	Weight
☐ Complex onset > Coda (ze.bra vs. zeb.ra)	0	☐ Coda maximization in stressed syllables (ˈhæm.ər vs. ˈhæ.mər)	0
☑ Tautosyllabic sonority plateau allowed (ne.ktar vs. nek.tar)	0	☐ Tautosyllabic geminates (a.fa.qqus vs. a.faq.qus)	0
☐ Diphthong > Hiatus (maim vs. ma.im)	0	☑ Long vowel > Hiatus (paam vs. pa.am)	0
☐ No word-initial SSG/SSP (nka.la vs. n.ka.la)	0	☐ Align morpheme to syllable (/ater/+/eper/+/em/ → a.ter.#e.per.#em)	0
☑ Onset (a.ter.#e.per.#em vs. a.te.r#e.pe.r#em)	1	☐ No super-heavy syllables (ˈzi:.brə vs. zi:b.rə)	0

☐ Keep manual syllabification

* Check this box to maintain manually inserted syllable boundaries. If the box is unchecked and the data is already parsed, running this macro will overwrite the existing parsing.

☐ Select data manually

Figure 5: Syllabification parameters

	Trigger	Tier	Position	Process	Result
1	[+STRID][+STRID]	Features	Coda	Vowel epenthesis	ə
2	Unstressed vowel	CV		Vowel reduction	ə
3	Sonority decrease	Sonority	Onset	Vowel epenthesis	ə

Table 3: Post-prosody transcription rules

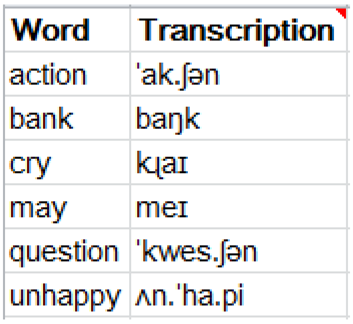
The basic sites of syllable boundaries can be adjusted by a set of binary parameters, which handle various cases, such as consonant sequences (e.g., whether /dɪspleɪ/ 'display' should be parsed as dɪs.pleɪ or dɪ.spleɪ). The system currently has 10 built-in parameters, which can be switched on and off according to the properties of the examined language (Figure 5). Some of the parameters require phones to be recognized as vowels or consonants. This information is also specified in CPA's phonetic table (Figure 4). For example, if the *Complex onset > Coda* parameter is switched on, consonant sequences will be parsed as complex onsets (dɪ.spleɪ). If the parameter is switched off, consonant sequences will be split between coda and onset positions (dɪs.pleɪ).

When two parameters are potentially in conflict, they can be ranked relative to each other by assigning different integer weights to them. For example, if the *Onset* parameter is on, onsetless syllables will be dispreferred (e.g., ˈmʌni → ˈmʌ.ni 'money'). This can be overridden (e.g., ˈmʌn.i) by switching on the *Coda maximization in stressed syllables* parameter and giving it a higher weight than the onset parameter (this requires that stress would be marked on the word before running syllabification).

4.3 Stress Assignment

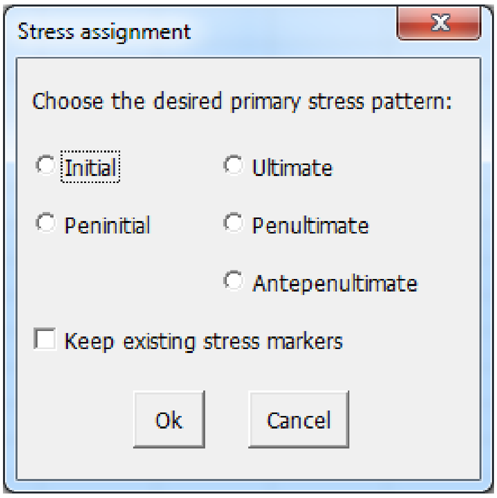
When the phonetic transcription requires modifications due to processes related to stress (e.g., reduction of unstressed vowels), stress markers should be added to the phonetic word forms. The stress assignment component of the software takes as input a vector of syllabified words and the desired stress pattern. The output is a vector of syllabified words with stress markers inserted at the appropriate positions (e.g., for the input word ak.ʃən 'action' and penultimate stress pattern, the output will be ˈak.ʃən; Figure 6).

The software has five built-in stress patterns (at present, only primary stress is handled): Initial, Peninitial, Ultimate, Penultimate, and Antepenultimate (Figure 7). For languages with a non-fixed stress pattern (e.g., English), this procedure can be used for applying the most frequent stress pattern. Manual corrections can be made afterwards. If stress position depends on the number of syllables, it is possible to run stress assignment multiple times, starting with the rule for the longer words. Checking the 'Keep existing stress markers' option will prevent stress rules for shorter words from applying to longer words, for which stress has been assigned already.



Word	Transcription
action	ˈak.ʃən
bank	baŋk
cry	kɻaɪ
may	meɪ
question	ˈkwes.ʃən
unhappy	ʌn.ˈha.pi

Figure 6: Phonetic word forms with stress



Stress assignment

Choose the desired primary stress pattern:

○ Initial ○ Ultimate

○ Peninitial ○ Penultimate

○ Antepenultimate

□ Keep existing stress markers

Figure 7: Stress parameters

4.4 Post-Prosody Transcription

This components modifies phonetic word forms according to phonological rules related to prosodic structure. It takes as input a vector of phonetic word forms, a table of post-prosody transcription rules (Table 3), and a phonetic table. The procedure applies the transcription rules in successive order to the list of words.

The table of post-prosody transcription rules has five fields (Table 3): (1) Trigger: the phonological structure triggering the required modification. A trigger can be a specific element or a sequence of elements defined in the phonetic table (e.g., [+STRID][+STRID] stands for a sequence of two stridents such as /s/ and /z/). In addition, there are several types of special pre-defined triggers: The *Sonority decrease*, *Sonority increase*, and *Sonority plateau* triggers handle phone sequences in which the sonority level decreases, increases, or remains unchanged, respectively (see Figure 4). The *No vowel* trigger handles syllables with no vowels. The *Unstressed vowel* trigger handles vowels in unstressed syllables.

(2) Tier: the phonological tier relevant to the trigger. *Features* tier is used with phonological features triggers (e.g., [+STRID]), while *CV* tier is used with *No vowel* and *Unstressed vowel* triggers. *Sonority* tier is used with all sonority-related triggers.

(3) Position: for triggers applying to consonants (sonority and feature triggers), this field indicates the prosodic position (*Onset* or *Coda*) in which the trigger must be found in order to trigger the modification.

(4) Process: the type of modification applied to phonetic word forms in which the trigger is found. Currently, the software can perform two types of modifications: *Vowel epenthesis* inserts a vowel to correct ill-formed sequences, and *Vowel reduction* replaces unstressed vowels with a default neutral vowel.

(5) Result: this field specifies inserted elements (epenthetic vowels and neutral vowels).

The following examples demonstrate the application of post-prosody rules. Rule 1 in Table 3 inserts an epenthetic ə to break sequences of two stridents in coda position (e.g., makss → maksəs 'Max's', where *makss* is the output of the pre-prosody transcription, which converted *M* to *m* and *x* to *ks*, and deleted the apostrophe in Max's). Rule 2 in Table 3 replaces vowels in unstressed syllables by ə (e.g., ˈe.le.fant → ˈe.lə.fənt 'elephant', where ˈe.le.fant is the result of pre-prosody transcription, syllabification and assignment of antepenultimate stress to elephant).

5 Discussion

This paper describes a system of text-to-phonetics conversion. The system is incorporated in a general-purpose linguistic software that includes tools for building dictionaries, as well as corpus analysis functions. Thus, the described system can help studying the phonological properties of text corpora and it is also useful for creating resources for under-resourced languages. For example, it was used for creating a phonological dictionary for Hebrew (Gafni, 2019). In addition, the linguistic model of the software, by itself, can be used as a research and educational tool. The pre-prosody transcription tool, in particular, can be used for exploring and demonstrating the effect of rule-ordering – a common practice in theoretical phonology. In fact, the studied language need not have a writing system at all; the input corpus can be a list of hypothesized phonological underlying representations, and the transcription rules can be phonological rules transforming the underlying representations to surface representations.

In addition, the linguistic model can be used for calculating indices of linguistic complexity by assessing the proportion of words that have regular spelling in a given language and the number of deterministic rules needed to capture the patterns of orthographic regularity in a language. Such measures of complexity can be valuable for literacy education (e.g., Smythe et al., 2008).

It should be noted that the described system is still under development. At its current state, the transcription system can perform perfectly on completely regular orthographies with a fixed stress pattern. Several planned improvements will allow the system to handle more complex cases. For example, the stress assignment component should handle secondary stress and stress rules that are sensitive to syllable weight. In addition, the post-prosody transcription should include more options, such as referring to pretonic syllables, which are relevant sites for certain phonological processes like vowel reduction in Russian (Asherov et al., 2016).

Furthermore, the generalizability of the system can greatly improve by adding machine learning procedures, such as sequence-to-sequence models with greedy decoding (Chae et al., 2018). This will allow the system to generate rules automatically based on examples. It will also be able to handle cases of homography (e.g., whether *wind* should be transcribed /wɪnd/ (noun) or /waɪnd/ (verb)) by analyzing token frequency and contextual effects (syntax and semantics). Such improvements will make the transcription system more powerful and reliable.

Two Discourse Tree - Based Approaches to Indexing Answers

Boris Galitsky[1] **and Dmitry Ilvovsky**[2]
[1]Oracle Inc. Redwood Shores CA
[2]National Research University Higher School of Economics
boris.galitsky@oracle.com; dilvovsky@hse.ru

Abstract

We explore anatomy of answers with respect to which text fragments from an answer are worth matching with a question and which should not be matched. We apply the Rhetorical Structure Theory to build a discourse tree of an answer and select elementary discourse units that are suitable for indexing. Manual rules for selection of these discourse units as well as automated classification based on web search engine mining are evaluated concerning improving search accuracy. We form two sets of question-answer pairs for FAQ and community QA search domains and use them for evaluation of the proposed indexing methodology, which delivers up to 16 percent improvement in search recall.

1 Introduction

Much online content is available via question-answer pairs such as frequently-asked questions stored on customer portals or internal company portals. Question-answer pairs can be an efficient manner to familiarize a user with content. In some cases, autonomous agents (chatbots) can import such question-answer pairs in order to field user questions.

But such question-answer pairs can contain content that is not central to a topic of an answer. For example, content can include text that is irrelevant or misleading, non-responsive to the particular question, or is neutral and not helpful. If irrelevant text is indexed by a keyword-based search engine, the precision of the search engine is lowered. Moreover, an autonomous agent attempting to answer a user question based on erroneously-indexed text may answer the question incorrectly, resulting in lowered user confidence in the agent. Despite the fact that standard relevance techniques such as ontology, keyword frequency models and separate discourse features (Chali et al., 2009; Jansen et al., 2014) can be applied to solve this problem, a solution is needed for identifying informative parts from all text.

In this paper we propose a new discourse-based approach to determine informative parts of an answer. This approach accesses a body of text including fragments and creates a searchable index including multiple entries, each entry corresponding to a selected fragment. We propose two different methods of fragment selection based on rules and on classification model respectively.

The paper structure is as follows. In Section 2 we introduce the methodology of ***rhetorical anatomy of an answer*** and present an example of that. In Section 3 we propose two Q/A algorithms which is the core part of our approach. In Section 4 we describe and discuss evaluation for the question answering task on a few datasets that were compiled for this research.

2 Rhetoric Anatomy of an Answer

2.1 RST and Discourse Trees

Discourse analysis was proved to be useful in different aspects of question-answering: answer extraction (Zong et al., 2011), modeling rationale in design questions (Kim et al., 2004), query expansion based on relations between sequential questions (Sun and Chai, 2007), etc.

Discourse trees (DT) originate from Rhetorical Structure Theory (RST, Mann and Thompson, 1988). RST models a logical organization of text, relying on relations between parts of text. RST simulates text coherence by forming a hierarchical, connected structure of texts via ***discourse trees***.

Rhetoric relations are split into the classes of coordinate and subordinate; these relations hold across two or more text spans and therefore implement coherence. These text spans are called elementary discourse units (EDUs). The leaves of a discourse tree correspond to EDUs, the contiguous atomic text spans. Adjacent EDUs are connected by coherence relations (e.g., attribution, sequence), forming higher-level discourse units.

The term "nuclearity" in RST refers to which text segment, fragment, or span, is more central to an author's purpose. A "***nucleus***" refers to a span of text that is more central to an author's purpose than a "***satellite***", which is less central to the topic.

More particularly, we use the determined EDUs of a discourse tree for a body of text and the relations between the EDUs to determine which EDUs should be indexed for search. Different rhetorical relations (e.g., *elaboration*, *contrast*, etc.) can employ different rules.

In general, we hypothesize that a satellite may express a detail of information that is unlikely to be explicitly queried by a user (Galitsky, 2015; Jasinskaja and Karagjosova, 2017).

2.2 Example of Analysis

Let's illustrate our analysis with a question-answer pair and a discourse tree for an answer.

Q: *How should I plan to pay for taxes resulting from converting to a Roth IRA?*
A: *To help maximize your retirement savings, it's generally a good idea to consider not using the proceeds from the conversion to pay the resulting tax costs. Instead, you should consider using cash or other savings held in nonretirement accounts. Using retirement account funds to pay the taxes will reduce the amount you would have available to potentially grow tax-free in your new Roth IRA. Additionally, if you are under 59½, using funds from your retirement account could result in an additional 10% tax penalty, which may significantly reduce the potential benefit of conversion.*

The discourse tree for the answer is shown in Figure 1, and elementary discourse units selected for indexing are circled in green.

The answer could be obtained from a source such as a Frequently Asked Questions (FAQ) database, or a question-answer index. A question-answer index can include multiple questions and corresponding answers. But some fragments in each answer are more informative to answering the corresponding question than other fragments. For example, the phrase "*it is generally a good idea*" adds little to the answer, whereas "*consider not using the proceeds from the conversion*" is informative to the user who posed the original question. Each answer in the question-answer index may provide additional insight in terms of additional questions that can be answered, which are in turn indexed, increasing the usefulness of the data. For example, "*at what age do I pay a penalty for using retirement funds?*" could be answered by the text (e.g., "*age 59 ½*"). We can determine informative text from a body of text and such additional questions that can be answered from the body of text.

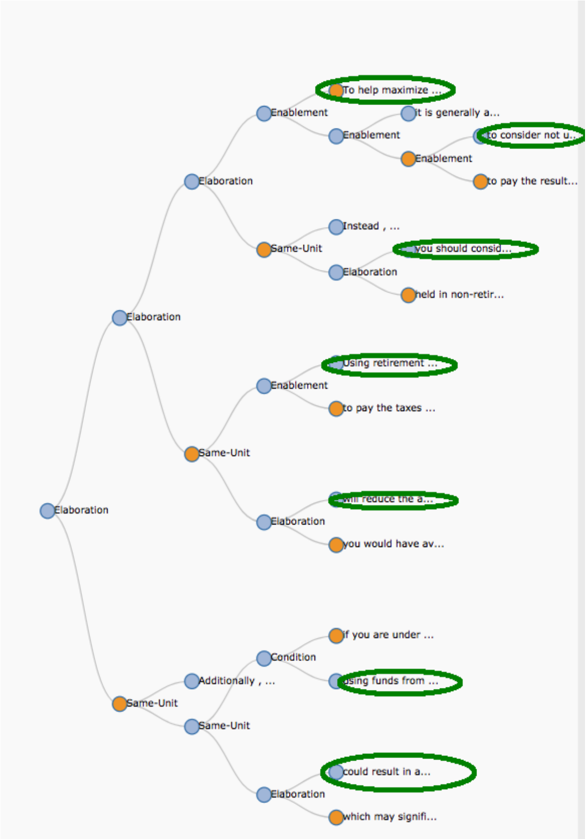

Figure 1: Discourse tree for an answer with the EDUs selected for indexing

2.3 Indexing Rules for Different Rhetorical Relations

The above hypothesis that only EDUs that are ***nucleus*** of rhetoric relations should be indexed and all ***satellite*** EDUs should not be selected for indexing is illustrated by the "*elaboration*" relationship where the nucleus expresses more important information than satellite. But the general rule described above can be subject to certain exceptions. For example, under certain conditions, the "*contrast*" relation can require indexing of the satellite rather than the nucleus. Additionally, for the “*same-unit*” and “*joint*” relations, both the nucleus and the satellite are indexed. Different rhetoric relations can have different rules, as shown in Table 1 below.

3 The Methodology of Question Answering

The developed methodology of the DT-based analysis of answers is going to be applied in the following way, given an index of Q/A pairs:

1. Search a user query against an index of available questions;
2. If no or too few results, generate additional search queries from the answers indexed by proposed approach;
3. If still no or too few results, search against original answers.

We now focus on 2) and consider two methods for indexing answers: **rule-based** and **classification-based**.

Relation	**Example**	**Indexing rule**
Elaboration	To achieve some state [nucleus] | *do this and that* [satellite]	Nucleus
Enablement	A query may be of the form “*how to achieve some state?*” but less likely be of the form “*what can I achieve doing this and that?*”	Nucleus
Condition	A query may be of the form “*how to achieve some state?*” but less likely of the form “*what can I achieve doing this and that?*”	When the question is of the type “***when/where/under what condition …***”, index the ***if*** part (the satellite).
Contrast	Index the nucleus. The satellite includes facts which are unusual, unexpected.	
Same-Unit, Joint	Index both nucleus and satellite because of the symmetric relationship of same-unit.	

Table 1: Indexing rules for rhetorical relations

Once our method construct the indexes, we can build the online search algorithm which combines default functionality provided by the Lucene search engine and syntactic similarity between answer and a query. Search results candidate are selected by Lucene and then matched with the query via finding a maximal common sub-parse tree (Galitsky, 2017).

3.1 Rule-Based Indexing

We take question-answer pairs and create, for each answer, a discourse tree using RST-parser (Surdeanu et al., 2015; Joty et al., 2013). For each non-terminal node in each answer, we then identify a rhetorical relationship associated with the non-terminal node and label each terminal node associated with the non-terminal node as either a ***nucleus*** or a ***satellite***. Then we apply a set of rules (see Table 1) associated with the rhetorical relationships and select, based on the rule, one or more of the fragment associated with the nucleus or the fragment associated with the satellite. Finally, we create a ***searchable index*** of additional questions which includes multiple entries corresponding to one of the selected fragments for the answers.

3.2 Classification-Based Indexing

We use machine learning to learn rules such as those depicted in Table 1. A machine learning problem is formulated as a classification problem that classifies EDUs into a first class that is suitable for indexing (i.e., ***informative***) and forming alternative questions for an answer and a second class that is not suitable for indexing (i.e., ***not informative***).

To accumulate training question-answer pairs with marked answers, we ran selection of queries against short texts. Because longer queries are necessary to assure a corresponding match is nontrivial, we used public question-answer Yahoo! Answers dataset (Webscope, 2017). More specifically, questions from this dataset were formed from a first sentence of the dataset and executed as queries by Microsoft Cognitive Services (Bing Search engine API). Search results which are short texts (4-6 sentences) were selected as such texts suitable for parsing and discourse analysis. Matched fragments of these texts were taken as elements of the training set. Such fragments from the top ten or more pages of search result formed a positive dataset, i.e. informative fragments. For the negative dataset, fragments with matched keywords from the set of lower ranked (100-1000+) search results pages were taken, as these results are assumed to be less relevant.

We applied SVM tree kernel learning (Moschitti, 2006; Severyn and Moschitti, 2012) to train the model since this algorithm is capable to learn directly on a parse tree structure.

4 Datasets and Evaluation

We used a few datasets to evaluate the contribution of our methodology to search quality.

Yahoo! Answer (Webscope, 2017) subset of question-answer pairs with broad topics where main question is a single sentence (possibly, compound) with ten-fifteen keywords. The dataset includes various domains, and domain knowledge coverage is shallow.

Financial questions[1] scraped from Fidelity.com. This dataset demonstrates how search relevance improvement may occur in a vertical domain with reasonable coverage.

Car repair conversations[2] selected from www.2carpros.com including car problem descriptions and recommendation on how to rectify them. These pairs were extracted from dialogues as first and second utterances.

For each search session, we only consider the first results and reject the others. For all these datasets we assume that there is only one correct answer (from the Q/A pair) and the rest of answers are incorrect.

Evaluation results for the proposed methodology are presented in Table 3. Recall of the baseline search is on average 78% including the improvement by 8% by using syntactic generalization on top of Lucene search (not shown). The relevance of this system is determined by many factors and is therefore not very insightful, so we focus at the change in recall (Δ), from this search system to the one extended by the proposed approach.

Dataset	**Question/Answer**	**Total #**	**# generated AQ / # sent**	**Avg # words**
Yahoo! Answers	**Q**	3700	5.5	12.3
	A	3700	8.1	124.1
Fidelity	**Q**	500	3.4	6.2
	A	500	6.2	118.0
Car Repair	**Q**	10000	4.2	5.5
	A	10000	7.0	141.3

Table 2: Dataset statistics

The proposed method delivers about 13 % improvements in the recall have the precision almost unaffected, for the Nucleus/Satellite rules. There is a further 3% improvement by using the automated classifier of EDUs. Since the deployment of such classifier in a domain-dependent manner is associated with substantial efforts, it is not necessarily recommended when this 3% improvement in search accuracy is not critical.

We also compare performance of the proposed search on the extended framework derived from SQuAD 2.0 dataset (Rajpurkar et al., 2018) and applied to *why?* and how-*to?* questions. Instead of addressing a question to a single Wikipedia text as standard evaluations do, we run them against all text. We use our approach vs neural extractive reading comprehension one and exceed recall of BiDaf (Gardner et al., 2017) and DeepPavlov (Burtsev et al., 2018) by at least 8% with the search engine trained on our corpus (Table 4).

Dataset / Method	**Baseline**		**Nucleus /Satellite rules,** improvement		**Classification-based,** improvement	
	R	P	ΔR, %	ΔP, %	ΔR, %	ΔP, %
Yahoo! Answers	79	74	+12.5	+0.1	+14	-0.04
Fidelity	77	80	+10	-0.1	+6	+0.1
Car Repair	79	81	+**16**	+0.0	+**18**	+0.0

Method	**Recall**	**Precision**
BiDaf (AllenNLP)	68	71
DeepPavlov	67	72
Rule-based	75	71
Classification-based	**76**	71

Table 4: Evaluation results for SQuAD dataset

5 Conclusions

In the search engines and chat bot industry, whole texts are usually indexed for search. Because of that, frequently irrelevant answers are delivered because their insignificant keywords (the ones providing auxiliary information and not central for the document) were matched. To overcome this well-known problem, only questions from Q/A pairs are indexed, which dramatically decreases the search recall. To address this limitation of indexing, we proposed and evaluated our approach of indexing only those EDUs of text which are determined to be important (and therefore form alternative questions). This substantially improves the recall in applications such as FAQ search where only questions of Q/A pairs are indexed.

Discourse-Based Approach to Involvement of Background Knowledge for Question Answering

Boris Galitsky[1] **and Dmitry Ilvovsky**[2]

Abstract

We introduce a concept of a *virtual discourse tree* to improve question answering (Q/A) recall for complex, multi-sentence questions. Augmenting the discourse tree of an answer with tree fragments obtained from text corpora playing the role of ontology, we obtain on the fly a canonical discourse representation of this answer that is independent of the thought structure of a given author. This mechanism is critical for finding an answer that is not only relevant in terms of questions entities but also in terms of inter-relations between these entities in an answer and its style. We evaluate the Q/A system enabled with virtual discourse trees and observe a substantial increase of performance answering complex questions such as Yahoo! Answers and www.2carpros.com.

1 Introduction

In spite of the great success of search technologies, the problem of leveraging background knowledge is still on the agenda of search engineering, for both conventional and learning-based systems. Background knowledge ontologies are difficult and expensive to build, and knowledge graphs – based approaches usually have a limited expressiveness and coverage. In this study we explore how a discourse analysis (which is domain-independent) can substitute certain features of ontology-based search. There are few popular discourse theories describing how Discourse Trees (DT) can be constructed from the text. In our work we used Rhetorical Structure Theory (RST, Mann and Thompson, 1988).

Ontologies are in great demand for answering complex, multi-sentence questions with a precise answer in such domain as finance, legal, and health. In the educational domain this type of questions is referred to as *convergent*: answers to these types of questions are usually within a very limited range of acceptable accuracy. These may be at several different levels of cognition including comprehension, application, analysis, or ones where the answerer makes inferences or conjectures based on material read, presented or known. Answering convergent questions is an underexplored Q/A domain that can leverage discourse analysis (Kuyten et al, 2015).

Discourse trees have became a standard for representing how thoughts are organized in text, in particular in a paragraph of text, such as an answer. Discourse-level analysis has been shown to assist in a number of NLP tasks where learning linguistic structures is essential (Louis et al., 2010; Lioma et al., 2012). DTs outline the relationship in between entities being introduced by an author. Obviously, there are multiple ways the same entities and their attributes are introduced, and not all rhetoric relations that hold between these entities occur in a DT for a given paragraph.

When DTs are used to coordinate questions and answers, we would want to obtain an "ideal" DT for an answer, where all rhetoric relations between involved entities occur. To do that, we need to augment an actual (available) DT of answer instance with a certain rhetorical relations which are missing in the given answer instance but can be mined from text corpora or from the web. Hence to verify that an answer *A* is good for a given question *Q*, we first verify that their DTs (*DT-A* and *DT-Q*) agree and after that we usually need to augment the *DT-A* with fragments of other DTs to make sure all entities in *Q* are communicated (addressed) in augmented *DT-A*.

Hence instead of relying on an ontology that would have definitions of entities which are missing in a candidate answer we mine for the rhetorical relations between these entities online. This procedure allows us to avoid an offline building of bulky and costly ontologies. At the same time, the proposed approach can be implemented on top of a conventional search engine.

The paper structure is as follows. In Section 2 we compare the related work with our proposal. In Section 3 we introduce the concept of a ***virtual discourse tree*** and present a number of examples illustrating how they can be used and constructed. In Section 4 we propose Q/A filtering algorithm which is the core part of our approach. In Section 5 we describe and discuss evaluation for the question answering task on a few datasets that were compiled for this research.

2 Related Work

2.1 Discourse and IR

Typically, every part in most coherent text has some plausible reason for its presence, some function that it performs to the overall semantics of the text. Rhetorical relations, e.g. *contrast*, *cause*, *explanation*, describe how the parts of a text are linked to each other. Rhetorical relations indicate the different ways in which the parts of a text are linked to each other to form a coherent whole.

Marir and Haouam (2004) introduced a thematic relationship between parts of text using RST based on cue phrases to determine the set of rhetorical relations. Once these structures are determined, they are put in an index, which can then be searched not only by keywords, as traditional information retrieval systems do, but also by rhetorical relations.

It was observed (Teufel and Moens, 2002) that different rhetorical relations perform differently across evaluation measures and query sets. The four rhetorical relations that improve performance over the baseline consistently for all evaluation measures and query sets are: *background, cause-result, condition* and *topic-comment*. Topic-comment is one of the overall best-performing rhetorical relations, which in simple terms means that boosting the weight of the topical part of a document improves its estimation of relevance. Regretfully these relations are relatively rare.

Sun and Chai (2007) investigated the role of discourse processing and its implication on query expansion for a sequence of questions in scenario-based context Q/A. They consider a sequence of questions as a mini discourse. An empirical examination of three discourse theoretic models indicates that their discourse-based approach can significantly improve Q/A performance over a baseline of plain reference resolution.

In a different task (Wang et al, 2010) authors parse Web user forum threads to determine the discourse dependencies between posts in order to improve information access over Web forum archives.

Suwandaratna and Perera (2010) present a re-ranking approach for Web search that uses discourse structure. They report a heuristic algorithm for refining search results based on their rhetorical relations. Their implementation and evaluation is partly based on a series of ad-hoc choices, making it hard to compare with other approaches. They report a positive user-based evaluation of their system for ten test cases.

Since rhetoric parsers for English (Joty et al., 2013, Surdeanu, 2015) have become more available and accurate, their application in search engine indexing is becoming more feasible. Precision and recall of search systems ignore discourse level information and users do not find products, services and information they need. It was shown that discourse features are valuable for passage re-ranking (Jansen et al., 2014). DTs have been also found to assist in answer indexing to make search more relevant: query keyword should occur in nucleus rather than a satellite of a rhetoric relation (Galitsky et al., 2015). In this study we go beyond leveraging discourse features and construct DTs from actual candidate answers and also virtual DTs for necessary background knowledge.

2.2 Discourse Analysis and Entities

At any point in the discourse, some entities are considered more salient than others (occurring in nucleus parts of DTs), and consequently are expected to exhibit different properties. In Centering Theory (Poesio et al., 2004), entity importance determines how they are realized in an utterance, including pronominalized relation between them.

Barzilay and Lapata (2008) automatically abstracts a text into a set of entity transition sequences and records distributional, syntactic, and referential information about discourse entities. The authors formulated the coherence assessment as a learning task and show that their entity-based representation is well-suited for ranking-based generation and text classification tasks.

Nguyen and Joty (2017) presented a local coherence model based on a convolutional neural network that operates over the distributed representation of entity transitions in the grid representation of a text, can model sufficiently long entity transitions and can incorporate entity-specific features without losing generalization power.

Kuyten et al., (2015) developed a search engine that leverages the discourse structure in documents to overcome the limitations associated with the bag-of-words document representations in information retrieval. This system does not address the problem of rhetoric coordination between *Q* and *A*, but given a *Q*, this search engine can retrieve both relevant A and individual statements from A that describe some rhetorical relations to the query.

Our approach is to discover ontological relations between entities on the fly, finding document fragments where a rhetorical relation links these entities. Once all such text fragments are found, we add the respective DT fragments as virtual DTs to our main answer DT.

3 Answering Questions via Discourse Trees

3.1 Virtual Discourse Tree

The baseline requirement for an *A* to be relevant to *Q* is that entities (*E*) of *A* cover the entities of *Q*:

$$E\text{-}Q \subseteq E\text{-}A. \qquad (1)$$

Naturally, some *E-A* (entities in an answer) are not explicitly mentioned in *Q* but are needed to provide a recommendation yielded by *Q* (recipe-type *A*).

The next step for an *A* to be good for *Q* is to follow the logical flow of *Q*. Since it is hard to establish relations between entities *E*, which are domain dependent, we try to approximate these relations by using logical flow of *Q* and *A*, expressible in domain-independent terms, such as rhetorical relation. Hence we require a certain correspondence between DT-Q and DT-A, considering additional labels for DT nodes by ***entities*** (we denote such DT as EDT):

$$EDT\text{-}Q \sim EDT\text{-}A. \qquad (2)$$

However a common case is that some entities *E* are not explicitly mentioned in *Q* but instead are assumed. Moreover, some entities in *A* used to answer *Q* do not occur in *A* but instead are substituted by more specific or general entities do. How would we know that these more specific entities are indeed addressing issues from *Q*? We need some external, additional source which we call ***virtual*** *EDT-A* to establish these relationships.

This source contains the information on inter-relationships between E which is omitted in *Q* and/or *A* but is assumed to be known by the interlocutor. For an automated Q/A system, we want to obtain this knowledge at the discourse level:

$$EDT\text{-}Q \sim EDT\text{-}A + virtual\ EDT\text{-}A. \qquad (3)$$

3.2 Discourse Trees for Answer and Question

We start with a simple example:

Q: *What is an advantage of electric car?*

A: *No need for gas.*

How can search engine figure out that *A* is a good one for *Q*? We have an abstract general-sense entity *advantage* and a regular noun entity *car*. We need to link explicit entities in *A* {*need, gas*}. Fragments of a possible *virtual EDT-A* are shown below:

Q: *[When driving the cruise control][the engine will turn off][when I want to accelerate ,][although the check engine light was off .] [I have turned on the ignition][and listen for the engine pump running][to see][if it is building up vacuum .] [Could there be a problem with the brake sensor under the dash ?] [Looks like there could be a little play in the plug.]*

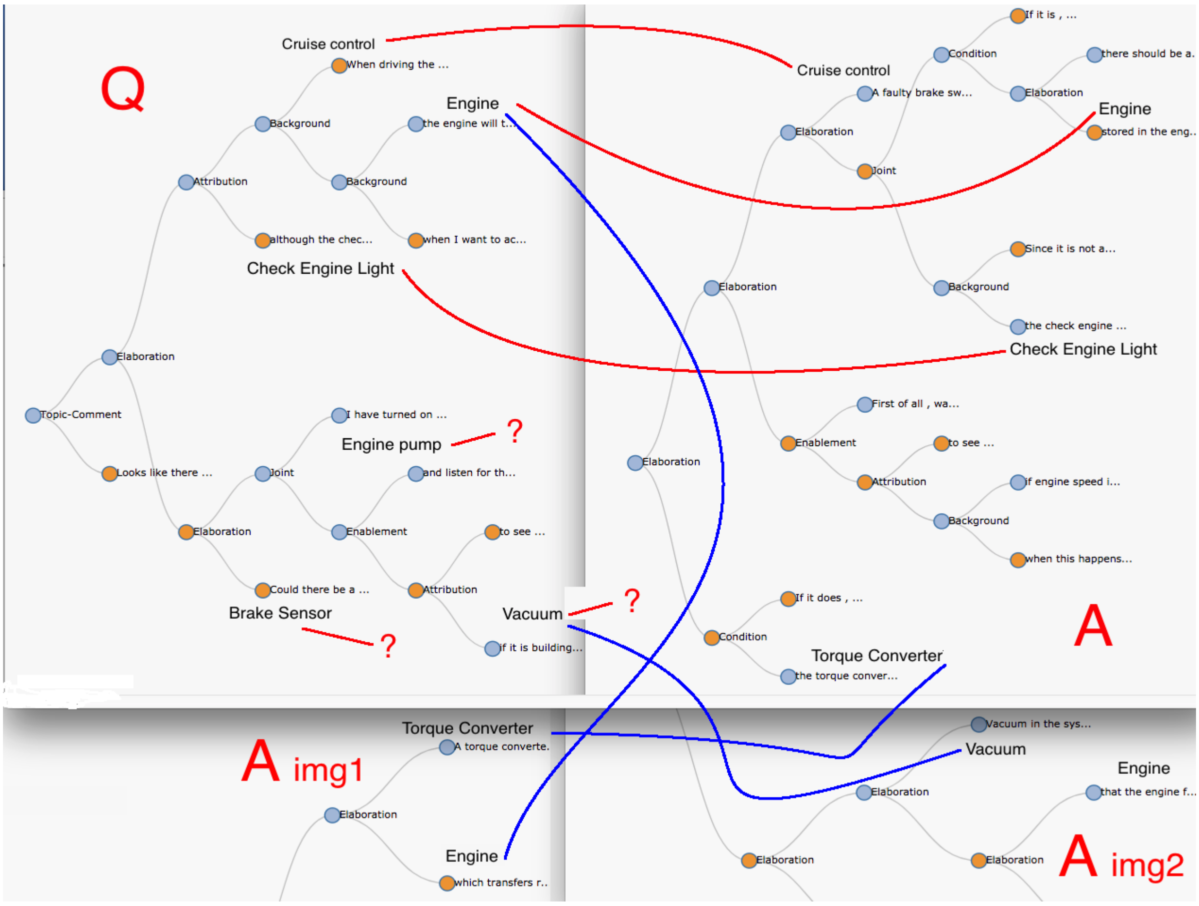

Figure 1: DTs of Q, A and imaginary $DT\text{-}A_{img1}$ and $DT\text{-}A_{img2}$

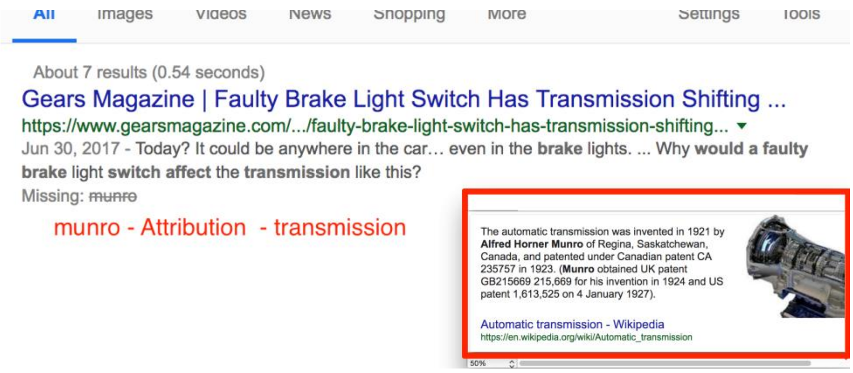

About 7 results (0.54 seconds)

Gears Magazine | Faulty Brake Light Switch Has Transmission Shifting ...

https://www.gearsmagazine.com/.../faulty-brake-light-switch-has-transmission-shifting...

Jun 30, 2017 - Today? It could be anywhere in the car… even in the **brake** lights. ... Why **would** a **faulty brake** light **switch affect** the **transmission** like this?

Missing: ~~munro~~

munro - Attribution - transmission

The automatic transmission was invented in 1921 by **Alfred Horner Munro** of Regina, Saskatchewan, Canada, and patented under Canadian patent CA 235757 in 1923. (**Munro** obtained UK patent GB215669 215,669 for his invention in 1924 and US patent 1,613,525 on 4 January 1927).

Automatic transmission - Wikipedia

https://en.wikipedia.org/wiki/Automatic_transmission

Figure 2: How Virtual DTs would enable Google search to explain missing keywords

A: *[A faulty brake switch can effect the cruise control .] [If it is,][there should be a code][stored in the engine control module .] [Since it is not an emissions fault ,][the check engine light will not illuminate .] [First of all, watch the tachometer][to see][if engine speed increases 200 rpm][when this happens .] [If it does ,][the torque converter is unlocking transmission .]*

We do not need to know the details concerning how this *Enablement* occurs, we just need evidence that these rhetorical links exist. We could have used semantic linked between entities but for that we would need a domain-specific ontology.

Let us explain how a match between a *Q* and an *A* is facilitated by DTs (Fig. 1). *A* explains a situation and also offer some interpretation, as well as recommends a certain course of action. *A* introduces extra entities which are not in *Q*, and needs to involve background knowledge to communicate how they are related to *E-Q*. We do it by setting a correspondence between *E-Q* and *E-A*, shown by the horizontal curly (red) arcs.

Notice that some entities E_0 in *Q* are *unaddressed*: they are not mentioned in *A*. E_0-*Q* includes {*Engine pump*, *Brake sensor* and *Vacuum*}. It means that either *A* is not fully relevant to *Q* omitting some of its entities E_0 or it uses some other entities instead. Are E_0-*Q* ignored in *A*? To verify the latter possibility, we need to apply some form of background knowledge finding entities E_{img} which are linked to both E_0-*Q* and *E-A*.

It is unclear how *E-A = Torque Convertor* is connected to *Q*. To verify this connection, we obtain a fragment of text from Wikipedia (or another source) about *Torque Convertor*, build *DT*-A_{img1} (shown on the left-bottom of Fig. 1) and observe that it is connected with *Engine* via rhetoric relation of *elaboration*. Hence we confirm that *E-A = Torque Convertor* is indeed relevant for *Q (a vertical blue arc).*

It is also unclear how *E-Q pump* is addressed in *Q*. We find a document on the web about *Engine Pump* and *Vacuum* and attempt to connect them to *E-A*. It turns out that *DT*-A_{img2} connects *Vacuum* and *Engine* via *elaboration*.

Hence the combined *DT-A* includes real *DT-A* plus *DT*-A_{img1} and *DT*-A_{img2} . Both real and virtual DTs are necessary to demonstrate that an answer is relevant by employing background knowledge in a domain independent manner: no offline ontology construction is required.

Search relevance is then measured as the inverse number of unaddressed E_0–*Q* once *DT-A* is augmented with virtual *DT*-A_{img} . This relevance is then added to a default one.

Fig. 2 shows an example how Virtual DT component would improve a web search. Currently, search engines show certain keywords they do not identify in a given search result. However, it is possible to indicate how these keywords are relevant to the search result by finding documents where these unidentified keywords are rhetorically connected with the ones occurring in the query. This feature would naturally improve the answer relevance on one hand and provide an "explainability" for the user on how her keywords are addressed in the answer. In the default search, *munro* is missing. However, by trying to rhetorically connect *munro* with the entities in the question, the Virtual DT approach finds out that *Munro* is an

4 Question Answering Approach

4.1 Question Answering Filtering Algorithm

Given a *Question*, we outline an algorithm (Algorithm 1) that finds the most relevant *Answer* such that it has as much of *E-Q* addressed by *E-A*, having a source for virtual DTs (background knowledge) *B*.

Discourse trees are constructed automatically using state-of-the-art RST-parser (Surdeanu et.al, 2015).

4.2 Learning on Q/A Pairs

Besides this algorithm, we outline a machine learning approach to classify <*EDT-Q, EDT-A*> pair as correct or incorrect. The training set should include good Q/A pairs and bad Q/A pairs. Therefore a DT-kernel learning approach (SVM TK, Joty and Moschitti, 2014, Galitsky, 2017, 2018) is selected which applies SVM learning to a set of all sub-DTs of the DT for Q/A pair. Tree kernel family of approaches is not very sensitive to errors in parsing (syntactic and rhetoric) because erroneous sub-trees are mostly random and will unlikely be common among different elements of a training set.

Learning framework is available on our GitHub repository.

5 Evaluation

5.1 Experiments on "Convergent" Q/A Datasets

Traditional Q/A datasets for factoid and non-factoid questions, as well as SemEval and neural Q/A evaluations are not suitable since the questions are shorter and not as complicated to observe a potential contribution of discourse-level analysis. For our first evaluation, we formed two convergent Q/A sets.

Yahoo! Answer [1] set of question-answer pairs with broad topics. Out of the set of 140k user questions we selected 3300 of those, which included three to five sentences. Answers for most questions are fairly detailed so no filtering by sentence length was applied to the answers.

Car repair conversations (available online [2]) selected from www.2carpros.com including 9300 Q/A pairs of car problem descriptions vs recommendation on how to rectify them. These pairs were extracted from dialogues as first and second utterances so that a question is one to three sentences and answer is three to six sentences in length. Each dialogue is a comprehensive, cohesive sequence of questions and problem solving recommendations. Most recommendations include a set of conditions to check and actions to perform, not necessarily in the same terms as the problem was formulated. Therefore, traditional search engineering based on keyword statistics performs poorly on this dataset; both semantic and syntactic similarities between Q and A are low.

|EDT-Q∩EDT-A|	66.3	64.1	65.1	66.8	60.3	63.4
|EDT-Q∩EDT-A +EDT-A_{imgi}|	76.3	78.1	77.2± 3.4	72.1	72.0	72.0± 3.6
SVM TK for <EDT-Q, EDT-A +EDT-A_{imgi}>	83.5	82.1	82.8± 3.1	80.8	78.5	79.6± 4.1
Human assessment of SVM TK for <EDT-Q∩EDT-A +EDT-A_{imgi}>	81.9	79.7	80.8± 7.1	80.3	81.0	80.7± 6.8

Table 1: Evaluation results on convergent Q/A datasets

For each of these sets, we form the positive one from actual Q/A pairs and the negative one from $Q/A_{similar\text{-}entities}$: $E\text{-}A_{similar\text{-}entities}$ has a strong overlap with E-A, although $A_{similar\text{-}entities}$ is not really correct, comprehensive and exact answer. Hence Q/A is reduced to a classification task measured via precision and recall of relating a Q/A pair into a class of correct pairs.

Top two rows in Table 1 show the baseline performance of Q/A and demonstrate that in a complicated domain transition from keyword to

[1] https://webscope.sandbox.yahoo.com/catalog.php?datatype=l

[2] https://github.com/bgalitsky/relevance-based-on-parse-trees/examples/CarRepairData_AnswerAnatomyDataset2.csv.zip.

matched entities delivers more than 13% performance boost. For the baseline we used standard implementation of Lucene search engine based on matching keywords.

The bottom three rows show the Q/A quality when discourse analysis is applied. Assuring a rule-based correspondence between DT-A and DT-Q gives 13% increase over the baseline, and using virtual DT gives further 10%. Finally, proceeding from rule-based to machine learned Q/A correspondence (SVM TK) gives the performance gain of about 7%.

The difference between the best performing *SVM TK for <EDT-Q ∩ EDT-A+EDT-A*$_{img}$*i>* row and the above row is only the machine learning algorithm: representation is the same.

