3.2 Proposed Architectures

The basic structure of the Siamese neural network architecture used in our experiments is shown in Figure 1. It consists of an embedding layer which represents each sentence as a sequence of word vectors. This sequence of word vectors is fed into a Recurrent Neural Network (RNN) cell which learns a mapping from the space of variable length sequences of 300-dimensional vectors into a 50 dimensional vector. The sole error signal backpropagated during training, stems from the similarity between these 50 dimensional vectors, which can be also used as a sentence representation. Initially, the similarity function we used was based on Manhattan distance. To make sure that the prediction is between 0 and 1, we took the exponent of the negative Manhattan distance between 2 sentence representations. The similarity function was adopted from Mueller and Thyagarajan (2016). The proposed variants of our architecture are:

1. LSTM - Block A in Figure 1 contains a single LSTM cell. This is the architecture suggested by Mueller and Thyagarajan (2016)

2. Bi-directional LSTM - Block A in Figure 1 contains a single Bi-directional LSTM cell. Bi-directional LSTM tends to understand the context better than Unidirectional LSTM (Schuster and Paliwal, 1997).

3. GRU - Block A in Figure 1 contains a single GRU cell. GRUs have been shown

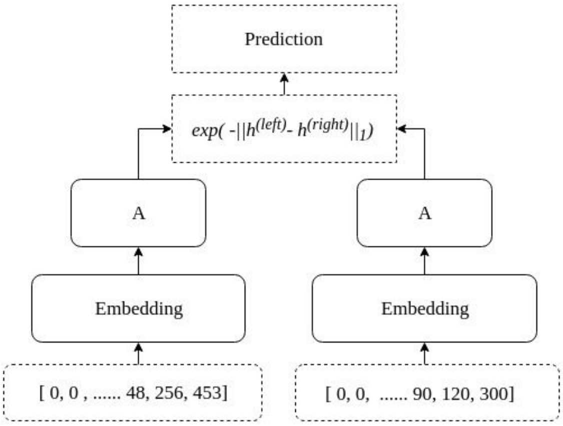

Figure 1: Basic structure of the Siamese neural network. Unit A is changed over the architectures.

to exhibit better performance on smaller datasets (Chung et al., 2014).

4. Bi-directional GRU - Block A in Figure 1 contains a single Bi-directional GRU cell. Bi-directional GRUs tend to understand the context better than Unidirectional GRUs (Vukotic et al., 2016).

5. LSTM + Attention - Block A in Figure 1 contains a single LSTM cell with self attention (Bahdanau et al., 2014).

6. GRU + Attention - Block A in Figure 1 contains a single GRU cell with self attention (Bahdanau et al., 2014).

7. GRU + Capsule + Flatten - Block A in Figure 1 contains a GRU followed by a capsule layer and a flatten layer. Dynamic routing used between capsules performs better than a traditional max-pooling layer (Sabour et al., 2017).

4 Evaluation Results

Table 1 shows the results obtained for the proposed architectures on the SICK test set. The table only reports the best results for each architecture [3]. The first group of results are top SemEval 2014 submissions and the second group are recent neural network methods (best result from each paper shown). † denotes the experiments we conducted in this research. All the models were evaluated using the three evaluation metrics normally employed in the STS tasks: Mean Square Error (MSE), Pearson correlation (τ) and Spearman correlation (ρ).

MALSTM (Mueller and Thyagarajan, 2016) is the baseline that we defined for this research. The baseline is the best result achieved by the architecture reported in Mueller and Thyagarajan (2016). Interestingly, we were able to beat the baseline using the same architecture using the Adagrad optimiser (Duchi et al., 2011) (LSTM:Adagrad).

The best result was obtained when block A in figure 1 contains a single GRU. As can be seen in the table 1, the proposed architecture outperformed both the benchmark and all the other architectures in all 3 evaluation metrics.

As can be seen in Table 1, the architectures with bidirectional GRU, LSTM with Attention and GRU with Attention also surpassed the benchmark. However uni-directional GRU out performed them on all 3 evaluation metrics.

We experimented with other similarity functions and other embedding models. Using Euclidean distance for the similarity function instead of Manhattan distance did not improve the results for the model because semantically different sentences could end up being represented by nearly identical vectors due to the vanishing gradients of the Euclidean distance (Chopra et al., 2005). Changing the embedding model to GloVe (Pennington et al., 2014), fastText (Mikolov et al., 2018) or concatenating them with word2vec model did not improve the results either. For this reason, none of these results are presented here.

The Siamese neural network with GRU was tested with a cyclical learning rate (Smith, 2015), which has the advantage of forcing the model to find another local minimum if the current minimum is not robust and makes the model generalize better to unseen data. However, neither cyclical learning rate nor reducing learning rate on plateau increased the performance further. We do not report these results too.

Table 2: Pearson correlation (τ) for STS2017 test set.

Table 2 shows the results obtained for STS2017 test dataset comparing our experiments with other top performing models in SemEval 2017 Task 1 (Cer et al., 2017). † denotes the experiments we conducted in this research. As SemEval 2017 Task 1 used Pearson correlation (τ) to evaluate the submissions, we evaluated our models using Pearson correlation (τ) too.

GRU based Siamese neural network performs better than existing systems for STS2017 dataset too, as it is shown in table 2.

4.1 Error Analysis

In order to understand better why the GRU based architecture performed better than the LSTM baseline, we compared sentences where the GRU architecture was better. Table 3 shows examples of such sentences from the SICK testset. Our analysis suggests that the GRU based architecture handles the additional words better than LSTM. Mueller and Thyagarajan (2016) report that their architecture does not perform well with active-passive equivalence. However, as shown in Table 4,

[3] These results are reported in Marelli et al. (2014)

Sentence 1	Sentence 2	GOLD	LSTM	GRU
The people are walking on the road beside a beautiful waterfall	The people are walking on the road beside a waterfall, which is beautiful	0.9750	0.5260	0.9569
The woman is frying a chop of breaded pork	The woman is frying a breaded pork chop	0.9250	0.5278	0.8561
A white dog is standing on the leaves on the ground	A dog, which is white, is standing on fallen leaves	0.9500	0.3611	0.7618
The man is erasing the other man's work from the board	The man is erasing the drawing on the board	0.7500	0.5128	0.7584

Table 3: Example sentence pairs from the SICK test data. LSTM denotes the baseline and GRU the best model

Sentence 1	Sentence 2	GOLD	LSTM	GRU
A man is mixing vegetables in a pot	Vegetables are being mixed in a pot by a man	0.9750	0.6684	0.8154
Carrots are being sliced by a woman	A woman is slicing carrots	1.0000	0.6739	0.7206
The elephant is being ridden by the woman	The woman is riding the elephant	0.9500	0.2249	0.5939

Table 4: Example active-passive sentence pairs from the SICK test data.

our architecture performs slightly better than the LSTM based architecture.

5 Conclusions

This paper evaluated several neural architectures based on Siamese recurrent neural network for calculating semantic similarity between pairs of texts. Most of these architectures fared better than the approach proposed in (Mueller and Thyagarajan, 2016). The variant with a GRU performed best, capitalising on GRU's ability to exhibit better performance on smaller datasets like the ones available for STS. Our architectures can be easily ported to other languages which have training data available, and we are currently experimenting with other languages.

Abstract

Traditional approaches to automatic term extraction do not rely on machine learning (ML) and select the top n ranked candidate terms or candidate terms above a certain predefined cut-off point, based on a limited number of linguistic and statistical clues. However, supervised ML approaches are gaining interest. Relatively little is known about the impact of these supervised methodologies; evaluations are often limited to precision, and sometimes recall and f1-scores, without information about the nature of the extracted candidate terms. Therefore, the current paper presents a detailed and elaborate analysis and comparison of a traditional, state-of-the-art system (TermoStat) and a new, supervised ML approach (HAMLET), using the results obtained for the same, manually annotated, Dutch corpus about dressage.

1 Introduction

Automatic term extraction (ATE), also known as automatic term recognition (ATR), has long been an established task within the field of natural language processing. It can be used both in its own right, to automatically obtain a list of candidate terms (cts) from a specialised corpus, or as a preprocessing step for other tasks, such as machine translation (Wolf et al., 2011). The traditional method for ATE is a hybrid approach, combining both linguistic and statistical information. In a first step, linguistic preprocessing is performed and a preliminary list of cts is produced based on part-of-speech (POS) patterns. Next, statistical metrics are applied to measure termhood (to what degree a term is related to the domain) and unithood for multi-word terms (whether the individual tokens combine to form a lexical unit) (Kageura and Umino, 1996). These metrics are used to sort the cts based on their likelihood to be actual terms. To filter the list, one can either determine a cut-off value or select the top n or top n percent of terms. As a final step, manual validation is required.

This has been a standard methodology for some time (Daille, 1994) and is still used by state-of-the-art systems such as TermoStat (Drouin, 2003) and TExSIS (Macken et al., 2013). However, the problem with these methodologies is determining the cut-off point (Lopes and Vieira, 2015) and combining multiple features (e.g., separate measures for termhood and unithood). It has become clear that multiple evidence (i.e. combining multiple features) is highly beneficial for ATE (Dobrov and Loukachevitch, 2011; Loukachevitch, 2012). Supervised machine learning (ML) methodologies are now being used in answer to these problems. By automatically learning an optimal combination of features and cut-off points, many features can be efficiently combined.

One of the biggest hurdles for the progress of ATE technologies has been the data acquisition bottleneck, both for evaluation and now also as training data. Manually annotating terms is a slow and arduous task, with notoriously low inter-annotator agreement due to the ambiguous nature of terms. This lack of agreement on the basic characteristics of terms is also reflected in the different methodologies of various ATE research, e.g., min./max. length and frequency, POS patterns and degree of specialisation. As a result, the supervised methodologies that have been developed are extremely difficult to compare (both to each other and to non-ML systems) and qualitative analyses that go beyond calculating precision (how many of the extracted cts are true terms), recall (how many of the true terms are extracted) and f1-scores (weighted average of precision and recall) are rare.

The construction of a diverse and extensive dataset for ATE (Rigouts Terryn et al., 2019) pro-

Proceedings of Recent Advances in Natural Language Processing, pages 1012–1021,
Varna, Bulgaria, Sep 2–4 2019.

vided an opportunity to (1) develop a supervised ML approach for ATE (HAMLET) and (2) perform a detailed evaluation of this system compared to a traditional tool without ML: TermoStat (Drouin, 2003). These specific systems were chosen because they both allow extraction of single- and multi-word terms (swts and mwts) and are not restricted to only nouns and noun phrases, but instead also allow verbs, adjectives and adverbs to be extracted. Moreover, their methodology is similar, so the research can focus on one main difference: the fact that HAMLET uses supervised ML to combine different features, rather than relying on manually set filters and thresholds like TermoStat. This is important to better understand the impact of the methodology. Are the same terms found with both methodologies? Do they make similar mistakes? Is it possible to see the impact of the training data? The analysis is performed by a terminologist, in her native language (Dutch) and on a subject for which she is a domain specialist (equitation - dressage).

2 Related Research

Some of the original supervised approaches to ATE start appearing in the early 2000s. Vivaldi and Rodríguez (2001) claim to be the first to combine different methodologies for term extraction into a single system. Based on two manually annotated Spanish corpora in the medical domain, four different strategies are combined. The first strategy is to use EuroWordNet (EWN) (Vossen, 1998) to determine whether a word belongs to the medical domain. Next, Greek and Latin word forms are detected. Context is analysed as well, focusing on prime term candidates, i.e. those that are validated with EWN as medical terms. Finally, three unithood measures help to find relevant multi-word terms. Combining these four techniques leads to better results than using any one of them separately. The system is only tested on the Spanish medical domain; performance may vary significantly depending on EWN coverage of the corpus and relevance of the Latin and Greek words. Later research does test on multiple domains, for instance, an evolutionary algorithm based on the optimisation of the Receiver Operating Characteristics curve for the extraction of mwts (Azé et al., 2005), tested on the domains of biology and HR; or a system for both swts and mwts (Yuan et al., 2017), elaborately evaluated with different algorithms, using undersampling to obtain more balanced data, and cross-domain training/testing on four domains.

In 2016, neural network word embeddings are applied to ATE for the first time (Amjadian et al., 2016), first as a filter on an existing tool (TermoStat), later on also as a full ATE pipeline (Amjadian et al., 2018). The success of multiple features for ATE has been proven repeatedly (Dobrov and Loukachevitch, 2011; Loukachevitch, 2012; Nokel, Michael et al., 2012) and aside from the original binary classification approach of cts, sequence labelling approaches are also gaining interest (Judea et al., 2014; Kucza et al., 2018). Additionally, There has been an increased interest in more nuanced term labels (Ljubei et al., 2019; Hätty and Schulte im Walde, 2018), even though binary classification is still the norm.

Unsupervised and semi-supervised approaches are starting to appear as well, which is interesting considering the time and effort associated with constructing good gold standard data. Judea, Schütze and Brügmann (2014) use the specific layout of patents to generate training data. Cts are extracted based on their POS pattern and filtered with an elaborate stopword list. When these cts were preceded by a figure reference in patents, 95% of them were true terms. Since these terms could be identified with high precision, they were used as training data to detect other terms without figure references. Another strategy is fault-tolerant learning, which has been used for Chinese ATE (Yang et al., 2011). Two sets of seed terms are extracted from the same, unlabelled dataset, with two different termhood metrics methods. By comparing the results of the two classifiers and retraining on only the best results (for n iterations), a system can be trained without any labelled training data. Human annotation is only used for evaluation, where an approximation of precision is calculated by randomly sampling and annotating 10% of the extracted cts. Patry and Langlais (2005) take an unusual approach regarding the difficulty of obtaining data and ask users to provide an annotated corpus. This added effort on the part of the user would be rewarded in the form of a customised tool, considering the user's own definition of the ambiguous concept of a term. They also cite two of the most common problems for ATE: the lack of a common benchmark for evaluation and the difficulty extracting hapax terms, especially considering that these make up 75% of the terms in their test corpus.

Despite the increasing research interest, research on the impact of ML approaches on ATE is limited (Amjadian et al., 2018; Nokel, Michael et al., 2012). Comparative evaluations are highly problematic for several reasons. First, established benchmarks such as the GENIA corpus (Kim et al., 2003) and the ACL RD-TEC (Qasemizadeh and Schumann, 2016) are rare and often only available in a single language and domain. Second, reported evaluation scores (usually precision, recall and f1-score) differ greatly depending on the strictness of the evaluation (e.g., whether or not partial matches are approved). Third, the difficulty of the task varies considerably depending on the ct selection. For instance, limiting POS patterns and frequency thresholds can result in a more balanced data set and narrower search space. Finally, results are rarely discussed beyond reporting the scores, which may result in a distorted image, given the ambiguous nature of terms, as will be discussed further on. Therefore, while researchers regularly mention the suspected impact of methodology, term definitions, language and domain, little is known about how these factors influence the actual results. The research presented in this paper presents an elaborate and qualitative evaluation and comparison of two tools and will focus on the difference between a supervised ML approach and a traditional approach.

3 Data and Tools

3.1 Data

The dataset is described in detail in (Rigouts Terryn et al., 2019). The Dutch corpus on dressage was chosen as the evaluation corpus. The annotation scheme is based on lexicon-specificity (whether a term belongs to general language or only the vocabulary of experts) and domain-specificity (how relevant the term is to the given domain). Terms are annotated with three different labels: Specific Terms (which are both domain-specific and lexicon-specific), Common Terms (which are domain-specific but not lexicon-specific) and Out-Of-Domain (OOD) Terms (which are not domain specific but are lexicon-specific). Named Entities are annotated as well. In this corpus of around 55k tokens (64 documents), this resulted in 1326 different manual annotations (excluding Split Terms).

3.2 TermoStat

TermoStat is a hybrid term extractor developed by Drouin (2003) which is still continuously updated. It is currently available in French, English, Spanish, Italian, and Portuguese, with beta versions for German, Catalan, Korean, Chinese and Dutch. It is customisable in the sense that users can choose to extract swts, mwts, or both and can also select which POS (nouns, adjectives, adverbs and/or verbs) should be extracted. TermoStat selects cts based on their POS pattern and filters and sorts these cts with the Specificity score, a measure that takes into account the relative frequency of a ct in the specialised corpus, compared to that in a general reference corpus to calculate termhood.

3.3 HAMLET

HAMLET stands for Hybrid Adaptable Machine Learning approach to Extract Terminology and is a supervised methodology for ATE based on the data described in (Rigouts Terryn et al., 2019). HAMLET's architecture is inspired by traditional hybrid systems such as TermoStat. First, cts are extracted based on their POS pattern. However, rather than a predefined list, the patterns are obtained from the annotated training corpus. Since there were no restrictions on which POS could be annotated, this results in an extensive list. Moreover, incorrect patterns due to POS-tagging errors are included as well. This may result in a lot of noise but could also increase recall if similar tagging mistakes are made on terms in the test corpus.

Next, a series of features are calculated for each ct. There are six different feature groups: morphological/shape (e.g., term length, capitalisation, special characters), frequency (e.g., relative frequencies in specialised corpus, newspaper corpus and Wikipedia corpus), statistical (e.g., various termhood and unithood measures), related cts (e.g., information about terms with same lemma or normalised form), linguistic (e.g., POS pattern) and corpus features (e.g., domain of corpus of origin). There are 152 distinct features in total. In contrast to most other term extractors, no restrictions are placed on term length or frequency.

This information is fed to a binary decision tree classifier in Scikit-learn (Pedregosa et al., 2011). Hyperparameter optimisation with grid search is performed in 5 folds on the training data. All values are scaled to a value between 0 and 1. For the experiment discussed in the current contribution, HAMLET was trained on the Dutch corpora about heart failure and wind energy and tested on the Dutch corpus about dressage. Irrelevant features (with the same value for all instances) are discarded, leaving 136 features in this case. The data is highly imbalanced, with fewer than 10% positive instances (similar distribution in train and test sets). While other algorithms were able to reach better scores (e.g., a random forest classifier obtained an f1-score of 61% on the same dataset), only the decision tree model is discussed, because it offers both decent performance and is easy to interpret. Future research will devote more attention to the differences between algorithms for this task.

4 Experiments and Comparisons

4.1 Candidate Terms and Part-of-Speech Patterns

The gold standard data (test data) contains 1326 unique annotations: 985 Specific Terms, 190 Common Terms, 45 OOD Terms and 106 Named Entities. For this experiment, HAMLET was trained to find all annotation types, which is the configuration that lead to the best results for TermoStat. However, HAMLET could also be trained on specific combinations of these labels to customise the results for different applications. Out of the 1326 annotations which were considered true terms, only two could not be found because the annotations were made below token-level and were therefore never selected as a ct by either extractor: *promotie* (promotion, i.e. moving to a higher level of competition) and *k* (one of the letters indicating a certain position in the riding arena). Another portion could not be found due to their POS pattern. This is always a problem for non-ML extractors, since it is nearly impossible to manually define all possible patterns, especially considering that POS taggers can make mistakes. However, the supervised system has similar troubles. HAMLET's preprocessing can only select terms for which the POS pattern occurred in the training corpora (the two Dutch corpora on heart failure and wind energy). In this case, there are 216 different patterns in the training data, but the test corpus still contains terms with 63 patterns that are not in the training data. This illustrates how domain-specific terminology can be. Dressage terminology contains many terms that start with a preposition. For instance, there are 85 annotations of the preposition+determiner+noun pattern, e.g., *aan het been* (responsive to a rider's leg aids). Patterns including verbs are common in dressage as well, e.g., *vierkant halthouden* (stopping the horse so all four hoofs form a rectangle). Due to the absence of such patterns in the training data, 104 terms were not extracted by HAMLET, while 11 of these were found by TermoStat.

Across all 3 languages and 4 domains in the complete dataset, a total of 1345 distinct POS patterns are identified (419 in Dutch in all four domains), meaning that these types of errors are greatly reduced when HAMLET is trained on a larger portion of the data, though that also leads to more noise. This emphasises the importance of diverse datasets to train robust term extractors and to evaluate extractors in multiple domains.

4.2 Decision Tree

The decision tree (of depth 8) that was created based on the training data of Dutch corpora on heart failure and wind energy uses 64 out of the 152 distinct features. All feature categories are represented, except corpus features. In other experiments involving more domains and languages, corpus features are regularly used, but in this setting, with only two different domains in the training data, they did not appear to be informative. Statistical features are used most often (66 nodes, using 17 distinct features), followed by linguistic features (35 nodes, 16 features), related ct features (28 nodes, 9 features), morphological/shape features (25 nodes, 9 features), and frequency features (16 nodes, 11 features).

The most discriminating feature (first node in the decision tree) is Vintar's termhood score (Vintar, 2010), calculated for the original, unlemmatised ct, compared to a reference corpus of newspaper articles. This is also the feature that, following domain consensus, is used most often (10 times and 8 times, respectively). The most frequently used features in the other categories are: number of characters (morphological/shape feature used 7 times), number of cts that contain the current ct (related feature used 6 times), the presence of either a preposition or a noun (linguistic features, both used 4 times). The frequency features are all used 0-2 times and none stand out. A possible explanation for the comparative irrelevance of frequency features, is that frequency is most informative when already incorporated into termhood or unithood measures and that many frequency features are strongly correlated.

A feature indicating presence in a list of stopwords is not used, even though lists of stopwords are generally very useful for ATE. This may be related to the limited list used for Dutch (414 tokens) or the way it is currently implemented (only complete matches are counted). This analysis shows how the statistical termhood and unithood features are indeed most useful for ATE, but that there are many other informative features as well, in a range of different categories.

4.3 Precision, Recall and F1-scores

HAMLET extracts 1352 cts with a precision of 55.03%, a recall of 56.11% and an f1-score of 55.56%. TermoStat extracts many more cts (4671) and has a much lower precision of only 18.18% but a higher recall at 64.03%, resulting in an f1-score of 28.31%. This is where the supervised ML component becomes immediately apparent: HAMLET is trained to optimise f1-score, whereas the cut-off point for TermoStat had to be set manually based on a limited set of experiments. Figures 1 and 2 show the precision, recall and f1-score curves for HAMLET and TermoStat. In this case, HAMLET did not print the predicted label of the classifier, but the predicted probability of label 1, i.e. the predicted probability that the ct is a true term. In Figure 1, only terms with a probability higher than 50% (up until rank 1352) were labelled as terms by HAMLET. However, for the sake of comparison with TermoStat, the graph was calculated supposing that all 4671 highest ranked cts were predicted as terms. As can be seen in the graph, the decision boundary is very close to the highest possible f1-score. According to this ranking, that would have been 57.05%, if HAMLET had extracted the highest ranked 1619 cts instead of the first 1352. The TermoStat results in Figure 2 show a different trend. Here, the ideal cut-off point would have been after the 1307th highest ranked term (Specificity of 16.06), which would have resulted in an f1-score of 42.61%. Instead, 3362 more terms were extracted, causing a large drop in f1-score.

Another notable peculiarity in these curves is that the TermoStat curves are smoother and follow a more predictable pattern: precision starts high and decreases gradually, recall increases but starts to slowly flatten out. The recall curve for HAMLET follows this pattern and even reaches over 80% at rank 4671, where TermoStat's recall is still only at 64%. However, HAMLET's precision curve is far from smooth in the beginning, with the highest precision only around rank 285. These fluctuations are due to two factors. First, precision curves are very susceptible to small changes at the start, when it is calculated for few examples. Second, surprisingly, HAMLET's predicted probability that a ct is a true term does not always correspond with the reality. For instance, 13 cts were given a 100% probability and only 7 of these were actual terms. So, while the predicted true term probability for these cts was 100%, the actual precision was only 54%. One of the false positives should have been in the gold standard and was missed by the annotators. Two were parts of terms and the remaining three were very common words: *bovenstaande* (above), *moet* (has to), and *werd* (became). Further research is needed to explain this behaviour and compare results with other algorithms and corpora.

4.4 Term Labels

While the extractors only performed binary classification, the gold standard does contain more detailed labels (Specific Terms, Common Terms, OOD Terms and Named Entities, see section 3.1). It was already established that TermoStat extracts many more terms, resulting in a lower precision but also a higher recall. An additional analysis can show whether both tools extract the same term types based on the more fine-grained labels. Regarding these labels, two hypotheses were formulated. First, we expect HAMLET to be better than TermoStat at extracting Named Entities and maybe also OOD Terms, since these were included in the training data, while TermoStat's Specificity score is designed mostly to detect domain-specific terms, i.e. Specific and Common Terms. TermoStat may still extract Named Entities and OOD Terms, since they share many characteristics with the other two categories, but the hypothesis is that it will extract comparatively fewer than HAMLET. This hypothesis was partly confirmed by the results. Even though HAMLET extracts fewer terms in total, it extracts more Named Entities than TermoStat (63 versus 43) and a larger percentage of all HAMLET's extractions are Named Entities (5% versus 1%). For OOD Terms the hypothesis could not be confirmed. since the difference was too small. This may be due, at least

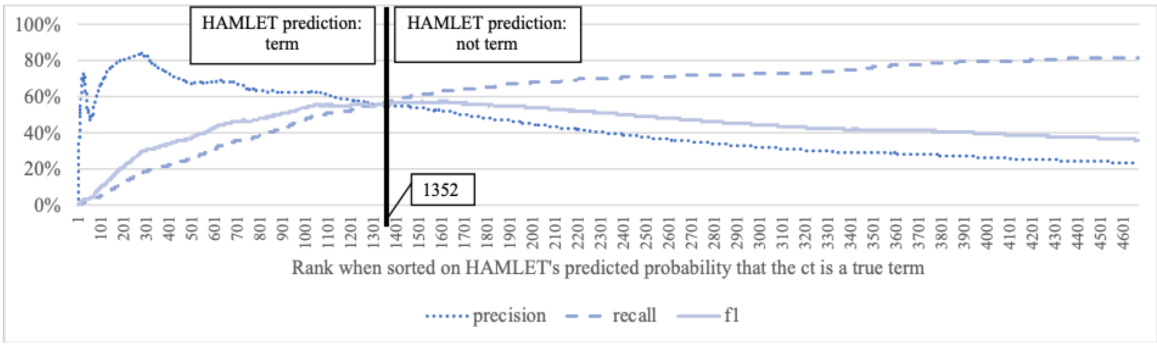

Figure 1: Precision, recall and f1-curves of HAMLET, including the 4671 highest ranked cts based on predicted probability that the ct is a true term; black line indicates boundary between cts that were predicted to be terms and those that were predicted not to be terms.

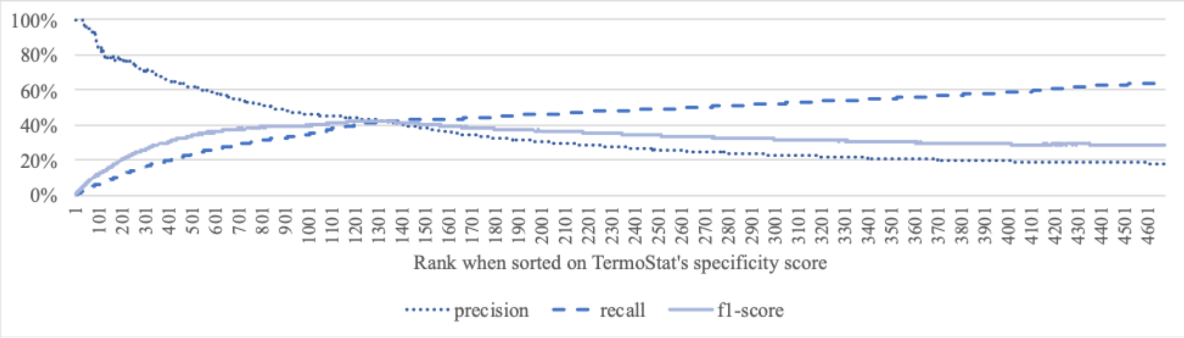

Figure 2: Precision, recall and f1-score curves of TermoStat for all 4669 extracted terms, ranked based on specificity score

in part, to the annotation. Since the corpus subject was dressage (a subdomain of equitation), rather than equitation as a whole, many terms that are specific to other branches of equitation were annotated as OOD Terms. These are nearly all terms related to other equitation disciplines, such as *gymkhana* (same in English) or *voltige* (equestrian vaulting). Had the annotation been slightly less strict about the domain-specificity, at least 27 of the 34 OOD Term annotations would have been Specific Terms. This illustrates how a subjective decision about whether or not to include a certain group of terms, can have a large impact on the results.

The second hypothesis concerns Specific Terms: we expect HAMLET to outperform TermoStat for Specific Terms. TermoStat relies heavily on a single termhood measure, which means it has the typical drawback of being very sensitive to frequency, leading to low recall on rare terms. HAMLET combines many more features, which may mean that it is less sensitive to frequency. This is important for Specific Terms, since they are often rare. The average relative frequency of Specific Terms versus Common Terms in the domain-specific corpus, calculated by HAMLET is 0.0001268 versus 0.0003642 (similar for document frequency). Again, the hypothesis could only partially be confirmed. HAMLET extracts fewer Specific terms than TermoStat (540 versus 626), though this is similar when considering the comparative difference in total number of extracted terms. However, HAMLET does extract more hapax terms (291 versus 241 by TermoStat), despite extracting fewer terms in total, confirming the part of the hypothesis about HAMLET's improved ability to extract rare terms.

4.5 Agreement between HAMLET and TermoStat

The agreement between HAMLET and TermoStat is very low, with a Cohen's Kappa score of only 0.162. Part of the disagreement is due to the much higher number of non-terms extracted by TermoStat, but even agreement on true terms is only slightly more elevated (0.28). These numbers indicate that the two tools have different strengths and weaknesses. In previous sections, two main strengths of the supervised approach were already discussed: it is better at optimising for f1-score and it is better at extracting rare terms. The variety of features also visibly results in other improvements. For instance, there is a feature indicating the presence of a dash at the end of a ct. HAMLET has incorporated this feature into the decision tree and extracts only 3 wrong cts that begin or end with a dash. This is not included in TermoStat's preprocessing, resulting in 43 wrong extractions. This does not always explain the results, as illustrated by the fact that the feature indicating the presence of digits in a ct is never used, but HAMLET still correctly extracts 10 out of 21 gold standard terms with digits, whereas TermoStat does not recognise any. Another notable result is that TermoStat extracts 90 cts that begin or end with an article (compared to only 5 such error extracted by HAMLET). These types of mistakes were actually expected from HAMLET, rather than TermoStat, since HAMLET selects cts based on a list of POS patterns that is not manually validated and includes wrong patterns. The fact that only TermoStat makes this error, indicates that the former may have learnt to exclude such cts, while the latter may include wrong patterns, due to its susceptibility to human error. Another possibility is that the POS tagger used by TermoStat is less accurate, resulting in more such errors.

There are also disadvantages to the supervised method, specifically due to the differences between training and test data. For instance, single letters, indicating certain positions in a dressage arena, can be terms. This is not be the case in most other domains, so a supervised system may learn rules that obstruct the extraction of single-character terms. HAMLET only extracts 3 out of 10 single-character terms in the gold standard, while TermoStat extracts 6. This is an illustration of how domain-dependent term characteristics can be and how this could impact supervised systems. Furthermore, HAMLET's lower sensitivity to frequency is not only an advantage but can also backfire. A few seemingly obvious terms with very high frequencies are not extracted, e.g., *hulpen* (aids) and *hand* (meaning both literally hand, but also the direction the horse is going in the arena). Even *paarden* (horses) received a 0% probability of being a term by HAMLET. A final category of terms both extractors struggle with, are those that are also part of general language and only become terms in this context. An example is *pijp*, which usually means pipe, but, in the context of dressage, refers to a part of a horse's leg. At least half of the terms that were not found by either tool concern terms that are also part of general language.

	H = 1	**H = 0**	**SUM**
TS = 1	852	3819	4671
TS = 0	500	9360	9860
SUM	1352	13179	14530

Table 1: Agreement between TermoStat (TS) and HAMLET (H); =0.162

The described differences illustrate various strengths and weaknesses of both approaches and inspires a few suggestions for improvement. TermoStat's approach could benefit from more elaborate preprocessing (e.g., removing cts ending in a dash) and an evaluation of the POS patterns. The supervised approach is clearly influenced by the domain-dependence of term characteristics and could benefit from in-domain training data or training data in more domains. The two approaches are at least partly complementary and a combination of the output results in a recall of 77.45%, which is high, considering the strictness of the evaluation and the gold standard.

4.6 Agreement Between Tools and Gold Standard

Even though the gold standard was rigorously annotated, there is always the possibility of human error and the ambiguous nature of terms, which means that these annotations are not the only possible correct annotations. Therefore, it is worth looking at the ATE results in more detail. Are there any terms that should have, or could have been annotated among the false positives? Or the opposite: terms which could or should not have been annotated among the false negatives? Are the mistakes made by the tools understandable or undeniably wrong? In an attempt to answer these questions, HAMLET's results were analysed in more detail.

Only a single annotation was found to be undeniably wrong: *veel* (many) was mistakenly annotated as a term. However, there were 76 others which were labelled: should (not) have been annotated, including terms such as *uitzwaaien* (wrong positioning of the horse's hindquarters, mostly during a turn), and *verruim* (specific way of lengthening the horse's stride; other forms of this verb were annotated correctly). Looking at the 608 false positives, at least 217 of them could have been terms, which would increase precision to over 70%. It implies that there is at least some logic in the errors and that, overall, HAMLET does appear to have learnt informative general characteristics of terms. However, this analysis should also be interpreted as a cautionary tale regarding ATE evaluation. When evaluating a list of already extracted cts, annotators are biased to evaluate favourably. Therefore, results compared to a predetermined gold standard may tend to be worse than results based on the annotation of the ATE output. Any comparisons between such results should be interpreted with due caution.

Nevertheless, it is encouraging to see logical patterns in the ATE results. For instance, many cts were extracted related to body parts (of both horse and rider). These were not always consistently annotated but are still logical terms in the field of dressage, which is a sport where the positioning of horse and rider are crucial. At least 171 cts extracted by HAMLET were related to body parts or bodily functions (e.g., *schuimproductie*, the production of foam in the horse's mouth). They were actually extracted by HAMLET more consistently than they were labelled by the human annotator. Also encouraging was the fact that, despite only very limited information about term variation, HAMLET often makes the same decision for related terms, such as terms with different full forms sharing the same lemma. Still, TermoStat's strategy of grouping terms with the same lemma is more effective and should be considered as an option to improve HAMLET.

One last item to mention here is that HAMLET is still susceptible to classic ATE errors, such as wrongly extracting parts of terms, combinations of different terms, or very frequent terms in combination with a non-term. For instance, 35 false positives contain the word *paard* or *paarden* (horse(s)), but in combinations that are not terms, e.g., *paard gaat* (horse goes), *paard niet* (horse not), and *paard symmetrisch* (horse symmetrical). These are typical errors because such combinations are much more frequent in the domain-specific corpus than in reference corpora, so they get high termhood values. Even though HAMLET still makes these mistakes, there is a marked improvement compared to TermoStat, which relies more heavily on termhood statistics. For instance, TermoStat wrongly extracts 320 cts that contain *paard(en)*, compared to only 35 for HAMLET. This further illustrates the positive effect of multiple features to limit frequency-related errors.

5 Conclusions and Future Research

The research described in this paper presents an elaborate evaluation of a supervised ML approach to automatic term extraction (HAMLET), compared to a traditional system without training data (TermoStat). As expected, the supervised system obtains higher f1-scores by combining features with various types of information and optimising f1-score. A closer look at the results confirms that the system has clearly learnt informative general characteristics of terms. It is less reliant on frequency, leading to fewer mistakes on rare terms or frequent non-terms. However, the supervised system also has a distinct weakness, namely its domain-dependence, since it was trained on out-of-domain data. This emphasises the need for annotated data, though there are also indications that very little training data could suffice (Amjadian et al., 2018). Nevertheless, annotated data remains critical for a nuanced evaluation.

Current versions of HAMLET can already obtain an average f1-score of 53%, using cross-validation on all domains and languages combined. Preliminary results already show the impact of factors such as algorithm, language, domain, term definition, and in-domain training data, with f1-scores of up to 66% depending on the combination. Precision and recall are not always as balanced as for the presented use-case, and results vary greatly per corpus. Future research will concentrate on further exploring the robustness of HAMLET, with more contrasting results for different configurations and data. Aside from the binary classifier, a sequence labelling approach, which is further removed from the original methodology, will also be explored and will provide further material for comparison.

Abstract

News articles often convey attitudes between the mentioned subjects, which is essential for understanding the described situation. In this paper, we describe a new approach to distant supervision for extracting sentiment attitudes between named entities mentioned in texts. Two factors (pair-based and frame-based) were used to automatically label an extensive news collection, dubbed as RuAttitudes. The latter became a basis for adaptation and training convolutional architectures, including piecewise max pooling and full use of information across different sentences. The results show that models, trained with RuAttitudes, outperform ones that were trained with only supervised learning approach and achieve 13.4% increase in F1-score on RuSentRel collection.[1]

1 Introduction

Relation extraction nowadays remains one of the popular tasks in the natural language processing domain. The relation types to be extracted from texts may vary and result in different tasks: semantic classification of relations between a pair of common nominals (Hendrickx et al., 2009), source-target sentiment relation extraction (Ellis et al., 2014), opinion expression towards entities and events (Deng and Wiebe, 2015a), attitude extraction between mentioned named entities (Rusnachenko and Loukachevitch, 2018), etc.

Dealing with one of these tasks, the greatest difficulty one encounters is the complexity of the sentence structure. As for analytical articles, the idea expressed by the author could be conveyed in different variants, which is a feature of natural languages.

When relation extraction is performed automatically using machine learning approaches, this complexity results in a lack of training examples. One technique that helps to accomplish this task is *distant supervision* (DS), initially proposed by (Mintz et al., 2009). It assumes to extract and label data by relying on assumptions based on a prepared knowledge base. Although many methods have been proposed in such domains as sentiment analysis and relation extraction (Turney, 2002; Zeng et al., 2015), the domain of sentiment attitude extraction remains understudied.

This paper describes a new approach to distant supervision for extracting sentiment attitudes between named entities mentioned in texts. It is worth noting that DS faces the problem of wrong labels, which becomes a reason of noisy labeled data. To address the shortcomings of noisy labeling, in this paper we exploit two primary sources of automatic annotation:

- Prior knowledge about current attitudes between political entities (figures);
- Sentiment frames that define attitudes between participants of a situation.

The obtained corpus annotated with attitudes was used to train convolutional neural networks (CNNs), adapted for relation extraction and full use of information across multiple sentences. Our key contributions in this work are two-fold:

- We propose a workflow of automatic sentiment attitudes extraction, which exploits news title simplicity to perform annotation;
- We conduct extensive experiments on RuSentRel (Loukachevitch and Rusnachenko, 2018) and the results demonstrate that CNNs trained on two types of training data achieve F1-score increase by 13.4% over models that do not employ obtained corpus in training.

2 Related Work

The task of attitude recognition toward named entities or events, including opinion holder identification from full texts did not attract much attention. In 2014, the TAC evaluation conference in Knowledge Base Population (KBP) track included so-called sentiment track (Ellis et al., 2014). The task was to find all the cases where a query entity (sentiment holder) holds a positive or negative sentiment about another entity (sentiment target). Thus, this task was formulated as a query-based retrieval of entity-sentiment from relevant documents and focused only on query entities[2].

MPQA 3.0 (Deng and Wiebe, 2015b) is a corpus of analytical articles with annotated opinion expressions (towards entities and events). The annotation is sentence-based. For example, in the sentence «When the Imam issued the fatwa against Salman Rushdie for insulting the Prophet ...», Imam is negative to Salman Rushdie but is positive to the Prophet.

In paper (Choi et al., 2016), authors studied the approach to the recovery of the documents attitudes between subjects mentioned in the text. The approach considers such features as frequency of a named entity in the text, relatedness between entities, direct-indirect speech, etc. The best quality of opinion extraction obtained in this work was only about 36% F-measure, which shows that the necessity of improving extraction of attitudes at the document level is significant and this problem has not been sufficiently studied.

A corpus of analytical articles, obtained from authoritative foreign sources and translated into Russian has been invented in (Loukachevitch and Rusnachenko, 2018). The collected articles contain both the author's opinion on the subject matter of the article and a large number of attitudes mentioned between the participants of the described situations. Authors experiment with automatic attitudes extraction within the developed corpus. In comparison with (Choi et al., 2016) where documents much smaller and written in English, authors mentioned the closest F-measure and conclude that the task still remains complicated.

Each attitude may be considered in terms of related article context, or sentence. The sentence consists of words which could be gathered and treated as an *embedding*, where each word represents a feature vector. Convolving embedded sentence representation by a set of different filters, in paper (Zeng et al., 2014) authors implemented and trained the Convolutional Neural Network (CNN) model for the relation classification task. Being applied for the SemEval-2010 Task 8 (Hendrickx et al., 2009), the obtained model significantly outperformed the results of other participants.

This idea was developed further in terms of *max-pooling* operation (Zeng et al., 2015). This is an operation, which is applied to the convolved by filters data and extracts the maximal values within each convolution. However, for the relation classification task, original max-pooling reduces information extremely rapid and blurs significant relation aspects. Authors proposed to treat each convolution in parts. The division into parts depends on attitude entities: *inner* (between entities), and *outer*. This approach resulted in an advanced architecture model and was dubbed as "Piecewise Convolutional Neural Network" (PCNN).

3 Resources

This section describes resources (collections and lexicons) that were used for the dataset annotation.

3.1 RuSentRel Collection

In our experiments, we use the RuSentRel corpus[3] consisted of analytical articles from Internet-portal `inosmi.ru` (Loukachevitch and Rusnachenko, 2018) devoted to international relations. In this corpus, the manual annotation of the sentiment attitudes towards mentioned named entities had been carried out at the document level. The annotation is subdivided into two subtypes:

- The author's relation to mentioned named entities;
- The relation of subjects expressed as named entities to other named entities.

An analytical document can refer to an entity with several variants of naming (*Vladimir Putin – Putin*), synonyms (*Russia – Russian Federation*), or lemma variants generated from different wordforms. For correct inference of attitudes between named entities in the whole document, the corpus is provided with a list of variant names for the same entity found in the corpus.

[2] https://tac.nist.gov/2014/KBP/Sentiment/index.html

[3] https://github.com/nicolay-r/RuSentRel/tree/v1.1

In this paper, we utilize RuSentRel corpus in experiments for the proposed approach. Table 1 describes the corpus statistics.

Parameter	Value
Number of documents	73
Total opinion pairs	1361
Sentences (avg./doc.)	105.75
Opinion pairs (avg./doc.)	18.64
Positive opinion pairs (avg./doc.)	8.71
Negative opinion pairs (avg./doc.)	9.93
Avg. dist. between named entities within a sentence in words	10.2

Table 1: Attitude statistics of RuSentRel-v1.1 corpus.

3.2 RuSentiFrames Lexicon

The RuSentiFrames[4] lexicon describes sentiments and connotations conveyed with a predicate in a verbal or nominal form (Rashkin et al., 2016; Klenner and Amsler, 2016). The structure of the frames includes the set of predicate-specific roles and frame dimensions.

For role designation, the approach of PropBank (Palmer et al., 2005) is used. In this approach, individual verb's semantic arguments are numbered, beginning with zero. For a particular verb, Arg0 is generally the argument exhibiting features of a Prototypical Agent (Dowty, 1991), while Arg1 is a Prototypical Patient or Theme.

In the main part of the frame, the following dimensions are described:

- the attitude of the author of the text towards mentioned participants;
- positive or negative sentiment between participants;
- positive or negative effects to participants;
- positive or negative mental states of participants related to the described situation.

All assertions are provided with the score of confidence, which currently has two values: 1, if this assertion is true almost always, or 0.7, the assertion is considered in default. We do not describe assertions about neutral sentiment, effect or state of participants.

Type of lexical unit	Number
Verbs	2 794
Nouns	822
Phrases	2 401
Other	49
Unique entries	6 036
Total entries	6 412

Table 2: Quantitative characteristics of the RuSentiFrames entries.

The created frames are associated not only with a single entry but with a "family" of related words and expressions, which have the same attitudes. The following lexical units can be associated with a sentiment frame: single words, idioms, light verb constructions, and some other multiword expressions.

Currently, RuSentiFrames contains 277 frames with 6,412 associated *frame entries*. Table 2 shows the distribution of the RuSentiFrames entries according to parts of speech (POS) and other characteristics. Let us consider frame "Одобрить" (Approve) presented in Example 1.

Example 1: Frame "Одобрить" (Approve)

```
"roles": {"a0": "who approves",
          "a1": "what is approved"}
"polarity": {["a0", "a1", "pos", 1.0],
             ["a1", "a0", "pos", 0.7]},
"effect": {["a1", "pos", 1.0]},
"state": {["a0", "pos", 1.0],
          ["a1", "pos", 1.0]}
```

Nowadays, the lexicon is under development. For the proposed distant supervision approach, we utilize only the dimension of attitudes towards Prototypical Patient conveyed by Prototypical Agent. Table 3 provides related statistics.

Effect	Sentiment	Number
A0 → A1	pos	2 252
A0 → A1	neg	2 802

Table 3: The distribution of RuSentiFrames text entries according to attitudes.

3.3 News Collection

The collection to be used for sentiment attitude extraction consists of Russian articles and news of major news sources, specialized political sites, and

[4] https://github.com/nicolay-r/RuSentiFrames/tree/v1.0

Russian sites of world known news agencies published in 2017.

Each article is separated into the title and the contents. The collection statistics presented in Table 4.

Parameter	Value
Number of documents	2.8×10^6
Sentences (avg./doc.)	13.24

Table 4: News collection statistics.

4 Automatic Forming of Training Collection for Sentiment Attitude Extraction

This section discusses two different methods of sentiment attitude annotation: pair-based, and frame-based. Both methods apply to the title as it provides the main idea of the article and usually has a relatively simple sentence structure. Figure 1 illustrates the collection development flow. Further subsections describe the flow components in detail.

4.1 Text Processing and Named Entity Recognition

For attitude extraction, it is necessary to parse a text. This process involves the *tokenization* to demarcate text string into words and punctuation signs. Numbers and URL-links are considered as non-meaningful and masked.

Each attitude is based on a pair of named entities. For named entity recognition (NER, Figure 1), we utilize the following resources:

1. The pre-trained neural network model[5], which is state-of-the-art for the Russian language (Burtsev et al., 2018);

2. The list of named entities from RuSentRel corpus, organized in *authorized objects*.

The list of authorized objects is necessary to avoid accidental misses from the NER model.

The text of news articles may refer to an entity in several naming variants (Putin – Vladimir Putin), and synonyms (EU – Europe). To match named entity synonyms, in this paper we utilize both stemming[6] and list of synonyms, provided along with the RuSentRel corpus.

4.2 Pair-Based Annotation

This attitude annotation method utilizes the preassigned attitudes organized in a *list of pairs* (Figure 1).

Given a processed title with labeled named entities set E, we select pairs $\{\langle e_i, e_j\rangle \mid e_i, e_j \in E\}$, suitable for sentiment attitudes role. For relevant pairs filtering, the following restrictions should be met:

1. The presence of synonymous attitude in a given attitudes list;

2. All the entities appeared between pair endings should be authorized objects;

However, in a specific sentence, the supposed relation between countries can be false. For example, in the sentence "Зрители смогут увидеть показательные выступления спортсменов - чемпионов России и Европы" (Spectators will be able to see demonstrations of athletes - champions of Russia and Europe), prior negative relations between Russia and Europe are not mentioned. Therefore we need an additional factor to provide the quality of the annotation, and the RuSentiFrames lexicon can be used as such a factor.

4.3 Frame-Based Annotation

This attitude annotation method utilizes frame entries from the RuSentiFrames lexicon. Given a processed title with labeled named entities set E, an entry pair with $e_i, e_j \in E$, where e_i appears before e_j, considered as sentiment attitude when all the following criteria are met:

- All the frame entries between e_i and e_j have polarity;

- All the entities that appeared between e_i and e_j should be authorized.

We assign a positive sentiment score when all the polarities of inner frame entries have a positive sentiment. Otherwise, it assigns the negative sentiment score. We also consider frame entry polarity as *inverted*, when it is used with "не" (not) particle.

4.4 Attitude Filtering

To combine the annotation methods described above (attitudes filter, Figure 1), we intersect the annotations and separate the intersection into the

[5] https://github.com/deepmipt/ner

[6] https://tech.yandex.ru/mystem/

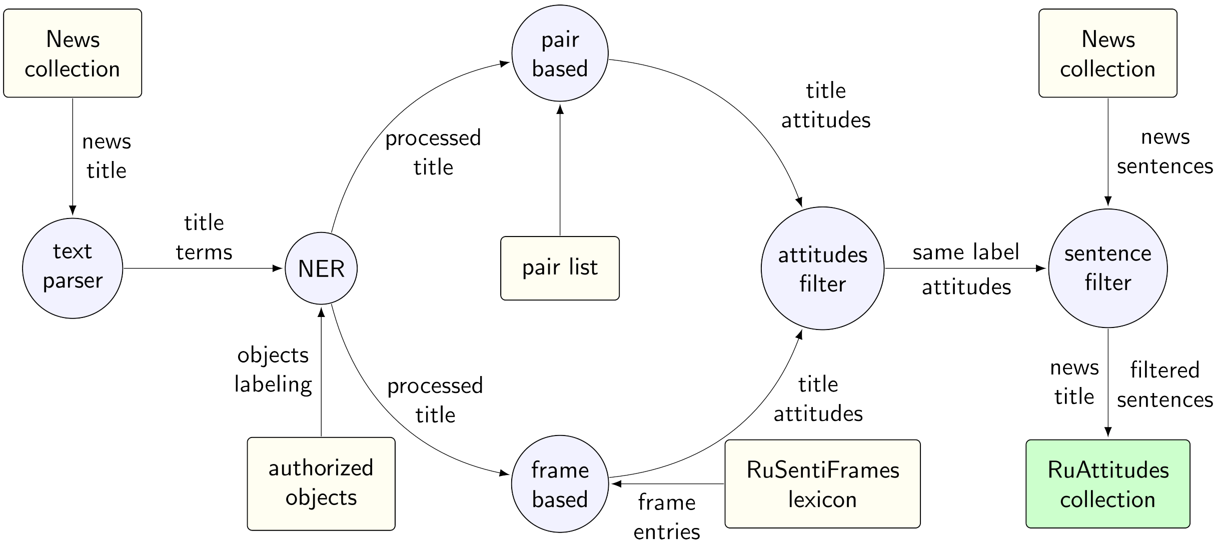

Figure 1: Training collection development flow

following sets: (i) with the same polarity and (ii) with different polarity according to both sources.

In the case of the non-empty set with the same polarity (SAME), at last step we utilize *sentence filter* (Figure 1). Given a set of processed news sentences, we select those which contain at least a single entity pair, presented in the SAME set.

Corpus	doc. level attitudes	texts count	titles and sentences
Pair-Based	60 788	52 377	136 496
Frame-Based	55 566	43 383	104 205
Intersection	22 589	20 885	50 958
Different	7 929	7 435	17 939
Same RuAttitudes	14 660	13 450	33 019

Table 5: The statistics of automated annotation of texts and sentences.

Finally, the workflow (Figure 1) is applied to the news collection (Section 3.3), and we obtain the **RuAttitudes**[7] dataset, automatically labeled with sentiment attitudes between named entities. Table 5 provides statistics separately for each step. Evaluated accuracy of randomly selected sentences from different texts presented in Table 6.

5 Convolutional Neural Networks for Attitude Classification

For automatic sentiment attitude classification, the following CNN-based architectures were used:

Corpus	Accuracy
Pair-Based	67.0
Frame-Based	62.5
RuAttitudes	89.0

Table 6: Accuracy of attitude annotation in the generated collections.

- Classic CNN (Zeng et al., 2014);
- Piecewise-CNN (Zeng et al., 2015);

To predict the attitude polarity, both models utilize sentences in the input. Given a context (a set of sentences) with a mentioned attitude in it, the output of models is the class label. Two different approaches to training were considered: single-sentence training and multi-sentence training.

5.1 Sentence Embedding

We use *sentence embedding* to present sentences in model input. This is a matrix with rows related to words or token (for example, punctuation marks) embeddings.

For words, we look up for vectors in precomputed and publicly available Word2Vec model[8] based on news articles with *window size* of $w = 20$. For tokens, we utilize a set of predefined types (size of 17), where each type is a randomly initialized vector of the same size as word vector.

Each word and token vectors have been additionally expanded with the following features:

[7] https://github.com/nicolay-r/RuAttitudes/tree/v1.0

[8] http://rusvectores.org/static/models/rusvectores2/news_mystem_skipgram_1000_20_2015.bin.gz

- Distance embedding (Rusnachenko and Loukachevitch, 2018) – is vectorized distance in words from entities e_i and e_j of an entry pair $\langle e_i, e_j \rangle$ to a given word or token;

- Part-of-speech (POS) tags embedding; we use "unknown" tag in case of tokens.

For features, we use randomly initialized vectors. Table 7 provides parameter values of each embedding described above.

Type	Parameters	Values
POS	v_{size}	5
Distance	v_{size}	5
Tokens	$\langle size, l_t \rangle$	$\langle 17, 10^3 \rangle$
Words	$\langle size, l_w, w \rangle$	$\langle 147 \cdot 10^3, 10^3, 20 \rangle$

Table 7: Embedding parameters, where v_{size} is the size of embedding vectors.

5.2 Single Sentence Training

This training process assumes to predict a sentiment label by a single sentence. Given an attitude context, we consider that each sentence should be labeled with an attitude sentiment.

We utilize training process described in (Rusnachenko and Loukachevitch, 2018). The input organized in minibatches, which yields n *bags*.

Each bag has a set of m sentences $\{s_1, \ldots, s_m\}$, where $s_j = \langle e_s, y \rangle$ includes sentence embedding e_s and related label $y \in \mathbb{R}^c$. The training process is iterative, and iteration includes the following steps:

1. Composing a minibatch $I = \{b_1, \ldots, b_n\}$ where $b_i = \{s_1, \ldots, s_m\}$;

2. Performing a forward propagation through the network; the result is a vector $\{o_k\}_{k=1}^q$, where $o_k \in \mathbb{R}^c$, and $q = n \cdot m$;

3. Computing cross entropy loss for output:

$$l_k = \sum_{j=1}^{c} \log p(y_i | o_{k,j}; \theta), \; k \in \overline{1 \ldots q} \quad (1)$$

4. Composing cost vector $\{cost_i\}_{i=1}^n$, where $cost_i = \max \left[l_{i \cdot g} \; \ldots \; l_{(i+1) \cdot g} \right)$ is a maximal loss within i'th bag;

5. Using *cost* to update hidden variables set;

5.3 Multiple Sentence Training

This training process assumes to predict a sentiment label for sentences set. This process refers to a single sentence case described in Section 5.2 with the following modifications:

- Each minibatch presented as a sequence of n bags $b_i = \langle E_s, y \rangle$, where E_s is a set of embedded sentences (Section 5.2);

- Result output vector $\{o_l\}_{l=1}^n$ obtained by an application of max-pooling operation over separately convolved context sentences (Jiang et al., 2016);

6 Datasets and Experimential Setup

We consider the problem of sentiment attitudes classification as a two-class task at the document level. We conduct three different experiments using the following datasets:

1. RA – RuAttitudes dataset, described in this paper (Section 4);

2. RSR – RuSentRel based dataset with sentence-level attitude labeling (Section 3.1);

3. RSR+RA – a combination of RSR and RA datasets;

By default, the RuSentRel dataset provides a document level attitude labeling. This labeling was used to complete RSR and therefore treat RuSentRel in the same format as RuAttitudes. We consider sentence-level attitudes as bidirectional pairs of named entities. We filter sentences from RuSentRel with sentiment pairs according to the following rule. For each sentence among the all documents we check, whether at least a single pair has the labeled attitude, presented in document attitude annotation.

Statistical comparison of the RSR and RuAttitudes datasets is presented in Table 8. We use 10-fold cross-validation (CV) in RA experiment. In other experiments, the 3-fold CV has been chosen due to a small number of documents in RSR dataset. In experiments with RSR+RA, the cross-validation procedure applies to RSR; the RuAttitudes dataset combines with each training block of RSR. It is worth noting that RuSentRel sentences have a larger amount of opinions per sentences (2.26), mainly due to the nature of their content – these are analytical articles, while RuAttitudes has been based on news reports. This fact makes experiments with the RSR dataset significantly challenging.

For models to be trained, we apply *named entity masking* for pairs due to: (i) omit entity-related feature dependency, and (ii) prevent models from learning the distribution of the latter.

Parameter	RuAttitudes	RSR
Documents	20 855	73
k-fold cross-validation	10	3
Opinions on sentence level	35 125	2 879
Negative opinion pairs	26 904	1 602
Positive opinion pairs	8 221	1 277
Avg. opinions per sentence	1.06	**2.26**
Avg. sentences per opinion	2.40	2.57

Table 8: Comparison of RuAttitudes and RuSentRel based (RSR) datasets for experiments.

Description	Parameters	Values
Minibatch	$\langle n, m\rangle$	$\langle 8, 3\rangle$
Optimiser	$\langle lr, \rho, \epsilon\rangle$	$\left\langle 0.1, 0.95, 10^{-6}\right\rangle$
Terms	k	50
Window size	w	3
Filters count	c	300
Dropout	ρ	0.9

Table 9: Predefined training parameters.

Table 9 illustrates model parameter values. Each minibatch has n bags. As for the sentence count per bag parameter, we select $m = 3$ to cover the average sentence count per opinion (Table 8). To translate the labels onto the document level, we utilize *average* function across all the sentences (sentence sets) of a given attitude. All the sentences were limited by k words, including tokens. Each word is considered in a lemmatized[9] form. The convolutional window size and the filters count were chosen according to (Zeng et al., 2015). We use the *adadelta* optimizer with parameters according to (Zeiler, 2012).

Several baselines were also added in experiments: **baseline_neg** – all pairs of named entities are labeled as negative; **baseline_rand** – pairs are labeled randomly according to the sentiment distribution in the training collection;

We measure average values of accuracy every five epochs. The training process terminates if one of the following conditions are met: (i) average epoch accuracy reaches 99%; (ii) the training error exceeds the prior related value (except RSR experiment). The latter exception is due to an unstable training process, that might be caused by the relatively small training set passed per a single epoch.

For this task, we adopt macroaveraged (over documents): F1-score (F_1^{PN}), precision (π^{PN}), and recall (ρ^{PN}).

7 Result Analysis and Discussion

Table 10 provides the results of both evaluated baselines and models for each dataset. For RuAttitudes dataset, where the negative class significantly exceeds positive, and most documents lack positive attitudes, both baselines show high values.

For a certain model and related experiments α and β, let $C_{\alpha,\beta}$ is a set of labeling contradictions of two experiments. All the pairs of contradictions could be then treated as correctly or wrongly labeled by each experiment. We let $C^*_{\alpha,\beta}$ as a subset of contradictions where β corrects the errors of α. This subset yields of only those pairs, where the sentiment class has been correctly defined in β. Table 11 provides the comparison statistics between RSR and RSR+RA experiments, separately for each model, where $|L|$ is an opinion pairs count (Table 1). While the contradiction represents 34% of total opinion pairs, with an average 61% of corrections and 38% of wrong labeling, we can conclude the average result error corrections are 7% in case of RSR+RA experiment (Table 10).

The contribution of RuAttitudes corpus in RSR+RA experiment could be considered in terms of frequencies of following entry types E: nouns, verbs, frames. Due to the task considered as sentiment attitudes classification, it is significant to separate statistics by positive and negative classes. To define a sentence class, we utilize sentiment of attitude that appears in it. We utilize semantic orientation (SO) function (Turney, 2002) to reveal a discrepancy in entries between sentiment classes:

$$SO(e) = PMI(e, pos) - PMI(e, neg) \quad (2)$$

where $PMI(e, c)$ is a *pointwise mutual information* of entry e and sentiment class c. For each entry type separately, we utilize Formula 2 towards RuAttitudes to complete a set of entries, bounded with positive ($SO(e) > 0$) and negative ($SO(e) < 0$) classes. We order these sets by descending of $|SO(e)|$ to select k most distinctive entries and complete RA^c_k subsets, $c \in \{pos, neg\}$.

V_{neg}	«обвинять» (to blame)	0.05
	«вводить» (to introduce)	0.06
	«продлять» (to extend)	0.00
F_{neg}	«наказать» (to punish)	**0.59**
	«обвинить» (to blame)	0.06
	«бороться» (to fight)	0.44

Table 12: List of $k = 3$ most distinctive nouns (N), verbs (V), and frames (F) of RA_k^c with related frequencies in $C^*_{2,3}$; E is an entry type.

To assess how RuAttitudes effects on error corrections, we provide statistic of entries both appears in $C^*_{2,3}$ and RA_k^c. For each entry $e \in RA_k^c$ we calculate $tf(e, C^*_{2,3})$ – is an averaged (among all models) normalized term frequency of entry e in $C^*_{2,3}$. Table 12 lists three ($k = 3$) most distinctive entries by each entry type, where entries with $tf(e, C^*_{2,3}) > 0.5$ are bolded. It is possible to investigate that $C^*_{2,3}$ mostly saturated with positively bounded frames of RA_k^{pos} and negatively bounded nouns of RA_k^{neg}.

Conclusion

This paper proposes an approach to the automatic development of a train collection for the sentiment attitude extraction task in the news domain. The combination of two different techniques was used to provide the double-check and keep labeled results of the common intersection. The first proposed technique obtains contexts by a manually implemented list of pairs of named entities with sentiment scores. The other technique, on the contrary, extracts relations from contexts using sentiment frames. The latter became possible due to the assumption of title simplicity.

Sentiment attitude extraction was considered as a two-class classification task. This result analysis demonstrates the model classification improvements achieve 13.4% increase in F_1^{PN} when the latter being trained with the developed collection.

In further work, we plan to address the shortcomings in the following directions: to emphasize the difference between sentiment and non-sentiment relations and to reduce noisy labeling of the existed approach.

Acknowledgments

The reported study was funded by RFBR according to the research project № 19-37-50001. The development of Russian sentiment frames is supported by the RFBR research project № 16-29-09606.

Self-Attentional Models Application in Task-Oriented Dialogue Generation Systems

Mansour Saffar Mehrjardi, Amine Trablesi, Osmar R. Zaïane
Department of Computing Science, University of Alberta
{saffarme,atrabels,zaiane}@ualberta.ca

Abstract

Self-attentional models are a new paradigm for sequence modelling tasks which differ from common sequence modelling methods, such as recurrence-based and convolution-based sequence learning, in the way that their architecture is only based on the attention mechanism. Self-attentional models have been used in the creation of the state-of-the-art models in many NLP tasks such as neural machine translation, but their usage has not been explored for the task of training end-to-end task-oriented dialogue generation systems yet. In this study, we apply these models on the three different datasets for training task-oriented chatbots. Our finding shows that self-attentional models can be exploited to create end-to-end task-oriented chatbots which not only achieve higher evaluation scores compared to recurrence-based models, but also do so more efficiently.

1 Introduction

Task-oriented chatbots are a type of dialogue generation system which tries to help the users accomplish specific tasks, such as booking a restaurant table or buying movie tickets, in a continuous and uninterrupted conversational interface and usually in as few steps as possible. The development of such systems falls into the Conversational AI domain which is the science of developing agents which are able to communicate with humans in a natural way (Ram et al., 2018). Digital assistants such as Apple's Siri, Google Assistant, Amazon Alexa, and Alibaba's AliMe are examples of successful chatbots developed by giant companies to engage with their customers.

There are mainly two different ways to create a task-oriented chatbot which are either using set of hand-crafted and carefully-designed rules or use corpus-based method in which the chatbot can be trained with a relatively large corpus of conversational data. Given the abundance of dialogue data, the latter method seems to be a better and a more general approach for developing task-oriented chatbots. The corpus-based method also falls into two main chatbot design architectures which are pipelined and end-to-end architectures (Chen et al., 2017). End-to-end chatbots are usually neural networks based (Shang et al., 2015; Dodge et al., 2015; Wen et al., 2016; Eric and Manning, 2017a) and thus can be adapted to new domains by training on relevant dialogue datasets for that specific domain. Furthermore, all sequence modelling methods can also be used in training end-to-end task-oriented chatbots. A sequence modelling method receives a sequence as input and predicts another sequence as output. For example in the case of machine translation the input could be a sequence of words in a given language and the output would be a sentence in a second language. In a dialogue system, an utterance is the input and the predicted sequence of words would be the corresponding response.

Self-attentional models are a new paradigm for sequence modelling tasks which differ from common sequence modelling methods, such as recurrence-based and convolution-based sequence learning, in the way that their architecture is only based on the attention mechanism. The Transformer (Vaswani et al., 2017) and Universal Transformer (Dehghani et al., 2018) models are the first models that entirely rely on the self-attention mechanism for both encoder and decoder, and that is why they are also referred to as a self-attentional models. The Transformer models has produced state-of-the-art results in the task neural machine

Proceedings of Recent Advances in Natural Language Processing, pages 1031–1040,
Varna, Bulgaria, Sep 2–4 2019.

translation (Vaswani et al., 2017) and this encouraged us to further investigate this model for the task of training task-oriented chatbots. While in the Transformer model there is no recurrence, it turns out that the recurrence used in RNN models is essential for some tasks in NLP including language understanding tasks and thus the Transformer fails to generalize in those tasks (Dehghani et al., 2018). We also investigate the usage of the Universal Transformer for this task to see how it compares to the Transformer model.

We focus on self-attentional sequence modelling for this study and intend to provide an answer for one specific question which is:

- How effective are self-attentional models for training end-to-end task-oriented chatbots?

Our contribution in this study is as follows:

- We train end-to-end task-oriented chatbots using both self-attentional models and common recurrence-based models used in sequence modelling tasks and compare and analyze the results using different evaluation metrics on three different datasets.

- We provide insight into how effective are self-attentional models for this task and benchmark the time performance of these models against the recurrence-based sequence modelling methods.

- We try to quantify the effectiveness of self-attention mechanism in self-attentional models and compare its effect to recurrence-based models for the task of training end-to-end task-oriented chatbots.

2 Related Work

2.1 Task-Oriented Chatbots Architectures

End-to-end architectures are among the most used architectures for research in the field of conversational AI. The advantage of using an end-to-end architecture is that one does not need to explicitly train different components for language understanding and dialogue management and then concatenate them together. Network-based end-to-end task-oriented chatbots as in (Wen et al., 2016; Bordes et al., 2016) try to model the learning task as a policy learning method in which the model learns to output a proper response given the current state of the dialogue. As discussed before, all encoder-decoder sequence modelling methods can be used for training end-to-end chatbots. Eric and Manning (2017a) use the copy mechanism augmentation on simple recurrent neural sequence modelling and achieve good results in training end-to-end task-oriented chatbots (Gu et al., 2016).

Another popular method for training chatbots is based on memory networks. Memory networks augment the neural networks with task-specific memories which the model can learn to read and write. Memory networks have been used in (Bordes et al., 2016) for training task-oriented agents in which they store dialogue context in the memory module, and then the model uses it to select a system response (also stored in the memory module) from a set of candidates. A variation of Key-value memory networks (Miller et al., 2016) has been used in (Eric and Manning, 2017b) for the training task-oriented chatbots which stores the knowledge base in the form of triplets (which is (subject,relation,object) such as (yoga,time,3pm)) in the key-value memory network and then the model tries to select the most relevant entity from the memory and create a relevant response. This approach makes the interaction with the knowledge base smoother compared to other models.

Another approach for training end-to-end task-oriented dialogue systems tries to model the task-oriented dialogue generation in a reinforcement learning approach in which the current state of the conversation is passed to some sequence learning network, and this network decides the action which the chatbot should act upon. End-to-end LSTM based model (Williams and Zweig, 2016), and the Hybrid Code Networks (Williams et al., 2017) can use both supervised and reinforcement learning approaches for training task-oriented chatbots.

2.2 Sequence Modelling Methods

Sequence modelling methods usually fall into recurrence-based, convolution-based, and self-attentional-based methods. In recurrence-based sequence modeling, the words are fed into the model in a sequential way, and the model learns the dependencies between the tokens given the context from the past (and the future in case of bidirectional Recurrent Neural Networks (RNNs)) (Goodfellow et al., 2016). RNNs and their variations such as Long Short-term Memory

(LSTM) (Hochreiter and Schmidhuber, 1997), and Gated Recurrent Units (GRU) (Cho et al., 2014) are the most widely used recurrence-based models used in sequence modelling tasks. Convolution-based sequence modelling methods rely on Convolutional Neural Networks (CNN) (LeCun et al., 1998) which are mostly used for vision tasks but can also be used for handling sequential data. In CNN-based sequence modelling, multiple CNN layers are stacked on top of each other to give the model the ability to learn long-range dependencies. The stacking of layers in CNNs for sequence modeling allows the model to grow its receptive field, or in other words context size, and thus can model complex dependencies between different sections of the input sequence (Gehring et al., 2017; Yu and Koltun, 2015). WaveNet (2016), used in audio synthesis, and ByteNet (2016), used in machine translation tasks, are examples of models trained using convolution-based sequence modelling.

3 Models

We compare the most commonly used recurrence-based models for sequence modelling and contrast them with Transformer and Universal Transformer models. The models that we train are:

3.1 LSTM and Bi-Directional LSTM

Long Short-term Memory (LSTM) networks are a special kind of RNN networks which can learn long-term dependencies (Hochreiter and Schmidhuber, 1997). RNN models suffer from the vanishing gradient problem (Bengio et al., 1994) which makes it hard for RNN models to learn long-term dependencies. The LSTM model tackles this problem by defining a gating mechanism which introduces input, output and forget gates, and the model has the ability to decide how much of the previous information it needs to keep and how much of the new information it needs to integrate and thus this mechanism helps the model keep track of long-term dependencies.

Bi-directional LSTMs (Schuster and Paliwal, 1997) are a variation of LSTMs which proved to give better results for some NLP tasks (Graves and Schmidhuber, 2005). The idea behind a Bi-directional LSTM is to give the network (while training) the ability to not only look at past tokens, like LSTM does, but to future tokens, so the model has access to information both form the past and future. In the case of a task-oriented dialogue generation systems, in some cases, the information needed so that the model learns the dependencies between the tokens, comes from the tokens that are ahead of the current index, and if the model is able to take future tokens into accounts it can learn more efficiently.

3.2 Transformer

As discussed before, Transformer is the first model that entirely relies on the self-attention mechanism for both the encoder and the decoder. The Transformer uses the self-attention mechanism to learn a representation of a sentence by relating different positions of that sentence. Like many of the sequence modelling methods, Transformer follows the encoder-decoder architecture in which the input is given to the encoder and the results of the encoder is passed to the decoder to create the output sequence. The difference between Transformer (which is a self-attentional model) and other sequence models (such as recurrence-based and convolution-based) is that the encoder and decoder architecture is only based on the self-attention mechanism. The Transformer also uses multi-head attention which intends to give the model the ability to look at different representations of the different positions of both the input (encoder self-attention), output (decoder self-attention) and also between input and output (encoder-decoder attention) (Vaswani et al., 2017). It has been used in a variety of NLP tasks such as mathematical language understanding [110], language modeling (Dai et al., 2018), machine translation (Vaswani et al., 2017), question answering (Devlin et al., 2018), and text summarization (Liu et al., 2018).

3.3 Universal Transformer

The Universal Transformer model is an encoder-decoder-based sequence-to-sequence model which applies recurrence to the representation of each of the positions of the input and output sequences. The main difference between the RNN recurrence and the Universal Transformer recurrence is that the recurrence used in the Universal Transformer is applied on consecutive representation vectors of each token in the sequence (i.e., over depth) whereas in the RNN models this recurrence is applied on positions of the tokens in the sequence. A variation of the Universal Transformer, called Adaptive Universal

Transformer, applies the Adaptive Computation Time (ACT) (Graves, 2013) technique on the Universal Transformer model which makes the model train faster since it saves computation time and also in some cases can increase the model accuracy. The ACT allows the Universal Transformer model to use different recurrence time steps for different tokens.

We know, based on reported evidence that transformers are potent in NLP tasks like translation and question answering. Our aim is to assess the applicability and effectiveness of transformers and universal-transformers in the domain of task-oriented conversational agents. In the next section, we report on experiments to investigate the usage of self-attentional models performance against the aforementioned models for the task of training end-to-end task-oriented chatbots.

4 Experiments

We run our experiments on Tesla 960M Graphical Processing Unit (GPU). We evaluated the models using the aforementioned metrics and also applied early stopping (with delta set to 0.1 for 600 training steps).

4.1 Datasets

We use three different datasets for training the models. We use the Dialogue State Tracking Competition 2 (DSTC2) dataset (Williams et al., 2013) which is the most widely used dataset for research on task-oriented chatbots. We also used two other datasets recently open-sourced by Google Research (Shah et al., 2018) which are M2M-sim-M (dataset in movie domain) and M2M-sim-R (dataset in restaurant domain)[1]. M2M stands for Machines Talking to Machines which refers to the framework with which these two datasets were created. In this framework, dialogues are created via dialogue self-play and later augmented via crowdsourcing. We trained on our models on different datasets in order to make sure the results are not corpus-biased. Table 1 shows the statistics of these three datasets which we will use to train and evaluate the models.

Dataset	Num. of Slots	Train	Dev	Test
DSTC2	8	1618	1117	500
M2M-R	9	1116	349	775
M2M-M	5	384	120	264

Table 1: Statistics of DSTC2, M2M-R, and M2M-M Datasets

The M2M dataset has more diversity in both language and dialogue flow compared to the the commonly used DSTC2 dataset which makes it appealing for the task of creating task-oriented chatbots. This is also the reason that we decided to use M2M dataset in our experiments to see how well models can handle a more diversed dataset.

4.1.1 Dataset Preparation

We followed the data preparation process used for feeding the conversation history into the encoder-decoder as in (Eric and Manning, 2017a). Consider a sample dialogue D in the corpus which consists of a number of turns exchanged between the user and the system. D can be represented as $(u_1, s_1), (u_2, s_2), ..., (u_k, s_k)$ where k is the number of turns in this dialogue. At each time step in the conversation, we encode the conversation turns up to that time step, which is the context of the dialogue so far, and the system response after that time step will be used as the target. For example, given we are processing the conversation at time step i, the context of the conversation so far would be $(u_1, s_1, u_2, s_2, ..., u_i)$ and the model has to learn to output (s_i) as the target.

4.2 Training

We used the tensor2tensor library (Vaswani et al., 2018) in our experiments for training and evaluation of sequence modeling methods. We use Adam optimizer (Kingma and Ba, 2014) for training the models. We set $\beta_1 = 0.9$, $\beta_2 = 0.997$, and $\epsilon = 1e - 9$ for the Adam optimizer and started with learning rate of 0.2 with noam learning rate decay schema (Vaswani et al., 2017). In order to avoid overfitting, we use dropout (Srivastava et al., 2014) with dropout chosen from [0.7-0.9] range. We also conducted early stopping (Goodfellow et al., 2016) to avoid overfitting in our experiments as the regularization methods. We set the batch size to 4096, hidden size to 128, and the embedding size to 128 for all the models. We also used grid search for hyperparameter tuning for all of the trained models. Details of our training and hyperparameter tuning and the code for reproducing the results can be found in the *chatbot-exp*

github repository[2].

4.3 Inference

In the inference time, there are mainly two methods for decoding which are greedy and beam search (Freitag and Al-Onaizan, 2017). Beam search has been proved to be an essential part in generative NLP task such as neural machine translation (Wu et al., 2016). In the case of dialogue generation systems, beam search could help alleviate the problem of having many possible valid outputs which do not match with the target but are valid and sensible outputs. Consider the case in which a task-oriented chatbot, trained for a restaurant reservation task, in response to the user utterance *"Persian food"*, generates the response *"what time and day would you like the reservation for?"* but the target defined for the system is *"would you like a fancy restaurant?"*. The response generated by the chatbot is a valid response which asks the user about other possible entities but does not match with the defined target.

We try to alleviate this problem in inference time by applying the beam search technique with a different beam size $\alpha \in \{1, 2, 4\}$ and pick the best result based on the BLEU score. Note that when $\alpha = 1$, we are using the original greedy search method for the generation task.

4.4 Evaluation Measures

BLEU: We use the Bilingual Evaluation Understudy (BLEU) (Papineni et al., 2002) metric which is commonly used in machine translation tasks. The BLEU metric can be used to evaluate dialogue generation models as in (Eric and Manning, 2017a; Li et al., 2015). The BLEU metric is a word-overlap metric which computes the co-occurrence of N-grams in the reference and the generated response and also applies the brevity penalty which tries to penalize far too short responses which are usually not desired in task-oriented chatbots. We compute the BLEU score using all generated responses of our systems.

Per-turn Accuracy: Per-turn accuracy measures the similarity of the system generated response versus the target response. Eric and Manning (2017a) used this metric to evaluate their systems in which they considered their response to be correct if all tokens in the system generated response matched the corresponding token in the target response. This metric is a little bit harsh, and the results may be low since all the tokens in the generated response have to be exactly in the same position as in the target response.

Per-Dialogue Accuracy: We calculate per-dialogue accuracy as used in (Bordes et al., 2016; Eric and Manning, 2017a). For this metric, we consider all the system generated responses and compare them to the target responses. A dialogue is considered to be true if all the turns in the system generated responses match the corresponding turns in the target responses. Note that this is a very strict metric in which all the utterances in the

dialogue should be the same as the target and in the right order.

F1-Entity Score: Datasets used in task-oriented chores have a set of entities which represent user preferences. For example, in the restaurant domain chatbots common entities are meal, restaurant name, date, time and the number of people (these are usually the required entities which are crucial for making reservations, but there could be optional entities such as location or rating). Each target response has a set of entities which the system asks or informs the user about. Our models have to be able to discern these specific entities and inject them into the generated response. To evaluate our models we could use named-entity recognition evaluation metrics (Jiang et al., 2016). The F1 score is the most commonly used metric used for the evaluation of named-entity recognition models which is the harmonic average of precision and recall of the model. We calculate this metric by micro-averaging over all the system generated responses.

5 Results and Discussion

5.1 Comparison of Models

The results of running the experiments for the aforementioned models is shown in Table 2 for the DSTC2 dataset and in Table 3 for the M2M datasets. The bold numbers show the best performing model in each of the evaluation metrics. As discussed before, for each model we use different beam sizes (bs) in inference time and report the best one. Our findings in Table 2 show that self-attentional models outperform common recurrence-based sequence modelling methods in the BLEU, Per-turn accuracy, and entity F1 score. The reduction in the evalution numbers for the M2M dataset and in our investigation of the trained model we found that this considerable reduction is due to the fact that the diversity of M2M dataset is considerably more compared to DSTC2 dataset while the traning corpus size is smaller.

5.2 Time Performance Comparison

Table 4 shows the time performance of the models trained on DSTC2 dataset. Note that in order to get a fair time performance comparison, we trained the models with the same batch size (4096) and on the same GPU. These numbers are for the best performing model (in terms of evaluation loss and selected using the early stopping method) for each of the sequence modelling methods. Time to Convergence (T2C) shows the approximate time that the model was trained to converge. We also show the loss in the development set for that specific checkpoint.

5.3 Effect of (Self-)Attention Mechanism

As discussed before in Section 3.2, self-attentional models rely on the self-attention mechanism for sequence modelling. Recurrence-based models such as LSTM and Bi-LSTM can also be augmented in order to increase their performance, as evident in Table 2 which shows the increase in the performance of both LSTM and Bi-LSTM

Model	T2C (sec)	Dev Loss
LSTM	1100	0.89

Bi-LSTM	1865	0.60
Bi-LSTM+Att	2120	0.49
Transformer	**612**	**0.31**
UT	1939	0.36
UT+ACT	665	0.33

Table 4: Comparison of convergence performance of the models

when augmented with an attention mechanism. This leads to the question whether we can increase the performance of recurrence-based models by adding multiple attention heads, similar to the multi-head self-attention mechanism used in self-attentional models, and outperform the self-attentional models.

To investigate this question, we ran a number of experiments in which we added multiple attention heads on top of Bi-LSTM model and also tried a different number of self-attention heads in self-attentional models in order to compare their performance for this specific task. Table 6 shows the results of these experiments. Note that the models in Table 6 are actually the best models that we found in our experiments on DSTC2 dataset and we only changed one parameter for each of them, i.e. the number of attention heads in the recurrence-based models and the number of self-attention heads in the self-attentional models, keeping all other parameters unchanged. We also report the results of models with beam size of 2 in inference time. We increased the number of attention heads in the Bi-LSTM model up to 64 heads to see its performance change. Note that increasing the number of attention heads makes the training time intractable and time consuming while the model size would increase significantly as shown in Table 5. Furthermore, by observing the results of the Bi-LSTM+Att model in Table 6 (both test and development set) we can see that Bi-LSTM performance decreases and thus there is no need to increase the attention heads further.

Our findings in Table 6 show that the self-attention mechanism can outperform recurrence-based models even if the recurrence-based models have multiple attention heads. The Bi-LSTM model with 64 attention heads cannot beat the best Trasnformer model with NH=4 and also its results are very close to the Transformer model with NH=1. This observation clearly depicts the power of self-attentional based models and demonstrates that the attention mechanism used in self-attentional models as the backbone for learning, outperforms recurrence-based models even if they are augmented with multiple attention heads.

Model	T2C (sec)	Dev Loss

6 Conclusion and Future Work

We have determined that Transformers and Universal-Transformers are indeed effective at generating appropriate responses in task-oriented chatbot systems. In actuality, their performance is even better than the typically used deep learning architectures. Our findings in Table 2 show that self-attentional models outperform common recurrence-based sequence modelling methods in the BLEU, Per-turn accuracy, and entity F1 score. The results of the Transformer model beats all other models in all of the evaluation metrics. Also, comparing the result of LSTM and LSTM with attention mechanism as well as the Bi-LSTM with Bi-LSTM with attention mechanism, it can be observed in the results that adding the attention mechanism can increase the performance of the models. Comparing the results of self-attentional models shows that the Transformer model outperforms the other self-attentional models, while the Universal Transformer model gives reasonably good results.

In future work, it would be interesting to compare the performance of self-attentional models (specifically the winning Transformer model) against other end-to-end architectures such as the Memory Augmented Networks.

Abstract

Vectorial representations of meaning can be supported by empirical data from diverse sources and obtained with diverse embedding approaches. This paper aims at screening this experimental space and reports on an assessment of word embeddings supported (i) by data in raw texts vs. in lexical graphs, (ii) by lexical information encoded in association- vs. inference-based graphs, and obtained (iii) by edge reconstruction- vs. matrix factorisation vs. random walk-based graph embedding methods. The results observed with these experiments indicate that the best solutions with graph-based word embeddings are very competitive, consistently outperforming mainstream text-based ones.

1 Introduction

As neural networks are becoming a central technology in natural language processing, interest on distributional semantics, with its vector space models of meaning, has been a driving factor for research on natural language semantics. When focusing on the meaning of words under this approach, information on lexical semantics has been sought to be encoded into appropriate vectorial representations, also known as word embeddings. The source for this information has consisted mostly of large collections of raw text, and thus ultimately on the frequencies of co-occurrence of words with other neighbouring words in certain windows of context, (Mikolov et al., 2013a; Pennington et al., 2014; Mikolov et al., 2018) among others. A few research trends have been gaining momentum concerning the application of neural networks to natural language technology, and *a fortiori* in what concerns distributional semantics. On the one hand, there has been a growing interest in the linguistic information that may be ultimately encoded in vectorial representations (Belinkov et al., 2017; Conneau et al., 2018), also relating to their eventual ”universality”, in view of possibly transferring these representations from one language processing task or application to another (Shi et al., 2016; Cífka and Bojar, 2018).

On the other hand, growing attention has been devoted to sources of information for word embeddings other than what may be conveyed and extracted from co-occurrences in text. This includes information that is encoded in sophisticated lexical collections of data that are carefully crafted and densely loaded with accurate information on lexical semantics (Goikoetxea et al., 2015; Saedi et al., 2018).

The results reported in the present paper lies at the intersection of those research goals. In particular, we aim here to gain a better insight into these two sources of lexical information, and the quality of the resulting word embeddings, by assessing how graph-based word embeddings compare to mainstream text-based ones. To pursue this objective, we explore an experimental space that takes into account lexical semantic networks of essentially different types as well as different sorts of methods, with different strengths, to convert those graphs into embeddings. In the experimental space that will be explored here, text-based embeddings will be represented by top performing solutions from the literature.

In the next Sections 2 and 3, the lexical graphs and the graph embeddings techniques used are introduced. Each one of the following Sections 4 and 5 will indicate how each graph was handled and what was the outcome of applying graph embedding techniques to them.

Section 6 is devoted to ponder on the lessons that can be learned from the results obtained. Finally, in the last two Sections 7 and 8 the related work will be taken into account and the conclusions of this paper will be presented.

2 Lexical graphs

How to represent the meaning of words has been at the core of research on lexical semantics. Besides distributional semantics (Harris, 1954; Osgood et al., 1957) that word embeddings adhere to, two other broad families of approaches have emerged, namely those advocating that lexical semantics is better represented as a semantic network (Quillan, 1966) or as a feature-based model (Minsky, 1975; Bobrow and Norman, 1975).

In a nutshell, in an inference-based semantic network, a lexical unit, typically a word, is recorded as a node in a graph while the semantic relations among words, such as hyponymy or synonymy, etc., are recorded as labelled edges among the nodes of the graph — with the inference being ensured by the relation that happen to be transitive. Feature-based models representing lexical semantics, in turn, resort to a hash table that stores the lexical units as keys, and the semantically related units as the respective values.

The motivation for these two families of lexical representation is to be found in their different suitability and success in explaining a wide range of empirical phenomena, in terms of how these are manifest in ordinary language usage and how they are elicited in laboratory experimentation. These phenomena are related to the acquisition, storage and retrieval of lexical knowledge (e.g. the spread activation effect (Meyer and Schvaneveldt, 1971), the fan effect (Anderson, 1974), among many others) and to how this knowledge interacts with other cognitive faculties or tasks, including categorization (Estes, 1994), reasoning (Rips, 1975), problem solving (Holyoak and Koh, 1987), learning (Ross, 1984), etc. Feature-based models seek to respond primarily to our outstanding ability as speakers of associating concepts with other concepts, while inference-based ones seek to respond to the also outstanding ability to reason on the basis of semantic relations among concepts.

In the scope of the formal and computational modelling of lexical semantics, these approaches have inspired a number of initiatives to build repositories of lexical knowledge. Prominent examples of such repositories are, for semantic networks, WordNet (Fellbaum, 1998) and for feature-based models, Small World of Words (SWOW) (De Deyne et al., 2013). Interestingly, to achieve the highest quality, repositories of different types typically resort to different empirical sources of primary data. For instance, WordNet is constructed on the basis of lexical intuitions systematically handled by human experts, while the information encoded in Small World of Words are the associations between concepts evoked and collected from laypersons.

Even when motivated in the first place by (psycho-)linguistic research goals, these repositories of lexical knowledge have been extraordinarily important for language technology. They have been instrumental for major advances in language processing tasks and applications such as word sense disambiguation, part-of-speech tagging, named entity recognition, sentiment analysis (e.g. Li and Jurafsky (2015)), parsing (e.g. Socher et al. (2013)), textual entailment (e.g. Baroni et al. (2012)), discourse analysis (e.g. Ji and Eisenstein (2014)), among many others.[1]

In our experiments, we resort to these two major representatives of inference- and feature-based lexical networks, namely WordNet[2] and SWOW[3].

3 Graph embedding methods

As for methods to convert graphs into embedding, we are resorting also to one outstanding representative per major family of techniques.

Following the recent comprehensive survey by (Cai et al., 2017), graph embeddings methods divide into those that represent a whole graph as a single vector and those that output a vector for each node in the graph. For our experiments, we are interested in the latter, for which there are three major families of approaches, viz. based on edge reconstruction, on matrix factorisation and on random walks. Each of these techniques has its advantages and drawbacks, capturing the information encoded in the graph with different emphasis.

Graph embeddings techniques based on edge reconstruction operate on graphs represented by edge lists. An edge is a triple $\langle lhs, rel, rhs \rangle$, where lhs (left-hand side) and rhs (right-hand) are nodes connected by a relation of type rel. The system is trained to recognise triples that are feasible (present in the graph) from the infeasible ones.

The objective function optimised in the model

[1] For the vast number of applications of WordNet, see http://lit.csci.unt.edu/~wordnet

[2] Princeton's WordNet 3.0 is the version used here, obtained from http://wordnet.princeton.edu/ in February 2019.

[3] From http://github.com/SimonDeDeyne/SWOWEN-2018 in March 2019.

is either maximising the edge reconstruction probability or minimising the edge reconstruction loss. The latter can be further divided into distance-based loss and margin-based ranking loss. Since most of the existing knowledge graph embedding methods choose to optimise margin based ranking loss (Cai et al., 2017), we choose a method from this subgroup as a representative of the edge reconstruction models, namely Semantic Matching Energy (SME) from (Bordes et al., 2014).

Edge reconstruction methods support a relatively efficient training, but ensures optimisation using only local information between nodes close to each other.

Another family of graph embedding methods is based, in turn, on graphs represented by matrices. This is perhaps the family of techniques with the largest number of instances, which in many cases result from slight variants from one another in the tricks used to weight and condense the nodes in the matrix.

As a representative of the matrix factorisation methods for graph embedding, we use the so-called Katz index (Newman, 2010, Eq. (7.63)) as this is the technique used in previous works on WordNet (Saedi et al., 2018) and on SWOW (De Deyne et al., 2018).

This method starts by creating a matrix with all of the possible semantic relations between all the words, resulting in an adjacency matrix M. Then it populates each cell M_{ij} of the matrix resorting to a lexical semantic graph G. Each cell M_{ij} is set to 1 if and only if there is a direct edge between nodes including the two words $word_i$ and $word_j$ the cell represents. If there is no edge between the two words, that cell is set to 0. For all nodes not directly connected, that is connected through other nodes in between, the representation of their affinity strength is obtained by following the cumulative iteration:

$$M_G^n = I + \alpha M + \alpha^2 M^2 + \cdots + \alpha^n M^n \quad (1)$$

M^n is the matrix where every two words, $word_i$ and $word_j$, are transitively related by n edges. I represents the identity matrix and α is used as a decay factor for longer paths.

The iteration converges into the matrix M_G, obtained by an inverse matrix operation:

$$M_G = \sum_{e=0}^{\infty} (\alpha M)^e = (I - \alpha M)^{-1} \quad (2)$$

Matrix factorisation inverts the trade off found with edge reconstruction methods. Differently from the latter, it is able to take into account the affinity between nodes at the global level of the graph, but at the cost of a large time and space consumption though.

A third family of graph embedding methods is based on a ”text” generated from graphs, where the word embeddings are obtained from some deep learning technique used over that text. This is an ”artifical” text that results from concatenating the words in the nodes that are visited in a random walk through the edges in the graph.

Starting at a random node in the graph, at each iteration, this technique randomly chooses a neighbour node (with a probability α) to be the starting point of the next iteration or stopping the walk (with a probability 1 - α) .

Improving over the matrix factorisation and the edge reconstruction approaches, the random walk technique is effective and accommodates global information on the nodes. However, as it only considers the local context within a path at each iteration, that makes it hard to find an optimal sampling strategy.

In the next Sections, we report on the application of these three different graph embedding techniques, with their different advantages and drawbacks, over the two lexical networks, from two distinct lexical semantic families, thus encoding lexical knowledge from quite distinct primary sources of empirical data. This leads to different word embeddings that encode and emphasise different shades of lexical information, thus contributing to an encompassing and discriminating experimental space.

4 Inference-based graph embeddings

This section describes the conversion of WordNet to word embeddings under each of the three graph embedding techniques.

4.1 Edge reconstruction

In models based on edge reconstruction, the objective is to rank a true triplet $\langle lhs, rel, rhs \rangle$ over a false triplet $\langle lhs', rel, rhs' \rangle$ that does not exist in the graph. Under the SME technique (Bordes et al., 2014) we are following here, this is achieved by designing an energy function $f_{rel}(lhs, rhs)$, interpreted as a distance between the nodes lhs and rhs in the context of relation rel, where the energy value should be lower for feasible triplets and higher for infeasible ones. SME seeks to minimise the margin-based ranking loss, defined as:

$$O_{rank} = \min \sum_{\substack{\langle lhs,rel,rhs\rangle \in S \\ \langle lhs',rel,rhs'\rangle \notin S}} \max\Big(0, \gamma + f_{rel}(lhs, rhs) - f_{rel}(lhs', rhs')\Big) \tag{3}$$

where γ is the margin size (set by default to 1).

The SME function is designed as a neural network that first combines the nodes separately with the relation type, putting the combinations of $\langle lhs, rel\rangle$ and $\langle rel, rhs\rangle$ in a common space, where they can be *matched*. The matching is performed using a dot product of the resulting vectors. The combination function comes in two flavours: *linear* and *bilinear*. We opted for the former here given its lower complexity.

The triples were generated in the following manner: for each word w_{lhs} in the vocabulary and for each synset s_{lhs} this word belongs to, a triple is generated for each word w_{rhs} in each synset s_{rhs} (that w_{rhs} belongs to), such that there exists a relation rel between synsets s_{lhs} and s_{rhs}, and both w_{lhs} and w_{rhs} are in the vocabulary.

rel is one of the semantic relations used in WordNet.[4] Three of these relation types, namely *antonym, derivationally related form*, and *pertainym* exist not between synsets, but directly between the word forms (lemmas). These were also taken into account to generate triples.[5]

For training, we used a publicly available implementation of SME.[6] The models were trained for 500 epochs, with evaluation at every 10 epochs, a learning rate of 0.01 and 200 batches. The remaining parameters were left the same as the default ones used in Bordes et al. (2014). The model with the best performance on the validation set was picked.

Since the the edge reconstruction based methods are retaining the local neighbourhood only, we experimented also with extending the data sets by generating relations resulting from the concatenation of two simple relations. The data sets created in this way, however, suffer from an exponential growth in size. Due to resource limitations, we managed to conduct the experiments on a 15k vocabulary only, which gave significant boost in the performance of the model on the evaluation tasks. Further exploration of this path could be beneficial, but needs to be left for future work.

For a fair comparison with other methods, the data used for training the models is based though on the same 60k vocabulary as in the matrix factorisation based method (see details in Section 4.2), and thus eventually restricted to 1-hop relations. The vocabulary was selected with the same procedure as in Saedi et al. (2018). Also for the sake of comparison with the other experiments with text-based embeddings available from the literature (see details in Section 6), we chose vectors of dimension 300. Since there is a random element in the system (the initialisation of the neural network), we trained three models using different seeds for the random number generator and averaged the results.

4.2 Matrix factorisation

For matrix factorisation, we started by building an adjacency matrix from WordNet 3.0, which produced a square matrix of a size above 155k.

Tests with different weights for each type of relation — namely hyponymy and hyperonymy weighing the most, — showed that symmetrical weights performed the best. Also the parameters in equation 2 and other options to tackle computational complexity were empirically determined in and taken from Saedi et al. (2018).

The matrix inversion raises substantial challenges in terms of the memory footprint. To cope with this issue, we resorted to sub-graphs of WordNet of manageable size, and we will be using here a vocabulary with 60k words. To mitigate the impact of this downsizing, we sorted the words by the decreasing number of outgoing edges in the graph and picked the 60k top ones.

Another parameter to consider is the decay value (α) in equation 2, which discounts the strength of a connection if the nodes are far away from each other in the graph. Several values for α were experimented with, with 0.75 performing the best, which is also the value for α we used here.

After going through the procedure in equation 2, a Positive Point-wise Mutual Information transformation (PMI+) was applied to reduce the frequency bias, followed by an L2-norm to normalise each line of M_G, and finally, a Principal Compo-

[4] For a list of relation types, see http://wordnet.princeton.edu/documentation/wninput5wn.

[5] To extract the data from the WordNet 3.0 files, we used the NLTK library, available at www.nltk.org/_modules/nltk/corpus/reader/wordnet.html.

[6] http://github.com/glorotxa/SME.

nent Analysis (PCA) was applied to reduce the dimension of the vectors.

This procedure was evaluated with different vector sizes by Saedi et al. (2018), namely 100, 300, 850, 1000 and 3000, with 850 performing the best. For the sake of comparability with the other models we resort to, namely the text-based ones, we set a vector size of 300 for the matrix factorisation embedding technique.

4.3 Random walk

The random walk was based on UKB (Agirre and Soroa, 2009; Agirre et al., 2014; Goikoetxea et al., 2015), which performs a random walk through edges on graphs and in each step writes a word in the node into an artificial text. With the resulting corpus, a two-layer neural network model (Skip-Gram) (Mikolov et al., 2013b) was trained to predict for each vocabulary word its neighbouring words, thus generating in one of the layers the resulting word embedding vectors.

We restricted the original technique to use only the information from the graph and to ignore the glosses. The random walk was applied to the same WordNet graph (60k vocabulary) described in the Sections 4.1 and 4.2.

We discarded the three lemma-lemma relations not supported by UKB, namely antonym, derivationally related form, pertainym.

To create the artificial corpus, we used the default UKB random walk parameters[7] and to obtain the word embeddings, we used the default Gensim's (Řehůřek and Sojka, 2010) Skip-Gram implementation, with a vector dimension of 300.

4.4 Results

The assessment of the word embeddings obtained from the conversion of lexical graphs use the same tasks used for this purpose when the embeddings are obtained from corpora. These tasks consist in predicting the semantic similarity and the semantic relatedness between words in pairs and in seeking to match the gold scores assigned by humans to those test pairs. The cosine between the vectors of the words in a pair is mapped into the scale used for the gold scores.

For semantic similarity, we resorted to the test sets SimLex-999 (with 999 pairs) (Hill et al., 2016), WordSim-353-Similarity (203 pairs) (Agirre et al., 2009) and RG1965 (65) (Rubenstein and Goodenough, 1965). For semantic relatedness, WordSim-353-Relatedness (252) (Agirre et al., 2009), MEN (3000) (Bruni et al., 2012) and MTURK-771 (771) (Halawi et al., 2012) were used.

The results with WordNet embeddings are displayed in Table 1.[8]

	Edge	Factor.	Walk
Similarity			
Simlex-999	39.63±1.55	49.90	**50.93**±0.15
WordSim-353	54.93±2.31	50.80	**67.40**±0.30

Table 1: Performance of WordNet embeddings (columns) over test sets (rows) in terms of Spearman's Correlation Coefficient (higher is better), with deviation from averaging over three runs indicated where relevant. Bold denotes best results.

5 Feature-based graph embeddings

This section describes the conversion of SWOW to word embeddings under each of the three graph embedding techniques.

5.1 Edge reconstruction

The data for the application of the SME method was generated on the basis of the associative strength among words, described in detail in De Deyne et al. (2018). The vocabulary was restricted to their 12 216 cue words.

The relations were generated with the support of the associative strength files that were generated by using the publicly available implementation.[9] The strength file is generated for three association types separately (*R1, R2, R3*), which induced the three relation types taken into by the SME method with SWOW.

We used the same implementation and methodology as in Section 4.1. We empirically chose a smaller interval between the evaluations (every 5

[7] http://github.com/asoroa/ukb/

[8] The coverage of the test sets is the following: 100% of Simlex-999; 100% WordSim-353 S; 98.0% RG1965; 97.6% WordSim-353 R; 83.4% MEN; 99.9% MTurk-771.

[9] http://github.com/SimonDeDeyne/SWOWEN-2018

epochs instead of 10) and a lower learning rate (0.001 instead of 0.01) for a better training quality. The validation and test sets each made up for around 5% of the data set. For the sake of comparison, we again chose the vector size of 300.

Similarly, as in Section 4.1, we trained three models and average the results.

5.2 Matrix factorisation

We follow the same methodology, data and implementation in De Deyne et al. (2018). The data set contained 12 216 cue words, a shorter vocabulary and matrix than the one selected from WordNet.

The data is pre-processed before generating the adjacency matrix, where the cue words and responses are spell-checked, and the adjustment of capitalisation and americanisms takes place. From the cue-response data, only 100 participants for each cue are considered. Since each participant responded with three associated tokens, this associates each cue with 300 word instances.

The adjacency matrix was then created similarly to the matrix factorisation of WordNet in section 4.2, yielding a square matrix A_G, with every word displayed in the rows and in the columns. The cell A_{Gij} contains the associative strength of word i with word j, obtained from the frequency with which word j is responded when word i is cued.

The adjacency matrix is factorised using the same parameters as described in Section 4.2, namely with the decay factor α set at 0.75, and with a vector dimension of 300. Due to the small, 12k vocabulary available here, no extraction of a subset was necessary as it formed a data set computationally manageable.

The processing of the output matrix is also the same as in section 4.2, with an application of PMI+ to reduce frequency bias and PCA for dimension reduction.

5.3 Random walk

The random walk used the same technique as used for the inference-based graph, in Section 4.3.

The SWOW data set described in the previous Sections 5.1 and 5.2 was converted into a graph input for UKB. Each word in the vocabulary was considered a node. Each relation from a SWOW cue word to the associated word was considered as a relation between nodes. With the resulting graph, we created the artificial corpus by using the default UKB random walk parameters. To obtain the word embeddings, we used the default Gensim's Skip-Gram implementation (Řehůřek and Sojka, 2010) with vectors of dimension 300.

5.4 Results

The results with SWOW embeddings are displayed in Table 2.[10]

	Edge	Factor.	Walk
Similarity			
Simlex-999	54.13±6.20	67.80	**69.33**±0.06
WordSim-353	77.07±4.76	**85.00**	84.53±0.06
RG1965	83.50±4.50	**92.90**	90.23±0.49
Relatedness			
WordSim-353	70.70±3.68	**79.30**	77.73±0.23
MEN	78.50±3.90	**87.20**	84.27±0.06
MTurk-771	74.77±4.21	80.90	**81.10**±0.17

Table 2: Performance of SWOW embeddings (columns) over test sets (rows) in terms of Spearman's Correlation Coefficient (higher is better).

6 Discussion

The results in the Sections above were obtained with word embeddings whose source of information are specifically designed and carefully curated lexical collections whose primary empirical source of data are human lexical intuitions elicited and gathered under a tightly controlled experimental protocol. This range of results should be enlarged with results obtained also with word embeddings that have, as the source of lexical information, collections of raw texts that were produced with purposes other than to serve specifically for word embeddings.

6.1 Text-based embeddings

For this purpose, we resort to mainstream text-based word embeddings. For a fair comparison, we focus on embeddings that rely solely on lexical information, thus not possibly enhanced with supra-lexical information, like for instance Dependency word embeddings (Levy and Goldberg, 2014), etc. The three word embeddings selected are Glove (Pennington et al., 2014),[11] word2vec

[10] The coverage of the test sets is the following: 99.6% of Simlex-999; 83.1% WordSim-353 S; 90.6% RG1965; 87.3% WordSim-353 R; 89.4% MEN; 93.2% MTurk-771.

[11] These embeddings have Vectors of dimension 300 trained over 840B Token text. They were obtained from

(Mikolov et al., 2013a),[12] and fastText (Mikolov et al., 2018).[13]

The evaluation results for these text-based word embeddings are displayed in Table 3.

	Glove	word2vec	fastText
Similarity			
Simlex-999	37.52	43.61	**49.24**
WordSim-353	62.98	74.08	**79.74**
RG1965	65.77	74.77	**81.31**
Relatedness			
WordSim-353	57.09	60.97	**71.33**
MEN	67.65	69.89	**80.87**
MTurk-771	63.07	65.69	**76.13**

Table 3: Performance of text-based embeddings (columns) over test sets (rows) in terms of Spearman's Correlation Coefficient (higher is better).

The word embeddings trained with a 600B token collection of texts, fastText, outperforms the other ones trained with 100B (word2vec) and 840B (Glove) token collections.

6.2 Analysis

The experimental space explored gave rise to the range of results displayed in Tables 1 to 3. We discuss in turn the observed impact of different graph embedding techniques, different lexical graphs, and different sources of lexical information.

The edge reconstruction technique consistently delivers the worst results across all lexical graphs and test sets. The top position, in turn, is shared by the random walk and matrix factorisation methods. While the former originates the best results with WordNet for most test sets, the latter does so with SWOW.

A possible explanation for this contrast may lie in that the systematic and exhaustive structuring of WordNet with regards the semantic knowledge pertaining to a given node of the graph may mitigate (more than SWOW does) the known drawback of the random walk in terms of not ensuring an optimal sampling strategy.[14]

In the reverse direction, a factor that may be favouring matrix factorisation with SWOW may lie in that the systematic coverage of all the paths within the graph ensured by that technique may mitigate (more than random walk does) the less systematic nature of the lexical knowledge encoded in an association-based graph, like SWOW.

In what concerns comparison among lexical graphs, in turn, SWOW stands out as supporting results consistently far better for every test set than the ones supported by WordNet, with a range of deltas that go from 20% (15 points) with RG1965, to 159% (48 points) with WordSim-353 Relatedness. It is also interesting to note that the largest deltas are observed with data sets that test semantic relatedness, with deltas from 53% (28 points) with MTurk-771 to 159% (48 points) with WordSim-353, than with data sets for semantic similarity, with deltas from 20% (15 points) with RG1965, to 36% (18 points) with Simlex-999. This seems to indicate that the lexical knowledge necessary to solve the semantic tasks embodied in these test sets is better encoded in SWOW than in (a subset of) WordNet.

We look now into the impact of different sources of empirical data that inform word embeddings. While the best scores of text-based consistently outperform the best scores of WordNet embeddings, they are though consistently outperformed by the best scores of SWOW embeddings, with a range of deltas that go from 7% (5 points) with MTurk-771, to 41% (20 points) with Simlex-999. It is also interesting to note that the largest deltas are observed this time with data sets that test similarity, with deltas from 7% (5 points) with WordSim-353 Similarity to 41% (20 points) with Simlex-999, than with data sets for relatedness, with deltas from 8% (6 points) with MEN, to 11% (8 points) with WordSim-353 Relatedness.

As usual, this type of results needs to be taken with a prudent grain of salt. The kind of individual scores registered above depend on the size of the supporting data sets, be they graph- of text-based embeddings, and are expected to improve as the data sets get larger. Nevertheless, the patterns ob-

http://nlp.stanford.edu/projects/glove/ in February 2019.

[12] These embeddings have Vectors of dimension 300 trained over 100B Token text. They were obtained from http://code.google.com/archive/p/word2vec/ on 22/04/2019.

[13] These embeddings have Vectors of dimension 300 trained over 600B Token text. They were obtained from http://fasttext.cc/docs/en/english-vectors.html on 22/04/2019.

[14] It is of note that the random walk graph embedding technique is not limited by the excessive memory footprint of the matrix factorisation method, and it is thus probably even better suited to take advantage of the full information and strength of WordNet.

served with this experimental space seems to provide a clear indication that graph-based embeddings are very competitive, with the best scoring solutions consistently outperforming mainstream text-based ones by a substantial margin.

It is of note that this is obtained with data sets of a much smaller size (12k) than the ones used for text-based embeddings (600B) — whose collection can be obtained with quite affordable costs in the case of SWOW, the graph that is informing the top-performing embeddings.

7 Related Work

There have been some publications pioneering the issue of obtaining word embeddings from lexical semantic networks. Each has focused though on a particular graph embedding technique or in a particular lexical graph, and thus a systematic study of graph embeddings under comparable settings was not undertaken, and *a fortiori* a comparative assessment of their strengths with regards text-based ones is also lacking.

The application of Katz index for matrix factorisation was undertaken by De Deyne et al. (2016) over SWOW and by Saedi et al. (2018) over a WordNet subset. These are the results from previous works that we follow more closely here.

The graph embedding SME technique based on edge reconstruction was pioneered by Bordes et al. (2014), who applied it to a small WordNet subset restricted to 1-hop relations, which we expanded in the experiments reported here.

The random walk methods for graph embeddings were experimented with by Goikoetxea et al. (2015) over full WordNet. This however does not represent a ”purely” graph-based approach given the raw text in the glosses was also used. In our implementation here, the embeddings were based solely on the information in the graph.

In this connection, it is worthy of note the work by Hughes and Ramage (2007), which resorts also to random graph walks over WordNet. Differently, from the goal here, its goal was to obtain word-specific stationary probability distributions — such that the semantic affinity of two words is based on the similarity of their probability distributions —, rather than to obtain vectorial representations for words.

It is also worth mentioning that the task of determining the semantic similarity between two words can be performed not only on the basis of the distance of their respective vectors in a semantic space, but also on the basis of the distance of the respective concepts in the semantic network itself. There has been a research tradition on this issue whose major proposals include (Jiang and Conrath, 1997; Lin, 1998; Leacock and Chodorow, 1998; Hirst and St-Onge, 1998; Resnik, 1999) a.o., which received nice comparative assessments in (Ferlez and Gams, 2004) and (Budanitsky and Hirst, 2006). The focus of the present paper, though, is rather on vectorial representations and semantic distances based on them.

8 Conclusions

This paper reports on the insights gained on word embeddings with an experimental space that systemically explored empirical data from radically different sources (raw texts vs. lexical graphs), lexical information encoded in graphs from essentially different paradigms of lexical semantics (association- vs. inference-based), and methods to obtain vectorial representations of the nodes in graphs from each major family of graph embedding techniques (edge reconstruction- vs. matrix factorisation vs. random walk-based). Following mainstream practice, the resulting embeddings were evaluated for semantic similarity and relatedness prediction tasks.[15]

The results obtained permit to observe a clear pattern indicating that the best scoring solutions with graph embeddings are very competitive, consistently outperforming mainstream text-based ones by a substantial margin. They indicate also that the graphs that are informing the top-performing word embeddings are of a type that can be obtained with quite affordable costs, as they belong to the family of feature-based lexical graphs, which can be collected from lexical associations evoked from laypersons.

In future work, it will be interesting to study how the distinct performance of word embeddings that are informed by different empirical data and embedding methods may have an equally distinctive impact into downstream tasks that take pretrained word embeddings as input.

Abstract

Language Models (LMs) are important components in several Natural Language Processing systems. Recurrent Neural Network LMs composed of LSTM units, especially those augmented with an external memory, have achieved state-of-the-art results. However, these models still struggle to process long sequences which are more likely to contain long-distance dependencies because of information fading and a bias towards more recent information. In this paper we demonstrate an effective mechanism for retrieving information in a memory augmented LSTM LM based on attending to information in memory in proportion to the number of timesteps the LSTM gating mechanism persisted the information.

1 Introduction

Language Models (LM) are important components in Natural Language Processing systems, such as Statistical Machine Translation and Speech Recognition (Schwenk et al., 2012). An LM is generally used to compute the likelihood of a sequence of words appearing in a given language. Recently, Recurrent Neural Networks LMs (RNN-LMs) have became the state-of-the-art approach to LMs (Józefowicz et al., 2016). However, RNN-LMs struggle to keep their level of performance as the length of the input increases.

A typical RNN-LM propagates a context vector that integrates information about previous inputs to use for the next prediction. Consequently, the information that is captured at the beginning of a sequence containing a long-distance dependency is likely to have faded from the context by the time the model spans that dependency. To address these limitations, several "memory-augmented" RNN-LMs architectures have been developed that attempt to retrieve relevant information from its past timesteps (e.g., Tran et al. (2016), Cheng et al. (2016), Daniluk et al. (2017), Merity et al. (2017), Grave et al. (2017) and Salton et al. (2017))

In this paper, we demonstrate that an efficient and effective mechanism for a memory augmented LSTM based LM (LSTM-LM) to retrieve important information from its history is to construct a representation of the LSTM unit state history that weights information in proportion to the number of timesteps the unit persisted the information. Using this strategy reinforces the decisions of the LSTM gating mechanism at each timestep regarding what is important in a sequence. Our models achieve competitive results on the Penn Treebank (Marcus et al., 1994) and on the wikitext2 (Merity et al., 2017). Structure: §2 presents the architecture of LSTMs; §3 discusses the effect of uniformly weighting the hidden states of an LSTM; §4 illustrates persistence of information in an LSTM and describes our memory augmented LSTM-LM; §5 presents experiments and results; §6 contextualizes our findings; and §7 our conclusions.

2 Long Short-Therm Memory

LSTM units (*aka.* LSTM cells) are now a normal building block for neural based NLP systems (Bradbury et al., 2017; Murdoch and Szlam, 2017). LSTMs retain and propagate information through the dynamics of the LSTM memory cell, hidden state and gating mechanism (including the *input*, *forget*, and *output* gates). The LSTM memory cell retains information that is only known by the unit itself and the hidden state shares informa-

[*] Work done while the author was at the ADAPT Center and the Dublin Institute of Technology.

tion to other LSTM units in the same or any next layer of the network. This way, the units can decide what to keep in memory and how much of that information it wants the other units/layers to know about it. If something is deemed important, the units will both keep it in memory and let other units/layers to know about it. The gating mechanism controls the flow of information between the memory cell and the hidden state. Therefore, the gating mechanism plays an important role on the LSTM hidden dynamics.

The computations of a standard LSTM unit (Gers et al., 2000) (without *peephole connections*) involve iterating over the following equations

$$\widetilde{\mathbf{c}}_t = tanh(\mathbf{W}\mathbf{x}_t + \mathbf{W}\mathbf{h}_{(t-1)} + \mathbf{b}) \quad (1)$$

$$\mathbf{i}_t = \sigma(\mathbf{W}_{ii}\mathbf{x}_t + \mathbf{W}_{hi}\mathbf{h}_{(t-1)} + \mathbf{b}_i) \quad (2)$$

$$\mathbf{f}_t = \sigma(\mathbf{W}_{if}\mathbf{x}_t + \mathbf{W}_{hf}\mathbf{h}_{(t-1)} + \mathbf{b}_f) \quad (3)$$

$$\mathbf{o}_t = \sigma(\mathbf{W}_{io}\mathbf{x}_t + \mathbf{W}_{ho}\mathbf{h}_{(t-1)} + \mathbf{b}_o) \quad (4)$$

$$\mathbf{c}_t = \mathbf{f}_t \times \mathbf{c}_{(t-1)} + \mathbf{i}_t \times \widetilde{\mathbf{c}}_\mathbf{t} \quad (5)$$

$$\mathbf{h}_t = \mathbf{o}_t \times \tanh(\mathbf{c}_t) \quad (6)$$

where the weight matrices $\mathbf{W}_{i*}$ are associated to the input; the weight matrices $\mathbf{W}_{h*}$ are associated with the recurrence; the vectors $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{o}_t$ are the activation vectors produced by the *input*, *forget* and *output gates* respectively; $\widetilde{\mathbf{c}}_t$ is the candidate memory cell state; $\mathbf{c}_t$ is the new memory cell state; and $\mathbf{h}_t$ is the output of the unit.

The *candidate vector* (Eq. 1) contains information extracted from the input to the LSTM and, together with the *input gate vector* (Eq. 2) and *forget gate vector* (Eq. 3), is used to update the *memory cell* (Eq. 5). That update decides how much of the input is important to the memory cell, how much the *memory cell* will keep from its own content and what will be remembered in the memory cell for the next iteration.The *output vector* (Eq. 4) decides how much of the content in the memory cell $\mathbf{c}_t$ will be known on the next timestep (and by cells in the next layer if it is a multi-layered LSTM or to any layer that may come next o the network).

The success of LSTM-RNNs is attributed to their ability to retain information about the input sequence for several timesteps in their internal memory cell $\mathbf{c}_t$. That information is then made available to the next layer in the network for the amount of timesteps it is considered relevant to the current sequence. As pointed by Murdoch and Szlam (2017), each input to an LSTM makes a contribution to the hidden state of the LSTM and that is reflected when Eq. 5 is iterated. At any given timestep t, the cell state $\mathbf{c}_t$ can be decomposed into

$$\mathbf{c}_t = \sum_{i=1}^{t}(\prod_{j=i+1}^{t} \mathbf{f}_i)\mathbf{i}_i\widetilde{\mathbf{c}}_i \quad (7)$$

which, according to the authors, can be interpreted as the contribution at timestep t to the memory block $\mathbf{c}_t$ by a particular past input at timestep j. In that view, the contribution of an input to a given timestep can be understood as an importance score weighted by the LSTM's gating mechanism. Therefore, if something is important to the current context if should receive a larger importance score and be held in the memory block for a number timesteps. In addition to retaining information, Murdoch and Szlam (2017) have also demonstrated that, despite the fact that it is still difficult to interpret what specific activations in the hidden dynamics of LSTM units mean, it is possible to extract semantically meaningful rules from the memory cells to train a powerful classifier that can approximate the output of the LSTM itself. Moreover, Strobelt et al. (2016) and Karpathy et al. (2015) have demonstrated that these networks can extract meaningful attributes from the data into the memory cells. These attributes carry fine grained information and keep track of attributes such as line lengths, quotes and brackets.

Although these and other work demonstrate the power of LSTM units and their gating mechanism, RNN-LMs based on such units (LSTM-LMs) struggle to process long sequences. In our view, the main reason for this degradation in performance happens exactly because of the hidden state dynamics of the LSTM units. Once the information retained in the memory cell $\mathbf{c}_t$ is outdated, the *forget gate* $\mathbf{f}_t$ erases that block enabling the unit to store fresh data without interference from previous timesteps (Gers et al., 2000, 2003). This behaviour creates a natural bias towards more recent inputs given that the memory cell has limited capacity to store previous information and, once the memory cell is saturated, the *forget gate* will start to drop information in favour of more recent inputs. Even though the LSTM units can learn which information it must retain and for how long, the model will struggle with long sequences that are more likely to contain LDDs and that saturate the memory cell.

Once a memory cell has been saturated then, although some content has received a large importance score in past steps, it may be dropped from the memory cell (because of the inherent limitation of the LSTM's capacity of storing content) and will not be available to contribute to the next steps. For example, an LSTM-LM trained on English may persist the information related to a subject of a sentence for a number of time steps because the subject is important but this information may still have faded by the time the verb is reached. However, by augmenting the network with a memory buffer the information relating to the subject continues to be accessible so long as the memory buffer is not reset. This behaviour is an indication of why the memory augmented models such as the Neural cache model of Grave et al. (2017) and the Pointer LSTM of Merity et al. (2017) has gained success and achieved state-of-the-art results in LM research. Even though the required content has already faded from the context, the memory augmentation make it available for subsequent timesteps.

3 The Curious Effectiveness of Uniform Attention

As noted in Section 1, in recent years a number of extensions to RNN-LMs have been proposed to overcome the fading of information from context by adding a memory buffer (that is used to store the LSTM hidden states) and then at each timestep construct a representation of this history to inform the current prediction. A variety of relatively sophisticated mechanisms for retrieving information from the memory buffer have been proposed. In many cases these retrieval mechanisms include an extra neural network in the RNN-LMs that at each timestep predicts what elements in the memory buffer should be retrieved.

Salton et al. (2017) is a recent example that uses an extra neural network[1] to learn what to retrieve from memory. In this architecture at the end of a timestep the current LSTM hidden state is added to the memory buffer. At the beginning of the next timestep the additional neural network predicts an attention distribution over the elements of the buffer (*i.e.*, the previous LSTM hidden states). Using this distribution a compact representation of the RNN-LMs history is constructed by calculating a weighted sum of the elements in the memory (where the weight of each element is the attention attributed to it by the RNN). Curiously, although this architecture was successful in terms of performance the attention mechanism did not work as expected. Instead of focusing attention for each time step on particular relevant elements in memory it spread out the attention nearly uniformly across the memory. It might appear that this architecture was using a strategy of "pay equal attention to everything in the past". However, we argue this interpretation ignores the power of the LSTM gating mechanism.

Our interpretation of the uniform attention mechanism presented by Salton et al. (2017) is that their *Attentive* RNN-LM is in fact (indirectly) reinforcing the decisions of the gating mechanism of the LSTM units and is retrieving information that is persisted across multiple timesteps. This is important because it indicates that it may be more fruitful and efficient to leverage the decisions made by the LSTM gating mechanism (decisions that the network must make anyway) to drive the retrieval of information from the memory buffer rather than train a separate neural network. It is worth emphasising that to date none of the different retrieval mechanisms proposed in the literature on memory augmented LSTM-LMs have explicitly considered the behaviour of the LSTM gating mechanism.

4 The Persistence of Information

The LSTM gating mechanism will attempt to persist important information for as long as possible (or until the state is saturated). We propose that when retrieving/constructing a representation of the LSTM history from a memory buffer the information held for more than one timestep should be weighted in proportion to the number of timesteps the LSTM gating mechanism persisted it across. This way, we let the gating mechanism of the LSTM determine what is important about the input and, anything that is persisted for more than one timestep, will have a greater impact on the final prediction even if that information has already faded from the current context.

A simple and efficient way to implement this strategy is at each time point to construct a representation of the history of the RNN-LM that is simply an average of the LSTM hidden states in

[1] Similar to that proposed by Bahdanau et al. (2015) and Luong et al. (2015) for Neural Machine Translation (NMT)

the memory buffer. Pieces of information that the LSTM unit persists for several time steps will have a bigger impact on this average (simply because they are included multiple times) relative to items that are not persisted. In effect, this average weights each piece of information in proportion to the number of time steps the LSTM persisted it and so an RNN-LM that uses this average as its representation of history pays attention to what the LSTM gating mechanism persisted.

4.1 Averaging the Outputs

In this work we simplify the architecture of Salton et al. (2017) and use an average of previous outputs instead of a neural network based attention mechanism. Our intuition for this modification is that the gating mechanism of the LSTM is telling us what is important about an input and that we must find a way to make that information available for long distances in the future. In fact, Ostmeyer and Cowell (2017) have presented a model that computes a recurrent weighted average (RWA) over every past hidden state. However, the authors limit themselves to evaluate the model over simple tasks and the effectiveness of that model over language modelling is still to be demonstrated.

Compared to other memory augmented models our architecture is relatively simple. A multilayered LSTM-RNN encodes an input at each timestep and the outputs of the last recurrent layer (*i.e.*, its hidden state called h_t) is added to memory. At each timestep an average of the vectors in the memory buffer is calculated and concatenated with the h_t generated by the processing of the current input. This concatenated vector is then feed into the softmax layer which predicts the distribution for the next word in the sequence.

In our experiments with this uniform attention, we found that initialising the memory with a zero vector $\mathbf{h}_0$ and allowing the model to count this vector as part of the memory when calculating the average[2] improved the performance of the model.

5 Experiments

To test our intuitions, we evaluate the averaging process of the model using the PTB dataset using the standard split and pre-processing as in Mikolov et al. (2010) which consists of 887K, 70K and 78K tokens on the training, validation and test sets respectively. We also evaluate the model on the wikitext2 dataset using the standard train, validation and test splits which consists of around 2M, 217K tokens and 245k tokens respectively.

5.1 PTB Setup

Following Salton et al. (2017) we trained a multilayer LSTM-RNN with 2 layers of 650 units for the PTB experiment. We trained them using Stochastic Gradient Descent (SGD) with an initial learning rate of 1.0 and we halved the learning rate at each epoch after 12 epochs. We train the model to minimise the average negative log probability of the target words until we do not get any perplexity improvements over the validation set with an early stop counter of 10 epochs. We initialize the weight matrices of the network uniformly in $[-0.05, 0.05]$ while all biases are initialized to a constant value at 0.0 with the exception of the *forget gate* biases which is initialised at 1.0 as suggested by Jozefowicz et al. (2015). We also apply 50% dropout (Srivastava et al., 2014) to the non-recurrent connections and clip the norm of the gradients, normalized by the mini-batch size of 32, at 5.0. We also tie the weight matrix used for the transformation in the softmax layer to be the embedding matrix as in Press and Wolf (2016). Thus, the dimensionality of the embeddings is set to 650.

5.2 wikitext2 Setup

For the wikitext2 experiments we trained a multilayer LSTM-RNN with 2 layers of 1000 units. We also used SGD to minimise the average negative log probability of the target words with an initial learning rate of 1.0. We decayed the the learning rate by a factor of 1.15 at each epoch after 14 epochs and we used an early stop counter of 10 epochs. Similarly to the PTB experiment, we initialize the weight matrices of the network uniformly in $[-0.05, 0.05]$ while all biases are initialized to a constant value at 0.0 with the exception of the *forget gate* biases which is initialised at 1.0. For this model we apply 65% dropout to the non-recurrent connections and clip the norm of the gradients, normalized by the mini-batch size of 32, at 5.0. Once again, we tie the weight matrix used for the transformation in the softmax layer to be the embedding matrix. Thus, the dimensionality of the embeddings is set to 1,000.

[2] In other words, the index of the memory starts at timestep 0 instead of timestep 1. Thus, the memory at any given timestep t will be of length $t + 1$.

5.3 Data Manipulation and Batch Processing

When training each model, we use all sentences in the respective training set, but we truncate all sentences longer than 35 words and pad all sentences shorter than 35 words with a special symbol so all have the same length. We use a vocabulary size of 10k for the PTB and 33,278 for the wikitext2. Each of the mini-batches we use for training are then composed of 32 of these sentences taken from the dataset in sequence.

Contrary to the recent trend in the field, we do not allow successive mini-batches to sequentially traverse the dataset. We reinitialize the hidden state of the LSTM-RNN at the beginning of each mini-batch, by setting it to all zeros. Our motivation for not sequentially traversing the dataset is that although sequentially traversing has the advantage of allowing the batches to be processed more efficiently, some dependencies between words may not be learned if batch traversing is in use as the mini-batch boundaries can split sentences. We also found that allowing the initial state of all zeros to be included in the memory when averaging improves the performance of the Average RNN-LM.

5.4 Results

Table 1 presents the results in terms of perplexity of the models trained over the PTB dataset. As we can see, the results obtained by the Averaging RNN-LM are similar to those obtained by the *Attentive* RNN-LMs of Salton et al. (2017). Despite the simple method to retrieve information from the previous timesteps, the Averaging RNN-LM achieves the same level of performance of more complex models with less computation overhead.

Table 2 presents the results in terms of perplexity of the models trained over the wikitext2 dataset. Although the Averaging RNN-LM is still behind the *Attentive* RNN-LMs and the Neural cache model of Grave et al. (2017) on this dataset, the results are encouraging given the simplicity of the Averaging RNN-LM.

However, we should note that none of these models perform at the same level of the state-of-the-art models such as those of Merity et al. (2017) and Takase et al. (2018) as we can see in Tables 1 and 2. These models use advanced regularization techniques and matrix factorization for training the RNN-LMs whilst our Averaging RNN-LM use standard LSTM trainig regime and regularization techniques. Nevertheless, we believe that by adding the regularization scheme of the AWD-LSTM and the direct output connection of AWD-LSTM-DOC to our models we can bridge that performance gap.

6 Discussion

The Averaging LSTM-LM achieves the lowest perplexity for a single model on the PTB (see Table 1). Given the similarity of the results between the *Attentive* RNN-LMs of Salton et al. (2017) and the Averaging LSTM-LM it would appear that our hypothesis that the *Attentive* RNN-LMs was (indirectly) learning to use the dynamics of the LSTM gating mechanism is correct.

Focusing on the results for the wikitext2 dataset, the Neural cache model (Grave et al., 2017) has a higher performance than our model on this dataset. We are not able to estimate the number of parameters for the Neural cache model so we have not included the parameter size of that model in the table. In discussing the wikietext2 results it is worth noting that the *Attentive* RNN-LMs of Salton et al. (2017) and the Averaging LSTM-LM are the only models in Table 2 that reset their memory at each sentence boundary whereas the memory buffers of other models were allowed to span sentence boundaries.

The results for the wikitext2 dataset highlights an interesting trade-off and design choice for memory augmented LSTM-LMs. One approach is to use a dynamic length memory buffer which resets at sentence boundaries and uses a simple mechanism, such as averaging, to construct a representation of the memory to inform the prediction at each timestep. This is the approach we have proposed in this paper. This approach has the advantages of simplicity and that the memory length can be anchored to landmarks in the history, such as sentence boundaries. This approach is most appropriate for sentence based NLP tasks such as sentence based Machine Translation. There is a question, however, regarding whether this approach will scale to very long sequences (such as documents) as averaging over long-histories may result in all histories appearing similar. We have done some initial experiments where we have permitted the memory buffer to hold longer sequences before being reset and the performance of the Averaging LSTM-LM dipped. The alternative approach is to use a larger memory buffer and a

more sophisticated retrieval mechanism, for example the Neural cache model of Grave et al. (2017). As the wikitext2 results demonstrate this second approach works well for large datasets where the sentences are in sequence, the cost of this approach being a more complex architecture.