The bottom row shows the human evaluation of Q/A on a reduced dataset of 200 questions for each domain. We used human evaluation to make sure the way we form the training dataset reflects the Q/A relevance as perceived by humans. This is important to confirm, in particular, that the negative dataset includes unsatisfactory answers. For a 1/3 fraction of this dataset we measured Krippendorff's alpha measure for the inter-annotator agreement (two annotators) which exceeds 80%.

To summarize this experiment, the tree kernel learning of virtual discourse trees turned out to be a preferred approach. The contribution of virtual DTs might be insignificant for simpler, shorter, factoid questions when traditional measures of similarity between Q and A work well. However, we demonstrate that involvement of background knowledge via virtual DTs for complex convergent questions requiring entailment is significant.

5.2 Experiments on a Standard Q/A Dataset

We also compare the performance of virtual DT Q/A with neural extractive reading comprehension approaches (Table 2). We made this comparison on the *why?* and h*ow-to?* questions from SQuAD 2.0 (Rajpurkar et al., 2018), the dataset with unanswerable questions which look similar to answerable ones. In total 460 questions were selected.

Deep learning systems can often locate the correct answer to a question in a short text, but experience difficulties on questions for which the correct answer is not stated in the context. Rajpurkar et al. (2018) trained their system on SQuAD and evaluated on the unseen questions. Whereas a deep learning system gets 86% F1 on SQuAD 1.1, it achieves only 66% on SQuAD 2.0 where some questions should not be answered.

Approach	**F1**	**Reference**
BiDaf (Allen NLP) (Gardner et al., 2017)	64.8	Our experiments
DeepPavlov (Burtsev et al., 2018)	61.0	Our experiments
Microsoft Asia (Hu et al., 2018)	74.2	As reported by the authors (full dataset)
SVM TK for <EDT-Q, EDT-A +EDT-A$_{imgi}$>	73.3	Current study

Table 2: Evaluation results on the SQuAD 2.0 dataset

We applied the model trained on Yahoo!Answers and Car Repair to our subset of questions from SQuAD 2.0. Because most unanswerable questions contain entities or entity types which do not occur in text, virtual DT is a good means to handle such cases. At the same time, by the nature of neural learning, it is hard to learn to refuse to answer. The best performance on SQuAD 2.0 for the totality of questions, including much simpler ones than our formed 460 questions dataset, is achieved by (Hu et al., 2018) and exceeds our model by less than 1%.

The model of Hu et al. is specific to Wikipedia pages and the way questions are formulated, whereas our model learns once and for all which discourse structures is correlated with which forms of background knowledge. We believe this performance, achieved by training and testing on the same kind of Q/A dataset is comparable with the results of the general model of the current study with the focus on convergent *why/how to* questions.

6 Conclusions

Answering questions in the domain of this study is a significantly more complex task than factoid Q/A such as Stanford Q/A dataset, where it is just necessary to involve one or two entities and their parameters. To answer a "how to solve a problem" question, one needs to maintain the logical flow connecting the entities in the questions. Since some entities from *Q* are inevitably omitted, these would need to be restored from some background knowledge text about these omitted entities and the ones presented in *Q*. Moreover, a logical flow needs to complement that of the *Q*. The complexity of multi-sentence convergent questions, which was evaluated in, for example (Chen et al., 2017) is way below that one of a real user asking questions in the domains of the current study. Factoid, Wikipedia-targeted questions usually have fewer entities and simpler links between entities than the ones where virtual DT technique is necessary. At the same time, neural network – based approach require a huge training set of Q/A pairs which is rarely available in industrial, practical Q/A domains.

In spite of the great success of statistical and deep learning from a vast set of Q/A pairs, it is still hard to answer questions underrepresented in a training set. Most of the failures of learning approach occur when the user feels that the needed background knowledge is absent. The proposed technique does not require extensive training sets for all Q/A pairs which can be potentially encountered in real time. Instead, we consult necessary texts on demand in real time and avoid maintaining huge training sets on one hand and tackling extensive manually built ontologies on the other hand. Hence we propose a solution to one of the hardest and most sought after problem in AI of how to rely on background knowledge in industrial applications.

Domain-specific ontologies such as the ones related to mechanical problems with cars are very hard and costly to build. In this work we proposed a substitute via domain-independent discourse level analysis where we attempt to cover unaddressed parts of *DT-A* on the fly, finding text fragments in a background knowledge corpus such as Wikipedia. Hence we can do without an ontology that would have to maintain relations between involved entities.

The proposed virtual DT feature of a Q/A system delivers a substantial increase of performance answering complex convergent questions, where it is important to take into account all entities from a question. We observed that relying on rhetoric agreement between Q and A (matching their DTs) improves Q/A F1 by more than 10% compared to the relevance-only focused baseline. Moreover, employing virtual DTs gives us further 10% improvement.

Since we explored the complementarity relation between *DT-A* and *DT-Q* and proposed a way to identify virtual *DT-A* on demand, the learning feature space is substantially reduced and learning from an available dataset of a limited size such as car repair becomes plausible.

On a Chatbot Providing Virtual Dialogues

Abstract

We present a chatbot that delivers content in the form of virtual dialogues automatically produced from the plain texts that are extracted and selected from the documents. This virtual dialogue content is provided in the form of answers derived from the found and selected documents split into fragments, and questions that are automatically generated for these answers based on the initial text.

1 Introduction

Presentation of knowledge in dialogue format is a popular way to communicate information effectively. It has been demonstrated in games, news, commercials, and educational entertainment. Usability studies have shown that for information acquirers, dialogues often communicate information more effectively and persuade stronger than a monologue most of times (Cox et al., 1999, Craig et al., 2000).

We demo a chatbot that delivers content in the form of virtual dialogues automatically produced from plain texts extracted and selected from documents. Given an initial query, this chatbot finds documents, extracts topics from them, organizes these topics in clusters according to conflicting viewpoints, receives from the user clarification on which cluster is most relevant to her opinion, and provides the content for this cluster. This content is provided in the form of a virtual dialogue where the answers are derived from the found and selected documents split into fragments, and questions are automatically generated for these answers.

Once the proper piece of content is identified, users frequently like to consume it in the form of frequently asked question pages, discussion forums and blogs, rather then formal lengthy document. However, for the majority of knowledge domains, from legal and medical to engineering, most reliable information is only available as documents and web pages. Hence we convert plain documents into dialogues, imitating multiple people conversing on the specific topic of interest.

A virtual dialogue is defined as a multi-turn dialogue between imaginary agents obtained as a result of content transformation. It is designed with the goal of effective information representation and is intended to look as close as possible to a genuine dialogue. Virtual dialogues as search results turn out to be more effective means of information access in comparison with original documents provided by a conventional chatbot or a search engine.

2 Related Systems

Piwek et al. (2007) were pioneers of automated construction of dialogues, proposing Text2Dialogue system. The authors provided a theoretical foundation of the mapping that the system performs from RST structures to Dialogue representation structures. The authors introduced a number of requirements for a dialogue generation system (robustness, extensibility, and variation and control) and reported on the evaluation of the mapping rules.

An important body of work concerns tutorial dialogue systems. Some of the work in that area focuses on authoring tools for generating questions, hints, and prompts. Typically, these are, however, single utterances by a single interlocutor, rather than an entire conversation between two agents. Some researchers have concentrated on generating questions together with possible answers such as multiple choice test items, but this work is restricted to a very specific type of question–answer pairs (Mitkov et al., 2006).

Proceedings of Recent Advances in Natural Language Processing, pages 382–387,
Varna, Bulgaria, Sep 2–4 2019.

Conversion a text into a dialogue is different from the dialogue generation problem; the former is a training set–based foundation for the latter. Response generation for dialogue can be viewed as a source-to-target transduction problem. (Sordoni et al., 2015) rescores the outputs of a phrasal machine translation-based conversation system with a neural model incorporating prior context. Recent progress in sequence-to-sequence models has been leveraged to build end-to-end dialogue systems that firstly applies an utterance message to a distributed vector representation using an encoder, then generates a response from this representation.

(Li et al., 2016) simulate dialogues between two virtual agents, using policy gradient methods to reward sequences that display three useful conversational properties: “informativity”, coherence, and ease of answering.

We measured comparable dialogue effectiveness, properties such as the speed of arrival to a search result, a decision and domain coverage, in the current study.

Dialogue acts are an important source which differentiates between a plain text and a dialogue. Proposed algorithm of virtual dialogues can assist with building domain-specific chatbot training datasets. Recently released dataset, DailyDialog (Li et al., 2017), is the only dataset that has utterances annotated with dialogue acts and is large enough for learning conversation models.

3 Demo Description

3.1 Dialogue Construction from Plain Text

To form a dialogue from text sharing information or explaining how to do things, we need to split it into parts which will serve as answers. Then for each answer a question needs to be formed. The cohesiveness of the resultant dialogue should be assured by the integrity of the original text; the questions are designed to “interrupt” the speaker similar to how journalists do interviews.

We employ a general mechanism of conversion of a paragraph of text of various styles and genres into a dialogue form. The paragraph is split into text fragments serving as a set of answers, and questions are automatically formed from some of these text fragments. The problem of building dialogue from text T is formulated as splitting it into a sequence of answers $A = [A_1 \ldots A_n]$ to form a dialogue

$[A_1, <Q_1, A_2>, \ldots, <Q_{n-1}, A_n>]$,

where A_i answers Q_{i-1} and possibly previous question, and $\cup A_i = T$. Q_{i-1} needs to be derived from the whole or a part of A_i by linguistic means and generalization; also some inventiveness may be required to make these questions sound natural. To achieve it, we try to find a semantically similar phrase on the web and merge it with the candidate question.

The main foundation of our dialogue construction algorithm is Rhetorical Structure Theory (RST, Mann and Thompson, 1988). RST represents the flow of entities in text via Discourse Tree – a hierarchical structure that sets inter-relations between text fragments: what elaborates on what, what explains what, what is attributed to what, what is contradicting what, etc. Such text fragments are called elementary discourse units (EDUs). Most rhetorical relations are binary anti-symmetric, specifying which EDU has more important (nucleus) compared to less important (satellite).

A dialogue is formed from text by the following rule: once nucleus EDU is finished, and before satellite EDU starts, questions against this satellite EDU is inserted. In terms of dialogue flow between a text author and a person asking question, the latter “interrupts” the author to ask his question such that the satellite EDU and possibly consecutive text would be an answer to this question. The question is supposed to be about the entity from the nucleus, but this nucleus does not contain an answer to this question. The person asking questions only interrupts the text author when his question sounds suitable; it does not have to be asked for any nucleus-satellite transition.

Once we split a text into EDUs, we know which text fragments will serve as answer to questions: satellites of all relations. *Elaboration* rhetorical relation is default and *What*-question to a verb phrase is formed. *Background* relation yields another *What*-question for the satellite ‘…*as <predicate>-<subject>’*. Finally, *Attribution* relation is a basis of “What/who is source” question.

A trivial approach to question generation would be to just convert satellite EDU into a question. But it would make it too specific and unnatural, such as ‘*the linchpin of its strategy handled just a* *small fraction of the tests then sold to whom*?’. Instead, a natural dialogue should be formed with more general questions like ‘*What does its strategy handle?’*.

An example of converting a text into a virtual dialogue is shown in Fig. 1. Answers are obtained by splitting text into EDUs, and questions are inserted in text before satellite EDUs. Questions are shown in angle brackets and bolded. Each rhetorical relation in this example such as contrast ranges over a nucleus and a satellite. Each leave of this discourse tree starts with ‘TEXT’ (Fig. 1).

The reader of a virtual dialogue might feel that the interviewer is guessing what the speaker is going to answer for each question. A discourse – tree based approach does not deliver most natural dialogues however it is a systematic method of building ones without distorting the logical flow of answers.

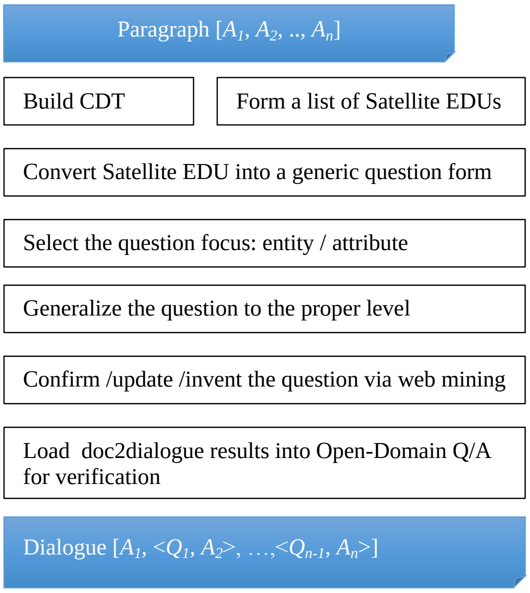
        TEXT: that they controlled the territory from which the missile was supposedly fired .

Fig. 1. A discourse tree for a paragraph of text with questions formulated for satellite EDUs as answers

3.2 System Architecture

System Architecture for building a dialogue from text is shown in Fig. 2. Each paragraph of a document is converted into a dialogue via building a communicative discourse tree for it and then building questions from its Satellite Elementary Discourse Units. Current chatbot is a development of the previously built tool that conducted task-oriented conventional dialogues (Galitsky et al., 2017).



Paragraph [A_1, A_2, .., A_n]
Build CDT
Form a list of Satellite EDUs
Convert Satellite EDU into a generic question form
Select the question focus: entity / attribute
Generalize the question to the proper level
Confirm /update /invent the question via web mining
Load doc2dialogue results into Open-Domain Q/A for verification
Dialogue [A_1, <Q_1, A_2>, …,<Q_{n-1}, A_n>]

Fig. 2. System architecture

4 Evaluation of Effectiveness

Evaluating the effectiveness of information delivery via virtual dialogues, we compare the conventional chatbot sessions where users were given plain-text answers, and the ones where users were given content via virtual dialogues.

We present the results on comparative usability of conventional dialogue and virtual dialogue. We assess dialogues with respect to following usability properties.

The speed of arriving to the sought piece of information. It is measured as a number of iteration (a number of user utterances) preceding the final reply of the chatbot that gave an answer wanted by the user. We measure the number of steps only if the user confirms that she accepts the answer.

The speed of arriving to a decision to commit a transaction such as purchase or reservation or product selection. A user is expected to accumulate sufficient information, and this information such as reviews should be convincing enough for making such decision;

We also measure **how many entities** (in linguistic sense) were explored during a session with the chatbot. We are interested in how thorough and comprehensive the chatbot session is, how much a user actually learns from it. This assessment is sometimes opposite to the above two measures but is nevertheless important for understanding the overall usability of various conversational modes.

Table 1. Evaluation of comparative effectiveness of conventional and virtual dialogues

	Conventional dialogues			Virtual dialogues		
	# of iterations till found	# iterations till decision	Coverage of exploration # of entities	# of iterations till found	# iterations till decision	Coverюexploration # of entities
Conventional only	4.6	6.3	10.8	-	-	-
Virtual only	-	-	-	4.1	6.0	13.7
Conventional followed by virtual	4.0	5.7	7.6	6.1	11.3	15.1
Virtual followed by conventional	5.6	7.1	12.3	3.7	7.0	11.5

We do not compare precision and recall of search sessions with either dialogue mode since the same information is delivered, but in distinct modes.

In the first and second rows, we assess the stand-alone systems. One can observe that virtual dialogues take less iteration on average for information access and about the same number of iterations for decisions as conventional dialogues do.

Notice that the bottom row, the chat scenario proceeds from right to left. In the bottom two rows, we observe the usability of the hybrid system. When a conventional dialogue is followed by a virtual one, a lower portion of users is satisfied by the first step in comparison to the inverse architecture, where virtual is followed by conventional.

5 Sample Chatbot Session

We present an exploratory session that combines information delivery in the form of traditional textual answers (conventional dialogue) and also in a form of a virtual dialogue.

Bot>*ask a new question*
User>**advantages and new features of 5G**
Bot>exploring….

I believe these are the main topics of your query: is that what you meant? Please select demonstrating the benefits of the technology[1]. wide range of people from student'[2]. 5g new radio nr specification'[3]. … next generation mobile networks alliance[4]. the next stage in mobile technology[5].

User> **next stage in technology (or [5])**

Bot> Put simply, it’s the next stage in mobile technology. It follows 4G and 4G LTE and builds on what they offer, delivering everything at a faster speed. …

Are you OK with this answer? yes/more/no/specify [different topic] / reduce search to web domain / virtual dialogue

User > **virtual dialogue**
Bot> This is what other people are chatting about your topic:

User1>**What Are the Benefits of Technology?**
Bot1> If you hopped over to Ericsson, you'd find a "5G avenue" with multiple exhibits demonstrating the benefits of the technology…
User1>**How are these benefits leveraged by new tablets?**
Bot1>Samsung kicked off its press conference not with its new tablets, but 5G is the next wireless network in telecom industry …
User2>**Are the features right for them?**
Bot1>It is important for people to start learning about 5G technology now so that they can decide if the features are right for them...
User2 >**Which are the dual 4G VoLTE sim smartphones in India?**
Bot1> The current 4G VoLTE smartphones with dual SIM slots that are available in the Indian markets may support 4G on single or both SIM slots.

Fig. 3. Chatbot session with conventional and virtual dialogue

The dialogue starts from the user question, ‘*advantages and new features of 5G’*. The chatbot consults the sources (in this case, public URLs) and extracts the content from each page (or documents) expected to be relevant for the query. In this example, seven URLs were processed, from domain-specific to general knowledge portals like Quora.com. The chatbot forms the list of topics extracted from these search results so that the user might select one of his interest.

Once the chatbot forms the topics for clarification of the user search intent, it shows them as a list.

The user selects his topic of interest and requests a specific answer via the topic number of the topic expression. Once the answer is read, there are multiple options:

- navigate to the next answer from the chatbot list;
- navigate to a specific answer from the chatbot list;
- reject this answer and attempt to reformulate the query;
- reduce search to a specified web domain (such as quota.com, for example);
- proceed in the same direction to more search results in the form of a virtual dialogue;
- accept the answer and conclude the session.

The user selects the last option and the chatbot builds a virtual dialogue. It is a conversation between an imaginary people but the topic stays the same, matching the original query. Virtual dialogues are shown in frames. As long as an imaginary chatbot responds to the same person, the dialog is intended to stay cohesive; coreferences in the follow-up questions are maintained. The main dialogue can be viewed as a one in the meta-level, and the object-level dialogue is naturally embedded into the meta-level one.

Now the user can either browse the built virtual dialogue or search it to find a fragment of conversation which is relevant to the user current exploration intent. The user now types the query ‘*Are the features right for me?*’ and gets directed to the virtual dialogue fragment where some other users are discussing if the technology is ‘*right for them’*. The search matches the query either against the fragments of an original text, generated questions or both.

6 Conclusions

We proposed a novel mode of chatbot interaction via virtual dialogue. It addresses sparseness of dialogue data on one hand and convincingness, perceived authenticity of information presented via dialogues on the other hand. We quantitatively evaluated improvement of user satisfaction with virtual dialogue in comparison to regular chatbot replies and confirmed the strong points of the former. We conclude that virtual dialogue is an important feature related to social search to be leveraged by a chatbot.

Chatbot demo videos (please, check **10 min** video) and **instructions** on how to use it are available at https://github.com/bgalitsky/relevance-based-on-parse-trees in the “**What is new?**” section.

Abstract

Every day, the emotion and opinion of different people across the world are reflected in the form of short messages using microblogging platforms. Despite the existence of enormous potential introduced by this data source, the Twitter community is still ambiguous and is not fully explored yet. While there are a huge number of studies examining the possibilities of inferring gender and age, there exist hardly researches on socioeconomic status (SES) inference of Twitter users. As socioeconomic status is essential to treating diverse questions linked to human behavior in several fields (sociology, demography, public health, etc.), we conducted a comprehensive literature review of SES studies, inference methods, and metrics. With reference to the research on literature's results, we came to outline the most critical challenges for researchers. To the best of our knowledge, this paper is the first review that introduces the different aspects of SES inference. Indeed, this article provides the benefits for practitioners who aim to process and explore Twitter SES inference.

1 Introduction

The ability to identify the socioeconomic status of social media users accurately is beneficial for the individual scale as well as the societal one. This field starts to be a well-explored research domain. The difficulty to identify the socioeconmic status of authors and the lack of explicit personal information have brought with them some challenge for computer scientists.

Nowadays, Twitter's monthly active members exceed 300 millions. These members generate over 500 million conversations (tweets) daily [1]. These conversations are short text messages including a maximum of 140 characters (recently extended to 280). Indeed, this shortage of characters leads to unstructured and noisy texts to the point that natural language processing (NLP) tools cannot manage successfully (Ritter et al., 2011). Moreover, more deduction is required to detect the underlying features of Twitter users. In this regard, researchers and specialized centers will explore and analyze the available demographic information of Twitter users. The results provided by the Pew Research Center (Smith and Brenner, 2012), a subsidiary of the Pew Charitable Trust, show that the majority of Twitter users in the United States are young, with high educational level and exposing a bigger political interest. Authors concluded that focusing on a community characterized by high level of involvement in societal issues (Li et al., 2015) could be fruitful. In a first study (Preoţiuc-Pietro et al., 2015a) prove that language use in social media is an indicator of user's occupational class. In a second study, (Preoţiuc-Pietro et al., 2015b) provide a comparison between income and psycho-demographic traits of Twitter users; among the results of this research they concluded that the rich users expose less emotional status but more neutral content, expressing anger and fear, but less surprise, sadness, and disgust. Recently, (Flekova et al., 2016) found that the writing style can also indicate the income of the users. The higher income is an indicator of education and conscientiousness. Moreover, (Volkova and Bachrach, 2016) concluded that the highly educated users have a stronger tendency to express less sadness and are likely to show more neutral opinions.

User's socioeconomic status (SES) is the most

[1] https://about.twitter.com/company

important predictors of a person's morbidity and mortality experience (Kitagawa and Hauser, 1973; Marmot et al., 1987). The significant impact of SES on public health renders its definition and measurement of critical importance. When the SES is low, it does not only involves poverty and poor health, but it also affects the educational achievements hence the whole society. Thus, the research of (Morgan et al., 2009) finds that children from low-SES households develop a slow academic behavior than children belonging to higher SES groups. For these reasons, marketing campaigns, as well as economic and sociological studies, have found it interesting to determine the socioeconomic status of particular persons.

This article is going to be divided into six sections. After the introduction, section 2 will discuss the metrics of socioeconomic status used with Twitter data. Section 3 will discuss SES indicators and its features. Section 4 will examine the different techniques employed in SES inference and section 5 will present the data collection and analysis process. Section 6 is going to be the conclusion for this article opening the horizons for further discussions.

2 Evaluation of Socioeconomic Status

Socioeconomic status (SES) can be defined as one's possession of social, financial, cultural, and human capital resources. Parental and neighborhood properties are considered as additional components (Cowan et al., 2012). We can also note that SES is a complex unit of measurement of a person's economic and sociological standing, like for instance, his prestige, power or else his economic well-being (Hoff et al., 2002; Oakes and Rossi, 2003). Consequently, one can conclude that the SES is a complex measure of evaluation that differs from a research to another because it takes into account the work experience, the economic position, or the social status.

The concept of the SES detection in literature goes back to the beginning of the 20^{th} century (Chapman and Sims, 1925). In the 20^{th} century the evaluation of SES was based on questions like: How many years did your father go to school?", Do you have a telephone?" or Do you work out of school hours?". Currently, there is an agreement that SES is influenced by three significant factors: the cultural (comprised of skills, capacities, and knowledge), the social (social network combined with the status and power of the people in that network) and the material capital (Jones et al., 2007). Similarly, the primary metrics of the SES are education, occupation, income levels and wealth or lifestyle (Van Berkel-Van Schaik and Tax, 1990; White, 1982).

People are usually divided into groups according to these metrics, from the least advantaged to the most advantaged, medium, or high SES. **Education** is one of the widely used indicator and it is considered by many to be the canonical element of SES because of its influence on later income and occupation (Krieger et al., 1997). This index can be defined by two dimensions: the field of education and the level at which the education was followed. **Income** reflects spending power, housing, diet, and medical care. **Occupation** measures like prestige, responsibility, physical activity, as well as work exposures. The occupational status influences the social capital of individuals and it strengthen the connection with more professional people enjoying wealth and power. Similarly, education indicates skills requisite for acquiring a positive social, psychological, and economic resources (Antonovsky, 1967). Likewise, social classes are measurements that, like SES, aim to locate ones position in the social hierarchy. classes are social categories sharing subjectively-salient attributes used by people to rank those categories within a system of economic stratification" (Wright and Ritzer, 2003). By refering to the definition presented by (Wright and Ritzer, 2003), classes refer to how people are objectively located in distributions of material inequality".

Before the rise of social networks, different studies have looked into other data sources from various domains, like internet browsing behaviors, written texts, telephone conversations, real-world mobile network and communication records.

- (French, 1959): introduced the relationship between different measures of 232 undergraduate students and their future jobs. This work concluded that occupational membership could be predicted with the use of variables such as the ability of persons in using mathematical and verbal symbols, the social class of family and the personality components.

- (Schmidt and Strauss, 1975): have also designed the relationship between the types of occupation and the particular demographic attributes such as gender, race, experience, education, and location. Their study identified biases and the types of discrimination that can possibly exist in various types of occupations.

The recent excessive use of online social media and the user-generated content in microblogging platforms such as google+, Facebook, or Sine Weibo [2] has allowed the study of author profiling on an unprecedented scale.

- (Li et al., 2014): proposed a framework for assessing the user's features on Twitter using Google+ API. They constructed a publicly available dataset using distant supervision. They submitted their model on three user profile attributes, i.e., Job, Spouse and Education.

- (Zhong et al., 2015): investigated the predictive power of location check-in, extracted from points of interest of Sina Weibo. In order to determine the demographic attributes of the users such as education background (university and non-university), marital status (single, courtship, in love or married) using human mobility as an informative and fundamental user behavior. They developed a comprehensive location to profile (L2P) framework to detect temporality, spatiality, and location knowledge at the same time.

- (Sullivan et al., 2018) has recently reported that Facebook has patented technology that utilizes a sample decision tree to determine its users' social class. Decision tree uses as an input information about a user's demographic information, device ownership, internet usage, household data, etc. The output provides a probability that the user belongs to a given socioeconomic class: working class, middle class or upper class.

Recent studies tackled the inference of socioeconomic characteristics of Twitter users.

- (Lerman et al., 2016): analyze a large corpus of geo-referenced tweets posted by social media users from US metropolitan areas. They measure emotions expressed in the tweets posted from a particular area with the inference of socioeconomic characteristics. They collect Twitter accounts which users are located in Los Angeles. Concerning the sentiment analysis, they used SentiStrength [3]. The study shows that people with higher incomes are associated with weaker social ties.

- (Quercia et al., 2012): treat the relationship between sentiment expressed in tweets and the community socioeconomic well-being. In their research, they collect Twitter accounts which users are located in London. Concerning the sentiment analysis, they used word count technique and the maximum entropy classifier. Socio-demographic data obtained from Index of Multiple Deprivation scores (composite score based on income, employment, education, health, crime, housing, and the environmental quality for each community) of each of the 78 census areas in London.

3 SES Features and Indicators

The quality of features influences the value of a machine learning pattern from which it originates. Microblogging platforms offer a different number of potential features. Different traditional text-based corpora features are used to explore the relationship between these characteristics. Different types of indicators can help infer the SES of Twitter users used over years. This idea is going to be developed later in the article.

3.1 Message Content

Twitter message text represents the backbone of most research works within the field of SES inference as this helps to understand the context of messages themselves. The messages of the social media platform include abbreviations and non-standard formulation as there is no precise rule of writing since most of the tweets are sent via mobile phones.

In his thesis, (Mentink, 2016) used Bag-of-Words to analyze the discussed topics of users. (Preoţiuc-Pietro et al., 2015b) used clustering algorithms to build a list of most frequent unigrams and then they reached their vector representations, consequently using Word2Vec model to compute dense word vectors (grouping words into clusters or topics). While (Lampos et al., 2016) applied spectral clustering to derive clusters of 1-gram that

[2] http://www.weibo.com/signup/signup.php

[3] http://sentistrength.wlv.ac.uk/

capture some potential topics and linguistic expressions, (Preoţiuc-Pietro et al., 2015a) used Normalized Pointwise Mutual Information (NPMI) to compute word to word similarity, then applied singular value decomposition (SVD) to obtain an embedding of words into a low-dimensional space. A good approach of content analysis would take into consideration all possible instances of SES indicators being expressed within the message. For most studies, the use of message content aims at inferring morphological characteristics and language use.

(Barberá, 2016) used the emoji characters as features (bag-of-emoji) and the author used word counts as another features (bag-of-words) with the application of TF-IDF transformation. In order to obtain a robust result, the most successful techniques used employ message content initially, alongside other features.

3.2 User Profiles

Although it must be admitted that in creating a new Twitter account, personal information are limited, however, they can give beneficial insights for the SES of particular users. Users' profiles contain a different number of metadata such as the user's biography, followers, name, and location. The expectation is that a user's biography offers an important source of demographic data. However, Twitter users' biography is left empty for 48% of users, and others do not supply good-quality information (Culotta et al., 2016). (Preoţiuc-Pietro et al., 2015a) use the profile information of the account to capture users with self-disclosed occupations by annotating the user description field. (Lampos et al., 2016) use also profile description field of UK Twitter users to search for occupation mentions. In order to infer the user's socioeconomic status, most studies use description field and attempt to search for related information given by a particular user. These data are also useful in order to validate other SES features inferred from tweet messages.

3.3 Social Network Relations

The followers of a user represent a good indicator of their SES. Following reciprocal relationship can provide evidence of strong user connection. Some indicators can group regular exchanges of messages or frequent mention to names in messages. The number of tweets, mentions, links, hashtags and retweets, the number of followers, friends and the ratios of tweets to retweets are considered as statistical features. (Lampos et al., 2016) use these features to compile a set of latent topics that Twitter users were communicating. (Culotta et al., 2016) use the Twitter REST API and *followers/ids* request to sample many followers for each account, and the results are ordered with the most recent following first. And with the same methods, they use *friends/ids* API request to collect a list of friends. The example of (Barberá, 2016) best illustrates this idea it enables to overcome the collection of information about the entire network of a particular user that is costly and requiring multiple API calls, focuses on verified accounts. (Ikeda et al., 2013) use a community-based method with the extraction of the community from follower/followee relations followed by estimation of the demographics of the extracted communities. The demographic category of each community group is estimated using text-based method and the use of Fast Modularity Community Structure Inference Algorithm. Some studies assume that people within a given social class tend to have similar lifestyles using their income levels and common experience. Their interaction is called homophily. In the same context (Aletras and Chamberlain, 2018) use the information extracted from the extended networks of Twitter users in order to predict their occupational class and their income. They demonstrated that user's social network and their language use are complementary.

3.4 Spatial Information

The majority of smartphones are now equipped with Global Positioning System (GPS) functions and they work with geo-satellites which accurately infer the user's location with latitudes and longitudes coordinates. This would be an optional field for a particular user to enable due to their privacy choice. This indicator is very helpful when the person is mobile and usually updates their location profile. (Bokányi et al., 2017) obtained 63 million of Twitter geolocated messages from the area of the United States and assigned a county to each tweet. Once aggregated, daily tweeting activity allows to measure human activities and constitutes an important socioeconomic indicator whether a particular user is employed or not. In order to build a social class dataset, some studies attempt to show that the wealthier the place, the richer the users who usually visit it. (Miranda Filho et al., 2014) used the lifestyle and the wealth of neighborhood people typically visit to label Brazilian users into various social classes. Then, they utilized Foursquare to label places according to the wealth of the neighborhood. They selected users who had at least one Foursquare interaction (Foursquare interactions include check-in (the user told a friend he/she was at a given place), tips (the user posts tips and opinion about a given place) and mayorship (title given to the most frequent user in a given location in the past 60 days). (Zhong et al., 2015) investigate the predictive power of location and the mobility to infer users' demographics with the use of location to profile (L2P) framework. The data crawling module accumulates user profiles and location check-in with corresponding information on Sine Weibo.

3.5 Temporal Information

Twitter enables researchers to analyze human activities during the 24 hours of the day because they are biologically bound to exhibit daily periodic behavior. In this context (Bokányi et al., 2017) aggregate monday to friday relative tweeting activities for each hour in each US County to form an average workday activity pattern, assuming that the activity patterns form a linear subspace of the 24-hour ”time-space”. This study shows that this measure correlates with county employment and unemployment rates in relation to lifestyles connected to regular working hours. The relationship between daily activity patterns and employment data can be captured using Twitter data.

3.6 Demographic Attributes

Some researchers attempted to include demographics as features. Age, for example, has a vital role in income prediction. Old people earn significantly more than young ones. Higher age leads to, on average, more work experience and education, which is translated into higher income. (Flekova et al., 2016) explored the relationship between stylistic and syntactic features, authors' age, and income, to conclude that the hypothesis of numerous feature type writing style and age use is predictive of income.

4 Inference Methods for SES Evaluation on Twitter

Different techniques have been used in the past and are being employed now to improve the accuracy of SES inference methodologies and algorithms. This burgeoning field lends techniques ranging from different areas of study involving machine learning, statistics, natural language processing to regression models. Various methods achieved different levels of success. The effectiveness and granularity levels produced by these methods continue to be improved.

Most recent researchers use a three-step methodology to infer the SES. First, they collect available information about a number of Twitter users. Secondly, they develop the classification method using additional data (number of followers, the content of tweets). And finally, they classify users who do not provide any concrete information according to SES. (Preoţiuc-Pietro et al., 2015a) for example, extracts occupation information from Twitter user profiles and uses text analysis to categorize users into occupational classes.

In general, a common approach to demographic inference is supervised classification, from a training set of labeled users, a model is fit to predict user features from the content of their writings. In other words, inferring user characteristics is framed as a predictive task validated on held-out data. This is done by establishing regression or classification methods.

4.1 Regression Methods

Various techniques for the inference of SES of Twitter users have been adopted from data mining and machine learning techniques. Some studies used the linear regression method, others used non-linear regression method and a third party used a hybrid approach that combines both linear and non-linear methods. A standard non-linear method does not inform which features are the most important in the predictive task. Then, the interpretability of linear methods allows performing an extensive qualitative and quantitative analysis of the input features. (Flekova et al., 2016) used both linear with Elastic Net regularization methods and non-linear with Support Vector regression together with an RBF kernel method. The authors found that machine learning regression methods can be used to predict and analyze user's income. (Lampos et al., 2016) used a non-linear generative learning approach, which consists of Gaussian Process (GP) and Kernel, to classify Twitter users according to SES as having upper, middle or lower level. Further, in (Preoţiuc-Pietro et al., 2015b), the authors used similar methods to study the user behavior and its power to predict income. It is important to note that GPs is a Bayesian nonparametric statistical framework that formulates priority functions. (Hasanuzzaman et al., 2017) used linear and non-linear methods. The linear method is a logistic regression with Elastic Net regularization. In order to capture the non-linear relationship between a user's temporal orientation and their income, the authors used GP for regression. (Culotta et al., 2016) used a regression model for the prediction in order to understand the demographics of users. Due to the high dimensionality of features, the authors used elastic net regularization. Since each output variable consists of subject categories of demographic characteristics. They used a multitask variant of the elastic net to ensure the same features as selected for each category.

4.2 Classification Methods

(Mentink, 2016) employed two different approaches to classify the users in the dataset. The first is named the individual approach, it determines the performing classifier per feature group and consequently combines them via a soft-voting ensemble method. The second is named the combined approach, it calculates the performance scores for all possible combinations of classifiers and their respective ensemble (also via soft-voting). The author used Logistic Regression, Support Vector Machines, Naive Bayes and Random Forest algorithms. The author runs the algorithm to determine what occupation and what education-level label should be given to a particular user, to overcome the data imbalance, noise and bias, (Chen and Pei, 2014) used a typical imbalance classification approach which uses multiple classifier systems (MCS) and a sampling method which is a class-based random sampling method an extension of random under-sampling. The objective is to classify users according to their occupation. (Miranda Filho et al., 2014) evaluated a large number of classifiers using their WEKA version to generate classification models, including multinomial Naive Bayes (MNB), Support Vector Machine (SVM), and Random Forest. As MNB is more efficient than other algorithms, the authors used this method to infer social class for each particular user.

5 Tweet Gathering and Analysis

Messages on Twitter are publicly accessible in the online domain and can be gathered for study purposes. This availability makes Twitter an efficient tool in retrieving and analyzing public messages by allowing its users to become social sensors within the population.

5.1 Data Corpuses and Ressources

The corpus size of tweets grouped have varied from relatively small datasets to as large as three billion tweets (Mentink, 2016). The time span of the data collected was usually in the range of a few weeks to a couple of months, and sometimes a year. Table 1 shows some datasets and their sizes over the past years. First, the REST API is helpful for gathering particular user tweets, allowing the backtracking of their timeline. For example, to collect their most recent 3.200 tweets. Second, the streaming API that manages the tweets as they are being broadcast would only be able to receive 1% of the Firehose. Twitter data partners furnish a premium service that supplies messages covering a longer duration as well as 100% access to the Firehose. (Preoţiuc-Pietro et al., 2015a) created a publicly available data-set [4] of users, including their profile information and historical text content as well as a label to their occupational class from the "Standard Occupational Classification" taxonomy.

This public available dataset used by several researchers containing a group of $5,191$ users in total. However, the extraction of social network information of some accounts are not allowed. These accounts may have been annulled or become private. For example (Aletras and Chamberlain, 2018) reported results of $4,625$ users, from the original subset, that are still publicly available. Various studies (Preoţiuc-Pietro et al., 2015b; Lampos et al., 2016; Preoţiuc-Pietro et al., 2015a; Flekova et al., 2016) in the dataset creation mapped Twitter users to their income or their job title using standardized job classification taxonomy. The Standard Occupational Classification (SOC) is a UK-governmental system developed by the Office of National Statistics (ONS) for listing and grouping occupations. Jobs are organized hierarchically based on skill requirements and content.

(Culotta et al., 2016) mapped Twitter users according to their educational level (No College, College, Grad School) and other traits using Quantcast.com, an audience measurement society that tracks the demographics of users of millions of websites. The estimated demographics of a large number of sites are publicly accessible through the

use of searchable web interface. For each variable, Quantcast gives the expected percentage of visitors to a website with a given demographic.

5.2 Results and Metrics

The conclusions reached by different studies have been significantly improved over time with regards to increased accuracy and other measurements. Table 2 shows some techniques and their results over the past years. This has been driven by improvements in algorithms and inclusion of more useful features. It is important to note that the effectiveness and the reliability of occupation representativeness increase when estimating profession, using non-standard and out-of-vocabulary (OOV) occupation names. In this context, to overcome the limitation of the work of (Sloan et al., 2015) and (Mac Kim et al., 2016), (Kim et al., 2016) builded a machine learning model attempts to capture linguistically noisy or open-ended occupations in Twitter. This induces in more reliable occupation representativeness.

Different approaches have been introduced to compare the performance and results of the methods. They include accuracy and use of two other standard metrics: Pearson's correlation coefficient and Mean Absolute Error (MAE). To validate the effectiveness of the approaches against different baselines, the k-fold cross validation has been well utilized for precision, recall and F-measure: the standard metrics for classification methods.

Over time, accuracy levels of results have continued to be improved starting from 2013 when the inference of users' occupation was used. taking into consideration other information such as Twitter links, friends, user tweets, profiles, and other metadata associated with the message. Furthermore, with the adoption of various features such as user profile features, users psycho-demographic features, or user emotion features, accuracy has improved with the recent studies of (Mentink, 2016; Lampos et al., 2016) achieving a 75% accuracy.

6 Conclusion and Future Prospectives

The study of socioeconomic status inference is one of the most active field of information retrieval. Such works are positioned at a crossroads of multiple disciplines.

Different studies that introduced the inference of hidden user characteristics (Al Zamal et al., 2012; Miranda Filho et al., 2014; Volkova et al., 2015) are salient in the field. The results of these works are not only of interest to statistics agencies but also necessary for studies in the social science (targeted advertising, personalized recommendations of user posts and the possibility of extracting authoritative users (Pennacchiotti and Popescu, 2011)). It is important to introduce the role of SES in politics such as the works of (Barberá and Rivero, 2015), (Burckhardt et al., 2016), (Kalsnes et al., 2017), (Vargo and Hopp, 2017) and (Brown-Iannuzzi et al., 2017). Twitter is increasingly considered as politically transformative communication technology that allows citizens and politicians to connect, communicate, and interact easily (Chadwick, 2006). The flaw in previous studies of political behavior using Twitter data is the lack of information about the sociodemographic characteristics of individual users. Policy makers have recently suggested introducing well-being community which will help governments do a better job at directing public policy towards promoting quality of life.

The inference of SES is an ambitious problem as it may belong to a combination of environmen-

Table 2: Results and Techniques Used Over the Past Years.

tal variables and individual characteristics. Some of these characteristics can be easier determined like gender or age while others, are sometimes complicated with privacy issues and relying to some degree on self-definition, are harder to determine like occupation, ethnicity, education level or home location. Neverthless, there are many challenges in the inference of SES for Twitter users. Manual classification and data sampling are time-consuming, hard process and not scalable. Models are learned by referring to a datasets which were manually labeled using Amazon Mechanical Turk at a high monetary cost. Another issue is that people often misrepresent themselves on various online social platforms. This can lead to false data interpretations which as a result can affect the accuracy of the research. Automated detection tools are based on the supposition that users will introduce information on their demographic background through profile information or metadata. While it is not possible to expect that all users do this, those who did were a random group of the Twitter population, then we would not expect to discover conflicts in prevalence rates for sociodemographic characteristics (Sloan et al., 2015). Another problem is that Twitter data cannot represent all the populace as discussed previously. (Sloan, 2017) treated the issue of using human validation to find the accuracy of methods applying profile data to assign users to occupational groups and, he deduced that this process could provide misclassifications due to users reporting their hobbies and interests rather than their actual occupations (e.g, writer, artist). Another limit is that deriving income statistics from job labels is not a suitable method.

Given the findings presented above, the following are important issues to address in future Twitter socio-demographic inference studies. First, there is a need to look at the relationship between a user's actual demographic characteristics and how demographic categorization tools classify that user as a function of how profile information is presented and a virtual identity constructed. To conclude, there is a need to link Twitter profiles and survey data. Researchers can start theorizing better working machine learning models to improve accuracy and scalability. In addition, the methodologies used in different research projects can be coupled to increase efficiency. Another purpose for future research projects is to construct a less human effort, low computational cost and focus on the construction of a stronger evaluation framework.

Divide and Extract –
Disentangling Clause Splitting and Proposition Extraction

Darina Gold **Torsten Zesch**
Language Technology Lab
University of Duisburg-Essen, Germany
{darina.gold,torsten.zesch}@uni-due.de

Abstract

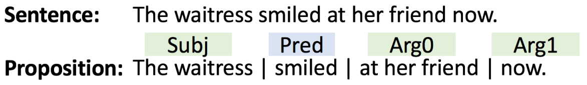
Proposition extraction from sentences is an important task for information extraction systems. Evaluation of such systems usually conflates two aspects: splitting complex sentences into clauses and the extraction of propositions. It is thus difficult to independently determine the quality of the proposition extraction step.

We create a manually annotated proposition dataset from sentences taken from restaurant reviews that distinguishes between clauses that need to be split and those that do not. The resulting proposition evaluation dataset allows us to independently compare the performance of proposition extraction systems on simple and complex clauses.

Although performance drastically drops on more complex sentences, we show that the same systems perform best on both simple and complex clauses. Furthermore, we show that specific kinds of subordinate clauses pose difficulties to most systems.

1 Introduction

Propositions are predicate-centered tuples consisting of the *verb*, the *subject*, and other *arguments* such as *objects* and *modifiers*. For example in Figure 1, "smiled" is the *predicate* and the other elements are *arguments*. The first argument is reserved for the role of the *subject*, in this case "The waitress", while "at her friend" and "now" are arguments, without further sub-specification. Propositions are used in language understanding tasks such as relation extraction (Riedel et al., 2013; Petroni et al., 2015), information retrieval (Löser et al., 2011; Giri et al., 2017), question answering (Khot et al., 2017), word analogy detection (Stanovsky et al., 2015), knowledge base construction (Dong et al., 2014; Stanovsky and Dagan, 2016), summarization (Melli et al., 2006), or other tasks that need comparative operations, such as equality, entailment, or contradiction, on phrases or sentences.