7 Conclusions

In this paper we have highlighted the power of the LSTM gating mechanism and argued that the persistence dynamics of this mechanism can provide useful clues regarding what information is important within a sequence for language modelling. We believe that attending to the information that an LSTM gating mechanism has decided is important in an input sequence at a given timestep (and hence has persisted to a later timestep) is a natural way of deciding what information will be useful again at a subsequent timestep. Even if the information contained in the LSTM is replaced or altered later in the process, we argue that it is relevant to the entire history in proportion to the amount of timesteps it was held. Informed by this hypothesis, in our work we demonstrated that a simple average of the previous LSTM hidden states in memory is an effective mechanism for providing information to the current timestep about previous inputs.

Admittedly, rating the importance of information in terms of the number of timesteps the LSTM persisted it for is a relatively simplistic view of the dynamics of LSTM units and of the complexity of language. Furthermore, implementing this strategy using an average of past states is also a relatively blunt way of instantiating this approach. However, as our results demonstrate this simple approach is effective and we understand this is a starting point. By drawing attention to the signals implicit in the dynamics of LSTM units we hope to contribute to the development of more efficient LMs. At the same time, the fact that the internal dynamics of an LSTM unit may be used to explicitly signal what is important and what should be retrieved from a memory buffer may suggest alternative constraints and opportunities that should be considered in the design of neural units and by doing so contribute to the development of a new class of units for use in RNN-LMs.

Abstract

In this paper we present a rule- and lexicon-based system for the recognition of Named Entities (NE) in Serbian newspaper texts that was used to prepare a gold standard annotated with personal names. It was further used to prepare training sets for four different levels of annotation, which were further used to train two Named Entity Recognition (NER) systems: Stanford and spaCy. All obtained models, together with a rule- and lexicon-based system were evaluated on two sample texts: a part of the gold standard and an independent newspaper text of approximately the same size. The results show that rule- and lexicon-based system outperforms trained models in all four scenarios (measured by F_1), while Stanford models have the highest recall. The produced models are incorporated into a Web platform NER&Beyond that provides various NE-related functions.

1 Introduction

Named Entity Recognition is the task of identifying named entities in text (Nadeau and Sekine, 2007), which is often used as a first step in question answering, information retrieval, anaphora resolution, topic modeling, etc. The first Named Entity set had 7 types (Grishman and Sundheim, 1996): organization, location, person, date, time, money and percent expressions. Sekine et al. (2002) proposed a NE hierarchy which contains about 150 NE types.

There are three categories of NER systems: 1) The rule-based (RB) (Krupka and Hausman, 1998; Friburger and Maurel, 2004); 2) the Machine Learning (ML) based (Finkel and Manning, 2009; Singh et al., 2010); and 3) hybrid methods (Jansche and Abney, 2002). The ML-based methods can often be "black boxes", in comparison with RB techniques which are easy to interpret. Yet, ML-based methods are state-of-the-art. Such example is a Stanford Named Entity Recognizer (Manning et al., 2014), which can be trained for many languages. Other notable NER platforms include GATE (Desktop application that enables NER across many languages and domains),[1] OpenNLP (rule-based and statistical NER),[2] spaCy (Honnibal and Montani, 2017) (module written in Python, used for advanced NLP)[3] and many others.

For Serbian, thus far a rule-based and lexicon-based NER system was developed – SrpNER (Krstev et al., 2014). Its development started with the recognition of a NE class present in all NE schemes, personal names (Krstev et al., 2005), while the recognition of other main NE classes was subsequently added. In the next Section we present briefly this system and how it was used to produce the corpus of newspaper texts annotated with personal names – the gold standard. Section 3 describes NER systems based on Machine Learning methods that were trained on the corpus derived from the gold standard, while the evaluation and discussion of results are presented in Sections 4 and 5, respectively. In Section 6 we present a web platform that enables use and evaluation of these systems. Finally, some directions for future work are given in the last Section.

2 SRPNER and the Gold Standard

2.1 Rule-Based NER for Serbian

The first NER system for Serbian was a rule- and lexicon-based system developed several years ago. It has been designed to recognize the main classes of NEs: 1) numerical expressions (measurement and money), 2) temporal expressions (date and time, and 3) name expressions (personal, geopolitical and organization names).

The system was designed in a form of the cascades of Finite-State Transducers (FST) in which every transducer recognizes and tags a certain class of NEs (Friburger and Maurel, 2004; Maurel et al., 2011). Each transducer rely in its work on the results of previous transducers and on e-dictionaries of Serbian (Vitas and Krstev, 2012). E-dictionaries play an important role specifically in the recognition of name expressions, since, beside general lexica, they contain many proper names, both personal and geopolitical. The system is modular which means that steps can be omitted and can change order; however, it performs best when used in predefined way since in each step the disambiguation of some names is performed.

SRPNER presented in (Krstev et al., 2014) recognizes 11 classes of NEs: dates (moments and periods), time (moments and periods), money expressions, measurement expressions, geopolitical names (countries, settlements, oronyms and hydronyms), and personal names (one or more last names with or without first names and nicknames). The presented evaluation results for the recognition of all mentioned NEs obtained on a sample of newspaper texts were $F_1 = 0.96$ ($R = 0.94$; $P = 0.98$). The system also recognized titles, roles and functions of persons when they accompany personal names.

Since this first results, system has been continually improved by adding new NE classes (organization names) and new sub-classes (e.g. for geopolitical names: regions, super-regions and city counties). In addition, the e-dictionaries of Serbian were also continually improved and enhanced, and that by itself contributes to better performance of SRPNER.

The new version of this system recognizes more variations for naming persons: distinguished persons and first names alone. Moreover, system distinguishes names used for men from those used for women (Krstev et al., 2015). Presented results show that the system was more successful in recognizing names of men than women.

The output of the system are texts with XML tags for recognized entities inserted in them. Since the system allows embedded NEs, recognized names of persons can be components of other NEs, e.g. organizations.

2.2 The Preparation of the Gold Standard

The system presented in the previous section was used for the preparation of the gold standard – a large text sample annotated with personal names dubbed GOLDPERS. The sample consists of short news published on the Web in the period 2009–2016 by 4 Serbian daily newspapers (*Politika*, *Danas*, *Blic*, *Novosti*), one news portal (*B92*) and one weekly magazine (*Bazar*). The sample consists of 321,127 tokens (simple running words).

The forms of personal names taken into account and their tagging are presented in Table 1. The gold standard was produced following these steps:[4]

- Each text was annotated using SRPNER;
- Tags that did not refer to personal names were deleted;
- The remaining tags were evaluated as correct, partially correct (overlapping), not correct (not a name);
- The missing tags were inserted, and typos that led to incorrect tagging were corrected.

For some texts this process was repeated from one to four times which yielded "four levels" of gold standard. Between these repeated runs the development of SRPNER continued, as well as the enhancement of e-dictionaries of Serbian.

3 Training Different NER Systems

3.1 Training Sets

The gold standard GOLDPERS contains $9,046$ sentences, each one enclosed in `<seg>...</seg>` tag. Named entities in sentences are annotated using tags listed in Table 1. These tags contain different levels of information: name type, role, gender. We wanted to examine the recognition of NEs on different level of details. Therefore, on the basis of the gold standard, we developed its four versions by

[4] The evaluation was performed as a homework by several generations of students of Library and Information Sciences at the Faculty of Philology, University of Belgrade, in the scope of the course Information Retrieval. Their work was checked by their professor, which means that texts were twice evaluated in each run.

Table 1: Examples of types of personal names and their tags; M - masculine, F - feminine personal names

defining different mappings of XML tags. These mappings are named and represented in Table 2. Different versions of GoldPers are illustrated with examples presented in Table 3.

We split each of these four versions of the gold standard (namely PERS_$\{1, 3, 4, 9\}$) into training and test sets (containing $8,151$ and 895 sentences, respectively). We named this gold test set Students-Gold.

As we wanted to have an independent text of the similar structure and content we prepared an additional set of news articles from *Danas* daily journal. This was one of the source journals for the Students-Gold, but for this new sample, we have randomly chosen recent news (from year 2018, that is 2 years after the most recent news in GoldPers). This set of articles containing 860 sentences was tagged with SrpNER and manually corrected, thus producing the second test set Danas-Gold. The distribution of NE tags in the training set, and both test sets is given in Table 4.

We used four versions of the gold standard to train two different Named Entity Recognition systems: spaCy NER (Subsection 3.2) and Stanford NER (Subsection 3.3). Trained models for Serbian are available on NER&Beyond platform, which is presented in Section 6.

3.2 spaCy NER

spaCy (Honnibal and Montani, 2017) is a free, open-source library for advanced Natural Language Processing in Python. For different natural languages, it is able to perform tokenization, POS-tagging, dependency parsing, lemmatization, sentence boundary detection, named entity recognition, similarity comparing, text classification, etc. It offers statistical models for a variety of languages, which can be installed as individual Python modules. It supports training new language models, as well.

We used it for training NER on our four versions of GoldPers. We coded a Python script that transforms each sentence into a training sample, represented as a list of triplets.[6] For example, for the sentence “srpski reditelj Aleksandar Saša Petrović” (*Serbian director Aleksandar Saša Petrović*), the corresponding triplet representation for the PERS_4 model would be:

$$(0, 14, "ROLE"), (16, 39, "PERS\_FULL")$$

where the first and the second element represent the start and the end character offset, while the third element represents the NE itself. Each of the four models were trained in 10 iterations, using 0.5 value for the drop-out parameter. These trained models can be inspected online.[7]

3.3 Stanford NER

Stanford NER (Manning et al., 2014) is a Java implementation of a Named Entity Recognizer by the Stanford Natural Language Processing group. It is also known as *CRFClassifier*, since

Table 3: The same sentence in four versions of the gold standard – PERS_$\{1, 3, 4, 9\}$

it is based on Conditional Random Fields (Lafferty et al., 2001). For training this model,[8] we had to transform our texts into CoNLL02 IOB format (namely, "inside - outside - beginning") with *conll* extension (Sang, 2002). For this purpose, we used XML ↦ CoNLL converter available within NER&Beyond on-line tool. An example of this format is given in Table 5.

4 Evaluation

In order to evaluate three NER system for personal names in Serbian, we need to have the output results in the same format. After running spaCy NER on a text, an output is provided in BRAT format with *ann* extension. This format is similar to the one for spaCy training, described in subsection 3.2. For the example given in the same subsection, an output file has the following content:

T1 ROLE 0 14 srpski reditelj
T2 PERS_FULL 16 39 Aleksandar Saša Petrović

After running StanfordNER on a text, an output is provided in already mentioned CoNLL02 format. We used CoNLL02 ↦ BRAT converter available within NER&Beyond online tool.

Finally, for both spaCy NER and StanafordNER output files, we applied ANN + TEXT ↦ XML converter offered by Gemini, also available within NER&Beyond online tool. An output of SrpNER is already an XML file with marked named entities, as is the gold standard explained in Section 2 and illustrated in Table 3.

We evaluated three NER systems using the open source Gemini tool, described in Section 6, that offers various options for files comparison (Feng, 2018). It is possible to select matching type: *strict*,

šarmom...	O

Table 5: CoNLL02 IOB format – the beginning of the sentence *I was fascinated by Sonja Savić and her transformation, Anica Dobra and her charm...*

where exact overlapping of NE annotations is subsumed (both annotation labels are the same) or *weighted*, where partial overlapping is taken into account, but with some weighted value to measure overlapping segment. To indicate alignment type, one can choose among the two options: the first option is *greedyMatching*, where the matching of annotations in the first and second files is done with a greedy algorithm that tries to match the closest annotations first. The second option is *maxMatching*, where the matching of annotations in the first and second file is done optimally using a maximum matching algorithm in bipartite graphs. An annotation in the first file will correspond to at most one annotation in the second file, and vice versa, in both cases.

We run 2 × 3 × 4 evaluation rounds: two test sets, three NERs and four models per each. All trials were run with *strict* matching type and *maxMatching* alignment type.

To indicate the chosen score type to evaluate the correspondence between one annotation from the first file and one annotation from the second file, calculation of precision P, recall R and F-measure in Gemini comes in three different flavors:

weak an annotation of the first file will be considered as corresponding to an annotation of the second file if they intersect on at least one character;

strict an annotation of the first file will be considered as corresponding to an annotation of the second file if they start and end exactly at the same characters;

weighted the match is scored by the ratio of the number of characters common to both annotations divided by the total number of characters covered by at least one of the two annotations.

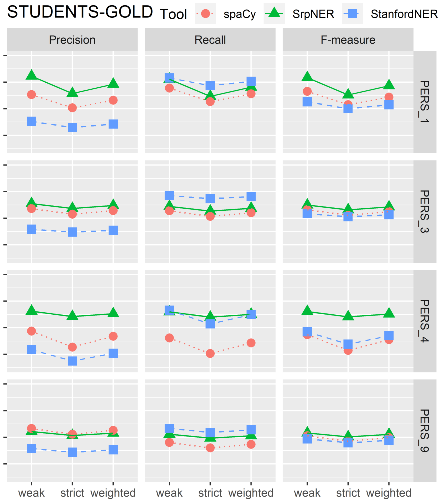

Figure 1: The evaluation of SPACY NER, SRPNER and STANFORD NER on STUDENTS-GOLD

5 Discussion

The results of three NER systems, four models and two test texts are presented in Table 6. The results show that in all cases (except one) SRPNER achieved the best precision, in all cases (except one) STANFORD NER achieved the best recall,

		spaCy NER			SrpNER			Stanford NER		
	model	***P***	***R***	***F_1***	***P***	***R***	***F_1***	***P***	***R***	***F_1***

	PERS_4	0.807	0.792	0.799	**0.907**	0.824	**0.863**	0.716	**0.825**	0.767
	PERS_9	0.818	0.794	0.806	**0.872**	0.800	**0.835**	0.761	**0.808**	0.784

Table 6: The comparison of strict precision, recall and F_1 between NER systems, models and test sets.

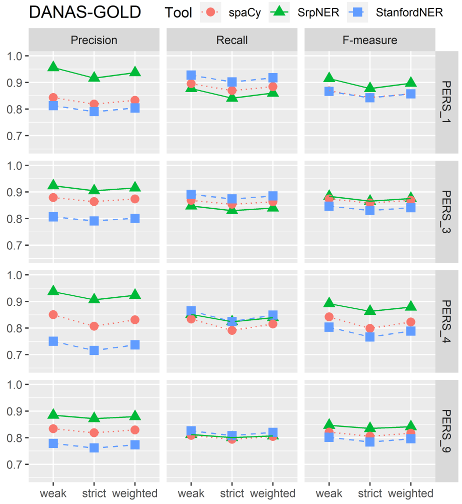

Figure 2: The evaluation of spaCy NER, SrpNER, and Stanford NER on Danas-Gold

while SrpNER achieved the highest F_1 measure in all cases. Stanford NER and SrpNER performed better on both test texts with models that use less tags (PERS_1 and PERS_2), while SrpNER performed significantly worse only for the model with 9 tags. Contrary to our expectations, all NER systems for all models achieved better results for the independent test text Danas_Gold than for the test set randomly chosen from the gold standard. Namely, a number of news in Gold-Pers that come from 6 different sources were produced at the same time period, and thus involved same persons. However, that did not influence results favorably towards Students_Gold test text.

All measures are for all NER systems and models highest for weak calculation, followed by weighted, the strict calculation giving the lowest result. However, as displayed in Figure 1 for the Students-Gold test set and in Figure 2 for the Danas-Gold test set the mutual relationship between three NER system remains the same.

We also compared performance of all three NER systems by each named entity type (Figure 3). Results for all three models distinguishing entity types show that all three systems perform poorly in recognizing first names only. For Stanford NER and spaCy NER it can be explained by the considerably smaller number of these tags in training texts compared to other tags (see Table 4). As for SrpNER one can presume that developers devoted less effort to this entity type occurring only occasionally in newspaper texts. Similarly, in all experiment settings, the recognition of full names was better than the recognition of last names only. Again, the number of last name tags was smaller than the number of full name tags (Table 4). A rule based system SrpNER makes use of a personal name context in cases of disambiguity which tends to be less specific in the case of the use of a last name only.

One can also note that when using the model PERS_4, SrpNER system performs best in recognizing the role entity. Between other two systems, Stanford NER achieves better recall and SpaCy NER slightly better precision.

The chart for model PERS_9 shows that all systems according to F_1 measure recognize better masculine names than feminine names regardless of entity types. Feminine names show grater variety of forms than masculine names, especially when only last names are used; moreover, they occur significantly less than masculine names in newspaper texts (as pointed in (Krstev et al., 2015) there is approximately one feminine name per 7 seven masculine names) and confirmed in our training sets (Table 4).

We compared the performance of SRPNER with its previously reported results. In (Krstev et al., 2005) results for the recognition of personal names were $P = 0.97$, $R = 0.86$, $F_1 = 0.91$. One notes that all measures are higher than those obtained when using the GOLDPERS (see rows PERS_1 in Table 4), which can partly be due to the inclusion of first names only into the present version of SRPNER. On the other hand, results obtained for the recognition of roles with GOLDPERS ($F_1 = 0.87$ for STUDENT and $F_1 = 0.86$ for DANAS) were higher than those presented in the same paper ($F_1 = 0.83$). The same goes for the recognition of last names only: the previous result was $F_1 = 0.78$, while the use of SRPNER on the gold standard yielded $F_1 = 0.86$ for STUDENT and $F_1 = 0.85$ for DANAS.

The capability to distinguish masculine and feminine names was compared to the results presented in (Krstev et al., 2015). The results obtained in presented experiments were lower for all NE types: masculine full $F_1 = 0.97$ vs. $F_1 = 0.90/0.94$ (STUDENT/DANAS), feminine full $F_1 = 0.94$ vs. $F_1 = 0.86/0.86$, masculine last $F_1 = 0.89$ vs. $F_1 = 0.85/0.83$, feminine last $F_1 = 0.79$ vs. $F_1 = 0.49/0.64$. One can presume that the use of gold standard produces more reliable results.

To the best of our knowledge, STANFORD NER and SPACY NER were used for the first time for the recognition of personal names in Serbian texts. Ljubešić et al. (2013) used STANFORD NER to build models for Croatian and Slovene. When they used distributional similarity to improve results, on texts coming from different sources they obtained the following results: for Croatian $P = 0.91$, $R = 0.93$ and $F_1 = 0.92$, higher than STANFORD NER for the model PERS_1, and for Slovene $P = 0.82$, $R = 0.87$ and $F_1 = 0.84$, comparable with STANFORD NER for the model PERS_1 (Table 6). One should note, however, that their test set contained a smaller number of personal names (approximately one third of number of personal names in our test sets).

Jiang et al. (2016) compared 4 NER systems, two of which were STANFORD NER and SPACY NER, for English. Their test set consisting of Wiki articles contained approximately the same number of personal names as our both sets – around 900. Their results were for STANFORD NER $P = 0.72$, $R = 0.87$ and $F_1 = 0.79$, and for SPACY NER $P = 0.73$, $R = 0.73$ and $F_1 = 0.73$. Our results are comparable in the sense that they also show that STANFORD NER achieves the best recall, while SPACY NER tends to have the more balanced precision and recall.

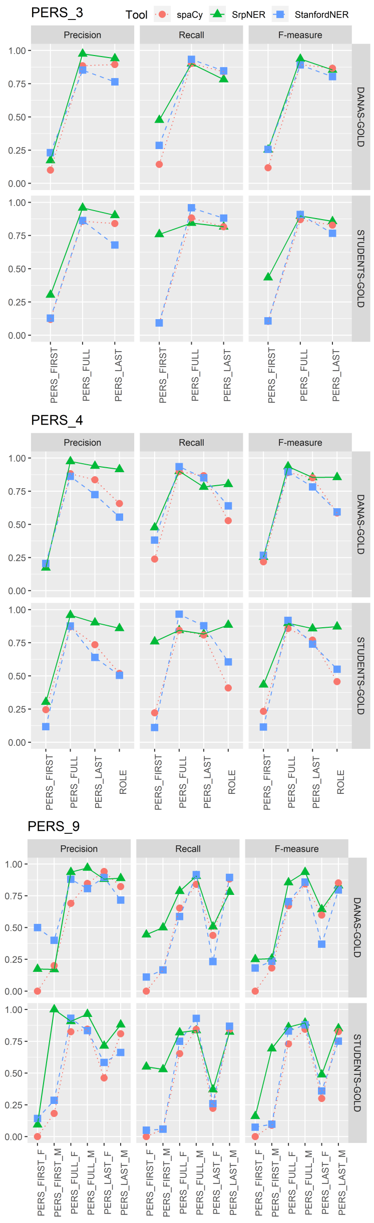

Figure 3: Evaluation of SRPNER, SPACY NER and STANFORD NER on two test sets, by each named entity type

6 Online Tool for NER

Serbian NER team (2019) offers an on-line tool for different purposes related to Named Entity Recognition. First, it supports conversion among different formats common for representations of NEs:

BRAT, CoNLL02 and XML. BRAT (Stenetorp et al., 2012) is a web-based tool[9] for text annotation, i.e., for adding notes to existing text documents. It is designed for structured annotation, allowing embedded annotations, which are especially convenient for NER. Annotations are external, so for each text file, an additional annotation file contains annotation data described in Section 4. CoNLL02 is a two-column format, also described in Section 4. An example of XML file whit tags interpreted as NEs is given in Table 3.

NER&BEYOND contains nine different modules:

XML ↦ BRAT module supports transformation of XML files which tags are interpreted as named entities, to BRAT format;

BRAT ↦ XML module supports transformation of files in BRAT format and their corresponding textual files to XML format;

BRAT ↦ CoNLL02 module supports transformation of files in BRAT format and their corresponding textual files to CoNLL02 format, using a Python script that is a part of BRAT package;

CoNLL02 ↦ BRAT module supports transformation of files in CoNLL02 format to BRAT format and their corresponding textual files, using a Python script that is a part of BRAT package;

XML ↦ CoNLL02 module supports transformation of XML files which tags are interpreted as named entities, to CoNLL02 format;

spaCy NER module provides NE annotation using spaCy (Honnibal and Montani, 2017), a free, open-source library for advanced NLP tasks in Python. This portal offers automatic annotation of texts in English, Spanish, German, Portuguese, French, Italian, Dutch and Serbian;

StanfordNER module provides Named Entity annotation using STANFORD NER models (Manning et al., 2014), which are available for Serbian, English and German with different levels of details, e.g. number of NE classes. Serbian model is developed withing presented research, while English and German are integrated from Stanford repository;

NER statistics module is developed for analysis of annotated text co llections in BRAT, that can be automatically downloaded via BRAT web interface. Various statistics related to distributions of named entities and attributes can be computed, including frequencies of annotated entities, classes, attributes per document and collection;

Gemini tool allows comparison of two text annotation files and provides different alignment scores. It is possible to compare a pair of XML files, a pair of files in BRAT for mat and one XML file against a file in BRAT format. The first file is the output of a NER system and the second file represents a gold standard.[10]

7 Future Work

For the upcoming research, we plan to apply the procedure we used for personal names to other NE classes (organization, location, event, temporal, quantitative, etc) and to experiment with other ML NER methods and tools with an ultimate goal to produce a successful hybrid system. The important next step is the enhancement of our newspaper corpus with other types of text (Wikipedia articles, domain texts, literary texts). The literary texts would be particularly important for improving the recognition of first names. Finally, another intended step is Entity Linking (EL), i.e. disambiguation of recognized named entities to a knowledge base, such as Wikidata, DBpedia WordNet and BabelNet. Such example would be automatically assigning Wikidata URL that points to a biography of a famous person to the corresponding named entity detected in text.

Moral Stance Recognition and Polarity Classification from Twitter and Elicited Text

Wesley Ramos dos Santos

Abstract

We introduce a labelled corpus of stances about moral issues for the Brazilian Portuguese language, and present reference results for both the stance recognition and polarity classification tasks. The corpus is built from Twitter and further expanded with data elicited through crowd sourcing and labelled by their own authors. Put together, the corpus and reference results are expected to be taken as a baseline for further studies in the field of stance recognition and polarity classification from text.

1 Introduction

Computational sentiment analysis may be understood as a wide range of tasks intended to identify opinions, emotions and other types of stance expressed in natural language text (Tsytsarau and Palpanas, 2012; Liu, 2015). Among these, opinion mining is arguably the most well-studied form of sentiment analysis, consisting of identifying the target of an opinion, and/or the polarity (positive, negative, neutral etc.) of the sentiment expressed towards this target (Tsytsarau and Palpanas, 2012).

Stance recognition (Anand et al., 2011; Hasan and Ng, 2013; Lai et al., 2016; Mohammad et al., 2016b; Zarrella and Marsh, 2016; Wei et al., 2016; Mohammad et al., 2017), by contrast, consists of deciding whether the author of a piece of text shows a favourable or unfavourable attitude (or position) towards a certain target (Mohammad et al., 2017). The distinction between sentiment and stance is motivated by the observation that a sentiment, regardless of being positive or negative, may reflect a favourable or unfavourable position towards the target (Mohammad et al., 2016b). For instance, given the target topic 'veganism', a sentence as in 'beef tastes wonderful' expresses a positive feeling (which would indeed be recognised as such by traditional sentiment analysis systems), but it also reflects an unfavourable position towards this particular target.

Stance recognition from text is a well-known and yet challenging research topic. Systems of this kind enable the development of more complex sentiment analysis applications, and have been at the centre of a recent shared task (Mohammad et al., 2016b) focused on the use of supervised and unsupervised methods for stance recognition in the English language. For other less-resourced languages, however, resources remain scarce.

Based on these observations, this paper presents a labelled corpus of stances in Brazilian Portuguese, and a number of computational models addressing two related issues: *stance recognition*, is presently regarded as the binary classification problem of deciding whether a given text conveys *any* attitude towards a certain target topic or not, and *stance polarity classification*, which is regarded as the binary classification problem of deciding whether a given stance expressed as text shows a *positive or negative* attitude towards the target topic. Examples of both tasks for the target topic 'veganism' are as follows.

Stance recognition:

- *She says that avoiding animal products is just a fad (no stance towards veganism)*
- *Veganism will save the world! (a stance towards veganism)*

Stance polarity classification:

- *No one should ever eat beef (a positive stance towards veganism)*

Proceedings of Recent Advances in Natural Language Processing, pages 1069–1075,
Varna, Bulgaria, Sep 2–4 2019.

- *Vegans tend to have health issues (a negative stance towards veganism)*

As in the case of the English stance corpus in (Mohammad et al., 2016b), we will favour the recognition of stances about moral issues (e.g., abortion, drugs legislation etc.) in the Twitter domain. In addition to that, however, Twitter data will be presently expanded with a collection of moral stances elicited through crowd sourcing as well, and which were labelled by their own authors as a gold standard. Put together, the corpus and its reference results are expected to be taken as a baseline for further studies in moral stance recognition and stance polarity classification tasks.

2 Related Work

The work in (Anand et al., 2011) is among the first to address the computational recognition of stances from text, analysing a corpus of 4873 posts in on-line discussion forums. The data set considered covers 14 topics, ranging from entertainment to ideological issues. Favourable and unfavourable stances are recognised with accuracy of up to 69%, outperforming a unigram baseline model that obtained up to 60% accuracy.

Stance recognition in discussion forums is also addressed in (Hasan and Ng, 2013). In this case, however, the work focuses on the question of how the performance of a stance classifier varies in relation to the volume and quality of training data, regarding the complexity of the underlying model, the richness of the set of learning features and the use of extra-linguistic restrictions in a wide range of scenarios. The experiments leave a series of contributions on how to build models of this type, and on which kinds of knowledge to consider.

More recently, the SemEval-2016 competition (Mohammad et al., 2016a) brought together 19 participating systems engaged in the task of supervised stance recognition from tweets in the English language. The training corpus, described in detail in (Mohammad et al., 2016a), contains 2914 tweets about five target topics (atheism, climate change, feminism, Hillary Clinton and abortion legislation.) The corpus contains, on average, 583 tweets per target, but the set is unbalanced. On average, there are 25,8% positive and 47,9% negative stances. The test set, with 1249 tweets, is even more unbalanced, with 24,3% of positive stances and 57,3% negative stances. The SemEval corpus is the basis of some of studies discussed as follows.

The work in (Zarrella and Marsh, 2016) presents the best overall performance in the SemEval-2016 shared task (Mohammad et al., 2016b) on supervised stance recognition. The proposal makes use of a recurrent neural network with features learned by distant supervision from large unlabelled datasets. Word and phrase embedding models are trained using Word2Vec skip-gram (Mikolov et al., 2013), and then used for learning sentence representations with the aid of a hashtag prediction model. Finally, sentence vectors are optimised for stance recognition based on the labelled examples from the training corpus.

Also in the context of the SemEval-2016, the work in (Wei et al., 2016) presents an approach based on convolutional neural networks that, instead of simply predicting when the validation accuracy will reach its maximum, uses a voting scheme and other secondary improvements. The model is trained individually for each of the five targets of the SemEval-2016 corpus, and obtains the second best overall results for the supervised stance recognition track.

Subsequent to SemEval-2016, a number of improved systems have been proposed. The work in (Lai et al., 2016), for instance, explores the use of world knowledge - in the form of rules about friendships and political enmities - to enhance the task of recognising political stances in the SemEval-2016 corpus. The proposal consists of a stance recognition model enriched with semantic features of each target topic, which outperforms the participant systems of the original shared task.

Finally, the work in (Mohammad et al., 2017) presents a post-hoc evaluation of the SemEval-2016 stance recognition task, proposing a much simpler and more accurate model than the overall winner of the competition in (Zarrella and Marsh, 2016). The proposed model makes use of linear SVM and a set of features computed from the training data, such as word and character n-grams and word embeddings computed from an additional data set.

3 Current Work

The present investigation of moral stance recognition and polarity classification consists of a corpus data collection (described in Section 3.1), and two individual experiments: stance recognition (Section 3.2) and stance polarity classification (Section 3.3). In both cases, we shall focus on methods that rely on lexical and morphological knowledge only by making use of word and char n-grams.

3.1 Corpora

Our initial goal was to create a corpus of moral stances in the Brazilian Portuguese language that would preferably be (a) at least as large as the English training dataset for SemEval-2016 supervised stance recognition task (Mohammad et al., 2016b), (b) more well-balanced if possible, and (c) not limited to the Twitter domain. To this end, we collected a 180k-word corpus conveying over 5,000 moral stances from two sources - Twitter and stances elicited through crowd sourcing - about five topics: abortion, death penalty, drug legalisation, criminal age, and racial quotas. Elicited texts are, on average, 3.5 times longer than tweets.

Corpus descriptive statistics for our two domains are summarised in Table 1.

Twitter messages were collected by searching Brazil Twitter for specific key words (e.g., 'abortion' etc.). For each topic, an initial 7000-message set was selected for manual inspection and labelling.

Elicited stances were obtained from a crowd sourcing task involving 490 Brazilian Portuguese native speakers. Participants were requested to give their opinions about each of the target topics by providing answers in a 0 (totally disagree) to 5 (totally agree) scale and, subsequently, were requested to provide motivation for each of their opinions by writing a short text. The elicited corpus has been subject to spell-checking and it is overall much more well-formed than the Twitter data, and with a larger vocabulary.

Twitter messages were manually labelled by assigning a positive/negative class to all messages that unequivocally expressed a stance on the intended topic, and by assigning the class 'other' to any message that did not meet these criteria. Thus, the class 'other' represents the fact that, despite containing a key word of interest, the message did not convey any obvious stance about the target topic, and it was therefore regarded as noise[1].

Twitter text labelling proceeded until a minimum of 240 instances of each of the three class were identified, or until the end of the dataset was reached. This allowed us to obtain a certain balance between for/against stances for most topics, but resulted in a vast majority of samples labelled as 'other'. Thus, the 'other' class - which corresponds to non-stance text - is several times larger than the positive and negative classes in all five topics.

Elicited stances, by contrast, were assigned labels automatically based on the opinion scores provided by the crowd sourced participants. More specifically, scores 0 and 1 were taken as representing negative stances, 2 and 3 as neutral stances, and 4 and 5 as positive stances. Unlike the Twitter dataset, we notice that all elicited texts contain, by definition, some stance on the topics under discussion, and hence there is no 'other' (or non-stance) class in this domain.

Class label distributions for the Twitter and elicited datasets are summarised in Table 2.

3.2 Stance Recognition

Our first experiment - stance recognition - is presently defined as the binary classification problem of deciding whether a given text conveys any attitude towards a certain target topic or not. Since all texts from our elicited data (cf. the previous section) express, by definition, some stance about the target topic, the present task is applicable to Twitter data only.

3.2.1 Models

For the stance recognition task, a range of n-gram models - from 1 to 5 words and from 3 to 16 characters - was considered, and we found that character-based models always outperform word-based models. As a result, all models under consideration for this task are based on character n-grams only.

In what follows we consider the use of TF-IDF character counts (here by called our *Select.char* model) with k-best univariate feature selection using ANOVA F1 as a score function. By combining relatively long character sequences (which in most cases encompass words) with feature selection, we expect *Select.char* to outperform the alternatives under consideration, as discussed below.

The *Select.char* model was trained by making use of the best out of three possible learning methods - Naive Bayes, Logistic Regression and Mul-

[1] For instance, annotators came across a number of references to 'Aborto Elétrico' (electrical abortion), which is the name of a rock band with no relation to any stance about the target topic.

Table 1: Corpus descriptive statistics

Source	vocab. size	words	messages	words / msgs
Twitter	5,789	44,564	2,792	16
Elicited	9,081	137,122	2,450	56
Overall	11,845	181,686	5,242	35

Table 2: Class distribution for Twitter and elicited data.

	Twitter stances			Elicited stances		
Topic	for	against	other	for	neutral	against
Abortion	240	384	2570	310	105	75
Death penalty	801	244	1518	105	125	260
Drugs	335	181	1482	263	129	98
Criminal age	243	240	1433	198	104	188
Racial quotas	240	364	2596	205	128	157
Overall	1859	1413	9599	1081	591	778

tilayer perceptron, with optimal k-values selected in the 5000 to 90000 range at 1000 intervals by performing grid search on the training dataset.

In addition to that, the entire input feature set (i.e., with no feature selection) is taken as the basis for two simpler methods - logistic regression (*LogReg.char*) and multilayer perceptron (*MLP.char*). The latter consists of 3 layers conveying 150 neurons each, and using rectified linear units (ReLU) as an activation function.

The three models of interest - *Select.char*, *LogReg.char* and *MLP.char* are to be evaluated against a majority class baseline *Majority*.

3.2.2 Data

The experiment makes use of the Twitter dataset described in Section 3.1 with random 80:20 train-test split.

3.2.3 Evaluation

Table 3 shows F1 results of stance recognition on Twitter data for both positive (stance) and negative (others, or non-stance) classes, and overall weighted F1 scores obtained by each model under consideration. Best weighted F1 scores for each target topic are highlighted.

As expected, all models easily outperform the *Majority* baseline, and the combination of char n-grams and feature selection in *Select.char* generally outperforms the alternatives under consideration, albeit for a small difference. This may be partially explained by the heavy data imbalance (cf. Table 2), which may have obscured possible differences across models. Moreover, we notice that variation across target topics is also small, suggesting that stance recognition is relatively topic-independent.

3.3 Stance Polarity Classification

Our second experiment - polarity classification - is presently defined as the binary classification problem of deciding whether a given stance expressed as text shows a positive or negative attitude towards the target topic. For this task we consider both elicited stances, and also the portion of Twitter data that conveys a positive or negative stance, that is, disregarding only those tweets labelled as 'other' (cf. section 3.1.)

3.3.1 Models

Given the overall positive results of character-based models and feature selection in the case of stance recognition (cf. the previous section), we will consider models of this kind for stance polarity classification as well. To this end, we make use of a char n-gram model - hereby called *MLP.char* that is similar to *Select.char* in the previous section, except that in the present case we will focus on the use of MLP classifiers only.

In addition to *MLP.char*, we also consider a mode based on skip-gram word embeddings (Mikolov et al., 2013), hereby called *MLP.w2vec*. The model makes use k-best univariate feature selection with the ANOVA F1 function over TFIDF-weighted word embeddings of size 50, 100 and 300. Learning methods under considerations are

Table 3: Weighted average F1 results for Twitter stance recognition

	Majority			LogReg.char			MLP.char			Select.char		
Topic	stance	other	avg	stance	other	avg	stance	other	avg	stance	other	avg
Abortion	0.00	0.89	0.71	0.40	0.85	0.76	0.43	0.88	**0.79**	0.42	0.89	**0.79**
Death penalty	0.74	0.00	0.44	0.62	0.74	0.69	0.65	0.78	0.73	0.72	0.81	**0.78**
Drugs	0.84	0.00	0.61	0.43	0.76	0.67	0.41	0.82	0.71	0.41	0.84	**0.72**
Criminal age	0.00	0.85	0.64	0.45	0.80	0.71	0.55	0.84	**0.76**	0.53	0.84	**0.76**
Racial quotas	0.00	0.89	0.70	0.36	0.85	0.75	0.36	0.86	0.76	0.33	0.89	**0.77**
Overall	0.32	0.53	0.62	0.45	0.80	0.72	0.48	0.84	0.75	0.48	0.85	**0.76**

MLP classifiers of 1-3 layers with numbers of neurons ranging from 33 up to the size of the embedding vector, and using either ReLU or hyperbolic tangent (tanh) as an activation function. Optimal parameters and vector sizes were determined by performing grid search on the training data.

Finally, given the affective nature of the topics in the corpus, we will also consider the use of psycholinguistic knowledge as provided by the LIWC dictionary (Pennebaker et al., 2001). LIWC models word categories such as love, money, power etc. that are known to play a significant role in a range of NLP tasks such as sentiment analysis and, in particular, personality recognition from text. Psycholinguistic knowledge will hence be the basis of a simple model - hereby called *LIWC* - consisting of a 64-feature subset of LIWC category counts for Brazilian Portuguese (Filho et al., 2013).

The three models of interest - *MLP.char*, *MLP.w2vec* and *LIWC* - are to be evaluated against two baseline systems: a majority class baseline *Majority*, and a word-based TFIDF model with k-best feature selection - hereby called *LogReg.word*, in both cases making use of logistic regression.

3.3.2 Data

The experiment makes use of the elicited stance dataset, and also the stance portion of the Twitter dataset as described in Section 3.1. In both cases, a random 80:20 train-test split was performed.

3.3.3 Evaluation

Table 4 shows weighted F1 score results obtained by each model under consideration for the Twitter domain, and Table 5 shows results for the elicited data. In both cases, best weighted F1 scores for each target topic are highlighted.

Although all Twitter models outperform the *Majority* baseline, results are overall mixed and, for two topics (death penalty and criminal age), the word-based baseline model *LogReg.word* actually outperforms the alternatives. Moreover, we notice that the psycholinguistics-based *LIWC* approach produces the second lowest results of all, and that none of the top-performing models seems clearly superior to the others. We hypothesise that the close results obtained by *LogReg.word*, *MLP.w2vec* and *MLP.char* may be partially explained by the use of the same underlying feature selection method, which turned out to be more significant than the actual choice of text representation or learning method.

Contrary to the Twitter scenario, results for the elicited data were uniform, with the *MLP.char* approach outperforming all alternatives by a large margin, and once again leaving the *Majority* baseline and *LIWC* models at the bottom. We hypothesise that, as in the case of the stance recognition experiment in the previous Section 3.2, the use of long char n-gram sequences does help the present task as well, and that it may have been particularly successful in combination with the higher text quality of elicited stances in our data.

Finally, a note on the use of char n-grams. As expected, the k-best n-grams in the models that use feature selection largely correspond to single words (e.g., ‘unacceptable’) or short expressions (e.g., ‘I agree’), both of which clearly denoting stances in our domains. As a result, the model is comparable to a variable-length word n-grams, but with greater flexibility to include subwords (e.g., ‘believ*’). To illustrate this, Figure 1 shows the char n-grams distribution among the k-best terms in the polarity classification task from the elicited dataset. From these results, we notice that the selected char n-grams largely fall within the 4..10 range, peaking at n-grams with a length of 6.

Table 4: Weighted average F1 results for polarity classification from Twitter data

Topic	Majority	LogReg.word	LIWC	MLP.w2vec	MLP.char
Abortion	0.41	0.68	0.61	0.66	**0.71**

4 Final Remarks

This paper addressed the issue of moral stance recognition from text. We introduced a labelled corpus of stances taken from Twitter and additional crowd-sourced texts, and a number of supervised models of stance recognition and stance polarity classification.

Initial results suggest that both tasks may be performed with relatively high accuracy by making use of simple models based on char n-grams and feature selection. As expected, best results were observed when using more well-formed (in our case, crowd-sourced) texts, rather than when using Twitter data.

The corpus and the present results are expected to be taken as a reference for further studies in moral stance recognition in Brazilian Portuguese natural language processing. As future work, we intend to expand the current dataset in both domains by adding more instances and topics, and assess the use of deep learning methods for both the stance recognition and the polarity classification tasks.

The “Jump and Stay” Method to Discover Proper Verb Centered Constructions in Corpus Lattices

Bálint Sass
Research Institute for Linguistics, Hungarian Academy of Sciences
Budapest, Hungary
sass.balint@nytud.mta.hu

Abstract

The research presented here is based on the theoretical model of corpus lattices. We implemented this as an effective data structure, and developed an algorithm based on this structure to discover essential verbal expressions from corpus data. The idea behind the algorithm is the “jump and stay” principle, which tells us that our target expressions will be found at such places in the lattice where the value of a suitably defined function (whose domain is the vertex set of the corpus lattice) significantly increases (jumps) and then remains the same (stays). We evaluated our method on Hungarian data. Evaluation shows that about 75% of the obtained expressions are correct, actual errors are rare. Thus, this paper is 1. a proof of concept concerning the corpus lattice model, opening the way to investigate this structure further through our implementation; and 2. a proof of concept of the “jump and stay” idea and the algorithm itself, opening the way to apply it further, e.g. for other languages.

1 Introduction

In this paper we present a novel, original verbal construction discovery method. Our starting point will be our former paper (Sass, 2018) which describes a theoretical model considered an appropriate basis for extracting so-called *proper verb centered constructions* from analysed corpora.

First, let us look at our target. In this terminology, verb centered constructions (VCC) are verb + slot structures, where slots can be unfilled (free) or filled (by a filler word). In English, subject (SBJ), direct object (OBJ) and all prepositions can be considered as slots. For example, ‘*take* + *SBJ* + *OBJ* + *into:account*’ has two free slots (SBJ and OBJ) and a filled ‘*into*’ slot where the filler (marked by a colon) is the word ‘*account*’. In this approach, a filler is the head of the phrase realizes the slot. Length of a VCC (l) is defined as number of slots and fillers added up, the above example has a length of 4.

Then, what are *proper* verb centered constructions (pVCC)? They are complete and clean. That means they contain all necessary elements, and does not contain any unnecessary element for expressing the core meaning of the verbal expression in question. For example, ‘*take* + *SBJ* + *OBJ:part* + *in*’ is proper, while ‘*take* + *SBJ* + *OBJ:part*’ is not proper (because not complete), and ‘*read* + *SBJ* + *OBJ*’ is proper, while ‘*read* + *SBJ* + *OBJ:book*’ is not proper (because not clean). In other words, free slots in pVCCs are complements (subject included) and fillers in pVCCs are idiomatic, carrying some special meaning.

It is clear that pVCCs are constructions. They are form–meaning pairs (Goldberg, 2006; Kay and Michaelis, 2015), they are units of meaning (Teubert, 2005; Danielsson, 2007). Their meaning is assigned to the whole form, they cannot be divided into smaller units if we want to keep the original meaning.

On the other hand, pVCCs are not necessarily multiword. They are multiword in most cases as we have seen in the examples, but there are cases when the multiword property is not satisfied in the strict sense that they consists of two or more whole *words*. Consider for example ‘*read* + *SBJ* + *OBJ*’, it consists of three elements, from which only one is a word, the other two are just slots. Or consider a Hungarian example. In this language slots are specified mostly by bound morphemes, namely case markers. The Hungarian counterpart of ‘*believe* + *SBJ* + *in*’ is ‘*hisz* + *NOM* + *INE*’

Proceedings of Recent Advances in Natural Language Processing, pages 1076–1084,
Varna, Bulgaria, Sep 2–4 2019.

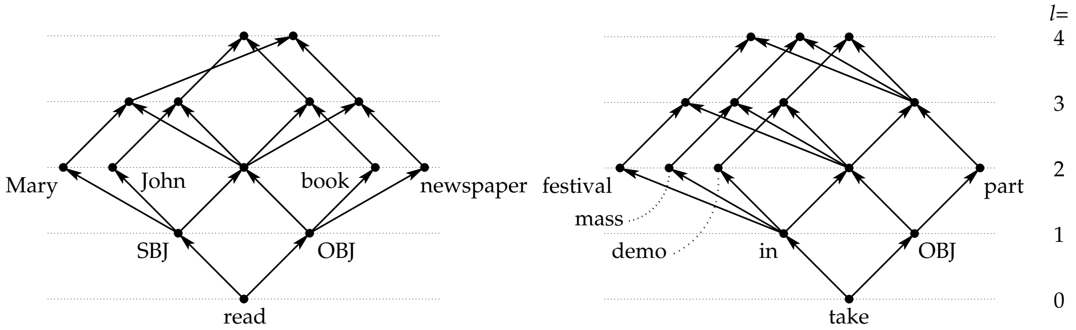

Figure 1: This pair of figures illustrate the notion of double cube and the notion of corpus lattice. On the left, the double cube of '*John reads a book*' ('*read SBJ:John OBJ:book*') and the double cube of '*Mary reads a newspaper*' ('*read SBJ:Mary OBJ:newspaper*') are combined together to create a small corpus lattice. On the right, three clauses are combined. This figure presents two dimensional structures. The subject slot is not depicted in the latter case, it would require three dimensional double cubes.

respectively, where '*NOM*' is for nominative (subject) case, and '*INE*' is for inessive case (appearing as a '*-ban/-ben*' suffix). The English version is strictly multiword, while the Hungarian is not.

We saw that a pVCC should be complete. '*take part*' is a MWE, but '*take + SBJ + OBJ:part + in*' is a pVCC of full value containing all necessary elements. According to Siepmann (2005, page 416) „collocation and verb complementation are intimately related . . . a two-word combination cannot possibly be viewed as a fully-fledged collocation." Simply put, the free slots are just as important as the words/fillers. They turn MWEs into real constructions.

This concept of completeness is essential and unique here. We barely see it neither in classical papers, nor in recent works. Formerly, many papers dealt with just e.g. verb+noun expressions (Evert and Krenn, 2001; Fazly and Stevenson, 2006; Iñurrieta et al., 2016), but recently, also, even the definition of verbal MWEs does not explicitly include the preposition or case marker constituting a complement that, we are convinced, is an inherent part of the expression (Ramisch et al., 2018; Walsh et al., 2018). It is maybe the dependency annotation itself which does not support the approach presented here as case markers are usually not taken as separate units (see Simkó et al., 2017, Fig. 4). Because of the above, we can evaulate our method in itself only.

pVCCs are a large and key group of verbal expressions: they bear the different meanings and usage patterns linked to verbs. We think that it is a good idea if a dictionary presents exactly the set of pVCCs concerning a verb. It is not crucial that they are formally multiword or not. To cover all patterns, we should handle MWEs and constructions uniformly, in one framework. The method presented here shares this attitude.

2 The Initial Model and the Conjecture

Let us summarize the initial model here. The basic processing unit is the clause, the unit which contains a verb together with its complements and adjuncts, and consequently, a pVCC. So as preprocessing, clause boundary detection and some shallow parsing is needed on the input corpus to determine the verb and the top level slots and fillers.

Corpus clauses are represented as so-called *double cubes* (Sass, 2018, Fig. 3), which are a kind of mathematical lattice structures. The verb is at the bottom, every edge adds a slot or a filler to an existing slot (chosen from the clause in question). Vertices are VCCs, they represent nested VCCs of the clause with slots and fillers present or not in all variations. The top represents the original clause: all slots are there and filled as in the original clause. One distinguished vertex is the pVCC.

In the next step, the so-called *corpus lattice (CL)* is created from double cubes containing the same verb. Using a kind of lattice combination operation, double cubes are projected onto each other in a way that where they are identical they will overlap, where they are different they will split up (Fig. 1). It is important that, at the end, the evolving large semilattice structure will represent all clauses of a given verb, and also the distribution of all free and filled slots occurring beside this verb.

The initial paper contains only vague conjectures about how to actually apply the corpus lattice

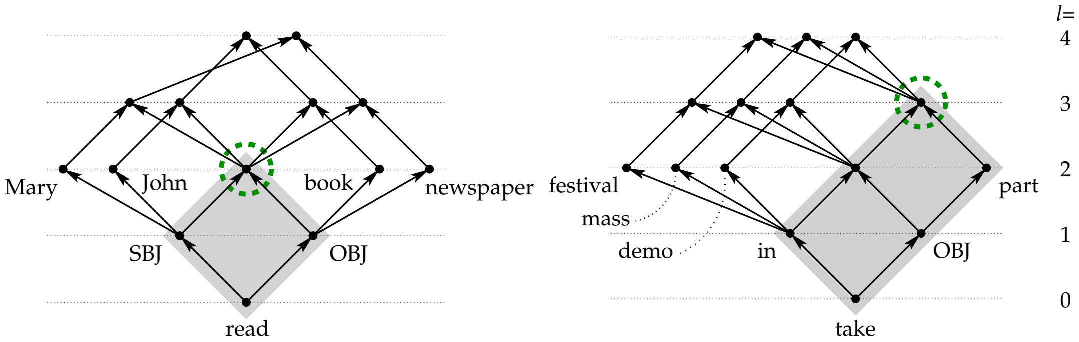

Figure 2: These are the same CLs as in Fig. 1, but here the pVCCs are marked: they are circled. The pVCC is '*read + SBJ + OBJ*' and '*take + SBJ + OBJ:part + in*' in the two figures respectively. f values are also depicted: $f > 1$ in the gray areas ($f = 2$ in the left lattice and $f = 3$ in the right one), at the other vertices $f = 1$.

structure for discovering pVCCs. We thought, the fact that the corpus lattice contains all information about the distribution of slots and fillers makes it a suitable "representation which can be a basis" for finding pVCCs. We introduced a function (we call it f now) on vertices of the corpus lattice: it is essentially the corpus frequency of the VCC represented by the given vertex. In other words, this f shows how many corpus clauses are represented by the given vertex, or how many corpus clauses this VCC fits to. We formulated the conjecture that pVCCs should be "at some kind of thickening points of the corpus lattice", and added that a future algorithm would move through the corpus lattice somehow systematically to find them.

3 The Idea of "Jump and Stay"

The model described above was purely theoretical. Our current contribution are implementation of the data structure, elaboration and implementation of an algorithm for discovering pVCCs using this data structure, and evaluation of the algorithm on real data.

For outlining our idea which leads to the algorithm, let us take a look at the already known figure from another perspective (Fig. 2). The CLs in the figure are for demonstration purposes: they are, of course, very small, but suitable for presenting the main point (cf. a real CL can be very wide (≈ how many words are there in the corpus), but not too tall (2 × how many slots are in the longest clause)). We mention that f always grows monotonically downwards in a CL.

Looking at Fig. 2, how can vertices representing pVCCs be characterized? Firstly, as we go top-down in the CL, f suddenly increases at certain points. Secondly, of these vertices, we should prefer those which are located higher in the corpus lattice. As it may be suspected, the first observation will be the basis of "jump" and second one will be the basis of "stay".

The principle of "jump and stay" can be formulated as follows: *jump* means that we advance from a vertex to an adjacent one downwards in the CL if f substantially increases, and *stay* means that we advance from a vertex to an adjacent one upwards in the CL if f remains more or less the same. (Please note, that *stay* also means advancing between vertices, the term itself refers to the fact that the value of f does not change during this step.) In other words, where one (or only few) arrows originate from a vertex, it tend to be a place of stay, similarly, when we have many arrows from the same vertex, it is usually a place of jump. Notice that if we apply the two rules of the principle starting from any of the vertices in Fig. 2, we end up at the circled pVCC. This is the point, this is the main idea of this paper itself.

If we look a bit more closely, in fact, we can end up at one of the top vertices depending on the application order of the two rules, at least in case of the CL on the left. As we will see, top vertices (fully filled clauses) will be excluded from being a pVCC.

pVCCs can be considered as some kind of thickening points indeed, where many edges converge (see the left lattice in Fig. 2), but stating the principle of "jump and stay" is much more clearer.

In addition, we have an independent argument in support of our idea. The "jump and stay" idea

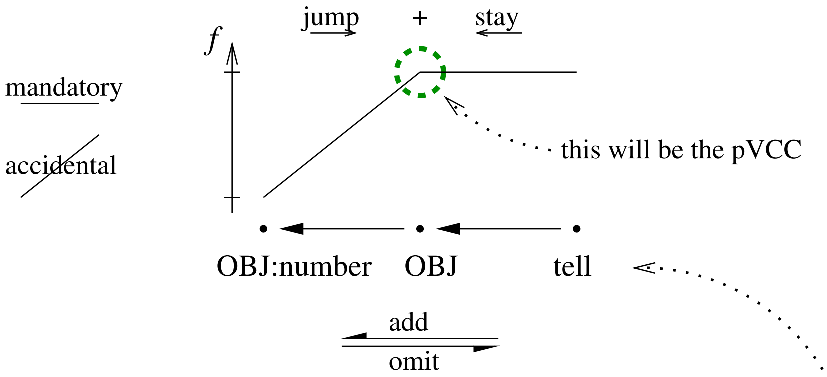

Figure 3: A summing-up of the "jump and stay" principle. A three-vertex piece of the CL of '*tell*' is shown together with the f values for each vertex. It is clear, that this verb requires a direct object, but the direct object itself can be several different words from which '*number*' is quite rare. In this case, there is a stay from '*tell*' to '*tell + OBJ*', and a jump from '*tell + OBJ:number*' to '*tell + OBJ*' so the pVCC is '*tell + OBJ*' here, and that is correct. At the bottom, the directions to add/omit an element to a VCC are shown. On the left, it is shown how a part of the graph of the f function basically look like in the case of mandatory/accidental elements.

is nicely consistent with the fact that constructions have mandatory and accidental elements, some elements are necessary while some are not, as it is also reflected in the definition of the pVCC.

When we jump, we try to omit something which is not mandatory. A typical case of jump, when there are several different fillers (e.g. the various foods as direct object of '*eat*', which are obviously relatively rarer one by one) in a given slot, and the lower vertex is the one, where this slot is free. Advancing to this vertex, we omit this diversity of fillers, we omit something that does not seem to be mandatory (cf. the vertex marked with '*in*' and the three arrows originating from it pointing to the left in Fig. 2).

When we stay, we try to add something which is mandatory. A typical case of stay, when we add an element (a slot or a filler to an existing slot) to a vertex/VCC, but we still cover roughly the same amount of original corpus clauses. This shows, that the added element is mandatory, namely it occurs in nearly all clauses represented by the original VCC. (cf. the vertex marked with '*in*' and the arrows above it in the gray area in Fig. 2).

We always advance by jump downwards (and by stay upwards) in a CL, the other way round – discarding what is needed and adding what is not needed – would not make much sense.

Yet another argument supporting our idea. As we investigate the structure of different CLs, it turns out that a typical pVCC is an endpoint of both jumps and stays, or to put it another way no jump and no stay originate from it (Fig. 2). Plain (not proper) VCCs, however, does not have this property. Almost always, they are a starting point of a jump or a stay (see '*take + OBJ:part + in:festival*' or '*take + OBJ:part*' in Fig. 2 again).

To end this section, look over the "jump and stay" principle in a summary figure (Fig. 3).

Recall the definition of pVCC: stays increase completeness, and jumps increase cleanness. We think that those vertices have the most chance to be a pVCC which can be reached by a stay from below and by a jump from above at the same time.

4 Implementation of the Data Structure

The corpus lattice is a special kind of graph structure. What crucially important to use it effectively is to be able to effectively advance from one vertex to another connected by an edge. For this purpose, we store vertices and edges in hashes (dictionaries) in our python implementation. Edges are stored firstly in one direction, and secondly in the other direction separately.

Starting from a language resource consisting of clauses represented in the form of verb + slots + fillers we build a CL (for each verb separately) as follows:

1. We go through the corpus and take clauses one by one.
2. We build the appropriate double cube of the given clause: starting from the fully filled

clause, we add adjacent edges and vertices omitting slots/fillers one by one recursively.

3. Our graph data structure for a double cube and for a CL both will be the following: we store vertices in a hash, and edges in a hash of hashes (as we have said, in each direction separately). The key of the hashes is a "canonical" JSON string form of the given VCC, its slots ordered alphabetically by slot names.
4. Finally, we combine the current double cube to the corpus lattice being built recording and updating the appropriate f values.

This way we obtain a quite effective representation of a CL.

Input data should be in a specific JSON format which can be generated from either a (shallow) dependency or a (shallow) constituency parse of the input corpus: the verb, the slots and the fillers need to be identified. It is similar to "top level syntactic sequence of the constituent tree" (Shi et al., 2016), with the difference that the order of constituents is not taken into account in our approach.

We used Hungarian data (Sass, 2015) for our experiments. This dataset contains 28 million clauses in a format which was not complicated to convert to the needed input format.

5 The Algorithm

In this section we describe how we implemented the "jump and stay" principle (section 3) using the data structure presented above (section 4).

At the beginning of work, we separated about 7 percent of the data for development purposes. That means, during developing the algorithm we used data only from this part. Developing the algorithm is a kind of learning phase, we draw conclusions based on the input data. It is very important not to use test data for this.

The algorithm consists of the following steps:

1. We go through each vertices of the CL. (The order does not matter, but we chose to begin with the bottom, and continue upwards as pVCCs tend to occur not too far from the bottom.)
2. Some kind of vertices are omitted early on: which are too long (has a length more than 8 ($l > 8$)), which are too rare (has $f < 3$), and which have no out-edge (that means which is at the top of the CL).
3. Firstly, we look for a stay, i.e. try to add a needed element. If the ratio of $f(\text{actual})/f(\text{above}) < 1.7$, then we consider this a stay, and advance to the vertex above. In case of several stays we choose the one with the smallest ratio.
4. Secondly, when no stay can be found, we look for a jump, i.e. try to discard an element which is not needed. If the ratio of $f(\text{below})/f(\text{actual}) > 4$, then we consider this a jump, and advance to the vertex below. In case of several jumps we choose the one with the largest ratio.
5. If we get to a new vertex, we repeat steps 3. and 4.
6. If neither a stay nor a jump can be found, we stop, and if the current VCC is not at the top of the CL (that means it has out-edges) then it is tagged as a pVCC.

Dealing with Hungarian data, at the beginning we do a modification based on Hungarian verb conjugation. Some Hungarian verb suffixes imply that the verb is transitive even when the direct object is not present in the clause. In such cases we add a free OBJ slot. Besides that, Hungarian being a pro-drop language we add a free SBJ slot to every clause without an explicit subject.

A small addition to step 4. In fact, we do not do a jump in every case. If the jump would omit the *last* filler from a VCC, we do not take this step. That is because specific fillers are usually important parts of a pVCC, and full-free VCCs would usually be frequent enough to swallow all pVCCs (being longer only by one filler) performing a jump. So we do the jump only if there remains at least one filler in the resulting VCC or there is no filler in the initial VCC already.

Threshold values (exactly 1.7 for stays, and 4 for jumps) are manually tested and set values. They gave the best results after some experimenting on the development corpus.

Fig. 4 shows some specific examples on how exactly our algorithm works in practice.

The source code of the algorithm and also for building and handling the CL data structure, together with some sample data, is available at `https://github.com/sassbalint/double-cube-jump-and-stay`. The algorithm is fast enough. Building a 365000 vertex CL and investigate it for pVCCs took 63 seconds in total on our server.

```
#4                                                  f= l=
["FAC", null]                                      309  1
 Processing.
 A stay found, we follow.
["FAC", null, "NOM", null]                         309  2
 A stay found, we follow.

 A stay found, we follow.
["ACC", null, "FAC", "jó", "NOM", null]            300  4
 No stay (ratio=5.17 > 1.7), we stop.
 No appropriate jump (keeping a filler, 1.02 < 4), we stop.
["ACC", null, "FAC", "jó", "NOM", null]            300  4  pVCC

#22699                                              f= l=
["ACC", "költségvetés", "FAC", "jó", "NOM", null]    4  5
 Processing.
 No stay (ratio=2.00 > 1.7), we stop.
 An appropriate jump (keeping a filler, 4<) found, we follow.
["ACC", null, "FAC", "jó", "NOM", null]            300  4
 No stay (ratio=5.17 > 1.7), we stop.
 No appropriate jump (keeping a filler, 1.02 < 4), we stop.
["ACC", null, "FAC", "jó", "NOM", null]            300  4  pVCC
```

Figure 4: Two examples from the output of the algorithm. This demonstrates how the algorithm works: it starts from a vertex and after some jumps and stays it finds the appropriate pVCC in the end. In the first example, we start from a one-free-slot VCC, and get to the pVCC through three stays, adding three mandatory elements (in bold), while the f value decreases from 309 only to 300. In the second example, we start from a longer VCC where also ACC is filled. Here, only one jump is needed, omitting the accidental element '*költségvetés*' ('*budget*') (in bold), to get to the pVCC. (VCCs are in black, additional info is in gray. VCCs are presented here as JSON lists in the form of: slot, filler, slot, filler. . . , where *null* stands for a free slot.) The verb is '*hagy*' ('*allow*'), input data is taken from the development corpus. As we see, the same pVCC is found in both examples, it is '*hagy + NOM + ACC + FAC:jó*' which is word by word '*allow + SBJ + OBJ + FAC:good*' meaning '*approve + SBJ + OBJ*'. (ACC is for accusative case, FAC is for factive case.) This figure gives a good example of a typical pVCC which "is an endpoint of both jumps and stays", as we said earlier (on page 4).

6 Evaluation and Discussion

The evaluation was carried out in the following manner. Two moderately frequent verbs was chosen: '*húz*' ('*draw/pull*') and '*vet*' ('*cast/throw*'). Their data was taken from the testing part of the corpus (which was 93 percent of the corpus). Our "jump and stay" algorithm was run on these two verbs, and then – according to the f value – the first 20 pVCCs was investigated whether they are correct or not. The input data for these verbs were not only taken from the test corpus, but these verbs were not even looked at in any way during the development phase.

See the results of the evaluation in Table 1. Third column of the table contains the results of the algorithm: the Hungarian pVCCs, fourth column is f value, fifth column is an English translation word by word (or element by element), sixth column is an approximate English counterpart. pVCCs are shown as usual, the verb is taken separately at the top. Slots in Hungarian are marked by the three letter abbreviation of the given case marker: NOM is for nominative (subject) case, ACC is for accusative (direct object) case, and there are some others. Their surface form is not important here, their approximate translation can be seen in the fifth column. Unfilled NOM slots are not shown. (In Hungarian there are also postpositions. Apart from that they are separate words they play similar role as the case markers. Thus,

#	eval	Hungarian pVCC	*f*	word by word	English counterpart

40.	p	ACC + NOM:aki	201	OBJ + SBJ:who	who casts/throws sg

Table 1: Evaluation of the "jump and stay" method on '*húz*' ('*draw/pull*') and '*vet*' ('*cast/throw*'). Correct pVCCs are marked with ✓. Further explanation is in the main text.

they have their own slots in some pVCCs, we can find '*után*' ('*after*'), '*felé*' ('*towards*') or '*közé*' ('*between*') in the table.)

Nevertheless, the most important column is the second one which contains the evaluation of the given pVCC in column three. There are four possible values here: ✓ means correct, ≈ means roughly correct, p means contains a pronoun as a filler, and × means not correct (i.e. not complete or not clean).

On the one hand, we see that 70-80 percent of the pVCCs are completely correct, which can be considered a high value in itself. On the other hand, only one single real error is found among 40 constructions which is only 2.5 percent. This one is #17, it is not complete, the direct object slot would be filled by '*vonal*' ('*line*'). The p code indicates a rather trivial problem, which seems to be easily eliminated. Pronouns are very common so they can appear as fillers, but they very rarely bear idiomatic meaning. So the solution could be simply to delete them in a preprocessing step and leave a free slot instead. Note that '*oneself*' and '*each other*' are certainly exceptions here.

Looking through the table, we can make some interesting observations. We see several correct pVCCs, they are complete and also clean. Considering the last column we see that different pVCCs are often translated using completely different verbs. Optionality appears in the form of two (or more) versions of the same construction. #2 and #20 shows essentially the same construction, without and then with a specific complement. This shows that this expression is used both ways, and the ratio of f values (77/420 = 18%) tells us something about which one is how frequent. Constructions #28, #29, and #30 show the importance of our concept of completeness (see secton 1) which takes both collocation and complementation into account. A certain filler often brings in a certain complement, and a new complement is often a sign of a new pVCC.