Sentence: The waitress smiled at her friend now.

Proposition: The waitress | smiled | at her friend | now.

Figure 1: Example Sentence and Extracted Proposition

The main goal of this paper is to empirically measure the influence of sentence complexity on the performance of proposition extraction systems. Complexity worsens the extraction of dependencies, on which propositions are built. Hence, proposition extraction performance should decrease with increasing sentence complexity.

The contribution of this work is threefold a) a gold standard corpus for propositions[1], b) an analysis of proposition extraction systems without the influence of complex sentences, and c) an analysis of proposition extraction systems with the influence of complex sentences.

The knowledge of how proposition extraction systems perform on complex sentences will 1) help to identify the system that deals with them best 2) by showing the difficulty with complexity, give a direction towards which proposition extraction systems can be improved.

If different systems perform well on simple or complex sentences, the complexity distinction could help to identify the complexity of a sentence. The complexity of a sentence would then give a direction towards which system would be better to use.

2 Related Work

Proposition are relational tupels extracted from sentences in the form of *predicate-argument struc-*

tures (Marcus et al., 1994). There are proposition models that further distinguish between the type of arguments. They do not only identify the subject, but more complex roles such as temporal and locational objects or causal clauses.

Besides the theory and formalization of proposition, proposition extraction systems have performance issues on real data.

2.1 Comparison of Proposition Systems

Although there have been comparative studies of proposition extraction systems, there has been no extensive study on the impact of sentence complexity on proposition extraction system performance.

Comparative Studies Niklaus et al. (2018) presented an overview of proposition extraction systems and classified them into the classic categories of learning-based, rule-based, and clause-based approaches, as well as approaches capturing inter-propositional relationships. They described the specific problems each system tackles as well as gaps on the overall evolution of proposition extraction systems.

Schneider et al. (2017) present a benchmark for analyzing errors in proposition extraction systems. Their classes are *wrong boundaries*, *redundant extraction*, *wrong extraction*, *uninformative extraction*, *missing extraction*, and *out of scope*. Their pre-defined classes do not map directly to sentence complexity, although *wrong boundaries* and *out of scope* would also be of some interest in an even more detailed error analysis.

Furthermore, according to Stanovsky and Dagan (2016) and Niklaus et al. (2018) there are no common guidelines and followingly no gold standard defining a valid extraction.

Systems Table 1 shows the outputs from different systems, our baselines, and our gold standard.

In their study, Gashteovski et al. (2017) aim at finding a system with minimal attributes, meaning that hedging[2] and attributes expressed e.g. through relative clauses or adjectives, can be optionally removed. Thus, they use recall and two kinds of precision in the evaluation in order to account for the feature of minimality. To explain this in more detail does not lie within the scope of this paper. Gashteovski et al. (2017) evaluates OLLIE (Mausam et al., 2012), ClausIE (Del Corro and Gemulla, 2013), and Stanford OIE (Angeli et al., 2015) against their own system.

Sentence	The waitress smiled at her friend now		
Systems	**Subject**	**Predicate**	**Other Elements**
Allen	The waitress	smiled	at her friend | now
ClausIE	The waitress	smiled	at her friend now
	The waitress	smiled	now
	her	has	friend
ReVerb	The waitress	now smiled at	her friend
Stanford	waitress	smiled at	her friend
	waitress	now smiled at	her friend
OLLIE	The waitress	now smiled at	her friend
OpenIE	The waitress	smiled	now | at her friend
BL1	The	waitress	smiled at her friend now
BL2	The waitress	smiled	at her friend now
Us	The waitress	smiled	at her friend | now

Table 1: Output of Proposition Extraction Systems and Our Two Baselines for the Sentence *The waitress smiled at her friend now*

Stanovsky et al. (2018) evaluates ClausIE, PropS (Stanovsky et al., 2016), and Open IE-4 against their new system, that we will call *Allen* (Stanovsky et al., 2018) herein, using precision-recall, area under the curve, and F1-score. They compare the individual proposition elements. For a proposition to be judged as correct, the predicate and the syntactic heads of the arguments need to be the same as the gold standard.

Saha et al. (2018) evaluate ClausIE, OpenIE-4, and CALMIE (a part of OpenIE) using precision. With the findings of this comparison, they introduce a new version of their system, OpenIE-5[3],

In all described comparisons, the system of the respective authors is the best, which makes sense as it addresses the issue shown by the authors.

2.2 Propositions from Simple Sentences

According to Saha et al. (2018) conjunctive sentences are one of the issues in proposition extraction, as conjunctions are a challenge to dependency parsers (Ficler and Goldberg, 2016) which proposition extraction systems are mostly built upon. Hence, Saha et al. (2018) built a system that automatically creates simple sentences from sentences with several conjunctions that are used for proposition extraction. For the proposition extraction of the simple sentences they used ClausIE and OpenIE. They evaluated their data using three different proposition datasets. The correctness of the extracted proposition from the original sentence were evaluated manually. In their study, simple sentences were sentences without conjunctions.

[2] In pragmatics, hedging is a textual construction that lessens the impact of an utterance. It is often expressed through modal verbs, adjectives, or adverbs.

[3] http://knowitall.github.io/openie/

Quirk (1985) defines a *simple sentence* as a sentence consisting of exactly one independent clause that does not contain any further clause as one of its elements. Hence, a *complex sentence* consists of more than one clause. This is also the definition that we use in our study.

2.3 Crowdsourcing Gold Standard Propositions

Recent work used crowdsourcing for creating and evaluating proposition extraction (Michael et al., 2018; FitzGerald et al., 2018) in the setting of question answering. In short, they asked their crowdworkers to produce questions and answers in a way that resulted in the extraction of their predicates and arguments, without directly asking for predicate-argument structures.

3 Corpus Creation

We create a corpus to evaluate the performance of proposition extraction systems entangled with and disentangled from the task of clause splitting.

Our source corpus is the portion of the Aspect Based Sentiment Analysis (ABSA) task (Pontiki et al., 2014) concerned with restaurant reviews within one aspect – *service*. We use all 423 sentences that were annotated with this aspect. In a preliminary step, we produce a corpus of *reduced* sentences. To examine the influence of sentence complexity, we classify the reduced sentences as either 1) *simple* sentences, meaning sentences with potentially just one proposition, and 2) *complex* sentences, meaning sentences with potentially multiple propositions. Then, we produce propositions from the reduced sentences using expert annotation and evaluate it by calculating the inter-annotator agreement.

Our corpus contains 2,181 sentences (class distribution in Table 2) and 2,526 propositions.

3.1 Preliminary Step: Creating Reduced Sentences

As a preliminary step, we created a gold corpus of reduced sentences formed from originally more complex sentences.

To do so, we use 423 sentences from review texts[4]. As these are quite difficult for producing propositions, even for humans, we included a preliminary step of creating *reduced sentences*. A *reduced sentence* is a sentence that contains only a portion of the original sentence, e.g. the original sentence “The server was cool and served food and drinks” could be reduced to “The server was cool” or “The server served food”. The intention behind this step was to create sentences with one proposition only. Hence, the guidelines contained rules such as decomposing conjunctive sentences or creating independent sentences from relative clauses.[5] We perform this preliminary step via crowdsourcing and evaluate it qualitatively.

Definition of Reduced Sentences We instructed our workers to produce reduced sentences from the original sentence. To prevent nested structures, a reduced sentence was not allowed to be split in further reduced sentences, at least within the output of one worker.[6] Ideally, the crowdworkers could have created sentences that contain exactly one proposition. However, this might even be a difficult task for experts, as there are non-trivial sentence constructions that would need long guidelines to create sentences with exactly one proposition. However, our guidelines insured that sentences were reduced in comparison to the original version, if possible. In this way, we are able to create a sufficiently big set of both simple and more complex sentences, as shown in Table 2.

Crowdsourcing We used Amazon Turk for crowdsourcing our data. Michael et al. (2018) crowdsourced gold data for evaluating propositions. The sentence reduction performed here and also in Saha et al. (2018) is very similar to syntactic sentence simplification as performed by Lee and Don (2017). We paid 0.04 $ per HIT and 0.01 $ for each further reduced sentence. Each sentence was reduced by 3 workers. In this process, 2181 unique reduced sentences, which are all used in the following corpus creation process, were created from 423 original sentences.

Evaluation of Reduced Sentences To measure the quality of the crowdsourced reduced sentences, we chose 100 random reduced sentences together with their original sentence and evalu-

[4] Online users’ restaurant reviews are a fruitful domain for proposition extraction, as propositions extracted from reviews would be useful for several user-centered tasks, as they would allow to display only information pieces of interest.

[5] However, this step turned out to be more difficult than expected, as some sentences contained several factors that could be reduced. However, this did not influence our goal of determining the influence of sentence complexity.

[6] The annotation instructions are also available on our Github page.

Complexity Class	# of Occurrences
No Verb	101
Simple	1,648
Complex	432
All	2,181

Table 2: Distribution of Sentence Complexity Classes in Our Reduced Sentence Set

ated their correctness using the following non-exclusive categories: ORIGINALSIMPLE, REDUCED, SIMPLE, GRAMMAR, and INFERENCE (see Table 3b).

In Table 3a, we provide an exemplary sentence for each category, except for ORIGINALSIMPLE, as it means that the original is already a simple sentence, containing only one proposition which cannot be further reduced. 20 sentences in the random sample were categorized as being ORIGINALSIMPLE. However, some workers still tried to reduce some of these sentences – 2 of them were grammatically incorrect (GRAMMAR) and 3 fell into the class INFERENCE. This means that their content was not explicitly mentioned in the original sentence, but was lexically inferred.

There were 66 REDUCED sentences, meaning that the sentences have been successfully reduced. 60 of the REDUCED resulted in SIMPLE sentences, which means that they contained only one proposition after the reduction, and 6 were simpler than the original sentence, but contained more than one proposition.

We believe that the results are usable as is, as the error rate is quite low – only 17 of the reduced sentences in the random sample were incorrect (GRAMMAR and INFERENCE), as many of the GRAMMAR errors stem from the original sentence. Furthermore, we show that our reduction step was necessary to produce enough simple sentences for our experiment, as 80% of the random sample were originally complex.

3.2 Creating Propositions from Simple Sentences

To evaluate the performance of proposition extraction systems, we created a gold standard corpus for propositions from the reduced sentences.

In this paper, we follow the most simple possible annotation, similar to Stanovsky et al. (2018).

We want to extract English propositions with one main verb and all arguments that are linked to it. In our notation, the first position of the proposition is the subject, the second is the predicate and the order of the other elements is irrelevant.[7]

The arguments may also contain further propositions, e.g. here, the sentence "I think their food is great" is split in two propositions – "I | think | their food is great" and "their food | is | great ". This definition is restrictive in that it asks for exactly two propositions in the given example. Additionally, it is not bound to a clearly defined theory (as there is no clearly defined theory on propositions). However, it is the representation that is needed to extract information from reviews, as it would help to reduce redundancies, e.g. by clustering sentences such as "Their food is great" and "I think their food is great". Furthermore, we are not interested in inferred information, e.g. "They | have | food" from the previously discussed sentence. This choice will also be reflected in the performance of systems that do not adhere to our understanding of propositions. However, this does not necessarily cloud the performance comparison of simple and complex sentences, as we will still measure the influence of sentence complexity. Each sentence is processed by two annotators and the disagreements are curated in a subsequent step.

Creation As the creation of propositions is not a trivial task, due to many different cases that need to be explained in the guidelines[8], this task should be performed by people who were trained longer than a crowdsourcing platform allows for. Thus, we produced proposition annotations in a double-annotation process by three graduate students[9]. The disagreements were curated by the first author of the paper. The result of the curation builds the gold standard. The gold standard, all annotations, and the guidelines are available.

3.3 Evaluation of Proposition Creation

To evaluate our dataset, we report inter-annotator agreement as well as agreement with the curator

[7] We are not interested in different types of objects and modifiers, similar to Stanford, OpenIE, and AllenNLP, and thus we do not discuss this information. For a better overview, we asked the annotators to present the other elements in their order of occurrence.

[8] The guidelines include explanations of what predicates, arguments, and nested propositions are. This in itself is not difficult. However, such instructions consume more time and need more training, as simple mistakes are made by untrained annotators. We saw this in a training set for this task, that is not included or discussed here due to space restrictions.

[9] The result is shown in Table 4. A1 annotated the whole set, while A2 and A3 annotated parts.

Original Sentence	The server was cool and served food and drinks.
REDUCED	The server was cool and served food.
SIMPLE	The server was cool.
GRAMMAR	The server was.
INFERENCE	The server is good.

(a) Classification Examples

Sentence Class	#
ORIGINALSIMPLE	20
REDUCED	66
SIMPLE	87
GRAMMAR	5
INFERENCE	12

(b) Distribution of Classification

Table 3: Classification of Reduced Sentences

on both the proposition (see Table 4a) and proposition element level (see Table 4b).

Evaluation Metric In order to see differences in the annotation, we performed inter-annotator agreement using %-agreement (accuracy). We use the same measure for system performance, which enables a direct comparison. Although we are aware that agreement is ignorant of chance agreement, we believe that it is the best measure for this problem, as chance agreement is quite low in the case of this complex annotation problem. Furthermore, it is difficult to interpret these results in comparison to other works. As previously described, there are no clear guidelines for propositions and also no manual gold datasets created explicitly for this purpose. We could compare the results of our inter-annotator agreement to similar tasks, where sentences are split into components, as e.g. answers prepared for question answering, paraphrase alignment, translation alignment etc. However, they also have different setups and evaluation metrics and it is out of the scope of this work to discuss these differences.

Levels of Evaluation We perform the evaluation on two levels - *proposition level* and *proposition element level*. On the proposition level, we calculate the agreement of whole propositions. On the proposition element level we calculate the agreement of individual elements of the propositions whilst taking their label (subject, predicate, or other element) into account.

Inter-annotator Agreement Table 4a shows that the inter-annotator agreement on the proposition level is .39 and .53 on complex sentences and .61 and .71 on simple sentences. These agreement differences show that clause splitting is also difficult for humans.

Agreement with Curator The agreement with the curator is .05 to .19 higher than the inter-annotator agreement. The agreement on the proposition element level is .67 and .7 on complex sentences and .83 and .85 for simple sentences - nearly double of the whole proposition agreement.

	Simple		**Complex**		**All**	
	A1	Gold	A1	Gold	A1	Gold
A1	-	.80	-	.66	-	.76

4 Evaluation of Proposition Extraction Systems

Similar to Saha et al. (2018); Schneider et al. (2017) and Niklaus et al. (2018), we evaluate proposition system performance. They do not, however, regard the task of proposition extraction disentangled from the intrinsic subtask of clause splitting. By showing the performance of both simple and complex sentences, we are furthermore able to show the impact of clause splitting.

4.1 Setup

To identify the system that performs best when disentangled from the task of clause splitting, we use the herein produced corpus to analyze and evaluate the performance of various proposition extraction systems as used in evaluations by Stanovsky and Dagan (2016), Gashteovski et al. (2017), Saha et al. (2018), and Stanovsky et al.

(2018). Hence, we will analyze proposition extraction performance using AllenNLP, ClausIE, ReVerb, Stanford Open Information Extraction, OLLIE, and OpenIE-5.[10] Furthermore, we provide two baseline systems.

We use %-agreement to measure the performance of systems. We want full agreement, not just matching phrase heads, as performed by Stanovsky et al. (2018). Furthermore, we evaluate only agreement, as in our setup the argument or the predicate matching is what we are interested in, meaning we do not need precision and recall in our setting. In this way, our evaluation setup is similar to Saha et al. (2018), who also identified specific issues in proposition extraction systems.

As in inter-annotator agreement, we calculate agreement on two levels: proposition and proposition element level. The results of the performance comparison is shown in Table 5.

4.2 Baselines

We provide two baselines in order to better compare the systems. Both baselines create propositions with three elements at most: subject, predicate, and one other element. The first baseline (BL1) takes the first word as subject, the second word as predicate and the rest as one other element. The second baseline (BL2) is a little more engineered and uses POS-tags. It makes a proposition for each verb. All words before the verb are the subject and all words after the verb are one other element. Examples for the baselines are shown in the Table 1. The baselines are kept simple on purpose to show how simple algorithms can solve the given problem. A baseline that appears intuitive is using a dependency parser and filtering for the root and its dependants. However, deciding which parts are its dependents and especially the span of arguments is ambiguous. This would not be a baseline, it would be a rule-based system that is not out of the box. Hence, we decided not to do it.

4.3 System Performance

Table 5a shows that performance of proposition extraction on whole propositions is equally bad for both simple and complex sentences. Table 5b shows that performance on proposition elements is much better than on proposition level. Furthermore, the table shows that for all systems but ReVerb, the performance is much better on the simple sentences, which was expected.

It is also interesting that although the performance of both baselines on whole propositions is 0, the performance of the second baseline on proposition elements is competitive. This shows, that the task of proposition extraction can, to a big part, be solved by correct verb extraction. It outperforms ReVerb, Stanford, and on simple and complex sentences also OLLIE. The second baseline performs a little worse on all sentences, as these also include sentences without a verb and this baseline is verb-based. This shows that either the automatic systems have problems with the extraction of verbs or they have deeper issues, e.g. they do not extract from a lot of sentences, as is discussed in Section 4.4.1. The second baseline performs almost equally on both simple and complex sentences. This may show correct verb extraction alone solves only a particular portion of proposition extraction.

Other systems, especially the two best ones, perform about two times better on the simple sentences but then have a much bigger drop on the complex sentences. This may show that clause splitting has a bigger impact on better or probably more intelligent systems than on more simple systems.

On both levels, OpenIE is the best system, very closely followed by Allen, whereas the other systems are well-beaten.

4.4 Analysis of System Performance

Identifying further problems except clause splitting could improve current proposition extraction systems. On the one hand there are sub-issues in clause splitting. On the other hand, there are issues besides clause splitting.

In the case of ClausIE and ReVerb, many further clauses and also arguments are cut, as these consist of a maximum of three elements, which makes the comparison difficult.

4.4.1 General Issues

We first manually examined some potential issues in the proposition extraction from simple sentences. After the manual analysis of potential issues, we calculated the system performance if the issue would be eliminated. One big issue we found is **missing propositions**, meaning that systems do

[10] We will not use MinIE (Gashteovski et al., 2017), as it is an extension of ClausIE providing additional information such as modality and whether an argument is necessary or unnecessary, which is disregarded in this work.

Systems	Simple	Complex	All
Allen	.08	.09	.08

(b) System Performance on Proposition Elements Excluding Specific Issues

Table 6: System Performance Excluding Specific Issues

not always extract propositions. Except for the missing propositions, there was no big difference in the system performance with or without the issue. Also, some systems have different models of propositions, which may also affect their performance. On the one hand, there are issues with previous steps, e.g. **negations** or **quantifiers** are ignored. On the other hand, there are issues with formatting, e.g. a different treatment of **prepositions** or conditionals.

Missing Propositions One big issue is that proposition extraction systems often do not produce any extraction from a sentence. Unsurprisingly, this issue is bigger among the systems that do not perform well - namely ReVerb (58% of sentences do not have an extraction), Stanford (39%), and OLLIE (33%), whereas the better performing systems have much lower rates - Allen (3%), ClausIE (4%), and OpenIE (10%). In ReVerb, Stanford, and OLLIE we could not find a clear reason why there are no extractions. In the case of Allen, there are only no extractions from sentences without verbs.[11] ClausIE and OpenIE have no extractions from sentences that are missing a verb or a subject. Additionally, OpenIE has no extractions from existential clauses.

In Table 6a, where we show the performances of systems on full propositions without the discussed issues, it is shown that systems perform slightly better when eliminating missing propositions from simple sentences. However, the improvement is clearer in Table 6b on the element level. Especially for the systems that had more missing propositions, namely Stanford, ReVerb, and OLLIE, the change is between .06 - .17.

Conjunctions As already stated by Saha et al. (2018), conjunctive sentences pose an issue to proposition extraction systems. In our case, we wanted to separate all conjunctive sentences in individual propositions, e.g. the sentence “The waitress smiled at her friend and at me.” contains the propositions “The waitress | smiled | at her friend” and “The waitress | smiled | at me.”. OpenIE and Stanford have the same guidelines on conjunctions, whereas Allen, ClausIE, and ReVerb keep the conjuncted elements together – from the previous sentence they would create one proposition – “The waitress | smiled | at her friend and me.”.

Negations Stanford does not extract from negated

[11] These sentences are classified as neither simple nor complex, but are included in all.

sentences and Allen has problems with negated sentences missing a verb. The rest can deal with negations. These specific problems are difficult to show in numbers, as they are rare – only about 7% of the sentences contained negations.

Prepositions OLLIE, ReVerb, and Stanford place the prepositions with the predicate, whereas all other systems as well as our gold standard place it with the associated argument, as is shown in the example in Table 1. For these cases we would need adjusted evaluations that ignore this difference.

Quantifiers Stanford ignores "every" in propositions.

4.4.2 Issues with Complex Sentences

We looked at issues within complex clauses, namely conditional and temporal clauses.

Conditional Clauses In some cases, Allen, ClausIE, OLLIE, and OpenIE extract the if-clause for the argument, but delete the "if", which leads to disagreements on both full proposition and proposition element level. Comparing the performance on all complex clauses as shown in Table 5a to complex clauses without conditional clauses, as shown in Table 6a, all systems, except for ReVerb and Stanford, clearly perform better. Allen is better by .04 and OpenIE by .05, which shows that they have the biggest issues with conditional clauses. On proposition element level this becomes even clearer. Here, the three better systems, ClausIE, Allen, and OpenIE perform .04 - .17 better without conditional clauses.

Temporal Clauses Conceptually, Allen, OLLIE, and OpenIE extract temporal clauses correctly, but have some problems if the sentence is too long. Stanford cuts out the "when". For temporal clauses, the performance is similar to conditional clauses. The three better systems perform .06 -.11 better on full proposition level, and .02-.09 better on proposition element level. Stanford and OLLIE perform worse without the temporal clauses.

5 Summary

In this work, we described a method on how to create a dataset of reduced sentences from originally complex ones. We created an English dataset according to this method and further classified this dataset as simple and complex. It can be used for further evaluation of proposition extraction systems. The dataset enabled us to research the performance of proposition extraction detached from the task of clause splitting.

On the one hand, we showed that sentence complexity has a measurable impact on proposition extraction performance of both humans and machines. Hence, one step towards improving the performance of such systems, is the improvement of clause splitting. Furthermore, we believe that the performance of the original complex sentences, without the preliminary reduction step, would pose an even bigger problem to proposition systems, which implies that using these systems on real data could be problematic.

On the other hand, our study also showed that the ranking of systems is similar among simple and complex sentences. This means, that the best performing systems among simple sentences that are disentangled from the task of clause splitting, are also the best in complex sentences, where clause splitting also needs to be performed. This may mean that to find the overall best system, one does not need to classify between simple and complex sentences. However, it is necessary to find that sentence complexity is one problem of proposition extraction.

Also, our intelligent baseline system, that was able to extract verbs, outperformed three of the systems. However, the better systems did not only perform much better, but they were also more affected by sentence complexity.

Additionally, we looked into further problems of proposition extraction systems. The main issues in complex sentences that we could identify were conditional and temporal clauses.

6 Future Work

In future work, we plan to enlarge the corpus in order to use it for studies on user-specific recommendations. We plan to display proposition-like information to the user to provide more specific information than is given by a long sentence. This work may help in clause splitting, as we not only provide a gold standard for it, but also describe a method on how to create it. Furthermore, we plan to built a proposition extraction system based on the findings from this paper.

Abstract

The study explores application of a simple Convolutional Neural Network for the problem of authorship attribution of tweets written in Polish. In our solution we use two-step compression of tweets using Byte Pair Encoding algorithm and vectorisation as an input to the distributional model generated for the large corpus of Polish tweets by word2vec algorithm. Our method achieves results comparable to the state-of-the-art approaches for the similar task on English tweets and expresses a very good performance in the classification of Polish tweets. We tested the proposed method in relation to the number of authors and tweets per author. We also juxtaposed results for authors with different topic backgrounds against each other.

1 Introduction

The problem of authorship attribution is one of the major areas of text classification. However, the issue is usually undertaken in the context of longer texts, such as book fragments, journal articles or emails. In recent years, mass media channels started playing a huge role in social life and made it possible to participate in global discussions, especially through social media. Twitter is one of the most influential social media platforms where anyone can share their opinion in form of a short text. Along with the growing influence of such platforms and limited user verification possibilities, importance of verifying the authorship of tweets and other short texts published on social media platforms has grown considerably. Such need is also motivated by moral responsibility of providing reliable media channels and discriminating propaganda messages.

Inspired by the results obtained in (Shrestha et al., 2017) as well as the simplicity of their method, we decided to verify its abilities in terms of classifying tweets written by selected Polish influencers. We treat the problem as a multiclass classification of texts. Our method differs from the original approach in terms of a chosen method for text encoding and next the way of obtaining its distributional vector representation as well as the scope of usage of data prepared in the processing pipeline, i.e. we use different data, unrelated to that used for classification, to train the distributional model.

2 Related Works

A big part of research done in terms of authorship attribution is relevant for big chunks of texts, where the sample of author's writing is relatively big (Gollub et al., 2013), (Frantzeskou et al., 2007), (Koppel et al., 2011). Recently, a lot of work has been done regarding authorship attribution of short texts, especially tweets due to their accessibility. The problem is challenging in comparison to the classification of longer texts as it is harder to maintain the classification accuracy along with the input pruning (Koppel and Winter, 2014). Some methods are based on stylistic features (Macleod and Grant, 2011) or word and character n-grams (Schwartz et al., 2013), (Sapkota et al., 2015).

Considering the fact that tweets may be of highly varying character with usage of multiple special characters, notorious misspellings and mixes of languages, character n-grams seem to be intuitively best-fit for the problem. Moreover, such approach appears to hold both topic-specific and morphology-specific information on the text (Koppel et al., 2011)

Proceedings of Recent Advances in Natural Language Processing, pages 409–417,
Varna, Bulgaria, Sep 2–4 2019.

(Sapkota et al., 2015). There were a couple of attempts to classify tweets based on their character n-gram representations (Schwartz et al., 2013) (Sari et al., 2017) (Zhang et al., 2015) with different approaches to extracting a subset of meaningful characters (Plakias and Stamatatos, 2008) (Sapkota et al., 2015). In terms of a classifier used for such a task, CNNs have been recently widely explored and proved successful for text analysis (Sierra et al., 2017) (Ruder et al., 2016).

A combination of the two approaches appears in (Shrestha et al., 2017) where a text is classified based on a sequence of input characters. The method uses straightforward sequences of characters and their n-grams which are then embedded and processed in a CNN classifier. Another approach which is using a byte pair encoding algorithm for text encoding together with the application of the same CNN classifier, proves that the method is comparable to the state-of-the-art despite another level of text compression (Wang, 2018). The latter, however, uses a limited range of characters with at least punctuation and white space characters ignored. Additionally, in both works the embedding layer is trained simultaneously with the classifier, which makes it impossible to transfer the acquired knowledge to external data sets.

3 Contribution

In our work we extend the solution presented in (Shrestha et al., 2017) by using *SentencePiece* with *Byte-Pair Encoding* algorithms (Kudo and Richardson, 2018), without exclusion of any characters. Moreover, instead of using a data-specific text embedding trained simultaneously with the classifier, we teach a separate distributional language model on a corpus of Polish tweets. We also test robustness of our solution by alternating topics in the training and testing corpora, as well as using disjunctive time windows for texts in both corpora.

4 Data

For the needs of the development and testing of our solution we collected two separate data sets:

Tweet Corpus – 1 020 234 Polish tweets (including 95 435 564 characters in total) obtained through Twitter API[1] by applying Polish language filter (automatic Twitter filter that can produce some noise) and in addition tracking the top 100 words from the frequency list generated for the Polish language (Kazojć, 2009) in the search query,

Influencer Set – 138 486 tweets written by 28 Polish influencers who were chosen manually.

The *Tweet Corpus* consists mostly of tweets in Polish. We decided not to filter out tweets including fragments in foreign languages as it is a common practice for the Twitter users to write their content with injections of other languages. Data has been gathered using **twint** Python module (Zacharias and Poldi, 2018).

For the *Influencer Set* we selected the authors mainly due to their activity and the number of followers. In addition we pre-selected four categories of authors, namely: *journalists* (8 authors), *politicians* (6 authors), *publicists* (4 authors) and *computer gamers* (2 authors). The topic-related groups are extrated as one of the goals of the experiments was to verify whether the subject on which particular users tweet is a strong distinguishing factor which affects obtained results. As the activity of different authors is diversified, the *Influencer Set* is highly unbalanced with the number of tweets per author deviating from 314 to 18 204 tweets per account. This problem was mediated by subsampling during the experiments.

5 Text Representation

Tweets are very short texts and do not include many repeated occurrences of typical stylometry markers like functional words. We can observe prevalence of the information content over typical stylistic markers. Thus, we need to search for semantic elements reoccurring for a single author, as well as characteristic idiosyncrasies of his language, e.g. words or expressions.

Tweet mostly include many abbreviations, typos, or language errors that result in relatively high variability of the language and complexity of the statistical picture. Thus, we need

[1] https://twitter.com

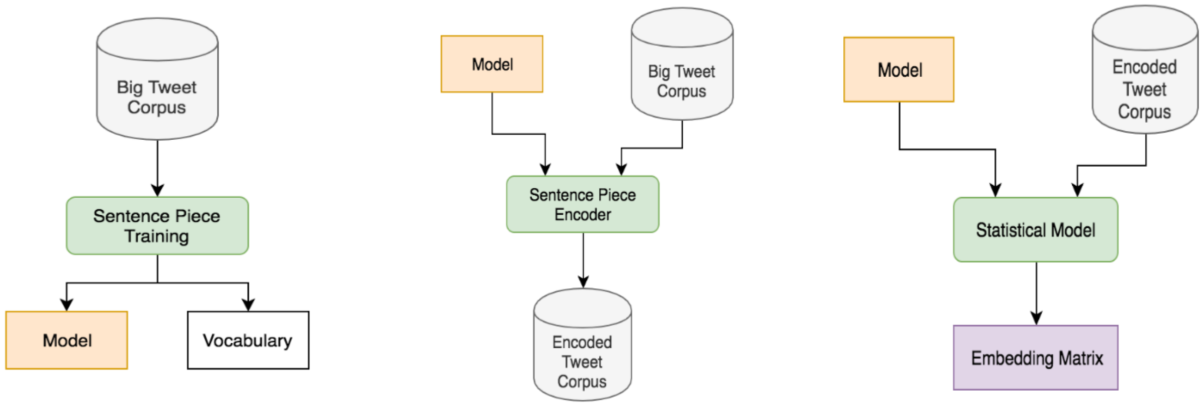

Figure 1: High-level structure of the processing pipeline used for obtaining text representation in our solution. From left to right: encoding model training, data encoding, embedding training.

to transform the original texts into a representation reducing this complexity. Very often, e.g. (Shrestha et al., 2017), tweets are represented by n-grams instead of words. However, the number of different n-grams is still very high. Instead of using n-grams, we processed the tweets with the help of the *Byte Pair Encoding* algorithm from *SentencePiece* library. *Byte Pair Encoding* (henceforth BPE) is a text compression method that constructs a tree-like structure of codes: recursively, two adjacent characters or symbols are encoded with a code represented by a single character that does not occur in the whole text. All punctuation and white characters are treated in the same way as other symbols. So there is no need for tokenisation. The algorithm starts from the most frequent pairs of characters (and next codes) and ends when all sequences are covered or it has reached the vocabulary size. Due to its recursive work the codes mostly represent not only bigrams but also higher-level n-grams, e.g. frequent words or even expressions. In all our experiments we used the BPE vocabulary size of: *4000 codes*. We tested vocabulary sizes from 1000 to 8000 codes and we did not notice improvement in performance for vocabulary size larger than 4000 codes.

BPE is often used for text compression, but our purpose was to make it a basis for a subword distributional semantics model. Texts encoded by BPE (i.e. tweets) were transformed into sequences of BPE codes separated by white spaces and delivered in such a form to the *Skip gram* algorithm from the *word2vec* library (Mikolov et al., 2013). As a result, every code receives its vector representation. The whole process is presented in Figure 1.

As codes represent different character sequences: from bi-grams, through sub-words up to even sub-expressions, we obtain a distributional semantics model which describes text units of varied granularity that reflect to some extent the statistical granularity of a corpus used for building the particular BPE model. A side effect is that vectors are also built for codes representing single letters that are rather meaningless, but this causes no harm to the overall properties of the model, as it will be visible.

The vector size in *Skip gram* was set to 300 elements. As the maximum length of a single tweet is 140 characters, so we made the representation of a single tweet to be a matrix of 140 code vectors[2]. In case BPE encoding for a tweet uses less than 140 codes (that often happens) the rest of the matrix is padded with a special null vector, i.e. not produced by *word2vec*.

In order to visualise the internal character of a BPE-encoded text, we present the histogram of initial tweet lengths in Figure 2, and contrast it with the histogram of the BPE-encoded tweet lengths in Figure 3. It can be noticed that the tweet lengths has become shorter, more evenly distributed with a slight dominance of the shorter representations. So,

[2] In the worst case of the weakest BPE mode codes correspond to single characters (symbols) in text, i.e. no more than 140 codes per a single tweet.

BPE-encoding results in a more packed text representation based sometimes on a few codes (representing sequences of letters).

Figure 4 presents the lengths of letter sequences represented by BPE codes obtained for the domain of politicians. The histograms are based on a subset of *Influencer Set*, containing tweets of 6 authors. When we compare it with the histogram of the whole domain in Figure 5 it can be observed that the code dictionary which is specific for the given domain contains slightly larger number of longer specialised codes. If we take a look into this domain specific dictionary we can find codes representing sometimes whole words that seem to be quite accidentally included into the dictionary. Thus, a dictionary built on the basis of a large corpus can be better suited to analysis of the authors' style that will be visible in Section 7 and especially in the results presented in Tables 4 and 3.

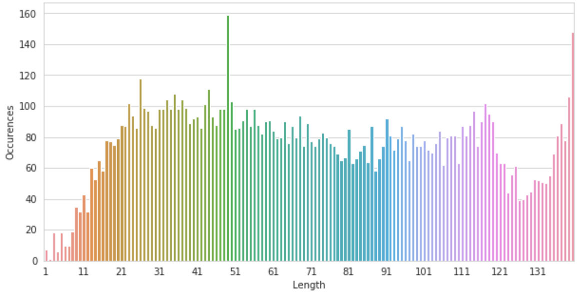

Figure 2: Histogram of tweet lengths for 28 635 tweets of politicians.

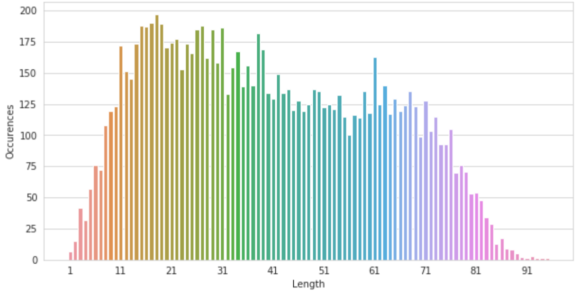

Figure 3: Histogram of BPE-encoded tweet lengths for 28 635 tweets of politicians.

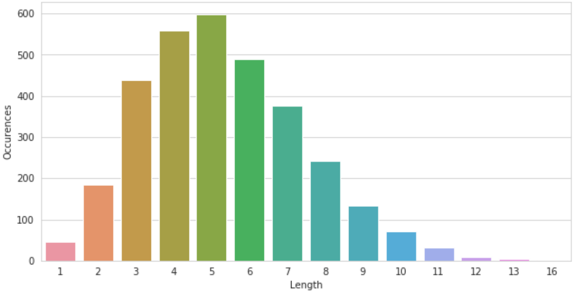

Figure 4: Histogram of BPE code lengths obtained by training the model on tweets of politicians (28 635 tweets).

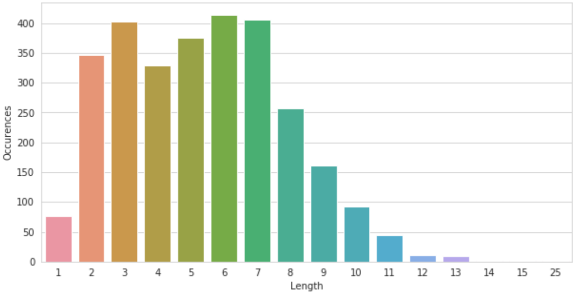

Figure 5: Histogram of BPE code lengths obtained by training the model on *Tweet Corpus* (1 020 234 tweets).

6 Classification Model

Our classification model follows the main lines *N-gram CNN* (Shrestha et al., 2017), but with BPE-based distributional representation in place of the original n-gram based one, i.e. instead of dividing the text into n-grams of characters directly from tweets, we split them into symbols obtained from the SentencePiece model. BPE-based model significantly limits the domain of possible symbols to the most common ones. It saves the vocabulary and the embedding matrix size. The neural network model architecture used in our research is visualised in Figure 6.

The architecture consists of an embedding layer and three parallel convolutional layers. Each convolutional layer contains 500 filters of sizes 3 × 3, 4 × 4 and 5 × 5 and is followed by max-pooling and dropout with 0.2 probability. The convolutional layers are merged and passed to a single dense layer with a 100 units and ReLU activation which is followed

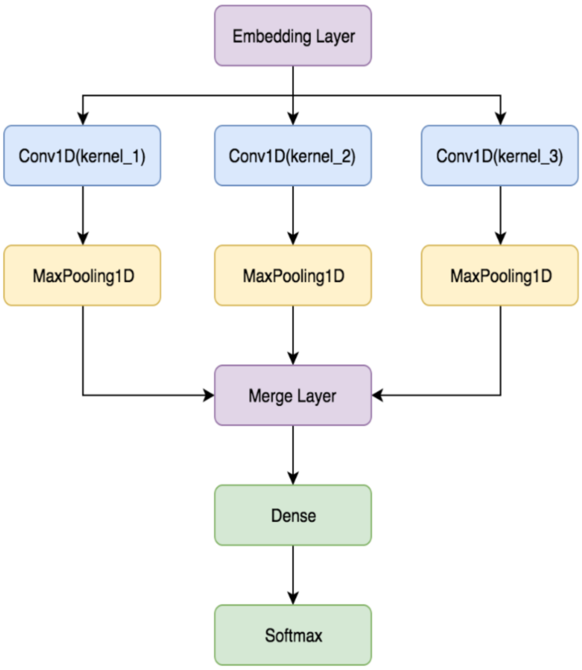

Figure 6: High-level structure of the N-gram CNN model used for author classification.

by dense layer with softmax activation.

Texts on the input to the embedding layer are represented by vectors pre-trained on the BPE encoded *Tweet Corpus*. During training the classifier, this layer was not completely frozen. Instead, it was adapted but with a significantly reduced learning rate as compared to the one used in the remaining layers. In this way, we manage to preserve high level generalisation obtained during training on the tweet corpus while slightly adapting to the training data domain.

The hyperparameters were slightly tuned from their initial state but their values are comparable to the ones used in the model of (Shrestha et al., 2017). We used Adam optimiser with 0.001 learning rate and categorical cross-entropy loss function. We trained the classifier with data batches of 4 samples in 5 epochs with L2 regularisation scaled by a 0.001 factor.

7 Experiments

7.1 Data Preprocessing

Before building the distributional semantics model and training the classifiers, we performed text preprocessing on tweets aimed at removing elements that seemed to be not relevant for the authors' styles and which could bias the classification process towards topic recognition. Thus, we removed all hashtags, mentions and URLs before constructing BPE encoding. The BPE models were generated from the preprocessed *Tweet Corpus* and selected subcorpora. Nonetheless, the very fact of using such extra-linguistic tweet elements, their placement and frequency might be important and relevant to authors' tweeting styles. Thus, we replaced all occurrences of extra-linguistic elements with symbols representing their types:

- *hashtags* were exchanged with '#' sign,
- *mentions* with the '@' sign,
- *URLs* with the 'ň' sign (not present in neither *Tweet Corpus* nor *Influencer Set*).

7.2 Multi-domain Authorship Attribution

In all experiments *Tweet Corpus* was used only to build a distributional semantics model and *Influencer Set* (not overlapping with the former) was used as training and testing data in a way following the k-fold cross validation scheme.

During the first experiment, we wanted to analyse the overall performance of the proposed approach on the whole *Influencer Set*. In order to balance the data set in relation to the number of tweets per author, we generated different subsets of the authors with random sub-sampling of tweets from more active authors. We wanted to investigate how many authors' styles our model can learn and how many tweets of each author are necessary to achieve satisfying results. The results are presented in Table 1.

7.3 Baseline Comparison

We compare our method against the baseline method of (Shrestha et al., 2017), using the same data set, i.e. the set presented in (Schwartz et al., 2013). This data set does not contain external data for language model training, so our approach of using a separate corpus for this task could not be applied. Thus in this experiment our solution differs only in the method for text encoding – the baseline

Tweets	Acc - 2	Acc - 4	Acc - 8	Acc - 12	Acc - 17	Acc - 23	Acc - 26	Acc - 28
16000	97.82 %	-	-	-	-	-	-	-
8000	97.41 %	90.89 %	-	-	-	-	-	-
4000	95.12 %	87.42 %	84.08 %	-	-	-	-	-
2000	93.25 %	84.11 %	81.19 %	72.44 %	71.34 %	-	-	-
1000	92.53 %	82.37 %	73.18 %	66.13 %	62.38 %	57.81 %	-	-
500	87.50 %	81.25 %	71.46 %	57.25 %	49.29 %	49.61 %	51.77 %	-
250	88.03 %	69.52 %	63.00 %	44.67 %	48.47 %	38.43 %	40.23 %	42.14 %
100	82.51 %	63.25 %	58.62 %	42.08 %	39.41 %	31.11 %	32.48 %	30.53 %

Table 1: Classification results for a varying number of authors and number of tweets. First column indicates the number of tweets per user used in experiment and the first row presents how many authors were classified in it. For instance, Acc-8, means the column under this cell presents accuracy results for 8-class classification (8 authors).

No. of tweets	**N-gram CNN**	**Ours**
50	**0.562**	0.528
100	**0.617**	0.609
200	**0.665**	0.657
500	0.724	**0.742**
1000	**0.761**	0.758

Table 2: Accuracy results for (Schwartz et al., 2013) data set, compared with results obtained in (Shrestha et al., 2017) for 50 authors.

method tokenises text into n-grams, while ours is using the BPE algorithm to encode tweets. For this data set we used the vocabulary size of 4000, with embedding length of 300, 128 batch sizes and 1.0 for the learning rate for Stochastic Gradient Descent in embedding training. For the classifier, we used Adam optimizer with 0.0001 learning rate, trained for 50 epochs with batches of 8 samples. Our results are averaged over 10-fold cross-validation. The baseline results are taken from (Shrestha et al., 2017), where we took the best achieved scores out of two studied architectures.

The comparison of classification accuracy for 50 authors and varying number of tweets in presented in Table 2.

As it is visible in Table 2, the baseline method is slightly better in majority of the experiment setups. However, the data set provided by (Schwartz et al., 2013) does not have an explicit train/test split or even a specified pool of 50 authors to perform classification on. Each fold has been randomly subsampled from a large pool of 7 026 authors. Moreover, for each author a specified number of tweets has been also randomly subsampled from a pool of 1 000 tweets.

The results presented in (Shrestha et al., 2017) are also not explicitly said to be averaged over folds. Considering the above mentioned preconditions, the results obtained cannot be used to unambiguously determine a superior method out of the two in a straightforward manner.

7.4 Cross-domain Encoding and Embedding

In the next group of experiments we investigated to what extent the model reflects particular domains of the authors (i.e. reacting first to the domain signal), and to what extent it represents the authors' style by themselves. Thus, we tried to classify authors from a specific domain by using the encoding-embedding model built on some other domain. Three configurations of both data sets were analysed:

1. the same data for building encoding model and tests,
2. data from another domain is used to construct encoding model,
3. the Polish *Tweet Corpus* is used for build-

Table 3: Accuracy score for authors of different domains (rows) with usage of encoding and embedding trained on different data (columns) with embedding layer active during training.

		Encoding and embedding training data					
	Author Domain	Sport	Social	Politics	Publicists	Gamers	Corpus
Classified	Sport	0.89	0.85	0.79	-	-	0.94
	Social	0.94	0.94	-	-	0.98	0.95
	Politics	0.86	-	0.89	0.79	-	0.90
	Publicists	0.87	-	0.86	0.90	-	0.88
	Gamers	-	0.96	-	-	0.97	0.99

ing the encoding mode (i.e. this is the baseline case).

For domains in which the number of authors is not the same, we subsample from the larger pool and average the results over possible combinations (e.g. Sport: 3 authors vs Gamers: 2 authors – we subsampled 3 times).

In addition, we run the experiments in two setups:

- with the embedding layer active during training a classifier
- and with embedding layer remaining frozen.

The results from the first scenario are shown in Table 3, while the effects of the second setting are presented in Table 4. The label "Corpus" means that the encoding model and the embeddings were constructed on the large *Tweet Corpus*, while the classifiers were trained on the given domain.

The lack of a value means that for the given pair we did not have enough data to build a balanced training-testing subset by subsampling to the size of the smaller domain.

8 Results

During the experiments on the whole set of authors, as expected, the results significantly decrease with the increasing number of authors taken into account and consequently the decreasing number of tweets per an author (due to the subsampling). While the results fall behind those presented in (Shrestha et al., 2017), they still surpass initial expectations. It is worth to take into consideration that the Polish language is more complex than English from the statistical point of view due to the rich morphology and a weekly constrained word order. However the latter was of minor importance as the model works mostly on the subword level and the distributional semantics model that does not depend on the word order (i.e. it is not sequential). The subword embeddings seem to be useful in decomposing Polish morphological forms into their natural components.

In addition, Polish tweets often include fragments written in English (of varied correctness) that also adds to the complexity of the problem and models. It is worth mentioning that in our experiments we used a significantly smaller amount of data than it was done in (Shrestha et al., 2017).

We initially suspected that the model would be biased by the authors' domains bias (i.e. topics of tweets or characteristic elements of the domain jargon). However, the result in the cross-domain model scenario, see Table 3 and Table 4, show a different picture. Firstly, in all cases the BPE-based embedding model built on the large corpus appeared to be superior to the domain-based model. Definitely, the difference in size of the corpora mattered in all cases in favour of *Tweet Corpus*. However, the size of the code dictionary was constant and equal to 4 000, i.e. it was quite small, and we can expect that the generalisation in the case of the big corpus was substantial. When the embedding layer got frozen in the second cross-domain experiment, all the results decreased, but only slightly. So, in the case of the limited code dictionary – providing a sparse and generalised picture of texts – the domain-focused tuning of the embedding layer appeared to not be very important.

The comparison with the method of

Table 4: Accuracy score for authors of different domains (rows) with usage of encoding and embedding trained on different data (columns) with embedding layer frozen during training.

		Encoding and embedding training data					
	Author Domain	Sport	Social	Politics	Publicists	Gamers	Corpus
Classified	Sport	0.90	0.84	0.82	-	-	0.95
	Social	0.86	0.94	-	-	0.97	0.96
	Politics	0.85	-	0.86	0.82	-	0.91
	Publicists	-	-	0.85	0.86	-	0.90
	Gamers	-	0.98	-	-	0.99	0.99

(Shrestha et al., 2017) in Table 2 showed that this reference method performs slightly better, however, the top results come from an ensemble of the two different models while our results are achieved by the single method. Moreover, our model is targeted on languages with rich inflection.

9 Conclusions and Further Research

The proposed method for the authorship attribution for Polish tweets expressed good performance for a large group of authors and large data set. It is based on the idea of an application of the Convolutional Neural Network proposed by (Shrestha et al., 2017), but it expands this approach with a distributional semantics model based on the prior application of BPE text encoding (i.e. embedding vectors are built for BPE codes, not words). As a result the proposed methods seems to be better suited for processing short texts in a highly inflectional language. It is worth to emphasise that the proposed approach is language independent, as the BPE model is driven by the statistical patterns in the training corpus.

The idea of an adaptive, coarse-grained distributional text representation for the needs of non-semantic classification seems to be attractive and opens several questions. There are various points in which the whole process could be improved, including but not being limited to:

- collecting a larger tweet corpus,
- improving language-based filtering of obtained tweets,
- investigating more closely the influence of the code dictionary size,
- comparing the proposed approach with other embedding learning methods,
- and optimise the classifier architecture.

While language filtering for using tweets in the Polish language exclusively seems to be a reasonable thing to do, it might not be perfectly adequate for the content such as tweets. We can observe a growing trend for users to post content with both languages present and the usage of such a practice may also be considered as a characteristic feature of their writing style. Language switch recognition in such a short text like tweets might be erroneous, but its tracking can improve the representation.

The question to what extent the method recognises an author's style, and to what extent this is only due to the correlation with some topics can be answered by the analysis of the confusion matrices between authors, distinctive features and stability of the recognition in time. Such an analysis could be combined with a strict filtering of tweets concerning the same events or topics and then verifying the classification performance. This is especially important due to the fact that Twitter data gets quickly irrelevant as topics change very fast.

Automatic Question Answering for Medical MCQs: Can It Go Further than Information Retrieval?

Le An Ha and Victoria Yaneva
Research Institute in Information and Language Processing,
University of Wolverhampton, UK
{ha.l.a, v.yaneva}@wlv.ac.uk

Abstract

We present a novel approach to automatic question answering that does not depend on the performance of an information retrieval (IR) system and does not require training data. We evaluate the system performance on a challenging set of university-level medical science multiple-choice questions. Best performance is achieved when combining a neural approach with an IR approach, both of which work independently. Unlike previous approaches, the system achieves statistically significant improvement over the random guess baseline even for questions that are labeled as challenging based on the performance of baseline solvers.

1 Introduction

Automatic question answering has seen a renewed interest in recent years as a challenge problem for evaluating machine intelligence. This has driven the development of large-scale question-answering data sets such as SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2016), WikiMovies benchmark (Chen et al., 2017), TriviaQA (Joshi et al., 2017) (to name a few), as well as the organisation of workshops such as the Machine Reading for Question Answering 2018 workshop[1]. In spite of the optimistic advances over crowd-sourced questions and online queries, automatic question answering for real exam questions is still a very challenging and under-explored area. For example, the Allen AI Science Challenge[2] invited researchers worldwide to develop systems that could solve standardized eight-grade science questions. The best system out of all 780 participating teams achieved a score of 59.31% correct answers using a combination of 15 gradient-boosting models (random baseline of 25%), while the authors report that using Information Retrieval (IR) alone results in a score of 55%.

The difficulties related to answering exam questions are partly due to the complexity of the reasoning involved and partly to the lack of large training data. Another significant reason is the fact that the existing approaches to question answering are dependent on the performance of IR systems and can rarely go far beyond the performance of such systems. While IR is a powerful method when answering questions where the correct answer is a string contained within a document, the systems fail when the sentences within the question do not individually hold a clue to what the correct answer might be (Clark et al., 2018). This is one of the characteristics of Multiple Choice Questions (MCQs) from the science domain that makes them so challenging for both machines and for humans.

In this paper we aim to address these shortcomings by developing an approach that: i) does not require that the training data (often unavailable) be in the form of multiple-choice questions and ii) does not depend on matching strings of text with one another. We use a challenging set of medical exam questions developed for the United States Medical Licensing Examination (USMLE®), a standardized medical exam that university students need to pass in order to obtain the right to practice medicine in the US. As such, the USMLE represents a very difficult set, requiring a high level of specialized professional knowledge and reasoning over facts. Furthermore, the USMLE contains a wide variety of question types such as selecting the most appropriate diagnosis, treatment, specific further examination needed, etc., all of which require application of clinical knowledge over facts.

Proceedings of Recent Advances in Natural Language Processing, pages 418–422,
Varna, Bulgaria, Sep 2–4 2019.

Contributions We introduce and compare two approaches for automatic question answering that do not require training data in the form of MCQs, using Information Retrieval (IR) techniques and standard neural network models. Unlike previous work, our neural approach is independent of the performance of the IR system, as it does not build upon it. Thus, it is possible to achieve improvements over both systems by combining them, as each system has an individual contributions towards solving the problem. The best combination results in 18% improvement over a random guess baseline. The neural models achieve a statistically significicant improvement over the random baseline on the challenging sets. The code used in this study, as well as the public data[3] are made available at: https://bit.ly/2jNW2ym.

2 Related Work

Most of the recent work in the field focuses on answering reading comprehension questions from benchmark datasets such as SQuAD (Rajpurkar et al., 2016), the release of which ignited a rapid progress in the field. For example, Wang et al. (2017) use gated self-matching networks and report accuracy as high as 75.9% over a random guess baseline of around 4% and a logistic regression baseline of around 51%. Among the most successful approaches in other studies are ones that use neural models such as match-LSTM to build question-aware passage representation (Wang and Jiang, 2015), bi-directional attention flow networks to model question-passage pairs (Seo et al., 2016), or dynamic co-attention networks (Xiong et al., 2016).

As mentioned in the previous section, automatic question answering for science exams is a lot more challenging than for crowd-sourced reading comprehension questions. When applied to science questions, IR techniques: i) still perform somewhat close to the state-of-the-art and ii) fail on tasks where the correct answer is not specifically contained in relevant sentences. Clark et al. (2018) implement five of the best models from the studies on the reading comprehension data sets (TableILP (Khashabi et al., 2016), TupleInference (Khot et al., 2017), Neural entailment models (DecompAttn, DGEM, and DGEM -OpenIE) (Parikh et al., 2016), and BiDAF (Seo et al., 2016)), as well as IR models and test them on a total of 7787 science questions. The questions are divided into two sets, challenging and easy, and are targeted at students between the ages of 8 and 13. It is important to note that the authors define a question as being challenging or easy not on the basis of human performance or the age of the students it is targeted at, but based on whether it has been answered incorrectly by at least two of the baseline solvers. The results indicated that none of the algorithms performed significantly higher than the random guess baseline of 25% on the challenging set, while the performance on the easy set was within the range of 36% and 62%. According to the authors, a possible explanation for the low accuracy is that nearly all models use some form of information retrieval to obtain relevant sentences, and the retrieval bias in these systems is towards sentences that are very similar to the question, as opposed to sentences that individually differ but together explain the correct answer (Clark et al., 2018). Notably, the neural solvers performed poorly on the easy set, while the best result was achieved by an IR-only system.

3 Data

In the USMLE data each test item is a single-best-answer MCQ consisting of a stem (question) followed by several response options (distractors), one of which is the correct answer (key). An example of such an item is provided in Table 1. We divide our data into two sets: private and public (Table 2). The private data set consists of a total of 2,720 MCQs and they are not available to the public due to test security reasons. The public data set consists of 454 items from USMLE 2015 Step 1, USMLE 2016 Step 1, USMLE 2014 Step 2, and USMLE 2017 Step 2 sample leaflets. These are available at the USMLE website[4] and in our repository. For the purpose of this study, we have selected only those items that fulfill the following criteria: i) whose correct answer contains at least one heading from the Medical Subject Headings (MeSH[5]) database that is at most three words, and ii) have exactly 5 options that have at least one MeSH heading that is at most three words. The

[3] See Section 3. The Public data set used in this study consists of questions released as training materials by the USMLE.

[4] The items can be accessed at the USMLE web site at http://www.usmle.org/, for example: http://www.usmle.org/pdfs/step-1/samples_step1.pdf

[5] https://www.nlm.nih.gov/mesh/

A 56-year-old man comes to the emergency department because of a 4-day history of colicky right flank pain that radiates to the groin and hematuria. Ultrasound examination of the kidneys shows right-sided hydronephrosis and a dilated ureter. Which of the following is most likely to be found on urinalysis? (A) Erythrocyte casts (B) Glucose (C) Leukocyte casts (D) Oval fat bodies (E)* Uric acid crystals

Table 1: An example of an item from the USMLE exam (question 128, USMLE 2015 step 1 sample test questions)

	Public	Private
Number of Items	164	921
Average words per item	116	87

Table 2: Characteristics of the two sets

latter is in order to keep the random guess baseline at a constant for all items (20%). As a result, the final data that we have is 164 items for the public set and 922 for the private one.

4 Method

We develop and compare two methods for answering the USMLE questions, both of which do not require training data in the form of MCQs. The details of each method are described below.

4.1 IR-Based Method

We use a standard IR approach. First, we index 2012 MEDLINE abstracts using Lucene[6] with its default options. Then, for each item we build the five queries, where each query contains the stem and an option. We use three settings for the queries:

- All words (IR-All) (baseline)
- Nouns only (IR-Nouns)
- Nouns, Verbs, or Adjectives only (IR-NVA),

We then get the top 5 documents returned by Lucene and calculate the sum of the retrieval scores. The picked answer is the one that has the highest score when combined with the stem to form the query. This method is similar to the IR baseline described in Clark et al. (2018) and variations of it have been previously applied to medical MCQs for the purposes of distractor generation (Ha and Yaneva, 2018) and predicting item difficulty (Ha et al., 2019).

4.2 Neural Network Method

For this approach we train neural networks to predict the MeSH headings for each abstract. The premise of this approach is that we hypothesise that the task of answering an USMLE item could be considered to be similar to the task of identifying the topics of a snippet of text: in the case of MEDLINE indexing, indexers read the abstract, and then choose the topics that are most relevant to the abstract; whereas in the case of taking USMLE exam, test takers read the stem, and then choose the option that is most relevant to the stem. Approaching the problem this way, we can benefit from the availability of the MEDLINE data, in which each abstract has been manually (or semi-manually) assigned most relevant subject headings. We focus only on headings that appear in the options of the set of items (see above). For our set, there are around 1000 headings. Our neural networks[7] were trained using Keras[8]. We use two main structures:

- Bidirectional LSTM (LSTM). Specifications: an input layer, followed by an embedding layer and a bidirectional layer, each of size 250. The final two layers are a flattening layer and a dense layer. The classes are weighted inversely to their frequency.
- Convoluted 1d with attention (Conv1d). Specifications: an input layer, followed by an embedding layer, three convolutional layers, and a concatenating layer, each of size 250.

[6] https://lucene.apache.org/

[7] Preprocessing includes tokenization (using keras.preprocessing.text package in python), no lower case normalization, no number normalization, recording words with a min frequency of 5. The neural network models then further restrict the vocabulary to the first 200000 most frequent words. Out of vocabulary rate was 1%. Nadam optimizer was used with its default options (learning rate = 0.002, beta_1 = 0.9, beta_2 = 0.999, epsilon = None, schedule_decay = 0.004). Batch size = 128, activation function used in the last layer was Softmax.

Neural correct when IR tie	9 out of 15	26 out of 89

Table 3: Accuracy of the different systems. The values marked with * signify statistically significant difference over the random guess baseline and ** signifies statistically significant improvement over both baselines.

These are followed by an attention layer and a densely connected layer.

We train the models on 10,000,000 MEDLINE abstracts (the same set used in the IR approach), going through them twice. We experiment with pre-trained GloVe840b (Pennington et al., 2014) and word2vec[9], but the results are inferior to training the embedding layers from scratch. We then use the trained models to predict the probability of a MeSH heading in an option given the stem. We then average the probabilities if the option contains more than 1 heading.

4.3 Combined Method

We use two methods to combine the IR and neural model scores. The first method just adds the log value of the two scores together (log(IR_Noun)+log(Conv1d)). The second method uses the neural model scores as a tie breaker ('Neural as tie breaker'): if the IR method returns a single option, we take the result from the IR. If the IR method returns more than one options, we take the results from the neural model instead.

4.4 Baselines

We compare our results to two baselines: the probability of a random guess to pick the correct answer and the IR-All model described above.

5 Results and Discussion

The results from our study are presented in Table 3. Best performance is achieved by using neural model scores as a tie breaker. This result significantly outperforms both the random guess baseline and the IR-All approach.

It is interesting to note that while neural approaches alone present a significant improvement only over the random guess baseline, using neural approaches to solve ties leads to an overall increase in performance for the best combined models. The independent nature of the neural approach is best illustrated when testing its performance over items that were incorrectly solved by the best IR approaches. This is the case for 110 items from the public data set, and 587 items from the private data set, which, if we follow the definition of Clark et al. (2018), can be regarded as "challenging" since the best IR solver could not answer them correctly. In the case of Clark et al. (2018) none of the tested solvers achieved significant improvement over the random guess baseline when evaluated on the challenging questions. In our case, the neural approaches achieve 29% accuracy (32 items) for the public data set and 27.6% accuracy (162 items) for the private one, which are both statistically significant when comparing to random guess. This independence, resulting from the use of humanly produced subject headings, indicate that these headings do provide additional information with regards to the task.

[9] https://code.google.com/archive/p/word2vec/

A drawback of the neural approach proposed in this paper is that it relies on the availability of a manually indexed database such as MEDLINE. This limits the applicability of the approach to other domains, however, this may change when more resources become available in the future. It is important to note that in this restricted setting the method solves a very difficult problem better than any other approach so far. In the future, instead of using the adhoc neural network architectures presented in this paper, we plan to utilise state-of-the-art architectures such as Elmo (Peters et al., 2018) or BERT (Devlin et al., 2018), while using the prediction of MESH headings as an additional learning objective.

6 Conclusion

We presented an approach to automatic question answering that does not rely on training data in the form of MCQs and can perform independently from IR. We first train neural networks to predict the MeSH headings for a set of MEDLINE abstracts and then use the trained network to predict the correct answers of medical MCQs. Best performance was achieved when combining this approach with an information retrieval approach and the model significantly outperformed both a random guess baseline and one based on a common IR approach.

Abstract

Since deep learning became a key player in natural language processing (NLP), many deep learning models have been showing remarkable performances in a variety of NLP tasks, and in some cases, they are even outperforming humans. Such high performance can be explained by efficient knowledge representation of deep learning models. While many methods have been proposed to learn more efficient representation, knowledge distillation from pretrained deep networks suggest that we can use more information from the soft target probability to train other neural networks. In this paper, we propose a new knowledge distillation method *self-knowledge distillation*, based on the soft target probabilities of the training model itself, where multimode information is distilled from the word embedding space right below the softmax layer. Due to the time complexity, our method approximates the soft target probabilities. In experiments, we applied the proposed method to two different and fundamental NLP tasks: language model and neural machine translation. The experiment results show that our proposed method improves performance on the tasks.

1 Introduction

Deep learning has achieved the state-of-the-art performance on many machine learning tasks, such as image classification, object recognition, and neural machine translation (He et al., 2016; Redmon and Farhadi, 2017; Vaswani et al., 2017) and outperformed humans on some tasks. In deep learning, one of the critical points for success is to learn better representation of data with many layers (Bengio et al., 2013) than other machine learning algorithms. In other words, if we make a model to learn better representation of data, the model can show better performance.

In natural language processing (NLP) tasks like language modeling (LM) (Bengio et al., 2003; Mikolov et al., 2013) and neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015), when the models are trained, they are to generate many words in sentence, which is a sequence of classification steps, for each of which they choose a target word among the whole words in the dictionary. That is why LM and NMT are usually trained with the sum of cross-entropies over the target sentence. Thus, although language related tasks are more of generation rather than classification, the models estimate target probabilities with the softmax operation on the previous neural network layers and the target distributions are provided as one-hot representations. As data representation in NLP models, word symbols should also be represented as vectors.

In this paper, we focus on the word embedding and the estimation of the target distribution. In NLP, word embedding is a step to translate word symbols (indices in the vocabulary) to vectors in a continuous vector space and is considered as a standard approach to handle symbols in neural networks. When two words have semantically or syntactically similar meanings, the words are represented closely to each other in a word embedding space. Thus, even when the prediction is not exactly correct, the predicted word might not be so bad, if the estimated word is very close to the target word in the embedding space like 'programming' and 'coding'. That is, to check how wrong the prediction is, the word embedding can be used. There are several methods to obtain word embedding matrices (Mikolov et al., 2013; Pennington et al., 2014), in addition to neural language models (Bengio et al., 2003; Mikolov et al., 2010). Recently, several approaches have been proposed to make more efficient word embedding matrices, usually based on contextual information (Søgaard et al., 2017; Choi et al., 2017).

On the other hand, knowledge distillation was proposed by (Hinton et al., 2015) to train new and usually shallow networks using hidden knowledge in the probabilities produced by the pretrained networks. It shows that there is knowledge not only in the target probability corresponding to the target class but also in the other class probabilities in the estimation of the trained model. In other words, the other class probabilities can contain additional information describing the input data samples differently even when the samples are in the same class. Also, samples from different classes could produce similar distributions to each other.

In this paper, we propose a new knowledge distillation method, *self-knowledge distillation* (SKD) based on the word embedding of the training model itself. That is, self-knowledge is distilled from the predicted probabilities produced by the training model, expecting the model has more information as it is more trained. In the conventional knowledge distillation, the knowledge is distilled from the estimated probabilities of pretrained (or teacher) models. Contrary, in the proposed SKD, knowledge is distilled from the current model in the training process, and the knowledge is hidden in the word embedding. During the training process, the word embedding reflects the relationship between words in the vector space. A word close to the target word in the vector space is expected to have similar distribution after softmax, and such information can be used to approximate the soft target probability as in knowledge distillation. We apply our proposed method to two popular NLP tasks: LM and NMT. The experiment results show that our proposed method improves the performance of the tasks. Moreover, SKD reduces overfitting problems which we believe is because SKD uses more information.

The paper is organized as follows. Background is reviewed in Section 2. In Section 3, we describe our proposed method, SKD. Experiment results are presented and analyzed in Section 4, followed by Section 5 with conclusion.

2 Background

In this section, we briefly review the cross-entropy and knowledge distillation. Also, since our proposed method is based on word embedding, the layer right before the softmax operation, word embedding process is summarized.

2.1 Cross Entropy

For classification with C classes, neural networks produce class probabilities p_i, $i \in \{0, 1, ...C\}$ by using a softmax output layer which calculates class probabilities from the logit, z_i considering the other logits as follows.

$$p_i = \frac{\exp{(z_i)}}{\sum_k \exp{(z_k)}}. \tag{1}$$

In most classification problems, the objective function for a single sample is defined by the cross-entropy as follows.

$$J(\theta) \quad = \quad -\sum_k y_k \log p_k, \tag{2}$$

where y_k and p_k are the target and predicted probabilities. The cross-entropy can be simply calculated by

$$J(\theta) \quad = \quad -\log p_t, \tag{3}$$

when the target probability $\boldsymbol{y}$ is a one-hot vector defined as

$$y_k = \begin{cases} 1, & \text{if } k = t(\text{target class}) \\ 0, & \text{otherwise} \end{cases}. \tag{4}$$

Note that the cross-entropy objective function says only how likely input samples belong to the corresponding target class, and it does not provide any other information about the input samples.

2.2 Knowledge Distillation

A well trained deep network model contains meaningful information (or knowledge) extracted from training datasets for a specific task. Once a deep model is trained for a task, the trained model can be used to train new smaller (shallower or thinner) networks as shown in (Hinton et al., 2015; Romero et al., 2014). This approach is referred to as *knowledge distillation*.

Basically, knowledge distillation provides more information to new models for training and improves the new model's performance. Thus, when a new model which is usually smaller is trained with the distilled knowledge from the trained deep model, it can achieve a similar (or sometimes even better) performance compared to the pretrained deep model.

In the pretrained model, knowledge lies in the class probabilities produced by softmax of the model as in Eq. (1). All probability values including the target class probability describe relevant information about the input data. Thus, instead of one-hot representation of the target label where only the target class is considered in cross-entropy, all probabilities over the whole classes from the pretrained model can provide more information about the input data in cross-entropy, and can teach new models more efficiently. All probabilities from the pretrained model are considered as *soft target probabilities*.

In a photo tagging task, depending on the other class probabilities, we understand the input image better than just target class. When a class 'mouse' has the highest probability, if 'mascot' has a relatively high probability, then the image would be probably 'mickey mouse'. If 'button' or 'pad' has a high probability, the image would be a mouse as a computer device. The other class probabilities have some extra information and such knowledge in the pretrained model can be transferred to a new model by using a soft target distribution of the training set.

When the target labels are available, the objective function is a weighted sum of the conventional cross-entropy with the correct labels and the cross-entropy with the soft target distribution, given by

$$J(\theta) = -(1-\lambda)\log p_t - \lambda \sum_k q_k \log p_k, \quad (5)$$

where p_k is probability for class k produced by current model with parameter θ, and q_k is the soft target probability from the pretrained model. λ controls the amount of knowledge from the trained model. Note that the conventional knowledge distillation extracts knowledge from a pretrained model, and in this paper, we propose to extract knowledge from the current model itself without any pretrained model.

Furthermore, in a recently proposed paper by (Furlanello et al., 2018), they proved that knowledge distillation can be useful to train a new model which has the same size and the same architecture as the pretrained model. They trained a teacher model first, then they trained a student model with distilled knowledge from the teacher model. Their experiment results show that the student models outperform the teacher model. Also, even though when the teacher model has a less powerful architecture, the knowledge from the trained teacher model can boost student models which have more powerful (or bigger) architectures. It means that even the knowledge is distilled from a relatively weak model, it can be useful to train a bigger model.

2.3 Word Embedding

Word embedding is to convert symbolic representation of words to vector representation with semantic and syntactic meanings, which reflects the relations between words. Including CBOW, Skip-gram (Mikolov et al., 2013), and GloVe (Pennington et al., 2014), various word embedding methods have been proposed to learn a word embedding matrix. The trained embedding matrix can be transferred to other models like LM or NMT (Ahn et al., 2016).

CBOW predicts a word given its neighbor words, and Skip-gram predicts the neighbor words given a word. They use feedforward layers, and the last layer of CBOW includes the word embedding matrix, $\boldsymbol{W}$, as follows.

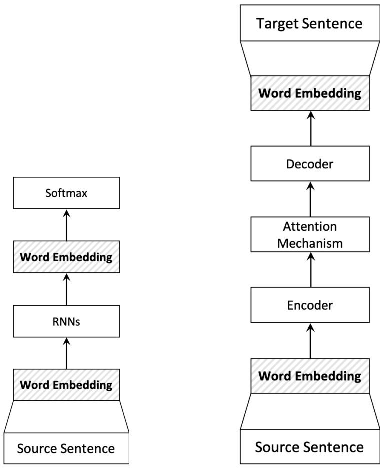
$$\boldsymbol{z} = \boldsymbol{W}\boldsymbol{h} + \boldsymbol{b}, \quad (6)$$

where $\boldsymbol{b}$ is a bias, $\boldsymbol{h}$ is hidden layer, and $\boldsymbol{z}$ is logits for the softmax operation.

Words in the embedding space have semantic and syntactic similarities, such that two similar words are close in the space. Thus, when the classification is not correct, the error can be interpreted differently depending on the similarity between the predicted word and the target word. For example, when the target word is 'learning', if the predicted word is 'training', then it is less wrong than other words like 'flower' or 'internet'. In this paper, we utilize such hidden information (or knowledge) in the word embedding space, while training. Fig. 1 shows where the word embedding is located in LM and NMT, respectively.

3 Self-Knowledge Distillation

We propose a new learning method *self-knowledge distillation* (SKD) which distills knowledge from a currently training model, following the conventional knowledge distillation. In this section, we describe an algorithm for SKD and its application to language model and neural machine translation.



(a) Language Model (b) NMT Model

Figure 1: Network architectures of LM and NMT. Word embedding is presented as gray boxes in the models.

3.1 SKD Equations

In order to apply knowledge distillation on a current training model, we need to obtain soft target probabilities as q_k in Eq. (5) for all classes, but they are not available explicitly. However, when the model is trained enough, then the word embedding has such information implicitly. If a word $\boldsymbol{w}_i$ is close to $\boldsymbol{w}_j$ in the embedding space, the probability p_i would be close to p_j for a given input sample.

When t is the target class, we calculate the soft target probabilities q_k based on the word embedding. First, we assume that q_t should be high, and if $\boldsymbol{w}_k$ is close to $\boldsymbol{w}_t$ in the embedding space, q_k should be also high. That is, the Euclidean distance between words is used to estimate the soft target probability. The other class probabilities (or soft target probabilities) q_k can be obtained by

$$q_k = \frac{1}{Z} \exp\{-\sigma \|\boldsymbol{w}_t - \boldsymbol{w}_k\|_2\}, \qquad (7)$$

where $\|\cdot\|_2$ is $l2$-norm, and Z is a normalization term. σ is a scale parameter and its value depends on the average distance to the corresponding nearest neighbors in the word embedding space. However, due to the expensive computational cost, we do not calculate q_k for all classes, and we choose just one of the other classes, which is the predicted class of the current model.

Assuming that the model predicts a class n for a given input sample, only q_t and q_n are used as distilled knowledge. We clip the q_n value with 0.5, meaning that the class n cannot be more correct than the real target t, so Eq. (7) becomes

$$\begin{aligned} q_n &= \min\{\exp\{-\sigma\|\boldsymbol{w}_t - \boldsymbol{w}_n\|_2\}, 0.5\}, \\ q_t &= 1 - q_n, \end{aligned} \qquad (8)$$

where $q_n + q_t = 1$. That is, we consider only two soft target probabilities as shown in Fig. 2. Note that we use Euclidean distance between $\boldsymbol{w}_t$ and $\boldsymbol{w}_n$ to calculate q_n, but other approaches like inner product would be possible.

Now, the objective function of SKD becomes similar to Eq. (5), and is defined by

$$\begin{aligned} J(\theta) &= -(1-\lambda)\log p_t \\ &\quad -\lambda(q_t \log p_t + q_n \log p_n), \end{aligned} \qquad (9)$$

where the second term of Eq. (5) is approximated by $\lambda(q_t \log p_t + q_n \log p_n)$, ignoring the other class probabilities. Eq. (9) can be rewritten simply as follows.

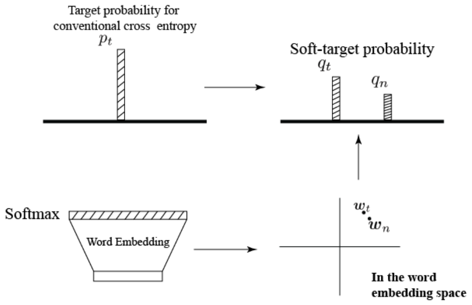
$$J(\theta) = -(1-\lambda q_n)\log p_t - \lambda q_n \log p_n. \qquad (10)$$

Eqs. (9) or (10) can be understood in three cases. First, if the prediction is correct ($n = t$), then Eq. (9) is the same as the conventional cross-entropy objective. Second, if $\boldsymbol{w}_n$ is far from $\boldsymbol{w}_t$ in the word embedding space, then q_n is close to zero and Eq. (9) becomes close to the conventional cross-entropy objective. Finally, if $\boldsymbol{w}_n$ is close to $\boldsymbol{w}_t$ (e.g. q_n = 0.4), it approximates the soft target probability with only two classes t and n, and the model is trained to produce probabilities for class t and n as close as q_t and q_n. This approach trains the model with different targets for different input samples.

Fig. 2 presents how SKD obtains simplified soft target distribution based on the distance of target and estimated vectors in the word embedding space.

3.2 SKD Algorithm

Since SKD distills knowledge from the current training model, at the beginning of the training process, the model does not contain relevant information. That is, we cannot extract any knowledge from the training model at the beginning. Thus, we start training process without knowledge distillation at first and gradually increase the amount of knowledge distillation as the training iteration goes. So, our algorithm starts with the conventional cross-entropy objective function in Eq. (3), and after training the model for a while, it gradually



Target probability for conventional cross entropy

Figure 2: Given a target class t, a soft target probabilities are obtained based on the distance in the word embedding space. However, only the target class and the predicted class have soft target probabilities in SKD.

transits to Eq. (10). To implement the transition, another parameter α is introduced to Eq. (10), leading to the final objective function as follows.

$$J(\theta) = -(1 - \alpha\lambda q_n) \log p_t - \alpha\lambda q_n \log p_n, \quad (11)$$

α starts from 0 with which Eq. (11) becomes the conventional cross-entropy. After K iterations, α increases by η per iteration and eventually goes up to 1 with which Eq. (11) becomes the same as Eq. (9). In our experiments, we used a simplified equation as in Eq. (12) without λ so that the objective function relies gradually more on the soft target probabilities as training goes.

$$J(\theta) = -(1 - \alpha q_n) \log p_t - \alpha q_n \log p_n. \quad (12)$$

Table 1 summarizes the proposed SKD algorithm.

3.3 NLP Tasks

SKD is applied to two different NLP tasks: language modeling (LM), and neural machine translation (NMT). Although LM and NMT are actually sentence generation rather than classification, they have classification steps to generate words for the target sentence. Also, the sum of cross-entropies over the words in the sentence is adapted as an objective function for them.

In addition, to check if SKD is robust against errors in the word embedding space, we also evaluate SKD when we add Gaussian noise in the word embedding space for target words in the decoder.

4 Experiments

To evaluate self-knowledge distillation, we compare it to the baseline models for language modeling and neural machine translation.

4.1 Dataset

For language modeling, we use two different datasets: Penn TreeBank (PTB) and WiKi-2. PTB was made by (Marcus et al., 1993), and we use the pre-processed version by (Mikolov et al., 2010). In the PTB dataset, the train, valid and test sets have about 887K, 70K, and 78K tokens, respectively, where the vocabulary size is 10K. The WiKi-2 dataset introduced by (Merity et al., 2016) consists of sentences that are extracted from Wikipedia. It has about 2M, 217K, and 245K tokens for train, valid, and test sets. Its vocabulary size is about 33K. We did not apply additional pre-processing for the PTB dataset. The WiKi-2 dataset is pre-tokenized data, therefore we only added an end-of-sentence token (<EOS>) to every sentence.

For machine translation, we evaluated models on three different translation tasks (En-Fi, Fi-En, and En-De) with the available corpora from WMT'15 [1]. The dictionary size is 10K for En-fi and Fi-En translation task, and 30K for the En-De translation task.

4.2 Language Modeling

Language modeling (LM) has been used in many different NLP tasks like automatic speech recognition (ASR), and machine translation (MT) to capture syntactic and semantic structure of a natural language. The neural network-based language models (NNLM) and recurrent neural network language model (RNNLM) catch the syntactic and semantic regularities of an input language (Bengio et al., 2003; Mikolov et al., 2013). RNNLM is our baseline, which consists of a single LSTM layer and

[1] http://www.statmt.org/wmt15/translation-task.html

single feed forward layer with ReLU (Le et al., 2015).

We evaluate four models: Baseline, Noise (with Gaussian noise on the word embedding), SKD, and Noise+SKD. To show that the information by SKD is more knowledgeable than random noise, we tested a noise injected model which injects only Gaussian noise to the word embedding space. The word dimension is set to 500 and the number of hidden nodes is 400 for all models. We set the σ and η in the SKD algorithm in Table 1 0.1 (both PTB and WiKi-2 dataset) and 0.0002 (PTB), 0.00011 (WiKi-2), respectively. We applied the SKD object function after 500 batches for PTB and 900 batches for WiKi-2. Note that Wiki-2 data is larger than PTB.

The evaluation metric is the negative log-likelihood (NLL) for each sentence (the lower is the better). Table 2 presents NLLs for the test data of two datasets with different models. It shows that our proposed methods (both noise injection and self-distillation knowledge) improve the results in the LM task. Note that SKD provides more knowledgeable information than Gaussian noise.

Table 2: NLLs for LM with different models on PTB and Wiki-2.

Model	PTB	Wiki-2
Baseline	101.40	119.49
+Noise	101.28	118.70
+SKD	99.38	116.85
+Noise+SKD	**97.41**	**116.60**

4.3 Neural Machine Translation

NMT has been widely used in machine translation research, because of its powerful performance and end-to-end training (Sutskever et al., 2014; Bahdanau et al., 2015; Johnson et al., 2017). Attention-based NMT models consist of an encoder, a decoder, and the attention mechanism (Bahdanau et al., 2015), which is our baseline in this paper except for replacing GRU with LSTM and using BPE (Sennrich et al., 2016). The encoder takes the sequence of source words in the word embedding form. The decoder works in a similar way to LM, except the attention mechanism. See (Bahdanau et al., 2015) for NMT and the attention mechanism in detail.

In the experiments, we check how much SKD can improve model's performance using the simple baseline architecture. Since SKD modifies only the objective function, we believe that the improvement by SKD is regardless of model architectures.

Table 3 shows that our proposed method improves NMT performance by around 1 BLEU score. For qualitative comparison, some translation results are presented below. The overall quality of translation of the SKD model looks better than baseline model's. In other words, when the BLEU scores are similar, the sentences translated by the SKD model look better.

- (src) Hallituslähteen mukaan tämä on yksi monista ehdotuksista, joita harkitaan.
  (trg) A governmental source says this is one of the many proposals to be considered.
  (baseline) *According to government revenue, this is one of the many proposals that are being considered to be considered.*
  (SKD) *According to the government, this is one of the many proposals that are being considered.*

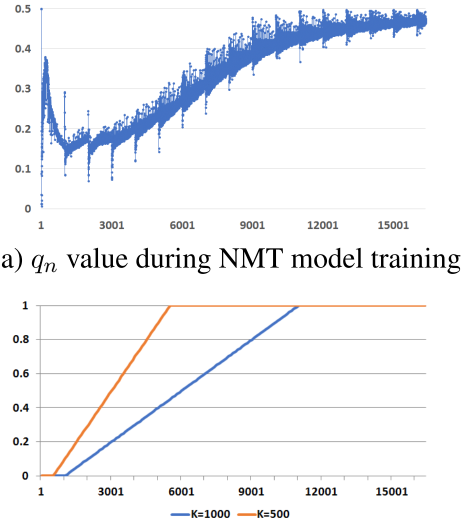
- (src) Meillä on hyvä tunne tuotantoketjunvahvuudesta.
  (trg) We feel very good about supply chain capability.
  (baseline) *We have good knowledge of the strength of the production chain.*
  (SKD) *We have a good sense of the strength of the production chain.*

- (src) En ole oikein tajunnut, että olen näin vanha.
  (trg) I haven't really realized that I'm this old.
  (baseline) *I have not been right to realise that I am so old.*
  (SKD) *I am not quite aware that I am so old.*

- (src) Ne vaikuttavat vasta tulevaisuudessa.
  (trg) They'll have an impact in the future only.
  (baseline) *They will only be affected in the future.*
  (SKD) *They will only affect in the future.*

Fig. 3 shows a trajectory of the q_n values and scheduling of the α value during training the En-Fi NMT model described in Eq. (12), respectively. As expected, the q_n value becomes larger than 0.5 which means that w_n (the predicted word vector) is close enough to the w_t (the target word vector). Fig. 3(b) shows the scheduled value of α in Eq. (12). The α value starts from 0 and increases up to 1 while training. The model is trained with only the cross-entropy for K iterations, and then when the model captures enough knowledge to be distilled, α increases to utilize knowledge from the model.

Also, as in Fig. 4, the SKD models are not (or more slowly) overfitted to the training data. We believe that SKD provides more information distilled by the training model itself to prevent overfitting. Note that there is no significant difference in the improvements by SKD and Noise, but Noise+SKD



(a) q_n value during NMT model training

(b) Scheduling of α value of NMT training

+Noise+SKD	**21.16(20.34)**	**23.07(21.64)**

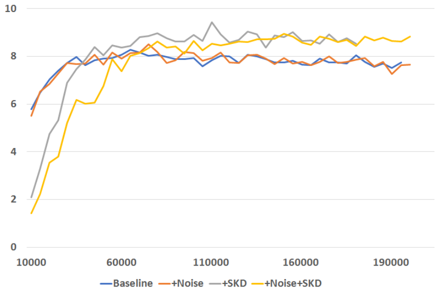

Figure 4: BLEU scores of validation data while training on En-Fi corpus with four different models: Baseline, +Noise, +SKD, and +Noise+SKD. The vertical axis indicates BLEU score and the horizontal axis the number of training iteration.

5 Conclusion

We proposed a new knowledge distillation method, self-knowledge distillation, from the probabilities of the currently training model itself. The method uses only two soft target probabilities that are obtained based on the word embedding space. The experiment results with language modeling and neural machine translation show that our method improves the performance. This method can be straightforwardly applied to other tasks where the cross-entropy is used.

As future works, we want to apply SKD to other applications with different model architectures, to show that SKD does not depend on tasks nor the model architectures. For image classification tasks, if we abuse the term ‘word embedding’ to refer to the layer right before the softmax operation, it may be possible to apply SKD in a similar way, although it is not guaranteed that comparable image classes are closely located in the word embedding space for image related tasks. Also, we can develop an automatic way for the parameters like α in Eq. (12), and generalize the equation for q_n in Eq. (8).

From the Paft to the Fiiture: a Fully Automatic NMT and Word Embeddings Method for OCR Post-Correction

Mika Hämäläinen[♠] Simon Hengchen[◇]

Abstract

A great deal of historical corpora suffer from errors introduced by the OCR (optical character recognition) methods used in the digitization process. Correcting these errors manually is a time-consuming process and a great part of the automatic approaches have been relying on rules or supervised machine learning. We present a fully automatic unsupervised way of extracting parallel data for training a character-based sequence-to-sequence NMT (neural machine translation) model to conduct OCR error correction.

1 Introduction

Historical corpora are a key resource to study social phenomena such as language change in a diachronic perspective. Approaching this from a computational point of view is especially challenging as historical data tends to be noisy. The noise can come from OCR (optical character recognition) errors, or from the fact that the spelling conventions have changed as the time has passed, as thoroughly described by Piotrowski (2012).

However, depending on the NLP or DH task being modelled, some methods can cope with the noise in the data. Indeed, Hill and Hengchen (2019) use a subset of an 18th-century corpus, ECCO,[1] and its ground truth version, ECCO-TCP,[2] to compare the output of different common DH methods such as authorship attribution, count-based vector space models, and topic modelling, and report that those analyses produce statistically similar output despite noisiness due to OCR. Their conclusion is similar to Rodriquez et al. (2012) in the case of NER and to Franzini et al. (2018) in the case of authorship attribution, but different from Mutuvi et al. (2018) who, specifically on topic modelling for historical newspapers, confirm the often repeated trope of data too dirty to use. However, reducing the noise of OCRed text by applying a post-correction method makes it possible to gain the full potential of the data without having to re-OCR it and opens up the possibility to process it with the myriad of more precise NLP tools designed for OCR-error free text.

This paper focuses on correcting the OCR errors in ECCO. We present an unsupervised method based on the advances neural machine translation (NMT) in historical text normalization[3]. As NMT requires a parallel dataset of OCR errors and their corresponding correct spellings, we propose a method based on word embeddings, a lemma list, and a modern lemmatizer to automatically extract parallel data for training the NMT model.

2 Related Work

OCR quality for historical texts has recently received a lot of attention from funding bodies and data providers. Indeed, Smith and Cordell (2019) present a (USA-focused) technical report on OCR quality, and aim to spearhead the efforts on setting a research agenda for tackling OCR problems. Other initiatives such as Adesam et al. (2019) set out to analyse the quality of OCR produced by the Swedish language bank Språkbanken, Drobac et al. (2017) correct the OCR of Finnish newspapers using weighted finite-state methods, Tanner et al. (2009) measure mass digitisation in the context of British newspaper archives, while the Euro-

[1] Eighteenth Century Collections Online (ECCO) is a dataset which "contains over 180,000 titles (200,000 volumes) and more than 32 million pages", according to its copyright holder Gale: https://www.gale.com/primary-sources/eighteenth-century-collections-online.

[2] ECCO-TCP (Text Creation Partnership) "is a keyed subset of ECCO, compiled with the support of 35 libraries and made up of 2,231 documents". (Hill and Hengchen, 2019)

pean Commission-funded IMPACT project[4] gathers 26 national libraries and commercial providers to "take away the barriers that stand in the way of the mass digitization of the European cultural heritage" by improving OCR technology and advocating for best practices.

Dong and Smith (2018) present an unsupervised method for OCR post-correction. As opposed to our character-level approach, they use a word-level sequence-to-sequence approach. As such a model requires training data, they gather the data automatically by using repeated texts. This means aligning the OCRed text automatically with matched variants of the same text from other corpora or within the OCRed text itself. In contrast, our unsupervised approach does not require any repetition of text, but rather repetition of individual words.

Different machine translation approaches have been used in the past to solve the similar problem of text normalization, which means converting text written in a non-standard form of a language to the standard form in order to facilitate its processing with existing NLP tools. SMT (statistical machine translation) has been used previously, for instance, to normalize historical text (Pettersson et al., 2013) to modern language and to normalize modern Swiss German dialects (Samardzic et al., 2015) into a unified language form. More recently with the rise of the NMT, research has emerged in using NMT to normalize non-standard text, for example work on normalization of medieval German (Korchagina, 2017) and on historical English (Hämäläinen et al., 2018).