7 Conclusion and Future Work

Taking the theoretical model of double cubes and corpus lattices we created a new method for discovering useful verbal expressions in corpora. Our idea is called "jump and stay" (see section 3) because, in simple terms, wandering through the corpus lattice the value of a certain function jumps up and then stays the same at certain locations, and these are the locations which points to our target expressions, the so-called proper verb centered constructions. These constructions are proper in the sense that they contain exactly the necessary elements. Consisting of a verb plus slots and fillers, they can be simple or even quite complex; they are not necessarily MWEs, but they are constructions indeed. The evaluation revealed that at least 70-80 percent of the obtained expressions are pVCCs. We worked with Hungarian data, but it would be more or less straightforward to experiment with other languages.

An encouraging feature of the algorithm that it provides complete expressions most of the time (see section 6), incomplete VCCs rarely turn up as pVCCs. However, it has limitations as well. We mentioned the problem with pronouns, another one that there is definitely place to work out some more sophisticated process for setting the threshold values for jumps and stays, but take a look at a more general observation now. In simple cases, if a stay is found (that means an additional element is needed), we add it to the VCC in question doing the step in the corpus lattice defined by this stay (cf. first listing in Fig. 4). But what if we have two (or more) potential additional elements which are not significant separately, but together (their f values added up) they would define a regular stay? In other words, what to do when two (or more) elements seem to be mutually exclusively mandatory at one point? This question can result in some incomplete pVCCs now, and solving this is a promising development direction.

Our conclusion is that the original idea works. The present implementation can be considered as a proof of concept with respect to the corpus lattice model. Clearly, properties of the corpus lattice refer to where pVCCs are located, the introduced lattice structure turned out to be suitable to find them. On the other hand, the "jump and stay" principle also proved to be promising. The basic algorithm presented here can be improved in several aspects, and also the properties, the natural structure of corpus lattices (of given verbs or verb classes) can be further investigated, explored and taken advantage of in the future.

Abstract

In recent years an increasing number of analyses of offensive language has been published, however, dealing mainly with the automatic detection and classification of isolated instances. In this paper we aim to understand the impact of offensive messages in online conversations diachronically, and in particular the change in offensiveness of dialogue turns. In turn, we aim to measure the progression of offence level as well as its direction – For example, whether a conversation is escalating or declining in offence. We present our method of extracting linear dialogues from tree-structured conversations in social media data and make our code publicly available.[1] Furthermore, we discuss methods to analyse this dataset through changes in discourse offensiveness. Our paper includes two main contributions; first, using a neural network to measure the level of offensiveness in conversations; and second, the analysis of conversations around offensive comments using decoupling functions.

1 Introduction

Offensive language is a complex problem, especially in social media where operators are required to counter illegal hate speech in user-generated content. However, it is not clear what counts as offensive language since even humans struggle to find objective definitions (Chen et al., 2012). The general approach to this problem is to train systems for the detection of such unwanted content based on human annotations of empirically gathered data instances.

Several shared tasks engaged with the topic of offensive language detection in recent years, for example *OffensEval-2019* for "Identifying and Categorizing Offensive Language in Social Media" (Zampieri et al., 2019b) or *GermEval-2018*, the "Shared Task on the Identification of Offensive Language" (Wiegand et al., 2018). The difficulty for machine learning systems at this task becomes apparent when considering the performance scores of the submitted systems. For example, at *GermEval-2018* the best performing submitted system reached a macro-averaged F_1-score of only 76.77 %. Here, systems struggle to simultaneously detect all various types of offensive language and it remains highly questionable if we can act on these automatic predictions and delete detected offensive language in practical applications.

Following the hint that deletion based on predictions of a machine learning system might not be the most appropriate course of action, we try to approach the problem of offensive language from another direction. In almost the same manner as mentioned above, we rely on machine learning of annotated instances to detect messages which might be offensive; however, we intend to act differently. Rather than deleting supposedly unwanted instances, we suggest to use tactics to counter offence. We aim for an empirical approach to automatically gather such tactics in a first step by a data analysis of instances where humans attempt to defuse offensive situations. In this paper we present our corpus creation using social media data from *Reddit* and discuss methods to analyse offensive dialogues. With our method we intend to classify conversations by offence direction, to facilitate future study on language use in offensive conversations. This research step could

Proceedings of Recent Advances in Natural Language Processing, pages 1085–1093,
Varna, Bulgaria, Sep 2–4 2019.

prove vital to Natural Language Generation researchers in their effort to tackle offensive language by developing similar tactics.

Hate speech detection, which is closely connected to the detection of offensive language, however, focusing on illegal offence, has also been researched extensively in recent years. An overview of seminal work in this field is given by Schmidt and Wiegand (2017).

Context aware models for hate speech detection have been analysed by Gao and Huang (2017). Their dataset also preserves the thread structure of microposts, however, their approach is to use the context to gather additional features for the detection process while they do not focus on analysing the change of offensiveness in the conversation.

In related work on offensive language detection in conversations, Khatri et al. (2018) present an extensive data collection strategy using different sources of social media data. While they also utilise *Reddit* as data source, they only analyse individual utterances regarding offence.

A corpus with a focus on analysing conversations is presented by Walker et al. (2012) as they mine data from a forum and specifically consider the structure of comments in threads. While this corpus has several annotations which might be useful for exploring issues pertaining to online debate, they do not discuss offensive language.

Our research shows similarities to Zhang et al. (2018) who try to identify conversations that are likely to turn into offenses and predict the point in which this is likely to happen. We would also like to refer to the notions of constructive language which is discussed by Kolhatkar and Taboada (2017) and to a certain extent related to cases of defusing offensive conversations.

For our analysis of contexts of offensive language in dialogues, we decided to acquire our own corpus material which we process using methods tailored for this task. In summary, the research questions which drive our data analysis are as follows: How do people in dialogues react to offensive language? – Especially in terms of: what tactics do they try to counter offence? From a methodological view, we are particularly interested in investigating how to measure the change of offensiveness in turns of a dialogue.

The further sections of this paper are structured as follows: Section 2 presents our data sources and outlines the corpus construction process. In Section 3 we list our methods for data processing and analysis which are then applied to our dataset in experiments as described in Section 4. Finally, we conclude by discussing the results and the efficiency of our methods in Section 5.

2 Corpus Data

The analysis of offensive comments in dialogues requires a dataset of user posted messages which are referencing other messages. Such data can mainly be found on online social media where multiple users discuss a certain topic while interacting with each other. In this section we discuss our corpus construction process and motivate our selection of dialogues.

2.1 Data Sources

The typical sources of online social media data, *Twitter* and *Facebook*, have been mined extensively for text data to be researched, also with regard to containing offensive language or hate speech. The microposts from *Twitter* often lead to flat conversation structures as users mostly initiate a discussion or directly reply to an initial post. Hence, we disregarded this data source for our research on the change of offensiveness in a dialogue. We also decided not to use data from *Facebook* as we could not locate a restricted domain. We were afraid that when only including messages from a few selected *Facebook*-sites, we would not be able to get enough data for a statistical analysis.

To acquire a corpus of deeply structured dialogues about constrained topics, we decided to sample comments from *Reddit*[2] which is a social news aggregation, web content rating, and discussion website. In our corpus we only include comments from the Europe-*Subreddit*[3] where users post news or discussions which are geographically or politically related to Europe. We reason this decision on the basis that we – as Europeans – feel eligible to assess the content of these posts and we assume this topic to include lively (possibly heated) discussions containing offensive language. While *Reddit* is an American organisation, authors of posts in the Europe-*Subreddit* are mostly Europeans, but this is not restricted. Non-European users are also allowed to participate in the discus-

[2] https://www.reddit.com/

[3] A *Subreddit* is a forum dedicated to a specific topic as part of the website *Reddit*. The Europe-*Subreddit* can be found at https://reddit.com/r/europe.

sions, however, the content has to be related to topics from Europe.

2.2 Source Data Structure

Comments on *Reddit* are structured in threads, each one being a directed graph form of a rooted tree – similar to forums. An initial post, called submission, is directly posted in a *Subreddit* where users share content by posting stories, links, images, and videos. It can also just consist of a headline. Users can then reply to the initial post or to previously posted replies in a recursive manner. Thus, a thread can comprise several comments structured in a tree with the submission as a main or top-level (level 0) post, which corresponds to the root of the tree. Direct replies to the top-level post, direct successors of the root, we consider as being on level 1, replies to those in turn as being on level 2, etc. Leaf nodes are posts which have no further direct replies. Thus, there is always exactly one directed path from the root to any comment in a thread. A comment can technically never be a direct reply to multiple comments, i. e. cannot have multiple direct predecessors.

2.3 Data Acquisition

The first step to construct our corpus is to download *Reddit* posts using the *Python 3 psaw*[4] module, which is a minimalist wrapper for searching public *Reddit* comments and submissions via the *pushshift.io Reddit API*[5]. Our script selects all comments in the time frame from 2009-12-31 23:00:00 (first posts in the Europe-*Subreddit*) until 2019-04-04 22:00:00 (date of our corpus initialisation). The downloaded submissions and comments are stored as individual dictionary objects, however, contain metadata (ID for itself and a link to the ID of the predecessor) which allows to reconstruct the abovementioned tree structure. We store them in a *pickle* object and save it into a file.

2.4 Corpus Format

To be able to efficiently process these threads automatically as well as manually by annotation, we convert the downloaded data into a specifically tailored *Extensible Markup Language (XML)* corpus format with the following general structure: A single root element `subredditcorpus` is defined as containing all the other elements. It consists of multiple `submission` elements which correspond to the threads in our Europe-*Subreddit* data. A `submission` element contains an optional `main_post` element (which is not present in a few cases when the submission consists only of a headline) and an arbitrary number of `comment` elements. A `main_post` element can either consist of a `link` element, in cases where no text comment is submitted and only a link to an external site or another *Reddit* post is given, or of a `comment` element itself. A `comment` consists of a text string and can recursively nest further comments – besides the `comment` element of the `main_post` element, which never has a successor; however, we do not ensure this in our *XML Document Type Definition (DTD)*.

Several types of metadata are maintained in our *XML* corpus, such as post IDs which allow us to find the original source on the website. Additionally, we store for each comment the `date` of the post, the `author` ID (*Reddit* user name), the `author_flair` (which is a customisable string appearing next to the user name and specific to each *Subreddit*; in the Europe-*Subreddit* it is possible to choose a country name as a flair and users usually select their country of origin) and the `score` of the post which was assigned by other users (via down- or upvoting the post).

3 Methods

In this section we describe our methods for corpus annotation and processing. First, we present our offensive language detection system in Section 3.1 which is based on a neural network and predicts offensiveness probabilities for each comment. Then we give our methods for automatically extracting uniformly structured linear dialogues containing offensive language from the corpus in Section 3.2. Finally, in Section 3.3, we show how we intend to further analyse these linear dialogues by applying decoupling functions to model the change of offensive probability.

3.1 Offensive Language Detection

To detect the level of offensiveness of comments we use a supervised machine learning method, which is a typical approach for this task. We train a model on manually labelled messages which have been classified whether they contain offensive language or not. Our system operates solely on the linguistic text of an individual comment

[4] https://github.com/dmarx/psaw

[5] https://github.com/pushshift/api

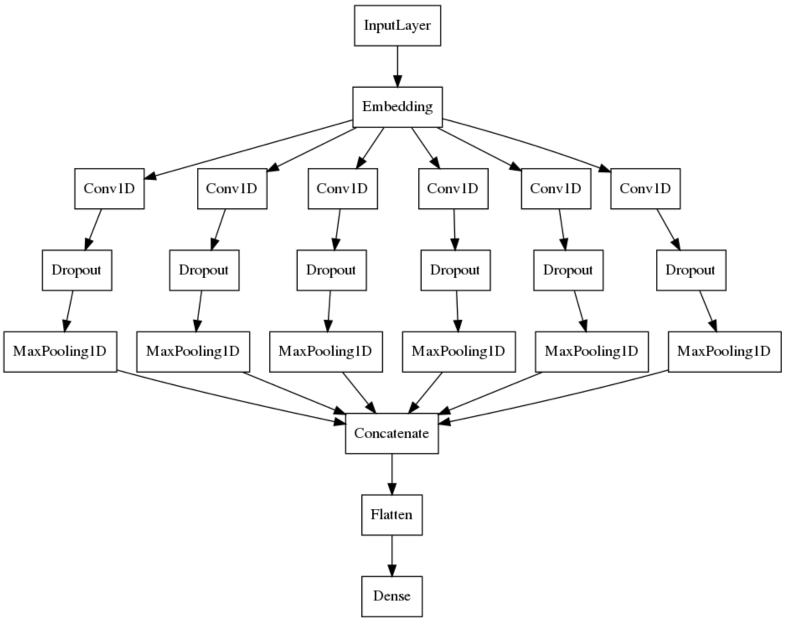

Figure 1: Neural network model architecture of our offensive language detection system.

as input since there is no overlap in the types of metadata between the training data and our corpus data. For each comment, given its text and the trained model, the system computes an offensiveness probability which is annotated in our corpus. In the remainder of this section we elaborate on a few details of our system – for the full configuration refer to our provided code.

We use a neural network to train a model of offensiveness of short text posts. A neural network is able to learn highly complex functions given enough labelled training data instances. Convolutional Neural Networks (CNNs) are structures commonly applied to natural language which can automatically identify sequences of words in a text that are significant features for a specific classification task. By design, CNNs contain regularisation which is capable to abstract from a limited set of training instances to unseen – ideally similar – test data instances.

Neural Network Architecture: Our overall neural network model is designed as follows (see also Figure 1). In a first step the tokenised[6] input text is encoded as a sequence in an embedding layer. We use (*Tweet-*) word embeddings by Deriu et al. (2017) to represent the meaning of our input text based on the principle of distributional semantics. To model offensive language based on the word embeddings of the input text, we apply six parallel CNNs with different window sizes (from one to six). These CNNs process the given sequence by moving a filter over it from left to right, in each step selecting a number (depending on its fixed window size) of consecutive words and computing a weighted combination of the dimensions of their word embeddings. Thereby, we aim to select word n-grams which are likely to be relevant to assess if a given text instance contains offensive language. Each CNN consists of a single convolutional layer followed by a dropout layer and a max pooling layer. With the inherent regularisation of a CNN by convoluting and max-pooling plus the additional dropout layer (here we use a dropout probability of 0.25), this step includes a considerabe amount of regularisation. We justify this design for our encoder by considering that our test data (*Reddit* comments) is vastly different from the training data (*Twitter* microposts) in terms of text type and website. By using a high amount of regularisation we intend to be able to generalise well when predicting on out-of-domain text. In the final steps of our neural network, the encoded output of the parallel CNNs is concatenated, reformatted using a flatten layer, and finally we compute a score which can be interpreted as offensiveness probability using a densely-connected layer with a sigmoid activation function. The exact parametrisation of the model is given in our provided code.

[6] For tokenisation we use the *NLTK TweetTokenizer* (`www.nltk.org/api/nltk.tokenize.html`) which includes custom-built methods to deal with social media text.

Training Procedure: We train our model using the *Offensive Language Identification Dataset (OLID)* (Zampieri et al., 2019a) which has been used for the *OffensEval 2019*[7] shared task of *"Identifying and Categorizing Offensive Language in Social Media"*. The training dataset consists of 13,240 *Tweets* as individual messages labelled for containing offensive language or not. The distribution of non-offensive to offensive messages in this dataset is approximately 2:1, i. e. there are 4,400 messages labelled as being offensive. Our training algorithm optimises the weights of the model based on 11,916 samples (90%) of these annotated instances and validates on the remaining 1,324 samples (10%) to avoid overfitting. Early stopping is executed when the performance on the validation set did not improve in the last few training epochs and we load the weights from after the epoch which lead to the maximum validation set performance.

Prediction: During testing we apply the abovementioned trained model to each comment of our corpus and annotate the predicted offence as follows. We add new metadata to our *XML* corpus by including the attributes `p_off` and `off` for the `comment` elements. While the predicted probability score is directly stored as value of `p_off`, the value of `off` expresses if the predicted probability of a comment to contain offensive language is higher than 0.5, which we annotate as one of the possible binary values `"True"` or `"False"`.

3.2 Extraction of Linear Dialogues

The abovementioned corpus creation process (cf. Section 2) provides us with a dataset of comments structured in a forum-like manner as a tree – a top post with direct replies which can in turn have direct replies themselves and so on. After we processed this corpus using our offensive language detection system, the comments in this corpus include annotations expressing their offensive probabilities. However, as we aim to analyse conversations as turn-based dialogues around offensive comments, we now have to filter the corpus and extract such linear dialogues. In this section we describe our method for this extraction process.

Our corpus can be formally described as a set of comments C, a set of submissions $S \subset C$ and a set of relations R, where each comment $c_i \in C$ is either a submission or top post $c_i \in S$ or a direct reply to exactly one other comment $c_j \in C$, i. e. $\forall_{c_i \in C} \exists!_{c_j \in C} : (c_j, c_i) \in R$.

#comments = n	#submissions
$n \leq 10$	265,068
$10 < n \leq 100$	83,295
$100 < n \leq 1000$	8,539
$n > 1000$	80
average	14
average$_{(n>1)}$	54

Table 1: Number of comments per submissions.

For our target of linear conversations we now need to extract a simplified dialogue out of this dataset, i. e. a linear structure of turns. In general, we consider a linear conversation an ordered list of comments from our corpus as $\{c_1, c_2, ..., c_n\}$ where $\forall_{i \in \{1,\ldots,n-1\}} : (c_i, c_{i+1}) \in R$.

We assert the following requirements to refine this structure. As we intend to compare dialogues around offensive comments with each other and find patterns amongst them, we have to analyse a uniform structure of contexts. Thus, we require all linear conversations to have a fixed length (number of comments) and the context before and after an offensive comment to be equal in size. Additionally, we included the the top-level comment for each linear conversation to give information about the general topic in each case.

Thus, we define a linear conversation from our corpus as $l = \{c_0, c_1, c_2, ..., c_n\}$, where $\forall_{i \in \{0,\ldots,n\}} c_i \in C$, $\forall_{i \in \{1,\ldots,n-1\}} : (c_i, c_{i+1}) \in R$, $c_0 \in S$, $\texttt{p\_off}(c_{\frac{n}{2}}) > 0.5$ with $n = 2 * k + 2$, where $k \in \mathbb{N}$ corresponds to the number of comments of the context to the left and right of the offensive comment (or window size) and there has to be a path from c_0 to c_1.

3.3 Decoupling Functions

In order to determine the progression of offensive probability we have preliminarily tested two gradient based approaches on linear dialogues of two users: firstly, using the gradient of all dialogue turns $(c_1, \ldots, c_n)$; secondly, comparing the gradient before and after the offensive comment (comparison of $(c_1, \ldots, c_{\frac{n}{2}-1})$ to $(c_{\frac{n}{2}+1}, \ldots, c_n)$). We visualise these approaches in our experiments in Section 4.4. In future work we intend to compare the gradient of the two different users. This will theoretically show the most meaningful forms of

c_i	author	off_p	comment
0	user_1	0	Do you find your government to be trustworthy?
1	user_2	0.11	So why exactly they don't feel safe? Because Russia planned Babchenko assasination? Or because SBU managed to prevent that and safe him and 30+ others?
2	user_1	0.20	The way I understood it, they were not feeling safe in the first place, and now they feel that the authorities undermined what little trust they had.
3	user_2	0.97	If your understanding is correct than I must state that those journalists are dumb as fuck and infantile people.
4	user_1	0.85	Why are they dumb? Because they are sceptical of this whole circus?
5	user_2	0.30	Because they can't set priorities between national security, life and death of people and their personal feelings.
6	user_1	0.52	The issue is that they don't trust the government. They don't believe this thing was needed, or even worse, they don't believe that there was an actual threat in the first place. Do you find your government to be trustworthy? Why do you believe that this was real?
7	user_2	0.64	"The issue is that they don't trust the government." No one trust gov-t in Ukraine. Any gov-t. It's a national feature. Sometimes it's good, sometimes it's bad. And up to 100% of journalists only criticizing the gov-t all the time - it's just how things work here. People don't trust the officials and journalists wat to be in trend. I doubt that any of those journalists actually lost some trust to gov-t. They just never had it and now using this situation to state it.

Table 2: Example of a linear dialogue containing offence from our corpus.

dialogue progression. We plan to publish a detailed analysis of these examples, but for illustrative purposes and to articulate the motivation in data collection, below are brief overviews of instances where offence probability declines.

4 Experiments

In this section we describe our observations when we applied the abovementioned methods to our corpus data.

4.1 Corpus Analysis

The download of *Reddit* submissions and comments using the mentioned API led to the total number of 11,217,768 posts (356,982 being submissions). In Table 1 we show the distribution of comments per submissions for certain ranges, to gain an understanding of how comments are structured in threads in this dataset. While the vast majority of submissions (approximately 74%) have very few replies ($\leq$ 10 comments), only 80 submission have more than 1000 comments. However, there is a substantial amount of threads with more than 10 comments and the average number of comments per thread – if we exclude threads with none or only one comment – is 54. Thus, we consider this dataset to be rich enough to study conversations and to be representative for different phenomena.

4.2 Offensive Language Detection

Our training algorithm for offensive language detection calls early stopping on training epoch 10, where a maximum binary accuracy is reached on the validation dataset. The evaluation after this epoch shows a binary accuracy of 0.82 on the training data and a binary accuracy of 0.73 on the validation data.

4.3 Extraction of Linear Conversations

To extract linear conversations as we defined them above, we tested different window sizes for the context. We decided to at least have 50k instances of conversations around offensive comments as we expect this to be a representative set of different types of phenomena. We set the window size $k = 3$ for the contexts before and after offensive comments, which leads to 67,456 instances of linear dialogues of length 7 (plus one for the top post), i. e. here $l = \{c_0, c_1, \dots, c_7\}$ while $\texttt{p\_off}(c_4) > 0.5$. In Table 2 we provide an individual example of a linear conversation from our

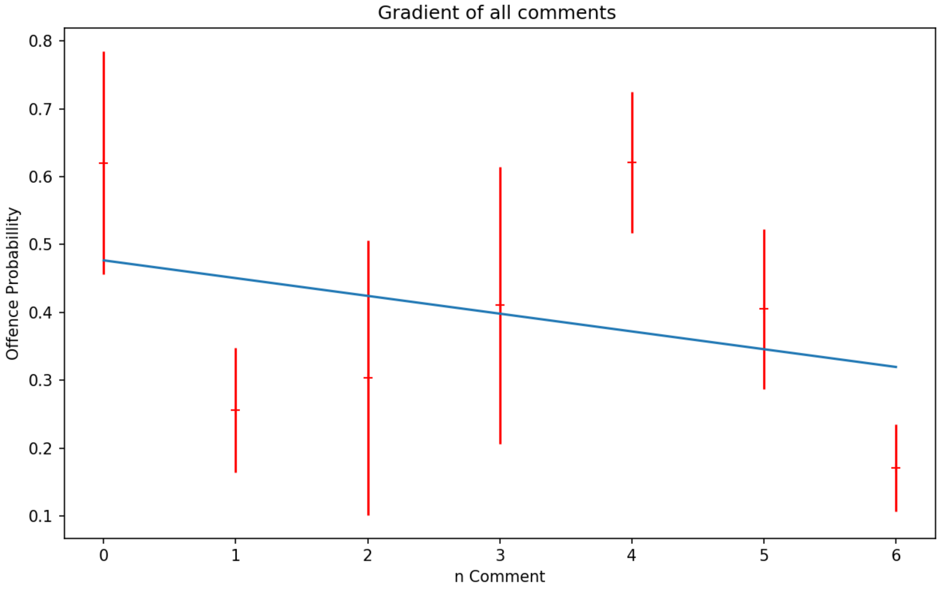

Figure 2: Gradient of all comments in extracted linear conversations.

dataset including offensive probabilities.

We have to consider that linear conversations from our dataset can have a certain partial overlap. From the data structure it only follows that the comments in the context before the offensive comment are given, here $\{c_0, c_1, c_2, c_3\}$. For the comments after the offensive comment (here $\{c_5, c_6, c_7\}$), there is the possibility to produce multiple linear conversations when there are multiple direct replies to one comment. We call this case branching, i. e. when we have multiple linear conversations which differ only in some of the comments $\{c_5, c_6, c_7\}$ – when following a different branch in the tree.

To analyse the frequency of this phenomenon, we counted how many unique first parts exist in our set of 67,456 linear conversations. If we only consider $\{c_0, \ldots, c_4\}$, there are 54,286 unique instances. If we add c_5, there are 57,077 unique instances and if we add c_6 there are 60,647 unique instances. Considering these values, we assume that branching is rather infrequent and we have mostly entirely different linear dialogues of this fixed length.

4.4 Progression of Offensive Probability

We now want to investigate the change of the level of offensiveness in turns of our linear dialogues statistically.

Complete Linear Dialogue Progression: We calculated the linear regression gradient of all comments in the collected linear dialogue, and searched for instances where gradient decline was the steepest. In simple terms, these reflect conversation where replies have been less offensive than the stimulus. The graph in Figure 2 shows the mean placement of each dialogue turn for the 50 steepest gradient dialogues, as well as standard deviation in red; a line of best fit is shown in blue. A clear downward vector in the overall gradient is shown, as well as a steep decline in the latter half of the dialogue, standard deviation accounted for.

Pre/Post Offence Comparison: We used the initiating offensive instance (comment 4) to split the dialogue into two halves (comment 1-4 and 4-7), and then we compared their gradients. We searched for instances with opposing directions. Unlike the above approach, comparing two halves allows us to see the impact on dialogue of the offensive comment, and measure how it was reacted to. The graph in Figure 3 shows a mean downward trajectory for the fifty most clear examples of this gradient.

In the example instance given in Table 2 the initiating comment probability is 0.85 in a reply to a clearly offensive comment towards a group of journalists (probability of 0.97). The latter half of the dialogue passively expands on that point, without returning to profanity or offence. We can reasonably say that user_1 is consistently responding to user_2 without offending, and therefore of interest to a study on inoffensive approaches to offensive dialogue.

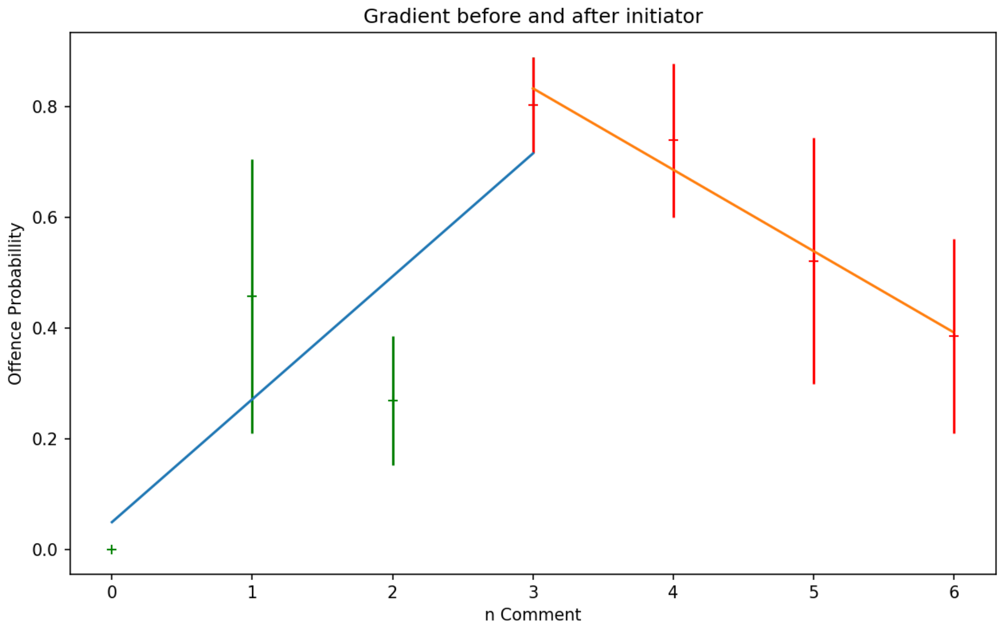

Figure 3: Gradient in comments before and after offensive comment trigger.

5 Conclusion

In this paper we presented our data collection strategy for a corpus containing conversations and discussed methods to analyse the corpus for linear dialogues around offensive comments. With a substantial dataset of over 11 million posts we are able to analyse over 50k unique linear dialogues, each consisting of seven turns predicted to contain offensive language. We now discuss our two main contributions.

Using offensive-tagged individual messages as training data for assessing the offensiveness of dialogue turns: Our method to detect offence is based on a machine learning model which predicts whether individual messages contain offensive language or not. In our model architecture, the computed probability expresses the confidence of the system that words and n-grams of the post are typical expressions of offensive language. We understand the offensiveness of a dialogue turn to be approximately in line with this assessment. A post can be seen as highly offensive when it contains several word sequences which are usually used to express offence. A low level of offensiveness can be expressed by using word sequences which are only incidentally used in offensive comments, i. e. they might for example not be offensive to everyone.

We also want to note that our offensive language detection model is not fully optimised: we intend in future work to experiment with different training data. The rather low scores given for the performance on the training/validation set can also be justified by the high amount of regularisation in our model which was implemented to make it generalise more when applied to our dataset (which is different from the training data). The training algorithm also does not optimise on accuracy as we use class weights, giving the more infrequent class of offensive comments a higher weight. If we further go into the direction to base methods for automatic analyses on the computed scores, it might be worth to investigate further how to optimise the detection system.

Analysing conversations around offensive comments using decoupling functions to find tactics to counter offence: We have shown that the analysis of gradients should be considered when we want to measure the change in offensiveness of a conversation. With the use of decoupling functions it especially seems suitable to split dialogues around offensive comments into two halves to find tactics to counter offence, i. e. especially instances where the gradient declines after the offensive comment trigger.

In future work we aim to focus on researching manual and statistical methods to find tactics to counter offence. However, the analyses of the given dataset and the provided code show promising results by pointing into the right direction.

EmoTag – Towards an Emotion-Based Analysis of Emojis

Abu Awal Md Shoeb   **Shahab Raji**   **Gerard de Melo**
Department of Computer Science
Rutgers University, New Brunswick, NJ, USA
{abu.shoeb, shahab.raji, gerard.demelo}@rutgers.edu

Abstract

Despite being a fairly recent phenomenon, emojis have quickly become ubiquitous. Besides their extensive use in social media, they are now also invoked in customer surveys and feedback forms. Hence, there is a need for techniques to understand their sentiment and emotion. In this work, we provide a method to quantify the emotional association of basic emotions such as anger, fear, joy, and sadness for a set of emojis. We collect and process a unique corpus of 20 million emoji-centric tweets, such that we can capture rich emoji semantics using a comparably small dataset. We evaluate the induced emotion profiles of emojis with regard to their ability to predict word affect intensities as well as sentiment scores.

1 Introduction

In recent years, information technology has profoundly altered the way humans communicate. A substantial proportion of the global population has adopted the use of social media platforms (such as Twitter, Facebook, and Instagram) and messaging technology (such as Facebook Messenger, WeChat, and WhatsApp) to interact and voice their opinion. The unique properties and expressive capabilities afforded by computer and mobile device-mediated communication has led to quite distinct forms of expression in comparison with classic email etiquette, let alone traditional written correspondence.

Meanwhile, for any meaningful analysis of social interactions or expression of opinions, it is critical to extract and understand the sentiment and the affect of the source. There are numerous studies investigating the connection between words or sentences and the affects they convey. However, emojis are a particularly prominent feature of modern online interaction. Thus, this paper introduces a new basis for studying this new modality with regard to conveyed affective associations. Emojis have become widespread in social media, and are variously used to carry emotional and contextual information pertaining to the content of social media posts. There have been studies exploring the relationship between hashtags and tweets (Ferragina et al., 2015), and between emojis and tweets (Campero et al., 2017). Additional research has aimed at conducting sentiment analysis based on emojis and hashtags (Novak et al., 2015). A number of other works study the connection between words and emotions, resulting in datasets such as *EmoLex* (Mohammad and Turney, 2013). Most of these studies relied upon a crowdsourcing approach to compile the data and lexicons and to capture relationships among linguistic and paralinguistic elements (Kulahcioglu and de Melo, 2019).

However, previous work has neglected to focus on the emotional aspects of emojis. For instance, we may ultimately be interested in devising a system that jointly assesses the affect conveyed by a tweet based not only on the words, but also in part on the emojis occurring within it. In some cases, an emoji may reinforce the emotion conveyed by the text. In other cases, it may reveal an additional dimension of affect. In some cases, it may also point in the opposite direction, e.g., by helping to discern sarcasm, which otherwise might be hard to ascertain in certain contexts. Currently, there are no readily available resources to understand the direct relationship between emojis and emotions.

We address this gap by harvesting an emoji-centric collection of tweets. From this, we create the *EmoTag* resource. The name alludes to its usefulness in exploiting emoji for emotional tag-

Proceedings of Recent Advances in Natural Language Processing, pages 1094–1103,
Varna, Bulgaria, Sep 2–4 2019.

ging. The resource is based on a series of co-occurrence statistics that allow us to quantify the emotional associations of individual emojis. We subsequently assess these connections in a series of experiments and case studies.

2 Background

Emotion and Communication. Facial expression has been an important aspect of communication that predates the emergence of mankind. Chevalier-Skolnikoff, in ascending order of phylogenetic complexity, draws connections between the degree of evolution of the brain and the spectrum of facial expression observed for a species (Chevalier-Skolnikoff, 1973). Charles Darwin's well-known volume on the expression of emotions (Darwin, 1872) analysed the connection between emotions and their expression. He remarked for instance, that for both animals and humans, anger coincides with eye muscle contractions and teeth exposure, and commented on the fact that humans lift their eyebrows in moments of surprise. His work then goes on to study the role of such forms of facial expression in conveying to others how an animal feels, studying primates as well as human infants and adults.

In light of this, humans continue to rely extensively on such nonverbal cues even in oral forms of linguistic communication. Although a person's emotion and mood can to some extent be conveyed by means of suitable content words (e.g., "I am happy to hear that!") or interjections ("Wow!"), face-to-face communication has important properties that written communication tends to lack (Bordia, 1997). These include facial expressions of the aforementioned sort, but also gesture and intonation. In certain circumstances, e.g. certain problem-solving settings, face-to-face communication may hence prove more efficient and effective (Bordia, 1997).

Accordingly, since the beginning of writing, humans have resorted to surrogate mechanisms to convey emotive signals, attempting to push the boundaries and overcome some of the inherent restrictions of plain written language as a medium. Examples include illustrative embellishments and ornaments, calligraphy, a judicious use of color, and various typographic instruments. For instance, it has been shown that the choice of font may radically alter the affective perception of a text (Juni and Gross, 2008; Kulahcioglu and de Melo, 2018).

Emoticons and Emoji. While emoticons such as ":-)" and Japanese 顔文字 (kaomoji) such as "(^_^)", both based on regular characters, have been in use for several decades, emojis originated in Japan in the 1990s and have only recently spread globally. Despite the lexicographic similarity between the two words *emoji* and *emotion*, etymologically, the former stems from the Japanese words 絵 (e, *picture*) and 文字 (moji, *character*). Emoji characters, similar to earlier dingbat characters, are pictorial and colorful.

Their principal use has indeed been to convey emotion, particularly via facial expression emojis. In 2015, Oxford Dictionaries declared the *Face with Tears of Joy* emoji its Word of the Year 2015. Kaye et al. (2017) explained how emojis may aid the interlocutor in disambiguating utterances that would otherwise remain ambiguous. Emojis may also be useful as a more instantaneously and widely recognized form of communicating degrees of satisfaction. Kay et al. go as far as suggesting them for consideration as possible alternatives to regular Likert scales (Kaye et al., 2017).

Historically, the spread of emojis has been driven in large part by their adoption in popular messaging and social media platforms, which led, among things, to their inclusion in Shift JIS, and, subsequently, the Unicode standard. Nowadays, they are ubiquitous in social media and chat applications, but increasingly also in emails and other digital correspondence.

3 Related Work

Emoticons. Early studies focused on the use of emoticons in social media. Go et al. (2009) proposed a form of distant supervision by using emoticons as noisy labels for Twitter sentiment classification. Davidov et al. (2010) adopted a fairly similar approach by handpicking smileys and hashtags as tweet labels and relying on a supervised method for sentiment analysis of tweets.

Emoji Semantics. A prominent work on emojis is the DeepMoji project (Campero et al., 2017) from MIT. It provided a model that recommends emojis given a natural language sentence as input. The deep learning model was trained on a collection of 1.2B tweets to learn the sentiment, emotions, and the use of sarcasm in short text.

Barbieri et al. (2016) proposed a method to learn vector space embeddings of emojis using the standard word2vec skip-gram approach, applied to a large collection of tweets. In contrast, Eisner et al. (2016) attempted to learn vector embeddings of emojis based on their short descriptions in the Unicode standard.

Emoji Associations. The first paper that thoroughly investigated the sentiment of emojis (Novak et al., 2015) proposed a sentiment ranking of 715 emojis on a corpus of 70,000 tweets. This work provides a basis for future research on the logographic usage of emojis in social media.

Zhou and Wang (2017) trained a natural language conversation model that accounts for the underlying emotion of utterances by exploiting the existence of emojis as a signal.

Rakhmetullina et al. (2018) proposed a method to classify emojis with regard to their sentiment and emotion. Their corpus consists of 500 labeled tweets, and they categorize emojis by assigning them labels for 8 emotions. For this, they applied a distant supervision technique for a reliable mapping based on manually annotated data.

4 EmoTag

Given the prominence of emojis in human communication, our work seeks to study relevant associations of emojis. We begin by assembling a dataset for this purpose (Section 4.1), and subsequently induce a series of lexicons that reveal potential connections (Section 4.2), including between words and emojis, as well as between emojis and emotions.

4.1 Data Collection

In assembling a collection of social media postings containing both emojis and hashtags with tweets, one strategy would be to rely on available datasets and filter them so as to retain only those entries that contain both emojis and hashtags. However, this approach results in a comparably small number of postings. Despite the overall surge in popularity of emojis, only a fraction of all postings includes emojis.

Instead, we proceeded to compile a new dataset of about 20.8 million tweets by specifically searching for postings that contain emojis. For the set of target emojis, our goal was to focus on emojis associated with emotions, as opposed to generic symbols from domains such as transportation or household appliances. To this end, we relied on a set of most frequently used 620 emojis from Novak et al. (2015) and from Emoji Tracker[1], a website that monitors the use of emojis on Twitter in realtime.

Using our set of frequent emojis as search terms, we retrieved tweets that specifically contain one or more of these target emojis. The number of tweets is evenly distributed across different emojis. While tweets can be in any language, we only collected tweets labeled as being in English. In total, we obtained a set of 20.8 million tweets over a span of one year. In addition to the volume that such a large time span provides, collecting the data for every day of the year aids in mitigating the effect of potential biases in the data. All collected tweets contain at least one emoji.

Note that only a fraction of all tweets have hashtags. Specifically, within our collected data, we found that only 10-15% of our tweets with emojis also include hashtags. To clean up the data, we removed usernames (marked with @-symbol), tweets consisting only of hashtags and emojis but no text, tweets that only contain a short time stamp such as “6AM” or simply a URL (with or without the “http://” prefix), as well as all duplicate tweets.

4.2 Lexicon Induction

Based on the corpus, EmoTag is constructed as a series of lexicons.

4.2.1 Co-occurring Emojis

We first collect a series of co-occurrence based lexicons. Each entry in such a lexicon is the representation of pairwise count of desired unigram tokens. These resources can be useful for the community, but also allow us to conduct analyses of the data.

In our tweet collection, there are roughly 36K tweets per emoji, and these have a uniform distribution across the collection time period.

Inspecting the results, we observe that the overall top-ranked pair of co-occurring emojis in our dataset is U+1F61D 😝 and U+1F61C 😜. These showed up together 42K times, which is fairly frequent in comparison with other pairs. Note that U+1F61D 😝 is the “face with stuck-out tongue and tightly-closed eyes” emoji, while U+1F61C 😜 is the “face with stuck-out tongue and winking eye” emoji.

Another emoji, U+1F602 😂, the “face with tears of joy” one, appears to be the most common emojis to co-occur saliently with others. It appears

[1] http://emojitracker.com/

Unicode	Emoji	Sentiment Score	Description
U+1F649	🙉	0.333	Hear-no-evil monkey
U+1F648	🙈	0.432	See-no-evil monkey
U+1F649	🙉	0.333	Hear-no-evil monkey
U+1F64A	🙊	0.459	Speak-no-evil monkey
U+1F62D	😭	-0.093	Loudly crying face
U+1F602	😂	0.221	Face with tears of joy
U+1F620	😠	-0.299	Angry face
U+1F608	😈	0.265	Smiling face with horns
U+1F620	😠	-0.299	Angry face
U+1F629	😩	-0.368	Weary face

Table 1: Similarities and Contrasts of Co-occurring Emojis

Word	Emoji	Description
miss	U+1F62D 😭	Loudly crying face
	U+2764 ❤	Heavy black heart
	U+1F622 😢	Crying face
happy	U+1F389 🎉	Party popper
	U+2764 ❤	Heavy black heart
	U+1F618 😘	Face throwing a kiss
love	U+1F60D 😍	Smiling face with heart-shaped eyes
	U+1F618 😘	Face throwing a kiss
	U+2764 ❤	Heavy black heart

Table 2: Co-occurring Emojis and Words

with a broad range of other emojis with a relatively high frequency. Three other popular emojis that co-occurred with U+1F602 😂 include U+1F62D 😭 (“loudly crying face”), U+1F648 🙈 (“see-no-evil monkey”), and U+1F629 😩 (“weary face”).

Somewhat different from the previous cases, the fourth pair in Table 1 involves the emoji U+1F62D 😭, i.e., a crying face, and U+1F602 😂, i.e., a face with tears of joy. This is unusual in the sense that these two emojis possess opposite sentiment polarities. According to Novak et al. (2015), the sentiment value of U+1F62D 😭 is -0.093, whereas the sentiment value of U+1F602 😂 is 0.221, i.e., a positive sentiment. This suggests that people tend to conflate the two due to their similar appearance, as both involve tears. Another possibility is that people may be using one of the two sarcastically. As shown in the table, similar observations can also be made for certain other pairs of emojis.

Our results also show a correlation between U+1F60D 😍 and U+1F629 😩. The two are paired up around 2,500 times, illustrating another connection between a positive and a negative sentiment emoji. U+1F629 😩 is the “weary face” emoji, whereas U+1F60D 😍 is the “smiling face with heart-shaped eyes” one. This appears to stem from tweets that express positive sentiment about a target entity, but also negative sentiment about the current situation.

4.2.2 Emoji–Words Lexicon

Another lexicon that we produce aims to provide co-occurring words for a given emoji, or, vice versa, emojis for a given word. Table 2 shows an excerpt of the emoji–word lexicon, grouped by words. For example, the word “miss” co-occurs with a wide range of emojis, but the top co-occurring emojis are U+1F62D 😭, U+2764 ❤, and U+1F622 😢. These emojis are likely to be used when someone misses someone or something. Similarly, the words “happy” and “love” appear with numerous emojis that carry happy and positive sentiment.

4.2.3 Emoji–Hashtags Lexicon

This lexicon provides a collection of hashtags along with the emojis that they co-occur with. The resource also includes the corresponding co-occurrence frequencies between emojis and hashtags. According to our findings, the emoji U+1F637 😷 (“face with medical mask”) co-occurs with the hashtags #sick, #flu, #yuck, #cold, #insomnia, and #dying, which all are clearly semantically relevant for this emoji.

4.3 Interpretable Emoji-Based Word Vectors

Interpretability and explainability are widely regarded as highly desirable attributes of AI-driven decision making (Xian et al., 2019). Dense word vectors such as those produced by word2vec (Mikolov et al., 2013) are ubiquitous in NLP (de Melo, 2017). However, it is often remarked that they lack interpretability, in the sense that individual values in such vectors do not carry any easily interpretable inherent significance. Previous work has proposed interpretable word vectors consisting of one or more sentiment polarity scores for a word (Dong and de Melo, 2018; Dong and de Melo, 2018). Given that emojis represent a wide spectrum of aspects considered relevant in human communication, we study to what extent emojis can serve as a means of inducing word vectors endowed with interpretability.

	dim_1	dim_2	...	dim_{300}
$word_1$	0.144288	-0.460809	...	0.135627
$word_2$	0.442811	0.128091	...	-0.196277
...	...	...	...	...
$word_n$	0.128221	-0.120809	...	-0.360207
$emoji_1$	0.284455	0.460809	...	-0.155627
$emoji_2$	0.142886	-0.608092	...	0.356227

$emoji_2$	0.714288	1	...	0.336127
...	...	...	...	...
$emoji_{620}$	0.154228	0.941080	...	1

Interpretable Emoji-Based Word Vectors (620D)

Figure 1: Inducing Interpretable Word Vectors via Emojis

This can be achieved by assigning every word a 620-dimensional word vector, in which each dimension reflects the association of that word with one out of 620 emojis. Since we use a list of the 620 most frequent emojis, the dimensionality of a vector becomes 620. An obvious method would be to adopt just simple frequency counts as the values in these vectors, i.e., for a given word, the entries in its word vector would simply reflect the number of times that word co-occurred with a given emoji.

However, we can improve over this by relying on the word2vec Skip-Gram with Negative Sampling algorithm (Mikolov et al., 2013) as an intermediate representation, as illustrated in Fig. 1. We first train such a word2vec model on the EmoTag corpus. Then a cosine similarity score is calculated between all words and emojis. This yields a semantic relatedness score in $[0, 1]$ for any word–emoji pair. Thus, we can view the score as reflecting to what extent a word correlates with an emoji. We use these correlation coefficients to form a word vector $\mathbf{v}_w \in [0, 1]^d$ for every word w, such that each of the $d = 620$ dimensions reflects the correlation with a particular emoji. This is the final EmoTag word vector representation that we use in all experiments.

5 Evaluation

In the following, we evaluate EmoTag for machine learning-driven emotion analysis of tweets and show how it can be used to reveal the sentiment and emotion of individual emojis.

The first study aims at evaluating the usefulness of our interpretable EmoTag word vectors in a downstream task, exploiting them in a machine learning-driven system that seeks to identify the emotion intensity of tweets.

Subsequently, we use our data to compute sentiment polarity scores for emojis, comparing these against existing human annotations of emoji sentiment.

Finally, we develop the first resource providing emotion scores for emojis. We evaluate these by showing how they can be used to automatically induce emotion scores for words.

5.1 Emotion Intensity Prediction with Interpretable Emoji-Based Word Vectors

We begin by evaluating the interpretable emoji-based word vectors, assessing to what extent they are able to keep up with regular word vectors in a downstream task relating to emotions.

Benchmark. In particular, we consider the EmoInt Shared Task from WASSA (Workshop on Computational Approaches to Subjectivity, Sentiment & Social Media Analysis) 2017 (Mohammad and Bravo-Marquez, 2017a), which involves determining the intensity or degree of emotion felt by a speaker when a tweet and a target emotion are given. Tweets were provided for four different emotion categories (anger, fear, joy, and sadness), and the ground truth intensity values range between 0 and 1.

The Affective Tweets (AT) package was provided to all participants as a baseline for the competition (Mohammad and Bravo-Marquez, 2017b), providing a rich set of features constructed based on several emotion and sentiment lexicons such as NRC-EmoLex, NRC10E, etc. (Mohammad and Bravo-Marquez, 2017a).

Model. We rely on a deep neural network to predict the emotion intensity for each tweet, adopting a similar CNN-LSTM architecture as that of IMS (Köper et al., 2017), the 2nd-ranked system among all participants in the competition, with the CNN architecture based on that proposed by Kim (2014). In training, each tweet is represented by a matrix of size m x d, where d is the dimensionality of the pre-trained word vectors and $m = 50$ is the maximal token sequence length considered for

Method	A	F	J	S	Avg	d
Interpretable						
AT	0.65	0.66	0.60	0.69	0.65	n/a
EmoTag	0.70	0.73	0.69	0.75	0.72	620
Non-Interpretable						
Random Init.	0.68	0.72	0.66	0.73	0.70	300
Google News	0.70	0.72	0.67	0.75	0.71	300
GloVe	0.70	0.73	0.68	0.76	0.72	300
GloVe–Twitter	0.72	0.74	0.68	0.76	0.73	200
IMS	0.71	0.74	0.71	0.71	0.72	300

Table 3: Comparing with other methods, with regard to anger (A), fear (F), joy (J), sadness (S), average (Avg), dimensionality (d).

a tweet. We can thus feed in either regular word vectors or our interpretable emoji-based EmoTag vectors for the series of words in the tweet. We applied a dropout rate of 0.25. The obtained matrix then serves as input to a convolutional layer with a window size of 3, followed by a max-pooling layer (size 2) and an LSTM (Hochreiter and Schmidhuber, 1997) to predict a numerical output for each tweet. This numerical value was then added as a feature along with other auxiliary features, and passed to a Random Forest regressor to obtain the final intensity score for a particular emotion. The IMS team used a total of 142 features, including the 45 baselines features from Affective Tweets. Since we are comparing our results with both the baseline features and the features used by the IMS team, our classifier is also fed with the 142 features. All features were passed to a random forest regressor with 800 trees for identifying the intensity of a given emotion. A separate model is trained for each of the four target emotions.

Results. Table 3 summarizes the results for the EmoInt task, providing Pearson correlations for each emotion as well the average Pearson correlation for all four emotions, along with the dimensionality of the respective word vectors used in the experiments. The results show that the interpretable word vectors in EmoTag are able to yield results that are comparable with those of other dense word representations that are not interpretable. It should be kept in mind that EmoTag was built based on a very small corpus, i.e., only 20M tweets, comparing to the massive size of the corpora used for pretrained word vectors such as the two GloVe models. For further comparison, we also report results on just the AffectiveTweets (AT) features, as well as the original IMS system. In some cases, for example for the *sadness* emotion, EmoTag actually outperforms the IMS team's baseline.

Unicode	Emoji	Novak Score	EmoTag Score	Description
U+1F61C	😜	0.455	0.482	Face with stuck-out tongue and winking eye
U+1F617	😗	0.611	0.591	Kissing face
U+1F49A	💚	0.656	0.654	Green heart
U+1F48B	💋	0.691	0.744	Kiss mark

Table 4: Comparison of emoji sentiment scores from EmoTag and Novak et al. (2015).

5.2 Evaluating the Sentiment of Emojis

Next, we evaluate to what extent our interpretable word–emoji vectors can aid in revealing the sentiment of emojis.

Method. For obtaining sentiment scores, we rely on the NRC Emotion Lexicon EmoLex (Mohammad and Turney, 2013), a list of English words and their associations with eight basic emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments (negative and positive). The associations are merely given as Boolean labels (0 or 1). To obtain a sentiment score for an individual emoji, we first consider all words with a sentiment score of 1 in EmoLex. Then, we rank all words associated with the given emoji based on their similarity score according to our interpretable word vectors, where a higher similarity score results in a higher rank. According to the ranking, the top $K = 3$ words are picked and their similarity scores are aggregated using a simple addition, which becomes the ultimate sentiment score for the given target emoji.

Results. To evaluate the sentiment score of emojis, we measure the Pearson correlations for several groups of emojis treating the scores by Novak et al. (2015) as gold scores. Table 5 summarizes the Pearson correlations for several groups of emojis. The first row of the table represents Novak's top 100 positive sentiment emojis. We also consider additional groups based on the Unicode standard emoji descriptions, particularly those with a face and those with monkey faces.

Note that we observed a high positive sentiment score for all emojis with kiss symbol or kissing face in our data, compared to Novak's scores. For some emojis, our model obtains a high sentiment score such as 0.991 for 😽 "Kissing Cat Face

Emoji Group	Correlations
Top 100 positive emojis	0.71
Emojis with face	0.45
Monkey face emojis	0.53
Emojis with kissing	0.14

Table 5: Pearson Correlations for Sentiment Score

with Closed Eyes" U+1F63D, whereas the score by Novak et al. (2015) is 0.571. This can happen for several reasons. In some cases, the sentiment scores they propose may be misleading for certain emojis, especially if they are less frequent in their dataset. An example is 😽 U+1F63D, which has an occurrence frequency of 88 only, compared to emojis such as 😂 "Face with Tears of Joy" U+1F602, which occurred 14,622 times. Thus, in some cases, their results may not be reliable.

Still, the results often show a strong agreement, although our method produces sentiment scores for emojis only indirectly via their associations with words. Table 4 provides examples of such sentiment scores generated by EmoTag and Novak et al. (2015).

5.3 Evaluating Emotion Profiles of Emojis

Finally, we use our data to evaluate to what extent emojis are associated with certain emotions. For this, we again rely on our emoji-based word vectors in conjunction with EmoLex, the NRC Emotion Lexicon (Mohammad and Turney, 2013). EmoLex provides a set of words along with a set of binary labels, where 1 signifies that the word carries a particular association, while 0 represents the negative case.

Method. First, for each emoji, we identify the top K in EmoLex according to their cosine similarity with the emoji, as obtained in our interpretable word vectors, where a higher similarity score entails a higher rank. For the top K words, we compute a weighted average of emotion labels. The emotion labels are taken from EmoLex, while the similarity scores are used as weights. This weighted average then serves as the final emotion score of the emoji. The same process is followed for all emojis. **Results.** We evaluate our induced emoji emotion scores indirectly by using them to reproduce emotion intensity scores for words, for which we have ground truth intensity scores in the Affect Intensity lexicon by (Mohammad, 2018). This lexicon comes with 6K tokens, where tokes are grouped by the four emotions *anger*, *fear*, *joy*, and *sadness*. It provides crowdsourced emotion intensity scores, which range between 0 and 1, with 1 meaning that the word exhibits the highest degree of association with a particular emotion and 0 referring to the lowest degree. Note that this ground truth resource is distinct from the NRC Emotion Lexicon used in inducing our scores. The latter merely provides Boolean labels for word–emotion pairs, and thus it is non-trivial to derive affect intensity scores from it, particularly via emojis.

To reproduce word emotion intensities based on our emoji emotion scores, we proceed as follows. For a given word w, we rank the top K emojis based on their similarity score in the EmoTag word vectors, where higher scores entail a higher rank. Once the top K emojis have been identified, we then compute the arithmetic mean of the emotion scores of those related emojis, which yields the final emotion score for the target word w. We chose $K = 10$, which led to better results than alternative values.

Table 8 depicts the Pearson correlations for different subsets of the Affect Intensity lexicon. These correlations reveal how close we are in predicting the emotion score for a given word based on our emoji emotion scores. The first row shows the scores for words that are common to all four emotion groups, whereas the last row includes all words. Table 7 provides examples of emotion scores for a few select emojis.

Analysis. For further analysis, we compare our scores with the classification obtained by Rakhmetullina et al. (2018). Table 6 compares the emotional label that their classification provides against our emotion scores for *anger*, *joy*, *sadness*. Note that this is the complete set of emoji results provided in their paper, apart from one additional emoji for the emotion *surprise*, which our method currently does not support, due to its omission in EmoLex. Their labeling did not include the emotion *fear*, so we omit it in our comparison. The bold scores in the last three columns indicate what emotion labeling we would obtain if we had to select a single label for an emoji based on our obtained emotion intensity scores. For example, in our case, emoji 🙏 "Folded Hands" U+1F64F obtains the highest score 0.485 for the emotion *joy*, which is labeled as being in the *joy* category in their study as well. There are three cases (high-

Unicode	Name	Emoji	E2E Label	Anger	Joy	Sadness
U+1F612	Unamused face	😒	anger	**0.418**	0.119	0.333
U+1F602	Face with tears of joy	😂	joy	0.381	0.099	0.326
U+1F60D	Smiling face with heart-eyes	😍	joy	0.307	**0.308**	0.137
U+1F60A	Smiling face with smiling eyes	😊	joy	0.067	**0.248**	0.247
U+1F495	Two hearts	💕	joy	0.172	**0.383**	0.142
U+1F601	Beaming face with smiling eyes	😁	joy	0.091	**0.123**	0.079
U+263A	Smiling face	☺️	joy	0.095	**0.245**	0.176
U+1F604	Grinning face with smiling eyes	😄	joy	0.184	**0.188**	0.149
U+1F618	Face blowing a kiss	😘	joy	0.233	0.215	0.144
U+1F64F	Folded hands	🙏	joy	0.187	**0.485**	0.351
U+1F62D	Loudly crying face	😭	sadness	0.246	0.198	**0.272**
U+1F629	Weary face	😩	sadness	0.236	0.186	0.234
U+1F622	Crying face	😢	sadness	0.284	0.210	**0.333**

Table 6: A comparison between Emoji2Emotion (E2E) and EmoTag

Emoji	Name	A	F	J	S
U+1F620 😠	Angry face	0.49	0.36	0.07	0.44
U+1F46E 👮	Police officer	0.34	0.49	0.16	0.27
U+1F492 💒	Wedding	0.09	0.14	0.63	0.25
U+1F4A9 💩	Pile of poo	0.35	0.34	0.15	0.47

Table 7: Emotion scores of emojis for anger (A), fear (F), joy (J), sadness (S).

Tokens	A	F	J	S	Avg
Common Words	0.51	0.41	0.19	0.50	0.40
All Words	0.45	0.40	0.20	0.45	0.37

Table 8: Pearson Correlations of gold scores and our predicted scores for Affect Intensity lexicon

lighted in red) at which our scoring would fail. According to their labeling system and results, emoji 😩 "Weary Face" U+1F629 should have obtained its highest score for *sadness* (0.234) instead of *anger* (0.236), though both scores are very close in our case.

The emoji 😂 "Face With Tears of Joy" U+1F602 scored 0.381 on *anger*, which is the highest among all scores for it, although the authors of Emoji2Emotion marked it as belonging to the *joy* category. This may stem from the phenomenon of people frequently confusing this emoji with the 😭 "Loudly Crying Face" U+1F62D emoji. In Table 1, we observe that both appear together very often, which results in a strong association with a negative emotion (anger) for an emoji that intrinsically ought to be more associated with joy.

6 Conclusion

The characteristics of a medium profoundly affect the way that people express themselves using said medium. While written communication lacks the non-verbal cues that make face-to-face communication particularly effective for problem-solving (Bordia, 1997), modern social media, and messaging platforms have unique properties that are interesting in their own right. Among these, the use of emojis stands out as meriting very special consideration, not least due to their ability to compensate for some of the shortcomings of written language as a medium in conveying emotion and affect.

While research in social science and social media analytics has extensively studied the use of emojis in everyday communication, previous work has not fully explored the connection between emojis and emotion. This paper presents a detailed analysis of how emojis and words co-occur in social media, including their connection to emotions. It also shows how an interpretable word embedding can be formed with the help of emojis, which shows promise as an additional ingredient in emotion detection-related tasks.

Another key contribution of this work is the creation of a large resource, consisting of several different sub-lexicons that describe connections among emoji, words, and other items, as well as emotion scores for emojis, which are released to the public[2]. We hence believe that this work will substantially benefit other researchers in several different fields.

Abstract

We propose a morphologically informed model for named entity recognition, which is based on LSTM-CRF architecture and combines word embeddings, Bi-LSTM character embeddings, part-of-speech (POS) tags, and morphological information. While previous work has focused on learning from raw word input, using word and character embeddings only, we show that for morphologically rich languages, such as Bulgarian, access to POS information contributes more to the performance gains than the detailed morphological information. Thus, we show that named entity recognition needs only coarse-grained POS tags, but at the same time it can benefit from simultaneously using some POS information of different granularity. Our evaluation results over a standard dataset show sizeable improvements over the state-of-the-art for Bulgarian NER.

1 Introduction

Although in recent years the *Named Entity Linking* (also known as Named Entity Disambiguation) task has been central in NLP research, the *Named-entity recognition* (NER) task has remained far from solve, having in mind the productivity of names and the amount of information available in the era of big and noisy data.

NER plays a critical role in the processing of texts with application to many real-world Natural Language Processing (NLP) tasks such as Question Answering, Information Extraction, Machine Translation, Dialog Systems, and chatbots, where it is sometimes called *Concept Segmentation and Labeling* (Saleh et al., 2014).

Traditionally, NER has focused on recognizing entities such as person (PER), organization (ORG), location (LOC), and miscellaneous (MISC). This tradition goes back to the Message Understanding Conference (MUC) for English (Grishman and Sundheim, 1996), and the subsequent CoNLL 2002/2003 shared tasks, which also targeted other European Languages such as Spanish, Dutch, and German (Tjong Kim Sang and De Meulder, 2003).[1] This same setup was followed in more recent work for a number of other languages, and we also follow it in the present work.

Early systems relied on hand-crafted rules with pattern-matching (Appelt et al., 1995). Unfortunately, this required an large pre-annotated datasets, collecting which was time-consuming and error-prone. The next step was to add gazetteers and lexicons that were generated automatically or semi-automatically (Popescu and Etzioni, 2005). Adding such resources required special approaches to resolve the ambiguity between names and common words. Such problems were solved using models such as Hidden Markov Models (Zhou and Su, 2002) and Conditional Random Fields (Sutton and McCallum, 2012).

In our work here, we use deep neural networks for Bulgarian NER. Lample et al. (2016) have shown remarkable results for English, using a combination of Bi-LSTMs (Bi-directional Long Short-Term Memory) and CRF. However, the approach is problematic for morphologically rich languages. The main problem is the missing information within word embeddings for the numerous word forms involved in multiword names that require additional grammatical knowledge in order to be processed properly. Here we incorporate such information as additional input to our neural model.

[1] Other schemata such as ACE (Doddington et al., 2004) used a richer inventory of entity types.

Proceedings of Recent Advances in Natural Language Processing, pages 1104–1113,
Varna, Bulgaria, Sep 2–4 2019.

Our contributions are as follows:

- We show that for morphologically rich languages such as Bulgarian the access to POS and morphological annotation is crucial and can yield very sizeable performance gains.
- We achieve sizable improvements over the state-of-the-art for Bulgarian NER.
- Finally, we make our data and code freely available, which should enable direct comparison in future work.[2]

2 Related Work

Our work is based on Bulgarian, but we claim that it is appropriate also for other languages with rich morphological systems like Slavic and Romance languages, for example. For that reason, we present first the best results for NER in other Slavic languages having in mind that they are synthetic, while Bulgarian is a predominantly analytic language whose morphological richness lies exclusively in the verbal system and not so much in the nominal one. Analytism implies more types of multiword named entities in Bulgarian but less inflection variety, and different distribution of the common types for these languages. The direct comparison of the numbers presented below should be taken with a grain of salt as they are on different datasets and for different languages. Yet, they are indicative for the different methods used for these languages.

For Russian, a Hybrid Bi-LSTM approach was applied by Le et al. (2018), who achieved precision of 89.57, recall of 84.89, and F1 score of 87.17. These results are comparable to the ones by our model using the same approach.

For Czech, Straková et al. (2013) reported precision of 88.27, recall of 78.00, and F1 score of 82.82 using a Maximum Entropy Markov Model. The feature modeling also proved to be working in Czech, as their best results used features based on morphological analysis, two-stage prediction, word clustering, and gazetteers.

For Polish, Piskorski et al. (2004) achieved precision of 91.0, recall of 77.5, and F1 score of 82.4. They used the SProUT system, which is an NLP platform, consisting of pattern/action rules.

In the last years, the interest in NER for Slavic languages grew. Two shared tasks were organized —- the first and the second Multilingual Named Entity Challenge in Slavic Languages. They have been descibed in (Piskorski et al., 2017) and (Piskorski et al., 2019). The challenges included several tasks: recognition of mentions of named entities in Web documents in seven Slavic languages (Bulgarian, Croatian, Czech, Polish, Russian, Slovak, Slovene, Ukrainian), their normalization/lemmatization as well as cross-lingual linking.

Our evaluation on NER in this paper is more similar to the relaxed evaluation parameter where the string is detected and classified, not the invariant. Considering the complexity of the task, the drop of the results per language and per entity types have been expected. Such a task, however, is also good motivation for improving the NER systems for Slavic languages, including Bulgarian.

There is some previous work on NER for Bulgarian. Georgiev et al. (2009) presented a model using Conditional Random Fields with several hand-crafted features. They combined well-established features used for other languages with language-specific lexical, syntactic, and morphological information. Their result is the previous state-of-the-art for Bulgarian.

So far, the highest reported results for NER are for English. For example, Chiu and Nichols (2016) reported an F1 score of 91.20 using Bi-LSTM + CNN + gazetteers + linking, while Passos et al. (2014) achieved an F1 score of 90.90 using a new form of learning word embeddings that can leverage information from relevant lexicons. For German, Gillick et al. (2016) achieved an F1 score of 82.84, which shows that the rich morphology causes a drop in the performance.

Currently, the prevalent paradigm in NLP is to use neural networks, typically based on LSTMs or CNNs. As we have mentioned above, Lample et al. (2016) proposed an LSTM-CRF model for NER.[3] The model uses a bi-directional LSTM to encode the left and the right context of the current input word. Then it passes the concatenation of the two hidden vectors (one produced by the left LSTM and one by the right LSTM) to a CRF model. Its task is to ensure the global consistency of the NER tags.

[2] http://github.com/lilia-simeonova/NER-bg/

[3] They also proposed a transition-based model inspired by shift-reduce parsers, but the results were worse.

In this model, each input word is represented as a concatenation of its word embedding and the character-level embedding for the word produced by a character Bi-LSTM. The character embedding provides features for the suffix and the prefix of the word. Thus, the left-to-right character-based LSTM embedding models the word suffix, while the right-to-left one models the word prefix. The word embeddings are trained in an unsupervised manner on external data, while the character-based LSTM embeddings are trained on the training data as part of the end-to-end training of the full LSTM-CRF model. This model does not need any explicit feature engineering nor does it need manual gazetteers; yet, it achieved state-of-the-art performance for four languages: English, German, Dutch, and Spanish. Here we take this model as a basis, and we augment it to model part-of-speech (POS) and grammatical information, which turns out to be very important for a morphologically complex language such as Bulgarian.

Strubell et al. (2017) extended the above model by substituting the LSTM with Iterated Dilated Convolutional Neural Networks, a variant of CNN, which permit fixed-depth convolutions to run in parallel across entire documents, thus making use of GPUs, which yields up to 20-fold speed up, while retaining performance comparable to that of the LSTM-CRF model. They further aggregated context from the entire input document, which they found to be helpful. In our preliminary monolingual experiments, this model performed very similarly, but slightly worse, than the LSTM-CRF model, and thus we chose LSTM-CRF for our experiments below.

3 Data

In this paper, we work with a Bulgarian corpus, annotated with BIO tags and positional tags, the same as in the CoNLL-2002 shared task (Tjong Kim Sang, 2002). The data is in BIO format, which encodes for each token in the text whether it is at the beginning of the expression of interest (Named Entity in our case), inside or outside of it. The annotation in the available Bulgarian data comes from the manually annotated Bulgarian treebank, known as BulTreeBank (Simov et al., 2004a). In the treebank, each NE is represented as a constituent consisting of one or more tokens. Each NE phrase is annotated by the categories Person, Organization, Location, and Other.

Христо Hristo	Стоичков Stoichkov	пристигна arrived	в in	София Sofia
B-PER	I-PER	O	O	B-LOC

Table 1: An example in BIO encoding.

The BIO tags for the tokens forming a given named entity (NE) in the treebank are created on the basis of the syntactic annotation. The first word in the phrase is marked as the beginning of the NE, while the rest of the tokens ar emarked as inside of the NE. The tokens that are not part of any NE are encoded as outside elements. In order to represent the category of the NE, each tag for begin and inside tokens includes a modifier for the category. Thus, we use nine labels: B-PER, I-PER, B-ORG, I-ORG, B-LOC, I-LOC, B-MISC, I-MISC, O. The example in Table 1 shows a simple sentence annotated with two named entities: a person name (*Hristo Stoichkov*) and a location name (*Sofia*).

Besides the BIO tagging, the texts in the dataset inherited the morphosyntactic annotation from the treebank. This annotation uses the BulTreeBank Morphosyntactic Tagset (Simov et al., 2004b). The tagset is positional. It encodes parts-of-speech and grammatical features for Bulgarian. For example, *Npfsi* stands for noun, proper, feminine, singular, indefinite. This annotation offers an opportunity to explore how the morphological features can affect NER.

The resulting dataset is divided into three disjoint sets: training set (Train), development set (Dev), and test set (Test). Table 2 shows statistics about the annotated data. We can see that a large number of examples are labeled as Person names, and that the distribution of Locations, Persons and Organizations is not balanced. While we can still build a stable system based on this data, the class imbalance makes our model more vulnerable to overfitting. Thus, we use early stopping in order to prevent the model from continuing to learn weights and parameters if it does not see an improvement in the final score.

	Sent.	**Tokens**	**PER**	**ORG**	**LOC**	**MISC**
Train	28,636	528,567	16, 804	3,028	6,786	911
Dev	4,063	64,014	2,514	515	1,021	227
Test	3,907	60,645	1,875	305	781	112

Table 2: Statistics about the data.

4 Model

As mentioned above, we construct our model as a modification of the Bi-LSTM-CRF architecture from (Lample et al., 2016). After some experiments with the original system, we decided to modify its input: we added a vector representing some of the information encoded in the morphosyntactic tags. Thus, we created the input vectors for the tokens in the sentences as a concatenation of three vectors: a word embedding vector, a character embedding vector, and a vector containing some grammatical features, called a *grammatical vector*. We experimented with different grammatical vectors, as explained below.

The rest of the Bi-LSTM-CRF architecture of (Lample et al., 2016) was kept as in the original model: First, we run a Bi-LSTM over the sequence of word vectors so that we could get their contextual word representation. We use a fully connected neural network to get a score for each of the tags. At the end, we run a CRF decoder to decide what the best combination of scores is.

The key takeout of our model is that we use some feature modeling to show that for a morphologically rich language such as Bulgarian using POS and grammatical information can improve the results. Thus, we mix automatically learned features — the word and the character embeddings —, with hand-crafted features encoded as a grammatical vector.

In the rest of this section, we describe the different components of our system.

LSTM-CRF Implementation For the implementation of the general LSTM-CRF architecture, we use Tensorflow (Sak et al., 2014).

Word Embedding Nowadays there are many different approaches to train word vectors such as Word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), FastText (Bojanowski et al., 2017), and many more. In our experiments, we use the pre-trained Bulgarian word embeddings from FastText (Bojanowski et al., 2017).[4] This choice was motivated by the fact that FastText uses the structure of the words by taking into consideration character n-grams, thus modeling morphology and many out-of-vocabulary words.

Character Bi-LSTM Embedding In order to produce character embeddings, we use a bidirectional LSTM over the character representation of the text. For each character in the text, each of the two LSTMs produces an hidden vector. For each word, the hidden vector for the last character produced by the left-to-right LSTM models information about the suffix of the word. Similarly, the hidden vector for the first character produced by the right-to-left LSTM models information about the prefix of the word. Following the approach, used in (Ling et al., 2015), we constructed the final character embedding of the word as a concatenation of the prefix and the suffix vectors.

Grammatical Vectors We use several types of grammatical vectors or their combinations. They are divided into POS vectors that encode different combinations of parts-of-speech and morphological vectors encoding other grammatical features.

POS Vectors The part-of-speech information for each word is represented as an a one-hot vector with eleven positions. This vector is concatenated to the vector for the word embedding. In the tagset, we have the following parts-of-speech: **N** — noun, **A** — adjective, **V** — verb, **H** — hybrid, **D** — adverb, **R** — preposition, **P** — pronoun, **C** — conjunction, **T** — particle, **M** — numeral, and **I** — interjection. In our experiments, we divided these parts-of-speech into different groups depending on the role they play in the representation of the named entities. For example, the tags A, N, H, R were viewed as a possible part of a named entity in contrast to the others that cannot form named entities. In this case, the one-hot vector contains only two positions. The groups are given in the experimental section below. The Hybrid tag (H) is special in the tagset. It refers to both family names and name adjectives. Bulgarian family names (as other Slavic ones) are proper names, but morphologically they behave like adjectives due to their adjectival origin.

Morphological Vectors The nominal system of Bulgarian shares some features with other Slavic languages, such as agreement in grammatical gender and number, rich pronoun system, etc. However, it has also specific features, such as the post-positioned definite article and lost nominal declension system. Our aim is to show the contribution of all these types of features to the named entity recognition task.

[4] In this work, we do not use any contextualization of the word embeddings such as ElMo (Peters et al., 2018) and BERT (Devlin et al., 2019), as our Bi-LSTM architecture already performs contextualization.

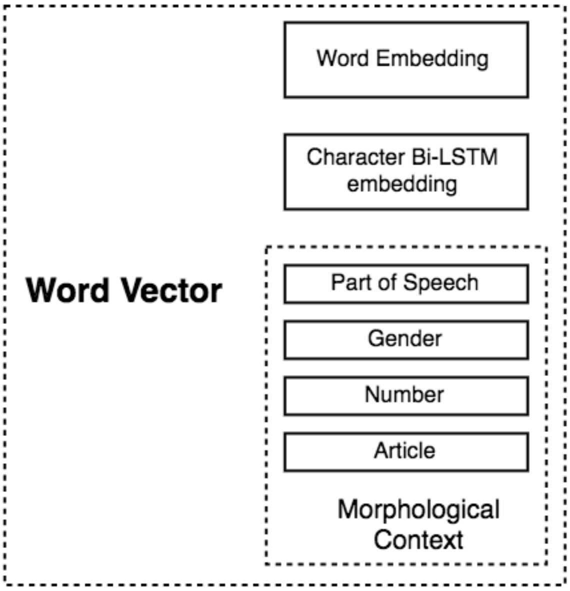

Figure 1: Full input vector representation with concatenation of word embeddings, character embeddings, and morphological features.

Another thing worth mentioning is that the nouns, adjectives and hybrid tags share some common features. This information appears to be very useful for recognizing the more specific types of named entities. Note that the existence of a preposition in a sequence can distinguish some further patterns as well.

The morphological features vary between the different entities, but there are few that can be defined for nouns, adjectives, hybrid tags and pronouns. Some of them are arguably useful, such as gender, number, and definiteness, and we will describe them briefly here:

Gender can have three values: *masculine, feminine, and neutral*;

Number can have four values: *singular, plural, only plural* and *count form* (which is only for masculine nouns for non-persons)'

Definiteness can have four values: *indefinite, definite, short definite* and *full definite*. The latter two are for singular masculine nouns only.

For each word with a POS tag of noun, pronoun, adjective or hybrid, we concatenate a one-hot vector representation for each of the features above (we use a zero vector for the rest). We form the final version of our word vector as a concatenation of all contextual vectors, as shown on Figure 1.

Dropout In order to prevent overfitting, we use a dropout layer on top of our word vectors as described in (Hinton et al., 2012). For each presentation of each training example, we randomly exclude a hidden unit from the network with a certain probability. In this way, the system learns to detect and use more useful features.

5 Experiments and Evaluation

In this section, we present the experimental setup and the evaluation results for the different models we experimented with.

5.1 Training and Hyper-parameters

We experimented with different values of the hyper-parameters and we found that changing some of them can result in sizeable improvements. The most considerable difference was for the learning method and the learning rate. Our best resulst were achieved using the Adam optimizer (Kingma and Ba, 2014), which is computationally efficient and has minimal memory requirements.

At the beginning, we set the learning rate to the initial value of 0.001, and then at each epoch, we multiplied it by a specific learning decay value. Decreasing our learning rate over time can help us find the minimum of our function without actually missing it. While Adam already decays the learning rate at each iteration, previous work has found that tuning the initial learning rate could yield sizeable improvements over the default settings. Thus, we use this additional decay. (Wilson et al., 2017)

The word embeddings we use from FastText have a dimensionality of 300, while the character embedding vectors have a dimensionality of 100. In order to produce them, we uses the TensorFlow default Xavier initializer and then we ran a Bi-LSTM on top of them in order to obtain contextual vectors with no additional layers.

We set the batch size to 20 and the dropout to 2. The Adam's parameters we used are as follows: $learningrate = 0.001$; $\beta 1 = 0.9$; $\beta 2 = 0.999$; $\epsilon = 1e - 08$; $use\_locking = False$. We also added a gradient clipping with a value of 1.

At decoding time, we used a linear-chain CRF (Lafferty, 2001). This model has been shown to outperform a simple SoftMax classifier as the tagging decision needs to be global.

Model	No Morphology	With Morpholofy		
	F1	F1	P	R
Model + POS-2	90.04	90.44	92.02	88.90
Model + POS-3	91.20	91.11	91.66	90.57
Model + POS-4	90.16	90.83	92.30	89.41
Model + POS-5	91.32	90.58	92.42	88.82
Model + POS-11	90.96	91.03	91.60	90.48
Model + POS-3+11	91.18	92.20	93.31	91.12
Model + POS-4+11	90.89	91.04	92.17	89.94

Table 3: Evaluation results for Bulgarian POS tagging. Shown are results where the standard input to the Bi-LSTM-CRF model is augmented with different POS tags and morphological features.

English	Ivan Valtchev visited the Bulgarian Academy of Sciences.						
Bulgarian	Иван Вълчев посети Българската академия на науките.						
Tokens	Иван	Вълчев	посети	Българската	академия	на	науките
POS11	N	H	V	A	N	R	N
POS2	ANHR	ANHR	O	ANHR	ANHR	ANHR	ANHR
POS3	ANH	ANH	O	ANH	ANH	R	ANH
POS4	NH	NH	O	A	NH	R	NH
POS5	N	H	O	A	N	R	N

Table 4: Example of the POS tags for annotation schemes of different granularities when applied to the same Bulgarian sentence.

5.2 Experiments

The experimental results suggest that adding grammatical features can have a sizeable impact on the performance of the general LSTM-CRF model for Bulgarian NER. In Table 3, we can see an example of different combinations of POS tags, where *Model* stands for Bi-LSTM-CRF and POS represents a one-hot encoding for the following:

POS11 = all part of speech tags separately

POS2 ”ANHR” vs. REST

POS3 ”ANH” vs. ”R” vs. REST

POS4 ”A” vs. ”NH” vs. ”R” vs. REST

POS5 ”A” vs. ”N” vs. ”H” vs. ”R” vs. REST

POS3 + POS11 POS11 vs. ”ANHR” vs. REST

POS4 + POS11 POS11 vs. ”ANH” vs. REST

Morph Gender, number, and definiteness

We further perform several experiments in order to determine whether we need the full set of part-of-speech tags or it is enough just to know whether the entity is part of the group of the nouns, adjectives, hybrid tags, and prepositions.

Model	F1
(Georgiev et al., 2009)	89.40
Our model	92.20

Table 5: Comparing the previous state-of-the-art results to our best morphologically informed Bi-LSTM-CRF model.

In Table 4, we see how the entities map to the different POS groups. It appears that knowing the concrete tag of each entity can help us improve the performance by almost one percent.

Table 5 shows our best result compared to the previous state-of-the-art result as reported in (Georgiev et al., 2009). They achieved an F1 score of 89.4% by sing regular expressions, gazetteers and non-local morpho-syntactic characteristics. Our model improves this to 92.20% without using any external resources.

More detailed evaluation results for our best model are presented in Table 6, where we show the precision, recall and F1 score for each type of named entity. We can observe relatively worse F1 score of 84.70 for Organization compared to 95.86 for Location and 94.95 for Person. We explain this drop in F1 score by the fact that many organizations are named after persons.

Entity	Precision	Recall	F1
Location	97.75	94.05	95.86
Person	95.67	94.23	94.95
Organization	75.57	96.34	84.70
Miscellaneous	96.15	22.73	36.76
Overall	93.31	91.12	92.20

Table 6: Detailed results for the different kinds of named entities.

Model	F1
(1) LSTM-CRF (words only)	82.03
(2) fwd-LSTM-char + (1)	85.15
(3) bwd-LSTM-char + (1)	85.40
(4) Bi-LSTM-char + (1)	86.44
(5) POS11 + (4)	90.96
(6) Morph + (5)	91.03
(7) POS3 + (6)	92.20

Table 7: The impact of different components and different component combinations on the performance of our best model.

Table 7 shows the cumulative effect of adding different components to our model. The basic model we started with is shown on line (4). Then, on lines (1)-(3) we remove different components from this basic model, and on lines (5)-(7) we add POS and morphological information to it. We can see sizeable improvement for the standard Bi-LSTM-CRF model with only word vector representationa and the model with character-level LSTM. Interestingly, there is almost no difference between the suffix and the prefix vectors. We can further see that adding POS11 (5) vector improves the performance by almost four percent absolute. The morphological vectors and POS3 also improved the F1 score to 92.20 points absolute. These improvements show that using known linguistic knowledge such as grammatical features could improve the representation vectors learned over huge text corpora. From the point of view of feature learning, we speculate that vectors trained over texts in morphologically rich languages do not learn enough grammar such as POS and morphology. The character embeddings also seem not to help much. One explanation for this could be that the suffixes and prefixes in Bulgarian are also highly ambiguous.

Model	Word (Bulgarian / English)
Model	Еминем / Eminem
Model + POS11	Фердинанд / Ferdinand
Model + POS2	Ваксберг / Vaksberg
Model + POS3	Гьоте / Goethe
Model + POS4	Обзървър / Observer
Model + POS5	Шехеразада / Scheherazade
Model + POS11 + POS3	Ингмар / Ingmar

Table 8: Examples of words which could not be handled correctly by the specific configuration

6 Error Analysis

Our manual analysis of the errors shows that one of the main reasons for our model to work better when POS tags are provided is due to the presence of many loanwords in the Bulgarian text. The LSTM-CRF model manages to learn the grammar of the language itself, but it needs additional help with words borrowed from other languages.

A common problem for the LSTM-CRF model is the mislabeling of foreign person or organization names. In such cases, the POS tags help by suggesting the possible part-of-speech for each word. In our test set, around 10% of the wrongly labeled words are loan words, borrowed primarily from English, Russian, German and Turkish. Table 8, shows some examples of words that could not be handled properly.

The loanwords cannot be successfully recognized by our algorithm in all cases. Even though some people try to write them in Cyrillic, their structure is different from the typical structure of the Bulgarian words. That is why, we further tried to add gazetteers and lexicons with existing loan words in Bulgarian. Similarly to the way we added POS vectors, we created a one-hot vector for each word that says whether that word is part of our lexicon with loan words or not. We then concatenated the vector to the rest of the word embeddings. However, this approach did not result in significant improvements because new words are added to the language almost every day, and it is impossible to capture them all.

Sometimes, the loanwords come in the Latin alphabet, as they are spelled in their original language. For such cases, we added a feature to the model that captures the information whether the words are in Latin or in Cyrillic. This feature, by itself, did not make much of a difference. Yet, we plan to explore it further in our future work.

	B-ORG	I-ORG	B-PER	I-PER	B-LOC	I-LOC	B-MISC	I-MISC	O
B-ORG	**258**	0	1	0	2	0	6	0	6
I-ORG	0	**31**	0	0	0	0	0	0	1
B-PER	9	1	**1,169**	6	8	0	7	0	58
I-PER	0	1	15	**595**	0	0	0	0	6
B-LOC	15	0	8	0	**676**	0	4	0	36
I-LOC	1	0	0	1	3	**36**	0	0	1

O	12	2	10	22	2	0	3	0	**57, 522**

Table 9: Confusion matrix for our best model on the test dataset: the columns represent the true labels and the rows show the predictions.

Table 9 shows a confusion matrix for the nine BIO tags that we used for the four kinds of named entities that we are recognizing. In the table, the columns represent the actual expected gold tags, while the rows show the predictions of our model. There are several interesting observations that we can make about this confusion matrix. First, it looks like the biggest problem for the model is with the tag B-PER, which is often confused with the tag O, i.e., Outside. This is probably due to the fact that in Bulgarian the first names sometimes have more than one meaning, which can confuse the model. The same argument holds for the tag B-LOC, which is also often confused with the tag O. Another place for improvements would be to distinguish better between B-LOC and B-ORG, as many places and organization have identical names, or at least the identical first words. The miscellaneous entities such as the names of books or movies can also have names that are identical to those of some organizations. Even more often, Miscellaneous entities could be confused with the Other category as they contain many common Bulgarian words.

7 Conclusion and Future Work

We explored the potential of using morphological information to a recurrent Bi-LSTM-CRF neural network architecture with the aim to improve named entity recognition for morphologically rich languages such as Bulgarian, which pose different challenges for named entity recognition compared to English. Our experiments have shown that adding morphological and part-of-speech information to the model's input yields sizable performance gains over a model that only relies on word-level and character-level embeddings as an input to the neural network.

In future work, we plan to extend the modeling of the morphological structure of the entities. Here, we only used a limited number of features, namely gender, number and definiteness, but it might be interesting to add the full linguistic knowledge encoded in the BulTreebank. We further plan to explore features and models that can help identify loan words in Bulgarian.

Another promising research direction is to compare the differences in the graphical representation of named entities in Bulgarian and English. For example, in English all components of a named entity are capitalized (except for the functional words). In order to have comparable data, we envision to pre-transform the Bulgarian dataset to which to apply the English capitalization rule for the phrasal named entities.

Finally, we plan to experiment with different monolingual representations from ElMo (Peters et al., 2018), BERT (Devlin et al., 2019), ROBERTa (Liu et al., 2019c), XLNet (Yang et al., 2019), and Ernie 2.0 (Sun et al., 2019), pooled representations from Flair (Akbik et al., 2019), distilled representations from MT-DNN (Liu et al., 2019a,b) or cross-language representations from XLM (Lample and Conneau, 2019).

Abstract

In this paper we discuss the named entity recognition task for Russian texts related to cybersecurity. First of all, we describe the problems that arise in course of labeling unstructured texts from information security domain. We introduce guidelines for human annotators, according to which a corpus has been marked up. Then, a CRF-based system and different neural architectures have been implemented and applied to the corpus. The named entity recognition systems have been evaluated and compared to determine the most efficient one.

1 Introduction

For a cybersecurity expert, it is vital to stay aware of all of the newly discovered vulnerabilities and exploits. Although various security databases, such as National Vulnerability Database (NVD) or MS Bulletins, contain detailed information on various cybersecurity problems, they do not usually provide any data on the latest discoveries. The most up-to-date descriptions of vulnerabilities are usually posted on specific websites and forums in form of **unstructured informal** texts. Therefore, a system extracting relevant cybersecurity information from unstructured publications could be of great use for a cybersecurity expert.

As there are a lot of NER systems for news documents, the first idea one comes up with is to apply such a system to the cybersecurity domain. Unfortunately, all such attempts prove to be unsuccessful for two reasons. Firstly, there is a great difference between general news documents and informal publications on cybersecurity: the latter contain a lot of non-vocabulary words (such as jargonisms, borrowings and domain-specific terms), include various grammar and spelling mistakes and use spoken syntax. What is more, changing the domain, where the extraction is conducted, usually means that some new named entity types should be accounted for (e.g. for cybersecurity domain these are names of programs and viruses). As none of the existing NER systems can be applied to the cybersecurity domain, our only option is to create a new system, which is trained on a newly labeled corpus, where all the domain-specific names and terms are taken into account.

This paper observes the named entity recognition (NER) task for unstructured Russian texts related to cybersecurity. Our first step is a thorough analysis of unstructured texts related to cybersecurity, elaboration of guidelines for human annotators and, finally, corpus labeling. At the second step, we implement several NER systems (one based on CRF-method and others based on artificial neural networks), apply them to the corpus, evaluate and compare of the results shown by the systems.

2 Related Work

The information extraction task in cybersecurity domain has been discussed in several works. However, the vast majority of the works consider information extraction only from structured or semi-structured English texts. For instance, (Bridges et al., 2013) and (Weerawardhana et al., 2014) use training corpora consisting of MS Bulletins and NVD vulnerability descriptions mainly. The training corpus presented in (Joshi et al., 2013) does contain unstructured blog posts, but those comprise less than 10% of the corpus.

NER systems elaborated in the works mentioned above are based on several different methods such as principle of Maximum Entropy in (Bridges et al., 2013), Conditional Random Fields (CRF) in (Weerawardhana et al., 2014: Joshi et al., 2013).

One of the latest works on the topic is (Gasmi et al., 2018). The authors use the corpus created by Bridges et al. (2013) as a dataset for two different NER systems. The corpus of over 850 000 tokens includes a large amount of NVD

Proceedings of Recent Advances in Natural Language Processing, pages 1114–1120,
Varna, Bulgaria, Sep 2–4 2019.

descriptions and also some MS Bulletins and Metasploit Framework's descriptions. The corpus was auto-labeled by a special algorithm. The labeling scheme is BIO. The two NER systems trained by Gasmi et al. (2018) are a CRF-model (CRFSuite implementation by Okazaki (2007)) and a neural network (NN) based model LSTM-CRF (as suggested by Lample et al. (2016)). The NN-based model combines bidirectional LSTM, word2vec models as a source of pre-trained word embeddings and CRFs as an output layer.

The only work that discusses the NER task for unstructured Russian text from cybersecurity domain is (Mazharov and Dobrov, 2018). The authors train their NER system on an early version of Sec_col collection, which was annotated with a CRF-classifier trained on news documents (Mozharova and Loukachevitch, 2016a).

3 Labeled Corpus Construction

The source of the text for our corpus is Sec_col collection. It consists of 2000 texts (posts and forum publications) from SecurityLab.ru website. These texts can be described as follows: they do not include any structured information; the writing style is informal; they contain quite a lot of lexical, spelling and grammar mistakes, many borrowings, words in foreign languages, words containing non-alphabetic characters and many instances of jargon. The average length of the texts in Sec_col collection is about 400 words.

The texts were manually marked up by four independent annotators, not all of which are cybersecurity experts. For the annotation purpose, the BRAT web based annotation tool was used.

There is no conventional set of labels for texts related to cybersecurity, but different authors usually consider quite similar classes of named entities to be relevant for the cybersecurity domain. For instance, both Bridges et al. (2013) and Joshi et al. (2013) annotate such types of named entities as software names, software versions, file names, vulnerability names. Taking into account the experience of the works mentioned above, we propose the following set of labels to annotate named entities: **Person** – people's names; **Loc** – locations; **Org** – names of organizations; **Hacker** – individual hackers' nicknames; **Hacker_Group** – names of hacker groups; **Program** – software products and parts of programs; **Device** – electronic gadgets; **Tech** – technologies; **Virus** – various malicious software; **Events** – for example, conferences.

At first, annotators had quite modest instructions on how various named entities must be annotated. Our assumption was that this would help to detect the trickiest contexts and regular mistakes that should be mentioned in the full-fledged guidelines for annotators.

In total 1124 publications have been marked up. Then those texts that do not contain any named entities that are relevant for cybersecurity were excluded. The final corpus contains 861 texts, which is more than 400 000 tokens.

In order to ascertain the degree of correctness and consistency of the annotation, we conducted a thorough analysis of the labeled texts. As the result, we found out that annotators tend to mark up similar contexts quite differently. For example, token *ICQ* was labelled as **Program** 18 times and received label **Tech** in 9 other cases.

Also some other instances of inconsistent markup were discovered:

- The number of named entities (one or two) in the contexts where an abbreviation is followed by the full name of the same entity or vice versa: *Software Defined Network (SDN)*; *MITM (Man-in-the-Middle)*;

- The number of named entities (one or two) in the contexts where a name or term in Russian is followed by the same name in English;

- Presence or absence of a named entity on a version of software or device when it is separated from the name by a punctuator or a conjunction: *Android 7.1, 7.1.1;*

- Inclusion or exclusion of paired punctuators (such as quotation marks or brackets) that surround a named entity: *сканер уязвимостей (nessus)* - (scaner ujazvimostej nessus) "vulnerability scanner nessus";

- Inclusion or exclusion of the second part of a compound noun with a hyphen, the first part of which is a named entity: *Android-устройств* – (android ustrojstv) "devices run on Android".

The vast variety of mistakes and instances of inconsistency reveal that there is a strong need for

Labels	Org	Loc	Person	Tech	Program	Device	Virus	Event	Hacker_group	Hacker
Amount of entities	3797	1553	1130	3280	3995	586	561	310	45	16

Table 1: Statistics of the annotated named entities.

guidelines for human annotators, whether they are cybersecurity experts or not.

3.1 Guidelines for Annotators

Within our study, comprehensive annotators' guidelines have been developed. It includes description of all the problematic and/or ambiguous contexts and indicates how named entities should be annotated in these contexts. Some passages from the guidelines are provided hereunder.

- If an abbreviation is followed by the full name of the same entity or vice versa, then the whole sequence is annotated as a single NE;
- If a name or a term in Russian is followed by the same name in English, then the whole sequence is annotated as a single NE;
- If a version of a software or a device is separated from its name by a punctuator or a conjunction, then it is annotated as a named entity only if it contains an alphabetic character, for example: *PowerPC G3, G4;*
- Paired punctuators (such as quotation marks or brackets) that surround a named entity are included in its annotation;
- The second part of a compound named entity with a hyphen is included in its annotation.

The guidelines also include detailed labels' description.

For each label we indicate the types of named entities that should receive this label. For example, label **Program** should be assigned to: operating systems (*iOS 9*); browsers (*Google Chrome*); programs that can be downloaded and installed (*Adblock*); websites (e.g. *SlideShare*, but not a link: *https://www.slideshare.net/);* files and processes, whose names are in format «name.extension» (*Autorun.exe*, *ipfilter.dat*) and some others. Likewise, label **Tech** should be assigned to: formats and filename extensions (when mentioned separately, e.g. *XML*); programming languages (*Javascript*); protocols (*pptp*), standards (*PCI DSS*) and some others.

For each label we also give the types of named entities that should not receive this label. For example, label **Program** should not be assigned to: links and directories, long instances of programmers' code, some abbreviations (*OS*). Likewise, label **Tech** should not be assigned to: abbreviations such as *BYOD, CYOD*, which are not technological, but business approaches.

The annotation of the corpus was corrected in accordance with the guidelines. To access how useful the introduction of the guidelines is, we could compare agreement between annotators before and after the guidelines were introduced. Unfortunately, at the current point annotator's agreement cannot be measured as there are no texts for which we would have several annotations from different annotators.

In Table 1 the statistics of the annotated named entities in the renewed corpus is presented.

The renewed corpus was used to train and test several NER systems based on the modern machine learning methods.

4 Labeling Scheme

In recent works on NER, several specific labelling schemes are usually used: IOB, BIO or IOBES. The general idea is to enrich standard labels with prefixes that indicate position of a token inside of a named entity: for example, whether it is the first word of a named entity.

It was shown that BIO-scheme is the one most efficient tagging schemes for NER system training: see (Mozharova and Loukachevitch, 2016a) for CRF-model and (Reimers and Gurevych, 2017) for neural networks. BIO-scheme suggests marking the first token of any named entity with a B- tag (beginning), every other token within the named entity should receive an I- tag (inside). Every token that is not a part of a named entity re-

5 CRF-Model

CRF-model is a discriminative classifier, which can be used to predict sequences (Lafferty et al., 2001). A CRF-classifier uses information about the whole sequence of observable states (words) and information from previous unobservable states (labels). CRFs proved to be one of the most successful methods for NER.

To test a CRF-model, we use an open source implementation CRF++[1].

The following set of tokens’ features was used for the model training:

- **String features**: length of the token; initial letter’s case; presence of non-alphabetic characters; presence of a vowel, etc.
- **Token’s lemma**;
- **Part of speech (POS) of a token**;
- **Lexicon features**: whether a token is mentioned in a special vocabulary list (see below);
- **Cluster feature**: a number of the token’s cluster (see below);
- **Context features**: all the features mentioned above for the two preceding tokens and for the two following tokens;
- **Bigram feature**: previous token’s label.

To determine lemma and POS of each token, an open source morphological analyzer MyStem[2] was used. For tokens that do not have any lemma (for example, punctuation marks), lemma feature coincides with the token. For tokens that are absent in MyStem’s vocabulary, POS feature gets value ‘N\A’ or ‘PUNCT’, if a token is a punctuation mark.

We explain lexicon and cluster features in more details.

5.1 Lexicon Features

To improve NER system’s results we can use vocabularies that contain lists of objects of a certain type. By object we mean a word or a phrase. Words can also be treated as single-word phrases.

At our disposal there are 12 lists (see Table 2 for more detailed information). To create these lexicons, a large collection of texts from different sources on cybersecurity was used. Mutli-word terms and names were extracted from the collection. Then the extracted objects were manually classified into several categories.

Each token has 12 lexicon features. For a token T, a lexicon feature gets value ‘0’ if there is no word T or phrases that include T in the correspondent list. If token T is included in some phase in the list, then the correspondent lexicon feature gets value which equals the matched phrase’s length.

Let us consider an example. For token *Google* (as a part of a named entity *Google Chrome*), the feature that corresponds to Org_name list will get

[1] https://taku910.github.io/crfpp/

[2] https://yandex.ru/dev/mystem/

value ‘1’, while the feature that corresponds to Program_name list will get value ‘2’.

5.2 Cluster Feature

To form word clusters, we use an open source model ruwikiruscorpora_upos_skipgram_300_2_2019 (RusVectōrēs[3], (Kutuzov et al., 2016)). In total 300 clusters were formed. For each token the cluster feature get value that equals the number of the cluster, that contains the token. If there is no such a cluster, then the feature gets value ‘-1’.

6 Neural Networks

Nowadays the most successful NER systems are usually those that are based on neural networks.

Within our study, six different neural network architectures were implemented:

(A) BiDirectional LSTM: **BiLSTM**;

(B) BiDirectional LSTM with a CRF-classifier as an output layer: **BiLSTM-CRF**;

(C) BiDirectional LSTM with BiDirectional LSTM embeddings: **BiLSTM$_{\mathbf{CHAR}}$-BiLSTM**;

(D) BiDirectional LSTM with BiDirectional LSTM embeddings and a CRF-classifier as an output layer: **BiLSTM$_{\mathbf{CHAR}}$-BiLSTM-CRF**;

(E) BiDirectional LSTM with CNN embeddings: **CNN$_{\mathbf{CHAR}}$-BiLSTM**;

(F) BiDirectional LSTM with CNN embeddings and a CRF-classifier as an output layer: **CNN$_{\mathbf{CHAR}}$-BiLSTM-CRF**;

The core layer in all the architectures is Bidirectional Long-Short Term Memory (BiLSTM) NN (Graves et al., 2013), (Huang et al., 2015). BiLSTM is capable of learning long-term dependencies and considers both left and right context of every token.

All the architectures use pre-trained word embeddings created by model araneum_none_fasttextskipgram_300_5_2018 (RusVectōrēs, (Kutuzov et al., 2016)). Fasttext models are able to build embeddings for non-vocabulary words (e.g. jargonisms or borrowings), which is vital for a big corpus like ours.

Models (B), (D) and (F) use a CRF-classifier as an output layer (Huang et al., 2015), (Lample et al., 2016), (Ma et al., 2016). Therefore, these models are capable of learning standard constraints of the markup such as that a token with I-label must always follow a token with B-label of the same class.

Models (C)-(F) also have special layers that build character embeddings (Lample et al., 2016), (Ma et al., 2016), which is said to improve the results shown by NER systems (Reimers and Gurevych, 2017), (Zhai et al., 2018). While models (C)-(D) use BiLSTM-layer to build character embeddings, models (E)-(F) use CNN-layer for the same purpose. Reimers and Gurevych (2017) and Zhai et al. (2018) have shown that both layers provide the same improvement of a NER system, but CNN-layer is characterized by higher computational efficiency.

7 Evaluation

To evaluate all the NER systems, standard metrics such as Precision, Recall and F-score were used for each named entity type (label).We also compute macro and micro metrics for each system. The evaluation method is as follows: a named entity considered to be correctly identified by a NER system (true positive decision) only when both the type and the boundaries are correctly defined. This method is called exact (full) matching method.

To calculate the metrics the 3:1 cross validation technique was used.

Table 3 presents Precision for all the systems, while Table 4 and Table 5 present Recall and F-measure, respectively. The letters in the head of the tables stand for NN-based models (as it was introduced in Section 6). We also use following notations: **P** for **Person** ; **L** for **Loc**; **O** for **Org**; **H** for **Hacker**; **Hg** for **Hacker_Group**; **Pr** for **Program**; **D** for **Device**; **T** for **Tech**; **V** for **Virus**; **E** for **Events**; **Ma** for macro measures; **Mi** for micro measures.

As we can see, the CRF-model outperforms all the NN-based models. A possible explanation could be the fact that only CRF-model uses lexicon features.

As far as NN-based models are concerned, BiLSTM$_{\mathrm{CHAR}}$-BiLSTM-CRF proves to be the most successful one, judging from micro and macro metrics. CNN$_{\mathrm{CHAR}}$-BiLSTM-CRF shows quite similar results and, as it was expected, it

Table 5: F-score.

outperforms BiLSTM$_{\text{CHAR}}$-BiLSTM-CRF model in training time.

As for the results shown for different classes of named entities (labels), we could also suggest several explanations. The poor quality for **Hacker** and **Hacker_group** could be explained by the small amount of named entities of these classes in the corpus (16 and 45 respectively). The reason for the low scores for **Virus** is possibly semantic heterogeneity of the class, which, according to our latest guidelines, comprises both malicious software and various technologies that hackers use (e.g. *DDos*). Therefore, **Virus** class is also semantically similar to **Tech** and **Program** classes, which could also influence the scores. As for **Event** class, it is also semantically heterogenic, as the label is assigned to both human arranged events (e.g. seminars and conferences) and historical and cultural events (e.g. holidays and wars).

Unfortunately, the results performed by our models cannot be compared to the results in (Mazharov and Dobrov, 2018) for two reasons.

Firstly, although the same text collection Seq_col was used in both studies, the markup of the collection differs significantly. Only about 300 texts from dataset in (Mazharov and Dobrov, 2018) were annotated manually and contained labeled named entities that are relevant for cybersecurity. Other 1700 texts in the dataset had poor quality automatic annotation, provided by a CRF-classifier trained on news documents. In our study the dataset contains 861 texts that were manually marked up in accordance with the annotators' guidelines.

Secondly, as it was mentioned above, we used full matching method of evaluation, whereas the method used in (Mazharov and Dobrov, 2018) is incomplete matching.

8 Conclusion and Future Work

In this paper we discuss the NER task for unstructured Russian texts concerning cybersecurity problems. Our first step is creating a labeled corpus of such texts. In order to ensure correctness and consistency of the markup, we elaborate detailed annotators' guidelines, which include description of every label and numerous examples of various tricky contexts. Within our study, the first consistently labeled corpus of unstructured Russian texts on cybersecurity was created. The corpus can now be used either as a dataset for NER systems or to conduct linguistic analysis of the text in question.

Our guidelines can be used to create new labeled corpora of texts on cybersecurity or to annotate the rest of the texts in Sec_col to increase our corpus.

We applied several NER systems based on CRF method and on NN to our corpus. The most successful is the CRF-model. Our hypothesis is that the CRF-model outperforms all the other models because it is the only one that uses lexicon features. Among NN-based models, BiLSTM$_{\mathrm{CHAR}}$-BiLSTM-CRF shows the best results.

As for the future work, the usefulness of our annotators' guidelines should be captured by comparing agreement between annotators before and after the guidelines were introduced. What is more, the set of features for the CRF-model could be widen by adding such features as text statistics or text collection statistics (Mozharova and Loukachevitch, 2016b). Furthermore, some additional features such as lexicon features and casing features could also be used to improve the performance of NN-based NER systems.

Abstract

We address the problem of cognate identification across vocabularies of any pair of languages. In particular, we focus on the case where the examined languages are low-resource, to the extent that no training data whatsoever in these languages, or even closely related ones, is available for the task. We investigate the extent to which training data from another, unrelated language family can be used instead. Our approach consists of learning a similarity metric from example cognates in Indo-European languages and applying it to low-resource Sami languages of the Uralic family. We apply two models, following previous work: a Siamese convolutional neural network (S-CNN) and a support vector machine (SVM), and compare them with a Levenshtein distance baseline. We test performance on three Sami languages and find that the S-CNN outperforms the other approaches, suggesting that it is better able to learn such general characteristics of cognateness that carry over across language families. We also experiment with fine-tuning the S-CNN model with data from within the language family in order to quantify how well this model can make use of a small amount of target-domain data to adapt.

1 Introduction

Cognate identification is a core task in the *comparative method*, a collection of techniques used in historical linguistics for the inference of language family trees, reconstruction of protolanguages, and other areas of study related to language history (List, 2013). Cognate information can also be used to improve natural language processing (NLP) applications, such as machine translation (Grönroos et al., 2018). In addition, knowledge of cognates can be useful for second-language learning (Beinborn et al., 2014).

For a subset of the world's languages, such as Indo-European, language-family trees, protolanguages, and etymological databases are well-established. However, the majority of languages have only few speakers, and such resources are scarce. Since the tasks of the comparative method are laborious to do manually, computational approaches have been taken to automatize these tasks. In addition to cognate identification, previous work addresses phonetic alignment (Kondrak, 2000; Prokić et al., 2009; List, 2013), inference of family trees (Chang et al., 2015; Jäger, 2014; Bouckaert et al., 2012), and reconstruction of proto-words (Bouchard-Côté et al., 2013).

Ideally, computational approaches to historical linguistics should be applicable to any language, even in the absence of hand-crafted resources and analyses. Recent work addressing cognate identification for *low-resource* languages assumes either the existence of high-resource relatives, to be used as training data (McCoy and Frank, 2018), or the availability of detailed dictionary definitions (St Arnaud et al., 2017).

In this paper, we address cognate identification in a scenario where we are only given a set of unannotated vocabularies from truly low-resource languages, namely South, North, and Skolt Sami of the Uralic family, without the aforementioned resources. We only assume a training dataset of example cognates in Indo-European languages, highly unrelated to our languages of interest. It might be expected that knowledge of general tendencies in patterns of correspondence between related languages, such as common phoneme substitutions, might be of some use, even

Table 1: Examples of cognates, i.e. etymologically related words. The degree of similarity in form and meaning may vary quite substantially.

when searching for potential cognates in a different language family. Naturally, some knowledge of more closely related languages, or of the language pair in question, is more informative, and we attempt to quantify how well one of these models is able to make use of that.

Our aim is to investigate the extent to which a similarity learning approach, that is learning a similarity metric in a data-driven manner, is able to generalize across language families. We experiment with two similarity learning approaches from previous work, namely a support vector machine (SVM, Hauer and Kondrak, 2011) and a Siamese convolutional neural network (S-CNN, Rama, 2016), compared with a Levenshtein distance baseline (LD, Levenshtein, 1966). We train the models on examples of cognates in Indo-European language pairs, then test how well they are able to identify cognates in the Sami language pairs, not seen at training time. In addition, we fine-tune the S-CNN model on labelled target-language pairs, in order to quantify how much the lack of target-family training data affects performance.

Next, we explain the cognate identification problem and its difficulties, and review previous approaches to the problem. Then we present the approaches we use in our experiments, as well as the experimental setup in more detail. Finally, we analyse the results of the experiments.

2 The Cognate Identification Problem

The term *cognate* has several distinct uses in the literature. In historical linguistics, two words are considered cognates only if they have descended from the same ancestor word in a common proto-language, implying that they also belong to two related languages (e.g. Jäger et al., 2017; List, 2013; Kondrak, 2009). Meanwhile, a number of broader definitions have been used in NLP, motivated by practical concerns. For example, some authors refer to any etymologically related pair of words (i.e. sharing a common origin) as cognates, including, for example, loanwords (e.g. Kondrak, 2001; Beinborn et al., 2013; Bloodgood and Strauss, 2017). Others assume that cognates share both a similar form and common meaning (e.g. Nakov and Tiedemann, 2012; Bergsma and Kondrak, 2007). This assumption is problematic for historical linguistics, since it excludes cognate words that have come to have different meanings since the languages diverged, but it may be more useful for some language learning applications. In this paper, we regard any pair of etymologically related words as cognates, including genetically related true cognates as well as direct loanwords or loans from a common origin.

We formulate the cognate identification problem as follows. We are given two string sets $X = \{x_1, \ldots, x_n\}$ and $Y = \{y_1, \ldots, y_m\}$. The task is to extract those pairs (x, y) in relation R:

$$R = \{(x, y) \in X \times Y | \; x \text{ is cognate with } y \}.$$

Each element $x \in X$ and $y \in Y$ is a string over alphabets Σ_x and Σ_y respectively. The alphabets do not necessarily overlap, since the orthographies of different languages may vary. This issue is often circumvented by using phonetic transcriptions of words. Lacking phonetic transcriptions for our test data, we deal with orthographic forms. Nonetheless, orthographic similarity often reflects phonetic similarity, in particular in the Sami languages we take as examples here, where the orthography is largely phonemic.

Several factors have been found to predict cognateness: phonetic similarity (reflected by orthographic similarity), semantic similarity, and the presence of *regular sound correspondences*, word segments regularly occurring in similar phonetic positions and contexts (Kondrak, 2009).

The example cognates in Table 1 illustrate the difficulty of cognate identification. A straightforward example is the Italian–Spanish pair *(notte, noche)*, with a similar form and common meaning. However, many cognates have similar surface forms, but differ in meaning, such as the English–French *(actual, actuel)* and Finnish–Estonian *(huvittava, huvitav)*. Such words are referred to as *false friends* in the context of language learning.

Furthermore, cognates might look very different on the surface. English–Swedish cognates *(oath, ed)* and Finnish–Swedish *(pöytä, bord)* look quite different, but share a meaning (and common origin). On the other hand, English–French *(bite, fendre)* are similar neither in form nor meaning. The only way to recognise such cognates from their surface forms alone is to identify regular correspondences, such as *th – d* for English–Swedish.

Consequently, and in contrast to much previous work, we make no strict assumptions about the degree of similarity in form or meaning that any two cognates should exhibit. Instead, following Jäger (2014), we treat regular correspondences as the main driving factor in the cognate relation and attempt to capture these in a completely data-driven manner.

3 Related Work

Earlier computational approaches to cognate identification attempt to design a string similarity (or distance) metric that assigns a higher score to cognate words and a lower score to unrelated ones. A common approach is to extend the traditional Levenshtein distance (Levenshtein, 1966) by associating specific weights to pairs of symbols using linguistic knowledge (e.g. Kondrak, 2000; List, 2013), or sets of example cognates (e.g. Bergsma and Kondrak, 2007; Rama, 2015).

Kondrak (2000) proposes the ALINE algorithm using specific weights based on several predetermined phonetic features. In addition, Kondrak (2005) generalizes the Levenshtein distance with the n-gram similarity measure. Turchin et al. (2010) use a heuristic based on mapping consonants to ten classes, and consider words matching in their first two consonant classes to be cognates. The SCA algorithm of List (2013) uses a larger set of sound classes and also considers prosodic aspects of words.

Other authors rely on learning regular correspondences (sometimes called *mismatches* or *substitution patterns*) from example cognates using an alignment algorithm. For example, Ciobanu and Dinu (2014) and Bergsma and Kondrak (2007) use a global alignment algorithm to align orthographic word pairs and extract substring pairs, which they use as features for an SVM. Gomes and Pereira Lopes (2011) use the same approach to develop a weighted string similarity metric for words in orthographic form. Rama (2015) use gap-weighted subsequences as features. McCoy and Frank (2018) use character embeddings and cosine similarity to extend Levenshtein distance.

Hauer and Kondrak (2011) convert word pairs into features for an SVM using a set of string similarity metrics. This approach has been extended with features for semantic similarity, for example using the lexical database WordNet (Jäger et al., 2017; St Arnaud et al., 2017; Kondrak, 2009). Bloodgood and Strauss (2017) improve further such an SVM model using global constraints and reranking. In addition, St Arnaud et al. (2017) utilise English and Spanish word embeddings of dictionary definitions. This SVM classification approach is one of the methods that we apply to cross-language family learning.

Jäger (2014) and Rama (2016) take data-driven approaches not relying on hand-designed features. Jäger proposes a similarity metric based on weights for symbol pairs given by *pointwise mutual information*, the values for which were learned from a training set of cognate pairs. Rama applies deep learning, encoding words into a grid-like representation and applying a Siamese convolutional neural network to cognate identification for multilingual wordlists. He uses two methods to encode a phonetic symbol into vector, a one-hot encoding and one based on phonetic features, achieving better performance with one-hot encodings for two out of three language families. This approach is another method in our comparison of models for cross-language family learning.

In recent work, Hämäläinen and Rueter (2019) take an alternative approach of applying neural machine translation methods to the problem of predicting a cognate given a word in a related language. The same model could in principle be applied to the task we present here and we intend to make a direct comparison in future work.

4 Methods

In this section, we present the three approaches to solving the cognate identification problem that we have used in our experiments: a string similarity metric based on the Levenshtein distance (Levenshtein, 1966) used as a baseline, an SVM with several string similarity metrics as features (Hauer and Kondrak, 2011), and a Siamese convolutional neural network (Rama, 2016).

4.1 Levenshtein Distance–Based Similarity

The *Levenshtein distance* $d_L(s_1, s_2)$, or *string edit distance*, between strings s_1 and s_2 over an alphabet Σ is the minimum number of insertion, dele-

tion, or substitution operations needed to transform one string to the other. To obtain the *normalised* Levenshtein distance, this number is divided by the length of the longer word, equal to the maximum possible distance between s_1 and s_2. The similarity metric is then:

$$sim_L = 1 - \frac{d_L(s_1, s_2)}{max(|s_1|, |s_2|)}.$$

For example, for the cognate pairs *(coupe, Kopf)* and *(pöytä, bord)*, the respective similarities are $1 - \frac{3}{5} = 0.4$ and $1 - \frac{5}{5} = 0$. It is assumed that both strings are drawn from overlapping alphabets, since the similarity is always zero for disjoint alphabet sets.

Previous work has introduced a variety of Levenshtein-based measures by defining different ways of learning or computing the cost associated with a character substitution. Here we apply the basic version, in which a matching pair of characters have a zero cost and any other a unit cost.

4.2 Support Vector Machine

The support vector machine (SVM) is a supervised learning model trained by finding the optimal separating hyperplane between multi-dimensional data points of different classes. The basic SVM is a non-probabilistic, linear binary classifier. For data that is linearly separable, the optimal hyperplane creates the maximum margin between training points in the two classes. When the data classes are not linearly separable, the margin can still be maximised while allowing some data points to be on the wrong side of the optimal hyperplane. Another approach is to use a non-linear kernel function, which enlarges the feature space using basis expansions, such as a polynomial or a radial-basis function.

For the model comparison in our experiments, we have implemented the SVM model used by Hauer and Kondrak (2011). In this model, a pair of strings (s_1, s_2) is represented by a feature vector $\mathbf{x} \in \mathbb{R}^6$ such that

- x_1 is the Levenshtein distance $d_L(s_1, s_2)$,
- x_2 is the number of common bigrams,
- x_3 is the prefix length,
- x_4 is the length of s_1,
- x_5 is the length of s_2, and
- x_6 is the absolute difference between the lengths, i.e. $x_6 = |x_4 - x_5|$.

We have chosen this SVM model as it is based on string similarity measures that are applicable to the low-resource language setting. More recent SVM-based approaches to cognate identification exist, but they either require detailed dictionary definitions in a high-resource language with high-quality pre-trained word embeddings (St Arnaud et al., 2017), or multilingual word lists aligned by concepts (Jäger et al., 2017).

4.3 Siamese Convolutional Neural Network

The Siamese convolutional neural network (S-CNN) is a supervised learning model originally proposed by Chopra et al. (2005) for the task of face verification, and applied with some modification to cognate identification by Rama (2016). Our implementation is based on the latter model. The architecture is presented in Figure 1.

The S-CNN is a two-input version of the convolutional neural network (CNN) specialized in processing data with a grid-like topology. CNNs have been very successful in computer vision, and they have also been applied to several NLP tasks, such as text classification (e.g. Zhang et al., 2015).

When applied to NLP tasks, the CNN requires a grid-like representation of the input. In the case of cognate identification, it is convenient to represent a word as a matrix $\mathbf{X} \in \{0,1\}^{|\Sigma| \times n}$ such

Dataset	# cognate	# all pairs	$\|\Sigma\|$
IE-TRAIN	73,238	732,380	329
sma–sme	1,460	11,234 × 47,312	42 (27)
sma–sms	838	11,234 × 29,401	75 (27)
sme–sms	2,188	47,312 × 29,401	77 (38)

Table 2: The datasets used in the experiments. Etymological WordNet is used for training, and other datasets are used for testing (see Table 3 for smaller fine-tuning sets). $|\Sigma|$ is the number of all characters observed in a dataset. The number of overlapping characters is given in parentheses (for language pairs). Languages: South Sami (sma), North Sami (sme), Skolt Sami (sms).

Dataset	# cognate	# all pairs
SAMI-FT	986	100,000
SAMI-FT-TEST	3,500	350,000

Table 3: The small-scale datasets sampled from the Sami vocabularies in Table 2. We use these in experiment 2 to fine-tune the S-CNN and analyse how the number of in-family training pairs affects the performance.

that $\mathbf{X} = [\mathbf{x}_1\mathbf{x}_2 \ldots \mathbf{x}_n]$, where each column vector $\mathbf{x}_i \in \{0,1\}^{|\Sigma|}$ is a one-hot vector representing a character in the alphabet Σ. The training data $D = \{(\mathbf{X}_{ai}, \mathbf{X}_{bi}), y_i\}_{i=1}^{N}$ then consists of pairs of words such that $y_i = 1$ if $\mathbf{X}_{ai}$ and $\mathbf{X}_{bi}$ are cognates, and $y_i = 0$ otherwise.

As shown in Figure 1, the S-CNN model is an extension of the CNN: first, one filter $\mathbf{W} \in \mathbb{R}^{p\times q}$ is convolved (cross-correlated) over character sequences of length q from both input matrices $\mathbf{X}_a$ and $\mathbf{X}_b$, producing a feature map for each input matrix. These are run through a rectified linear function, whereafter max-pooling is applied to the results. The number of rectified and max-pooled feature maps produced from each input matrix is equal to the number of filters. We fix the filter height at $p = |\Sigma|$, equal to the size of the alphabet and the height of the input matrix.

The representation vectors $\mathbf{r}_a$ and $\mathbf{r}_b$ are obtained by concatenating all the feature maps into single vectors. These vectors are then merged into one vector $\mathbf{m}$ using some distance metric. We use the absolute vector difference such that $\mathbf{m} = |\mathbf{r}_a - \mathbf{r}_b| = [|r_{a1} - r_{b1}|, |r_{a2} - r_{b2}|, \ldots, |r_{al} - r_{bl}|]^T$, where $l = |\mathbf{r}_a| = |\mathbf{r}_b|$. Finally, the merged vector $\mathbf{m}$ is fed as input to a fully-connected layer, itself connected to the output neuron. The dropout technique of Srivastava et al. (2014) is applied to the fully-connected layer, and the output neuron is activated with the sigmoid function. The output of a trained model can be regarded as a learned similarity metric between pairs of inputs.

5 Experiments

In this section, we present our datasets, experimental setup, training and fine-tuning procedures, and our evaluation scheme.

5.1 Datasets

A summary of the datasets is shown in Table 2. All source data for training and testing is publicly available and we release the exact processed training and test sets for reproducibility[1].

We use the Etymological WordNet (Gerard de Melo, 2014) as our training data for the SVM and S-CNN models. This is a database containing information of etymological origin, cognateness, as well as derivational and compositional links between words. The database consists of word pairs that each belong to one of the aforementioned relations. The database has been mined from Wiktionary, and its entries are mostly from widely spoken Indo-European languages.

Since we are concerned with the identification of cognates across languages, we only use as our training data those word pairs that are either cognates, or where one word is the root of the other. Thus, we exclude derivationally and compositionally linked word pairs from our training set. Furthermore, we filtered out those pairs where both words belong to the same language. In total, there were 73,238 cognate pairs in the filtered training set. In order to train a discriminative classifier, we generated negative examples by randomly pairing unrelated words, so that the ratio of cognate to unrelated word pairs was 10%. We refer to the resulting training set as IE-TRAIN.

[1] All datasets released at https://github.com/soisalon/LRCognates.

As a source of unannotated word lists from low-resource languages, we use a set of three vocabularies from North, South, and Skolt Sami of the Uralic family. We have retrieved these vocabularies from dictionaries compiled by Giellatekno[2]. We filtered out all words with upper-case (proper nouns) or non-alphabetic characters. We retrieved gold-standard cognate sets for evaluation and fine-tuning from Álgu[3], the etymological database for Sami languages. This database contains (positive-only) cognate information for only a subset of all the words in the vocabularies. We refer to this dataset as SAMI-FULL and average results over the three pairs of languages. The evaluation scheme is explained in detail in section 5.3.

In addition, to fine-tune and evaluate models in experiment 2 (see section 5.4), we sample small-scale sets with a higher proportion (1%) of cognates, presented in Table 3, SAMI-FT and SAMI-FT-TEST.

5.2 Training and Fine-Tuning

In our implementation of the S-CNN model, we used ten filters with width $q = 2$ and height $p = |\Sigma|$ (alphabet size). The alphabet was the set of all characters observed in both the training and test datasets, and its size was $|\Sigma| = 336$. We fixed the input matrix width to $n = 20$. For words shorter than this, the input matrices were zero-padded, and longer words were truncated at this length. In the fully-connected layer, we used a dropout rate of 0.5.

We trained the S-CNN model using binary cross-entropy as the loss function, and the Adadelta optimizer (Zeiler, 2012) with initial learning rate $\alpha = 1.0$, decay rate $\rho = 0.95$, and the constant $\epsilon = 1 \cdot 10^{-6}$. The batch size was set at 128, and number of epochs was 50. In fine-tuning (experiment 2), the respective values were 32 and 20. Otherwise, we used the same hyperparameters when fine-tuning the model. We implemented the model using the Keras library with Tensorflow backend [4].

For the SVM implementation, we used the SVM module of the Scikit-learn library for Python (Pedregosa et al., 2011), based on the C-support vector classification implementation of Chang and Lin (2011). We trained the model using a linear kernel and regularization parameter $C = 1$. For probabilistic prediction, the module uses Platt scaling (Platt et al., 1999), which is based on fitting a logistic regression on the initial binary scores using cross-validation.

5.3 Evaluation

A difficulty in evaluating on the Sami datasets is that the set of word pairs annotated as cognates in the Álgu database is known to be far from complete for the vocabularies covered. As a result, there are many word pairs in the vocabularies that are cognates, but are evaluated as unrelated. Measures such as accuracy and precision are therefore not useful for our problem setting, since we do not know whether a given word pair *not* among the annotated cognates is a cognate pair. We can, however, evaluate the *recall* of the known cognate pairs: what proportion of the annotated pairs make it into the set ranked as most likely cognates by the model. We use SAMI-FT-TEST to compute precision-recall curves for the fine-tuned S-CNN, unadapted S-CNN, SVM, and the baseline LD.

Computing scores for all pairs of words between two vocabularies is time consuming. Therefore, when evaluating on whole vocabularies, we only take those words q in vocabulary X that we know have at least one cognate in the other vocabulary Y. Then, we compute scores between each of these words, and all words in the other language. In order to evaluate these scores, we use recall@k averaged over the words q, the queries, and the set of language pairs in the test set. We call this metric the *mean average recall@k*:

$$\text{MAR@}k = \frac{1}{L}\sum_{l=1}^{L}\frac{1}{Q}\sum_{q=1}^{Q}\text{R@}k,$$

$$\text{where R@}k = \frac{\#\text{cognates within top-}k\text{ results}}{\#\text{cognates in }Y},$$

where Q is the number of queries, and L is the number of language pairs. That is, for each word query q, we rank the pairs $(q, y_i)\forall i$ and get the top 100 words y for each q. We then compute the recall@k for $k = 1, \ldots, 100$ for q, that is, counting the cognates found within the k highest-ranked words divided by the total number of cognates for q in Y. For most words q, there is only one, and for some there are several cognates in Y.

5.4 Experimental Setup

We present two experiments. We first train the SVM and S-CNN models on IE-TRAIN. (LD requires no training.)

In **experiment 1**, we apply these three models directly to the three pairs of Sami vocabularies (SAMI-FULL) to measure how well methods trained only on Indo-European data can identify cognates in Sami languages. This tells us how well the methods can exploit information from a different language family. In this experiment, we evaluate the models using the MAR@k metric (see section 5.3).

In **experiment 2**, we fine-tune the S-CNN on a small set of Sami cognates (SAMI-FT), containing example cognate pairs from all three language pairs. We test it on SAMI-FT-TEST to see how much of the performance loss from language transfer can be regained by providing the model with just a small amount of data from the target language family. We also analyse how the performance of the S-CNN improves with the amount of fine-tuning data it is given. In this experiment, we evaluate the models using precision-recall curves.

6 Results

6.1 Experiment 1: Indo-European Models for Sami Cognates

Figure 2 shows the MAR@k curves for Sami cognate identification for the three models trained on Indo-European data: S-CNN (without fine-tuning), SVM, and the baseline LD. The S-CNN outperforms the other approaches by a substantial margin, across values of k. This result suggests that the neural networks in the S-CNN are able to capture aspects of the cognateness relation that transfer across language families more effectively than the hand-designed features of the SVM. The SVM also outperforms LD – unsurprising, since the Levenshtein distance is included among its features.

Since the S-CNN performs best in this experiment, we use it in experiment 2, where we fine-tune the model on the target language family.

6.2 Experiment 2: Fine-Tuning on Target Language Family

Figure 3 shows how the number of cognate pairs used in fine-tuning improves average precision. Naturally, the average precision increases together with the number of cognates used in training. The improvement converges with about 500 training pairs, which is the number used for the fine-tuned model in Figure 4.

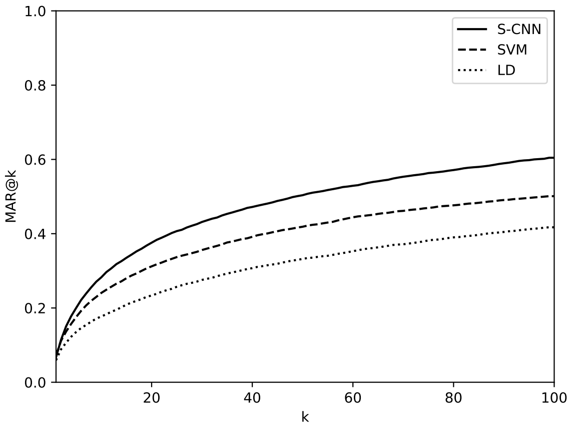

Figure 2: MAR@k for $k = 1 \ldots 100$, for SAMI-FULL, using models trained on IE-TRAIN. One curve is the average over all pairs of Sami languages.

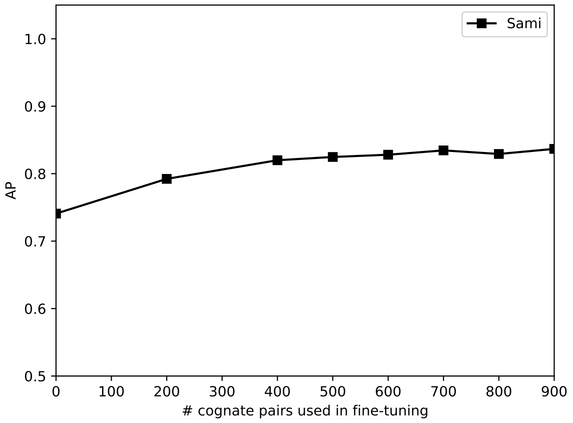

Figure 3: The learning curve of S-CNN fine-tuned on SAMI-FT, having been pre-trained on IE-TRAIN.

Figure 4 shows the precision-recall curves for each approach for the small-scale Sami test set (SAMI-FT-TEST). The corresponding values for average precision are given in Table 4. The pattern of results reflects that in Figure 2: the S-CNN outperforms the other two approaches based on string similarity metrics. The fine-tuned S-CNN substantially outperforms the untuned model. In terms of average precision, the improvement is approximately 11%.

This result tells us that, in addition to learning more general information about cognates that can be carried across language families than the SVM,

Approach	AP
S-CNN + FT	0.825
S-CNN	0.741
SVM	0.608
LD	0.540

Table 4: Average precision in the small-scale Sami test set for each approach.

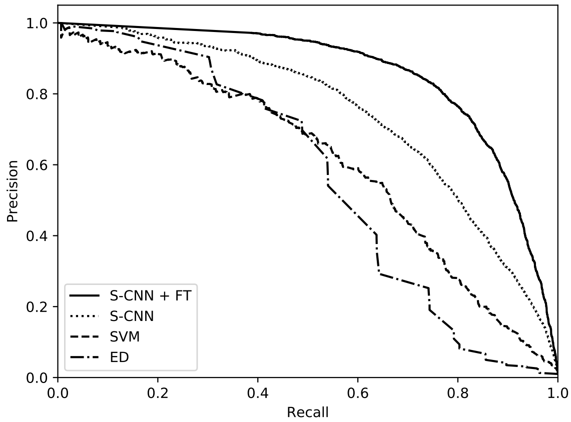

Figure 4: The precision-recall curves for each approach tested on SAMI-FT-TEST. S-CNN + FT was pre-trained on IE-TRAIN and fine-tuned on SAMI-FT. The unadapted S-CNN and SVM were trained on only IE-TRAIN.

the S-CNN is also able to make use of even a small number of annotated examples from the target languages to improve its predictions.