All of the normalization work cited above on using machine translation for normalization has been based on character-level machine translation. This means that words are split into characters and the translation model will learn to translate from character to character instead of word to word.

3 Model

As indicated by the related work on text normalization, character-level machine translation is a viable way of normalizing text into a standard variety. Therefore, we will also use character-level NMT in building our sequence-to-sequence OCR post-correction model. However, such a model requires parallel data for training. First, we will present our method of automatically extracting parallel data from our corpus containing OCR errors, then we will present the model designed to carry out the actual error correction.

3.1 Extracting Parallel Data

To extract a parallel corpus of OCR errors and their correctly spelled counterparts out of our corpus, we use a simple procedure consisting of measuring the similarity of the OCR errors with their correct spelling candidates. The similarity is measured in two ways, on the one hand an erroneous form will share a similarity in meaning with the correct spelling as they are realizations of the same word. On the other hand, an erroneous form is bound to share similarity on the level of characters, as noted by Hill and Hengchen (2019) in their study of OCR typically failing on a few characters on the corpus at hand.

In order to capture the semantic similarity, we use Gensim (Řehůřek and Sojka, 2010) to train a Word2Vec (Mikolov et al., 2013) model.[5] As this model is trained on the corpus containing OCR errors, when queried for the most similar words with a correctly spelled word as input, the returned list is expected to contain OCR errors of the correctly spelled word together with real synonyms, the key finding which we will exploit for parallel data extraction.

As an example to illustrate the output of the Word2Vec model, a query with the word *friendship* yields *friendlhip, friendihip, friendflip, friend-, affection, friendthip, gratitude, affetion, friendflhip* and *friendfiip* as the most similar words. In other words, in addition to the OCR errors of the word queried for, other correctly-spelled, semantically similar words (*friend-, affection* and *gratitude*) and even their erroneous forms (*affetion*) are returned. Next, we will describe our method (as shown in Algorithm 1) to reduce noise in this initial set of parallel word forms.

As illustrated by the previous example, we need a way of telling correct and incorrect spellings apart. In addition, we will need to know which incorrect spelling corresponds to which correct spelling (*affetion* should be grouped with *affection* instead of *friendship*).

For determining whether a word is a correctly spelled English word, we compare it to the lem-

[4] http://www.impact-project.eu

[5] Parameters: CBOW architecture, window size of 5, frequency threshold of 100, 5 epochs. Tokens were lowercased and no stopwords were removed.

mas of the Oxford English Dictionary (OED).[6] If the word exists in the OED, it is spelled correctly. However, as we are comparing to the OED lemmas, inflectional forms would be considered as errors, therefore, we lemmatize the word with spaCy[7] (Honnibal and Montani, 2017). If neither the word nor its lemma appear in the OED, we consider it as an OCR error.

For a given correct spelling, we get the most similar words from the Word2Vec model. We then group these words into two categories: correct English words and OCR errors. For each OCR error, we group it with the most similar correct word on the list. This similarity is measured by using Levenshtein edit distance (Levenshtein, 1966). The edit distances of the OCR errors to the correct words they were grouped with are then computed. If the distance is higher than 3 – a simple heuristic, based on ad-hoc testing –, we remove the OCR error from the list. Finally, we have extracted a small set of parallel data of correct English words and their different erroneous forms produced by the OCR process.

Algorithm 1: Extraction of parallel data

```
Draw $words\ w$ from the input word list;
for $w$ do
    Draw synonyms $s_w$ in the word embedding model
    for synonym $s_w$ do
        if $s_w$ is correctly spelled then
            Add $s_w$ to correct forms $forms_c$
        end
        else
            Add $s_w$ to error forms $forms_e$
        end
    end
    for error $e$ in $forms_e$ do
        group $e$ with the correct form in $forms_c$ by $Lev_{min}$
        if $Lev_{(e,c)} > 3$ then
            remove($e$)
        end
    end
end
```

We use the extraction algorithm to extract the parallel data by using several different word lists. First, we list all the words in the vocabulary of the Word2Vec model and list the words that are correctly spelled. We use this list of correctly spelled words in the model to do the extraction. However, as this list introduces noise to the parallel data, we combat this noise by producing another list of correctly spelled words that have occurred over 100,000 times in ECCO. For these two word lists, one containing all the correct words in the model and the other filtered with word frequencies, we produce parallel datasets consisting of words longer or equal to 1, 2, 3, 4 and 5. The idea behind these different datasets is that longer words are more likely to be matched correctly with their OCR error forms, and also frequent words will have more erroneous forms than less frequent ones.

BNC	7692	7491	6681	5926	4925

Table 1: Sizes of the extracted parallel datasets

In addition, we use the frequencies from the British National Corpus (The BNC Consortium, 2007) to produce one more dataset of words occurring in the BNC over 1000 times to test whether the results can be improved with frequencies obtained from a non-noisy corpus. This BNC dataset is also used to produce multiple datasets based on the length of the word. The sizes of these automatically extracted parallel datasets are shown in Table 1.

3.2 The NMT Model

We use the automatically extracted parallel datasets to train a character level NMT model for each dataset. For this task, we use OpenNMT[8] (Klein et al., 2017) with the default parameters except for the encoder where we use a BRNN (bi-directional recurrent neural network) instead of the default RNN (recurrent neural network) as BRNN has been shown to provide a performance gain in character-level text normalization (Hämäläinen et al., 2019). We use the default of two layers for both the encoder and the decoder and the default attention model, which is the general global attention presented by Luong et al. (2015). The models are trained for the default number of 100,000 training steps with the

Table 2: Results of the NMT models trained on different datasets

same seed value.

We use the trained models to do a character level translation on the erroneous words. We output the top 10 candidates produced by the model, go through them one by one and check whether the candidate word form is a correct English word (as explained in section 3.1). The first candidate that is also a correct English word is considered as the corrected form produced by the system. If none of the top 10 candidates is a word in English, we consider that the model failed to produce a corrected form. The use of looking at the top 10 candidates instead of the topmost candidates is motivated by the findings by Hämäläinen et al. (2019) in historical text normalization with a character-level NMT.

4 Evaluation

For evaluation, we prepare by hand a gold standard containing 200 words with OCR errors from the ECCO and their correct spelling. The performance of our models calculated as a percentage of how many erroneous words they were able to fix correctly. As opposed to the other common metrics such as character error rate and word error rate, we are measuring the absolute performance in predicting the correct word for a given erroneous input word.

Table 2 shows the results for each dataset. The highest accuracy of 58% is achieved by training the model with all of the frequent words in the BNC, and the lowest number of false positives (i.e. words that do exist in English but are not the right correction for the OCR error) is achieved by the model trained with the BNC words that are at least 3 characters long. The *No output* column shows the number of words the models didn't output any word for that would have been correct English.

If, instead of using NMT, we use the Word2Vec extraction method presented in section 3.1 to conduct the error correction by finding the semantically similar word with the lowest edit distance under 4 for an erroneous form, the accuracy of such a method is only 26%. This shows that training an NMT model is a meaningful part in the correction process.

In the spirit of Hämäläinen et al. (2018), whose results indicate that combining different methods in normalization can be beneficial, we can indeed get a minor boost for the results of the highest accuracy NMT model if we first try to correct with the above described Word2Vec method and then with NMT, we can increase the overall accuracy to 59.5%. However, there is no increase if we invert the order and try to first correct with the NMT and after that with the Word2Vec model.

5 Conclusion and Future Work

In this paper we have proposed an unsupervised method for correcting OCR errors. Apart from the lemma list and the lemmatizer, which can also be replaced by a morphological FST (finite-state transducer) analyzer or a list of word forms, this method is not language specific and can be used even in scenarios with less NLP resources than what English has. Although not a requirement, having the additional information about word frequencies from another OCR error-free corpus can boost the results.

A limitation of our approach is that it cannot do word segmentation in the case where multiple words have been merged together as a result of the OCR process. However, this problem is complex enough on its own right to deserve an entire publication of its own and is thus not in the scope of our paper. Indeed, previous research has been conducted focusing solely on the segmentation problem (Nastase and Hitschler, 2018; Soni et al., 2019) of historical text and in the future such methods can be incorporated as a preprocessing step for our proposed method.

It is in the interest of the authors to extend the approach presented in this paper on historical data written in Finnish and in Swedish in the immediate near future. The source code and the best working NMT model discussed in this paper has be made freely available on GitHub as a part of the natas Python library[9].

Abstract

Terminology translation plays a critical role in domain-specific machine translation (MT). In this paper, we conduct a comparative qualitative evaluation on terminology translation in phrase-based statistical MT (PB-SMT) and neural MT (NMT) in two translation directions: English-to-Hindi and Hindi-to-English. For this, we select a test set from a legal domain corpus and create a gold standard for evaluating terminology translation in MT. We also propose an error typology taking the terminology translation errors into consideration. We evaluate the MT systems' performance on terminology translation, and demonstrate our findings, unraveling strengths, weaknesses, and similarities of PB-SMT and NMT in the area of term translation.

1 Introduction

Over the last five years, there has been incremental progress in the field of NMT (Bahdanau et al., 2015; Vaswani et al., 2017) to the point where some researchers are claiming parity with human translation (Hassan et al., 2018). Nowadays, NMT is regarded as a preferred alternative to PB-SMT (Koehn et al., 2003) and represents a new state-of-the-art in MT research. The rise of NMT has resulted in a swathe of research in the field of MT, unraveling the strengths, weaknesses, impacts and commercialisation aspects of the classical (i.e. PB-SMT) and emerging (i.e. NMT) methods (e.g. (Bentivogli et al., 2016; Toral and Way, 2018)). In brief, the NMT systems are often able to produce better translations than the PB-SMT systems. Interestingly, terminology translation, a crucial factor in industrial translation workflows (TWs), is one of the less explored areas in MT research. In this context, a few studies (Burchardt et al., 2017; Macketanz et al., 2017; Specia et al., 2017), with their focus on high-level evaluation, have indicated that NMT lacks effectiveness in translating domain terms compared to PB-SMT. In this work, we aim to compare PB-SMT and NMT in relation to terminology translation, by carrying out a thorough manual evaluation. For this, we select a test set from legal domain data (i.e. judicial proceedings), and create a gold standard evaluation test set following a semi-automatic terminology annotation strategy. We inspected the patterns of the term translation-related errors in MT. From our observations we make a high-level classification of the terminology translation-related errors and propose an error typology. We discuss various aspects of terminology translation in MT considering each of the types from the proposed terminology translation typology, and dig into the extent of the term translation problems in PB-SMT and NMT with statistical measures as well as linguistic analysis. For experimentation, we select a less examined and low-resource language pair, English–Hindi.

2 MT Systems

To build our PB-SMT systems we used the Moses toolkit (Koehn et al., 2007). For LM training we combine a large monolingual corpus with the target-side of the parallel training corpus. Additionally, we trained a neural LM with the NPLM toolkit (Vaswani et al., 2013) on the target side of the parallel training corpus alone. We considered the standard PB-SMT log-linear features for training. We call the English-to-Hindi and Hindi-to-English PB-SMT systems EHPS and HEPS, respectively. Our NMT systems are Google Transformer models (Vaswani et al., 2017). In our experiments we followed the recommended best set-up from Vaswani et al. (2017). We call our the English-to-Hindi and Hindi-to-English NMT systems EHNS and HENS, respectively.

For experimentation we used the IIT Bombay English-Hindi parallel corpus (Kunchukuttan et al., 2017). For building additional LMs for Hindi and English we use the HindEnCorp monolingual corpus (Bojar et al., 2014) and monolingual data from the OPUS project (Tiedemann, 2012), respectively. Corpus statistics are shown in Table 1. We selected 2,000 sentences (test set) for the evaluation of the MT systems and 996 sentences (development set) for validation from the Judicial parallel corpus (cf. Table 1) which is a juridical domain corpus (i.e. proceedings of legal judgments). The MT systems were built with the training set shown in Table 1 that includes the remaining sentences of the Judicial parallel corpus.

Table 1: Corpus Statistics.

English–Hindi parallel corpus			
	Sentences	Words (En)	Words (Hi)
Training set	1,243,024	17,485,320	18,744,496
(Vocabulary)		180,807	309,879
Judicial	7,374	179,503	193,729
Development set	996	19,868	20,634
Test set	2,000	39,627	41,249
Monolingual Corpus		Sentences	Words
Used for PB-SMT Language Model			
English		11M	222M
Hindi		10.4M	199M
Used for NMT Back Translation			
English		1M	20.2M
Hindi		903K	14.2M

We present the comparative performance of the PB-SMT and NMT systems in terms of BLEU score (Papineni et al., 2002) in Table 2. Additionally, we performed statistical significance tests using bootstrap resampling methods (Koehn, 2004). The confidence level (%) of the improvement obtained by one MT system with respect to the another MT system is reported. As can be seen from Table 2, EHPS and EHNS produce reasonable BLEU scores (28.8 BLEU and 36.6 BLEU) on the test set given the difficulty of the translation pair. These BLEU scores, in fact, underestimate the translation quality, given the relatively free word order in Hindi, as we have just a single reference translation set for evaluation. As far as the Hindi-to-English translation task is concerned, HEPS and HENS produce moderate BLEU scores (34.1 BLEU and 39.9 BLEU) on the test set. As expected, translation quality in the morphologically-rich to morphologically-poor language improves.

Table 2: Performance of MT systems on BLEU.

System	BLEU	System	BLEU
EHPS	28.8	HEPS	34.1
EHNS	**36.6** (99.9%)	HENS	**39.9** (99.9%)

3 Creating Gold Standard Evaluation Set

To evaluate terminology translation with our MT systems, we manually annotated the test set by marking term-pairs on the source- and target-sides of the test set (cf. Table 1) with a view to creating a gold standard evaluation set. The annotation process is performed using our own bilingual term annotation tool, *TermMarker*. If there is a source term present in the source sentence, its translation equivalent (i.e. target term) is found in the target sentence, and the source–target term-pair is marked. The annotators are native Hindi evaluators with excellent English skills. They were instructed to mark those words as terms that belong to legal or judicial domains. The annotators were also instructed to mark those sentence-pairs from the test set that contain errors (e.g. mistranslations, spelling mistakes) in either source or target sentences. The annotators reported 75 erroneous sentence-pairs which we discarded from the test set. In addition, 655 sentence-pairs of the test set did not contain any terms. We call the remaining 1,270 sentence-pairs our *gold-testset*. Each sentence-pair of gold-testset contains at least one aligned source-target term-pair. We have made the gold-testset publicly available to the research community.[1]

Annotation Suggestions from Bilingual Terminology While manually annotating bilingual terms in the judicial domain test set, we took support from a bilingual terminology that was automatically created from the Judicial corpus (cf. Table 1). For automatic bilingual term extraction we followed the approach of Haque et al. (2018). We found 3,064 English terms and their target equivalents (3,064 Hindi terms) in the source- and target-sides of gold-testset, respectively.

Variations of Term A term may have more than one domain-specific translation equivalent. The number of translation equivalents for a source term could vary from language to language depending on the morphological nature of the target language. For example, translation of the En-

[1] https://www.computing.dcu.ie/~rhaque/termdata/terminology-testset.zip

glish word ‘affidavit’ has multiple target equivalents (LIVs (lexical and inflectional variations)) in Hindi even if the translation domain is legal or juridical: ‘shapath patr’, ‘halaphanaama’, ‘halaphanaame’, or ‘halaphanaamo’. The term ‘shapath patr’ is the lexical variation of Hindi term ‘halaphanaama’. The base form ‘halaphanaama’ could have many inflectional variations (e.g. ‘halaphanaame’, ‘halaphanaamo’) given the sentence’s syntactic and morphological profile (e.g. gender, case).

For each term we check whether the term has any additional LIVs pertaining to the juridical domain and relevant to the context of the sentence. If this is the case, we include the relevant variations as legitimate alternatives term.

We again exploit the method of Haque et al. (2018) for obtaining variation suggestions for a term. The automatically extracted bilingual terminology of Haque et al. (2018) comes with the four highest-weighted target terms for a source term. If the annotator accepts an annotation suggestion (source–target term-pair) from the bilingual terminology, the remaining three target terms are considered as alternative suggestions of the target term.

Two annotators took part in the annotation task, and two sets of annotated data were obtained. The term-pairs of gold-testset are finalised on the basis of the annotation agreement by the two annotators, i.e. we keep those source–target term-pairs in gold-testset for which both annotators agree that the source and target entities are terms and aligned. On completion of the annotation process, inter-annotator agreement was computed using Cohen’s kappa (Cohen, 1960) at word-level. For each word we count an agreement whenever both annotators agree that it is a term (or part of term) or non-term entity. We found the kappa coefficient to be very high (i.e. 0.95) for the annotation task. This indicates that our terminology annotation is of excellent quality.

The final LIV list for a term is the union of the LIV lists created by the annotators. This helps make the resulting LIV lists exhaustive.

4 Terminology Translation Typology

In order to annotate errors in (automatic) translations, MT users often exploit the MQM (Multidimensional Quality Metric) error annotation framework (Lommel et al., 2014). One of the error types in the MQM toolkit is terminology (i.e. *inconsistent with termbase, inconsistent use of terminology*) which is an oversimplified attribute and does not consider various nuances of term translation errors. We propose an error typology taking terminology translation into consideration. First, we translated the test set sentences with our MT systems, and sampled 300 translations from the whole translation set. Then, the terminology translations were manually inspected, noting the patterns of the term translation-related errors. From our observations we found that the terminology translation-related errors can be classified into eight primary categories. As far as the term translation quality of an MT system is concerned, our proposed typology could provide a better perspective as to how the MT system lacks quality in translating domain terms. The categories are as follows: (i) reorder error (RE): the translation of a source term forms the wrong word order in the target, (ii) inflectional error (IE): the translation of a source term inflicts a morphological error, (iii) partial error (PE): the MT system correctly translates part of a source term into the target and commits an error for the remainder of the source term, (iv) incorrect lexical selection (ILS): the translation of a source term is an incorrect lexical choice, (v) term drop (TD): the MT system omits the source term in translation, (vi) source term copied (STC): a source term or part of it is copied verbatim to target, (vii) disambiguation issue in target (DIT): although the MT system makes a potentially correct lexical choice for a source term, its translation-equivalent does not carry the meaning of the source term, and (viii) other error (OE): there is an error in relation to the translation of a source term, whose category, however, is beyond all remaining error categories. The proposed terminology translation error typology is illustrated in Figure 1 (cf. Appendix A).

Apart from the above error categories, we have a class for a source term being correctly translated into the target, i.e. the MT system produces a correct translation (CT) for a source term. As pointed out in Section 3, we wanted to see how diverse an MT model can be in translating domain terms, and how close the translation of a source term can be to the reference terms or its LIVs or to what extent (e.g. syntactically and morphologically) it differs from them. For this reason, we divide the CT class into seven sub-classes, and define them below: (i) CT given the reference term (CTR): the translation of a source term is the reference term, (ii) CT given one of the LIVs (CTV): the translation of a source is one of the LIVs of the reference term, (iii) variation missing (VM): a source term is correctly translated into the target, but the translation is neither the reference term nor any of its LIVs, (iv) correct inflected form (CIF): a source term is correctly translated into the target, but the translation is neither the reference term nor any of its LIVs. However, the base form of the translation of the source term is identical to the base form of either the reference term or one of the LIVs of the reference term, (v) correct reorder form (CRF): a source term is correctly translated into the target, and the translation includes those words that either the reference term or one of the LIVs has, but the word order of the translation is different to that of the the reference term or one of the LIVs, (vi) correct reorder and inflected form (CRIF): this class is a combination of both CIF and CRF, and (vii) other correct (OC): a source term is correctly translated into the target, whose category, however, is beyond the all remaining correct categories.

5 Manual Evaluation Plan

This section presents our manual evaluation plan. Translations of the source terms of gold-testset were manually validated and classified in accordance with the set of fine-grained errors and correct categories described above. This was accomplished by the human evaluator. The manual evaluation was carried out with a GUI that randomly displays a source sentence and its reference translation from gold-testset, and the automatic translation by one of the MT systems. For each source term the GUI highlights the source term and the corresponding reference term from the source and reference sentences, respectively, and displays the LIVs of the reference term, if any. The GUI lists the error and correct categories described in Section 4. The evaluator, a native Hindi speaker with the excellent English and Hindi skills, was instructed to follow the following criteria for evaluating the translation of a source term: (a) judge correctness / incorrectness of the translation of the source term in hypothesis and label it with an appropriate category listed in the GUI, (b) do not need to judge the whole translation, but instead look at the local context to which both source term and its translation belong, and (c) take the syntactic and morphological properties of the source term and its translation into account.

The manual classification process was completed for all MT system types. We measure agreement in manual classification of terminology translation. For this, we randomly selected an additional 100 segments from gold-testset and hired another evaluator having the similar skills. We considered the correct and incorrect categories for the calculation, i.e. we count an agreement whenever both evaluators agree that it is a correct (or incorrect) term translation, with agreement by chance = 1/2. We found that the kappa coefficient for this ranges from 0.97 to 1.0. Thus, our manual term translation classification quality can be labeled as excellent.

6 Terminology Translation Evaluation in PB-SMT and NMT

This section provides a comparative evaluation of the ability of PB-SMT and NMT to translate terminology accurately. In Table 5, we report the statistics of terminology translations from the English-to-Hindi MT task. We see that EHPS and EHNS incorrectly translate 303 and 253 English terms (out of total 3,064 terms) (cf. last row of Table 5), respectively, into Hindi, resulting in 9.9% and 8.3% terminology translation errors, respectively. We use approximate randomization (Yeh, 2000) to test the statistical significance of the difference between two systems, and report the significance-level (*p*-value) in the last column of Table 5. We found that the difference between the error rates is statistically significant. In Table 6, we report the statistics of terminology translations for the Hindi-to-English MT task. We see that HEPS and HENS incorrectly translate 396 and 353 Hindi terms (cf. last row of Table 6), respectively, into English, resulting in 12.9% and 11.5% terminology translation errors, respectively. As can be seen from Table 6, the difference between the error rates is statistically significant. When we compare these scores with those from Table 5, we see that these scores are slightly higher compared to those for the English-to-Hindi task. Surprisingly, the terminology translation quality from the morphologically-rich to the morphologically-poor language deteriorates compared to the overall MT quality (cf. Section 2).

6.1 Comparison with Fine-Grained Category

This section discusses the numbers and highlights phenomena for the fine-grained categories, starting with those that involve correct terminology translations.

CTV & VM We see from Tables 5 and 6 that the numbers under the CTV (correct term given one of the LIVs class are much higher in the English-to-Hindi task (695 and 662) compared to those in the Hindi-to-English task (241 and 245). CTV is measured as the count of instances where a source term is (i) correctly translated into the target translation and (ii) the translation-equivalent of that term is one of the LIVs of the reference term. As can be seen from Table 1, the training set vocabulary size is much higher in Hindi compared to that in English since the former is a morphologically-rich and highly inflected language, which is probably the reason why these numbers are much higher in the English-to-Hindi task.

In a few cases, the human evaluator found that the source terms are correctly translated into the target, but the translations are neither the reference terms nor any of its LIVs. The manual evaluator marked those instances with VM (variation missing) (cf. Tables 5 and 6). These can be viewed as annotation mistakes since the annotator omitted to add relevant LIVs for the reference term into gold-testset. In future, we aim to make gold-testset as exhaustive as possible by adding missing LIVs for the respective reference terms.

CRF, CIF, CRIF & OC We start this section by highlighting the problem of word order in term translation, via a translation example from gold-testset. The Hindi-to-English NMT system correctly translates a Hindi source term 'khand nyaay peeth ke nirnay' (English reference term: 'division bench judgment') into the following target translation (English): "it shall also be relevant to refer to article 45 - 48 of the *judgment of the division bench*". The manual evalautor marks this term translation as CRF (correct reorder form) since the term *'judgment of the division bench'* was not in the LIV list for the reference term, 'division bench judgment'.

We show another example from the Hindi-to-English translation task. This time, we highlight the issue of inflection in term translation. As an example, we consider a source Hindi term 'abhikathan' from gold-testset. Its reference term is 'allegation', and the LIV list of the reference term includes two lexical variations for 'allegation': 'accusation' and 'complaint'. A portion of the reference translation is 'an allegation made by the respondent ...'. A portion of the translation produced by the Hindi-to-English NMT system is 'it was *alleged* by the respondent ...'. In this translation, we see the Hindi term 'abhikathan' is translated into 'alleged' which is a correct translation of the Hindi legal term 'abhikathan' as per the syntax of the target translation. As above, the manual evalautor marked these term translations as CIF (correct inflected form) since the translation-equivalent of this term is not found in the LIV list of the reference term.

As stated in Section 4, CRIF (correct reorder and inflected form) is the combination of the above two types: CRF and CIF. As an example, consider a portion of the source Hindi sentence '*vivaadagrast vaseeyat* hindee mein taip kee gaee hai ...' and the English reference translation 'the *will in dispute* is typed in hindi ...' from gold-testset. Here, 'vivaadagrast vaseeyat' is a Hindi term and its English equivalent is 'will in dispute'. The translation of the source sentence by the Hindi-to-English NMT system is 'the *disputed will* have been typed in hindi ...'. We see that the translation of the source term ('vivaadagrast vaseeyat') is 'disputed will' which is correct. We also see that its word order is different to that of the reference term ('will in dispute'); and the morphological form of (part of) the translation is not identical to that of (part of) the reference term. As is the case with CRF and CIF, the manual evaluator marks such term translations as CRIF.

When translation of a source term is correct but its category is beyond the all remaining correct categories, the manual evaluator marks that term translation as OC (other correct). In our manual evaluation task, we encountered various such phenomena, and detail some of those below. (1) term transliteration: the translation-equivalent of a source term is the transliteration of the source term itself. We observed this happening only when the target language is Hindi. In practice, many English terms (transliterated form) are often used in Hindi text (e.g. 'decree' as 'dikre', 'tariff orders' as 'tarif ordars'), (2) terminology translation coreferred: translation-equivalent of a source term is not found in the hypothesis, however, it is correctly coreferred in target translation, and (3) semantically coherent terminology translation: the translation-equivalent of a source term is not seen in the hypothesis, but its meaning is correctly transferred into the target. As an example, consider the source Hindi sentence "sabhee apeelakartaon ne *aparaadh sveekaar nahin* kiya aur muqadama chalaaye jaane kee maang kee", and reference English sentence "all the appellants pleaded not guilty to the charge and claimed to be tried" from gold-testset.[2] Here, 'aparaadh sveekaar nahin' is a Hindi term and its English translation is 'pleaded not guilty'. The Hindi-to-English NMT system produces the following English translation "all the appellants did not accept the crime and sought to run the suit" for the source sentence. In this example, we see the meaning of

[2] In this example, the reference English sentence is the literal translation of the source Hindi sentence.

the source term 'aparaadh sveekaar nahin' is preserved in the target translation.

Table 3: CIF, CRF, CRIF and OC in PB-SMT and NMT.

	PB-SMT	NMT
English-to-Hindi	122 (4%)	98 (3.2%)
Hindi-to-English	90 (2.9%)	138 (4.5%)

We recall the rule that we defined while forming the LIV list for a reference term from Section 3. Our annotators considered only those inflectional variations for a reference term that would be grammatically relevant to the context of the reference translation in which they would appear. In practice, translation of a source sentence can be generated in numerous ways. It is possible that a particular inflectional variation of a reference term could be grammatically relevant to the context of the target translation, which, when it replaces the reference term in the reference translation, may (syntactically) misfit the context of the reference translation. As far as CRF and CRIF are concerned, a similar story might be applicable to the translation of a multiword term. A multiword term may be translated into the target in various ways (as shown above, 'division bench judgment' as 'judgment of the division bench', and 'disputed will' as 'will in dispute'). In reality, it would be an impossible task for the human annotator to consider all possible such variations for a multiword reference term. Additionally, as above, we saw more diverse translations with the domain terms under the OC category. In Table 3, we report the combined numbers under the above categories (CRF, CRIF, CIF and OC), with their percentage with respect to the total number of terms. We see that translations of a notable portion of source terms in each translation task are diverse. Therefore, investigating the automation of the terminology translation evaluation process (Haque et al., 2019), these phenomena have to be taken into consideration.

RE Now, we turn our focus to the error classes, starting with RE (reordering error). We compare the results under RE from Tables 5 and 6, and we see that NMT commits many fewer terminology translation-related reordering errors than PB-SMT. 15 REs are caught in the English-to-Hindi PB-SMT task compared to 5 in the English-to-Hindi NMT task. The same trend is observed with the reverse direction, with 18 reordering errors seen in the Hindi-to-English PB-SMT task compared to 5 in the Hindi-to-English NMT task. As can be seen from the last columns of Tables 5 and 6, the differences in these numbers in PB-SMT and NMT are statistically significant.

IE As far as the inflectional error type is concerned, the Hindi-to-English PB-SMT system makes nearly twice as many mistakes as the Hindi-to-English NMT system (118 vs 76) (cf. Tables 5 and 6), which is statistically significant. We see a different picture in the English-to-Hindi direction, i.e. the numbers of morphological errors are nearly the same, both in PB-SMT and NMT (77 vs 79). We found no statistically significant difference between them.

PE The numbers (cf. Tables 5 and 6) of partial term translation errors in PB-SMT and NMT are almost the same regardless of the translation directions. We found that the differences in these numbers are not statistically significant.

ILS PB-SMT appears to be more error-prone than NMT as far as a term's lexical selection is concerned. EHPS commits 77 incorrect lexical choices which is 35 more than EHNS. The same trend is observed with the Hindi-to-English direction. HEPS and HENS commit 139 and 90 incorrect lexical choices, respectively. We found that the differences in these numbers in PB-SMT and NMT are statistically significant.

TD Comparing the numbers of the term drop category from Tables 5 and 6, we see that the numbers of term omission by the PB-SMT and NMT systems are almost the same (53 versus 56) in the English-to-Hindi translation task. We found no statistically significant difference in these numbers. In contrast, in the Hindi-to-English translation task, HENS drops terms more than twice as often as HEPS (86 versus 38). This time, we found that the difference in these numbers is statistically significant.

STC & OE Now we focus on discussing various aspects with the STC (source term copied) and OE (other error) classes, starting with the English-to-Hindi task. We counted the number of source terms of gold-testset that are not found in the source-side of the training corpus (cf. Table 1). We see that 88 source terms (out of a total of 3,064 terms) are not found in the training data, with almost all being multiword terms. Nevertheless, only 5 unique words (i.e. adjudicary, halsbury, presuit, decretal, adj) that are either single-word terms or words of multiword terms are not found in the training data. In other words, these are out-of-vocabulary (OOV) items.

Table 4: STC in English-to-Hindi PB-SMT and NMT.

STC (PB-SMT)	translation (NMT)	class (NMT)
adjudicatory role	nyaay - nirnay keea koee bhoomika	PE
decretal		TD
halsbury 's laws	halbury ke kaanoonon	PE
presuit	poorva vaad	RE
adjudicatory		TD
learned **adj**	vidvat edeeje	CTR
learned **adj**	kaabil edeeje	CTV
mrtp act	mrtp adhiniyam	CTR
testatrix	testrex	OE
concealments	rahasyon	OE
res **judicata**	nyaayik roop	OE
subjudice	vichaaraadheen	CTV

We recall Table 5 where we see that the manual evaluator has marked 12 term translations with STC since in those cases the PB-SMT system copied source terms (or a part of source terms) verbatim into the target. In Table 4, we show those source terms in the PB-SMT task that belong to the STC class. The first column of the table shows source terms with the term itself or part of it in bold, which means those words are copied verbatim into target. We see from the table that the OOV terms (i.e. adjudicary, halsbury, presuit, decretal, adj), in most cases, are responsible for the term translations being marked with the STC tag. In one instance we found that a part of the English term ('mrtp') (cf. row 8 of Table 4) itself was present in the target-side of the training corpus. This could be the possible reason why 'mrtp' is seen in the target translation. Each of the remaining source terms (last 4 rows of Table 4) include words that are copied directly into the target translation despite the fact that they are not OOVs. This is a well-known problem in PB-SMT and rarely happens with the low frequency words of the training corpus. In short, these source terms (last 4 entries of Table 4) either alone or with the adjacent words of the test set sentences (i.e. as a part of phrase) are not found in the source-side of the PB-SMT phrase table.

Now we see how NMT performed with the 12 source terms above; their translations with EHNS and the corresponding manual class are shown in the second and third columns of Table 4, respectively. We see that out of 12 translations EHNS made a mistake on 8 occasions and correctly translated on 4 occasions. The errors are spread over different categories (e.g. TD, OE, PE). Unsurprisingly, we see NMT is capable of correctly translating rare and even unknown words, by exploiting the strength of the open-vocabulary translation technique (Sennrich et al., 2016). However, this method also has down-sides. For example, some of the term translations under the OE category in the NMT task are non-existent wordforms of the target language, for which the open-vocabulary translation technique is responsible. This phenomenon is also corroborated by Farajian et al. (2017) while translating technical domain terms. We discuss the OE class further below.

We see from Table 5 that the human evaluator has marked 24 term translations with OE in NMT. In this category we observed that the translations of the source terms are usually either strange words that have no relation to the meaning of the source term, repetitions of other translated words or terms, entities that are non-existent wordforms of the target language, or words with typographical errors. As far as PB-SMT is concerned, we see from Table 5 that the evaluator also tagged 12 term translations with OE, most of which are related to typographical errors.

Now we turn our focus on the Hindi-to-English task. We counted the number of those source terms from gold-testset that are not found in the source-side (Hindi) of the training corpus (cf. Table 1). We see that 160 source terms (out of a total of 3,064 terms) are not found in the training data, most of which are, in fact, multiword terms. However, only 18 unique Hindi words that are either single-word terms or words within multiword terms are not found in the training data. As in English-to-Hindi translation task, in this task we found that the OOV items are largely responsible for the term translations being marked as STC. We also examined how the Hindi-to-English NMT system performed with those 17 source terms that were marked as STC. We see that HENS makes a mistake on 13 occasions and correctly translates on 4 occasions. The error types are spread over different categories: TD (2), OE (6), PE (1) and ILS (4). We observed that 3 out of 4 source terms of the STC category for which the Hindi-to-English NMT system produces correct translations are OOV items. Here, we again see the strength of the open-vocabulary translation technique for the translation of novel terms. In the Hindi-to-English translation task, we found that the terminology translations under the OE category, as in English-to-Hindi translation, are roughly related to odd translations, non-existent wordforms of the target language, typological mistakes and repetition of other translated words or terms.

DIT We see from Table 5 and Table 6 that the manual evaluator marked 3 and 1 term translations as DIT (disambiguation issue in target) in English-to-Hindi and Hindi-to-English PB-SMT tasks, respectively. We found that the MT systems made correct lexical choices for the source terms, although the meanings of their target-equivalents in the respective translations are different to those of the source terms. This can be viewed as a cross-lingual disambiguation problem. For example, one of the three source terms from English-to-Hindi translation task is 'victim' (reference translation 'shikaar') and the English-to-Hindi PB-SMT system makes a correct lexical choice ('shikaar') for 'victim', although the meaning of 'shikaar' is completely different in the target translation, i.e. here, its meaning is equivalent to English 'hunt'.

Pairwise Overlap We report the numbers of pairwise overlaps, i.e. the number of instances in which NMT and PB-SMT have identical classification outcomes. We recall Table 5 & 6 whose fourth columns show the numbers of pairwise overlap for categories. The small number of overlapping instances in each category indicates that term translation errors from the PB-SMT system are quite different from those from the NMT system. As can be seen from the last row of Table 5 & 6, the numbers of overlaps in the combination of all error classes are 86 and 115, respectively, which are nearly one third or fourth of the number of errors committed by the NMT and PB-SMT systems alone, indicating that the majority of the errors in PB-SMT are complementary with those in NMT. This finding on terminology translation is corroborated by Popović (2017), who finds complementarity with the various issues relating to the translations of NMT and PB-SMT.

7 Conclusion and Future Work

In this paper, we investigated domain term translation in PB-SMT and NMT with two morphologically divergent languages, English and Hindi. Due to the unavailability of a gold standard for term translation evaluation, we adopted a technique that semi-automatically creates a gold standard test set from an English–Hindi judicial domain parallel corpus. The gold standard that we have developed will serve as an important resource for the evaluation of term translation in MT. We also propose a terminology translation typology focused on term translation errors in MT. From our evaluation results, we found that the NMT systems commit fewer lexical, reordering and morphological errors than the PB-SMT systems. The differences in error rates of the former (lexical selection and reordering errors) types are statistically significant in both MT tasks, and the difference of the morphological error rates is statistically significant in the Hindi-to-English task. The morphological errors are seen relatively more often in PB-SMT than in NMT when translation is performed from a morphologically-rich language (Hindi) to the a morphologically-poor language (English). The opposite picture is observed in the case of term omission in translation, with NMT omitting more terms in translation than PB-SMT. We found that the difference in term omission-related error rates in PB-SMT and NMT are statistically significant in the Hindi-to-English task, i.e. again from the morphologically-rich language to the morphologically-poor language. Another important finding from our analysis is that NMT is able to correctly translate unknown terms, by exploiting the strength of the open-vocabulary translation technique, which, as expected, are copied verbatim into the target in PB-SMT. We also found that the majority of the errors made by the PB-SMT system are complementary to those made by the NMT system. In NMT, we observed that translations of source terms are occasionally found to be strange words that have no relation to the source term, non-existent wordforms of the target language, and/or repetition of other translated words. This study also shows that a notable portion of the term translations by the MT systems are diverse, which needs to be taken into consideration while investigating the automation of the terminology translation evaluation process.

As far as future work is concerned, we plan to test terminology translation with different language pairs and domains.

Abstract

Recently, reading comprehension models achieved near-human performance on large-scale datasets such as SQuAD, CoQA, MS Macro, RACE, etc. This is largely due to the release of pre-trained contextualized representations such as BERT and ELMo, which can be fine-tuned for the target task. Despite those advances and the creation of more challenging datasets, most of the work is still done for English. Here, we study the effectiveness of multilingual BERT fine-tuned on large-scale English datasets for reading comprehension (e.g., for RACE), and we apply it to Bulgarian multiple-choice reading comprehension. We propose a new dataset containing 2,221 questions from matriculation exams for twelfth grade in various subjects —history, biology, geography and philosophy—, and 412 additional questions from online quizzes in history. While the quiz authors gave no relevant context, we incorporate knowledge from Wikipedia, retrieving documents matching the combination of question + each answer option. Moreover, we experiment with different indexing and pre-training strategies. The evaluation results show accuracy of 42.23%, which is well above the baseline of 24.89%.

1 Introduction

The ability to answer questions is natural to humans, independently of their native language, and, once learned, it can be easily transferred to another language. After understanding the question, we typically depend on our background knowledge, and on relevant information from external sources. Machines do not have the reasoning ability of humans, but they are still able to learn concepts. The growing interest in teaching machines to answer questions posed in natural language has led to the introduction of various new datasets for different tasks such as reading comprehension, both extractive, e.g., span-based (Nguyen et al., 2016; Trischler et al., 2017; Joshi et al., 2017; Rajpurkar et al., 2018; Reddy et al., 2019), and non-extractive, e.g., multiple-choice questions (Richardson et al., 2013; Lai et al., 2017; Clark et al., 2018; Mihaylov et al., 2018; Sun et al., 2019a). Recent advances in neural network architectures, especially the raise of the Transformer (Vaswani et al., 2017), and better contextualization of language models (Peters et al., 2018; Devlin et al., 2019; Radford et al., 2018; Grave et al., 2018; Howard and Ruder, 2018; Radford et al., 2019; Yang et al., 2019b; Dai et al., 2019) offered new opportunities to advance the field.

Here, we investigate skill transfer from a high-resource language, i.e., English, to a low-resource one, i.e., Bulgarian, for the task of multiple-choice reading comprehension. Most previous work (Pan et al., 2018; Radford et al., 2018; Tay et al., 2018; Sun et al., 2019b) was monolingual, and a relevant context for each question was available a priori. We take the task a step further by exploring the capability of a neural comprehension model in a multilingual setting using external commonsense knowledge. Our approach is based on the multilingual cased BERT (Devlin et al., 2019) fine-tuned on the RACE dataset (Lai et al., 2017), which contains over 87,000 English multiple-choice school-level science questions. For evaluation, we build a novel dataset for Bulgarian. We further experiment with pre-training the model over stratified Slavic corpora in Bulgarian, Czech, and Polish Wikipedia articles, and Russian news, as well as with various document retrieval strategies.

Finally, we address the resource scarceness in low-resource languages and the absence of question contexts in our dataset by extracting relevant passages from Wikipedia articles.

Our contributions are as follows:

- We introduce a new dataset for reading comprehension in a low-resource language such as Bulgarian. The dataset contains a total of 2,636 multiple-choice questions without contexts from matriculation exams and online quizzes. These questions cover a large variety of science topics in biology, philosophy, geography, and history.

- We study the effectiveness of zero-shot transfer from English to Bulgarian for the task of multiple-choice reading comprehension, using Multilingual and Slavic BERT (Devlin et al., 2019), fine-tuned on large corpora, such as RACE (Lai et al., 2017).

- We design a general-purpose pipeline[1] for extracting relevant contexts from an external corpus of unstructured documents using information retrieval.

The rest of this paper is organized as follows: The next section presents related work. Section 3 describes our approach. Details about the newly-proposed multiple-choice Bulgarian dataset are given in Section 4. All experiments are described in Section 5. Finally, Section 6 concludes and points to possible directions for future work.

2 Related Work

2.1 Machine Reading Comprehension

The growing interest in machine reading comprehension (MRC) has led to the release of various datasets for both extractive (Nguyen et al., 2016; Trischler et al., 2017; Joshi et al., 2017; Rajpurkar et al., 2018; Reddy et al., 2019) and non-extractive (Richardson et al., 2013; Peñas et al., 2014; Lai et al., 2017; Clark et al., 2018; Mihaylov et al., 2018; Sun et al., 2019a) comprehension. Our work primarily focuses on the non-extractive multiple-choice type, designed by educational experts, since their task is very close to our newly-proposed dataset, and are expected to be well-structured and error-free (Sun et al., 2019a).

These datasets brought a variety of models and approaches. The usage of external knowledge has been an interesting topic, e.g., Chen et al. (2017a) used Wikipedia knowledge for answering open-domain questions, Pan et al. (2018) applied entity discovery and linking as a source of prior knowledge. Sun et al. (2019b) explored different reading strategies such as back and forth reading, highlighting, and self-assessment. Ni et al. (2019) focused on finding essential terms and removing distraction words, followed by reformulation of the question, in order to find better evidence before sending a query to the MRC system. A simpler approach was presented by Clark et al. (2016), who leveraged information retrieval, corpus statistics, and simple inference over a semi-automatically constructed knowledge base for answering fourth-grade science questions.

Current state-of-the-art approaches in machine reading comprehension are grounded on transfer learning and fine-tuning of language models (Peters et al., 2018; Conneau et al., 2018; Devlin et al., 2019). Yang et al. (2019a) presented an open-domain extractive reader based on BERT (Devlin et al., 2019). Radford et al. (2018) used generative pre-training of a Transformer (Vaswani et al., 2017) as a language model, transferring it to downstream tasks such as natural language understanding, reading comprehension, etc.

Finally, there has been a Bulgarian MRC dataset (Peñas et al., 2012). It was used by Simov et al. (2012), who converted the question-answer pairs to declarative sentences, and measured their similarity to the context, transforming both to a bag of linguistic units: lemmata, POS tags, and dependency relations.

2.2 (Zero-Shot) Multilingual Models

Multilingual embeddings helped researchers to achieve new state-of-the-art results on many NLP tasks. While many pre-trained model (Grave et al., 2018; Devlin et al., 2019; Lample and Conneau, 2019) are available, the need for task-specific data in the target language still remains. Learning such models is language-independent, and representations for common words remain close in the latent vector space for a single language, albeit unrelated for different languages. A possible approach to overcome this effect is to learn an alignment function between spaces (Artetxe and Schwenk, 2018; Joty et al., 2017).

[1] The dataset and the source code are available at `http://github.com/mhardalov/bg-reason-BERT`

Moreover, zero-shot application of fine-tuned multilingual language models (Devlin et al., 2019; Lample and Conneau, 2019) on XNLI (Conneau et al., 2018), a corpus containing sentence pairs annotated with textual entailment and translated into 14 languages, has shown very close results to such by a language-specific model.