7 Conclusion and Future Work

We have addressed the problem of cognate identification within a set of three truly low-resource Sami languages of the Uralic family. We have examined the extent to which training data from a completely unrelated, higher-resource language family can be utilised for this task. We have taken two approaches to learn a similarity metric for cognateness from Indo-European etymological data, namely an SVM and an S-CNN, both applied to cognate identification in previous work, compared with a Levenshtein distance baseline. In addition, we have compared these with a fine-tuned S-CNN that has access to a small amount of training data in the target language family.

The results of our experiments have shown that the S-CNN is able to generalize more effectively across language families, compared with the SVM. Furthermore, a substantial improvement in performance can be attained by fine-tuning the model with only a small number of cognate examples from the target language set.

In future work, we will investigate whether language transfer for cognate identification can be further improved by making use of unsupervised multilingual character embeddings (Granroth-Wilding and Toivonen, 2019) instead of one-hot encoded characters. This could allow the model to exploit cross-lingual similarities in the usage patterns of symbols, replacing some of the manually encoded knowledge about correspondences across language pairs in previous work without the need to specify features by hand. In addition, due to the incomplete evaluation cognate sets, the experimental set-up could be complemented with a manual evaluation of top cognate suggestions in a manner similar to Hämäläinen and Rueter (2019).

Another avenue for future work is to investigate qualitatively how similar data-driven models generalize across other languages and language families, and how the choice of training language(s) affects performance. With such experimentation, we could gain more insight of what properties of sound change are carried over across families. In addition, we could investigate how the data-driven models presented here perform compared with models with more linguistically-informed handcrafted features.

Automatic Detection of Translation Direction

Ilia Sominsky and **Shuly Wintner**
Department of Computer Science
University of Haifa
31905 Haifa, Israel

Abstract

Parallel corpora are crucial resources for NLP applications, most notably for machine translation. The direction of the (human) translation of parallel corpora has been shown to have significant implications for the quality of statistical machine translation systems that are trained with such corpora. We describe a method for determining the direction of the (manual) translation of parallel corpora *at the sentence-pair level*. Using several linguistically-motivated features, coupled with a neural network model, we obtain high accuracy on several language pairs. Furthermore, we demonstrate that the accuracy is correlated with the (typological) distance between the two languages.

1 Introduction

Parallel corpora are used for various purposes, including for training and evaluation of statistical machine translation (SMT) systems (Koehn, 2010). While traditional SMT systems are agnostic with respect to the direction in which the parallel corpora they are trained on were (manually) translated, several studies have shown that taking directionality into account when training SMT systems has a significant effect on the quality of the translation (Kurokawa et al., 2009; Lembersky et al., 2012, 2013; Twitto-Shmuel et al., 2015). In this paper we show the same effect also holds for neural machine translation (NMT) systems.

We address the task of determining the direction of translation given a parallel text; this is cast as a binary classification task. To strain the classifier, we focus on retaining high accuracy when the size of text chunks to be classified is minimal: single sentence pairs. This is an extremely difficult task for humans, in most cases: a single sentence pair often does not reveal any obvious signal of which of the two sentences is the original. It is also a highly challenging task for machines: Figure 1 depicts a few English-French examples of sentence pairs whose translation direction none of our classifiers predicted correctly.

We define sets of features that reflect insights drawn from Translation Studies regarding the special properties of translated texts, and in particular the *asymmetric* nature of translation (Toury, 1980, 1995; Baker, 1993). These include the tendency of translated texts to be simpler (Blum-Kulka and Levenston, 1983; Vanderauwerea, 1985; Baker, 1993; Laviosa, 1998, 2002); the tendency of translators to explicate the source text (Blum-Kulka, 1986; Baker, 1993); the different distributions of various statistical phenomena (e.g., the frequencies of function words or certain syntactic structures) between the source and the translation (Gellerstam, 1986; Blum-Kulka, 1986; Øverås, 1998; Koppel and Ordan, 2011); and *interference* of language constructions from the source to the target (Toury, 1979; Teich, 2003).

The contribution of this paper is manifold. (1) First and foremost, we introduce a method for accurately determining the translation direction of sentence pairs in parallel corpora; the method is based on the introduction of several new, linguistically motivated, types of features for this task. We show that the combination of these features outperforms the previous state-of-the-art in detection of translation direction.[1] Importantly, these features help shed light on the characteristics of translated language. (2) Furthermore, we demonstrate the robustness of our method by evaluating it on several language pairs and on three different

[1] As we explain in Section 2, a direct comparison with the state of the art is problematic as not enough detail is provided in the original publications for us to replicate existing results.

datasets. (3) We show that detecting the translation direction can indeed be used for improving the quality of both statistical and neural machine translation systems. (4) Finally, from a theoretical perspective, this work corroborates the intuitive hypothesis that the translation detection task is easier when the two languages involved are typologically more distant.

After reviewing related work in the next section, we describe our experimental setup in Section 4, and the features we used in Section 5. The results are presented and discussed in Section 6. We conclude with suggestions for future research.

2 Related Work

The differences between original and translated texts have been a major field of investigation in Translation Studies (Toury, 1980, 1995; Baker, 1995). Translated texts have unique characteristics that set them apart from texts originally written in the same language. These are not necessarily artifacts of poor translation; rather, they reflect different statistical distributions across the two genres. The sub-language of translated texts (in any language) was referred to as *translationese* (Gellerstam, 1986). The unique properties of translationese are attributed to various reasons, some of which are considered “universal” (e.g., translated texts tend to simplify the original message; they tend to use more standard language than originals), while others are related to *interference*, namely the “fingerprints” of the source language found in the translation product.

Distinguishing between original and translated texts is a classic text classification task that has been extensively addressed both with supervised machine learning (Baroni and Bernardini, 2006; van Halteren, 2008; Kurokawa et al., 2009; Koppel and Ordan, 2011; Ilisei et al., 2010; Volansky et al., 2015; Avner et al., 2016) and with unsupervised methods (Rabinovich and Wintner, 2015; Nisioi, 2015; Rabinovich et al., 2016a). The main challenge, as is usually the case in text classification, lies in the choice of features with which text chunks are represented. For the task at hand, features frequently used include function words (FW), character n-grams, part-of-speech (POS) n-grams, special sets of words such as discourse markers, etc. With the right choice of features, accuracies can reach almost ceiling levels, depending on the dataset involved.

However, the classification unit used in all the above-mentioned research was larger chunks of text, typically 2,000 tokens. The accuracy of identifying translationese has been shown to drop significantly when the size of the text chunk used for classification decreases (Rabinovich and Wintner, 2015). One of our goals in this work is to improve the accuracy of translationese detection systems with much smaller text chunks, as available parallel texts are not guaranteed to be long.

Previous research focused on identifying translationese in monolingual texts. However, in realistic scenarios, parallel texts are available and the actual task is to determine the *direction of translation* given texts in *two* languages. For such tasks one can use features drawn from each of the two languages, as well as from the alignments between words and phrases in the two texts. This approach was taken by Eetemadi and Toutanova (2014), who used the Canadian Hansard corpus of parallel texts in English and French.

The motivation stems from the observation that linguistic structures tend to have different distributions in original and translated texts. Therefore, assessing the frequencies of syntactic structures in two parallel texts, especially for text chunks that are aligned with each other across two parallel sentences, may shed light on the direction of the translation. As base structures, Eetemadi and Toutanova (2014) used *minimal translation units (MTUs)*, defined as pairs of source and target word sets that satisfy two conditions: (i) no alignment links exist between distinct MTUs; (ii) MTUs are

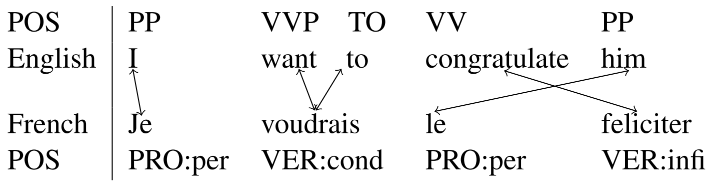

Figure 2: POS-MTUs, English–French

not decomposable into smaller MTUs without violating the previous rule. Once MTUs were identified, each word was replaced by its POS tag, thereby creating POS-MTUs. These are the structures used as features.

As an example, consider the two aligned English–French sentences in Figure 2; they yield the following POS-MTUs: [PP]↔[PRO:per], [VVP, TO]↔[VER:cond], [VV]↔ [VER:infi], and [PP]↔[PRO:per]. More specifically, the POS-MTU [VVP, TO]↔[VER:cond] reflects the fact that English word pairs such as *'want to'* translate to French verbs in the conditional form, e.g., *'voudrais'*. Incidentally, this mapping is much more common, by a factor of 10, in English-to-French translations than in the reverse direction.

As another example, the two aligned English–German sentences depicted in Figure 3 yield the following POS-MTUs: [CD]↔[PIS], [IN]↔[ART], [NP]↔[ADJA], [RB, JJS]↔[ADJA], [NNS]↔[NN]. In particular, the POS-MTU [RBS, JJ]↔[ADJA] reflects the fact that English word pairs such as *'most famous'* translate to German adjectives in the superlative form, e.g., *'berühmtesten'*.

Eetemadi and Toutanova (2014) do not provide sufficient details that would enable replication of their results, but they report 71% accuracy with these features. In a subsequent work, Eetemadi and Toutanova (2015) used Brown clusters (Brown et al., 1992), a method of clustering words according to syntactic and semantic relatedness, instead of POS tags. With *Brown cluster MTUs* as features, they reached 80% precision and 85% recall on the Hansard corpus. This is the present state of the art for this task.

3 Motivation

This work was partly motivated by previous research that demonstrated that *statistical* machine translation can be improved by training on source-translated-to-target corpora rather than target-translated-to-source texts (Kurokawa et al., 2009; Lembersky et al., 2013; Twitto-Shmuel et al., 2015). In this section we verify that such benefits hold also for *neural* machine translation (NMT). We used French–English data from three corpora (Hansard, Europarl and UN; see below). The total data that was available to us consisted of 1.6 million sentences annotated as French original, and 11.7 million sentences annotated as English original. Focusing on translating French to English, we trained three different NMT systems using Marian (Junczys-Dowmunt et al., 2018). In one system (FO), the training material consisted only of French original sentence pairs; in the other (EO), we only used English original sentence pairs; and in the third (MIX), we mixed equal portions of both. In all three cases we used an equal number of sentence pairs (1.6 million). We tested the three NMT systems on a reference set of 10,000 sentences taken from French original data, following the methodology of Lembersky et al. (2013). We evaluated the quality of the resulting NMT systems by comparing BLEU, METEOR and TER scores using MultEval (Clark et al., 2011).

The results, listed in Table 1, clearly corroborate our hypothesis: for the task of French to English translation, training data that were manually translated from French to English yield much better NMT systems than training data that were translated in the reverse direction.

Train Data	BLEU↑	METEOR↑	TER↓
FO	41.0	38.4	46.1
MIX	38.2	36.7	48.5
EO	34.4	35.0	52.8

Table 1: Accuracy of NMT systems with varying configurations of the training material

4 Methodology

Task Given a sentence pair in a parallel corpus, our task is to identify the direction of translation,

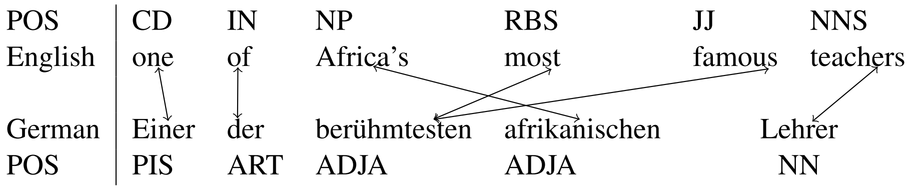

Figure 3: POS-MTUs, English–German

thereby determining the source and the target sentences. Our main challenge is to define a set of features that will yield the best accuracy.

Datasets We used sentence-aligned parallel corpora from three resources: the Canadian parliamentary proceedings (Hansard), with English–French sentence pairs; Europarl (Koehn, 2005), the proceedings of the European Parliament, where English is aligned with French and German; and the UN parallel corpora (Ziemski et al., 2016), in which English is aligned with Arabic, French, German, Russian and Spanish. We used subsets of these corpora in which the direction of translation has been accurately annotated (Kurokawa et al., 2009; Rabinovich et al., 2016b; Tolochinsky et al., 2018). We cleaned the data by removing editor's comments and sentences with fewer than 5 tokens. We then down-sampled the corpora and extracted equally-sized subsets with 50,000 sentence-pairs in each language pair, distributed evenly across translation direction. These are the data we used in all the experiments described below.[2] Details on the available data are presented in Table 2.

Prepprossessing We preprocessed the data as follows. First, all words in the two languages were tagged for part of speech using FARASA (Abdelali et al., 2016) for Arabic and TreeTagger (Schmid, 1995) for the other languages. Second, all the sentence pairs were word aligned using FastAlign (Dyer et al., 2013). With the word alignments we were able to extract the features that will be explained in the next section.

Classification For the task of identifying the translation direction, we implemented various feature sets and used them for training a Logistic Regression classifier (with the implementation of Pedregosa et al. (2011)), mainly because it is faster yet no less accurate than SVM. We performed tenfold cross-validation for evaluation and report accuracy in %. As our datasets are balanced, the trivial baseline is 50%.

Neural network In addition to the classifiers described below, we also approached the task of determining translation direction with a neural network. Our main goal here was to guarantee best performance, even the cost of interpretability. We used a network consisting of one bi-directional Long Short-Term Memory (BiLSTM) layer with 100 units, followed by a fully connected layer with a single output; the loss is defined as binary cross-entropy (the network was implemented with Keras.) The input of the network is the two sentences, where the words are mapped to pre-trained GloVe word embedding vectors of 50 dimensions (we used Pennington et al. (2014) for English and Bojanowski et al. (2017) for the other languages.)

5 Features

We defined several novel features motivated by various insights from Translation Studies. We motivate and explain these feature in this section.

Baseline As a baseline, we implemented some of the features that were suggested by Volansky et al. (2015), including:

POS trigrams We used the frequencies of the 2000 most frequent POS trigrams for each language.

Function words Function words for many languages are available online. We used the frequencies of all the function words in each language (between 160 in Arabic and 600 in German).

Positional token frequency In different languages, the choice of words with which sentences begin is rather different, and is more constrained and formulaic than elsewhere in the sentence (Volansky et al., 2015). A clear example is greetings: parliament speakers may choose to begin their speeches

[2] The only other parallel corpora that we are aware of where the direction of translation is marked are the Dutch Parallel Corpus (Macken et al., 2011), aligning Dutch with English abd French, and EuroParl-UdS (Karakanta et al., 2018), which largely overlaps with our dataset.

	Europarl		UN				Hansard
	EN-FR	EN-DE	EN-FR	EN-ES	EN-RU	EN-AR	EN-FR
EN original	217	225	8100	6100	3600	4087	3377

EN translated, cleaned	128	153	683	381	91	65	678

Table 2: Dataset sizes (in thousands of sentence-pairs)

by *'Ladies and gentlemen'*, but this turns out to be much more common in French than in English. We used the frequencies of words that occur in the first, second, penultimate and last positions in the sentences.

MTUs Finally, to compare with the state of the art, we also computed POS-MTUs and Brown Cluster MTUs, as defined by Eetemadi and Toutanova (2014, 2015).

Word rank The *simplification hypothesis* conjectures that translated texts tend to be simpler than originals. As one realization of this hypothesis, we assume that translations would use more common, frequent words than originals. In order to determine how common each word is, we used pre-trained frequency lists in all languages (Michel et al., 2010).

Comparing the actual (frequency-based) ranks of word forms across languages is rather problematic, especially when the morphologies of the languages differ. (e.g., when one language has many more inflected forms per lexeme than the other). Therefore, we split the word frequency lists to seven *bins* that group together words by their frequency, and compared the bins rather than the actual ranks.[3] The first bin includes words whose accumulated frequency is up to 0.25; it includes the most frequent words in each language. The other bins include words with accumulated frequency up to 0.5, 0.7, 0.8, 0.88, 0.95 and all the rest. This facilitates comparison of words in the same frequency brackets across two different languages. This feature defines 14 bins (7 for each language); its actual value is number of words in each bin.

Additionally, we compared the (frequency-based) ranks of aligned word pairs. Given a pair of aligned sentences, consider the difference in rank between each pair of aligned words. We hypothesize that such differences would depend on the translation direction (as rarer words tend to be translated to more common ones). For example, we expect the English *'however'* (ranked 236th) to be typically translated to French *'mais'* (ranked 33rd), but French *'mais'* to be more often translated to English *'but'* (ranked 23rd).

To implement this observation, we defined a histogram representing the values of the differences in rank between pairs of aligned words in each sentence pair. For example, if the English word *'however'* is ranked 236th and its aligned French word *'mais'* is ranked 33rd, we used the value $236 - 33 = 203$. We computed these values for all the aligned words in a sentence-pair; we then used the highest and lowest values as the boundaries of a histogram and split it to 12 bins. For example, if the defined limits of the histogram are: [-100000, -50000, -25000, -8000, -4000, -300, 300, 4000, 8000, 25000, 50000, 100000] and the resulting value from the differences between the words in a sentence pair are -10953, -511, 402, -3159, 4099, 11267, 10535, 80, 4280, 345; then the resulting histogram is: [0, 0, 0, 1, 0, 2, 1, 2, 2, 2, 0 ,0]. The values of this feature for a given pair of sentences are the values of each bin in the resulting histogram.

Lexically-Anchored-POS-MTUs While POS-MTUs identify meaningful linguistic structures, they are too general and may lose important nuances of the correspondences between constructions in the two languages. For example, consider the POS-MTUs [IN]↔[ART] in Figure 3: clearly it is not the case that prepositions in English translate to determiners in German. However, it is reasonable to assume that the English genitive preposition *'of'* will be aligned to a German genitive article such as *'der'*.

To reflect this notion, and define finer, subtler cross-language correspondences, we propose *Lexically-Anchored-POS-MTUs* (LA-POS-MTUs): we only replace *content* words by their POS tag, leaving *function* words intact. The values

[3] The number of bins and their frequency ranges were determined empirically.

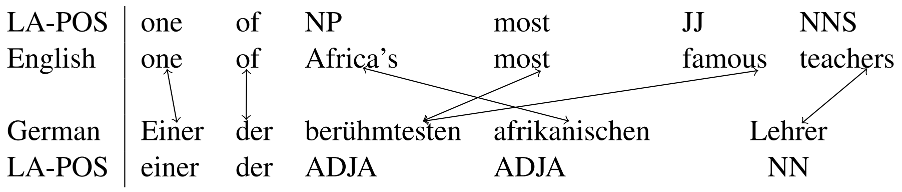

Figure 4: LA-POS-MTUs

of these features are the actual counts of each LA-POS-MTU in the sentences. Similarly to POS-MTUs, they are distributed differently in each of the translation directions.

As an example, consider the LA-POS-MTUs in Figure 4: [one]↔[einer], [of]↔[der], [NP]↔[ADJA], [most, JJ]↔[ADJA], [NNS]↔[NN]. In particular, the LA-POS-MTU [most, JJ]↔[ADJA] reflects the fact that in English, some superlative adjectives can come with the adverb *'most'* or with *'est'* as a suffix, while in German there is only one form: adding a suffix to the adjective. Indeed, the LA-POS-MTU [most, JJ]↔[ADJA] is much more frequent in English to German than in the reverse direction. This is presumably an instance of *interference* of German on the English translation product. While in English there are two ways to form the superlative, and sometimes both are valid (e.g., *'most clever'* and *'cleverest'*), German has only one possible form. When a superlative adjective is translated from German to English, the translator may tend to keep it with the suffix (if possible), rather than splitting it into two words. Hence, this LA-POS-MTU is more frequent in the English to German direction.

Syntactic structure The simplification hypothesis implies that the structure of translated sentences tends to be simpler than that of originals. We therefore parsed the corpus with universal dependencies (Straka and Straková, 2017) and defined several measures that supposedly reflect sentence complexity: the height of the dependency tree; its depth; and the average number of dependents per word. In addition, we used dependency tag trigrams as features, similarly to POS-trigrams.

Back translation Translated texts carry a unique signal; the challenge is to identify this signal at the sentence-pair level, where it may be extremely subtle. The motivation for the back translation feature is to amplify this signal.

To do so, we use machine translation (Google Translate) to translate the sentences again. Given a sentence pair $\langle e_1, f_1 \rangle$, we machine-translate both sentences, yielding the pair $\langle f_2, e_2 \rangle$, where $f_2 = MT(e_1)$ and $e_2 = MT(f_1)$, MT indicating machine translation. Now assume, without loss of generality, that e_1 is the original; hence f_1 is its manual translation, namely $f_1 = HT(e_1)$, where HT indicates human translation. Therefore, $e_2 = MT(f_1) = MT(HT(e_1))$. In other words, e_2 is "twice removed" from e_1, being translated once by a human and once automatically. In contrast, $f_1 = HT(e_1)$ and $f_2 = MT(e_1)$; both f_1 and f_2 are only "once removed" from e_1: f_1 was translated manually and f_2 automatically, but only once. Therefore, we expect f_1 and f_2 (two French sentences) to be closer to each other than e_1 and e_2 (two English sentences) are. This is only the case if f_1 is the translation of e_1; if the translation direction is reversed, we would expect e_1 and e_2 to be closer to each other than f_1 and f_2 are.

To measure the similarity between the two sentences we used three metrics: BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and Levenshtein distance (Levenshtein, 1965). Each metric results in two scores: one for the distance between the two English sentences and one for the two French sentences. These six scores were used as features for the classifier.

6 Results

Table 3 depicts the accuracy of 10-fold cross validation evaluation of classifiers reflecting the various features. The "All" column indicates a dataset constructed from the French–English sentence pairs in all the three different corpora; it is therefore a heterogenous dataset, which makes the task much more challenging (Rabinovich and Wintner, 2015). Indeed, the results on this dataset are worst, lower than each individual dataset in isolation. Still, even for this challenging experimental scenario, our best classifier achieves over 72% accuracy. For the Europarl and UN

Corpus	**Europarl**		**UN corpus**				**Hansard**	**All**

Table 3: Results: accuracy (%) of predicting the translation direction

datasets, however, our results range between 80% and over 90% accuracy; given the difficulty of the task (refer back to Figure 1), we view this as a significant contribution.

The "All" row indicates the concatenation of all features into one feature vector. Since these features encode different aspects of the relations between the two languages, we believe that they are at least partially independent. Indeed, the results of feature combination support this assumption.

The signal of translationese is indeed subtle, but the results show that many of our basic classifiers are able to detect it, albeit to a small extent. For most language pairs and datasets, each of the feature sets we defined yielded accuracy of over 60%, sometimes over 70%, and reaching 80% in a few cases. Brown cluster MTUs, which were used by the state of the art (Eetemadi and Toutanova, 2015), are indeed a good feature set. MTUs based on Brown clusters turned out to be better than LA-POS-MTUs; presumably, Brown clusters encode lexical semantic information that is helpful for the task. However, they are outdone in more than half of the cases by simpler features such as function words or positional token frequencies.

Back translation turned out to be a less beneficial feature than we have expected on Europarl. As it is a computation-intensive feature, we refrained from computing it on the other datasets.

Combining features together yielded a sizable boost in accuracy, advancing the state of the art to the area of 80-90% accuracy in all cases. The features that we defined are obviously not mutually independent; it therefore makes sense to try some dimensionality reduction method to remove redundant features. We tried several dimensionality reduction methods, with various dimensionalities, but none yielded better results (on the full datasets) than using all features.

As could be expected, the accuracy of the BiLSTM is higher than feature combination in all cases but one; yet we suspect that the features capture phenomena that are not reflected by the neural network. To test that, we used *stacking*. We defined three different classifiers: one with features computed from the English texts only (rank, POS trigrams, function words, positional tokens, and syntactic structure); another with the same features computed from the other language; and a third from the alignment features computed from both languages (the three MTU feature types). We additionally trained the neural network. We then used all four classifiers to predict the direction of translation, and used their confidence scores as features for a stacked classifier, whose prediction is the class we use. The results are listed in Table 3 under "Stacking", and show a small but consistent improvement for all language pairs.

Still, the BiLSTM turned out to be better for the Hansard corpus and for the mixed dataset. We do not have a clear explanation for this outcome. We used paired t-test to determine the statistical significance of the improvement in results between using all the features ("All") and the best results obtained by Stacking. The test yielded p-values <0.001 for all language pairs except English–Arabic. Similarly, comparing the neural network with Stacking in the same way, the test yielded p-values <0.001 in all language pairs except English–Spanish. We thus conclude that the generalizations of the neural network are, at least to some extent, different from the features we defined. In future work, we intend to consider new ways for incorporating linguistically-motivated features in neural network architecture, e.g., along the lines of Strubell et al. (2018).

Finally, observe that the results clearly support our theoretical hypothesis: the accuracy of the classification improves when the two languages involved are more typologically distant. The task is particularly hard for English-French and English-German, and easiest for English-Arabic and English-Russian. We tentatively conclude, therefore, that translationese is more pronounced, and interference is more powerful, when the two languages are more distant. This chimes in with recent results that show the relationships between interference and language typology (Rabinovich et al., 2017).

7 Conclusion

We have shown that linguistically-motivated features, based on Translation Studies insights pertaining to the asymmetry of the translation process, can yield high, state-of-the-art accuracy on the task of translation direction detection. We introduced several novel features and used stacking to produce highly accurate sentence-pair-level classifiers for five language pairs. We also confirmed the hypothesis that this task is harder when the two languages involved are more closely related.

In future work, we intend to provide a deeper analysis of the results, focusing on the constructions whose frequencies differ most across the two languages. We would also like to evaluate our systems cross-domain, as it has been shown (Rabinovich and Wintner, 2015) that the signal of translationese is subtle, and can be overshadowed by signals of the datasets used for training and testing. Finally, and depending on the availability of datasets, we would like to extend the experiments described herein to more language pairs.

Automated Text Simplification as a Preprocessing Step for Machine Translation into an Under-resourced Language

Abstract

In this work, we investigate the possibility of using fully automatic text simplification system on the English source in machine translation (MT) for improving its translation into an under-resourced language. We use the state-of-the-art automatic text simplification (ATS) system for lexically and syntactically simplifying source sentences, which are then translated with two state-of-the-art English-to-Serbian MT systems, the phrase-based MT (PBMT) and the neural MT (NMT). We explore three different scenarios for using the ATS in MT: (1) using the raw output of the ATS; (2) automatically filtering out the sentences with low grammaticality and meaning preservation scores; and (3) performing a minimal manual correction of the ATS output. Our results show improvement in fluency of the translation regardless of the chosen scenario, and difference in success of the three scenarios depending on the MT approach used (PBMT or NMT) with regards to improving translation fluency and post-editing effort.

1 Introduction

In spite of recent advances in machine translation (MT), the MT into under-resourced languages is still facing a number of problems. First, there is not enough parallel data to build robust phrase-based and neural systems. Second, the majority of those languages (including Serbian) have a very rich morphology and suffer from data sparsity when it comes to less frequently used cases, tenses, etc. Third, there is a number of syntactic differences which are difficult to capture. For English-to-Serbian phrase-based system, a number of language-related problems has been identified so far (Popović and Arčan, 2015). Most of them are related to syntactic differences, e.g. missing verb parts due to distinct structure of certain verb tenses, incorrect prepositions, or incorrect translations of English sequences of nouns. Although the neural approach better handles some grammatical aspects, it still often fails to generate correct inflections, prepositions and translations of the English noun phrases (Popović, 2017).

Text simplification (TS) has the goal of transforming given text or sentence into its simpler variant, while preserving the original meaning. What is considered to be a simpler variant depends on the target application, or the target reader in mind. In the case of simplifying texts for humans, a simpler variant is the one that requires a shorter reading time and leads to better text comprehension scores. In the case of text or sentence simplification used as a preprocessing step for a given natural language processing (NLP) task, e.g. machine translation (MT), information extraction (IE), summarization, and semantic role labeling (SRL), a simpler variant is the one that leads to better performances of that NLP system.

Text simplification was originally proposed as a pre-processing step for machine translation (Chandrasekar, 1994) and later for information extraction and parsing (Chandrasekar et al., 1996). At those early stages, automated text simplification (ATS) was not mature enough to help improving performances of those systems. Instead, the idea was explored only hypothetically, using manual text simplification (Chandrasekar, 1994; Vickrey and Koller, 2008). Evans (2011) later showed that an automated simplification of coordinate structures can improve IE systems.

Later, the focus of the ATS shifted towards text accessibility and better social inclusion, having the main goal of making texts easier to understand by

Proceedings of Recent Advances in Natural Language Processing, pages 1141–1150,
Varna, Bulgaria, Sep 2–4 2019.

various target readers, e.g. people with low literacy levels (Aluísio and Gasperin, 2010), or people with some kind of reading or cognitive impairments, such as aphasia (Devlin and Unthank, 2006), autism (Orăsan et al., 2018), Down's syndrome (Saggion et al., 2015), or dyslexia (Rello, 2012).

In this study, we want to return to the original motivation for text simplification and explore whether the state-of-the-art 'general purpose' ATS system can be used to improve machine translation from English to some under-resourced language, or not. Unlike the previous works, we focus on using fully automated TS output (without any manual corrections), and on filtering out simplifications that are not grammatical and do not preserve the original meaning. Furthermore, we perform experiments using two state-of-the-art MT systems with different architectures, a PBMT and a NMT system. We focus on English-to-Serbian machine translation, taking Serbian as an example of under-resourced languages.

We show that, regardless of the MT architecture (PBMT or NMT) and the strategy for using ATS system as a pre-processing step (without any manual correction, with filtering for its grammaticality and meaning preservation, and with minimal manual correction of the output), the fluency of the translation can be improved. With regards to improving translation adequacy and post-editting effort, our experiments show that the type of the translation architecture (PBMT or NMT), and the strategy for using ATS system, both play a significant role.

2 Related Work

For many language pairs (e.g. English-French, English-Spanish, English-Hindu), attempts were made at rewriting input sentences using paraphrasing or textual entailment to improve the performance of MT systems (Callison-Burch et al., 2006; Mirkin et al., 2009; Aziz et al., 2010; Tyagi et al., 2015; Mirkin et al., 2013a,b). However, they all focus only on out-of-vocabulary words, or difficult to translate shorter n-grams.

Štajner and Popović (2016) went one step further, using lexico-syntactic automatic text simplification systems as a pre-processing step for English-to-Serbian machine translation. In this way, they covered both lexical and syntactic transformations on the source side. The ATS outputs were manually inspected by human editors who were also allowed to do minor revisions (correcting the tense, gender, article, etc.) in order to preserve grammaticality and the original meaning on the source side. For both ATS systems used, it was found that (with this minimal human correction of the simplified output) such a pre-processing step improves fluency of the translations, and reduce the post-editing effort. However, the authors only considered manually post-edited ATS output and made no experiments with the raw (uncorrected) ATS output. Nor did they explore how the grammaticality and meaning preservation of the ATS output might influence the results.

In this work, we use one of the ATS systems used by Štajner and Popović (2016), only the system which does not remove any original information. Unlike Štajner and Popović (2016), who used only a phrase-based MT system for English-to-Serbian translation, we also use the current state-of-the-art neural MT system for that language pair (see Section 3.1). We explore three different scenarios for using ATS as the pre-processing step, in search for fully automatic use of ATS in MT, without human correction of the ATS output (see Section 3). We find that success of the ATS used as a pre-processing step heavily depends on the type of the MT system used (PBMT or NMT).

3 Experimental Setup

We randomly selected 10 original articles from the 100 news articles automatically simplified by the state-of-the-art lexico-syntactic ATS system (Siddharthan and Angrosh, 2014) in the work of Štajner and Glavaš (2017). The ATS system that consists of a rule-based syntactic simplification module and a supervised lexical simplification module built upon the English Wikipedia - Simple English Wikipedia corpus (Coster and Kauchak, 2011).

We further explored three possible scenarios in which ATS can be used as a pre-processing step for MT (Figure 1):

- **Scenario 1 (*Corrected*)**: Automatically simplified sentences are manually corrected before being used as the source sentences for MT, to ensure the preservation of the original meaning and the grammaticality of the MT input;

- **Scenario 2 (*Filtered*)**: Automatically simpli-

Scenario 2
Scenario 3
STEP 2.1
correcting (post editing) sentences with low G and M
STEP 2.2
filter sentences by G and M scores (take only those with G>3 and M>3)
STEP 3
machine translation with PBMT and NMT

Figure 1: Workflow. The fully-automated steps are shown in dark blue (steps 1 and 3); fully-manual in green (step 2.1); and those that can be used as either automated or manual, in orange (step 2.2).

fied sentences which did not preserve well the original meaning and/or are ungrammatical are filtered out, and in those cases, the original sentences are used instead of them as the MT input;

- **Scenario 3 (*Automatic*)**: Automatically simplified sentences are used as source sentences for MT without any manual correction or filtering beforehand.

The last scenario (*Automatic*) is troublesome in the context of ATS used as pre-processing step for MT, as one cannot be sure that the original meaning was preserved during automatic simplification. To account for possible changes of meaning, we slightly modify the common procedures for assessing fluency and adequacy of MT output in order to allow those scores to penalize such text simplification errors (see Section 3.3).

3.1 MT Systems

For English-to-Serbian phrase-based and neural machine translation, we use ASISTENT[1] (Arčan et al., 2016), a publicly available web-based MT system offering translation between three South Slavic languages (Croatian, Serbian and Slovenian) and English in both translation directions. Both NMT and PBMT variants were trained on the publicly available data originating from the OPUS website[2] (Tiedemann, 2009) where three domains were available for the Serbian-English language pair: the enhanced version of the SEtimes corpus[3] (Tyers and Alperen, 2010) containing "news and views from South-East Europe", OpenSubtitles[4] as well as KDE localisation documents and manuals, i.e. technical domain. In total, about 20.7M sentences were used for training (20.5M subtitles, 200k news, 30k technical), and 2k sentences from each of the three domains were used for tuning the systems.

The texts which we are translating in this study are external, i.e. they cannot be found in any of the above described corpora.

3.2 Assessment of Quality of ATS Output

The quality of the ATS output was assessed at the sentence level by:

- human assessment of grammaticality (G) and meaning preservation (M) on a 1–5 Likert scale (1 – very bad; 5 – very good).
- measuring the time needed to correct grammaticality and ensure that original meaning is preserved.

The first assessment was used in Scenario 2 (*Filtered*) for filtering simplified sentences according to their G and M scores, while the second assessment was used in Scenario 1 (*Corrected*). The schema of the workflow is presented in Figure 1.

We asked three native English speakers to rate our 130 sentences using the same guidelines as Štajner and Glavaš (2017). The annotators were also provided with several examples for each score. To obtain the final G and M marks used in Scenario 2 (*Filtered*), we averaged the three marks and rounded the results to the closest integers. The average G and M scores were 3.98 and 3.75, respectively. The average pairwise inter-annotator

Version	Sentence
Original	Ex-Soviet leader Mikhail Gorbachev says Russian authorities must annul the parliamentary vote results and hold a new election.
Simplification (uncorrected)	Ex-Soviet leader Mikhail Gorbachev says**.** Russian authorities must annul the parliamentary vote results. These authorities hold a new election.
Simplification (corrected)	Ex-Soviet leader Mikhail Gorbachev says **that** Russian authorities must annul the parliamentary vote results. These authorities **must** hold a new election.
Original	A 21-year-old man was arrested on April 30, on suspicion of murder and was released on bail until May 29 pending further enquiries.
Simplification (uncorrected)	A 21-year-old man was arrested on April 30, on suspicion of murder. This man was **followed** until May 29 pending further enquiries.
Simplification (corrected)	A 21-year-old man was arrested on April 30, on suspicion of murder. This man was **released** until May 29 pending further enquiries.

Table 1: Two examples of manual corrections performed on the simplified sentences. Differences between the automatically simplified sentences and their manually corrected versions are shown in bold.

	Adequacy
5	perfectly understandable (regardless of potential poor grammar)
4	understandable with minor ambiguities/differences
3	main gist is preserved but some things are unclear/different from the source
2	difficult to understand and different from the source meaning
1	very bad (regardless to potential grammaticality)
	Fluency
5	perfectly grammatical (regardless of potential meaning loss/change)
4	almost correct – a small number of minor errors
3	a number of grammatical errors although not very heavy
2	many grammatical errors
1	very bad (regardless to potential meaning preservation)

Table 2: Guidelines for assigning adequacy and fluency scores.

agreement was 0.72 and 0.61 (weighted Cohen's κ), for the G and M scores respectively.

In Scenario 1 (*Corrected*), we used the manual corrections already provided by Štajner and Glavaš (2017) for the ten selected articles. During manual corrections, only minimal corrections were performed where necessary to restore the original meaning and grammaticality of the sentences. As the goal of those correction was not to make any further simplifications, and the mistakes were easy to notice, the corrections were very fast (15.0 seconds per sentence). They did not even require a native speaker or trained annotator, but rather someone with a proficiency level of English (Štajner and Glavaš, 2017). Several examples of performed corrections are given in Table 1.

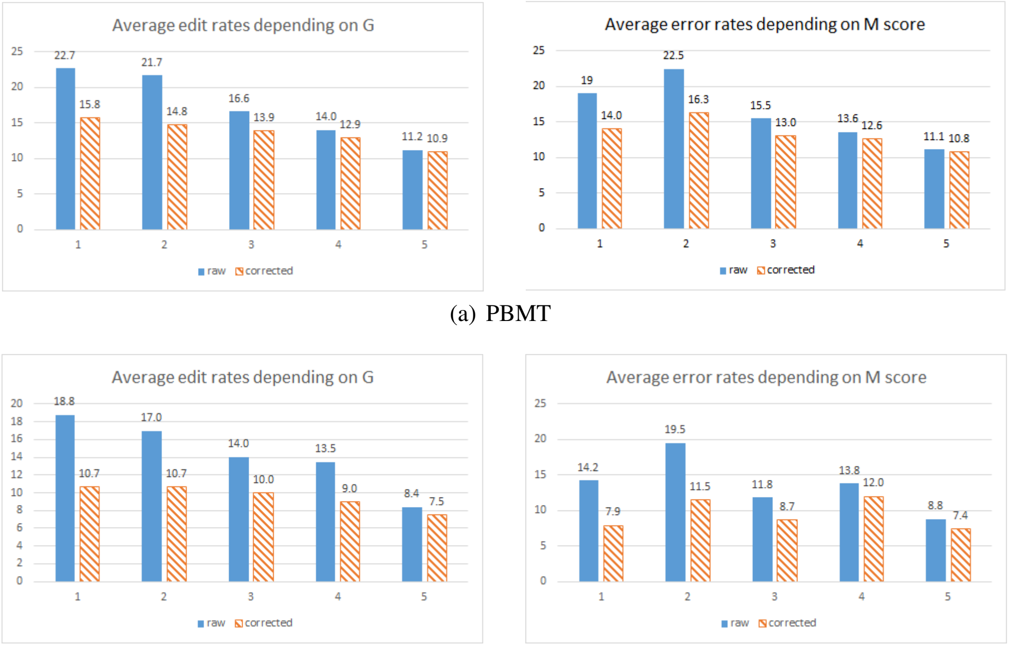
3.3 Evaluation of MT Output

All translation outputs (translations of the original sentences, their raw (uncorrected) automatic simplifications, and their manually corrected automatic simplifications) obtained by the two MT systems (PBMT and NMT), a total of 390 target sentences, were evaluated with respect to three aspects:

- adequacy, i.e. how well the sentence preserves the original meaning;
- fluency, i.e. how grammatical the sentence is;
- technical post-editing effort, i.e. the amount of necessary edit operations to correct the output.

These three evaluation aspects concentrate on three distinct things, which are not necessarily correlated. For example, if the reference translation is *"We will* **not** *finish on time."* and the obtained MT output is *"We will finish on time."*, the adequacy score will be very low (1), fluency perfect (5), and edit distance very low (only one edit).
Each of the tasks has been carried out separately, i.e. the evaluation of adequacy and fluency were carried out in two separate passes, and post-editing was carried out in the third pass.

The guidelines used for assigning adequacy and fluency scores are presented in Table 2.



(a) PBMT

(b) NMT

Figure 2: Average edit rates (y-axis) for corrected TS output (blue full) and uncorrected/raw TS output (orange pattern), depending on the grammaticality (G) and meaning preservation (M) scores (x-axis) after PBMT and NMT.

Raw edit counts and edit rates (raw counts normalised with the segment length) were calculated using Hjerson (Popović, 2011) for:

- the five classes of edits/errors: inflectional error, reordering error, omission, addition and mistranslation
- the sum of edit counts/rates of all classes

Each translated segment was post-edited, and assigned fluency and adequacy scores, while looking into the corresponding source segment, i.e. the English originals were used for evaluating the translations of the originals, while the corresponding simplified and corrected English sentences were used for evaluating the translations of the simplified sentences. This was done to ensure that the change of meaning during ATS (in scenarios with filtered and fully automatic ATS) is penalised. Reference translations were not available.

4 Results

We first explored the influence of grammaticality (G) and meaning preservation (M) scores of the automatically simplified sentences on the post-editing effort needed to correct their translations (Figure 2).[5]

We see that the differences in effort needed to post-edit the translations of automatically simplified sentences (uncorrected) and corrected simplified sentences (corrected) decrease with the increase of grammaticality (G) and meaning preservation (M) scores of the uncorrected simplifications. This supports our initial idea that, instead of correcting the automatically simplified sentences (Scenario 1 in Figure 1), one could filter out the automatically simplified sentences which did not achieve high enough G and M scores, and instead of those, use the original sentences (Scenario 2 in Figure 1). This filtering should ideally be done automatically. Given that here we just look for the proof of concept, we wanted to ensure that we correctly assign G and M scores, and this was thus done manually. However, it is important to note that several systems for automatic assignment of G and M scores to the ATS outputs have been proposed up to date (Štajner et al., 2016).

The initial exploration (Figure 2) indicated that a good cut-off point for filtering bad simplifications would be around G = 3 and M = 3.

[5] For the space constraints, we here present graphs only for the average edit rates, but we also analysed the raw counts and found that they follow the same trends as the avearage edit rates.

(a) PBMT

%	uncorrected		**corrected**		**G, M > 3**		G, M ≥ 3	
	Σer	r.e.c.	Σer	**r.e.c.**	Σer	r.e.c.	Σer	r.e.c.
better	27.7	21.5	**46.2**	**38.5**	**20.0**	**16.9**	24.6	21.5
worse	50.8	49.2	**27.6**	**26.2**	**13.8**	**12.3**	27.7	53.9
same	21.5	29.3	26.2	35.3	66.2	70.8	47.7	24.6

(b) NMT

%	uncorrected		**corrected**		G, M > 3		G, M ≥ 3	
	Σer	r.e.c.	Σer	r.e.c.	Σer	r.e.c.	Σer	r.e.c.
better	13.8	12.3	**46.2**	**36.9**	9.2	6.2	13.8	10.8
worse	67.7	64.6	**37.5**	**32.3**	27.7	26.2	41.6	40.0
same	18.5	23.1	32.3	30.8	63.1	67.6	44.6	49.2

Table 3: Percentage of raw simplified sentences (uncorrected), corrected simplified sentences (corrected) and simplified sentences filtered by high grammatical and meaning scores (G, M > 3, and G, M ≥3) with better/worse/same translations (in terms of edit rate (Σer) and raw edit counts (r.e.c.)) than their original counterparts when translated with phrase-based (a) and neural (b) MT system. Those cases in which more sentences improved than deteriorated are shown in bold.

We further investigated how the distribution of sentences with better, worse, and same post-editing effort differs in the two possible cut-offs: (1) where G and M scores are both greater than 3; and (2) where G and M scores are both greater or equal to 3. The results are presented in Table 3, together with the corresponding results for the fully automated simplification without any filtering (uncorrected) and for the manually corrected simplification output (corrected).

It seems that filtering automatically simplified sentences according to their grammaticality (G) and meaning preservation (M) score can substantially decrease the percentage of sentences whose translation is worse (needs more post editing) than the translation of their original counterparts, if the cut-off point is correctly set. This happens in both MT approaches used (PBMT or NMT), but the decrease is more pronounced in PBMT.

Interestingly, in PBMT, filtering sentences according to their G and M scores (with G, M > 3) results in a lower percentage of sentences with deteriorated translations than correcting the simplification output before translation (corrected). This happens at the cost of increasing the number of sentences with the same MT post-editing effort required, and decreasing the number of sentences with improved translation.

Table 4 shows the differences in fluency and adequacy scores between the translations of the original sentences and the translations of the corrected simplified texts, uncorrected simplified texts, and the filtered (G, M > 3) source sentences.

It can be seen that by using the ATS system in a pre-processing step (marginally) improves the translation adequacy, and only if the simplifications are manually corrected and used in the NMT system.

Using any of the three proposed scenarios (manually corrected simplifications, filtered simplifications, or fully automated simplifications) leads to a higher percentage of sentences with improved rather than those with deteriorated fluency of translation. Interestingly, the percentage of improved sentences is the highest when the uncorrected simplifications are used, but at the cost of the higher percentage of sentences with deteriorated translation adequacy (than in the case of using the manually corrected simplifications). Filtering automatic simplifications according to their grammaticality and meaning preservation substantially decreases the percentage of sentences with both improved and deteriorated translation fluency, but still results in substantially higher percentage of sentences with improved than those with deteriorated fluency.

Several examples of the original English sentences and their simplified versions, together with the scores for the fluency and adequacy of their Serbian translations are presented in Table 5.

5 Summary and Outlook

Going back to the initial motivation for automatic text simplification, using it as a pre-processing step to improve the performance of machine translation systems, we explored how the current state-of-the-art lexico-syntactic automatic text simplification system behaves in this role. We investigated three possible scenarios: (1) using the output of the ATS system as it is; (2) filtering out the automatic simplifications with low grammaticality and meaning preservation scores and using the original sentences instead; (3) minimally correcting the ATS output in order to preserve the original meaning and the grammaticality of the sentence.

The results of our experiments indicated that:

- The success of the ATS systems depends on the type of MT system used (phrase-based or neural).
- In the case of NMT, only the manually corrected ATS output can reduce the post-editing effort, and improve the adequacy scores in translation.
- In the case of PBMT, two scenarios (manual correction of ATS output and maintaining only automatic simplifications with high G and M scores) can reduce the post-editing effort in translation, but none of the three investigated scenarios can improve the adequacy of the translation.
- For both MT approaches, PBMT and NMT, all three scenarios for using ATS improve the fluency of the translation noticeably.
- The uncorrected ATS output improves the fluency of the PBMT translation noticeably more than it improves the fluency of the NMT translation.

We also found that even manually corrected ATS output can deteriorate translation adequacy (in about 15% of the cases) and fluency (in about

25% of the cases), and increases the post-editing effort in translation (in about 26-27% of the cases in PBMT, and about 32-37% of the cases in NMT). This indicates that the general-purpose ATS systems (which were not initially developed for improving MT performances) might not be suitable for this task. Depending on the source-target language combination, it might be better to design a MT-oriented text simplification system, which would target only the sentence structures and vocabulary which poses particular difficulties in that language pair and MT approach.

Our results also showed that there are notable differences in how the three scenarios for using ATS as a pre-processing step influence the performances of the PBMT and NMT (at least for the language pair investigated here). This indicates that the two MT approaches require different pre-processing strategies in order to improve their performances.

Investigating Multilingual Abusive Language Detection: A Cautionary Tale

Kenneth Steimel, Daniel Dakota, Yue Chen, Sandra Kübler
Indiana University
{ksteimel,ddakota,yc59,skuebler}@indiana.edu

Abstract

Abusive language detection has received much attention in the last years, and recent approaches perform the task in a number of different languages. We investigate which factors have an effect on multilingual settings, focusing on the compatibility of data and annotations. In the current paper, we focus on English and German. Our findings show large differences in performance between the two languages.

We find that the best performance is achieved by different classification algorithms. Sampling to address class imbalance issues is detrimental for German and beneficial for English. The only similarity that we find is that neither data set shows clear topics when we compare the results of topic modeling to the gold standard. Based on our findings, we can conclude that a multilingual optimization of classifiers is not possible even in settings where comparable data sets are used.

1 Introduction

The last decade has seen a massive increase in user generated content in social media. While most people are interested in connecting with family and friends and in exchanging experiences, there is an increasing number of posts that cross the line from sharing negative opinions to becoming abusive. Since the data is too massive for manual filtering, automated methods to detect abusive language reliably are required. This has created a novel research area under the titles of abusive language detection, hate speech detection, flame or cyberbullying detection.

While most of the work on abusive language detection has focused on English (Schmidt and Wiegand, 2017; Park and Fung, 2017; Lee et al., 2018), there is some work on other languages, and first attempts have also been made to develop methods that work across different languages (Fehn Unsvåg and Gambäck, 2018).

Our interest also focuses on multilingual abusive language detection. However, before we engage in a full scale investigation of which methods work well across multiple languages, we need to know more about which factors have an effect on multilingual settings, including but not restricted to the compatibility of data and annotations, differences between languages, and topic effects. In the current paper, we focus on two languages, English and German, where we have access to similar data (see section 3 for more information). We approach the following questions as we investigate an approach across the two languages:

1. Do classifiers behave similarly across the two languages? I.e., can we establish the best classifier on one language and then use it successfully for the second language?

2. Can we determine which types of features are necessary for a classifier? Are the types of features and the number of features comparable across the two languages?

3. The data sets are skewed towards non-abusive language, and research in sentiment analysis has shown that over-sampling methods can improve results (Liu et al., 2014). Thus, do over-sampling methods show consistent results across both languages?

4. For tasks related to sentiment analysis, it is often the case that a classifier learns topic information rather that sentiment (Pang et al., 2002). We investigate whether the two languages show similar effects with regard to topics.

Proceedings of Recent Advances in Natural Language Processing, pages 1151–1160,
Varna, Bulgaria, Sep 2–4 2019.

Our results show that the data sets differ in their answers to questions 1–3, only showing similarities with regard to topics, leading us to the the preliminary conclusion that we cannot transfer methodology across languages and data sets when the data sets for the individual languages have been collected opportunistically. Since it is highly unlikely that we can completely replicate the data collection methods from the "source" language, the implications of our findings are far reaching and necessitate further investigation into the issues of multilingual abusive language detection.

The remainder of the paper is structured as follows: We discuss related work in section 2 and the data sets in section 3. Then, we explain our experimental setup and feature sets in section 4. Section 5 presents the results, and section 6 draws conclusions and discusses future work.

2 Related Work

Research on abusive language detection has recently drawn much attention, as several recent shared tasks (Basile et al., 2019; Kumar et al., 2018; Wiegand et al., 2018; Zampieri et al., 2019) demonstrate. So far, research has mostly focused on English. For a comprehensive survey of NLP techniques to detect hate speech see (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018). Here, we will focus on issues relating to problems in multilingual abusive language detection.

There is work on abusive language detection in Arabic, Dutch, and German. For Arabic, Mubarak et al. (2017) developed a data set of abusive language by creating an abusive word list and then splitting their Twitter dump into abusive and non-abusive classes by user, where users are considered abusive if they have used at least one word from the list. They also created an algorithm to extend the list of abusive words.

Cyberbullying detection in Dutch social media was performed by Van Hee et al. (2015). They collected data from Ask.fm and annotated it with 7 categories including 'Threat', 'Insult', and 'Defamation'. For their classifier, they used a bag-of-words approach for word and character n-grams and a sentiment lexicon, with an SVM classifier. They found that sentiment features alone yield poor results, as does a substantial reduction in the number of bag-of-word features due to data sparsity.

The 2018 Germeval shared task focused exclusively on detecting abusive language in German tweets (Wiegand et al., 2018) (for a description of the data set, see section 3). While many of the best systems used neural architectures, the winning system (Montani and Schüller, 2018) used an ensemble method with classifiers trained on a subset of features (such as TF-IDF and character n-grams). The predictions were then combined with a maximum entropy model for a final prediction. They found that strategies such as feature selection, sampling, and extensive preprocessing ultimately reduced performance in their ensemble.

While most work focuses on identifying abusive language in a specific language, Fehn Unsvåg and Gambäck (2018) examined how a single approach can handle abusive language across multiple languages: English, Portuguese, and German. They used a number of existing twitter corpora including the corpus by Waseem and Hovy (2016) for English[1], the one by Ross et al. (2016) for German, and the one by Fortuna (2017) for Portuguese. They also incorporated "user features" (i.e., specific demographic information known about the author of the tweet) along with a standard set of word and character n-gram features using logistic regression. They noted slight improvements but only specific user features contributed improvements to a given language (e.g., network features boosting English and Portuguese).

Several systems for detecting abusive language in Hindi and English were developed as part of the 2018 *Trolling, Aggression and Cyberbullying* shared task (Kumar et al., 2018). This shared task used data from Facebook and Twitter. The systems had to label examples as 'Not Aggressive', 'Covertly Aggressive', and 'Overtly Aggressive'. Modha et al. (2018) achieved the best results on the Hindi side of the shared task using a convolutional neural network with fastText embeddings (Mikolov et al., 2018). Galery et al. (2018) identified abusive language in the English portion of the corpus as their initial survey found code-switching between Hindi and English. To address this code-switching, they used fastText embeddings for both languages and a SVD transformation of these two sets of embeddings to generate multilingual embeddings using sub-word units. These multilingual embeddings were used in a GRU-based recurrent neural network. They found that this approach was not effective on their particular data set due to

the limited instances of code-switching present.

3 Data Sets

For our work, we chose two data sets that were as similar as possible without creating a new, tightly controlled bilingual data set. For English, we used the publicly available Twitter hate speech data set created by Waseem and Hovy (2016). The original corpus included approximately 16 000 tweets; however we were only able to retrieve 15 715 tweets using the Twitter API, the rest were unavailable or deleted. The English data set was manually annotated with three different labels: 'racism', 'sexism' and 'none', where none refers to non-hate speech. For more information regarding the annotation guidelines, see (Waseem and Hovy, 2016). For classification, we split the data set using 90% (14 143 tweets) as training data and 10% (1 572 tweets) as test set. Every tenth tweet was assigned to the test set and removed from the training set to ensure the data sets were drawn from the whole corpus.

For the German data, we used the 2018 GermEval shared task data set (Wiegand et al., 2018) with the annotations for task 1 of the shared task. The annotations are binary: examples are either labeled as 'offensive' or 'other'. For our work, we use the training set of the shared task, which consists of 5 009 samples, and split it into our training and test sets, taking every tenth example for the test set. We do not use the official GermEval test set since we basically perform optimization experiments, and any scores obtained on the test data should not be directly compared to other research.

Since the English data set consists of a ternary classification while the German set uses a binary classification, we simplify the English data in order to make the data sets consistent across the two languages: We group 'racism' and 'sexism' into an 'abusive' group while the 'none' labels are maintained. Examples of the abusive class are shown in table 1, and a summary of the class distributions in the two data sets is shown in table 2.

The imbalance between classes is clear given the data in table 2. The non-abusive data outnumber the abusive data in a ratio of about 2:1 for both languages. This will negatively affect the performance of the classifiers since statistical classifiers tend to predict the majority class.

4 Methodology

We have developed two pipelines for detecting abusive language in tweets: One pipeline is trained on German data and the other is trained on English data.

Classifiers. For the first set of experiments, we use a range of classifiers including random forest, SVM, XGBoost and a neural network approach. For the former three classifiers, we use scikit-learn (Pedregosa et al., 2011), for the neural network architecture tensorflow's Keras API (Abadi et al., 2016). Based on previous research on related tasks (Park and Fung, 2017; Badjatiya et al., 2017), we experiment with several promising architectures, including fully connected neural networks and convolutional neural networks, along with different word embeddings, with both BERT and Flair embeddings (Devlin et al., 2018; Akbik et al., 2018), stand-alone and stacked respectively.

For the scikit-learn classifiers, we optimized hyper-parameters using grid search. For the neural networks, dropout and batch normalization techniques are applied, and architecture selection and hyper-parameter optimization are done in a non-exhaustive search.

Features. We use simple character n-grams along with stemmed word n-grams and dependency parse-derived features.

Stemming. Since we were unable to identify a good lemmatizer for German Twitter data, we decided to implement a stemmer for both the English and German data, in order to maintain compatibility between the two languages. The YASS stemmer (Majumder et al., 2007) is an unsupervised stemming algorithm that generates a minimum spanning tree of words based upon different string similarity distance metrics, cuts the hierarchy, and then stems a word by replacing the word with the centroid of the cluster the word belongs to. We use the YASS stemming method with a minor modification: While the YASS stemmer replaces all words that belong to a cluster with the cluster centroid, we replace all cluster members with the shortest member of the cluster. Stems are shorter than their morphologically related forms since affixes are not present. However, this step is not a departure from the YASS algorithm, instead it is an adaptation to increase the effectiveness of this algorithm on our particular domain. In addition, numbers, twitter handles, and URLs are removed from the data prior to stemming.

The distance metrics used by Majumder et al. (2007) rely heavily on the suffixing nature of German and English inflectional morphology. While these distance metrics fall flat for non-suffix based inflectional morphology like irregular past tense (primarily ablaut grades in words like ‘sleep’, ‘slept’), they produce less spurious stems compared to other common metrics like the Levenshtein distance. We use distance metric 4 from the YASS stemmer.

Dependency parsing features. To extract dependency features for English, we use the Tweebo parser (Kong et al., 2014), which is designed to parse Twitter data and requires minimal preprocessing to obtain useful parses. Unlike English, German does not possess a Twitter domain specific parser. For this reason, we use the Mate parser pipeline (Björkelund et al., 2010). However, in order to maximize the usefulness of Mate, which expects a more standard text structure, we preprocess the German Twitter data.

Preprocessing steps for parsing include: removing one or more hashtags or retweets after punctuation at the end of tweet as well as removing initial hashtags and retweets, removing the # sign from any hashtag in the middle of the tweet, removing all emojis, and detaching punctuation from words. We also use a base list of abbreviations[2] and add additional ones to ensure that these are kept during the tokenization process.

We extract dependency triples consisting of (dependent, head, label) that occurred a minimum of five times as features. These features are Boolean valued, denoting their presence or absence in a tweet.

Sampling methods. Given the imbalanced nature of the data sets, we investigate sampling techniques to examine whether sampling can yield better performance. We use imbalanced-learn (Lemaître et al., 2017) to perform both under-sampling and over-sampling techniques. More specifically, we use four over-sampling and two under-sampling methods: SMOTE (Chawla et al., 2002) constructs synthetic examples of the minority class by averaging over two randomly chosen minority examples. Borderline SMOTE (Han et al., 2005) focuses on the area around the decision boundary to create new examples, SVM SMOTE (Nguyen et al., 2011) uses an SVM to determine the examples to average while ADASYN (He et al., 2008) concentrates on the areas of the minority class search space that are difficult. Edited Nearest Neighbors (ENN; Wilson, 1972) uses a k-NN approach to identify examples that are untypical for their neighborhood; these are then deleted. One sided selection (Kubat and Matwin, 1997) uses Tomek links to identify and delete noisy examples.

Topic modeling. We train a topic modeler on the two data sets, i.e., we create an LDA (Blei et al., 2003) topic modeler per language and use it to group tweets into two topics. We have preprocessed the tweets in the same manner that was

XGBoost	68.50	60.00	59.50
SVM	74.41	70.97	72.01
NN	32.90	50.00	39.69

Table 4: German results for a range of classifiers

used for dependency parsing. We then use the top 100 words by frequency to produce two topics.

Evaluation. We report precision, recall, and F_1. Because of the skewing in the data set, all these measures are calculated as the macro average of precision, recall, and F_1, i.e., we calculate the measures per class and then average across both classes.

5 Results

5.1 Classifier Behavior across Languages

Here we investigate whether the classifiers show the same trends across both languages. This will allow us to decide whether we can select the classifier for one language and then keep the selection stable across further languages. For these experiments, we restrict the feature set to using only character n-grams of length 2-7 with a minimum frequency of 3, resulting in 137 434 features for German and 282 507 for English.

The results of the experiments for English are shown in table 3, the results for German in table 4. These results show that classifying all tweets as non-abusive, the majority class, results in a macro-F of around 40% for both languages. All classifiers but the neural networks perform better. All the neural network architecture/embedding combinations predict the majority class throughout.

For the other classifiers, we reach higher F-scores for English than for German: 80.49. vs. 72.01. This is not unexpected, since the English data set is larger than the German one. However, the best English results are reached by XGBoost while the same classifier only reaches 59.50 F for German. The highest results for German are reached by the SVM, which reaches a lower F-score on English (68.20). It is also interesting to see that for English, XGBoost reaches a recall that is more than 12 points higher than the SVM. In contrast, for German, XGBoost's recall is the lowest of all classifiers (except for the neural networks). For the SVM, recall is higher for German than for English, thus going against the general trend, but the difference is much less pronounced (> 4 points).

From these results, we draw the conclusion that we cannot choose a classifier for a new language based on experience with another language.

5.2 Feature Selection across Languages

The next set of experiments is concerned with the question of whether we can use the same features across languages, or if each language requires its own set of informative features. For these experiments, we decided to focus on SVMs since they show good performance and similar trends across the languages in the comparison of classifiers above and since they train much faster than XGBoost. We add two additional feature types into the vectors: stems and dependency features. For German, this results in a total number of features of 148 322 and for English, in 308 323.

We use Information Gain (IG) for feature selection and perform experiments using the set of features with the highest IG in incremental cutoffs. This results in a different amount of features for English and German, but this difference can be explained by the differences in the morphological complexity of the two languages and the data sizes. Results for English are reported in table 5, showing the overall results across both classes and specifically for the abusive class. Results for German are reported in table 6. The last row in each table repeats the results from the previous section, i.e., using all character n-gram features.

For English, a comparison of the two experiments with the character n-grams only as opposed to the full feature set including stems and dependency features shows that adding these features has a minimal negative effect, lowering the F-score from 68.20 to 67.70.

For the experiments on English using feature selection, we see that results with even 2 660 features improve significantly over the all features

		Overall			Abusive

Table 6: German results with IG feature selection, overall and for the abusive class.

baseline, and they continue their upward trend until around 14 000 features. At this point, however, a downward trend begins, suggesting that for English, a lower number of important features for the SVM classifier is beneficial. The results for the minority class follow the same trend: They also reach their peak at around 14 000 features. This means that the classifier's performance on the minority class is the driving factor (which is partly a result of using the macro-averaged values).

For German, the addition of stems and dependencies has a minimal positive effect, increasing the F-score from 70.01 to 72.20. For the experiments on feature selection, we see a steady upward trend as the number of features increases until we reach around 70 000 features, at which point results start to decrease. Again, the results on the abusive class follow the same trend. This means that, at a certain point, we reach a saturation of features in terms of modeling the abusive class. If we add more features, the classifier suffers from irrelevant features.

When we compare the results across the two languages, we notice a discrepancy in that the stems and dependencies help for German while they are harmful for English. Both effects are minimal. One possible explanation may be that for English, the additional features only increase data sparsity without providing novel information. For German, which is morphologically richer and has freer word order. Introducing the stems and dependencies may help alleviate data sparsity to a certain degree. This requires further investigation.

The second discrepancy concerns the optimal number of features. For German, we achieve our best results using slightly less than half the features; for English, the best results are based on approximately 4.5% of the data. This means that the results differ in terms of absolute numbers and percentage.

	Abusive		Non-Abusive		
Sampling method	Precision	Recall	Precision	Recall	F-score

One sided selection	69.57	56.14	79.28	87.23	72.60

Table 8: Results for German using sampling (69 541 features).

Consequently, we again come to the conclusion that we cannot generalize across languages with regard to which feature types are useful nor to the amount of features that are useful.

5.3 Sampling Methods across Languages

In this section, we look into the effects of sampling methods. Since the problem of abusive language detection is inherently skewed towards non-abusive language, instance sampling on the training set can help make the classifier more sensitive towards the minority class. We investigate the use of over-sampling of the minority class and under-sampling of the majority class using the best performing number of IG features for German (69541) and approximately the number of top IG features for English (70,000). The results of these experiments are shown in table 7 for English and in table 8 for German.