Zero-shot transfer and multilingual models had been a hot topic in (neural) machine translation (MT) in the past several years. Johnson et al. (2017) introduced a simple tweak to a standard sequence-to-sequence (Sutskever et al., 2014) model by adding a special token to the encoder's input, denoting the target language, allowing a zero-shot learning for new language pairs. Recent work in zero-resource translation outlined different strategies for learning to translate without having a parallel corpus between the two target languages. First, a many-to-one approach was adopted by Firat et al. (2016) based on building a corpus from a single language paired with many others, allowing simultaneous training of multiple models, with a shared attention layer. A many-to-many relationship between languages was later used by Aharoni et al. (2019), in an attempt to train a single Transformer (Vaswani et al., 2017) model.

Pivot-language approaches can also be used to overcome the lack of parallel corpora for the source–target language pair. Chen et al. (2017b) used a student-teacher framework to train an NMT model, using a third language as a pivot. A similar idea was applied to MRC by Asai et al. (2018), who translated each question to a pivot language, and then found the correct answer in the target language using soft-alignment attention scores.

3 Model

Our model has three components: (*i*) a context retrieval module, which tries to find good explanatory passages for each question-answer pair, from a corpus of non-English documents, as described in Section 3.1, (*ii*) a multiple-choice reading comprehension module pre-trained on English data and then applied to the target language in a zero-shot fashion, i.e., without further training or additional fine-tuning, to a target (non-English) language, as described in Section 3.2, and (*iii*) a voting mechanism, described in Section 3.3, which combines multiple passages from (*i*) and their scores from (*ii*) in order to obtain a single (most probable) answer for the target question.

3.1 Context Retriever

Most public datasets for reading comprehension (Richardson et al., 2013; Lai et al., 2017; Sun et al., 2019a; Rajpurkar et al., 2018; Reddy et al., 2019; Mihaylov et al., 2018) contain not only questions with possible answers, but also an evidence passage for each question. This limits the task to question answering over a piece of text, while an open-domain scenario is much more challenging and much more realistic. Moreover, a context in which the answer can be found is not easy to retrieve, sometimes even for a domain expert. Finally, data scarceness in low-resource languages poses further challenges for finding resources and annotators.

In order to enable search for appropriate passages for non-English questions, we created an inverted index from Wikipedia articles using Elasticsearch.[2] We used the original dumps for the entire Wikipage,[3] and we preprocessed the data leaving only plain textual content, e.g., removing links, HTML tags, tables, etc. Moreover, we split the article's body using two strategies: a sliding window and a paragraph-based approach. Each text piece with its corresponding article title was processed by applying word-based tokenization, lowercasing, stop-words removal, stemming (Nakov, 2003; Savoy, 2007), and n-gram extraction. Finally, the matching between a question and a passage was done using cosine similarity and BM25 (Robertson and Zaragoza, 2009).

3.2 BERT for Multiple-Choice RC

The recently-proposed BERT (Devlin et al., 2019) framework is applicable to a vast number of NLP tasks. A shared characteristic between all of them is the form of the input sequences: a single sentence or a pair of sentences separated by the [SEP] special token, and a classification token ([CLS]) added at the beginning of each example. In contrast, the input for multiple-choice reading comprehension questions is assembled by three sentence pieces, i.e., context passage, question, and possible answer(s). Our model follows a simple strategy of concatenating the option (candidate answer) at the end of a question. Following the notation of Devlin et al. (2019), the input sequence can be written as follows:

[CLS] Passage [SEP] Question + Option [SEP]

[2] http://www.elastic.co/

[3] http://dumps.wikimedia.org/

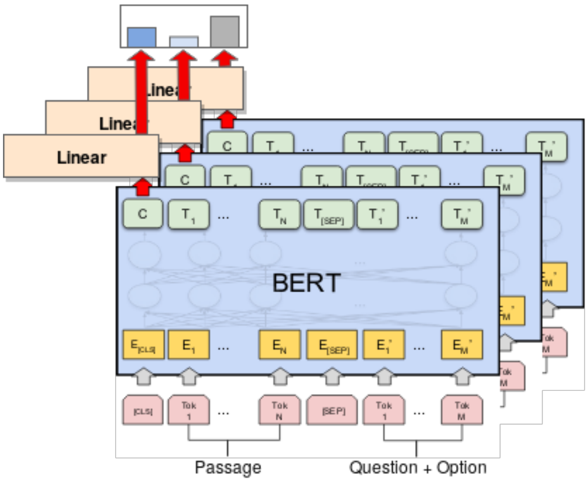

Figure 1: BERT for multiple-choice reasoning.

As recommended by Devlin et al. (2019), we introduce a new task-specific parameter vector L, $L \in \mathbb{R}^H$, where H is the hidden size of the model. In order to obtain a score for each passage-question-answer triplet, we take the dot product between L and the final hidden vector for the classification token ([CLS]), thus ending up with N unbounded numbers: one for each option. Finally, we normalize the scores by adding a softmax layer, as shown in Figure 1. During fine-tuning, we optimize the model's parameters by maximizing the log-probability of the correct answer.

3.3 Passage Selection Strategies

Finding evidence passages that contain information about the correct answer is crucial for reading comprehension systems. The context retriever may be extremely sensitive to the formulation of a question. The latter can be very general, or can contain insignificant rare words, which can bias the search. Thus, instead of using only the first-hit document, we should also evaluate lower-ranked ones. Moreover, knowing the answer candidates can enrich the search query, resulting in improved, more answer-oriented passages. This approach leaves us with a set of contexts that need to be evaluated by the MRC model in order to choose a single correct answer. Prior work suggests several different strategies: Chen et al. (2017a) used the raw predicted probability from a recurrent neural network (RNN), Yang et al. (2019a) tuned a hyper-parameter to balance between the retriever score and the reading model's output, while Pan et al. (2018) and Ni et al. (2019) concatenated the results from sentence-based retrieval into a single contextual passage.

In our experiments below, we adopt a simple summing strategy. We evaluate each result from the context retriever against the question and the possible options (see Section 3.2 for more details), thus obtaining a list of raw probabilities. We found empirically that explanatory contexts assign higher probability to the related answer, while general or uninformative passages lead to stratification of the probability distribution over the answer options. We formulate this as follows:

$$Pr(a_j|p;q) = \frac{exp(BERT(p, q + a_j))}{\sum_{j'} exp(BERT(p, q + a_{j'}))}, \quad (1)$$

where p is a passage, q is a question, A is the set of answer candidates, and $a_j \in A$.

We select the final answer as follows:

$$Ans = \arg\max_{a \in A} \sum_{p \in P} Pr(A|p;q) \quad (2)$$

4 Data

Our goal is to build a task for a low-resource language, such as Bulgarian, as close as possible to the multiple-choice reading comprehension setup for high-resource languages such as English. This will allow us to evaluate the limitations of transfer learning in a multilingual setting. One of the largest datasets for this task is RACE (Lai et al., 2017), with a total of 87,866 training questions with four answer candidates for each. Moreover, there are 25,137 contexts mapped to the questions and their correct answers.

While there exist many datasets for reading comprehension, most of them are in English, and there are a very limited number in other languages (Peñas et al., 2012, 2014). Hereby, we collect our own dataset for Bulgarian, resulting in 2,633 multiple-choice questions, without contexts, from different subjects: biology (16.6%), philosophy (23.93%), geography (23.24%), and history (36.23%). Table 2 shows an example question with candidate answers chosen to represent best each category. We use green to mark the correct answer, and bold for the question category. For convenience all the examples are translated to English.

Table 1 shows the distribution of questions per subject category, the length (in words) for both the questions and the options (candidate answers), and the vocabulary richness, measured in terms of unique words. The first part of the table presents statistics about our dataset, while the second part is a comparison to RACE (Lai et al., 2017).

RACE Train - Mid and High School					
RACE-M	25,421	4	9.0	3.9	32,811
RACE-H	62,445	4	10.4	5.8	125,120
Overall	87,866	4	10.0	5.3	136,629

Table 1: Statistics about our Bulgaria dataset compared to the RACE dataset.

(**Biology**) The thick coat of mammals in winter is an example of:
A. physiological adaptation
B. behavioral adaptation
C. genetic adaptation
D. morphological adaptation

(**Philosophy**) According to relativism in ethics:
A. there is only one moral law that is valid for all
B. there is no absolute good and evil
C. people are evil by nature
D. there is only good, and the evil is seeming

(**Geography**) Which of the assertions about the economic specialization of the Southwest region is true?
A. The ratio between industrial and agricultural production is 15:75
B. Lakes of glacial origin in Rila and Pirin are a resource for the development of tourism
C. Agricultural specialization is related to the cultivation of grain and ethereal-oil crops
D. The rail transport is of major importance for intra-regional connections

(**History**) Point out the concept that is missed in the text of the Turnovo Constitution: „Art. 54 All born in Bulgaria, also those born elsewhere by parents Bulgarian ______, count as ______ of the Bulgarian Principality. Art. 78 Initial teaching is free and obligatory for all ______ of the Bulgarian Principality."
A. residents
B. citizents
C. electors
D. voters

(**History Quiz**) Sofroniy Vrachanski started a family that plays a big role in the history of the Bulgarian National Revival. What is its name?
A. Georgievi
B. Tapchileshtovi
C. Bogoridi
D. Palauzovi

Table 2: Example questions, one per subject, from our Bulgarian dataset. The correct answer is marked in green.

We divided the Bulgarian questions into two groups based on the question's source. The first group (*12th Grade Matriculation Exam*) was collected from twelfth grade matriculation exams created by the Ministry of Education of Bulgaria in the period 2008–2019. Each exam contains thirty multiple-choice questions with four possible answers per question. The second set of questions (*Online History Quizzes*) are history-related and are collected from online quizzes. While they are not created by educators, the questions are still challenging and well formulated. Furthermore, we manually filtered out questions with non-textual content (i.e., pictures, paintings, drawings, etc.), ordering questions (i.e., order the historical events), and questions involving calculations (i.e., how much X we need to add to Y to arrive at Z).

Table 1 shows that history questions in general contain more words (14.0–38.9 on average), compared to other subjects (8.9–12.8 on average). A tangible difference in length compared to other subjects is seen for *12th grade History* and *PzHistory*, due to the large number of quotes, and document pieces contained in questions from these two groups. Also, the average question length is 15.7, which is longer compared to the RACE dataset with 10.0. On the other hand, the option lengths per subject category in our dataset follow a narrower distribution. They fall in the interval between 2.5 and 2.9 words on average, expect for *12th grade History*, with 3.6 words. Here, we note a significant difference compared to the option lengths in RACE, which tend to be 2.4 words longer on average – 5.3 for RACE vs. 2.9 for ours.

Finally, we examine the vocabulary richness of the two datasets. The total number of unique words is shown in the last column of Table 1 (Vocab Size). For our dataset, there are two numbers per row: the first one shows statistics based on the question–answer pairs only, while the second one, enclosed in parentheses, measures the vocabulary size including the extracted passages by the Context Retriever. The latter number is a magnitude estimate rather then a concrete number, since its upper limit is the number of words in Wikipedia, and it can vary for different retrieval strategies.

5 Experiments and Evaluation

5.1 BERT Fine-Tuning

We divide the fine-tuning into two groups of models (*i*) Multilingual BERT, and (*ii*) Slavic BERT. Table 3 below presents the results in the multiple-choice comprehension task on the dev dataset from RACE (Lai et al., 2017).

#Epoch	RACE-M	RACE-H	Overall
BERT 1	64.21	53.66	56.73
BERT 2	68.80	57.58	60.84
BERT 3	69.15	58.43	61.55
Slavic 2	53.55	44.48	47.12
Slavic 3	57.38	46.88	49.94

Table 3: Accuracy measured on the dev RACE dataset after each training epoch.

Multilingual BERT As our initial model, we use BERT$_{\text{base}}$, Multilingual Cased which is pretrained on 104 languages, and has 12-layers, 768-hidden units per layer, 12-heads, and a total of 110M parameters. We further fine-tune the model on RACE (Lai et al., 2017) for 3 epochs saving a checkpoint after each epoch. We use a batch size of 8, a max sequence size of 320, and a learning rate of 1e-5.

Slavic BERT The Slavic model[4] was built using transfer learning from the Multilingual BERT model to four Slavic languages: Bulgarian, Czech, Polish, and Russian. In particular, the Multilingual BERT model was fine-tuned on a stratified dataset of Russian news and Wikipedia articles for the other languages. We use this pre-trained Slavic BERT model, and we apply the same learning procedure as for *Multilingual BERT*.

5.2 Wikipedia Retrieval and Indexing

Here, we discuss the retrieval setup (see Section 3.1 for more details). We use the Bulgarian dump of Wikipedia from 2019-04-20, with a total of 251,507 articles. We index each article title and body in plain text, which we call a *passage*. We further apply additional processing for each field:

- *ngram*: word-based 1–3 grams;
- *bg*: lowercased, stop-words removed (from Lucene), and stemmed (Savoy, 2007);
- *none*: bag-of-words index.

We ended up using a subset of four fields from all the possible analyzer-field combinations, namely *title.bg, passage, passage.bg,* and *passage.ngram*. We applied Bulgarian analysis on the *title* field only as it tends to be short and descriptive, and thus very sensitive to noise from stop-words, which is in contrast to questions that are formed mostly of stop-words, e.g., *what*, *where*, *when*, *how*.

For indexing the Wikipedia articles, we adopt two strategies: sliding window and paragraph. In the window-based strategy, we define two types of splits: small, containing 80-100 words, and large, of around 300 words. In order to obtain indexing chunks, we define a window of size K, and a stride equal to one forth of K. Hence, each $\frac{K}{4}$ characters, which is the size of the stride, are contained into four different documents. The paragraph-based strategy divides the article by splitting it using one or more successive newline characters ([\n]+) as a delimiter. We avoid indexing entire documents due to their extensive length, which can be far beyond the maximum length that BERT can take as an input, i.e., 320 word pieces (see Section 5.1 for the more details). Note that extra steps are needed in order to extract a proper passage from the text. Moreover, the amount of facts in the Wikipedia articles that are unrelated to our questions give rise to false positives since the question is short and term-unspecific.

Finally, we use a list of top-N hits for each candidate answer. Thus, we have to execute an additional query for each question + option combination, which may result in duplicated passages, thus introducing an implicit bias towards the candidates they support. In order to mitigate this effect, during the answer selection phase (see Section 3.3), we remove all duplicate entries, keeping a single instance.

[4] http://github.com/deepmipt/Slavic-BERT-NER

Setting	Accuracy
Random	24.89
Train for 3 epochs	–
+ window & title.bg & pass.ngram	29.62
+ passage.bg & passage	39.35
– title.bg	39.69
+ passage.bg^2	40.26
+ title.bg^2	40.30
+ bigger window	36.54
+ paragraph split	42.23
+ Slavic pre-training	33.27
Train for 1 epoch best	40.26
Train for 2 epochs best	41.89

Table 4: Accuracy on the Bulgarian testset: ablation study when sequentially adding/removing different model components.

5.3 Experimental Results

Here, we discuss the accuracy of each model on the original English MRC task, followed by experiments in zero-shot transfer to Bulgarian.

English Pre-training for MCRC. Table 3 presents the change in accuracy on the original English comprehension task, depending on the number of training epochs. In the table, "BERT" refers to the Multilingual BERT model, while "Slavic" stands for BERT with Slavic pre-training. We further fine-tune the models on the RACE dataset. Next, we report their performance in terms of accuracy, following the notation from (Lai et al., 2017). Note that the questions in RACE-H are more complex than those in RACE-M. The latter has more word matching questions and fewer reasoning questions. The final column in the table, *Overall*, shows the accuracy calculated over all questions in the RACE testset. We train both setups for three epochs and we report their performance after each epoch. We can see a positive correlation between the number of epochs and the model's accuracy. We further see that the Slavic BERT performs far worse on both RACE-M and RACE-H, which suggests that the change of weights of the model towards Slavic languages has led to catastrophic forgetting of the learned English syntax and semantics. Thus, it should be expected that the adaptation to Slavic languages would yield decrease in performance for English. What matters though is whether this helps when testing on Bulgarian, which we explore next.

Zero-Shot Transfer. Here, we assess the performance of our model when applied to Bulgarian multiple-choice reading comprehension. Table 4 presents an ablation study for various components. Each line denotes the type of the model, and the addition (+) or the removal (–) of a characteristic from the setup in the previous line. The first line shows the performance of a baseline model that chooses an option uniformly at random from the list of candidate answers for the target question. The following rows show the results for experiments conducted with a model trained for three epochs on RACE (Lai et al., 2017).

Our basic model uses the following setup: Wikipedia pages indexed using a small sliding window (400 characters, and stride of 100 characters), and context retrieval over two fields: Bulgarian analyzed title (*text.bg*), and word n-grams over the passage (*passage.ngram*). This setup yields 29.62% accuracy, and it improves over the random baseline by 4.73% absolute. We can think of it as a non-random baseline for further experiments. Next, we add two more fields to the IR query: passage represented as a bag of words (named *passage*), and Bulgarian analyzed (*passage.bg*), which improves the accuracy by additional 10%, arriving at 39.35%. The following experiment shows that removing the *title.bg* field does not change the overall accuracy, which makes it an insignificant field for searching. Further, we add double weight on *passage.bg*, (shown as ^2), which yields 1% absolute improvement.

From the experiments described above, we found the best combination of query fields to be *title.bulgarian*^2, *passage.ngram, passage, passage.bulgarian*^2, where the *title* has a minor contribution, and can be sacrificed for ease of computations and storage. Fixing the best query fields, allowed us to evaluate other indexing strategies, i.e., bigger window (size 1,600, stride 400) with accuracy 36.54%, and paragraph splitting, with which we achieved our highest accuracy of 42.23%. This is an improvement of almost 2.0% absolute over the small sliding window, and 5.7% over the large one.

Next, we examined the impact of the Slavic BERT. Surprisingly, it yielded 9% absolute drop in accuracy compared to the multi-lingual BERT. This suggests that the latter already has enough knowledge about Bulgarian, and thus it does not need further adaptation to Slavic languages.

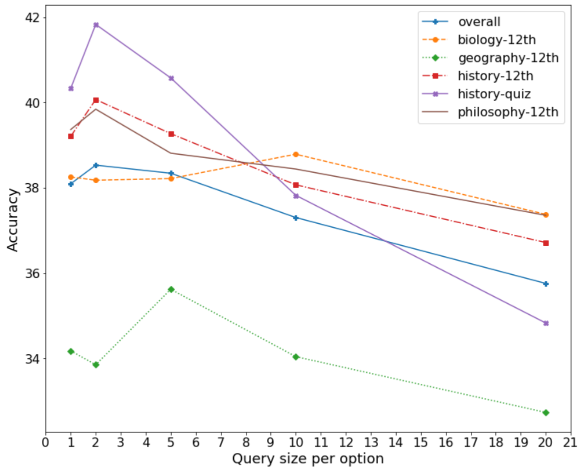

Figure 2: Accuracy per question category based on the number of query results per answer option.

Next, we study the impact of the number of fine-tuning epochs on the model's performance. We observe an increase in accuracy as the number of epochs grows, which is in line with previously reported results for English tasks. While this correlation is not as strong as for the original RACE task (see Table 3 for comparison), we still observe 1.6% and 0.34% absolute increase in accuracy for epochs 2 and 3, respectively, compared to epoch 1. Note that we do not go beyond three epochs, as previous work has suggested that 2-3 fine-tuning epochs are enough (Devlin et al., 2019), and after that, there is a risk of catastrophic forgetting of what was learned at pre-training time (note that we have already seen such forgetting with the Slavic BERT above).

We further study the impact of the size of the results list returned by the retriever on the accuracy for the different categories. Figure 2 shows the average accuracy for a given query size S_q over all performed experiments, where $S_q \in \{1, 2, 5, 10, 20\}$. We can see in Figure 2 that longer query result lists (i.e., containing more than 10 results) per answer option worsen the accuracy for all categories, except for *biology*, where we see a small peak at length 10, while still the best overall results for this category is achieved for a result list of length 5. A single well-formed maximum at length 2 is visible for *history* and *philosophy*. With these two categories being the biggest ones, the cap at the same number of queries for the overall accuracy is not a surprise. The per-category results for the experiments are discussed in more detail in Appendix A.

We can see that the highest accuracy is observed for *history*, particularly for online quizzes, which are not designed by educators and are more of a word-matching nature rather then a reasoning one (see Table 2). Finally, *geography* appears to be the hardest category with only 38.73% accuracy: 3.5% absolute difference compared to the second-worst category. The performance for this subject is also affected differently by changes in query result length: the peak is at lengths 5 and 10, while there is a drop for length 2. A further study of the model's behavior can be found in Appendix B.

6 Conclusion and Future Work

We studied the task of multiple-choice reading comprehension for low-resource languages, using a newly collected Bulgarian corpus with 2,633 questions from matriculation exams for twelfth grade in history and biology, and online exams in history without explanatory contexts. In particular, we designed an end-to-end approach, on top of a multilingual BERT model (Devlin et al., 2019), which we fine-tuned on large-scale English reading comprehension corpora, and open-domain commonsense knowledge sources (Wikipedia). Our main experiments evaluated the model when applied to Bulgarian in a zero-shot fashion. The experimental results found additional pre-training on the English RACE corpus to be very helpful, while pre-training on Slavic languages to be harmful, possibly due to catastrophic forgetting. Paragraph splitting, n-grams, stop-word removal, and stemming further helped the context retriever to find better evidence passages, and the overall model to achieve accuracy of up to 42.23%, which is well above the baselines of 24.89% and 29.62%.

In future work, we plan to make use of reading strategies (Sun et al., 2019b), linked entities (Pan et al., 2018), concatenation and reformulation of passages and questions (Simov et al., 2012; Clark et al., 2016; Ni et al., 2019), as well as re-ranking of documents (Nogueira and Cho, 2019).

Acknowledgments

We want to thank Desislava Tsvetkova and Anton Petkov for the useful discussions and for their help with some of the experiments.

This research is partially supported by Project UNITe BG05M2OP001-1.001-0004 funded by the OP "Science and Education for Smart Growth" and co-funded by the EU through the ESI Funds.

Appendix

A Per-Category Results

Table 5 gives an overview, including per-category breakdown, of our parameter tuning experiments. We present the results for some interesting experiments rather then for a full grid search. The first row shows a random baseline for each category. In the following rows, we compare different types of indexing: first, we show the results for a small sliding window (400-character window, and 100-character stride), followed by a big window (1,600-character window, and 400-character stride), and finally for paragraph indexing. We use the same notation as in Section 5. The last group in the table (*Paragraph*) shows the best-performing model, where we mark in bold the highest accuracy for each category. For completeness, we also show the accuracy when using the *Slavic BERT* model for prediction, which yields a 10% drop on average compared to using the *Multilingual BERT*, for each of the categories.

B Case Study

In Table 6, we present the retrieved evidence passages for the example questions in Table 2: we omit the answers, and we only show the questions and the contexts. Each example is separated by a double horizontal line, where the first row is the question starting with "*Q:*", and the following rows contain passages returned by the retriever. For each context, we normalize the raw scores from the comprehension model using Eq. 1 to obtain a probability distribution. We then select an answer using $\arg\max$, according to Eq. 2. In the table, we indicate the correctness of each predicted answer using one of the following symbols before the question:

- ✓ The question is answered correctly.
- ✗ An incorrect answer has the highest score.
- ? Two or more answers have the highest score.

We show the top retrieved result in order to illustrate the model scores over different evidence passages and the quality of the articles. The queries are formed by concatenating the question with an answer option, even though this can lead to duplicate results since some answers can be quite similar or the question's terms could dominate the similarity score.

The questions in Table 6 are from five different categories: biology, philosophy, geography, history, and online quizzes. Each of them has its own specifics and gives us an opportunity to illustrate a different model behavior.

The first question is from the biology domain, and we can see that the text is very general, and so is the retrieved context. The latter talks about *hair* rather than *coat*, and the correct answer (D) *morphological adaptation* is not present in the retrieved text. On the other hand, all the terms are only connected to it, and hence the model assigns high probability to this answer option.

For the second question, from the philosophy domain, there are two related contexts found. The first one is quite short, noisy, and it does not give much information in general. The second paragraph manages to extract the definition of *relativism* and to give good supporting evidence for the correct answer, namely that *there is no absolute good and evil* (B). As a result, this option is assigned high probability. Nevertheless, the incorrect answer *here is only one moral law that is valid for all* (A) is assigned an even higher probability and it wins the voting.

In the third example, from the domain of geography, we see a large number of possible contexts, due to the long and descriptive answers. We can make two key observations: (*i*) the query is drawn in very different directions by the answers, and (*ii*) there is no context for *Southwestern region*, and thus, in the second option, the result is for Russia, not for Bulgaria. The latter passage pushes the probability mass to an option that talks about transportation (D), which is incorrect. Fortunately, the forth context has an almost full term overlap with the correct answer (B), and thus gets very high probability assigned to it: 72%.

The fourth question, from the history domain, asks to point out a missing concept, but the query is dominated by the question, and especially by underscores, leading to a single hit, counting only symbols, without any words. As expected, the model assigned uniform probability to all classes.

The last question, a history quiz, is a factoid one, and it lacks a reasoning component, unlike the previous examples. The query returned a single direct match. The retrieved passage contains the correct answer exactly: option *Bogoridi* (C). Thereby, the comprehension model assigns to it a very high probability of 68%.

Tweaks and Tricks for Word Embedding Disruptions

Amir Hazem[1] **Nicolas Hernandez**[1]
[1] LS2N - UMR CNRS 6004, Université de Nantes, France
{Amir.Hazem,Nicolas.Hernandez}@univ-nantes.fr

Abstract

Word embeddings are established as very effective models used in several NLP applications. If they differ in their architecture and training process, they often exhibit similar properties and remain vector space models with continuously-valued dimensions describing the observed data. The complexity resides in the developed strategies for learning the values within each dimensional space. In this paper, we introduce the concept of disruption which we define as a side effect of the training process of embedding models. Disruptions are viewed as a set of embedding values that are more likely to be noise than effective descriptive features. We show that dealing with disruption phenomenon is of a great benefit to bottom-up sentence embedding representation. By contrasting several in-domain and pre-trained embedding models, we propose two simple but very effective tweaking techniques that yield strong empirical improvements on textual similarity task.

1 Introduction

Word embedding models are now a standard in many NLP applications. If the choice of the most appropriate model is not always straightforward, context word representation is at the core of each model and the performance is closely related to how well the context is exploited. In this paper, we introduce the notion of disruption, a phenomenon caused by the training process of word embedding models. Disruptions are a set of extreme embedding values that are more likely to be noise than reliable features. We consider this phenomenon as a negative side effect closely related to the data and to the training optimization decisions. If we observe the Gaussian distribution of word embedding dimensional-values, we notice a set of high positive and negative values of which the percentage varies from one embedding model to another. In the context of vector-space models where each word is represented as a point in the N-dimensional Euclidean space, disruptions may drastically affect word's position and so create unbalanced embedding values. If normalization tends to smooth this effect, our experiments reveal that detecting disruptions and adjusting them is far more efficient than a standard normalization. We show that dealing with disruptions is of a substantial benefit to bottom-up sentence embedding representation.

A bottom-up sentence representation is a weighted sum of the embedding vectors of its constituent words. This simple approach turned out to be very competitive in many NLP applications (Wieting et al., 2016; Arora et al., 2017) and outperformed several advanced RNNs and LSTM-based models of which the performance heavily depends on the quality and the large size of the training data set (Socher et al., 2011; Le and Mikolov, 2014; Kiros et al., 2015; Pagliardini et al., 2018). By contrast to sophisticated approaches, bottom-up sentence embedding models are less constrained and more easy to acquire. The core of the bottom-up model is the word embedding unit. An efficient sentence representation is then closely related to the quality of the used word embedding model. We state that the additive process of bottom-up sentence representation amplifies disruption's negative impact and propose to manage this phenomenon by introducing two tweaking techniques. Our approaches take into account and reduce the effect of disruptions in order to improve bottom-up sentence embedding representation. We evaluate bottom-up sen-

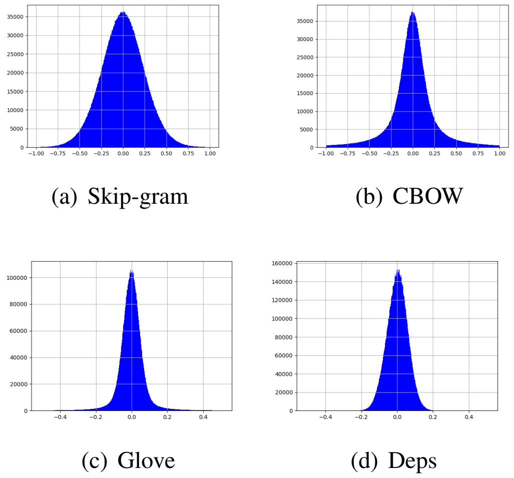
Varna, Bulgaria, Sep 2–4 2019.

tence embeddings using StackExchange Philosophy data set over several in-domain [1] and pre-trained embedding models on question to question similarity task and show significant improvements. The used pre-trained models are skipgram (Sg) (Mikolov et al., 2013), Glove (Pennington et al., 2014), dependency relation (Deps) (Levy and Goldberg, 2014), and the character Skipgram (ChSg) and character CBOW (ChC)[2] (Bojanowski et al., 2016).

2 Word Embedding Disruptions

Word embedding models are vector-spaces in which words are represented as points in an N-dimensional Euclidean space. Regardless of the complexity of the embedding models, the main concern remains weights estimation. At the end of the training process, the obtained model is expected to map and to efficiently represent the training data set. This supposes that each dimension has a degree of representativeness of a given word. Which means that each single dimensional value can potentially affect the word's position in the N-dimensional space. This also means that extreme values that we call disruptions might have a bigger impact on the word's position. This phenomenon is amplified by the mathematical properties and the additive process of bottom-up representation. If we consider for instance a 3-dimensional space in which one dimensional value is drastically high, the position in the 3-D space will be attracted by this dimension. This is not problematic on its own if the 3-D model well maps the data. However, if it is not the case, this might weaken the quality of the word's embedding vector.

Multiple reasons lend support to the idea that disruptions are more likely to be side effects of the training process rather than being discriminative values. The first reason comes from the characteristics of the training data set. Regardless of the size which in most cases greatly affects the quality of the embedding models, not all words are equally distributed and even using down-sampling and other sophisticated techniques to reduce the size impact, infrequent words will always be under-characterized at least for embedding models not involving character n-gram modeling. The second reason comes from the architecture and the training procedure of word embeddings (Nematzadeh et al., 2017). CBOW model for instance, predicts the target word based on a mean average weights of its context words. While, skip-gram maximizes the average log-probability of each word's context (Mikolov et al., 2013). Also, the process of weights computation is often based on batches which leads to a mean error minimization instead of a specific attention to each single training example. This optimization process might lead to some computation decisions that create margin values, potentially not relevant and so creates dimension disruptions. Even without using batches, and in order to allow efficient training, evaluating the normalization factor of the Softmax (Mikolov et al., 2013) for instance, introduces approximations. We don't claim that one of the above cited reasons is the main cause of disruptions, however we hypothesize that several parameters may lead to training side effects that lead to disruption values. If it is difficult to remove disruptions, we propose two tweaking techniques to reduce their effects.



(a) Skip-gram

(b) CBOW

(c) Glove

(d) Deps

Figure 1: 300 dimensional word embedding distributions on the StackExchange Philosophy data set.

Figure 1 illustrates the distribution values of some well-known state-of-art embedding models. We first observe that all the embedding models follow a Gaussian distribution with a mean around zero. The main differences concern the standard deviation, minimum and maximum values and the density. Also, Table 1 reports the statistics of in-domain and pre-trained embeddings. We observe that each model shows different characteris-

[1] In-domain embedding models are embeddings trained on the in-domain philosophy corpus.

[2] ChC is not available, and is only used as in-domain.

σ	0.35	0.47	0.12	0.77	0.17	0.13	0.38	0.29 2	0.05	0.05	0.05	0.295
min	-2.07	-5.51	-3.06	-8.01	-2.55	-4.06	-3.06	-5.09	-0.31	-0.358	-0.34	-10.1
max	2.20	7.57	2.57	9.98	2.26	4.18	3.52	3.25	0.32	0.354	0.29	13.6
disrupt (%)	7.56	17.3	7.11	15.8	22.1	8.1	18.3	17.1	36.6	37.9	38.4	21.5
Cove (%)	100	100	100	100	100	52.1	55.2	66.1	52.0	52.0	51.9	56.4

Table 1: Statistics over several in-domain and pre-trained embedding models on the Philosophy data set. The mean value over the entire set of embeddings (μ), its corresponding standard deviation (σ), minimum (min) and maximum (max) values, the percentage of disruptions ($disrupt$) and vocabulary coverage of the embedding models on the Philosophy data set ($Cove$).

tics which can be comparable in some cases (Sg and ChSg) or totally different in other cases such as Sg and CBOW. Also, we see that substantial dimensional values that we define as disruptions are beyond the standard deviation.

3 Tweaks Approach

In order to reduce disruption impact on bottom-up sentence representation, we introduce the mean correction trick. A tweaking process that adjusts extreme values and center them around the mean embedding value. Let's consider N the number of embedding dimensions, V the corpus vocabulary size and S the set of disruptions with $S \in N \times V$. All the S values are replaced by the mean.

Algorithm 1 Mean Tweak approach

```
Require: $Emb = SG, CBOW, Glove, ...$
Require: $\mu \leftarrow Mean(Emb)$
Require: $\sigma \leftarrow StandardDeviation(Emb)$
Require: $\alpha \in ]min, \mu - \sigma]$
Require: $\beta \in [\mu + \sigma, max[$

function TWEAK($Emb_w$,$\mu$,$\alpha$, $\beta$)
    for $i \in Dim(Emb_w)$ do
        if $Emb_w[i] \notin [\alpha, \beta]$ then
            $Emb_w[i] \leftarrow \mu$
        end if
    end for
    return $Emb_w$
end function
```

Algorithm 1 represents the mean tweak approach where the mean value is computed over the entire set of embedding models. By contrast, per dimension approach computes one mean value per dimension. In our experiments α and β were computed empirically on a development set, however, their values are often around the $\mu + \sigma$ for max and μ - σ for min intervals. In the dimensional space this procedure tends to center the words position in the space and to reduce the impact of disruptions. From the bottom-up sentence representation side, this can be interpreted as ignoring some dimensions in the additive process. As can be seen in Table 1, the mean is often around zero and this value will not have any effect on the position of the sentence in the space when we sum-up the words of a given sentence. We consider two ways of mean computation. The first is computed over the entire set of word embeddings and the second one is the computation of a mean per dimension. We contrast both techniques in our experiments.

4 Data Description

The data set was extracted from the philosophy community question answering forum StackExchange. Basically, each post is composed of a pair of questions and one or several answers and comments. Our data set contains 5.7k posts and 1.1M tokens. We took 10% of questions for dev and 10% for test set (575 questions).

Philosophy question pair example:

Q1: were there any pre-enlightenment philosophical consideration of the naturalistic fallacy or relate concept?

Q2: naturalistic fallacy was described and named by g.e. Moore at the beginning of the 20th century. but have there been pre-enlightenment philosopher who have treat the concept?

5 Experiments and Results

Similarly to (Arora et al., 2017), we evaluate the performance of the bottom-up approach on the questions similarity task. This consists in, first, computing for each question, an average sum of its embedding words and then compute the cosine similarity on the entire set of questions to

Table 2: Results (MAP%) of bottom-up sentence representation on the test question-to-question similarity task using the Philosophy data set, 5 in-domain 300 dimensions embedding models (CBOW and Skipgram (Mikolov et al., 2013)), Glove (Pennington et al., 2014), Character n-gram CBOW (ChC) and character Skip-gram (ChSG) (Bojanowski et al., 2016) and 7 pre-trained 300 dimensions models (W2V(sg) trained on googlenews (Mikolov et al., 2013), Glove6B trained on wikipedia and Gigaword, Glove42B trained on Common Crawl (Pennington et al., 2014), Bow5C(CBOW), Bow5W(Sg) and Deps trained on wikipedia (Levy and Goldberg, 2014) and Character skipgram (ChSG) trained on wikipedia (Bojanowski et al., 2016)).

rank the target candidates. The mean average precision (MAP) is used for evaluation. We compare the raw bottom-up approach (*baseline*) to the tweaks that we introduced. As a preprocessing step, we apply the L2 norm ($+Norm$) and our two tweaking techniques that is: $+MeanAll$ for a mean computation over the entire corpus and $+MeanDim$, for a per dimension mean adjustment. We also contrast the use of the L2 norm on the top of our tweaking techniques that we refer to as $+MeanAll + Norm$ and $+MeanDim + Norm$.

Table 2 reports the evaluation of in-domain and pre-trained embeddings of the bottom-up approach. Overall, we see that whether using in-domain or pre-trained embeddings, the baseline bottom-up approach gains significant improvements while using the proposed tweaking techniques. The gain depends on the model but the margin is in most cases very important especially for in-domain CBOW and ChC models where we notice a rise of about 20 points of Map score. We also observe improvements in all pre-trained embeddings while the gain is not as important as the one observed in the in-domain sets. This can be explained by the vocabulary coverage of pre-trained embeddings which is often between 50 and 60% as shown in Table 1. If in most cases a per dimension tweak ($MeanDim$) shows better results than $MeanAll$, we observe some margin improvements using L2 norm on the top of our tweaking techniques. If L2 norm on its own improves the performance of the baseline, the results clearly show that managing disruptions is more efficient than L2 Norm.

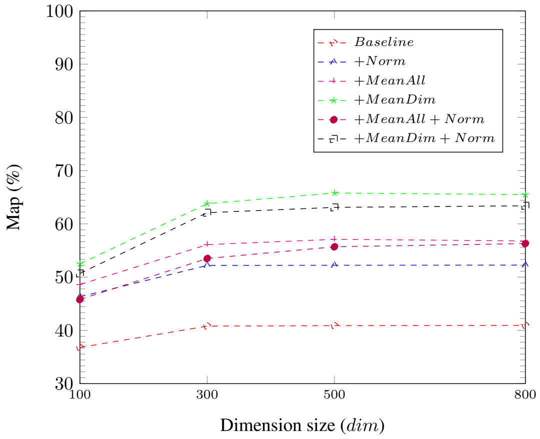

Figure 2: Contrasting several embedding dimension size of CBOW on Philosophy data set.

Figure 2 contrasts different embedding dimension size of the CBOW model[3]. The figure shows the same tendency of improvements regardless of the change in dimension size. Also, it shows that our tweaking techniques are very effective to improve question similarity using a bottom-up model.

6 Conclusion

We introduced disruption phenomenon, a negative side effect of word embedding training process. We consider the resulting set of extreme positive and negative dimensional-values as noise and as not reliable descriptive features. To reduce the effect of disruptions on bottom-up sentence representation, we proposed two tweaking techniques. Our procedure aims at adjusting the disrupted values by smoothing them around the mean value

[3] Other models are not presented for a matter of space. Except the skipgram in-domain model, all the 10 other embedding models show the same tendency as CBOW.

of embedding dimensions. Our results over in-domain and pre-trained models showed significant improvements for question similarity task.

Meta-Embedding Sentence Representation for Textual Similarity

Amir Hazem[1] **Nicolas Hernandez**[1]
[1] LS2N - UMR CNRS 6004, Université de Nantes, France
{Amir.Hazem,Nicolas.Hernandez}@univ-nantes.fr

Abstract

Word embedding models are now widely used in most NLP applications. Despite their effectiveness, there is no clear evidence about the choice of the most appropriate model. It often depends on the nature of the task and on the quality and size of the used data sets. This remains true for bottom-up sentence embedding models. However, no straightforward investigation has been conducted so far. In this paper, we propose a systematic study of the impact of the main word embedding models on sentence representation. By contrasting in-domain and pre-trained embedding models, we show under which conditions they can be jointly used for bottom-up sentence embeddings. Finally, we propose the first bottom-up meta-embedding representation at the sentence level for textual similarity. Significant improvements are observed in several tasks including question-to-question similarity, paraphrasing and next utterance ranking.

1 Introduction

According to Enkvist (1987): *"a model is a simplified representation of reality. It is simplified because it aims at reproducing a selection of relevant elements of reality rather than all of reality at once."*. If several word embedding models (Mikolov et al., 2013a; Pennington et al., 2014; Yin and Schütze, 2016; Arora et al., 2017) capture a selection of relevant features, different embedding sets can cover different characteristics which can also be complementary (Yin and Schütze, 2016). In order to capture a wide range of features, it is useful to perform models combination (ensemble models). The representation of longer pieces of texts such as sentences, by an element-wise sum of their word embeddings has recently shown promising results and outperformed sophisticated models in several textual similarity tasks (Mikolov et al., 2013a; Arora et al., 2017). This representation, also known as bottom-up sentence embeddings, is greatly affected by the choice of word embedding models. In this paper, we propose a systematic study of the impact of word embedding models on bottom-up sentence representation for textual similarity. We report the results of the main individual pre-trained embedding models that are publicly available as well as embedding models trained on in-domain data sets. Finally, we contrast multiple ensemble models and propose the first bottom-up meta-embedding sentence representation for textual similarity. We evaluate the different approaches on four tasks that is: question-to-question similarity (SemEval 2016/2017), textual entailment (SemEval 2014), paraphrasing (Sick) and next utterance ranking (NUR) and show under which conditions meta-embeddings can be beneficial to bottom-up sentence-based approaches.

2 Related Work

Embedding models at the word level representations have been widely explored in many applications (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013a; Pennington et al., 2014; Bojanowski et al., 2016). Naturally, they have been extended to sentence, paragraph and document level representations (Socher et al., 2011; Mikolov et al., 2013a; Le and Mikolov, 2014; Kalchbrenner et al., 2014; Kiros et al., 2015b; Wieting et al., 2016; Arora et al., 2017), thanks to the continuous advances of deep neural embedding methods such as Recurrent Neural Networks (RNN), Long Short Term Memory (LSTM) and Convolutional Neural Networks (CNN). Some sentence embedding representations can be seen as a direct inspiration from word embedding models. For instance, while the skip-gram model (Mikolov et al., 2013a) predicts the surrounding words given a source word, in the same way, *SkipThought* (Kiros et al., 2015a) and *FastSent* (Hill et al., 2016) models predict surrounding sentences given a source sentence. Also, the paragraph *DBOW* model (Le and Mikolov, 2014) learns representations for variable length pieces of texts and learns to predict the surrounding words based on contexts sampled from paragraphs. Recently, Pagliardini et al. (2018) introduced *Sent2Vec*, an approach based on word vectors along with n-gram embeddings simultaneously to represent sentences.

Another type of sentence embedding representation, also called bottom-up approach, represents sentences by a weighted sum of the embedding vectors of their individual words. This naive approach turned out to be competitive and outperformed sophisticated approaches based on RNNs and LSTMs in many natural language processing applications (Mikolov et al., 2013a; Wieting et al., 2016; Arora et al., 2017; Hazem and Morin, 2017). Mikolov et al. (2013a) for instance demonstrated the effectiveness of their model on the phrase analogy task. They used the hierarchical softmax and subsampling using large amount of data. Wieting et al. (2016) have shown that a simple but supervised word averaging model of sentence embeddings leads to better performance on the paraphrase pairs data set (PPDB). However, the performance of their approach is closely related to the supervision from the date set, while without supervision, their approach did not perform well on textual similarity tasks. More recently, Arora et al. (2017) proposed a new sentence embedding method where they first compute a weighted average sum of the word embedding vectors of sentences, and then, remove the projections of the average vectors on their first principal components. Like Mikolov et al. (2013a) and Wieting et al. (2016), their approach is based on word embedding sum, but the difference is remarkable on the weighted schema and on the use of principal component analysis (PCA) method to remove the correlation of sentence vectors dimensions. They significantly achieved better performance than the unweighted average on a variety of textual similarity tasks. A noticeable remark is that their approach outperformed sophisticated supervised methods such as RNN's and LSTM's. Finally, some approaches are supervised and need labelled data, such as *DictRep* (Hill et al., 2015) which uses structured data to map dictionary definitions of words with their pre-trained embeddings. With the encouraging results and simplicity of bottom-up approaches, we focus in this paper on this type of approaches and show their potential while used jointly with meta-embeddings.

3 Sentence Meta-Embedding Representation

To deal with textual similarity, we propose a new approach that we refer to as meta-embedding sentence representation (MetaSentEmb). In the next sections we first recall the principle of ensemble approach from which we drawn our inspiration, then we give the details of our approach.