For English, table 7 shows that we reach the highest precision for the abusive class using one-sided selection, an under-sampling method. The highest recall for the abusive class and the highest precision for the non-abusive class are reached by SMOTE, an over-sampling method. The highest recall for the non-abusive class is reached without any sampling. The highest F-score across both methods (77.94) is reached by using edit nearest neighbors, which reaches a somewhat lower precision on the abusive class than one-sided selection, but a recall that is about 12.5 points higher.

For German, table 8 shows a different picture: We reach the highest precision for the abusive class along with the highest recall for the non-abusive class and the highest overall F-score (73.26) in the experiments without any sampling. The highest recall for the abusive class along with the highest precision for the non-abusive class is reached by the edit nearest neighbors under-sampling method.

These results show that we again face a situation in which the two data sets behave completely differently. For English, we reach the best results with an under-sampling method while for German, all of the sampling methods perform worse that not using sampling at all. Additionally, while the experiments without sampling show the same trends – high precision for abusive language and high recall for non-abusive language – across both languages, this is not the case for edit nearest neighbors: Here the English results show a high precision for the abusive class, but the German results show high recall for the same class.

	Abusive		Non-Abusive		
Language	Precision	Recall	Precision	Recall	F-score
English	33.98	53.23	70.82	52.32	52.59
German	36.97	51.46	68.32	54.41	51.80

Table 9: LDA Topic Modeling Classifications

5.4 Topic Behavior across Languages

One important distinction that needs to be better understood during the classification process is whether our classifiers detect abusive language itself, or whether they detect topics that are more likely to induce abusive language. If certain topics are strongly associated with abusive language in the training data then the model obtained may focus on these topic associations and not model abusive language directly. More specifically, if this trend is more pronounced for one language, this may explain some of the differences in results across the two languages that we found in previous sections. In order to investigate this possibility, we perform topic modeling on the tweets of the two data sets. This experiment is based on the assumption that if the topic modeler groups tweets similar to the abusive, non-abusive classes, then we have evidence that the abusive language is closely associated with a content topic. We determine the overlap between the topic modeler and the abusive/non-abusive split by calculating precision, recall, and F_1 between the topic models decisions and the gold standard.

We perform topic modeling with the number of topics set to 2, parallel to the grouping into abusive and non-abusive language. However, the topic modeler does not tell us which of the two topics corresponds to abusive language. Thus we calculate precision and recall for both correspondences and choose the one with the higher F-score.

The outcomes of this comparison are presented in table 9. The table shows that both languages follow the same trend with an F-score slightly higher than chance (52.59 for English and 51.80 for German). For both languages, recall is around 50, and precision is higher for the non-abusive class and lower for the abusive one. We conclude from these results that there is no meaningful overlap between topics and abusive/non-abusive language. I.e., our SVM classifiers do learn characteristics of abusive and non-abusive language rather than characteristics of topics. However, this also means that the differences between the languages found in the previous experiments cannot be explained by differences in associating abusive language with specific topics, and we need to investigate further to determine the source of those differences.

6 Conclusion and Future Work

In this paper, we have started an in-depth investigation into two data sets for abusive language detection, one in English and one in German. While the data sets were collected independently and annotated with different classes, collapsing them into a binary annotation between abusive and non-abusive language resulted in data sets that superficially showed similar characteristics. However, our investigation has shown notable differences: For English, XGBoost provides the best performance, for German SVMs do. Stems and dependencies in addition to character n-grams help for German while they are harmful for English. For German, we need to use slightly less than half of all features while for English, we only need 4.5%. Even though the English data set is larger than the German one, the percentages translate into a much larger feature set for German than for English. Additionally, for English sampling improves results while for German, it does not. One hypothesis, namely that the differences may be related to a stronger topical effect in the abusive tweets, was rejected based on an experiment with a topic modeler.

Moving forward, we will investigate the differences between the German and English data sets in more detail. Finding the causes will allow us to better approach optimization of multilingual abusive language detection systems. The final goal of this work is the development of a system for detecting abusive language that can truly work in a multilingual fashion.

Abstract

Previous work on using BiLSTM models for PoS tagging has primarily focused on small tagsets. We evaluate BiLSTM models for tagging Icelandic, a morphologically rich language, using a relatively large tagset. Our baseline BiLSTM model achieves higher accuracy than any previously published tagger not taking advantage of a morphological lexicon. When we extend the model by incorporating such data, we outperform previous state-of-the-art results by a significant margin. We also report on work in progress that attempts to address the problem of data sparsity inherent in morphologically detailed, fine-grained tagsets. We experiment with training a separate model on only the lexical category and using the coarse-grained output tag as an input for the main model. This method further increases the accuracy and reduces the tagging errors by 21.3% compared to previous state-of-the-art results. Finally, we train and test our tagger on a new gold standard for Icelandic.

1 Introduction

Bidirectional long short-term memory (BiLSTM) models have in recent years been shown to be effective for various sequential labelling tasks, including Part-of-Speech (PoS) tagging (Ling et al., 2015; Plank et al., 2016).

BiLSTMs are an extension of general LSTMs (Hochreiter and Schmidhuber, 1997) that perform better on sequences where the complete input sequence is available. Two LSTMs are trained on the input sequence, one on its natural reading order and the other on its reverse (Graves and Schmidhuber, 2005). In addition to word embeddings (WE), character embeddings were first used for tagging with BiLSTMs by Dos Santos and Zadrozny (2014). This entails not only examining the sequence of words in a sentence during training but also the sequences of characters within those words.

In this paper we use BiLSTM models, with both word and character embeddings, to train a PoS tagger for a morphologically rich language, Icelandic, with a fine-grained tagset of 565 morphosyntactic tags. Only a small portion of previous work using neural networks for PoS tagging has focused on languages with rich morphology and large tagsets, e.g. Sagot and Martínez Alonso (2017).

Various taggers have been developed for Icelandic: data-driven taggers (Helgadóttir, 2005), a rule-based tagger (IceTagger) (Loftsson, 2008), and a hybrid tagger (Loftsson et al., 2009). Prior to the work presented here, an averaged perceptron tagger, IceStagger (Loftsson and Östling, 2013), was the current state-of-the-art tagger, achieving an accuracy of 93.84% by employing a morphological lexicon and external word embeddings.

This paper presents the first deep neural network tagger for Icelandic. We evaluate three models. First, we confirm the effectiveness of a BiLSTM model for PoS tagging using a fine-grained tagset. Second, we supplement the base model with an external morphological lexicon, thereby obtaining state-of-the-art results. Third, we propose an approach to further increase the accuracy by creating a coarse-grained tagset from the fine-grained one and using the resulting tagset to devise a two-step process. This approach is to our best knowledge novel in the context of neural network tagging. Specifically, we train a separate model on only the lexical category and use the coarse-grained output tag as an input into the main model. Combined, this results in an overall tagging accuracy of 95.15%, which is equivalent to

Proceedings of Recent Advances in Natural Language Processing, pages 1161–1168,
Varna, Bulgaria, Sep 2–4 2019.

an error reduction of 21.3% compared to the previous state-of-the-art. Finally, we train and test our model on a new gold standard for Icelandic, MIM-GOLD. The new standard is larger than the older one, IFD (see Section 2), and contains more diverse texts. We achieve an accuracy of 94.17% on MIM-GOLD.

2 Data

In this section, we describe the data and the tagset used in our work.

The IFD Corpus: The taggers developed for Icelandic so far have all been trained and tested on the Icelandic Frequency Dictionary (IFD) corpus (Pind et al., 1991), a balanced corpus containing about 590 thousand tokens. The IFD corpus was collected in the early 1990s and contains texts from published books, primarily fiction (60%) but also biographies (20%) and scholarly work (20%). As with the other taggers referenced in this paper, we use the so-called *corrected version* of the corpus, with the reduced tagset (565 tags) and ten-fold split from Loftsson et al. (2009).[1] The morphosyntactic tags in this tagset are mnemonic encodings, i.e. character strings where each character has a particular function. The first character denotes the *lexical category*. For each category there is a predefined number of additional characters (at most six), which describe morphological features, like *gender*, *number* and *case* for nouns; *degree* and *declension* for adjectives; *voice*, *mood* and *tense* for verbs, etc. To illustrate, consider the word form *maður* "man". The corresponding tag is *nken*, denoting noun (*n*), masculine (*k*), singular (*e*), and nominative (*n*) case.

The MIM-GOLD Corpus: MIM-GOLD[2] (Loftsson et al., 2010), a subset of the MIM corpus (Helgadóttir et al., 2012), contains a greater diversity of texts than the IFD corpus. In addition to texts from published books, it contains texts from news media, blogs, parliamentary speeches and more. Furthermore, MIM-GOLD contains approximately 1 million running words, about twice as many as IFD. The tagset used in MIM-GOLD consists of the same reduced tagset of 565 tags, mentioned above.

Morphological Lexicon: The Database of Modern Icelandic Inflections (DMII) is a lexicon of about 280 thousand paradigms and close to six million inflectional forms (Bjarnadóttir, 2012). The output from the database used in this project contains word form and morphological features. By incorporating DMII, the average unknown word rate in testing, using the IFD ten-fold split, drops from 6.8% to 1.1% (Loftsson et al., 2011).

3 The Three Models

3.1 Word and Character Embeddings

Word embeddings are vector representations of words based on their context in training data. Adding recurrent character embeddings has been shown to significantly improve performance for handling of unknown words (e.g. Plank et al. 2016; Dos Santos and Zadrozny 2014). For each word, both forward and backward expressions are generated, containing the sequence of characters in the word, as well as word initial and word final markers. This helps the model grasp morphological details.

In our baseline model, which is similar to Plank et al. (2016), both word embeddings and recurrent character embeddings are used as input. The character embeddings for a given word are input into a BiLSTM. The output from the BiLSTM is concatenated to the word embedding and the combined vector input into another BiLSTM, whose output is input into a hidden layer. The hidden layer feeds the output layer, which selects a PoS tag.

3.2 Using Data from an External Morphological Lexicon

Horsmann and Zesch (2017) replicated Plank et al. (2016) using a collection of corpora annotated with fine-grained tagsets of varying sizes, in contrast to the coarse-grained Universal Dependencies (UD) tagset in the previous study (17 tags). The replication confirmed the superior performance of the BiLSTM tagger, also on fine-grained tagsets. Furthermore, they found that the advantages of the BiLSTM tagger over other taggers grow proportionally with the tagset size of the corpus. However, they also claim that for large tagsets of morphologically rich languages, hand-crafted morphological lexicons are still necessary to reach state-of-the-art performance.

Using a morphological lexicon has become common practice for enriching training data for PoS taggers. Hajič (2000) marked the importance

[1] IFD can be downloaded from `http://malfong.is/?pg=ordtidnibok`.

[2] MIM-GOLD can be downloaded from `http://malfong.is/?pg=gull`.

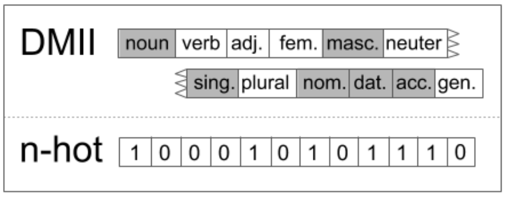

Figure 1: A partial n-hot vector and the corresponding features from DMII. The example shows 12 features, including the active features for the word form *strætó* "bus". The word, a noun, has the same form for nominative, dative and accusative and therefore all corresponding labels are activated. An actual vector in our model has 61 labels, which are either active, `1`, or inactive, `0`.

of this for morphologically rich languages. It was first done for Icelandic in Loftsson et al. (2011).

Sagot and Martínez Alonso (2017) first used morphological lexicons as supplemental input for PoS tagging with BiLSTM taggers and showed that it yields consistent improvement. Following their work, we extend the baseline model by adding an input layer that contains token-wise features obtained from the DMII lexicon (see Section 2). The input vector for a given word is an n-hot vector where each active value corresponds to one of 61 possible labels in the lexicon. An example of an n-hot vector is given in Figure 1.

The vector is concatenated to the two vectors described in the previous section, i.e. the word embedding and the character embedding, and the result is then fed into the BiLSTM layer. Previous taggers using DMII have had to map the information to the IFD tagset. As the tagsets of IFD and DMII are not completely compatible some information has been lost in the mapping process. Our method allows the model to use and learn from all the information encoded in the morphological lexicon, even though it uses a tagset slightly different from our training data.

3.3 Stepwise Tagging Model

When employing a fine-grained tagset with mnemonic encoding, the model does not place different significance on two tags when they differ in lexical category, on one hand, or share a lexical category but differ in morphological features, on the other. A human, however, would consider the former a more significant error than the latter. A PoS tagger is especially prone to such errors when the tagset is large and the amount of training data is insufficient to detect all the subtle differences between labels, as sometimes is the case for under-resourced or domain-specific languages.

To place a higher emphasis on assigning the correct lexical category, we devise a two-step process. First, we simplify the tagset from 565 to 10 tags by using only the first letter of the fine-grained tag mnemonic, i.e. the letter denoting the lexical category. We then train our model on this new coarse-grained tagset, using word and character embeddings as well as the morphological lexicon. This results in a lexical category tagger with very high accuracy, 98.97% in our case. In the second step, the output of that tagger is embedded as a one-hot vector and concatenated to the vectors input into the BiLSTM layer of the main model. This guides the tagger to the correct lexical category and eliminates some of the errors caused by insufficient training data.

This is a work in progress and other morphological features in the tags are promising for evolving this stepwise approach and further increasing overall accuracy. Thus, separate models for detecting gender, number and case agreement, for example, might be considered at each step.

We are not aware of other implementations of stepwise PoS tagging using BiLSTMs, but Horsmann and Zesch (2016) employ such a method in a slightly different setting. They use a Support Vector Machine for training, assume the coarse-grained tags are correct and then have their tagger assign the fine-grained tags based on them. In their Bidir tagger, Dredze and Wallenberg (2008) tag case separately in a second-pass, after running a general first-pass that uses the whole tagset. The second-pass tagger has access to the output of the first-pass, and is permitted to change its case and gender selections.

4 Experiments and Results

4.1 Experimental Setup

Our models were built using DyNet[3] (Neubig et al., 2017). We use the same hyperparameters for all models, SGD training with the initial learning rate of 0.13, which decays 5% in each epoch and runs for 30 epochs. The network has 128-dimensional embeddings for words and 20 for characters. The supplemental embeddings have 61

[3] The Dynamic Neural Network Toolkit, see `http://dynet.io`.

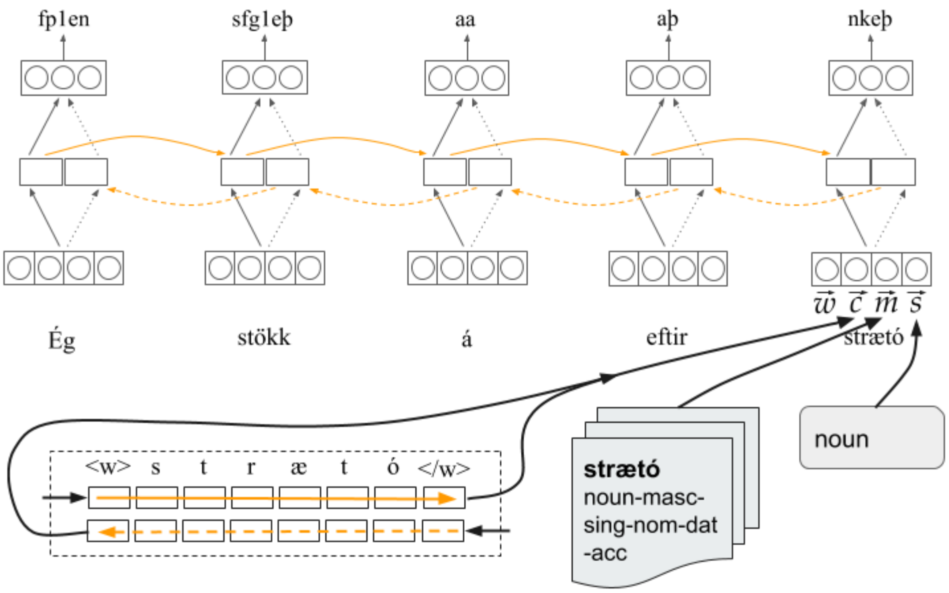

Figure 2: Our full model, employing word embeddings, character embeddings, a morphological lexicon, and the output of the first-pass of the stepwise model. The hidden layer is omitted for simplicity. Figure adapted from (Plank et al., 2016).

dimensions for the lexicon and 10 for the lexical categories. The hidden layer has 32 hidden states.[4]

Our experiments consist of three models:

Baseline: The first model uses word and character embeddings only. This corresponds to the model described in Section 3.1.

DMII: The second model adds external morphological data from DMII to the baseline model by encoding the information in n-hot vectors as described in Section 3.2.

LC: The third and full model then adds the lexical category embeddings created by a coarse-grained tagging step described in Section 3.3. This full model is shown in Figure 2.

	Acc.	Known	Unknown
Baseline	93.25%	95.19%	**66.84%**
+ DMII	94.84%	95.17%	54.61%
+ LC	**95.15%**	**95.48%**	54.06%

Table 1: Accuracy of the three models trained and tested on IFD. Note that when DMII is employed the number of unknown words falls almost 90%, from 4,036 to 476 out of an average total of 58,977 words in the splits.

4.2 Part-of-Speech Tagging Results

The test results for all three models are shown in Table 1, with the full model reaching 95.15% accuracy after 30 epochs. The baseline model (93.25%) already gets close to state-of-the-art results and surpasses existing taggers when not using an external morphological lexicon (cf. Loftsson and Östling 2013).

The substantial gain achieved by using DMII confirms the advantages of using an external morphological lexicon as discussed in Section 3.2. The accuracy gain is considerably higher than the corresponding gain in IceStagger (1.59 vs. 0.88 percentage points).

By employing the stepwise model discussed in Section 3.3 we try to guide the tagger to the highly accurate lexical category given by the coarse-grained tagger. This helps in assigning rare or ambiguous tags in the fine-grained tagset by raising the accuracy of the lexical category, resulting in a further 0.31 percentage point gain.

Note that the baseline model achieves the highest accuracy for unknown words because when adding data from DMII the unknown word ratio drops considerably (see Table 1), from 6.8%

[4] The source code for our implementation is available from https://github.com/steinst/ABLTagger

	Acc.	Known	Unknown
TnT	90.45%	91.82%	71.82%
IceTagger	92.73%	93.84%	**77.47%**
+ DMII	93.48%	93.85%	60.50%
IceStagger	92.82%	93.97%	77.03%
+ DMII	93.70%	94.02%	61.45%
+ DMII,WE	93.84%	94.15%	61.99%
Our model	**95.15%**	**95.48%**	54.06%

Table 2: Comparison to other taggers for Icelandic.

to 0.8%. This is in line with results of previous taggers (see Section 2), further reduction in unknown words is due to us using the latest version of DMII, while previous results were published in 2011. When DMII is employed the remaining unknown words are more likely to be foreign words, typos or to be irregular in some other way and therefore more difficult to tag. This explains the drop in accuracy for unknown words.

4.3 Comparison to Other Taggers

A comparison of our model to other previously published taggers for Icelandic is shown in Table 2. The results for TnT, IceTagger and IceStagger are presented in (Loftsson et al., 2009; Loftsson, 2008; Loftsson and Östling, 2013), respectively. All the reported results are fully comparable as they are based on exactly the same cross-validation split of the IFD corpus, with the exception that the TnT tagger does not employ data from DMII, and has therefore a higher ratio of unknown words.

Our model outperforms all previous taggers by a substantial margin, equaling a 21.3% reduction in errors compared to the highest accuracy (93.84%) obtained by IceStagger. It also has the highest accuracy for known words, i.e. those seen in the training data, including DMII. It should be noted though, that the numbers for accuracy of known and unknown words are not very well comparable between the different models, as using DMII eliminates a substantial part of unknown words, but the ones that remain tend to be more irregular, and can thus be harder to tag correctly.

4.4 Error Analysis

When comparing the most frequent kinds of errors our tagger makes to the errors of IceStagger, two differences stand out. The frequency of sng>sfg3fn and sfg3eþ>sfg1eþ are drastically reduced and are no longer among the ten most frequent kinds of errors (see Table 3). These are verbs that are assigned infinitive mood instead of indicative mood (sn...>sf...) and third person instead of first (sfg3...>sfg1...), respectively. These kinds of errors occur when the subject is far away from the verb itself and the more frequent tag for the word form is selected instead of the correct one. This corroborates that LSTMs are better at handling long-distance dependencies (Linzen et al., 2016) than other methods that have a limited context window during training.

	Our model		IceStagger
No.	Proposed tag > gold tag	Error rate	Proposed tag > gold tag
1.	aþ>ao	3.28%	aþ>ao
2.	ao>aþ	2.99%	ao>aþ
3.	nveo>nveþ	1.80%	nveo>nveþ
4.	nveþ>nveo	1.72%	nveþ>nveo
5.	ao>aa	1.18%	**sng>sfg3fn**
6.	aa>ao	1.09%	ao>aa
7.	nkeo>nkeþ	0.98%	**sfg3eþ>sfg1eþ**
8.	nheo>nhfo	0.92%	aa>ao
9.	nkeþ>nkeo	0.82%	nheo>nhen
10.	ct>c	0.81%	nhen>nheo

Table 3: Ten most frequent kinds of errors.

The remaining kinds of errors in the top ten list are for the most part mistakes in case assignment. For example, prepositions are often wrongly marked as governing accusative instead of dative and vice versa (1 and 2) and there is often a confusion between prepositions and adverbs (5 and 6). The same goes for nouns (7 to 9) and, in addition, they are often assigned the wrong number, i.e. singular instead of plural (8). The last kind of error (10) is caused by a lack of syntactic and contextual information: a conjunction is marked as a relativizer, i.e. conjunction introducing a relative clause.

The nearly even distributions (1+2, 3+4, 5+6, 7+9) at which these kinds of errors occur indicate that there is nothing in the training data to discern which tag to select in these instances. One way forward to try to tackle these errors is to supplement the model further, e.g. with verb subcategorization frames.

	Acc.	Known	Unknown
MIM-GOLD	94.04%	95.13%	68.34%
+ IFD	94.17%	95.62%	68.18%

Table 4: Accuracy when training and testing on MIM-GOLD.

5 Tagging a Different Gold Standard

In the previous sections, we have described the tagging process and compared the results to previous taggers using the same splits on IFD. We have demonstrated that our tagger achieves a significant gain in accuracy over previous taggers. Since the IFD corpus mainly contains literary work (see Section 2), these texts are not necessarily characteristic of texts that have to be tagged for language technology or research purposes. This is one of the reasons why a new gold standard, MIM-GOLD, was built containing more diverse texts (see Section 2). In 2015, Steingrímsson et al. (2015) trained IceStagger on MIM-GOLD, but found it had many inconsistencies and errors. Since then it has been reviewed and corrected and the final version, along with 10-fold splits, was made available in 2018.

We trained our BiLSTM tagger on these splits and measured the accuracy for our full model, employing both DMII and the two-step method. We carried out two experiments. In the first, we only trained and tested on the 10-fold splits for MIM-GOLD, but in the second we added the whole IFD corpus to the training data. As evident from Table 4, there is a substantial drop in accuracy compared to training and testing on IFD (see Table 1). The lower accuracy may, at least partly, be due to a greater variety in texts than before and a larger proportion of unknown words in the MIM-GOLD test set compared to IFD (Steingrímsson et al., 2015).

6 Conclusions and Future Work

We have shown that BiLSTM models with combined word and character embeddings achieve state-of-the-art accuracy in PoS tagging of Icelandic texts. We have also confirmed that BiLSTMs perform well with a fine-grained tagset, such as the one used in the Icelandic corpora, IFD and MIM-GOLD. When dealing with small corpora, as often is the case with under-resourced languages, supplementing the models with external data can be highly beneficial as shown by our experiments.

To deal with the problem of data sparsity, which is more prevalent when using fine-grained tagsets, we devised a stepwise method to guide the tagger in assigning lexical categories. This method is a work in progress – we have pinpointed morphological features that can be independently identified with very high accuracy and are therefore promising candidates for being handled in a separate step in the tagging process. Furthermore, it could be worthwhile to pre-train word embeddings on unlabeled data, such as the Icelandic Gigaword Corpus (IGC) of 1.2 billion words (Steingrímsson et al., 2018), e.g. employing the method described by Wang et al. (2015), which is specifically adapted to BiLSTMs.

The error analysis in Section 4.4 suggests that information on case governance is critical in reducing the most common errors the tagger makes. This could be external data on case governance of verbs and prepositions, or data derived from a method akin to the stepwise method that better discerns this information from the training data.

The final version of a new gold standard, MIM-GOLD, has recently been released and has not been used for training a PoS tagger for Icelandic before. IFD is heavily biased towards literary fiction but MIM-GOLD is a more balanced mix of different text genres and is thus more diverse. The lower accuracy for MIM-GOLD should thus not have been surprising, even though it has more data than IFD. Comparison of error analysis for both gold standards should reveal if there are other factors at play. We suggest that further work on developing PoS taggers for Icelandic texts focuses on this new gold standard.

Abstract

This paper addresses the task of categorizing companies within industry classification schemes. The dataset consists of encyclopedic articles about companies and their economic activities. The target classification schema is build by mapping linked open data in a semi-supervised manner. Target classes are built bottom-up from DBpedia. We apply several state of the art text classification techniques, based both on deep learning and classical vector-space models.

1 Motivation

The era of big data has made the task of integrating several heterogeneous sources quite common and important. This is a challenging task because, typically, data representation of the same object can significantly differ in different sources, both in level of detail and type of available information. In addition, different ontologies (classification schema) are used for the same concepts in different datasets. Ontology mapping is itself a challenge even for human experts. Thus the problem of concept classification is very important in data integration.

This paper presents a comparison of different techniques for solving the task of company industry classification based on textual descriptions of companies in DBpedia[1]. The problem of text-classification is defined as follows: for a collection of company descriptions $D = \{d_1, d_2, ..., d_n\}$, assign one or more industry categories to each company from a discrete set of labels $C = \{c_1, c_2, ..., c_k\}$.

There are more than fifteen different company industry classifications of varying granularity. Some of the most popular are: Industry Classification Benchmark (ICB)[2], Global Industry Classification Standard (GICS)[3], Thomson Reuters Business Classification (TRBC)[4], and International Standard Industrial Classification of All Economic Activities (ISIC)[5].

2 Text Classification Methods

Text classification methods are widely used in several applications like e-mail spam filtering (Youn and McLeod, 2007), news categorization (Lin and Hauptmann, 2002), in marketing for product reviews (Dang et al., 2009), etc.

The classical methods (Aggarwal and Zhai, 2012) in text classification are based on standard techniques. Usually the texts from the training corpus are transformed into vectors, where distinct words represent features. One of the simplest and most efficient methods is the probabilistic classifier Naïve Bayes (NB) that has really good performance even with few examples and sparse features and works with a ”naïve” assumption for attributes that are conditionally independent. However, usually not all words in a text are independent. Many techniques have been developed (Al-Aidaroos et al., 2010) to overcome the problems caused by the existence of attribute correlations that can lead to classification bias and negatively affect an NB classifier's performance. McCallum and Nigam (McCallum et al., 1998) demonstrate NB classifier applied on ”Industry Sector” data, that contains 6,440 company web pages classified in a hierarchy of 71 industry sectors, with a vo-

cabulary of size 29,964. The reported results for multinomial NB classifier for 20,000 words reach accuracy up to 0.74, and for 1,000 words multivariate Bernoulli model reaches accuracy up to 0.46. Frank and Bouckaert (Frank and Bouckaert, 2006) propose a solution based on multinomial NB that deals with the problem of unbalanced class sizes in Industry Sector dataset with 105 classes, where the largest category has 102 documents, the smallest has 27. They show how by using a centroid classifier and taking into account the significance of different industry sectors classes this method achieves significant gain in some categories. Maximum Entropy classifier used on Industry sector dataset (Nigam et al., 1999) shows better performance than NB and reaches a higher accuracy of 0.788. Ghani (Ghani, 2000) uses an error-correcting codes method and achieves an accuracy up to 0.886 for Industry Sector dataset with a vocabulary size of 10,000.

Support Vector Machines (SVM) (Joachims, 1998) are linear classifiers that, like NB, do not require large training datasets but need more computational time. The most important advantage of SVMs is that they have good performance even for a high dimensional space, such as text classification, where dimensions can be well over 10,000. Rennie and Rifkin (Rennie and Rifkin, 2001) propose application of SVM using one-vs-all and error-correcting output coding for Industry Sector dataset and the results show that this method significantly outperforms NB.

Logistic regression (Genkin et al., 2007) is quite efficient in cases where the dimensions of the feature space surpass the total number of training examples, which is typically the case for text classification datasets.

k-Nearest Neighbor (kNN) Classification method is a proximity-based classifiers that uses distance-based measures for classification task. Usually, such methods use all features in the vector space model which can cause lack of efficiency as not all of them are useful. Several methods for features selection are used, mainly based on the weight of the words in the text. To overcome this problem some modifications of kNN classifier for text documents were proposed, like Weight Adjusted k-Nearest Neighbor Classification (Han et al., 2001). Trstenjak et al.. 2014 present a method for text classification based on kNN and Term frequency inverse document frequency (TF-IDF). Tan (Tan, 2006) demonstrates the performance of kNN and DragPushing strategy based KNN classifier (DPSKNN) methods over subset of 48 sectors of Industry sector dataset (Sector-48 dataset). The Micro-F1 of kNN classifier for Sector-48 dataset is 0.8188 and its Macro-F1 is 0.8235. While DPSKNN shows slightly better performance with for Sector-48 dataset with Micro-F1 0.8544 and Macro-F1 0.8585. In order to emphasize the performance of the methods on common and rare classes, special averages of F1 scores over different classes are used- Micro-F1 - F1 over categories and documents; Macro-F1 - average of within-category F1 values.

Other classification techniques, like Random Forests (Xu et al., 2012), Decision Tree Classifiers (Harrag et al., 2009), Rule–based classifiers, and Conditional Random Fields (CRF) (Lafferty et al., 2001) are also used for this task.

Recent advances in Deep Learning and Transfer Learning introduce more complex methods (Kowsari et al., 2019) with significantly better performance on solving the multi-class multi-label task for industry sectors.

One of the breakthroughs in the area was done by word2vec (Mikolov et al., 2013) that proposes an efficient method for continuous semantics vector representation of words (continuous bag-of-words (CBOW) and skip-grams), by learning from a huge dataset with billions of words. Although its primary purpose is not directly related to text classification, word2vec was used as stepping stone for many other algorithms, because pre-trained word representations are widely used in deep contextual models for word embeddings.

Some more advanced models, like Glove (Pennington et al., 2014) for word representations were proposed, based on so called Global vectors - a new global log-bilinear regression model, where the learning is based on non-zero elements in word-word co-occurrence matrix.

The ELMo (Embeddings from Language Models) (Peters et al., 2018) representation uses deep bidirectional language model (biLM), where each token is assigned a representation which is a function for the whole input sentence.

Skip-thought unsupervised learning model (Kiros et al., 2015) is a generic, distributed sentence encoder that uses robust sentences representation in skip-thought vectors. It uses the idea of continuation of the information in the text and for an encoded sentence, it tries to reconstruct its surrounding sentences.

Because our dataset is based on DBpedia, the performance of neural networks (NN) algorithms over it for text-based classification task is of primary interest for us.

One of the latest algorithms XLNet (Yang et al., 2019) demonstrates the best performance for DBpedia with error 0.62. Where ”classification error” is defined as 1.0 minus classification accuracy. XLNet incorporates ideas from Transformer-XL (Dai et al., 2019). The main advantage of Transformer-XL(Dai et al., 2019) is that it allows the capture of longer-term dependencies and resolves context fragmentation problem.

Other methods with comparable results are Universal Language Model Fine-tuning (ULMFiT), (Howard and Ruder, 2018) with error 0.8 for DBpedia dataset.

Although deep learning algorithms show significant improvement in accuracy they require huge amount of labeled training examples and are computationally expensive in comparison to classical algorithms which do not need such large training datasets.

Some semi-supervised methods (Johnson and Zhang, 2016), (Sachan et al., 2019) and unsupervised methods (Xie et al., 2019) have been proposed for use in combination with supervised models to improve their performance. For example, combination $BERT_Large$+UDA of Unsupervised Data Augmentation (UDA) (Xie et al., 2019) and BERT (Devlin et al., 2018) demonstrate error 1.09 for text classification for DBpedia. The state-of-the-art (SOTA) $BERT_Large$'s error for the DBpedia is 0.64.

In this study we will compare the performance of some deep learning and transfer learning algorithms over DBpedia companies descriptions. We will present experiments with ULMfit and Glove to a baselines of one-hot unigram and one-hot bigram models. These methods were chosen because they are not so computationally expensive in comparison with the others and will serve as a baseline to exploit the potential of the deep learning approach for text-based classification of industry sectors.

3 Dataset

The dataset[6] we used for the experiments is encyclopedic data, consisting of approximately 300,000 textual descriptions of organizations and a classification based on DBPedia classes, which itself is based on Wikipedia. The descriptions are simply the English language abstracts[7] of the the Wikipedia articles about the organizations, and are thus relatively homogeneous in size and style. The *Industries* classification is based on the nature of organization's activity and is generated from the *industry*[8] property of DBPedia. The over 17,500[9] distinct ”industries” are normalized *via* a custom mapping we have developed in an iterative manner guided by the taxonomy's commercial applicability. The end result is a multi–level hierarchy but the experiments described in this paper concern only the 32 top-level classes. For example, the organization ”Bulgaria Air”[10] is, according to DBPedia, an *Airline*[11], which according to our mapping is a sub-industry of *Air Transport*[12], itself a sub-industry of *Transport*[13], the top-level industry in our mapping. Note that, some organizations, such for example, the ”East Japan Railway Company”[14] are directly classified the top-level industry. As is visible in Table 1, the largest classes have well over ten thousand positive examples while many of the smallest have much fewer than a thousand.

4 Experiments and Results

To compare the performance of the methods discussed, we trained a series of algorithms on the same split of our data to get comparable results. We randomly split the training data into three roughly equal parts that were used to carry out three-fold cross validation. In each fold, 60% of the data was used as training data, 7% as valida-

[14] http://dbpedia.org/resource/East_Japan_Railway_Company

tion data to determine when to stop training and 33% was used as the test data shown to the algorithm only after training is complete. The results reported here are the cumulative performance of the algorithms trained on each fold so each entry in the dataset has been seen as a testing example by one fold one time.

4.1 Linear Baseline

Serving as a baseline, we have a straightforward linear model- a perceptron with no hidden layers. The company descriptions are first processed through a standard NLP pipeline for stopword removal and stemming and then each unigram is converted into a one-hot vector representation[15]. The input for the perceptron is the sum of the unigram vectors.

4.2 Customized Linear Model

The second approach is a customized linear model. It utilizes the same NLP preprocessing of the text and feeds into the same linear perceptron but the features include unigrams and bigrams. Each feature is still represented as a one hot vector as in the baseline model.

4.3 GloVe

The third approach serves as a baseline attempt for incorporating context vectors. It uses the same preprocessing steps as the linear baseline approach (i.e. NLP pipeline for stopword removal and stemming, resulting text is processed into unigrams) but instead of one–hot vectors, GloVe vector embeddings are used. Specifically the 300-dimensional GloVe vectors trained on the large Common Crawl corpus of 840 billion tokens with a vocabulary of 2.2 million words. While there is no additional training of the GloVe embeddings for our specific data, the corpus used to extract context is many orders of magnitude greater than our text data.

The resulting vectors are once again fed into a linear perceptron but because the 300-dimensional resulting vector is much smaller than the one-hot representation in the first two experiments, this approach had much lower training times than the other examined alternatives. Training times were generally under a minute instead of 15-60 minutes.

4.4 ULMfit

Finally, we tested one of the state of the art algorithms for classification with context vectors- ULMfit(Howard and Ruder, 2018) by fast.ai[16]. This is the most sophisticated of the four approaches and the one that varies the most from the initial three.

The first major distinguishing aspect of this approach is the text preprocessing. Rather than the traditional NLP stemming pipeline feeding into one-hot vectors, we use all available company descriptions in order to train a fully custom Language Model based on AWD-LSTM which produces our context vectors directly. For the purposes of these experiments, we used the default settings for the network but there is significant opportunity for in-depth exploration of the language model's performance with various configurations.

The classification training step is implemented as an additional layer added onto an already trained language model. The effect allows relative quick initial training of the context vectors followed by some fine-tuning of the context vectors along the specific classification layer training.

5 Discussion

To compare the performance of the four experiments, let's first look at the class-by-class breakdown of their performance as shown in Table 1. There we can see the F1-score achieved by each algorithm on each of the 32 industries. The second column of the table shows the number of companies of that class and we can see there is a very big discrepancy- from over 76 thousand for the largest class to barely 300 for the smallest class. We can similarly observe that the algorithms achieve good results on the larger classes but their performance degrades and becomes increasingly erratic on the smaller classes.

Looking through the data we can make several other observations. Each algorithm has at least a few classes where they get very poor results and several classes where they achieve the highest results. The difference in results is generally inversely proportional to the size of the class although there are some notable exceptions e.g. the bigram linear model significantly underperforms on the 3rd and 4th largest classes. Overall it is not possible to identify a clearly superior algorithm

[15] binary vectors that are all zero values except for the index corresponding to the word or ngram

Table 2: Comparison of overall performance between the four algorithms

by looking at the individual classes although it is worth noting that the bigram linear model performance degraded on some of the largest classes.

If we turn our attention to Table 2, we can examine a micro and macro view of the algorithm performance. The micro-average is obtained by summing up each individual decision of the algorithm while the macro-average is obtained by averaging the scores for each class. The first observation here is that the macro-average recall of the ULMfit is particularly low which makes its macro-average F1 score similarly lower than the others. However, because of the huge class size imbalance demonstrated in Table 1, the macro-average is a poor metric for our particular problem. The conclusion we can draw from this is that ULMfit has achieved some abysmal recall on the smallest classes; a likely cause for this is the lack of stemming in the language model used.

Looking to the micro-averages, the algorithms have achieved much closer performance. The GloVe linear approach is the only one falling significantly behind in F1-score while the hot-bigram model narrowly achieves the best F1-score. To that end there is a clear trade-off, however, with the ULMfit approach having the higher precision while the ngram linear models achieve better recall. As already mentioned, this better recall is likely caused by the stemming in the NLP pipeline which the ULMfit context vectors cannot overcome with the limited size of the corpus.

6 Conclusion and Further Work

The analysis of the results shows that all of the tested approaches produce relatively close results with none emerging as clearly superior to all the others. Overall we observed that ULMfit achieves higher precision while one-hot vector linear models achieve better recall. The linear GloVe vector algorithm achieved inferior results to the other three options overall.

The analysis also shows that the different models have surprisingly varying behavior on the smaller classes indicating that there is still room for improvement in the scores achieved for those smaller classes. ULMfit, while giving comparable results to the linear approaches, presents the best opportunity for that improvement.

There are a few viable directions for exploring further improvement in the performance of the algorithm. One approach would be to work towards improving the reliability of the language model by testing the effect of various parameters or beginning with already trained embedding vectors that are only fine-tuned on our corpus. An alternative direction of experimentation would be to look at the data itself- we know it isn't a true gold standard and expect a relatively large rate of error so it is possible that many of the algorithm "mistakes" are actually errors in the underlying data rather than of the algorithms themselves.

A Quantum-Like Approach to Word Sense Disambiguation

Fabio Tamburini
FICLIT - University of Bologna, Italy
fabio.tamburini@unibo.it

Abstract

This paper presents a novel algorithm for Word Sense Disambiguation (WSD) based on Quantum Probability Theory. The Quantum WSD algorithm requires concepts representations as vectors in the complex domain and thus we have developed a technique for computing complex word and sentence embeddings based on the Paragraph Vectors algorithm. Despite the proposed method is quite simple and that it does not require long training phases, when it is evaluated on a standardized benchmark for this task it exhibits state-of-the-art (SOTA) performances.

1 Introduction

The introduction of the *prototype theory* by E. Rosch (1973), one of the most influential theories describing concept organisation at cognitive level, completely changed the perspective in semantics and nowadays most of the studies in computational semantics consider concepts membership and concepts similarity as graded features in a "semantic space".

In Natural Language Processing (NLP) all the recent and fundamental studies on word and sentence embeddings, e.g. (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2016; Le and Mikolov, 2014; Sutskever et al., 2014; Kiros et al., 2015; Subramanian et al., 2018; Cer et al., 2018), as well as the older works on word spaces based on co-occurence measures, e.g. see the reviews from (Turney and Pantel, 2010; Baroni and Lenci, 2010), rely on an high-dimensional vector space to represent concepts, through the application of the Harrisian distributional hypothesis, collecting contextual information from text corpora, and measuring their relationships by means of some kind of geometric distance.

The fundamental experiments of Tversky (1977) in cognitive psychology on concept similarity and concept combination challenged the common view to adopt the Classical, Kolmorogovian, Probability Theory (CPT) to explain and model these phenomena. Starting from Tversky's data, a large set of newer experimental studies in cognitive psychology showed a systematic violation of the basic axioms of CPT. For example, the classical problem known as the "pet-fish problem" or "guppy-effect" (Osherson and Smith, 1981) is a typical case of overextension in concept conjunction: if we denote as *pet-fish* the conjunction of the concepts *pet* and *fish* and ask people to rate "guppy" as member of *pet*, *fish* and *pet-fish*, they tend to consider it as a highly typical *pet-fish* but neither a particularly typical *pet* nor *fish*. This violates the CPT axiom stating that the probability of the events conjunction must be less or equal to the probability of the single events. In a similar way scholars in cognitive psychology proposed various experiments showing a systematic violations of CPT axioms in concept disjunction, conceptual negation, decision making and some other relevant cognitive processes: see, for example, (Hampton, 1988; Alxatib and Pelletier, 2011; Aerts et al., 2015). These studies show clearly the impossibility of modeling such cognitive phenomena by using CPT and even by using further elaboration of it such as the fuzzy-set probability theory.

In the same field a growing set of studies in the last decades started to explore the possibility of modeling such cognitive phenomena by using different, more sophisticated, probability theories, in particular Quantum Probability Theory (QPT), the foundational calculus of Quantum Mechanics Theory (QMT). We refer the reader to these books or comprehensive reviews for an in-depth introduction to these approaches in cog-

Proceedings of Recent Advances in Natural Language Processing, pages 1176–1185,
Varna, Bulgaria, Sep 2–4 2019.

nitive psychology (Busemeyer, 2012; Haven and Khrennikov, 2013; Pothos and Busemeyer, 2013; Yearsley et al., 2015; Wendt, 2015; Ashtiani and Azgomi, 2015; Aerts et al., 2016a,b; Haven and Khrennikov, 2018). A very large set of these works showed that, by applying the axioms of QPT and taking advantage from the peculiar phenomena modeled by this calculus, such as *superposition*, *interference* and *entanglement*, it is possible to build complete models which are able to well explain all the experimental data and incorporate in the theory all the deviations from CPT exhibited by human behaviours during cognitive experiments. Even if some studies try to find connections by QPT and brain functionality at neural level (Khrennikov et al., 2018), the use of QPT in this field is simply as an explanation theory useful to model real phenomena in the right way, but none of them is really claiming that our brain is working by applying QPT axioms. That is why it is common to use the term “quantum-like” to describe models making use of this calculus in cognitive psychology.

Even if QMT is one of the most successful theories in modern science, the attempts to apply it in other domains remain rather limited, excluding, of course, the large quantity of studies regarding Quantum Information Processing on quantum computers and Electronics. Only in recent years some scholars tried to embody principles derived from QMT into their specific fields, for example, by the Information Retrieval community (van Rijsbergen, 2004; Zuccon et al., 2009; Melucci and van Rijsbergen, 2011; González and Caicedo, 2011; Melucci, 2015), by the Economics and Finance community (Baaquie, 2018) and by the community studying Quantum Computation and Information Theory (Nielsen and Chuang, 2010; Wilde, 2013). In the machine learning field (Arjovsky et al., 2016; Wisdom et al., 2016; Jing et al., 2017) have used unitary evolution matrices to build deep neural networks obtaining interesting results, but we can observe that their works do not completely adhere to QPT and use unitary evolution operators in a way not allowed by QPT. (Moreira and Wichert, 2018) presented an interesting application of QPT for developing Quantum Bayesian Networks. In recent years, also the NLP community started to look at QPT with interest and some studies using it have already been presented (Blacoe et al., 2013; Liu et al., 2013; Kartsaklis et al., 2016; Basile and Tamburini, 2017).

Given this general framework, and the successful results in explaining cognitive experiments, it seemed natural trying to explore the possibility of applying QPT also in NLP and see if the peculiar properties of this calculus could introduce some benefits for solving NLP tasks.

In this paper we will apply QPT for modeling the Word Sense Disambiguation problem testing our proposal on well-known benchmarks. WSD is an historical task which aims to assign the correct word sense for a polysemous word given a linguistic context. The possible senses for a given word are extracted from a reference sense inventory. We refer the reader to the reviews of (Agirre and Edmonds, 2007; Navigli, 2009; Vidhu Bhala and Abirami, 2014) and to the papers describing the last evaluation results (Navigli et al., 2013; Moro and Navigli, 2015; Raganato et al., 2017a) to get a clear picture of the SOTA for this task.

Computational systems solving such task can be broadly divided into two main groups: knowledge-based systems do not require a sense-annotated corpus for training the model and are usually based on lexical or knowledge resources for performing the disambiguation process; on the contrary, supervised WSD systems require a sense annotated corpus in order to train the model and set up all the parameters. Looking at the previously cited evaluations, supervised WSD systems are able to produce the best results and are currently establishing the SOTA: see, for example, (Zhong and Ng, 2010; Iacobacci et al., 2016; Papandrea et al., 2017; Raganato et al., 2017b; Tripodi and Pelillo, 2017; Luo et al., 2018b,a; Melacci et al., 2018; Uslu et al., 2018). Despite these long time studies, the Most-Frequent-Sense baseline is still a strong algorithm challenging all new proposals, and the best systems results are only few points over that baseline.

2 Quantum Probability Theory

This section aims to introduce the basic background knowledge necessary to understand QPT and the underlying mathematical constructions. A more complete introduction about these topics can be found, for example, in (Nielsen and Chuang, 2010; Busemeyer, 2012). It is important to note that QPT is a probability theory more general than CPT and it includes it completely.

Quantum Events

QPT assigns probability to events as well as classical Kolmogorovian probability theory, but, unlike CPT that defines events as sets, it defines events as subspaces of a multidimensional complex Hilbert space $\mathcal{H} = \mathbb{C}^n$.

Quantum States

In QPT the state of a quantum system is defined, using the Dirac notation[1], as a complex vector $|\psi\rangle \in \mathcal{H}$ with $|\, |\psi\rangle \,| = 1$ and, in its general formulation, it can be expressed as

$$|\psi\rangle = \phi_1 |e_1\rangle + \phi_2 |e_2\rangle + ... + \phi_n |e_n\rangle \qquad (1)$$

where ϕ_j are complex numbers called *probability amplitudes*, $\phi_j = \langle e_j|\psi\rangle$, and $\{|e_j\rangle\}$ is a basis of the Hilbert space $\mathcal{H}$. The state in (1) is called a *superposition* state w.r.t. the basis vectors seen as basic states.

For each event subspace spanned by the vector $|x\rangle$, it is possible to build a projector operator $P_x = |x\rangle\langle x|$ that can project a generic state vector $|\psi\rangle$ onto the subspace corresponding to that event.

Quantum Measurements

In QPT, quantum measurements of a variable (or observable) M are usually represented by a set of measurement operators $\{M_k\}$ where the index indicates one of the possible measurement outcomes and $\sum_k M_k^\dagger M_k = I$ (I denotes the $n \times n$ identity matrix). Applying a measurement on a quantum system when in state $|\psi\rangle$ we can compute the probability of getting a specific result k as

$$P(k) = \langle\psi|M_k^\dagger M_k|\psi\rangle\,. \qquad (2)$$

When we measure a quantum system and an event is observed, the act of measuring it changes the state of the system from the superposed state $|\psi\rangle$ to a new state, it is said that the system *collapses*; this new state is given by

$$|\psi\rangle' = \frac{M_k\,|\psi\rangle}{\sqrt{\langle\psi|M_k^\dagger M_k|\psi\rangle}}. \qquad (3)$$

An important class of measurements is known as projective measurements. These measurements are represented by Hermitian observables that admit a spectral decomposition $M = \sum_k v_k P_k$ where $P_k = |u_k\rangle\langle u_k|$ is the projector onto the eigenvector $|u_k\rangle$ of M with eigenvalue v_k and we can compute the probability of obtaining the result k as $P(k) = \langle\psi|P_k|\psi\rangle = |\,\langle u_k|\psi\rangle\,|^2$. The eigensystem obtained by the spectral decomposition imply the assumption of orthogonality between the eigenvectors and thus force measurements on this orthonormal basis of $\mathcal{H}$. Once applied a measurement the system will collapse and no more uncertainty will remain. A further measurement of the outcome k will result in $P(k) = 1$.

There is also another type of measurements, the Positive Operator-Valued Measurement (POVM). Projective measurements require the assumption of orthogonality and are not well suited to measure non-orthonormal states and compute their probabilities. A POVM is a set of Hermitian positive operators $\{E_i\}$ such that $\sum_i E_i = \sum_i M_i^\dagger M_i = I$ is the only requirement. Note that for projective nonorthogonal operators all M_i can be written as outer products of general, non orthonormal, state vectors and we can introduce any number of operators E_i.

Quantum Interference

Interference is one of the most intriguing phenomena arising only in the domain of quantum systems. The classical double slit experiment is often used as a simple example to introduce this phenomenon, see, for example, (Zuccon et al., 2009). Let us shoot a physical particle towards a screen with two slits A and B and, once passed the screen, the particle hits a detector panel behind the screen in a specific position x. By closing one of the two slits, say B, we can compute the probability that the particle hits the detector at a position x passing through A, $P_A(x) = |\phi_A(x)|^2$, or the reverse, by closing A, $P_B(x) = |\phi_B(x)|^2$ where $\phi_A(x)$ and $\phi_B(x)$ are the probability amplitudes associated with the two events $|e_A\rangle$ and $|e_B\rangle$ forming an orthonormal basis for $\mathcal{H} = \mathbb{C}^2$. By applying the classical probability we can compute $P_{AB}(x)$ when both slits are open and the particle can pass either through A or B as

$$P_{AB}(x) = P_A(x) + P_B(x) = |\phi_A(x)|^2 + |\phi_B(x)|^2 \qquad (4)$$

but experimentally we can note that this equality does not hold and that we have to correct equation (4) by applying the QPT adding an *interference*

[1] In Dirac notation $|.\rangle$ is a column vector, or a *ket*, while $\langle.|$ is a row vector, or a *bra*. Using this notation the inner product between two vectors can be expressed as $\langle x|y\rangle$ and the outer product as $|x\rangle\langle y|$. Then $\langle x| = |x\rangle^\dagger$, where † marks the conjugate transpose operation on vectors or matrices.

term:

$$\begin{aligned} P_{AB}(x) &= |\phi_A(x)|^2 + |\phi_B(x)|^2 + I_{AB}(x) \\ &= |\phi_A(x)|^2 + |\phi_B(x)|^2 + \\ &\quad (\phi_A(x)^* \phi_B(x) + \phi_A(x) \phi_B(x)^*) \end{aligned}$$

In summary, the classical Kolmogorovian rule for addition of probabilities when the event can occur in various alternative ways is violated and we have to apply the QPT in order to completely explain the experiments results.

3 Quantum WSD

3.1 Background

The literature on cognitive psychology gives us precious suggestions about the definitions of the elements involved in our problem and on how operationalise them in the framework of QPT.

Concepts can be seen as quantum states described by state vectors, $|\psi\rangle$, in a complex Hilbert space $\mathcal{H}$.

Specific entities or exemplars or, more appropriately in the WSD domain, polysemous words are viewed as superposed states between the referring senses, or concepts, state vectors. For example the vector for a polysemous word $|W\rangle$ can be expressed as

$$|W\rangle = \phi_1 |S_1\rangle + ... + \phi_m |S_m\rangle \qquad (5)$$

where $\{|S_j\rangle\}$ represents the set of all its possible sense vectors.

A context, as a piece of text in a natural language (e.g. a sentence), provides a specific meaning to a polysemous word collapsing its superposition to one of its possible senses. It is described as a measurement operation projecting the system state into a specific subspace spanned by the linguistic context.

In order to transform these general intuitions into a practical system, the crucial step regards the possibility of generating vector representations of words and senses in the complex domain. The large set of works introducing word and sentence embeddings (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2016; Le and Mikolov, 2014; Sutskever et al., 2014; Kiros et al., 2015; Subramanian et al., 2018; Cer et al., 2018) produce representations in the real domain while we need similar vectors but in the complex domain. The next section will show how to transform a classical word embedding approach in order to obtain complex word/sentence embeddings.

3.2 Complex Word/Sentence Embeddings

There are some recent work in literature (Trouillon et al., 2016; Li et al., 2018) proposing techniques for computing complex-valued sentence embeddings to solve a specific task by training a Deep Neural Network (DNN) on the problem output classes. Although strictly connected with our work, these studies learn complex embeddings tailored to a specific task, while we are looking for a procedure to learn general complex representations of words and sentences potentially useful for solving a wide range of tasks.

We took inspiration from the unpublished underdocumented code made available by Théo Trouillon[2] extending `word2vec` code[3] (Mikolov et al., 2013) for working on complex numbers and generating complex word embeddings.

In `word2vec` the skip-gram negative-sampling model is trained minimising the objective

$$E = -log\, \sigma(\mathbf{v'}^T_{w_O} \mathbf{v}_{w_I}) - \sum_{w_j \in \mathcal{W}_{neg}} log\, \sigma(-\mathbf{v'}^T_{w_j} \mathbf{v}_{w_I})$$

where σ is the sigmoid function, w_O is the output word (a positive sample taken from the real context), $\mathbf{v}'_{w_O}$ is its corresponding vector taken from the output weight matrix and $\mathbf{v}_{w_I}$ is the value of the hidden layer that, for skip-gram models, is equivalent to the input word (w_I) vector taken from the input weight matrix.

For extending this model to work with complex numbers we have to transform the input and output weight matrices from real to complex values and adapt the objective function consequently. Unfortunately there are no studies, up to our knowledge, handling directly complex losses and most of the more recent attempts to work with complex neural networks (Trabelsi et al., 2018; Scardapane et al., 2018; Sarroff, 2018) transform the complex loss into a real one by applying some function f to the network output. We can then adapt the objective function as following

$$\begin{aligned} E' &= -log\, \sigma\Big(f\left(\langle \mathbf{v}'_{w_O} | \mathbf{v}_{w_I} \rangle\right)\Big) - \\ &\quad \sum_{w_j \in \mathcal{W}_{neg}} log\, \sigma\Big(f\big(-\langle \mathbf{v}'_{w_j} | \mathbf{v}_{w_I} \rangle\big)\Big) \end{aligned}$$

where $\mathbf{v}'_{w_x}$ and $\mathbf{v}_{w_x}$ are now complex vectors and

[2] https://github.com/ttrouill/imwords.git

[3] https://code.google.com/archive/p/\word2vec/

$f : \mathbb{C} \rightarrow \mathbb{R}$ can be defined as

$$f(z) = \Re(z) + \Im(z) = \frac{z + \overline{z}}{2} + \frac{z - \overline{z}}{2i}.$$

where $\overline{z}$ is the complex conjugate of z.

E' is still a real-valued loss function and, by leveraging the Wirtinger calculus to extend the complex derivative (well defined only for holomorphic functions) to non-holomorphic functions and real-valued analytic functions, we can calculate and backpropagate all the gradients needed to update the network weights:

$$\frac{\partial E'}{\partial \mathbf{v}'_{w_j}} = (1+i) \left[\sigma \left(\langle \mathbf{v}'_{w_j} | \mathbf{v}_{w_I} \rangle \right) - t_j \right] \mathbf{v}_{w_I}$$

$$\frac{\partial E'}{\partial \mathbf{v}_{w_I}} = (1-i) \left[\sigma \left(\langle \mathbf{v}'_{w_j} | \mathbf{v}_{w_I} \rangle \right) - t_j \right] \mathbf{v}'_{w_j}$$

where $t_j = 1$ if $w_j = w_O$ (positive sample), $t_j = 0$ if $w_j \in \mathcal{W}_{neg}$ (negative samples) and i is the imaginary unit.

Le and Mikolov (2014) proposed an extension to the `word2vec` model to build vectors referred to a generic piece of text (phrases, sentences, paragraphs or entire texts). They called this extension "Paragraph Vectors" (PVs). Following their paper and the suggestions given by T. Mikolov for implementing PVs[4], we extended the code accordingly, producing complex paragraph vectors (cPVs) for fragments of texts longer than a word. As in the cited paper, it was sufficient to insert a fake word at the beginning of the paragraph and training it together with all the other words forming the paragraph to obtain, at the end of the training process, reliable dense vector representations for the paragraph in the complex domain as well as complex vector representations for words (cWV). Although this vectors are not derived using QPT and we used the Dirac notation only for consistency, they will enable us to use such complex vectors as the basic elements in our WSD algorithm based on QPT.

3.3 The WSD Model

The proposed model for WSD relies heavily on an external lexical resource for getting all the glosses and examples connected to a specific meaning. WordNet (Miller, 1995), BabelNet (Navigli and Ponzetto, 2012) or other lexical resources providing a large set of senses with their glosses and examples can be used for our purpose.

Given the general considerations made in Sections 3.1 and the complex vector representations introduced in 3.2, we can list the ingredients for our WSD recipe in the following way:

- the target word W to be disambiguated will be represented as the corresponding cWV, namely $|W\rangle$;
- the subspace of $\mathcal{H}$ connected with the sense S, has to be build by combining all the glosses and examples provided by the external lexical resource, seen as the corresponding cPVs, and all the disambiguated contexts extracted from the training set belonging to this specific sense, again seen as cPVs. The whole set of vectors $\{|\mathcal{G}_j\rangle\}$ belonging to a specific sense S are, in general, non-orthogonal each other and thus cannot form a proper basis to define the subspace connected with the sense. A standard procedure to obtain an orthonormal basis spanning the same subspace of a specific set of vectors is based on the Singular Value Decomposition and it is available in any linear algebra library. Given the orthonormal basis spanning the same space of $\{|\mathcal{G}_j\rangle\}$, say $\{|\mathcal{O}_i\rangle\}$, we can build the projector over the subspace spanned by $\{|\mathcal{G}_j\rangle\}$ relative to the sense S as

$$P_S = \sum_i |\mathcal{O}_i\rangle\langle\mathcal{O}_i| \qquad (6)$$

- the context subspace will be represented by all the cPVs corresponding to the sentences belonging to the context and the projector P_C to this subspace can be computed following the same procedure as in the previous point.

Having defined such ingredients, the disambiguation process consists in projecting the word state $|W\rangle$ onto the context subspace by applying the quantum measurement operation of (3)

$$|W_C\rangle = \frac{P_C\,|W\rangle}{\sqrt{\langle W|P_C^{\dagger}P_C|W\rangle}}$$

and then compute, by applying another measurement on the new state $|W_C\rangle$, which of the possible

[4] https://groups.google.com/d/msg/word2vec\-toolkit/Q49FIrNOQRo/J6KG8mUj45sJ

senses of W, $\{S_k\}$, exhibits the maximum similarity with $|W_C\rangle$ or, in other words, the projection of $|W_C\rangle$ over S_k has the maximum probability:

$$\overline{S} = \underset{S_k}{\operatorname{argmax}}\, P(S_k) = \underset{S_k}{\operatorname{argmax}}\, \langle W_C | P^{\dagger}_{S_k} P_{S_k} | W_C \rangle$$

where P_{S_k} is the projector obtained by equation (6) for sense S_k.

4 Experiments

We made two kind of experiments: the first is aimed to evaluate if the proposed procedure to learn complex word/sentence embeddings from texts produces effective results, while the second is devoted to the specific evaluation of our Quantum WSD system (QWSD). Both experiments rely on standard, largely-used evaluations benchmarks.

4.1 Complex Embedding Evaluation

Producing complex sentence embeddings for getting the best performance is not the main focus of this work. We simply need word/sentence representations in the complex domain in order to use QPT to develop our new approach to WSD. Thus, the evaluation of the cPVs is simply devoted to be certain that the cVPs are reliable dense representations of our glosses and contexts sentences.

To test the cPVs we adopted the benchmark proposed by (Conneau and Kiela, 2018) to evaluate sentence embeddings focusing on the five Semantic Textual Similarity (STS) tasks. We chose to apply only these tasks because we are not interested in a complete evaluation, but only in getting a broad idea if our cPVs were reliable enough to build our QWSD model.

Table 1 shows the evaluation results. The performances of our model in the STS tasks are in line with the other basic method for producing sentence embeddings. For a fair comparison, cPVs have the same number of parameters as the other methods, thus, considering that the experiments in (Conneau and Kiela, 2018) were made with vectors of 300 dimensions, our result is referred to complex embeddings with 150 dimensions.

4.2 QWSD Evaluation

In order to evaluate the proposed method to solve the WSD problem we relied, as most of the recent studies, on the standardized evaluation proposed by (Raganato et al., 2017a) for English all-words WSD. This benchmark is based on two corpora for training the systems, namely SemCor (Miller et al., 1994) and OMSTI (Taghipour and Ng, 2015) and five test corpora taken from Senseval/SemEval evaluation campaigns: Senseval-2 (Edmonds and Cotton, 2001), Senseval-3 (Snyder and Palmer, 2004), SemEval-2007 (Pradhan et al., 2007), SemEval-2013 (Navigli et al., 2013) and SemEval-2015 (Moro and Navigli, 2015).

Table 1: Evaluation of sentence representations on the STS benchmarks as the average of Pearson correlations. Systems marked with * use embeddings bigger than 300 dim. Data were taken from (Conneau and Kiela, 2018) and (Perone et al., 2018). At the end the results of the cPVs and the standard PVs in the real domain.

We compare our evaluation results with all the systems already evaluated by (Raganato et al., 2017a) and with the new studies presented in the last two years (Papandrea et al., 2017; Zhong and Ng, 2010; Iacobacci et al., 2016; Raganato et al., 2017b; Luo et al., 2018b,a; Melacci et al., 2018; Uslu et al., 2018).

Most of the studies cited before required complex training phases and they use the SemEval-2007 dataset as the validation set, thus, although we did not need to use it in this way, it has to be excluded from the test sets for evaluating WSD systems. Moreover, most of the previous results were obtained by using only SemCor as training set and we stick to this practice to enable a complete comparability of the various results. The standard metric for this task is the F-score.

The setting for our experiments is very simple:

- we collected the glosses and the examples for a given sense, a Wordnet synset, from BabelNet v3.7.

- with regard to the creation of cPVs, by following the unsupervised procedure described in 3.2, we created a single corpus formed by all the sentences contained in the British

National Corpus[5] joined with the BabelNet glosses and examples for the various senses and all the training and test sets contexts to be used during the evaluation. It is important to underline that we connected the training set context with the correct target word sense, but for the test set we simply connected the contexts to their instance id without any explicit link to the correct results. In other words, the fake words we inserted for generating the cPVs are the correct WordNet sense id string for the training context and the test instance id string for the test contexts. In this way we can retrieve the cPVs when needed without compromising the evaluation. We used the hyperparameters setting proposed in the Mikolov's post cited before without any parameter optimisation (emb. size = 400, win. size = 10, neg. samples = 5, sub-sampl. = 1e-4, iter. = 20, min. word freq. = 5).

- the disambiguation procedure is deterministic and does not have any parameter to tune. We only introduced a limit to the number of senses for each target word equal to 20.

4.3 Results

Table 2 shows the results obtained by the proposed system (QWSD) compared with the results obtained by the SOTA systems on the evaluation framework proposed by (Raganato et al., 2017a). QWSD, despite its simplicity, obtained very good results, not far from those obtained by the best systems on the same benchmark, and it exhibits the best performances in the last evaluation datasets, namely SemEval 2013 and 2015, the best performance when classifying polysemous nouns and the second best for adjectives.