3.1 Ensemble Approach

The principle of the ensemble approach is to combine different models in order to catch the strength of each individual model. The main combination techniques that have shown their effectiveness are: vector addition (Garten et al., 2015) and vector concatenation (Garten et al., 2015; Yin and Schütze, 2016). For vector addition, given two embedding models, the procedure consists of applying a simple dimension-wise vector addition[1]. For vector concatenation, given two embedding models of dimensions $dim1$ and $dim2$, the resulting concatenated embedding vector will be of size $dim1 + dim2$. The vectors have to be normalized before concatenation. Usually L2 norm is performed[2]. Yin and Schütze (2016) performed a weighted concatenation of 5 embedding models. They also experienced the SVD on top of weighted concatenation vectors of dimension 950. This resulted in a reduced model of 200 dimensions.

3.2 Proposed Approach

The bottom-up sentence embedding representation consists of representing each given sentence (or piece of text of any length) by an embedding vector which is the sum of the vector embedding of each word of the sentence (Mikolov et al.,

[1] This technique can not be applied when embeddings are not of the same dimension size.

[2] L2 norm can be performed either at dimension level (as suggested by Glove authors) or at vector length level.

2013b; Wieting et al., 2016; Arora et al., 2017). This representation is illustrated in the following equation:

$$Sent_i = \sum_{j=1}^{n}(Embedding(w_j)) \qquad (1)$$

with $Sent_i$ a given sentence i and n the number of words in $Sent_i$. $Embedding(w_j)$ corresponds to the embedding model used to represent each word of the sentence $Sent_i$. We refer to this baseline approach as $SentEmb$ for sentence embedding representation. A variant of this representation is the use of a weighted sum as presented in (Wieting et al., 2016) for instance.

In this work, we extend the baseline representation ($SentEmb$) and propose $MetaSentEmb$, a meta-embedding sentence representation. We aim at improving sentence representation based on the sum of its word embeddings. As we mainly operate at the word level representation, we study different word meta-embedding techniques for sentence representation. We basically use an ensemble approach to represent each word, which means that each word has its own meta-embedding. Then, we sum each meta-embedding word of a given sentence to obtain a meta-embedding sentence representation (equation 2).

$$Sent_i = \sum_{j=1}^{n}(Ensemble(w_j)) \qquad (2)$$

with $Sent_i$ a given sentence i and n the number of words in $Sent_i$. $Ensemble(w_j)$ corresponds to the ensemble technique used to represent word meta-embeddings. $Ensemble(w_j)$ can be the additive or the concatenation technique. We refer to our proposed approach as $MetaSentEmb$ for sentence meta-embedding representation. Each sentence is pre-processed (Tokenization, part-of-speech tagging and lemmatization). Depending on the targeted task, stop-words can be removed and part of speech filtering can be applied (keeping only nouns, verbs and adjectives for instance).

4 Data and Tasks Description

In this section, we briefly outline the different textual resources used for our experiments, namely: (i) the Qatar Living corpus used in SemEval 2016/2017 for question similarity task, (ii) the Sick corpus used in SemEval 2014 for textual entailment and relatedness, (iii) the Microsoft Research Paraphrase Corpus (MSRPC) used for paraphrase detection and (iv) the Ubuntu Dialogue Corpus used for Next Utterance Ranking (NUR).

4.1 Embedding Models

To study the impact of external data and context representation, we chose different embedding models. In addition to the word2vec model trained on Google News (Mikolov et al., 2013a), we used the two Glove models respectively trained on Wikipedia+GigaWord ($Glove6B$) and on Common Crawl ($Glove42B$) (Pennington et al., 2014). We also used three Wikipedia pre-trained models (Levy and Goldberg, 2014), that is, two linear bag of word contexts and one dependency-based context. The bag of word models use a context size of 5 ($Bow5_C$ corresponds to CBow and $Bow5_W$ to skipgram). The dependency-based model used syntactic relations ($Deps$). Finally, we experienced the recent proposed character n-gram model (Bojanowski et al., 2016) by using the character Skip-gram model trained on Wikipedia ($ChSG$). A summary of the pre-trained out-of-domain embedding sets is presented in Table 1. We also trained embedding models (CBOW, Skipgram, Glove and character n-gram models) on in-domain data sets (Qatar Living and Sick corpus of SemEval, MSPR for paraphrasing and Ubuntu for NUR). We respectively noted in domain trained embeddings as $CBow$, $SkipGram$, $Glove$, $CharSG$ and $CharCBOW$.

4.2 Data Sets

4.2.1 Qatar Living Corpus

The Qatar Living corpus is a community question answering data set made of original and related questions and their n corresponding answers. The training and development data sets consist of 317 original questions and 3,169 related questions[3]. The test sets of 2016 and 2017 respectively consist of 70 original/700 related questions and 88 original/880 related questions. The SemEval (2016/2017) question-to-question similarity shared task (Task3, SubtaskB) consists of identifying for each original question, its corresponding related questions over 10 candidates (Nakov et al., 2016, 2017). The question-to-question similarity task of SemEval offers an appropriate and interesting framework for evaluating our meta-

[3] http://alt.qcri.org/semeval2016/task3/index.php?id=data-and-tools

Model	Vocab	Dim	Training Data
word2vec	93k	300	Google News (Mikolov et al., 2013a)
Glove6B	400k	50-300	Wikipedia-Gigaword (Pennington et al., 2014)
Glove42B	1.9M	300	Common Crawl (Pennington et al., 2014)
Bow, Deps	175K	300	Wikipedia (Levy and Goldberg, 2014)
CharSG	175K	300	Wikipedia (Bojanowski et al., 2016)

Table 1: Pre-trained embedding sets (Dim: dimension size).

embedding approach since an evaluation of multiple approaches including sentence embeddings have been already performed.

4.2.2 Sick Corpus

The sick data set consists of 10,000 English sentence pairs annotated for relatedness in meaning (a score form 1 to 5) and for entailment (Neutral, Entailment or Contradiction). The SemEval 2014 shared task (Task1) consists of predicting whether two given sentences are entailed, contradictions or neutral. Using sentence embeddings as well as meta-embeddings for entailment prediction is an appropriate textual similarity task for evaluation, however, dealing with contradictions and neutral sentences is more difficult than a binary classification which consists of predicting whether sentences are entailed or not. In any case and for the sake of comparison, we perform the same evaluation as the state of the art approaches by keeping the three classes (Neutral, Entailment or Contradiction) instead of two classes (Entailment or Not Entailment). As this work is mainly dedicated to the evaluation of sentence representations in sentence similarity, we only focus on the entailment part and don't consider the relatedness (we only report the results of the accuracy).

4.2.3 Microsoft Research Paraphrase Corpus

The Microsoft Research Paraphrase (MSRP) Corpus (Dolan et al., 2004) is composed of 5,801 news paraphrase sentence pairs extracted from the web. Each sentence pair has been annotated by humans as being in paraphrase relationship (label=1) or not (label=0). 67% of sentence pairs are positive examples (in paraphrase relationship) and 33% are negative examples which make the corpus unbalanced. The corpus has been divided into 4,076 training pairs and 1,725 test pairs. The paraphrasing task consists of identifying if a paraphrase relation exists between two given sentences. By contrast to the question similarity and entailment prediction tasks, sentence embedding similarity for paraphrasing might not be appropriate for evaluation since the MSRP corpus includes many sentence pairs which are not paraphrases but contain many similar words. Sentence similarity based approaches should fail in this case to detect paraphrases. However, showing the behaviour and the performance of sentence similarity approaches including meta-embeddings on such a task may offer some clues and may constitute a baseline for more sophisticated approaches.

4.2.4 Ubuntu Dialogue Corpus

The Ubuntu Dialogue Corpus is a large freely available multi-turn dialogue data set (Lowe et al., 2015) constructed from the Ubuntu chat logs[4]. The corpus (Human-Human chat) consists of approximately 930,000 two person dialogues, 7,100,000 utterances[5] and 100,000,000 words. The task of NUR consists of retrieving the most probable utterance among a database of existing human productions given a similar context. This task offers a key challenge for sentence similarity approaches since the relations between dialogue utterances are more generic. Here also, evaluating sentence similarity based approaches on a different task, should give some insights about their behaviour and to what extent it might help utterance prediction.

[4] The first version can be found in `http://irclogs.ubuntu.com/`. A newer version has been recently released in `https://github.com/rkadlec/ubuntu-ranking-dataset-creator`

[5] All the replies and initial questions are referred to as utterances

Table 2: Results of SentEmb for five distinct textual relation detection tasks (question-to-question with SemEval16 and SemEval17, paraphrase with MSRP, entailment with SICK and Next Utterance Ranking with UDC) using different pre-trained out-of-domain and in-domain embedding models. The numbers in brackets refer to the model rank in the given task, except for the last column which ranks the models regardless of the task. The score of the three best models for each task are in bold.

5 Results and Discussion

We conducted two sets of experiments. The first one aims at providing insights about the behaviour of pre-trained and in-domain embeddings used individually. The second one aims at studying the contribution of ensemble models.

Table 2 shows that, regardless of the task, the skipgram models (in-domain SkipGram, in-domain CharSG, out-of-domain Wikipedia Bow5W) outperform the other models. In addition, the two best models are in-domain and the two following are out-of-domain. The fourth position is hold by the Wikipedia/GigaWord Glove6B model. Among the worst models, we observe two CBOW models (in-domain Cbow out-of-domain Bow5C) as well as the in-domain Glove and the out-of-domain Glove42B models. Having said that, even if the differences between the extremities are notable, the coefficients of variability between two successive ranked scores are often very low. A closer look at the results shows that the out-of-domain and in-domain character skipgram models (CharSG) performed best for the paraphrase prediction task (MSRP). The entailment detection task (SICK) is the only one for which best models are largely out-of-domain. This can be explained by the very small size of the in-domain training data set. Surprisingly, the in-domain CBow which is globally one of the two worst models achieves the second best position for the next utterance ranking task (NUR). This can be explained by the large size of the in-domain Ubuntu data set while compared to other in-domain data sets.

Table 3 reports the results of MetaSentEmb approach for the four tasks using several pre-trained embedding combinations. Overall, we observe that pre-trained embedding combination is useful in the majority of tasks (except the SICK task where no significant improvements were observed). That said, not all the combinations are efficient. It depends on the tasks and on the nature of the training data sets. For instance, in the question-to-question similarity task (Semeval) the best meta-embedding models combination were Glove6B with Glove42B (76.2% using addition and 76.4% using concatenation on 2016 edition) and CharSG with Glove42B (76.5% using addition and 76.2% using concatenation on 2016 edition), while for 2017 edition the best models were Glove6B with word2vec (47.3% using concatenation) and Deps combined with Glove42B (47.4% using addition). It is to note that Deps concatenated to Bow5W obtained similar results with

Table 4: Meta-Embedding results using addition ($_A$) and concatenation ($_C$) along with in-domain embedding models. $SE16$ and $SE17$ stand respectively for SemEval16 and SemEval17.

47.1%.

For the paraphrasing task (MSPR), the best meta-embedding model was CharSG with Glove42B (72.6% using addition and 72.7% using concatenation). Other interesting combinations can be observed such as CharSG with Deps (71.5% using concatenation) and Deps with word2vec (71.5% using addition), etc. Concerning the NUR task, the best meta-embedding model is Glove6B combined with Glove42B (65.1% using addition and 65.6% using concatenation) closely followed by Glove6B combined with word2vec (65.0% using addition and 65.3% using concatenation) and CharSG (64.9% using addition and 65.1% using concatenation). Surprisingly, the majority of other models failed to improve the performance of SentEmb. One particular remark is that the best meta-embeddings always involve the Glove models. Finally, no significant improvements were observed for the entailment task (SICK). This may be due to the task itself which consists of recognizing not only the entailment relation but also the opposite and the neutral relations. In this study, no particular attention was given to opposite and neutral labels. If the combination of different embedding models is useful for 3 out of 4 tasks, the nature of the data sets also plays an important role. Embedding models trained on different data sets may provide complementary information. This can be observed for instance when combining Glove6B (trained on Wikipedia and Gigaword) and Glove42B (trained on Common Crawl). An important observation regarding Tables 2 and 3 is that best individual models are not necessary the most appropriate for combination. For instance,

Data	Tasks				
Models	SemEval16 Map (%)	SemEval17 Map (%)	MSRP Accuracy	SICK Accuracy	NUR 1 in 10 R@1
Best@1	**76.7** (1)	47.2 (3)	**80.4**	**84.6**	55.2
Best@2	76.0	46.9	77.4	83.6	48.8
Best@3	75.8	46.6	76.8	83.1	37.9
SentEmb	76.16	46.75	72.2	64.4	**68.5**
MetaSentEmbADD (In)	75.5	46.0	70.7	63.9	66.5
MetaSentEmbConcat (In)	74.1	44.0	69.4	63.1	66.7
MetaSentEmbADD (Out)	76.5 (2)	**47.4** (1)	72.6	64.8	65.1
MetaSentEmbConcat (Out)	76.4 (3)	47.3 (2)	72.7	64.3	65.6

Table 5: Results obtained by the 3 best state of the art models proposed during the official competitions of each task. Results obtained by the SentEmb baseline and with our proposed MetaSentEmb using addition and concatenation techniques over pre-trained and in-domain embeddings as well as their combinations.

Bow5W (rank 3 overall the four tasks) was less efficient while combined to other models, on the contrary, Glove42b which performed poorly individually (rank 10 overall the four tasks), turned out to be very efficient while combined to other models.

To study the impact of in-domain embeddings, we report in Table 4 the results of MetaSentEmb while using embeddings trained on the in-domain data set of each task. According to the results, we observe the same tendency as for pre-trained embeddings. However, the improvements seem to be task dependent. For instance, the best obtained results were 76.5% for pre-trained versus 75.5% (Semeval 2016) and 47.4% for pre-trained versus 46.0% (Semeval 2017) while for NUR task, the in-domain embedding obtained better results with 66.5% versus 65.6% for the pre-trained models. That said for the NUR results, the different is not significant. Generally speaking, the results of Tables 3 and 4 confirm the usefulness of using external data in addition to various embedding models and also put forward the possibility to combine embeddings trained on both in-domain and external data sets.

Table 5 reports the 3 best state of the art results obtained during the official competition of each task. Also, it contrasts the SentEmb baseline with our proposed MetaSentEmb using addition and concatenation techniques over pre-trained (Out) and in-domain (In) embeddings as well as their combinations. Below the header, the first horizontal frame reports the state of the art results. The second frame depicts results for similarity measures and the last frame contains results of classification-based approaches.

Globally, except for the NUR task, the meta-embedding configurations using pre-trained models are slightly better than the ones using in-domain models and enhance the performance of the SentEmb model. In particular, they outperform the SentEmb baseline and are ranked among the three best models for the SemEval tasks. Concerning the NUR task, the SentEmb baseline and all the meta-embedding models outperform the three best state of the art models. For this specific task, the combination of in-domain models give better results than out-of-domain models. Concerning the MSRP and the SICK tasks, while meta-embedding models build on out-of-domain corpora achieve better results than in-domain models, none of them succeeded in beating the state of the art models.

If additional efforts are certainly needed to understand the weak results on the entailment task and the different errors over all the evaluations, our observations through an error analysis showed different findings, depending on the task of course but also on the proposed method itself which is quite naive, especially for tasks like paraphrasing or entailment. First, MetaSentEmb performed well on the question-to-question similarity task and was competitive with regards to the best SemEval systems. This is certainly due to the adequacy of the task with our way of measuring sentence similarity. The questions in the Qatar Living corpus contain few ambiguities and the main errors were due to the specific forum vocabulary and mistakes that can be done by users. Also, one notable remark is the size of the original and related questions which is very important. Our way to deal with that was to filter stop-words and keep only nouns, verbs and adjectives to limit the impact of long sentences. Using POS-tagging also provided tagging errors that introduced some errors of our system. Second, MetaSentEmb did not compete with the three best systems on the paraphrasing task (MSPR), however, if we compare the results of MetaSentEmb with state of art sentence embedding representations such as FastSent (72.2%) and Skipthough (73.0%) (Hill et al., 2016), our approach obtained similar results (72.7%) with much simpler training. This finding is encouraging while no particular attention was given to the characteristics of paraphrase. Concerning textual entailment, MetaSentEmb failed to improve the performance of SentEmb. Here also the particularities of the small data set as well as the prediction of three classes including contradiction and neutral sentences may explain the low results. Finally, for the NUR task, our approach turned out to be very efficient. Utterance characteristics, at least for the Ubuntu corpus exhibit strong similarities which are certainly better captured by our meta-embedding approach.

6 Conclusion

In this paper we introduced the first bottom-up meta-embedding sentence representation for textual similarity. We have explored a variety of pre-trained and in-domain embedding models and there impact on question-to-question similarity, paraphrasing, textual entailment and next utterance ranking tasks. We have also proposed meta-embedding sentence representations based on vectors addition and concatenation and have shown under which conditions they can be jointly used for better performance. If further investigations are needed, the preliminary results lend support the idea that using meta-embeddings improve the performance of bottom-up sentence-based embedding approaches and offer an appropriate way to deal with textual similarity. One notable advantage of our approach is its simplicity, especially when using pre-trained embeddings since no computational cost is incurred.

Abstract

This paper describes a novel research approach to detect type and target of offensive posts in social media using a capsule network. The input to the network was character embeddings combined with emoji embeddings. The approach was evaluated on all the subtasks in SemEval-2019 Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media. The evaluation also showed that even though the capsule networks have not been used commonly in NLP tasks, they can outperform existing state of the art solutions for offensive language detection in social media.

1 Introduction

Social media has become a normal medium of communication for people these days as it provides the convenience of sending messages fast from a variety of devices. Unfortunately, social networks also provide the means for distributing abusive and aggressive content. Given the amount of information generated every day on social media, it is not possible for humans to identify and remove such messages manually, instead it is necessary to employ automatic methods. Recently, many shared tasks have been introduced to encourage the development of methods capable of classifying messages from social media as offensive. As an example, the First Workshop on Trolling, Aggression and Cyberbullying has organised the First Shared Task on Aggression Identification to classify messages from Facebook and Twitter into three categories Overtly Aggressive (OAG), Covertly Aggressive (CAG) and Non-aggressive (NAG) (Kumar et al., 2018). The task was organised for English and Hindi.

Recently, more complete dataset covering different aspects of offensive identification was released for the shared task in SemEval-2019 Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media. The task was not only to identify offensive messages in social media. The participants had to categorize the offensive language and also had to identify the targeted audience (Zampieri et al., 2019). We used this dataset to experiment our novel architecture since it covers more aspects in offensive language detection in social media. More details about the tasks and the dataset will be discussed in Section 2.

People from all over the world uses social media. Therefore, a random sample of social media messages can be written in several languages. As a result, systems that detect offensive posts without relying too much on language dependent features would be valuable in real life scenarios. In the offensive language identification shared tasks too, most researches have worked on systems that rely on word/character embeddings rather than linguistics features. As an example Galery and Charitos (2018) has taken an approach to feed fasttext (Mikolov et al., 2018) character embeddings to a Gated Recurrent Neural Network architecture (Chung et al., 2014). As the system doesn't rely on linguistic features, it is easily portable between Hindi and English. These type of architectures can be easily implemented for other languages once the data for training is available.

Most approaches in shared tasks are based on word/character embeddings feeding to a neural network (Kumar et al., 2018). Most of these architectures use max pooling or successive convolutional layers that reduce spacial size of the data flowing through the network and therefore increase the view of higher layers neurons, allowing them to detect higher order features in a larger region of the input embeddings. However recent introduction of capsule networks shows that while pooling works better in most of the scenarios, it nonetheless is losing valuable information (Hinton et al., 2018). The solution that has been brought forward is Capsule Networks. How it overcomes the weaknesses in max pooling layer will be discussed in Section 3.

Since the Capsule Networks are very new to the field, they have not been used much in NLP tasks. However, their good performance in image classification tasks motivated us to use them in offensive language detection tasks too. To the best of our knowledge, no prior work has been explored in offensive language identification with Capsule Networks. Also, it might be important to explore how the Capsule Networks performs in NLP domain. Additionally we analyzed that most of the social media posts contain not only text but emojis too, which can be a contributing factor for offense. Therefore we propose a method to incorporate emoji knowledge to the Capsule Network architecture. Generally, this paper proposes a Capsule Network architecture with emoji information to detect offensive posts in social media. The rest of the paper is organised as follow. Section 2 would briefly describe the tasks and the dataset. Section 3 would describe the capsule network architecture we used and how we integrated emoji information to the architecture. After that we evaluate the system comparing with the architectures provided in Zampieri et al. (2019). Finally, the conclusions are presented.

2 Dataset and Task Description

Dataset that we used was released for the Task 6 in SemEval-2019 : OffensEval: Identifying and Categorizing Offensive Language in Social Media. It has been collected from Twitter using its API and searching for keywords and constructions that are often included in offensive messages, such as she is, to:BreitBartNews, gun control etc (Zampieri et al., 2019).

There were three tasks associated with the shared task.

- *Subtask A: Offensive language Detection* : Goal of the task was to discriminate between the following types of tweets:
  - **Not Offensive (NOT)** : Posts that do not contain offense
  - **Offensive (OFF)**: Posts containing any form of non-acceptable language. These posts can include insults, threats swear words etc. (Zampieri et al., 2019)
- *Subtask B: Categorization of Offensive Language :* Task's goal was to categorize the type of offense.
  - **Targeted Insult (TIN)** : Posts that contain targeted insults and threats.
  - **Untargeted (UNT)** : Posts containing non targeted insults or threats.
- *Subtask C: Offensive Language Target Identification :* Goal of the task was to categorize the targets of insults/threats.
  - **Individual (IND)** : Insults that target individuals.
  - **Group (GRP)** : Insults that target a group of people.
  - **Other (OTH)** : The target does not belong to any category mentioned above.

Few examples from the training set is shown in Table 1.

As you can see, the nature of the three tasks are different and it would interesting to explore how one architecture can be used to capitalise all of the three tasks.

3 Research Approach

We first describe the existing approaches mentioned in Zampieri et al. (2019). Then we will describe the proposed capsule network architecture.

3.1 Existing Approaches

There are three approaches considered in Zampieri et al. (2019) which will be described in the following list. We describe them briefly in this sub section before introducing the capsule network architecture.

1. **SVM** - A linear SVM trained on word unigrams. SVMs have achieved state-of-the-art results for many text classification tasks (Zampieri et al., 2018).

2. **BiLSTM** - The model consists of (i) an input embedding layer,(ii) a bidirectional LSTM layer (Schuster and Paliwal, 1997), and (iii) an average pooling layer of input features. The concatenation of the LSTM layer and

id	tweet	a	b	c
44209	@USER @USER what a baby! URL	NOT	NULL	NULL
97670	@USER Liberals are all Kookoo !!!	OFF	TIN	OTH
74831	@USER Trump kicks dem butt - its so fun.	OFF	TIN	IND
17259	IM FREEEEE!!!! WORST EXPERIENCE OF MY FUCKING LIFE	OFF	UNT	NULL

Table 1: Example rows from the dataset

the average pooling layer is further passed through a dense layer, whose output is ultimately passed through a softmax to produce the final prediction. The model is adapted from a pre-existing model for sentiment analysis (Rasooli et al., 2017).

3. **CNN** - A convolutional neural network based on the model proposed in Kim (2014). It consists of an (i) an input embedding layer, (ii) a convolutional layer (Collobert et al., 2011) and (iii) a max pooling layer (Collobert et al., 2011) of input features. The output of the max pooling layer is further passed through a dropout (Srivastava et al., 2014) and softmax output.

Both BiLSTM and CNN architectures above have pooling layers which is a very primitive type of routing mechanism. The most active features in a local pool is routed to the higher layer and the higher-level detectors don't have an impact in the routing. However in the Capsule Network, only those features that agree with high-level detectors are routed. It has a superior dynamic routing mechanism. With this advantage we propose a novel capsule network architecture for aggression detection which will be described in the next section.

3.2 Proposed Architecture

The proposed architecture is depicted in Figure 1. The architecture consists of four layers.

1. *Embedding Layer* - We represent every text x_i , as a sequence of one-hot encoding of its words, $x_i = (w_1, w_2, ...w_n)$ of length n, which is the maximum length of the all of the texts in the training set, with zero padding. Such a sequence becomes the input to the embedding layer. Most of the words exist in social media texts are not proper words. If we used word embeddings to initialize the embedding matrix in the embedding layer, most of the words that are fed will be out-of-vocabulary words. Therefore we used character embeddings (Mikolov et al., 2018) as it provides embeddings for misspelling words and new words. Also character embeddings handle infrequent words better than word2vec embedding as later one suffers from lack of enough training opportunity for those rare words. We used fasttext embeddings pre trained on Common Crawl (Mikolov et al., 2018). Using the model we represented each word as a vector with a size of 300 values. The embedding layer is improved more with emoji information, which will be described in Section 3.3.

2. *Feature Extraction Layer* - We used this layer to extract long term temporal dependencies within the text. We experimented both LSTMs (Hochreiter and Schmidhuber, 1997) and GRUs (Chung et al., 2014) for this layer. Due to the fact that we had a small number of training examples, GRUs performed better than LSTMs, capitalising on GRU's ability to exhibit better performance on smaller datasets. For the final architecture we used a bi directional GRU layer with 50 time steps, each getting initialised with glorot normal initialiser.

3. *Capsule Layer* - The Capsule layer we used is primarily composed of two sub-layers *Primary Capsule Layer* and *Convolutional Capsule Layer*.

   (a) *Primary Capsule Layer* - The primary capsule layer is supposed to capture the instantiated parameters of the inputs, for example, in case of texts, local order of words and their semantic representation is captured with the primary capsule layer.

   (b) *Convolutional Capsule Layer* - The convolutional capsule layer outputs a lo-

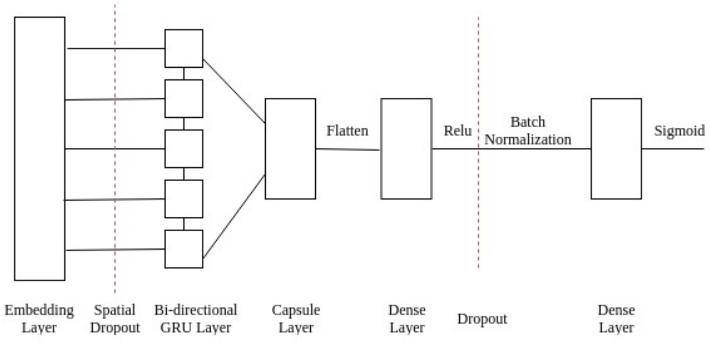

Figure 1: Capsule Network

cal grid of vectors to capsules in earlier layers using different transformation matrices for each capsule. This is trained using dynamic routing algorithm described in Sabour et al. (2017) that overlooks words that are not important or unrelated in the text, like stopwords and name mentions which are common in social media texts.

4. *Dense Layers* - Output of the Capsule layer is flattened and then fed in to two dense layers. First dense layer had 100 units and was activated with relu function. After applying batch normalization to the output of first dense layer, it was fed in to the second dense layer with 1 unit and and sigmoid activation.

Apart from the major sections in the architecture described above, we used a spatial dropout (Tompson et al., 2015) between the embedding layer and the feature extraction layer and a dropout (Srivastava et al., 2014) between the two dense layers to minimize over fitting of the network. The implementation was done using Keras (Chollet et al., 2015) and Python[1].

The next section would describe how we integrated emoji knowledge to this architecture.

3.3 Integrating Emojis

Emojis are ideograms which are used with text to visually complement its meaning. In present, emojis are widely used by social media. A global analysis done on Twitter has been found that 19.6% of tweets contain emojis. Further it stated, emojis are used by 37.6% of users (Ljubesic and Fiser, 2016). A research conducted by (Barbieri et al., 2017) has been showed that there is an unique and important relation between sequences of words and emojis. When analyze the top 10 emojis belong to both categories; Offensive and Not Offensive, in the selected dataset, it also shows a clear distinction of emojis corresponding to its category as shown in Figure 2. Due to the extensive usage of emojis in social media and the relationship lie between emojis and text, integration of emojis can be used to improve the social media offensive language detection.

Since the proposed architecture is based on embeddings, we decided to integrate emojis also using the embeddings. But most of the available pre-trained word embedding sets include few or no emoji representations. Therefore in addition to the character embeddings, separate embedding set; emoji2vec (Eisner et al., 2016) was chosen for emojis. Emoji2vec consists of pre-trained embeddings for all Unicode emojis using their descriptions in the Unicode emoji standard. This maps emojis into 300-dimensional space similar to other available word embeddings; word2vec, glove, etc. to make the integration easy with word vectors. Emoji2vec embeddings were evaluated based on sentiment analysis on tweets and it showed word2vec with emoji embeddings advances the classification accuracy while proving that the emoji2vec embeddings are useful in social natural language processing tasks.

Following (Eisner et al., 2016), there were two pre-trained emoji2vec models[2]. One model is based on the sum of vectors corresponds to the words found in phrases which describe the emojis. As an extended version of it, other model feeds the actual word embeddings to an LSTM layer. We

used 300 dimensional embedding spaces generated by both models; sum based and LSTM based for this experiment.

Two approaches were used to integrate emoji embeddings with the above mentioned architecture as follows:

1. *300 dimensional embedding layer* - Shared same 300 dimensional vector space for both word and emoji embeddings.

2. *600 dimensional embedding layer* - Used concatenation layer and resulted 600 dimensional vector space by both word and emoji embeddings.

Among the experiments we conducted using both emoji2vec models and integration approaches, combination of sum based emoji embeddings with 600 dimensional embedding layer and LSTM based emoji embeddings with 300 dimensional embedding layer resulted improvements compared to word embeddings only approaches. More details on experiment results are mentioned in Section 4.

3.4 Training

The network was trained on the training dataset provided for SemEval-2019 Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media. It was trained using adam optimiser (Kingma and Ba, 2015), with a reduced learning rate once learning stagnates. Also the parameters of the network was optimized using five fold cross validation.

4 Evaluation

The capsule network architecture we proposed above was evaluated using the testing set provided for each of the subtask in SemEval-2019 Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media.

4.1 Offensive Language Detection

The performance on identifying offensive (OFF) and non-offensive (NOT) posts is reported in Table 2. The Capsule Network we proposed outperforms the RNN model, achieving a macro-F1 score of 0.81.

4.2 Categorization of Offensive Language

The results for the offensive language categorization is shown in Table 3. In this subtask too Capsule Network architecture outperforms all the other models having a macro F1 score of 0.71.

4.3 Offensive Language Target Identification

The results for the offensive language target identification is shown in Table 4. Capsule Network architecture outperforms all the other models having a macro F1 score of 0.49.

Table 4: Results for offense target identification. We report Precision (P), Recall (R), and F1 for each model/baseline on all classes (GRP, IND, OTH), and weighted averages. Macro-F1 is also listed (best in bold). † denotes the capsule net architecture integrated with emoji embeddings.

As shown in Table 2, 3 and 4 capsule network architecture outperformed all the other models in all sub tasks. It is worth noticing that the unbalanced nature of the dataset did not affect the performance of the capsule network architecture. Also eventhough the capsule layer is seemingly complex, results show that it does not need a large training set to optimize its parameters.

We did not fine tune the model analyzing data in this dataset since we wanted a general model capable of identifying offense. Hence, we did not compare our results with the final results of the shared task.

5 Conclusion

We have presented a novel capsule network architecture to detect type and target of offensive posts in social media. Also we propose a method to incorporate emoji knowledge to the architecture. Our approach was able to improve on the baseline system presented at SemEval-2019 Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media. Importantly our system does not rely on language dependent features so that it is portable for any other language too.

The main conclusion of the paper is that even though the capsule networks are not widely used in NLP domain, they can achieve state of the art results. Also with the shown way of integrating emoji information to the network, results can improve.

In the future we hope to implement a multi purpose capsule network architecture for several tasks in NLP domain such as spam detection, gender identification etc. We hope to further explore capsule network architectures in various NLP tasks.

Abstract

Researchers use wordnets as a knowledge base in many natural language processing tasks and applications, such as question answering, textual entailment, discourse classification, and so forth. Lexical semantic relations among words or concepts are important parts of knowledge encoded in wordnets. As the use of wordnets becomes extensively widespread, extending the existing ones gets more attention. Manual construction and extension of lexical semantic relations for WordNets or knowledge graphs are very time consuming. Using automatic relation extraction methods can speedup this process.

In this study, we exploit an ensemble of LSTM and convolutional neural networks in a supervised manner to capture lexical semantic relations which can either be used directly in NLP applications or compose the edges of wordnets. The whole procedure of learning vector space representation of relations is language independent. We used Princeton WordNet 3.1, and FarsNet 3.0 (the Persian wordnet), as gold standards to evaluate the predictive performance of our model and the results are comparable on the two languages. Empirical results demonstrate that our model outperforms the state-of-the-art models.

1 Introduction

Lexical semantic relation classification is the task of identifying s semantic relation**(s)** which holds between word pairs among a set of predefined relation types. Relation classification can be done in a supervised manner, using a dataset, labeled with a certain number of relation classes. In addition to classification with known relations, there are some methods which go even further and learn new semantic relations and suggest new relation categories (Shamsfard and Barforoosh, 2003).

Relation identification plays an essential role in many natural language processing application such as question answering, recognizing textual entailment and discourse understanding.

There are two main approaches for classification of lexical semantic relations; distributional and path-based (Wang et al., 2017).

Path-based approaches try to recognize the type of semantic relation between word pairs according to their co-occurrence information in the corpus. These methods mainly use the dependency path between word pairs as their input feature (Snow et al., 2004; Riedel et al., 2013). As Ziph's law states that most of the words in vocabulary rarely occur in the corpus (Powers, 1998) these methods have some limitation for word pairs who do not co-occur in a context.

On the other hand according to the distributional hypothesis which states "words that occur in similar contexts tend to have similar meanings" (Harris, 1954), distributional approaches try to recognize the relation between words based on their separate occurrence in the corpus which can

Proceedings of Recent Advances in Natural Language Processing, pages 481–486,
Varna, Bulgaria, Sep 2–4 2019.

be represented for example by their word embedding vectors (Mikolov et al.,2013) and these methods have shown great performance (Baroni et al., 2012; Turney and Pantel, 2010; Roller et al., 2014).

In the last decades, several researches have been conducted on discovering hypernymy as an example of lexical semantic relations, and a key part of taxonomies and state-of-the-art models show significant results (Shwarts et al., 2016; Roller et al., 2016).

However, other types of relations have been less investigated.

Several types of models have been used for the task of semantic relation classification, but the results are not sufficiently admissible (Vu and Shwarts, 2018).

In this paper, we use an ensemble of models to improve prediction performance of relation classification. The idea of ensemble methodology is to combine some weighted classifiers in order to obtain a more accurate one (Rokach et al. 2009).

Main building blocks of this combinational model are some inducers named weak learner which perform slightly better than random. According to Condorcet Jury theorem which states " the ensemble of independent voters each of which performs better than random (p>0.5) has a probability of L>p to make the right decision." we used different structured neural networks as the model's weak learners.

The input of our model is a concatenation of word embedding vectors corresponding to target word pairs, and the output is a class label predicted based on learned vector space distributional representation of the semantic relation which holds between them.

Our final model has the best validation F1 score of 0.894 in predicting the relation between FarsNet (Shamsfard, et al., 2010) word pairs and 0.768 to predict Princeton Wordnet (Miller, 1995; Felbaum 1998) relation classes.

We summarize the contribution of this paper as follow:

- We propose EoANN, an ensemble of artificial neural networks for classifying all types of lexical semantic relations in target datasets, without any hand-crafted features.

- Our model addresses the sparseness issue and can classify word pairs which do not necessarily co-occur in the corpus.

- According to human expert reviews, our model goes beyond relation discovery and can be employed to correct the potential error in wordnet edges and suggest new missed relation instances.

The rest of this paper is structured in 6 sections:
Section 2 presents the existing approaches for the classification of lexical semantic relations; the next one presents our model in detail, section 4 describes the data set we used for evaluating our model, section 5 reports experimental results and finally section 6 dedicated to the conclusion and future works.

2 Related Work

There are two main lexical semantic relation extraction models, distributional and path-based (pattern-based) (Wang et al., 2017) and also there are methods that use an integration of these two approaches (Shwartz et al., 2016).

Distributional methods learn the relation between word pairs based on the disjoint occurrence of them. These methods usually use a combination of word embedding vectors (Mikolov et al., 2016) as their input features. Considering v1 and v2 being word embedding vector corresponding to w1 and w2, most common combinations are:

- concatenation of v1 and v2 (**Concat**)

- the offset of v1 and v2 (**Offset**)

- point-wise multiplication of v1 and v2 (**Mult**)

- squared difference between v1 and v2 (**Sqdiff**)

Offset (Roller et al., 2014; Weeds et al., 2014; Fu et al., 2014), **Concat** (Baroni et al., 2012) and **Concat**+**Offset** (Washio and Kato, 2018) is the most common type of feature vector combination which is used in this task. To capture the different notion of interaction information about relation Vu and Shwartz (2018) add **Mult**, studied by Weeds et al. (2014) and **Sqdiff** introduced by themselves as input feature and report **Mult**+**Concat** performs better than other combination.

These methods mostly focus on lexical entailment and relation classes such as hypernym, causality and other instances of relation which exemplified inference and have a state-of-the-art F1 score of 0.91.

Path-based or pattern-based methods utilize features derived from the context in which word pairs co-occur. For example, the dependency path between a word pair and observed predefined patterns are used as an informative feature to classify the relation. The methods of this category are limited to use only the word pairs that co-occur in corpus (Hearst et al., 1992; Snow et al., 2004; Navigli and Velardi 2010; Shamsfard et al,. 2010; Boella and Di Caro, 2013; Pavlick and Pasca, 2017)

Recently some approaches use an integration of these two methods and combine both distributional and dependency path information to obtain better results. HypNet (shwarts et al., 2016) is an examples of these approaches.

3 Our Model

In this paper, we propose a model to classify lexical semantic relations between a word pair using their word embedding vectors.

The rarity of co-occurring every candidate word pair which possibly involves in a semantic relation leads us to exploit a method which does not necessarily need to see the word pair in a context together.

The output of our model is a class label prediction based on learned vector space distributional representation of the semantic relation which holds between target word pairs.

Although using a single deep neural network (as a distributional method) showed some improvement in capturing semantic relations, in order to get the advantage of the diversity among predictions of separately trained models, we use an ensemble of two artificial neural networks.

The ensemble is a general statistical enhancing technique to improve the representational capacity of the model. This enhancement helps to find a hypothesis which is independent of the space of the model from which it starts to learn.

First, we train two neural networks separately on data our labeled data and evaluate their test results, then put these two models in an ensemble and re-evaluate the result. Comparing two result sets shows 0.1 improvement in F1 score of learned hypothesis.

Models can be assembled in many different ways like boosting, bagging and stacking. We use stacking which involves training a learning algorithm to combine the predictions of several learning algorithms.

The advantage of stacking is to increase the prediction power of the classifier. As the using of another neural network above the weak learners in order to learn the final prediction imposes excess overhead, we use the simplest stacking method which is averaging. Averaging has no parameter, so no training is needed.

We transfer the input embedding vector of word pairs to dense-valued feature vectors, next feed these vectors to both ANN to compose their own distributional representation of them. At the final layer of each, a softmax classifier predicts the label of input sample.

Finally, a weighted averaging mechanism is used to decide the relation class in which input words participate.

3.1 Input of EoANN

Our inputs are raw lexical entries (multi word expressions are excluded) of Wordnets. We first transform every single word to its embedding vectors using word embedding.

Word embedding is a method to map words and phrases from space with one dimension per word, to a continuous low dimensional vector space. There are many word embedding frameworks. We use Fasttext (Piotr et al., 2017) which represents words as the sum of the n-gram vectors. This method is actually an extension of the continuous skip-gram model (Mikolov et al., 2013), which considers sub-word information as well. We denote the word embedding vector of word w by vw ∈ ℝ

Given *R (a, b)* as a sample of semantic relation triple in target Wordnet, R is the class of relation which connects a to b and v_a and v_b are the embedding vectors corresponding to them. The input vector and labels of our classifiers is the concatenation of word vectors:

$$h1(a,b) = [va{:}\,vb]$$
$$out(a,b) \; = \; R$$

3.2 Weak Learners Structure

We use both convolutional neural network and LSTM network in the simplest structure as our model base inducers. These two learners are chosen because of their power in capturing of hierarchical patterns and the extraction of the temporal behavior.

The simple CNN inducer is composed of 3 main layers, a convolutional layer with 20 filters of size (1, 2), a pooling layer which is used to reduce the dimensions of feature map and finally a fully connected layer that flattens the results and passes it to a softmax classifier to decide which relation class the input belongs to.

LSTM neural network which we use as another weak learner is composed of a fully connected layer to encode 2-dimentional input feature vector to a dense flat vector, then passes its output to a LSTM layer with 200 memory units and a softmax classifier finally decides about data class label.

Combiner is responsible for getting the final decision by combining individual classifiers predictions. This component holds a majority voting among classifiers and declares the ultimate predicted label.

4 Datasets

In this study, we use four common data set to evaluate the performance of our model, FarsNet (Shamsfard, 2008), Princeton Wordnet (Miller, 1996), Root09 (Santus et al., 2015) and EVALution (Santus et al., 2016) as common semantic relation resources in Persian and English.

Table 1 shows the details about datasets, their relation class and number of instances used for train and test (90% for train and validation and 10% for test).

For embedding model, we used the Wikipedia dump in both English and Persian Languages. Our English word embedding model vocabulary contains 999,994 words and our Persian model has 347,636 words.

Fasttext embedding models had the following parameter set for training:

- Vector dimention:300
- Learning rate:0.04
- Min and max length of char n-gram:[3,6]
- Number of epochs:10

The rest of the parameters are as Fasttext default configuration.

data set	relation classes	# of instances
WordNet	Hypernym, Hyponym, Entailment, Cause, Instance-Hypernym, Instance-Hyponymy, Member, Holonym, Attribute	634,330
Farsnet	Hypernym, Hyponym, Antonym, Instrument, Domain, Instance-Hypernym, Instance-Hyponym Location, Patient	322,554
ROOT09	**Hypernym, co-Hyponym, Random**	**12,762**
EVALution	Hypernym, Antonym, meronym, possession, Attribute, Part Of	7,378

Table 1: data sets we use for evaluating our model, their main relation categories and the number of relation instances of each

5 Experimental Results

We use four wordnet-like data sets as our benchmark to evaluate the performance of our model:

We compared the results on root09 and EVALution with two most recent work, LexNet proposed by Vu and Schwartz (2018) and KSIM previously used and reported to be successful by Levy et al. (2015). We also compared our model performance with the previous effort result in extracting FarsNet relation in Persian which is a semi-automated pattern-based approach (Shamsfard et al., 2010).

Our experimental results which are summarized in table 2, show that our model can classify FarsNet word pairs relations with F1 score of 0.894 which is significant and it has an average F1 of 0.768 for WordNet relation classification.

As shown in table 2 the state-of-the-art models in the best case, has the F1 score of 0.606 on detecting relations in EVALution and 0.81 in ROOT09 and our model with F1 score of 0.655 for first and F1 score of 0.868 for last outperforms these methods.

Model	Data Set	Classifier feature composition	**F1**
EoANN	Root09	LSTM+**CNN Concat**	**0.868**

	EVALution	LSTM+**CNN Concat**	**0.655**
LexNet	Root09	RBF **Sum**+**SqDiff**	0.814
	EVALution	RBF **Concat**+**Mult**	0.6
KSIM	Root09	RBF **Sum**+**SqDiff**	0.723
	EVALution	RBF Concat+Mult	0.505

Table 2: best precision recall and F1 score for root09 and EVALution in 4 compared models

model	dataset	Model and Features	F1 score
EoANN	farsnet	LSTM+CNN **Concat**	**0.894**
Semi-auto	farsnet	Pattern-based +structured_based+ statistical	0.605

Table 3: best F1 score on farsnet

6 Conclusion and Future Works

Our objective in this research was to automatically classify lexical semantic relation employing the power of the simple but effective structured neural networks, which have shown their proficiency in many tasks of natural language processing (Collobert et al., 2011; Yao et al., 2013).

We used both LSTM and convolutional network to benefit the exhibition of temporal behavior by first and the extraction of the hierarchical pattern by last.

We also used the simplest distributional feature as input and entrusted the extraction of the most proper composition of features to the model.

In case of ROOT09 and EVALution our model has an improvement of 0.05 in F1 score from state of the art (LexNet). And for FarsNet dataset we have 0.11 improvement in F1 score.

The next step in extending lexical ontologies is to complete missed relation edges, then to learn new relation classes, which can be added to the target wordnet.

Opinions Summarization: Aspect Similarity Recognition Relaxes the Constraint of Predefined Aspects

Abstract

Recently research in opinions summarization focuses on rating expressions by aspects and/or sentiments they carry. To extract aspects of an expression, most studies require a predefined list of aspects or at least the number of aspects. Instead of extracting aspects, we rate expressions by aspect similarity recognition (ASR), which evaluates whether two expressions share at least one aspect. This subtask relaxes the limitation of predefining aspects and makes our opinions summarization applicable in domain adaptation. For the ASR subtask, we propose an attention-cell LSTM model, which integrates attention signals into the LSTM gates. According to the experimental results, the attention-cell LSTM works efficiently for learning latent aspects between two sentences in both settings of in-domain and cross-domain. In addition, the proposed extractive summarization method using ASR shows significant improvements over baselines on the Opinosis corpus.

1 Introduction

Opinions Summarization is the collection of typical opinions mentioned in social media, blogs or forums on the web. This task helps customers to absorb better a large number of comments and reviews before making decisions as well as producers to keep track of what customers think about their products (Liu, 2012).

Due to the fast growth of data over the Internet, automatically opinions summarization has received a lot of attention in recent years. Most research focus on extractive summarization, where the most salient text units are identified and construct a summary. Ranking candidates for generic summarization usually bases on various handcrafted features such as sentence position and length (Radev et al., 2004), word frequency (Nenkova et al., 2006) or using neural networks for learning salient scores (Zhou et al., 2018).

In opinions summarization, however, this task is required to consider aspects and/or sentiments of text candidates for generating a concise and informative summary (Hu and Liu, 2006). The popular framework of this problem involves three subtasks (Hu and Liu, 2004): i) aspect discovery which extracts the properties of interested entities (e.g., battery life, design, customer service); ii) sentiment analysis which assigns sentiment polarity (positive and negative) towards the aspects extracted in the first step; and iii) summary generation which selects the most salient opinions to build a summary.

For the aspect discovery task, there are two main techniques: supervised and unsupervised learning. The former models the aspect extraction as a sequence labeling task. Due to predefining a list of aspect and heavily relying on annotated data, this approach suffers from domain adaptation problems. The latter uses a large amount of unlabeled data for abstracting aspects via the statistical topic modeling LDA (Blei et al., 2003) or the aspect-based autoencoder model (He et al., 2017a). However, these unsupervised techniques have limitations. First, we have to decide on a suitable number of aspects for each domain. Second, the existing methods require a sufficient amount of data while some domains may not have enough reviews, known as the cold-start problem (Moghaddam and Ester, 2013).

In extractive opinions summarization, most existing approaches use the aspects information for discarding potentially redundant units. For minimizing repeated information on the same aspect, we only need to identify whether two text

No.	Sentence	Aspect Similarity
1	The pc runs so fast. I like its performance and price.	Yes
2	The food is cheap. The shop's location is good.	No
3	I love its pizza. I bought food from the restaurant.	Yes

Table 1: Some samples of Aspect Similarity Recognition

units have at least one aspect in common, which is called Aspect Similarity Recognition - ASR (Nguyen et al., 2018), rather than explicitly extracting aspects of each text unit. Table 1 shows some samples of the ASR task. Follow this observation, we propose an aspect-based summarization using ASR instead of aspect discovery. The advantage of ASR is to learn patterns and relations between two text units and not need to identify the aspects of each unit, therefore it is potential to cross-domain application. Our contributions in this work are as follows:

- We propose an attention-cell LSTM model (ACLSTM) for ASR which enhances the LSTM model via employing attention signals into the input gate and the memory cell. ACLSTM shows improvements compared to the conventional attention models for both settings of in-domain and cross-domain.

- We introduce a novel aspect-based summarization using Aspect Similarity Recognition. According to the experiments, our method outperforms strong baselines on Opinosis corpus. We also evaluate our method in regard to domain adaptation.

The remainder of this paper is organized as follows: Section 2 reviews the related research, Section 3 describes the problem formulation, Section 4 and 5 respectively introduce the attention-cell LSTM for ASR and the proposed summarization using ASR, Section 6 discusses the experiments for ASR and summarization, and Section 7 concludes our work and future work.

2 Related Work

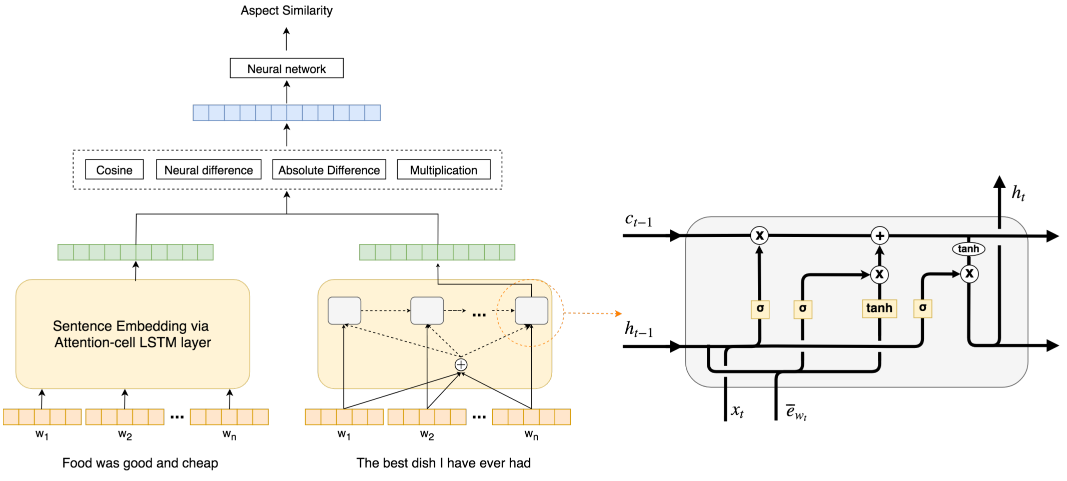
In the scope of this paper, we focus on discussing neural-based systems for generic and opinions summarization. For a comprehensive literature of non-neural techniques, we refer the reader to Liu and Zhang (2012).

For extractive generic summarization, Cao et al. (2015) rank sentences in a parsing tree via a recursive neural network. However, the model requires handcrafted features as input. Cheng and Lapata (2016) propose an end-to-end model for extracting words and sentences. In this system, a document is encoded via convolutional and recurrent layers, then an attention architecture is employed to extract sentences and words. Follow this work, Zhou et al. (2018) enhance the previous system by jointly learning to score and select sentences. By integrating sentence scoring and selecting into one phase, as the model selects a sentence, the sentence is scored according to the partial output summary and current extraction state.

To our knowledge, the first neural-based model of extractive opinions summarization is proposed by Kågebäck et al. (2014), which uses an unfolding recursive auto-encoder to learn phrase embeddings and measures similarity by Cosine and Euclidean distance. The limitation of this system is to purely rely on semantic similarity without taking into account the aspect information. Yang et al. (2017) use the unsupervised neural attention-based aspect autoencoder (ABAE) (He et al., 2017b) for presenting each aspect in an aspect embedding space. Then, the representative sentence for each aspect is selected via its distance with the centroid of that aspect. For summarization, however, ABAE is not efficient compared to K-mean in the aspects which occur more frequently in the dataset. Angelidis and Lapata (2018) introduce seed words of each domain to the autoencoder ABAE. This weakly-supervised model which is trained under multi-task objective outperforms the unsupervised model for aspect extraction. Different from the previous work in aspect-based opinions summarization, we apply aspect similarity recognition (ASR) instead of aspect extraction. ASR facilitates the problem of domain adaptation in summarization.

3 Problem Formulation

Every product e contains a set of reviews $R_e = \{r_i^e, ..., r_n^e\}$ expressing users' opinions on that product. A review r_i^e is viewed as a sequence of sentences $(s_1, ..., s_m)$. For each product e, our goal is to select the most salient sentences in reviews R_e for producing a summary. The proposed



The framework of Aspect Similarity Recognition

An attention cell of LSTM

Figure 1: The proposed framework for the aspect similarity task

approach is divided into subtasks as follows:

1. **Sentiment prediction** determines the overall polarity $p_s \in [-1, +1]$ a sentence carries, where $-1, +1$ respectively indicate maximally negative and positive. According to Angelidis and Lapata (2018), highly positive or negative opinions are more likely to contain informative text than neutral ones. In our system, we use the ensemble sentiment classifier proposed by Huy Tien and Minh Le (2017), which achieves strong performances at sentence level.

2. **Semantic textual similarity** measures the semantic similarity q_{ij} of two sentences i and j, which plays an important role in identifying the most informative sentences as well as redundant ones. We use the state-of-the-art multi-level comparison model (Tien et al., 2018) for this task.

3. **Aspect similarity Recognition (ASR)** predicts a probability r_{ij} that two sentences i and j shares at least one aspect. This subtask facilitates the elimination of redundant text in summarization, especially for domain adaptation.

4. **Summarization Generation** employs the three signals above for ranking sentences. A concise and informative summary of a product e is generated by selecting the most salient sentences from reviews R_e.

Section 4 describes in details the attention-cell LSTM for the ASR task and Section 5 explains how to combine the polarity, semantic and aspect similarity to produce a summary.

4 Attention Cell LSTM

According to Nguyen et al. (2018), recurrent neural networks efficiently capture aspect relationships. For dealing with the remaining difficulties of this task, the authors analyze the necessary of an attention mechanism. For that reason, we aim to emphasize salient words as encoding sentences over LSTM. A straightforward approach is to learn attention signals by self-attention and then apply these signals into inputs before feeding them into LSTM. In other words, these attention signals are applied to all gates of a LSTM cell. However, we assume emphasized input makes the cell forget more information on the previous state (the forget gate's function) while this state stores the most salient information by the support of attention signals. This conflict causes the inefficiency of integrating attention signals with LSTM. Therefore, we propose a novel LSTM cell which prevents the state from forgetting too much salient information as employing attention signals for encoding sentences. For the ASR task, the proposed attention-cell LSTM outperforms the conventional LSTM with/out using attention in both of settings: in-domain and cross-domain.

By representing a word w_i by a pre-trained word embedding e_{w_i}, we construct a sentence S of n words as a sequence of n word embeddings $S = [e_{w_1}, e_{w_2}, ..., e_{w_n}]$. Contextual information is incorporated in the word embeddings over the bidirectional GRU (Bahdanau et al., 2014) and then the self-attention signal a_i of w_i is learned as follows (from Yang et al. (2016)):

$$\overleftarrow{h_i} = \overleftarrow{GRU}(e_{w_i}) \tag{1}$$

$$\overrightarrow{h_i} = \overrightarrow{GRU}(e_{w_i}) \tag{2}$$

$$h_i = \overleftarrow{h_i} \oplus \overrightarrow{h_i} \tag{3}$$

$$u_i = tanh(W_a h_i + b_a) \tag{4}$$

$$a_i = \frac{exp(u_i^T u_a)}{\sum_i exp(u_i^T u_a)} \tag{5}$$

$$\bar{e}_{w_i} = e_{w_1} a_i \tag{6}$$

where $\oplus$ is concatenation operator, w_a, b_a, u_a are respectively a weight matrix, a bias, and a context vector. These parameters are randomly initialized and optimized during training.

A sentence s is transformed to a fix-length vector e_s by recursively applying a LSTM cell to each word embedding e_{w_t} and the previous step h_{t-1}. At each time step t, the LSTM unit with l-memory dimension defines six vectors in $\mathbb{R}^l$: input gate i_t, forget gate f_t, output gate o_t, tanh layer u_t, memory cell c_t and hidden state h_t (Tai et al., 2015). We modify the conventional LSTM cell to employ attention signals without the conflict of remembering and forgetting as follows:

$$i_t = \sigma(W_i \bar{e}_{w_t} + U_i h_{t-1} + b_i) \tag{7}$$

$$f_t = \sigma(W_f e_{w_t} + U_f h_{t-1} + b_f) \tag{8}$$

$$o_t = \sigma(W_o e_{w_t} + U_o h_{t-1} + b_o) \tag{9}$$

$$u_t = \tanh(W_u \bar{e}_{w_t} + U_u h_{t-1} + b_u) \tag{10}$$

$$c_t = f_t \odot c_{t-1} + i_t \odot u_t \tag{11}$$

$$h_t = o_t \odot \tanh(c_t) \tag{12}$$

$$e_s = h_n \tag{13}$$

where $\sigma, \odot$ respectively denote a logistic sigmoid function and element-wise multiplication; W_i, U_i, b_i are respectively two weights matrices and a bias vector for input gate i. The denotation is similar to forget gate f, output gate o, tanh layer u, memory cell c and hidden state h. In the attention-cell LSTM, we introduce the attention signal a_t to only the input gate i_t and the tanh layer u_t, which are in charge of deciding what new information is going to be stored in the cell state. This approach allows the LSTM cell to employ attention for remembering salient information and avoid the unexpected effect of attention on the forget gate.

We visualize how the attention-cell LSTM manipulates attention signals in Figure 1. The four metrics are used to evaluate the relationship between two sentences e_{s_1} and e_{s_2} as follows (from Nguyen et al. (2018)):

Cosine similarity:

$$d_{cosine} = \frac{e_{s_1} \cdot e_{s_1}}{\|e_{s_1}\| \, \|e_{s_2}\|} \tag{14}$$

Multiplication vector & Absolute difference:

$$d_{mul} = e_{s_1} \odot e_{s_2} \tag{15}$$

$$d_{abs} = |e_{s_1} - e_{s_2}| \tag{16}$$

where $\odot$ is element-wise multiplication.

Neural difference:

$$x = e_{s_1} \oplus e_{s_2} \tag{17}$$

$$d_{neu} = W^{neu} x + b^{neu} \tag{18}$$

where W^{neu} and b^{neu} are respectively a weight matrix and a bias parameter.

As a result, we have a sentence-sentence similarity vector d^{sent} as follows:

$$d^{sent} = d_{cosine} \oplus d_{mul} \oplus d_{abs} \oplus d_{neu} \tag{19}$$

The sentence-sentence similarity vector is transferred into an aspect similarity label $\hat{y}$ through a two layers neural network as follows:

$$sim^{sent} = \sigma(W^{sent} d^{sent} + b^{sent}) \tag{20}$$

$$s\bar{i}m^{sent} = dropout(sim^{sent}) \tag{21}$$

$$\hat{y} = \sigma(W^y s\bar{i}m^{sent} + b^y) \tag{22}$$

where W^{sent}, W^y, b^{sent}, and b^y are weight matrices and bias parameters, respectively.

Dropout layer (Srivastava et al., 2014) is applied to our model. Dropout prevents networks from overfitting via randomly dropping out each hidden unit with a probability p on each presentation of each training case. We train this model under the cross entropy loss function and AdaDelta as the stochastic gradient descent (SGD) update rule. Details of Adadelta method can be found in Zeiler (2012).

5 Opinion Summarization

Given a product e, we aim to rank a set of sentences $D = \{s_i\}$ from the reviews talking about the product e. The procedure of scoring and selecting sentences for constructing an opinion summary K of the product e is as follows:

1. In the first step $t = 0$, we score each sentence $s_i \in D$ and select the most salient sentence $\hat{s}^0$ for the summary K:

$$asp_{s_i}^{t=0} = \frac{1}{|D|} \sum_{j \in D} r_{ij} \tag{23}$$

$$sim_{s_i}^{t=0} = \frac{1}{|D|} \sum_{j \in D} q_{ij} \tag{24}$$

$$sal_{s_i}^{t=0} = (1 + \alpha |p_{s_i}|) * asp_{s_i}^{t=0} * sim_{s_i}^{t=0} \tag{25}$$

$$\hat{s}^0 = \arg\max_{s_i \in D} \{sal_{s_i}^{t=0}\} \tag{26}$$

$$K^{t=1} = K \cup \{\hat{s}^0\} \tag{27}$$

$$D^{t=1} = D \setminus \{\hat{s}^0\} \tag{28}$$

At the step $t = 0$, the salient sal_{s_i} is computed by the semantic similarity sim_{s_i}, the aspect coverage sim_{s_i} and the polarity p_{s_i}. Different from the previous works, we also take into account the aspect coverage in which a sentence carrying more aspects has a higher salient score. In addition, the polarity of a sentence contributes to its ranking by a coefficient $\alpha \in [0, 1]$.

2. In the next step t, the salient sentence $\hat{s}^t$ is selected as follows:

$$asp_{s_i}^{t} = \frac{1}{|D^t|} \sum_{j \in D^t} r_{ij} \tag{29}$$

$$sim_{s_i}^{t} = \frac{1}{|D^t|} \sum_{j \in D^t} q_{ij} \tag{30}$$

$$\bar{sal}_{s_i}^{t=0} = (1 + \alpha |p_{s_i}|) * asp_{s_i}^{t} * sim_{s_i}^{t} \tag{31}$$

To avoid the redundant information, we penalize each sentence s_i by the aspect similarity $acov_{s_i}^t$ and semantic similarity $scov_{s_i}^t$ of that sentence with the selected sentences, in which β is a coefficient:

$$acov_{s_i}^{t} = \frac{1}{|K^t|} \sum_{j \in K^t} r_{ij} \tag{32}$$

$$scov_{s_i}^{t} = \frac{1}{|K^t|} \sum_{j \in K^t} q_{ij} \tag{33}$$

$$sal_{s_i}^{t} = \bar{sal}_{s_i}^{t} - \beta * acov_{s_i}^{t} * scov_{s_i}^{t} \tag{34}$$

$$\hat{s}^t = \arg\max_{s_i \in D^t} \{sal_{s_i}^{t}\} \tag{35}$$

$$K^{t+1} = K^t \cup \{\hat{s}^t\} \tag{36}$$

$$D^{t+1} = D^t \setminus \{\hat{s}^t\} \tag{37}$$

3. We repeat step 2 until the number of selected sentences is reached or the most salient score at the current step t is lower than a threshold. To avoid missing topic words in a summary, in step 1 and 2, we only select sentences containing words belonging to the list of frequent words on that topic. According to our observation, the topic words are the most frequent.

6 Experiments & Results

6.1 Aspect Similarity Recognition

We evaluate the attention-cell LSTM on ASRcorpus (Nguyen et al., 2018), which contains sentences from the SemEval 2016 dataset with two domains: RESTAURANT and LAPTOP. Each sample is a pair of sentences annotated as aspect similarity ($label = 1$) or not aspect similarity ($label = 0$). Table 2 reports the statistic of ASRCorpus in details.

	RESTAURANT			LAPTOP		
	Train	Dev	Test	Train	Dev	Test
Sentences	1239	469	587	1657	382	573
Sentence pairs	458K	68K	98K	447K	26K	44K
Similarity	229K	34K	49K	223K	13K	22K
Not similarity	229K	34K	49K	223K	13K	22K
Vocabulary	3769			3649		

Table 2: Statistic of ASRCorpus

We compare our model to some strong baselines as well as the conventional recurrent networks using attention. We choose the optimal values of hyper-parameters in our model and baselines via a grid search on 30% of LAPTOP domain. Because the number of RESTAURANT's categories is smaller than LAPTOP's, the performance of RESTAURANT domain is better.

Table 3 reports the experimental results. By employing efficiently attention signals, the attention-cell LSTM outperforms the conventional recurrent models using attention. As we analysis in Section 4, applying attention to all gates of a LSTM cell causes the conflict of remembering and forgetting. This drawback makes the training of the LSTM-attention model inefficient. Consequently, the trained LSTM-attention model predicts the same label for all inputs.

We also evaluate how the models perform in cross-domain setting where the models are trained on one domain dataset and tested on the other.

These results also prove that these approaches are potential to cross-domain application. We observe that a set of salient words in each domain is different. Therefore, the support of attention signals in domain adaptation is not significant compared to the recurrent models without attention.

Method	RES	LAP	→RES	→LAP
Word Average	70.75	65.12	54.5	54.59
CNN	77.57	67.23	54.08	54.49
LSTM	79.4	70.21	59.1	57.59
BiLSTM	79.2	71.14	59.2	57.95
Attention	78.79	68	57.92	54.55
LSTM-attention	50	50	50	50
Attention-Cell LSTM	**80**	**72.73**	**59.77**	**58.1**
Attention-Cell BiLSTM	79.42	71.65	59.3	58

Table 3: The in-domain and cross-domain experimental results on the two domains: RESTAURANT and LAPTOP. ”→Y” denotes that models are tested on Y but trained on the other. Accuracy metric is used for evaluation. The results are statistically significant at $p < 0.05$ via the pairwise t-test.

To obtain deeper analysis, we inspect the attention-cell LSTM's performance on each class (e.g., “similarity” and “not similarity”) by precision, recall and F1 scores reported in Table 4. In both of the domains and settings, the model performs better on “not similarity” class than “similarity” class in terms of F1 score. According to the results in cross-domain setting, we could conclude that the models learn rules, patterns for identifying aspect similarity rather than remembering topic words and keywords in a particular domain.

Domain	*Class*	*Precision*	*Recall*	$F1$
RES	Not Similarity	0.76	0.88	0.81
	similarity	0.86	0.82	0.78
LAP	Not Similarity	0.68	0.87	0.76
	similarity	0.82	0.59	0.68
→RES	Not Similarity	0.58	0.68	0.63
	similarity	0.62	0.52	0.56
→LAP	Not Similarity	0.56	0.72	0.63
	similarity	0.61	0.44	0.51

Table 4: The attention-cell LSTM's performance on each class.

6.2 Opinion Summarization

The Opinosis dataset (Ganesan et al., 2010) includes user reviews of 51 different topics (e.g., hotel, car, product). Each topic includes between 50 and 575 sentences made by various authors and around 4 reference summaries created by human. The corpus is suited for opinion summarization as well as evaluating the ability of domain adaptation.

We use ROUGE to assess the agreement of generated summaries and gold summaries. Our experiments include ROUGE-1, ROUGE-2 and, ROUGE-SU4, which base on one-gram, bi-gram and skip-bigram co-occurrences respectively.

The model for each subtask in our summarization system is implemented as follows:

- Sentiment prediction: the ensemble classifier (Huy Tien and Minh Le, 2017) is trained on Stanford Sentiment Treebank (Socher et al., 2013) with the accuracy of 88.6%.

- Semantic textual similarity : the multi-level comparison model (Tien et al., 2018) is trained on STSbenchmark[1] with the accuracy of 82.45%.

- Aspect similarity recognition: the attention-cel LSTM is trained on the ASRcorpus of the both domains with the accuracy of 76.2%.

- Summary generation: we set $\alpha = 1.67$ and $\beta = 0.1$. The number of the most frequent words is three. These parameters are optimized over a set of 5 topics randomly selected from the Opinosis dataset. According to the analysis of (Ganesan et al., 2010), the size of a summary is two sentences.

For comparison, we use MEAD (Radev et al., 2000) and CW-Add$_{Euc}$ (Kågebäck et al., 2014) as baselines. MEAD is an extractive method based on cluster centroids which selects the salient sentences by a collection of the most important words. CW-Add$_{Euc}$ measures the Euclidean similarity between two sentences by their continuous vector space. In addition, we also report the contribution of using aspect and sentiment information in summarization. The results denoted OPT$_R$ and OPT$_F$ in Table 5 describe the upper bound score

Table 5: Performance comparison between the proposed methods and baselines.

of recall and F-score respectively. As the reference summaries of Opinosis are generated in abstractive approach by humans, our generated summaries cannot fully match with the reference summaries. For example, the maximum recall which an extractive method could achieve in ROUGE-1 is 57.86%.

While MEAD selects long sentences (around 75 words) containing a lot of salient words to achieve a high score in recall but low in precision, our approach obtains a balance between these scores with quite shorter sentences (around 17 words).

Positive sentences
I purchased a 2007 Camry because of the looks of the redesigned model and because of the legendary Toyota quality and reliability.
The Concierge staff, exceptional and extremely helpful, right from suggestions on transportation excursion options to recommending an amazing restaurant.
When I checked in, I asked to be shown several rooms and the staff was happy to do so.
Negative sentences
My wife does say the vehicle is not as comfortable for long trips as other cars we've owned.
We had to go up a floor and into a service area to find ice.
The rude and poor service started from the concierge who was curt when I asked a question .

Table 6: Some sentences carrying the most polarity in the Opinosis dataset.

To analyze why sentiment signals cause negative impacts on the summarization generation, we inspect the most polarity sentences in the corpus. Some typical sentences are listed in Table 6. We observe that most of these sentences express individual experiences and too subjective to be selected for summarization. According to the Opinosis dataset, overstrong words (i.e., rude, extremely) and subjective words (i.e., my wife, I, we) are seldom present in a summary. These factors lead to an unexpected result of using polarity information in summarization although sentences carrying the most polarity are still informative.

$Domain$	$Class$	$Semantic + Aspect$
Tablet	More informative	33%
	Less informative	13%
	Equally informative	54%
Others	More informative	17%
	Less informative	8%
	Equally informative	72%

Table 7: Informative test for using Semantic with Aspect against without Aspect.

We expect that aspect signals support to generate an informative summary, which is a summary carrying salient information on various aspects. However, the ROUGE metric measures the number of matches between two pieces of text, so it is difficult to compare which one is more informative. Therefore, we execute an **informative test** to understand whether aspect signals help to generate a more informative summary. Given reference summaries and two summaries generated by the system with/out using aspect signals respectively, three persons are asked to select one of the three answers: which system's summary is more informative, or both of them are equally informative. The inter-rater agreement Cohen's Kappa score for each pair of assessors is higher than 0.74. The overall answer is concluded by the majority vote scheme. In case of receiving three different answers, that pair of summaries is assigned as equally informative. The result reported in Table 7 includes domain specification (15 samples in $Tablet$ and 36 samples in $Others$), which facilitates the evaluation of domain adaptation. As the ASR system is trained on the restaurant and laptop

Summary on the Comfort of Toyota Camry 2007	
Human	[1] The Camry offers interior comfort, while providing a quiet ride. Comfortable seating and easy to drive. [2] Overall very comfortable ride front and back. Nice and roomy. [3] Its very comfortable and a quiet ride with low levels of noise.
Semantic	The ride is quiet and comfortable. Very comfortable, quiet interior.
Semantic + Aspect	The ride is quiet and comfortable. Very comfortable ride and seating.
Summary on the location of Holiday Inn London	
Human	[1] Location is excellent, very close to the Glouchester Rd. Tube stop. [2] Excellent location. Near the tube station. [3] The location is excellent. The hotel is very convenient to shopping, sightseeing, and restaurants. It is located just minutes from the tube stations.
Semantic	Great location but don't bring the car! Great location great breakfast!
Semantic + Aspect	Great location but don't bring the car! Great location for the tube and bus!

Table 8: Human and system summaries for some products/services. For each topic, we list three summaries by human.

dataset, we consider tablet's topics in the Opinosis corpus as in-domain and others as out-of-domain. According to the informative test, the system with aspect dominates in both of the domains ($Tablet$ and $Others$). This result proves the contribution of aspect signals and the domain adaptation of the ASR system.

To obtain a better view of the advantages and disadvantages in our system, we show some generated summaries against reference summaries in Table 8. In extractive methods, the most salient sentences are selected from different reviewers, so it is possible to have repeated information in a summary. For instance in the case #1, the first sentence mentions *quiet* and *comfortable ride* while the second one contains *ride* and *seating*. Although these sentences still have different opinions (i.e., *quiet* vs *seating*), the repeat of *comfortable ride* downgrades the generated summary's quality. For improvement, we suggest a post-processing for a more concise summary by filtering redundant information. As the proposed aspect-based system ranks a sentence by not only semantic cover but also aspect cover, it selects the more salient opinions for summarization. For instance, although both of the systems extract different features (e.g., interior vs seating, breakfast vs tube and bus), the opinions (i.e., seating, tube and bus) chosen by the system with aspect support are more suited to the reference summaries.

In each topic, although the reference summaries and generated summary share most of the meaning, they deliver information in different ways and words. This fact makes the quality evaluation of generated summaries difficult. In addition to the ROUGE metric, we conducted the informative test for quality evaluation. However, for a large corpus or multiple systems comparison, this test requires a huge amount of human effort. Therefore, it is a high demand to have a reliable metric for summaries evaluation without human involvement.

7 Conclusion

In this work, we introduced a novel aspect-based opinions summarization framework using aspect similarity recognition. This subtask relaxes the constraint of predefined aspects in conventional aspect categorization tasks. For ASR tasks, we proposed an attention-cell LSTM to integrate efficiently attention signals into LSTM. This approach outperforms the baselines on both settings of in-domain and cross-domain. For summarization, we evaluated our system on the Opinosis corpus. In addition to ROUGE metric, an informative test with human involvement was implemented to show the domain adaptation ability of our system and how informative our generated summaries are. In the corpus, we observe that sentences carrying the most polarity are not suited to summarization. Therefore, employing sentiment for summarization needs deeper analysis. Due to the ASR task's advantage, we believe that it has a high demand in some fundamental tasks of natural language processing such as information retrieval, and sentence comparison.

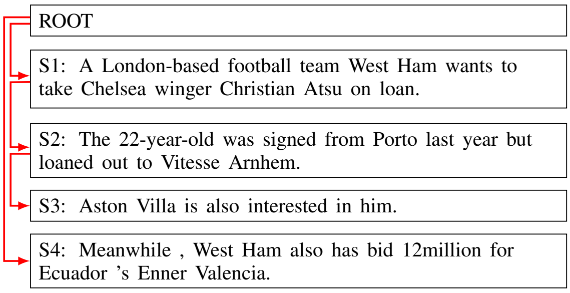
Abstract

Discourse relations between sentences are often represented as a tree, and the tree structure provides important information for summarizers to create a short and coherent summary. However, current neural network-based summarizers treat the source document as just a sequence of sentences and ignore the tree-like discourse structure inherent in the document. To incorporate the information of a discourse tree structure into the neural network-based summarizers, we propose a discourse-aware neural extractive summarizer which can explicitly take into account the discourse dependency tree structure of the source document. Our discourse-aware summarizer can jointly learn the discourse structure and the salience score of a sentence by using novel hierarchical attention modules, which can be trained on automatically parsed discourse dependency trees. Experimental results showed that our model achieved competitive or better performances against state-of-the-art models in terms of ROUGE scores on the DailyMail dataset. We further conducted manual evaluations. The results showed that our approach also gained the coherence of the output summaries.

1 Introduction

Document summarization is the task of automatically shortening a source document while retaining its salient information. In this paper, we present a recurrent neural network (RNN)-based extractive summarizer taking into account the discourse structure inherent in the source document.



ROOT

S1: A London-based football team West Ham wants to take Chelsea winger Christian Atsu on loan.

S2: The 22-year-old was signed from Porto last year but loaned out to Vitesse Arnhem.

S3: Aston Villa is also interested in him.

S4: Meanwhile , West Ham also has bid 12million for Ecuador 's Enner Valencia.

Figure 1: Example of discourse dependency structure.

The discourse structure consists of discourse relations between units in the input, and discourse information has been shown useful for summarization tasks. An example of a Rhetorical Structure Theory (RST) (Mann and Thompson, 1988)-based discourse structure, expressed as a dependency tree, is illustrated in Figure 1. In the figure, each node corresponds to a sentence. Regarding the relations between the sentences, sentence $S2$ elaborates the fact mentioned in sentence $S1$. In addition, $S2$ is further elaborated by $S3$. $S4$ is a contrast to the mention $S1$. Such relations are essential cues for generating a concise and coherent summary. For example, elaborated sentences tend to be more important than elaborating sentences, and the elaborated sentences should be included in the summary while the elaborating sentences are not.

Several Integer Linear Programming (ILP)-based summarizers (Hirao et al., 2013; Kikuchi et al., 2014) use the discourse information given by a discourse parser (Hernault et al., 2010). Thus, the performance of the summarizers is strongly affected by the performance of the discourse parsers. The performance of the parsers deteriorates especially when they are applied to documents of a domain different from the one which they were trained on.

Proceedings of Recent Advances in Natural Language Processing, pages 497–506,
Varna, Bulgaria, Sep 2–4 2019.

RNN-based approaches have achieved the state-of-the-art performance in document summarization (Cheng and Lapata, 2016; Nallapati et al., 2017). However, RNN-based summarizers treat the source document just as a sequence of sentences, and ignore the discourse tree structure inherent in the document. The lack of such information limits the ability to correctly compute relative importance between sentences and reduces the coherence of output summaries. Cohan et al. (2018) might be the only exception to the above, showing that the effectiveness of incorporating discourse information into an RNN-based summarizer for scientific papers by treating the source document as a sequence of sections such as "Introduction" or "Conclusion". However, they were not able to show how the tree-like discourse structure is effective in RNN-based approaches for extractive single-document summarization.

To effectively avoid the influence of parse errors and take advantage of the recent advances in neural network-based approaches, we propose a model that jointly learns the discourse tree structure of the source document and a scoring function for sentence extraction. Our model represents the discourse tree structure as an attention distribution and the probability of including a sentence in a summary as the softmax layer. In addition, recursive attention modules in our model can consider multi-hop dependencies between sentences. Therefore, our model can capture the relationships between sentences effectively and create a summary without losing the coherence between sentences.

We used an existing RST parser (Hernault et al., 2010) to add discourse dependency structure annotations to the DailyMail dataset (Hermann et al., 2015) and thereby obtained a large-scale annotated dataset to train the model. One of the advantages of our model is that we do not need the RST annotations in the inference phase because the model automatically infers the latent discourse tree structure of the source document and outputs the probability for each sentence as a salience score.

We empirically compared our model with other models. The results showed that discourse information improves the performance, and also that our models perform competitively with or better than state-of-the-art neural network-based extractive summarizers.

2 Related Work

There have long been many attempts at tackling extractive single-document summarization (Luhn, 1958), but there is still room for improvements in terms of ROUGE scores (Hirao et al., 2017). The recent focus has been on RNN-based approaches (Cheng and Lapata, 2016; Nallapati et al., 2017; Narayan et al., 2018). We further extend the attention mechanism used in RNN-based summarizers to capture a discourse structure.

RNN-based approaches were introduced to natural language processing tasks by the pioneering work by Bahdanau et al. (2015) and Luong et al. (2015), originally for machine translation. Rush et al. (2015) applied the approach to a sentence compression task. Nallapati et al. (2016) extended the model to abstractive document summarization. The DailyMail dataset (Hermann et al., 2015) has been commonly used for training abstractive summarizers. Cheng and Lapata (2016) and Nallapati et al. (2017) later proposed the methods to automatically annotate the binary labels, enabling us to train extractive models. Cohan et al. (2018) demonstrated the usefulness of incorporating discourse information into RNN-based summarizers. Unlike their model, our attention module explicitly captures the hierarchical tree structure inherent in the document.

Nallapati et al. (2016) and Yang et al. (2016) also used a hierarchical attention that consists of two simple attention modules; one is for words and the other is for sentences. Our attention mechanism differs from them in that ours captures discourse tree structures by new hierarchical attention networks, inspired by the models for capturing sentence-level dependency structures, e.g. machine translation (Hashimoto and Tsuruoka, 2017), dependency parsing (Zhang et al., 2017), constituency parsing (Kamigaito et al., 2017) and sentence compression (Kamigaito et al., 2018). Note that these models were designed for sentence-level tasks while we focus on the document-level summarization task.

Sentence selection modules that consider discourse structures of documents have been shown to be useful in ILP-based summarizers. Hirao et al. (2013) attempted to incorporate discourse information in ILP-based sentence extractors. Kikuchi et al. (2014) later proposed another ILP model that takes into account the discourse structure. Their model jointly selects and compresses sentences in an ILP summarizer. Unlike the researches above, our focus is on incorporating discourse information into RNN-based summarizers.

Penn Discourse TreeBank (PDTB) (Prasad et al., 2008) and RST are the most commonly used framework to represent a discourse structure. PDTB focuses on the relation between two sentences, and the annotated structure for a document is not necessarily a tree. In contrast, RST is forced to represent a document as a tree. Discourse parsers for both schema are available (Hernault et al., 2010; Feng and Hirst, 2014; Wang and Lan, 2015). There are at least two methods to convert an RST-based tree structure to a dependency structure (Hirao et al., 2002; Li et al., 2014). Hayashi et al. (2016) compared these methods and mentioned that DEP-DT by Hirao et al. (2002) has an advantage for applying to summarization tasks. We use DEP-DT for this research since we focus on integrating the tree structure into a summarizer.

We found only one model that jointly learns RST parsing and document summarization (Goyal and Eisenstein, 2016). They used the SampleRank algorithm (Wick et al., 2011), a stochastic structure prediction model, while our main focus is to take into account discourse structures in RNN-based summarizers.

3 Problem Formulation

We formulate extractive document summarization as a sentence tagging problem. We first briefly explain the notation in the paper and describe the details of the model in the following sections.

The source document $\boldsymbol{x}$ is represented as a sequence of sentences $x_1, ..., x_N$. Each sentence x_i is composed of a sequence of words $w_{i,j}$ $(1 \leq j \leq M_i)$, where M_i is the number of words in x_i. We also consider x_0 as a dummy root node. The summarizer outputs a sequence of binary decisions $\boldsymbol{y} = y_1, ..., y_N$, where $y_i = 1$ for the i-th sentence x_i to be included in the summary and $y_i = 0$ for the sentence not to be included. The binary decisions $\boldsymbol{y}$ are made by using a neural network-based probability distribution function $p(y_i|\boldsymbol{x}, \theta)$, where θ is the set of learned parameters. The model finds the best decisions $\boldsymbol{y}$ by a simple greedy search to maximize the sum of the probabilities within the length constraint.

Thus, our goal is to construct a better function $p(y_i|\boldsymbol{x}, \theta)$ given training data D. Each instance in D is a triple $(\boldsymbol{x}, \boldsymbol{E}, \boldsymbol{y})$, where $\boldsymbol{E}$ is a matrix to represent the discourse dependency tree of $\boldsymbol{x}$. Specifically, element $E_{k,l}$ equals 1 if the edge from x_k to x_l exists in the discourse tree; otherwise $E_{k,l} = 0$.

Note that we use the discourse structure matrices $\boldsymbol{E}$ only in the training phase. The model does not require the RST annotations of the source document when calculating the probability distribution $p(y_i|\boldsymbol{x}, \theta)$.

4 RNN-Based Extractive Summarizer

In this section, we first explain the base model and give the details of our proposed attention module in the following section. The base model is composed of two main components: a neural network-based hierarchical document encoder and a decoder-based sentence scorer. The document encoder is further split into two components; a sentence reader and a document reader. The hierarchical architecture is commonly used in recent neural network-based models (Cheng and Lapata, 2016; Nallapati et al., 2017; Cohan et al., 2018).

4.1 Word Reader

The goal of the Word reader is to convert sentence x_i to a sentence embedding h_i. For each word $w_{i,j}$ in a sentence x_i, the word reader first convert every word embedding $emb(w_{i,j})$ to hidden states $\overrightarrow{e}_{i,j} = LSTM(\overrightarrow{e}_{i,j-1}, emb(w_{i,j}))$ and $\overleftarrow{e}_{i,j} = LSTM(\overleftarrow{e}_{i,j+1}, emb(w_{i,j}))$ by using bi-directional Long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997). Then, $\overleftarrow{e}_{i,j}$ and $\overrightarrow{e}_{i,j}$ are concatenated into a hidden state $h_{i,j} = [\overrightarrow{e}_{i,j}; \overleftarrow{e}_{i,j}]$, where $[\,]$ represents a concatenation operation of a vector. After that, all $h_{i,j}$ in the sentence x_i are averaged and represented as a sentence embedding h_i.

4.2 Sentence Reader

Once we obtain sentence embeddings h_i for each sentence x_i, the Sentence reader then reads sentence embeddings h_i by another bi-directional LSTM and generates context-aware sentence representation H_i for each $\boldsymbol{x_i}$. Specifically, two vectors generated by the forward recurrent neural network $\overrightarrow{H}_i = LSTM(\overrightarrow{H}_{i-1}, h_i)$ and the backward $\overleftarrow{H}_i = LSTM(\overleftarrow{H}_{i+1}, h_i)$ are concatenated into sentence representation H_i for x_i:

$$H_i = [\overrightarrow{H_i}; \overleftarrow{H_i}]. \tag{1}$$

We now obtain the context-aware sentence representations $\boldsymbol{H} = \{H_1, ..., H_N\}$. Finally, all H_i are averaged to make a document embedding K.

4.3 Decoder-Based Sentence Scorer

This module outputs the probability of including x_i in the summary, $p(y_i = 1|\boldsymbol{x}, \theta)$, by using an LSTM-based decoder. At each time step t ($1 \leq t \leq N$), the previous state of the decoder s_{t-1} and the sentence representation h_t are fed into the LSTM, and the LSTM outputs a new state; $s_t = LSTM(s_{t-1}, h_t)$. The initial state s_0 is initialized by the last states of the backward LSTM in the document reader $\overleftarrow{H_0}$.

Extractive document summarization often adopts a "hard attention", which focuses only on the encoder hidden state H_t in the decoding time step t (Cheng and Lapata, 2016). In addition, document representation K is also important to decode summaries (Nallapati et al., 2017). Based on them, the output layer calculates the probability distribution of x_t being included in the summary as:

$$p(y_t|\mathbf{x}, \theta) = softmax(\mathbf{W}_o tanh(\mathbf{W}_c[H_t; s_t; K])). \quad (2)$$

5 Discourse-Aware Hierarchical Attention Network

We assume that taking into account the discourse dependency structure is also useful in determining whether the summary includes a target sentence or not. Here, we make the model capable of accounting for the information of the parent sentences on the discourse dependency structure by incorporating our proposed hierarchical attention mechanism into the RNN-based extractive summarizer.

As shown in Figure 2, the goal of our attention mechanism is to generate an attention vector Ω_i containing the information from the parent sentences of x_i through the three-step attention modules. Below, we first give an overview of each step in the procedure and then formulate the components after that.

Step1: Parent Attention Module This module calculates the probability of x_k being the parent of x_i for all combinations of k and i where $k \neq i$. We denote this probability as $p(k|i, \boldsymbol{H})$. In the figure, the starting point of an edge is the parent, and the end point is the child. The probability $p(k|i, \boldsymbol{H})$ is used as the weight for the edge from H_k to H_i. The edge weights are passed to the Recursive Attention Module.

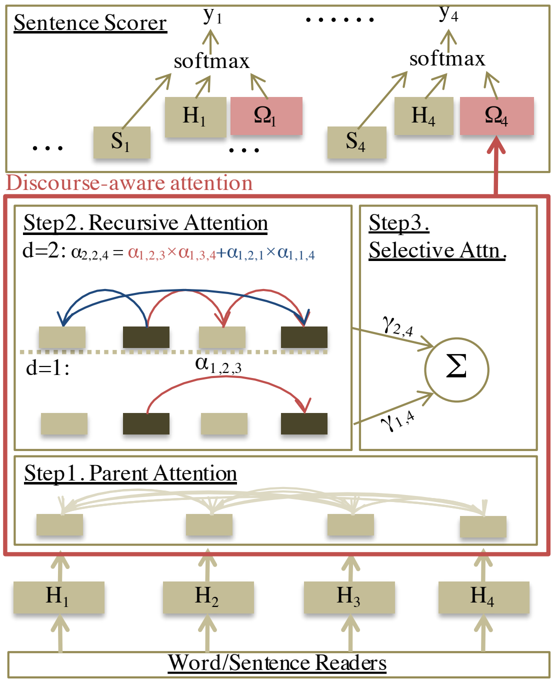


Figure 2: Overview of hierarchical attention mechanism for generating attention vector Ω_4. `Parent Attention` first calculates how likely the sentence x_i is the parent of x_j for all combinations. `Recursive Attention` then generates weighted sum vectors $\gamma_{d,4}$ over encoder hidden states H_i considering how likely the sentence x_i is the d-th order parent of x_4. `Selective Attention` finally generates another weighted sum vector Ω_4 over $\gamma_{d,4}$.

Step2: Recursive Attention Module This module outputs the weighted sum vectors $\gamma_{d,i}$ over $\boldsymbol{H}$, taking into account the d-th-order parents of x_i[1].

The module starts the calculation with the setting $d = 1$. Correspondingly, the module only considers the 1st-order parents of x_i. The Parent Attention Module has already calculated the probability of x_k being the parents of x_i. Thus, the Recursive Attention Module simply uses the probabilities as the weights $\alpha_{1,k,i}$ for every H_k and outputs the weighted sum vector $\gamma_{1,i}$.