5 Discussion and Conclusions

After the influential paper from Reimers and Gurevych (2017) it is clear that we should report the mean and standard deviation of various runs with the same setting in order to get a more accurate picture of the real systems performances. We had no possibility to reproduce all the results from the other systems because some of them lack of a public code, others do not work well or it is not sufficiently clear how to set up them and for others the results we obtained using the public code and the described parameters are so different from the published ones that, to be fair with the colleagues, we prefer not to take any position on it and thus we put in Table 2 our best result, as some other studies did. In any case, to be consistent with the community trend, we made ten different experiments to generate the cPVs and repeated the training procedure accordingly. Our results over the ten runs are very similar to the best one: 70.1±0.22. The problem of results reproducibility for empirical studies is becoming rather serious (Wieling et al., 2018).

But, why our method is working well? A possible explanation for these results could be traced back to the interference phenomenon. A superposition of state vectors is usually a valid state vector even if they are not orthogonal, thus we can consider the vector representing a polysemous word, $|W\rangle$ as in (5), as a superposition state. As showed by (Khrennikov and Basieva, 2014; Aliakbarzadeh and Kitto, 2016) this can still produce the interference phenomenon even if these vectors are non-orthogonal. The presence of the interference term when computing the word sense probability over the context subspace might explain the good results we obtained. This point deserves further studies in order to verify this idea and understand how to use this term to drive the disambiguation process and obtain even better results.

Our Quantum WSD system relies on complex vector representations for words and sentences; in this study, for ease of experimentation, we tested our proposal by using a simple extension of PVs to the complex domain, but in literature there are techniques to build better word/sentence embeddings that could be extended to the complex domain; the field of complex DNN is very active.

Another interesting idea worth to be explored regards the possibility of solving the disambiguation process for all ambiguous words in the sentence as a single process (Tripodi and Pelillo, 2017) by using specific properties of QMT.

We feel it is worth spending few words on the simplicity of the proposed system. The only training phase regards the production of cPVs and, as well as the standard `word2vec` application, is based on a very simple feedforward neural network employing very few non-linearities. The disambiguation phase based on QPT is fully deterministic and involves few linear algebra operations, namely matrix multiplications and orthogonalisation procedures. Looking at the perfor-

Table 2: Results obtained by the proposed system (QWSD) compared with the SOTA (F-score). The first four columns show the results for the different test sets, while the last five the performances on all the four test sets joined together analysed w.r.t. the different parts of speech.

mances in Table 2 it is clear that the results are very near, and in some case better, than those obtained by system based on intricate DNN structures that require long training processes and a careful parameter tuning. This paper presents the results of a basic quantum system for WSD and the results are very encouraging; more work in this direction could drive to even better systems.

Codes and data are freely available[6].

Abstract

In this paper, we try to understand neural machine translation (NMT) via simplifying NMT architectures and training encoder-free NMT models. In an encoder-free model, the sums of word embeddings and positional embeddings represent the source. The decoder is a standard Transformer or recurrent neural network that directly attends to embeddings via attention mechanisms. Experimental results show (1) that the attention mechanism in encoder-free models acts as a strong feature extractor, (2) that the word embeddings in encoder-free models are competitive to those in conventional models, (3) that non-contextualized source representations lead to a big performance drop, and (4) that encoder-free models have different effects on alignment quality for German→English and Chinese→English.

1 Introduction

Neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015) has emerged in the last few years and has achieved new state-of-the-art performance. However, NMT models are black boxes for humans and are hard to interpret. NMT models employ encoder-decoder architectures where an encoder encodes source-side sentences and an attentional decoder generates target-side sentences based on the outputs of the encoder. In this paper, we attempt to obtain a more interpretable NMT model by simplifying the encoder-decoder architecture. We train encoder-free models where the sums of word embeddings and sinusoid embeddings (Vaswani et al., 2017) represent the source. The decoder is a standard Transformer (Vaswani et al., 2017) or recurrent neural network (RNN) that attends to embeddings via attention mechanisms.

As motivation for our architecture simplification, consider the attention mechanism[1] (Bahdanau et al., 2015; Luong et al., 2015), which has been introduced to extract features from the hidden representations in encoders dynamically. Attention and alignment were initially used interchangeably, but it was soon discovered that the attention mechanism can behave very differently from traditional word alignment (see Ghader and Monz, 2017; Koehn and Knowles, 2017). One reason for this discrepancy is that the attention mechanism operates on representations that potentially includes information from the whole sentence due to the encoder's recurrent or self-attentional architecture. Intuitively, bypassing these encoder layers and attending word embeddings directly could lead to a more alignment-like, and thus predictable and interpretable behavior of the attention model.

By comparing encoder-free models with conventional models, we can better understand the working mechanism of NMT, figure out which components are more crucial, and learn lessons for improvement. Experimental results show that there is a significant gap between the two models. We focus on exploring what leads to the big gap.

As the embeddings in encoder-free Transformers (*Trans-noEnc*) are only influenced by attention mechanisms, without the help of encoders, we hypothesize that the quality of embeddings leads to the gap between Transformers and *Trans-noEnc* models. Thus we conduct both qualitative and quantitative evaluations of the embeddings from Transformers and *Trans-noEnc* models. We also hypothesize that the attention distribution in *Trans-noEnc* is not spread out enough for extract-

[1] We refer to the encoder-decoder attention mechanism unless otherwise specified.

Proceedings of Recent Advances in Natural Language Processing, pages 1186–1193,
Varna, Bulgaria, Sep 2–4 2019.

ing contextual features. However, we find that word embeddings and attention distributions are not the major reasons causing the distinct gap. We further explore NMT encoders. We find that even NMT models with one layer encoder get significant improvement compared to encoder-free models which indicates that non-contextualized source representations lead to the evident gap.

In encoder-free models, the attention attends to source embeddings rather than hidden representations fused with the context. We hypothesize that encoder-free models generate better alignments than default models. We evaluate the alignments generated on German→English (DE→EN) and Chinese→English (ZH→EN). We find that encoder-free models improve the alignments for DE→EN but worsen the alignments for ZH→EN.

2 Related Work

2.1 Understanding NMT

The attention mechanism has been introduced as a way to learn an alignment between the source and target text, and improves encoder-decoder models significantly, while also providing a way to interpret the inner workings of NMT models. However, Ghader and Monz (2017) and Koehn and Knowles (2017) have shown that the attention mechanism is different from a word alignment. While there are linguistically plausible explanations in some cases – when translating a verb, knowledge about the subject, object etc. may be relevant information – other cases are harder to explain, such as an off-by-one mismatch between attention and word alignment for some models. We suspect that such a pattern can be learned if relevant information is passed to neighboring representations via recurrent or self-attentional connections.

Ding et al. (2017) show that only using attention is not sufficient for deep interpretation and propose to use layer-wise relevance propagation to better understand NMT. Wang et al. (2018) replace the attention model with an alignment model and a lexical model to make NMT models more interpretable. The proposed model is not superior but on a par with the attentional model. They clarify the difference between alignment models and attention models by saying that that the alignment model is to identify translation equivalents while the attention model is to predict the next target word.

In this paper, we try to understand NMT by simplifying the model. We explore the importance of different NMT components and what causes the performance gap after model simplification.

2.2 Alignments and Source Embeddings

Nguyen and Chiang (2018) introduce a lexical model to generate a target word directly based on the source words. With the lexical model, NMT models generate better alignments. Kuang et al. (2018) propose three different methods to bridge source and target word embeddings. The bridging methods can significantly improve the translation quality. Moreover, the word alignments generated by the model are improved as well.

Our encoder-free model is a simplification and only attends to the source word embeddings. We aim to interpret NMT models rather than pursuing better performance.

Different from previous work, Zenkel et al. (2019) introduce a separate alignment layer directly optimizing the word alignment. The alignment layer is an attention network learning to attend to source tokens given a target token. The attention network can attend to either the word embeddings or the hidden representations or both of them. The proposed model significantly improves the alignment quality and performs as well as the aligners based on traditional IBM models.

3 Experiments

In addition to training Transformer and *Trans-noEnc* models, we also compare *Trans-noEnc* with NMT models based on RNNs (*RNNS2S*). We train *RNNS2S* models without encoders (*RNNS2S-noEnc*), without attention mechanisms (*RNNS2S-noAtt*), and without both encoders and attention mechanisms (*RNNS2S-noAtt-noEnc*) to explore which component is more important for NMT. We also investigate the importance of positional embeddings in *Trans-noEnc*.

3.1 Experimental Settings

We use the *Sockeye* (Hieber et al., 2017) toolkit, which is based on MXNet (Chen et al., 2015), to train models. Each encoder/decoder has 6 layers. For *RNNS2S*, we choose long short-term memory (LSTM) RNN units. Transformers have 8 attention heads. The size of embeddings and hidden states is 768. We tie the source, target, and output embeddings. The dropout rate of embeddings and Transformer blocks is set to 0.1. The dropout rate of RNNs is 0.2. All the models are trained with a single GPU. During training, each mini-batch contains 2,048 tokens. A model checkpoint is saved every 1,000 updates. We use *Adam* (Kingma and Ba, 2015) as the optimizer. The initial learning rate is set to 0.0001. If the performance on the validation set has not improved for 8 checkpoints, the learning rate is multiplied by 0.7. We set the early stopping patience to 32 checkpoints.

The training data is from the WMT15 shared task (Bojar et al., 2015) on Finnish–English (FI–EN). We choose *newsdev2015* as the validation set and use *newstest2015* as the test set. All the BLEU (Papineni et al., 2002) scores are measured by *SacreBLEU* (Post, 2018). There are about 2.1M sentence pairs in the training set after preprocessing. We learn a joint BPE model with 32K subword units (Sennrich et al., 2016). We employ the models that have the best perplexity on the validation set for the evaluation. We set the beam size to 8 during inference.

To test the universality of our findings, we conduct experiments on DE→EN and ZH→EN as well. For DE→EN, we use the training data from the WMT17 shared task (Bojar et al., 2017). We use *newstest2013* as the validation set and *newstest2017* as the test set. We learn a joint BPE model with 32k subword units. For ZH→EN, we choose the CWMT parallel data of the WMT17 shared task for training. We use *newsdev2017* as the validation set and *newstest2017* as the test set. We apply Jieba[2] to Chinese segmentation. We then learn 60K subword units for Chinese and English separately. There are about 5.9M and 9M sentence pairs in the training set after preprocessing in DE→EN and ZH→EN, respectively.

3.2 Results

Table 1 shows the performance of all the trained models. Encoder-free models (*NMT-noEnc*s) perform rather poorly compared to conventional NMT models.[3] It is interesting that *Trans-noEnc* obtains a BLEU score similar to the *RNNS2S* model. Even though the attention networks only attend to the non-contextualized word embeddings, *Trans-noEnc* still performs as well as the *RNNS2S* by paying attention to the context with multiple attention layers. Tang et al. (2018a) find that the superiority of Transformer models is attributed to the self-attention network which is a powerful semantic feature extractor. Given our results, we conclude that the attention mechanism is also a strong feature extractor in *Trans-noEnc* without self-attention in the encoder.

Model	Param.	PPL	BLEU
Transformer	104.4M	9.6	18.9
Trans-noEnc	71.4M	11.7	15.9
RNNS2S	91.5M	14.9	15.9
RNNS2S-noEnc	64.3M	25.2	12.5
RNNS2S-noAtt	90.3M	33.3	8.2
RNNS2S-noAtt-noEnc	63.1M	53.7	4.1
Trans-noEnc-noPos	71.4M	26.6	7.1

Table 1: The performance of NMT models. PPL is the perplexity on the development set. BLEU scores are evaluated on *newstest2015*. "Param." denotes the number of parameters.

The attention mechanism improves encoder-decoder architectures significantly. However, there are no empirical results to clarify whether encoders or attention mechanisms are more important for NMT models. We compare *RNNS2S-noAtt*, *RNNS2S-noEnc*, and *RNNS2S-noAtt-noEnc* to explore which component contributes more to NMT models.[4] In Table 1, *RNNS2S-noEnc* performs much better than *RNNS2S-noAtt*. Moreover, the gap between *RNNS2S-noEnc* and *RNNS2S-noAtt-noEnc* is distinctly larger than the gap between *RNNS2S-noAtt* and *RNNS2S-noAtt-noEnc*. These results hint that attention mechanisms are more powerful than encoders in NMT.

The positional embedding is also very important to Transformers which holds the sequential information. We are interested in the extent to which the positional embedding affects the translation performance. We further simplify the model by removing the positional embedding in the source (*Trans-noEnc-noPos*). *Trans-noEnc-noPos* has a dramatic drop in BLEU score. It is even worse than *RNNS2S-noAtt*. This result indicates that positional information is indeed crucial for Transformers.

[2] https://github.com/fxsjy/jieba

[3] We also trained a *Transformer* with less parameters (64.3M). The *Transformer* still achieved a significantly better BLEU score (18.2) than *Trans-noEnc* which means that the number of parameters is not the primary factor in this case.

[4] Because the encoders and decoders in Transformers are only connected via attention, we only conduct this experiment on *RNNS2S* models.

Word	Neighbors	
	Transformer	*Trans-noEnc*
more	less, better, greater, most, **further**	less, greater, better, **fewer**, most
for	to, in, on, of, **with**	to, in, of, on, **towards**
ole (not)	olekaan (not the), **kykene** (unable to), kuulu (part of), **pysty** (upright), **ollut** (been)	olekaan, kuulu (part of), **ei** (no/not), **ene** (a suffix), **liity** (sign up)
Arvoisa (honorable)	arvoisa, Arvoisat (honorable), **arvoisaa**, **arvoisan** (honorable), hyvät (honorable)	arvoisa, **arvoisat**, hyvät, Arvoisat, **Hyvä** (honorable)

Table 2: Neighbors of the selected word embeddings. Bold words are distinct neighbors.

4 Analysis

Trans-noEnc is obviously inferior to *Transformer* but we are more interested in investigating what causes the performance gap. In this section, we will test our hypotheses on embedding quality and attention distributions.

4.1 Embeddings

Word embeddings are randomly initialized by default and learned during training. As the embeddings in *Trans-noEnc* are only updated by attention mechanisms, we hypothesize that embeddings in *Trans-noEnc* are not well learned and therefore affect translation performance. We test our hypothesis by (1) evaluating the embeddings in the two models manually and (2) initializing *Trans-noEnc* with the learned embeddings in *Transformer* as pre-trained embeddings.

Qualitative Evaluation We select the 150 most frequent tokens from the vocabulary and then manually evaluate the quality of embeddings by comparing the 5 nearest neighbors.

The quality of English word embeddings is quite good based on the output of neighbors. Finnish word embeddings are not as good as English word embeddings. Table 2 exhibits four examples, two English words, “more”, “for” and two Finnish word, “ole” (not), “Arvoisa” (honorable). The neighbors of “more” in *Transformer* and *Trans-noEnc* are all quite related words, including comparatives and “most” which is the superlative of “more”. The words “further” and “fewer” are more different neighbors but both are related to “more”. For the Finnish word “ole” (not), both models have negative words as neighbors, but there are different unrelated words as well. We can see that the qualities of neighbors in two embedding matrices are close. We cannot easily distinguish which embedding matrix is better based on the neighbors.

Quantitative Evaluation In addition to the qualitative evaluation, we also conduct a quantitative evaluation. We first employ the learned embeddings from *Transformer* to initialize the embedding parameters in *Trans-noEnc*. The pre-trained embeddings can be either fixed or not fixed during training. Table 3 gives the BLEU scores of these models. The pre-trained embeddings slightly improve the BLEU score.

Embeddings	Random	Fixed	Not-fixed
BLEU	15.9	16.1	16.2

Table 3: BLEU scores of *Trans-noEnc*s with different embedding initialization. “Random” means no pre-trained embeddings. “Fixed” and “Not-fixed” denote using pre-trained embeddings.

The evaluation reveals that the embeddings from *Trans-noEnc* are competitive to those of *Transformer*. Thus, we can rule out differences in embedding quality as the main factor for the performance drop.

4.2 Attention Distribution

The attention networks in *Trans-noEnc* only attend to word embeddings. To better capture the sentence-level context, the attention networks need to distribute more attention to the context. We test our hypothesis that the attention distributions in *Trans-noEnc* are not as distributed as those in *Transformer*. If the attention distributions in *Transformer* are more spread out than those in *Trans-noEnc*, it means that smaller weights are distributed to contextual features by *Trans-noEnc*.

$$E_{At}(y_t) = -\sum_{i=1}^{|x|} At(x_i, y_t) \log At(x_i, y_t) \quad (1)$$

We use attention entropy (Equation 1) (Ghader and Monz, 2017) to measure the concentration of the attention distribution at timestep t. We then average the attention entropy at all the timesteps as the final attention entropy. x_i denotes the ith source token, y_t is the prediction at timestep t, and $At(x_i, y_t)$ represents the attention distribution at timestep t. The attention mechanism in Transformer has multiple layers, and each layer has multiple heads. In each layer, we average the attention weights from all the heads.

Figure 1 shows the entropy of attention distributions in both models. The attention distributions are consistent with the finding in Tang et al. (2018b) that the distribution gets concentrated first and then becomes distributed again. *Transformer* has lower entropy, which potentially is because the contextual information has been encoded in the hidden representations. The attention entropy of *Trans-noEnc* is clearly higher than that of *Transformer* in each attention layer. The attention in *Trans-noEnc* tends to extract features from source tokens more uniformly which indicates that the attention mechanism compensates for the fact that embeddings are non-contextualized by distributing attention across more tokens.

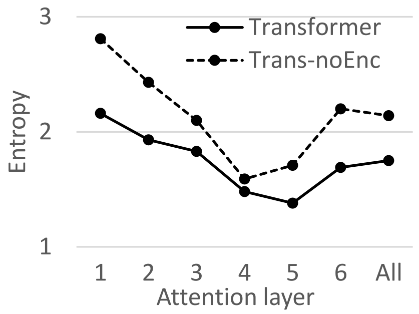

Figure 1: The attention entropy of each attention layer and the entire attention mechanism.

4.3 Encoders

We have shown that embeddings and attention distributions are not the primary reasons causing the gap between *Transformer* and *Trans-noEnc*. Therefore, we move to explore encoders.

Encoders are responsible for providing source hidden representations to the decoder. Encoder-free models have to use word embeddings to represent source tokens without the help of encoders. Thus, the source-side representations probably lead to the performance gap.

We train NMT models with different encoder layers. Table 4 displays the performance of Transformer models that have different layers in the encoder. It is clear that even the model with only a 1-layer encoder outperforms *Trans-noEnc* (0-layer) by 1.7 BLEU points, which accounts for 56.7% of the performance gap. The results seem to show that source-side hidden representations are crucial in NMT.

Layers	Param.	PPL	BLEU
0	71.4M	11.7	15.9
1	76.9M	10.3	17.6
3	87.9M	9.9	18.4
5	98.9M	9.5	18.6
6	104.4M	9.6	18.9

Table 4: The performance of Transformer models that have different layers in the encoder, including the perplexity (PPL) on the development set and the BLEU scores on *newstest2015*.

It has been shown that encoders could extract syntactic and semantic features in NMT (Belinkov et al., 2017a,b; Poliak et al., 2018). In the meantime, contextual information is encoded in hidden representations as well. Hence we conclude that the quality of source representations is the main factor causing the big gap between *Transformer* and *Trans-noEnc*.

In Table 5, our additional experiments on DE→EN and ZH→EN confirm that models with contextualized representations are much better. Transformer models always outperform *Trans-noEnc* models substantially.

Lan.	*Trans-noEnc*	*Transformer*	Impr.
DE→EN	29.5	32.6	10.5%
ZH→EN	18.5	20.9	13.0%

Table 5: The improvement (Impr.) of employing encoders in *Trans-noEnc*s on DE→EN and ZH→EN.

5 Alignment

The weights of the attention mechanism can be interpreted as an alignment between the source and target text. We further explore whether encoder-free models have better alignments than default models. We evaluate the alignments on two manually annotated alignment data sets. The first one has been provided by RWTH,[5] and consists of 508 DE→EN sentence pairs. The other one is from Liu and Sun (2015) and contains 900 ZH→EN sentence pairs. We apply alignment error rate (AER) (Och and Ney, 2003) as the evaluation metric.

Following Luong et al. (2015); Kuang et al. (2018), we also force the models to produce the reference target words during inference to get the alignment between input sentences and their reference outputs. We merge the subwords after translation following the method in Koehn and Knowles (2017).[6] We sum the attention weights in all attention heads in each attention layer.[7] Given a target token, the source token with the highest attention weight is viewed as the alignment of the current target token (Luong et al., 2015). However, a source token maybe aligned to multiple target tokens and vice versa. Therefore, we also align a source token to the target token that has the highest attention weight given the source token. Experimental results show that the bidirectional method achieves higher alignment quality.

Figure 2 displays the evaluation results. The alignment in the fourth attention layer achieves the best performance. Therefore, we only compare the alignments in the fourth layer. In DE→EN, the encoder-free model has a lower AER score (0.41) than the default model (0.43) which accords with our hypothesis. However, in ZH→EN, the alignment quality of the encoder-free model (0.46) is worse than that of the default model (0.43). The effect on alignment quality is not clear-cut for encoder-free models given limited language pairs.

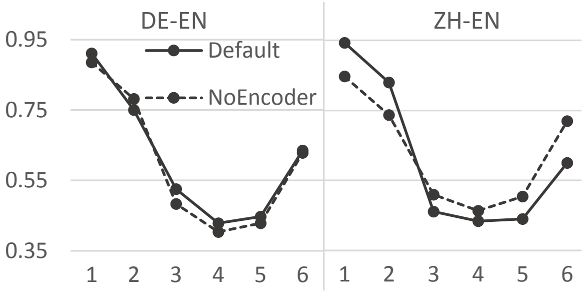

Figure 2: The AER scores of alignments in different attention layers on DE→EN and ZH→EN.

6 Conclusion

To better understand NMT, we simplify the attentional encoder-decoder architecture by training encoder-free NMT models in this paper. The non-contextualized source representations in encoder-free models cause a big performance drop, but the word embeddings in encoder-free models are shown competitive to those in default models. Also, we find that the attention component in encoder-free models is a powerful feature extractor, and can partially compensate for the lack of contextualized encoder representations.

Regarding the interpretability of attention, our results do not show that the attention mechanism in encoder-free models is consistently more alignment-like: only attending to source embeddings improves the alignment quality on DE→EN but makes the alignment quality worse on ZH→EN.

Text-Based Joint Prediction of Numeric and Categorical Attributes of Entities in Knowledge Bases

V Thejas
BITS Pilani, India

Abhijeet Gupta and **Sebastian Padó**
IMS, University of Stuttgart, Germany

Abstract

Collaboratively constructed knowledge bases play an important role in information systems, but are essentially always incomplete. Thus, a large number of models has been developed for Knowledge Base Completion, the task of predicting new attributes of entities given partial descriptions of these entities. Virtually all of these models either concentrate on numeric attributes (`<Italy,GDP,2T$>`) or they concentrate on categorical attributes (`<Tim Cook,chairman,Apple>`).

In this paper, we propose a simple feed-forward neural architecture to jointly predict numeric and categorical attributes based on embeddings learned from textual occurrences of the entities in question. Following insights from multi-task learning, our hypothesis is that due to the correlations among attributes of different kinds, joint prediction improves over separate prediction.

Our experiments on seven FreeBase domains show that this hypothesis is true of the two attribute types: we find substantial improvements for numeric attributes in the joint model, while performance remains largely unchanged for categorical attributes. Our analysis indicates that this is the case because categorical attributes, many of which describe membership in various classes, provide useful 'background knowledge' for numeric prediction, while this is true to a lesser degree in the inverse direction.

1 Introduction

Collaboratively constructed knowledge bases (CCKBs) such as WikiData (Vrandečić and Krötzsch, 2014), YAGO (Suchanek et al., 2008), FreeBase (Bollacker et al., 2008) or DBPedia (Bizer et al., 2009), capture world knowledge in the shape of a graph structure where nodes denote *entities* and edges denote *attributes* (Hitzler et al., 2009). Their collaborative construction importantly enables them to avoid the scaling problems encountered by expert-constructed knowledge bases. Thus, CCKBs have come to play an important role in information systems, forming the basis for a wide range of natural language processing applications (Hovy et al., 2013) such as question answering (Berant et al., 2013; Krishnamurthy and Mitchell, 2015) or representation learning for entities (Toutanova et al., 2015; Yaghoobzadeh et al., 2018).

The most crucial shortcoming of CCKBs is their incompleteness (Min et al., 2013; West et al., 2014) – not just with respect to the entities that they cover, but also with respect to the attributes present for entities that are nominally covered. This is not surprising: When a contributor to a knowledge base adds an entity, they will probably concentrate on the most salient attributes (e.g., for a scientist, *field* or *affiliation*), while other attributes (such as *parents* or *place of birth*) may be added later or never. This realization has led to a large boost to work in the area of *knowledge base completion*, that is, the prediction of attributes of entities that are currently missing from the CCKB (Bordes et al., 2013; Socher et al., 2013; Min et al., 2013; Guu et al., 2015; Gupta et al., 2017).

These methods, however, overwhelmingly concentrate on *categorical* attributes, that is, attributes whose values are themselves entities in the knowledge graph. As an example, consider the attribute *capital* that maps a *country* onto a *city* which is itself an entity (*Mexico – Mexico City, UK – London*). A prominent approach to the prediction of categorical attributes is as an operation in embedding space, which explains the popularity of embedding-based approaches for this task.

Much fewer studies has considered the prediction of *numerical* attributes of entities in CCKBs (Davidov and Rappoport, 2010; Gupta et al., 2015),

Proceedings of Recent Advances in Natural Language Processing, pages 1194–1202,
Varna, Bulgaria, Sep 2–4 2019.

Attribute	Value
latitude	41.90 N
longitude	12.49 E
GDP_per_capita::2015	29,957.8 US$
fertility_rate::2010	1.46
capital	Rome
containedBy	Western_Europe
containedBy	Europe
member_of	G8
member_of	European_Union

Table 1: Sample of numeric and categorical FreeBase attributes for *Italy*.

such as the attribute *GDP-1990* which maps a *country* onto a number denoting its gross domestic product in the year 1990. For many entities in CCKBs, numeric attributes actually form the majority of the attributes for entities. Still, these attributes are often seen as secondary because their values are not 'proper' entities but numeric constants that themselves do not possess interesting attributes.

In this paper, we investigate the hypothesis that *joint prediction of numeric and categorical attributes* can improve prediction quality for both attribute types. As a motivating example, consider the sample of both numeric and categorical attributes listed for the country *Italy* in the FreeBase CCKB (Bollacker et al., 2008), shown in Table 1. It is clear that, as assumed by most models concentrating on categorical attributes, these attributes correlate with one another, and therefore the presence of one attribute can serve as evidence for the presence of another attribute. For example, containment in Western Europe implies containment in Europe, and is correlated with membership in the European Union. However, similar correlations arguably hold between categorical and numeric attributes. For example, the high GDP per capita constitutes evidence for Italy's membership in the G8 political forum, or vice versa, membership in the European Union and the G8 points towards a high GDP per capita. Similarly, Italy's latitude and longitude (defined by FreeBase to be the capital's geolocation) determine Rome as the country's capital, and vice versa.

Concretely, in this paper we adopt two previous embedding-based models for the individual prediction of numeric and categorical attributes from textual data, respectively. We define a novel simple joint model that predicts both attribute types concurrently (Section 2) and evaluate these models on a sample of seven FreeBase domains (Section 3) and find that prediction improves substantially for numeric attributes, but remains constant for categorical attributes (Section 4). Our analysis indicates that this is the case because numeric attributes that are difficult to predict from text-based embeddings are still often correlated with categorical attributes, and that can thus profit from joint training, while this is not true for categorical attributes.

2 Predicting Numeric and Categorical Attributes from Text

The majority of methods to predict attributes for entities in CCKBs are based on techniques from representation learning. Specifically, they us distributed representations (i.e., vectors, also called *embeddings*) to represent the entities, and sometimes also the attributes. Embeddings can be built from different sources, such as the knowledge bases themselves (Bordes et al., 2013; Guu et al., 2015; Lin et al., 2015), from text corpora that mention these entities (Socher et al., 2013; Krishnamurthy and Mitchell, 2015), or from both (Toutanova et al., 2015; Yaghoobzadeh et al., 2018).

In this paper, we use two prediction models that build on embeddings that were built from text corpora, following the widely successful assumption that text corpora implicitly contain a large amount of world knowledge that can be extracted by observing the contexts in which words are used (the so-called distributional hypothesis) (Firth, 1957; Miller and Charles, 1991; Turney and Pantel, 2010; Mikolov et al., 2013). The formulation of attribute prediction on top of precomputed embeddings enables us to use rather simple supervised neural model which are generally considered the state of the art for computational models in natural language processing.

2.1 Numeric Prediction

The first model is a feed-forward neural network, shown on the left-hand side of Figure 1. It builds on a study that used a logistic regression model to predict the values of numeric values, scaled to the interval (0;1) (Gupta et al., 2015) to avoid the excessive influence of outliers that linear regression is sensitive to. The model uses an n-dimensional entity embedding as its input which is mapped through a $\tanh$ nonlinearity onto an h-dimensional hidden layer, which in turn maps onto an $|N|$-dimensional output layer (where $|N|$ is the number of the numeric attributes) using a sigmoid nonlinearity. In other words, each unit in the output layer corresponds to one numeric attribute, and the model predicts all numeric attributes simultaneously.

We use a variant of the mean cross-entropy loss function commonly used for logistic regression. Let $a \in A$ denote an attribute, $E(a) = \text{Tr}(a) \cup \text{Val}(a) \cup \text{Ts}(a)$ the set of entities for this attribute, partitioned into training, validation, and test sets, and $v_a(e)$ and $\hat{v}_a(e)$ the gold and predicted values for entity e, respectively. Then

$$\begin{aligned} L_{\text{num}} = -\sum_{a \in A} & \frac{1}{|A||Tr(a)|} \\ & \sum_{e \in Tr(a)} \big(v_a(e) \log \hat{v}_a(e) + \\ & \qquad (1 - v_a(e)) \log(1 - \hat{v}_a(e)) \big) \end{aligned} \tag{1}$$

Even though simple, this model shows good performance in predicting numeric attributes of entities in CCKBs, since distributed representations implicitly capture a large amount of world knowledge (Gupta et al., 2015) and the hidden layer enables the model to exploit correlations among numeric attributes.

2.2 Categorical Prediction

The second model (Gupta et al., 2017) is another feed-forward neural network, shown on the right-hand side of Figure 1. Again, it uses a precomputed n-dimensional entity embedding as its input. Since this model predicts only the value of one categorical attribute at one time, this embedding is complemented by a representation of the attribute, realized as a one-hot vector whose dimensionality is the number of categorical attributes $|C|$.[1] Again, the input is first mapped onto an h-dimensional hidden layer and then onto an output layer, passing through a $tanh$ nonlinearity in both steps.

In this model, the output layer is n-dimensional, like the input, and actually represents an embedding of the attribute value. For example, given the embedding for *Italy* and the attribute *capital* as input, the model should predict the embedding for *Rome*. To map the output of the model back onto an explicit entity, we perform a nearest-neighbor retrieval in the space of precomputed embeddings, which is feasible with specialized indexes (Babenko and Lempitsky, 2016).

The loss function we use for this model is a contrastive variant of mean squared error (MSE) loss: we minimize the MSE between the prediction and the correct embedding while maximizing the MSE between the prediction and a sample of confounders. Since MSE can be understood as (squared) Euclidean distance, this loss function pushes the predicted embedding towards the correct embedding and away from confounders:

$$\begin{aligned} L_{\text{cat}} = \sum_{a \in A} & \frac{1}{|A||Tr(a)|} \\ & \sum_{e \in Tr(a)} \big((v_a(e) - \hat{v}_a(e))^2 - \\ & \mu \sum_{e' \in \text{NN}(k, \hat{v}_a(e), Y - \{e\})} (v_a(e') - \hat{v}_a(e))^2 \big) \end{aligned} \tag{2}$$

The notation is the same as in Equation (1). Additionally, $\text{NN}(k, x, X)$ is a function that returns the k nearest neighbors of x in the set X, and μ a weight that trades off the positive and negative parts of the loss against each other. In this model, we do not need an indicator function as in the numeric attribute model, since the loss in this model is defined over seen attributes.

2.3 Joint Prediction

The similar structure of the two models described directly above makes it easy to define a joint model for the prediction of categorical and numeric attributes, shown in Figure 2. The new architecture re-uses the input layer from the categorical model, which subsumes the simpler architecture of the numeric one. It uses the same type of hidden layer, to which both the numeric output layer and the categorical output layer are attached. The nonlinearities are the same as in the individual models. Since the input to the model is still an entity embedding plus a categorical attribute, as in the categorical model, the model essentially predicts the numeric attributes of the entity "on the side".

Correspondingly, the loss function of this model is a weighted average of the losses of its parts:

$$L_{\text{joint}} = \alpha L_{\text{cat}} + (1 - \alpha) L_{\text{num}} \tag{3}$$

where α is the relative weight of the categorical loss. For the extreme values of $\alpha = 1$ and $\alpha = 0$, the joint model reverts to its component models.

[1] We experimented with learning a distributed representation of the attributes, but did not achieve better results.

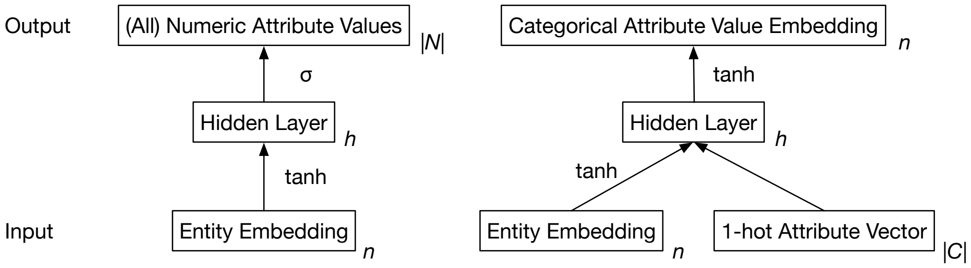

Figure 1: Individual model architectures. Prediction of numeric attributes (left-hand side) and categorical attributes (right-hand side). Subscripts in italics indicate dimensionality of layers (n: dimensionality of embedding space; h: dimensionality of hidden layer; $|N|$: number of numeric attributes, $|C|$: number of categorical attributes)

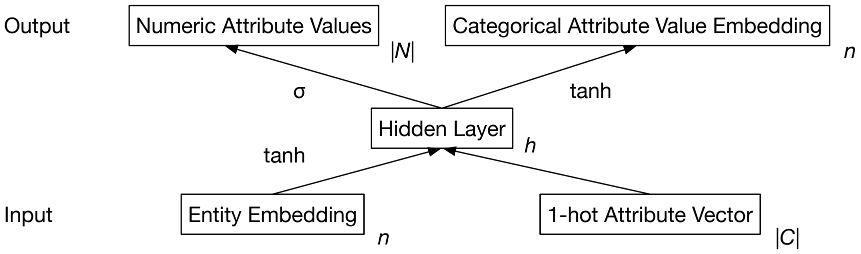

Figure 2: Joint model architecture for the simultaneous prediction of categorical and numeric attributes. Subscripts in italics indicate dimensionality of layers (n: dimensionality of embedding space; h: dimensionality of hidden layer; $|N|$: number of numeric attributes, $|C|$: number of categorical attributes)

Our hypothesis is that intermediate values of α will improve prediction quality for the two types of attributes. We expect this to be the case since joint training can be seen as an instance of multi-task learning, which is known to often positively impact the quality of the learned intermediate representations (Zhang and Yang, 2017). Note that this effect is not guaranteed, since we introduce competition among the two output layers, which may deteriorate the output of the 'losing' layer.

2.4 Discussion

Note that all three model assume that all entities share a common set of attributes: in the numeric model, these determine the shape of the output layer, and in the categorical mode, they determine the shape of the attribute input layer. While it is still possible to train global models, CCKBs are typically organized into top-level *domains* that share little to no attributes. For example, *people* (which have, e.g., birth and death dates) or *organizations* (which have e.g., personnel, turnover, profit numbers) have no attributes in common. Consequently, in the remainder of the paper, we adopt a *domain*-specific approach, learning and evaluating separate models for each domain.

3 Experimental Setup

3.1 Dataset and Embeddings

To our knowledge, there are no existing datasets that include both numeric and categorical attributes. For example, the widely used FB15K and WN18 datasets (Bordes et al., 2013) focus exclusively on categorical attributes. For this reason, we construct our own dataset which we make freely available on DANS at URL `https://doi.org/10.17026/dans-zxp-t7tf`.

We construct the dataset on the basis of the FreeBase CCKB (Bollacker et al., 2008). As sketched above, we proceed by domains and extract entities and attributes for six of the most populous top-level FreeBase domains (*animal, book, citytown, country, employer, organization, people*).

Since we build on pretrained embeddings for the entities in question, we only include entities if they are covered by the largest existing pretrained embedding space for proper names. This is the "Google News" embedding space that used a 100G token news corpus to compute embeddings specifically for FreeBase entities (Mikolov et al., 2013).[2] The embeddings are computed with the Word2Vec

[2] `https://code.google.com/p/word2vec/`

skip-gram algorithm, 1000 dimensions. Similarity, categorical attributes are only included if we have embeddings for both the entity and the value.

Finally, we split all domains into training, validation, and test sets (60%–20%–20%). The split is applied to each attribute type: at validation and test time, our models face no unseen attribute types, but unseen instances for each attribute. In the numeric and joint models, this means that the model will encounter 'incomplete' numeric output layers since some attributes of a given entity may be reserved for testing (cf. the left-hand side of Figure 1 as well as Figure 2). This does not hurt the model, though: The objective function, Equation (1), only ranges over attributes present in the training data.

Table 2 shows descriptive statistics for the resulting dataset. We consider just over 5000 entities for a total of 269 categorical attribute types and 1041 numeric attribute types.[3] Note that the domains differ considerably with regard to their numbers of entities, numbers of attributes, and relative prevalence of categorical and numeric attributes. For example, the *country* domain has the highest number of attributes, and about ten times as many numeric as categorical attributes. This reflects the large number of time series recorded for countries. In contrast, the *organization* domain has much fewer attributes overall, and more categorical than numeric attributes (e.g., location, founders, officers, business sector).

3.2 Evaluation

Categorical Attributes. As explained above in Section 2.2, we apply nearest neighbor mapping to the embedding output of the model to map its prediction back onto an entity symbol. Following earlier work (Gupta et al., 2017), we perform Information Retrieval-style ranking evaluation, mean reciprocal rank (MRR) (Manning et al., 2008). Reusing the notation from Sec. 2 and writing ra for rank, we define MRR as

$$\frac{1}{|T|}\sum_{a\in A}\sum_{e\in \mathrm{Ts}(a)}\frac{1}{\mathrm{ra}(\hat{v}_a(e), \mathrm{NN}(\infty, v_a(e), v_a(\mathrm{Ts}(a))))}$$

For each entity-attribute pair (e, a), MRR computes the (reciprocal) rank of the model's prediction $\hat{v}_a(e)$ in the nearest neighbor list of the true value $v_a(e)$. These values are averaged over all datapoints in the test set Ts.

Intuitively, MRR describes how close, on average, the predictions are to the correct one in terms of ranks: an MRR of 0.5 means that they are the second-nearest neighbors, an MRR of 0.3 means that they are the third-nearest neighbors, and so on. Thus, higher MRR values indicate better performance. We report results at the domain level as well as micro-averaged MRR for the complete dataset.

Numeric Attributes. For numeric attributes, we use the so-called normalized rank score (NRS). NRS is a variant of Spearman's correlation coefficient that takes into account both how correctly the entities in the test set are ranked with respect to each numeric attribute, and how consistent the predictions are with regard to the training set (Frome et al., 2013). We choose this evaluation over a numeric error-based one because it is more robust to outliers and sets a more realistic target for the prediction of numeric attributes (Gupta et al., 2015). NRS is defined as

$$\sum_{a\in A}\frac{1}{|A||\mathrm{Ts}(a)|}\operatorname*{med}_{e\in\mathrm{Ts}(a)}\{|\mathrm{ra}(\hat{v}_a(e), E(a)) - \mathrm{ra}(v_a(e), E(a))|\}$$

NRS measures divergence from the gold standard ranking. It has range [0;1], with smaller numbers indicating better performance: 0.2, for example, means that the prediction is, on average, off by 20% of the ranks. As before, we report the statistic for each domain, plus a micro-averaged NRS for the complete dataset.

3.3 Hyperparameters

Individual Models. We trained the two individual models and the joint model using AdaDelta optimization method, using the best parameters according to the literature (Zeiler, 2012), namely $\rho = 0.95$ and $\epsilon = 10^{-6}$. We trained until convergence or for at most 300 iterations with early stopping. All hyperparameters were explored on the validation set. We explored h, the size of the hidden layer, by setting it to values between 200 and 3000 with a step size of 200. We found h=2000 to yield good results for both models and adopted this number. In the model for categorical attributes, we followed earlier work (Gupta et al., 2017) by using just a single nearest neighbor for the negative part of the loss (k=1) and setting μ to 0.6.

Joint Model. To build the joint model, we retained the hyperparameter settings of the two individual models. We explored values of α between

[3] We removed attributes that were not populated for any entities in our entity set.

Domain	# Entities (train/val/test)	$\lvert C \rvert$	$\lvert N \rvert$
Animal	279/93/93	22	118
Book	16/5/6	8	2
Citytown	1783/594/595	57	62
Country	155/53/51	79	698
Employer	720/140/141	50	55
Organization	187/63/62	36	32
People	85/28/29	25	76
Sum	3225/976/977	277	1043

Table 2: Data set statistics. $|C|$: number of categorical attribute types. $|N|$: number of numeric attribute types

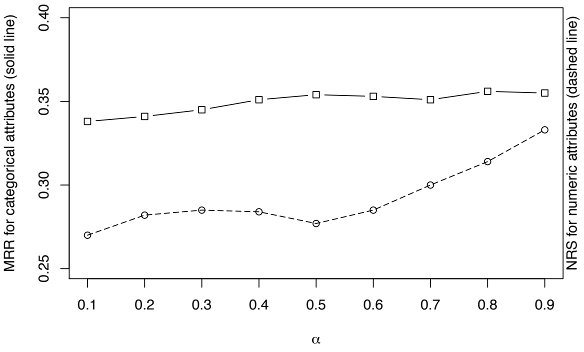

Figure 3: Hyperparameter exploration. Impact of different values of α on the *animal* domain for categorical (solid) and numeric (dashed) attributes (validation set).

0.1 and 0.99 on the validation set of the *animal* domain. The results for the joint model are shown in Figure 3. As expected, there is a trade-off between the two objectives: Results for categorical prediction improve for high values of α, where the model focuses on these attributes. Conversely, results for numeric prediction improve when the model pays more attention to these attributes, for low values of α (recall that lower NRS values are better). We chose $\alpha = 0.6$ as a value that gives both models a chance to profit from the joint setup.

3.4 Inference

Regarding inference in the models, the two individual prediction models are trivial, and so is the categorical part of the joint model:To predict the value of a categorical attribute for an entity, the numeric output can simply be ignored. To predict the value of a numeric attribute of entity, however, different inference procedures are possible. We used the simplest one, namely activating a random categorical attributes to query a numeric attribute (cf. Figure 2). We did not observe meaningful variance across the choice of different categorical attributes.

3.5 Baselines

We use two baseline models from previous studies. For categorical attributes, our baseline model ignores the entity. For each attribute, it predicts the frequency-ordered list of all values seen in the training set (Frequency Baseline). We also report on a baseline that simply models each attribute as a linear operation in embedding space (Mikolov et al., 2013; Bordes et al., 2013) defined as the centroid of all difference vectors for a given attribute between entities and their values for this attribute (Linear Baseline).

For numeric attributes, our baseline model predicts the mean value of the attribute seen in the training set (Mean Baseline).

4 Results and Discussion

Numeric Attributes. Table 3 shows the results as averaged normalized rank scores (NRS) for each domain as well as macro-averaged (Avg) scores for the complete test set. Recall that for NRS lower values are better.

We find that that the joint model (which predicts numeric and categorical attributes at the same time) yields substantially better results than the individual model on all domains, ranging between 0.03 (for *animal* and *people*) and 0.1 (*books*). Average performance on all domains improves from 0.3 by 0.07 to 0.23. In turn, the individual model outperforms the baseline on all domains except *people*, corresponding to a similar improvement by 0.07.

We see the best results of the joint model for *citytown* and the worst results for *people*. These numbers correlate with the numbers of entities present

	Domains							Mean
	Animal	Book	City	Country	Employer	Organization	People	
Joint Model	**0.284**	**0.276**	**0.211**	**0.293**	**0.215**	**0.225**	**0.387**	**0.229**
Individual Models	0.317	0.382	0.288	0.376	0.289	0.300	0.421	0.300
Mean BL	0.370	0.434	0.366	0.416	0.364	0.421	0.394	0.373

Table 3: Test set results on numeric attributes per domain (normalized rank score; lower is better). Best result for each domain marked in boldface.

	Domains							Mean
	Animal	Book	City	Country	Employer	Organization	People	
Joint Model	0.330	0.244	0.198	**0.105**	**0.118**	**0.096**	**0.352**	0.193
Individual Models	**0.331**	**0.256**	**0.202**	**0.105**	0.116	**0.096**	**0.352**	**0.195**
Linear BL	0.215	0.217	0.084	0.046	0.085	0.090	0.250	0.101
Frequency BL	0.247	0.225	0.045	0.018	0.028	0.022	0.173	0.064

Table 4: Test set results on categorical attributes per domain (mean reciprocal rank; higher is better). Best result for each domain marked in boldface.

for these domains (Table 2): citytown is the largest domain, with almost 1800 entities in the training set, while people is the smallest domain with 85 training entities. Thus, we surmise that the differences in performance are not due to inherent differences in the features to be predicted, but reflect the different amounts of training data available.

Categorical Attributes. Table 4 shows the results as mean reciprocal rank (MRR) scores for each domain as well as macro-averaged scores (Avg) for the complete test set. For MRR, higher values are better.

The joint and the individual model outperform both baselines for all domains, and outdistance them substantially in average performance. However, the two informed models show almost identical performance overall, with average MRRs of 0.193 and 0.195, respectively. For three domains (*country, organization, people*), they perform equally well. For one domain (*employer*), the joint model performs better, and for three domains (*animal, book, city*), the individual model does better. The results of the two models are generally extremely close to one another, with the largest difference between the models (of 0.012) appearing for *book*, the smallest domain where we would expect the largest variance. Overall, we attribute these differences to random fluctuation.

The performance of all models is markedly different across domains, with low results close to 0.1 for *organization* and *country* and high results over 0.3 for *animal* and *people*. This is in line with earlier results for categorical attributes that identified the predominance of one-to-many relations across domains as important predictor of performance (Gupta et al., 2017).

Discussion. Probably the most surprising outcome of our experiment is the asymmetry that we observe: Joint modeling achieves respective improvements over individual modeling for numeric attributes, but not for categorical attributes. In other words, the prediction of numeric attributes profits from the availability of categorical attributes, but not vice versa.

One potential explanation is a suboptimal setting of the α parameter (Equation (3)) that would let the joint model pay too much attention to the numeric attributes. However, Figure 3 indicates that this not the case: the change in performance on categorical attributes is relatively minor across values of α, in particular compared to the chance in performance on numeric attributes.

To search for alternative explanations, we performed a qualitative analysis of the models' predictions. What we observe is that many numeric attributes of entities have a relatively low degree of *contextual support* (Gupta et al., 2015), that is, the values of these attributes do not correlate well with salient textual characteristics of the occurrences of the entity name. For example, in the *animal* domain, attributes like 'life span' or 'litter size' describe relatively detailed properties of animal species. Such attributes are unlikely to be represented well in embeddings learned in an unsupervised manner from newspaper text. As another example, the *country* domain contains attributes like 'diesel price' or 'gender balance among members of parliament' that arguably suffer from the same problem.

We believe that the prediction of such attributes can profit from information added to the hidden layer by the categorical part of the objective (Fig. 2), since specific values of categorical attributes provide informative priors. For animals, life span and litter size differ, for example, among different animal classes, orders, etc.; for countries, fuel prices or gender equality are correlated with categorical attributes such as membership in organisations (OPEC, Nordic Council).

For categorical attributes, an earlier study (Gupta et al., 2017) found that difficulty arose both from lack of contextual support and from list-valued attributes. In contrast to the numeric side, though, lack of support for categorical attributes can often not be compensated by access to numeric information. An examples, consider attributes such as 'disputed territories' from the *country* domain, or 'supplier' from the *organization* domain; arguably the values of these attributes is so specific that numeric information cannot help. Nor can the fundamental problem of list-valued attributes be alleviated by numeric information. Instead, this would require a fundamentally different prediction mechanism that supports list-valued attributes (Lin et al., 2015).

5 Conclusion

This paper is located in the area of knowledge base completion, that is, the task of complementing knowledge bases with missing relations, which is particularly pressing for collaboratively constructed knowledge bases. We focus on an understudied subproblem of knowledge base completion, namely the prediction of numeric, as opposed to categorical, attributes.

We assume a text-based approach that uses corpus-derived entity embeddings as the basis for attribute prediction. Building on top of two existing models for categorical and numeric attributes, the first contribution of this paper is a joint model for the prediction of these two attribute types. The second contribution is an empirical evaluation of separate vs. joint modeling on a novel dataset, where we find that numeric attributes profit substantially from a joint model, while categorical attributes do not. A qualitative analysis of the predictions indicates that there is indeed an asymmetry: in cases where the values of numeric attributes are difficult to predict from text-based embeddings, categorical information about the entity can often serve as a prior, whereas difficult-to-predict categorical attributes are often so specific that numeric attributes do not help.

To the best of our knowledge, this paper presents the first joint model for the prediction of numeric and categorical attributes. The joint model that we present is a straightforward combination of individual models for the two attribute types, both of which are purely text-based. A first step to improve the models would be to learn, or at least fine-tune, text-based embeddings in a task-specific manner, in order to enable the embeddings to pay attention to infrequent context cues that are nevertheless highly informative for particular attributes. On a more fundamental level, embeddings can be made to take both textual evidence and the structure of the knowledge base into account, as has been demonstrated for categorical attributes (Toutanova et al., 2015; Yaghoobzadeh et al., 2018). Finally, a direction for future research that would address in particular the difficulties in predicting categorical attribute could be the development of a neural architecture that explicitly accounts for list-valued attributes.

Abstract

Arabizi is an informal written form of dialectal Arabic transcribed in Latin alphanumeric characters. It has a proven popularity on chat platforms and social media, yet it suffers from a severe lack of natural language processing (NLP) resources. As such, texts written in Arabizi are often disregarded in sentiment analysis tasks for Arabic. In this paper we describe the creation of a sentiment lexicon for Arabizi that was enriched with word embeddings. The result is a new Arabizi lexicon consisting of 11.3K positive and 13.3K negative words. We evaluated this lexicon by classifying the sentiment of Arabizi tweets achieving an F1-score of 0.72. We provide a detailed error analysis to present the challenges that impact the sentiment analysis of Arabizi.

1 Introduction

Arabizi, a portmanteau of *Arabic* and *Englizi* (English), is a written form of dialectal Arabic (DA) often used by Arabic speakers for informal communication in messaging applications and on social media enabling them to type Arabic words using Latin letters (Yaghan, 2008). Arabizi lacks a consistent orthography and reflects the various dialects of Arabic, which differ from one Arab region to another and from the formal Modern Standard Arabic (MSA) phonetically, morphologically, and syntactically.

Studies show that Arabizi has reached 12% of the Latin script tweets in Lebanon and 25% of the Latin script tweets in Egypt (Tobaili, 2016). It is a common way of communication among the youth (Keong et al., 2015; Muhammed et al., 2011; Allehaiby, 2013) and has been actively used during relevant events in the Arab world such as the Arab spring (Basis-Technology, 2012). Despite the growth of this newly born written language, Arabic sentiment analysis approaches often disregard Arabizi text due to the challenges it poses and the scarcity of NLP resources to process it (Bies et al., 2014).

In this work we contribute to the sentiment analysis of Arabizi by creating a new Arabizi sentiment lexicon (SenZi) for the Lebanese dialect. We annotated a 3.4K Arabizi Twitter dataset to evaluate the lexicon and to train an Arabizi language identifier. We used this identifier to create an Arabizi corpus of 1M public Facebook comments. We widened the coverage of SenZi by enriching it with inflectional and orthographic forms for each sentiment word using word embeddings on the corpus reaching 11.3K positive and 13.3K negative words. All resources and detailed description are made public and freely accessible on the project's webpage[1].

The rest of the paper is structured as follows: Section 2 explains the nature of Arabizi and the challenges it poses. Section 3 reviews the related work. Section 4 presents the annotated datasets and the compiled corpus. Section 5 presents the pipeline for creating SenZi. Section 6 presents the sentiment analysis and results. Section 7 discusses the contributions and limitations of this work. Finally, Section 8 concludes the paper.

2 Background and Challenges

Arabizi privileged its users to transcribe their mother tongue dialect in Latin script at their comfort, free of grammar and orthographic rules. This section dissects the formation of Arabizi, the linguistic issues associated with it, and the challenges it poses onto NLP.

2.1 Background

Arabizi naturally inherits the rich morphology of Arabic but introduces an inconsistent orthography

[1] https://project-rbz.kmi.open.ac.uk

Proceedings of Recent Advances in Natural Language Processing, pages 1203–1211,
Varna, Bulgaria, Sep 2–4 2019.

and codeswitching.

Morphology: Arabic is an inflectional language where a given word may have a wide range of inflectional forms to express gender, tense, case, number, or perspective. Each of these inflectional forms could be written with different pronoun affixes. An Arabic lemma is inflected by the attachment of clitics, prefixes, and suffixes, the insertion of infixes, or the deletion or replacement of some letters, resulting in a deep morphological shift. For example, the following dialectal words are few inflectional forms of the word زكي *zake / smart*: *azkiya, zakeya /smart-people* (regular and irregular plural forms), *tetzeka, tetzeke, tetzeko / you-are-outsmarting* (masculine, feminine, and plural), *azka / smarter-than*, and *ma azkek, azkekon, azkeke / how-smart-you-are!* (masculine, feminine, and plural).

Orthography: Arabic is rich in guttural phonemes. It contains two voiceless fricatives خ ح, two voiced fricatives ع غ, a voiced plosive ق, and a glottal stop ء. It also contains distinct consonants with similar phonemes known as soft and emphasised or heavy consonants. Arabic contains five pairs of light and heavy consonants: *q*: ك ق, *t*: ط ت, *d*: د ض, *s*: ص س, and *th*: ذ ظ. This is even exacerbated in Levant Arabic where the ق *q* is pronounced as a glottal stop ء, both ظ and ذ *th* (as in *them*) as ز *z*, and the ث *th* (as in *thrill*) as س *s*. Additionally, there are short and long vowel letters. Short vowels are the diacritics, marks above or below the letters as in كَتَبَ, but they are not scripted in most social texts as in كتب, because a native reader would comprehend the text without the diacritics. These factors had lead to an inconsistent orthography in the transcription of Arabic in Latin script. Moreover, users map the Arabic phonemes with Latin alpha numeral in accordance with their dialect, some transcription standards of the region, and their individual choice of letters. For example:

1. Dialect: The guttural ق *q* is expressed as a guttural *g* in Gulf Arabic but a glottal stop ء in some Levantine Arabic dialects, therefore it is mapped with the number 2 in Levant dialect Arabizi e.g., قلبي *qalbi / my heart* in MSA, *galbi* in Gulf Arabizi, and *2albi* or *albi* in Levant Arabizi.
2. Transcription Standards: Some transcriptions became normalised among Arab regions, such as mapping the guttural consonants غ and خ with the numerals 8 and 5 in some countries like Egypt and Jordan (Aboelezz, 2009; Allehaiby, 2013; BIANCHI, 2012) while *gh* and *kh* are more common in Lebanon (Sullivan, 2017).
3. Choice of Letters: It is up to every user's personal choice whether to transcribe some, all, or none of the vowel phonemes either because the short vowels are diacritics or the text is informal and readable without the vowel letters. The following words are few orthographic forms of the word حبيبي *habibi / darling* or *my-love*: *7abibi, 7bb, 7bbi, 7abebe, 7bibi, hbb, or habb*.

Codeswitching: Arabizi users constantly switch between Arabizi and Latin script languages, mainly English and French. For example, *Hi! kifak, cava?*, a common trilingual greeting from Lebanon. Codeswitching may occur within individual sentences or within conversations, posing a challenge for data collection and analysis.

2.2 Challenges

Lexical Sparsity: As mentioned earlier (in Section 2.1), Arabizi words can derive a large range of inflectional forms and each form can be transcribed in several orthographic variants. This leads to a high degree of lexical sparsity. Therefore, sentiment lexicons with one or few forms for each sentiment word are insufficient to capture the high number of inflections and variants that could be derived from each Arabizi word.

Word Ambiguity: Apart from words that are naturally polysemous, transcribing Arabic phonemes that have no equivalent in English Latin script may lead to ambiguity. Ambiguous words are generated by:

1. Transcribing a short Arabic vowel phoneme, a diacritic, as a vowel letter in Latin script. For example, transcribing the word ضيعة (short vowel *a*, a diacritic originally) / *village* as *day3a* becomes ambiguous with ضايعة (long vowel *a*) / *lost* or *confused*.
2. Transcribing one Latin script letter for two distinct Arabic letters. This is common for the soft and heavy consonants. For example, transcribing درب (soft *d*) / *route* as *dareb* be-

comes ambiguous with ضرب (heavy *d*) / *hit*.

Transliteration: Transliteration in this context is the automatic conversion of Arabizi into Arabic script. With the heterogeneity of Arabic dialects and the inconsistency of orthography, transliteration can not be achieved in a straightforward Latin to Arabic mapping. The most accurate transliterators are online tools that generate a list of possible transliterations for every input word such as Yamli[2] and Google Input Tools[3]. These tools are designed to help Arabic users output MSA text by typing in Latin script Arabic word by word. Transliterating whole Arabizi texts to Arabic produces orthographic errors. Google Translate for example, detects Arabizi, converts it to Arabic, and translates it to the target language. It translated the tweet *da5l jamelik w hadamtik / Oh-my (expression), your-beauty and your-humour (feminine)* to *inside your camel and demolished* due to the dialect (Lebanese), choice of letters, and word ambiguity.

3 Literature Review

Recent efforts in creating lexical resources for Arabic focus mainly on MSA (Badaro et al., 2014; Eskander and Rambow, 2015; Al-Twairesh et al., 2016) and DA (Abdul-Mageed and Diab, 2014). Several works that analysed sentiment from Arabic social data filtered out Arabizi completely from their datasets (Al-Kabi et al., 2013, 2014; Duwairi and Qarqaz, 2014), missing the sentiment from a considerable portion of the population in general and the youth in specific.

To the best of our knowledge, (Duwairi et al., 2016; Mataoui et al., 2016; GUELLIL et al., 2018) are the only works that looked into sentiment analysis for Arabizi. All three papers proposed to transliterate Arabizi to Arabic. (Duwairi et al., 2016) transliterated Jordanian dialect Arabizi to Arabic using their own transliterator without evaluating the transliterations. (Mataoui et al., 2016) transliterated Algerian dialect Arabizi as part of their sentiment analysis for Algerian Arabic pipeline. They used Google Translate without evaluating the transliterations as well. (GUELLIL et al., 2018) created a rule-based transliterator that generates several transliterations per word, then used a language model based on a large corpus to select the best transliteration. Thus, minimising the error of transliteration but maximising the complexity of the task.

The following papers propose sophisticated works for transliterating Egyptian (Darwish, 2014; Al-Badrashiny et al., 2014; Eskander et al., 2014) and Algerian dialect Arabizi (Guellil et al., 2017). The limitations of these works include transliterating datasets manually, hand-crafting rules to preprocess and normalise Arabizi, and mapping Arabizi with Arabic heuristically.

In this work we aim to advance the state of the art in Arabic sentiment analysis by analysing Arabizi directly, without the need to filter, preprocess, or transliterate it.

4 Data Collection and Annotation

This section describes the collection and annotation of Twitter datasets to evaluate SenZi and train an Arabizi identifier. It then describes the creation of a Facebook corpus that was used (in Section 5.2) to enrich SenZi with inflectional and orthographic forms.

4.1 Annotated Twitter Datasets

Collection: We used the Twitter stream API to collect live tweets that have geographic coordinates lying within the region of Lebanon. We collected 177K tweets intermittently over the period of one year, between 2016 and 2017. We filtered out the Arabic tweets that were identified by Twitter as Arabic: ar (80K). The remaining dataset contains 97K tweets in Latin script such as, Arabizi, English and French or codeswitched tweets among these languages. Twitter misidentified Arabizi and codeswitched tweets as (ht, tr, in, hi, pt, nl, ct, ey) where some stand for (Haitian, Turkish, Hindi, Portuguese, and Dutch). To accurately identify the Arabizi tweets, we resorted for a manual annotation task.

Preprocessing: We removed the URLs, hashtags, mentions, and non-ASC characters and deleted duplicated tweets and tweets that lack an alphabet, obtaining a filtered dataset of 66K tweets.

Annotation: We selected 30K tweets randomly and created a user friendly annotation platform that displays these tweets in different random order for every user. The platform asks each user:

1. Is the tweet written mostly in Arabizi?
   (*yes, no, I don't know*)

[2] http://www.yamli.com

[3] http://www.google.com/inputtools/try

2. What is the sentiment of the tweet? (*positive, negative, neutral, I don't know*)

We assigned this task to three Lebanese undergraduate students and guided them to:

1. Count the number of Arabizi words in codeswitched tweets to determine if these tweets are mostly written in Arabizi.
2. Consider the sentiment that the tweets infer regardless of present expressions e.g., *haha tabashna bl exam* / *haha we failed the exam* is a negative tweet.
3. Answer *I don't know* for ambiguous tweets.

A screenshot of the developed annotation platform is presented in Figure 1. Further details about the platform and the annotation process can be found on the project's webpage.

Results: Table 1 presents the annotation of the 30K tweets for Question 1: *Is the tweet written mostly in Arabizi?* We had a total of 4.3K *yes*, 27.6K *no*, and 641 *I don't know*. We applied Fleiss' Kappa (Fleiss, 1971) to measure the agreement among the annotators scoring a substantial agreement of 0.74 (Landis and Koch, 1977).

Table 1: Arabizi Annotation of 30K Tweets

Tweets	Arabizi	Not Arabizi	IDK	Kappa
30K	4.3K	27.6K	641	0.74

From the 4.3K Arabizi tweets, there were (3.4K tweets) where at least two answers match for *Arabizi-yes* and (2.2K Tweets) where all three answers match for *Arabizi-yes*. We balanced the 2.2K Arabizi with a 2.2K non-Arabizi tweets to create an Arabizi identification (AI) dataset.

Table 2 presents the annotation of the (3.4K tweets) for Question 2: *What is the sentiment of the tweet?* We had a total of 1.2K *positive*, 1.4K *negative*, 2.1K *neutral*, and 172 *I don't know* scoring a fair agreement of 0.33 Fleiss' Kappa.

Table 2: Sentiment Annotation of the (3.4K Tweets)

Tweets	Pos	Neg	Neutral	IDK	Kappa
3.4K	1.2K	1.4K	2.1K	172	0.33

From the 3.4K Tweets, there were (2.9K Tweets) where at least two answers match for the sentiment of the Arabizi tweets. They consist of 801 *positive*, 881 *negative*, 1.2K *neutral*, and 7 *I don't know*. We balanced an 800 positive with 800 negative tweets to create the sentiment analysis (SA) dataset.

As a result, we had two datasets:

1. AI Dataset: 4.4K Tweets (2.2K Arabizi and 2.2K not Arabizi).
2. SA Dataset: 1.6K Arabizi Tweets (800 positive and 800 negative).

We used the AI Dataset to train the Arabizi identifier (in Section 4.2) and the SA Dataset to evaluate SenZi (in Section 6.1).

4.2 Automatic Arabizi Identification

We used the AI Dataset (from Section 4.1) to train a Support Vector Machine (SVM) classifier with the tweets' unigrams as input features. We shuffled the dataset and split it into 10 folds for cross validation. The average of the classification results for all folds are presented in Table 3.

Table 3: Arabizi Identification
4.4K Tweets: 2.2K Arabizi - 2.2K non-Arabizi

Recall	Precision	F1-score	Accuracy
0.93	0.97	0.95	0.95

4.3 Facebook Corpus

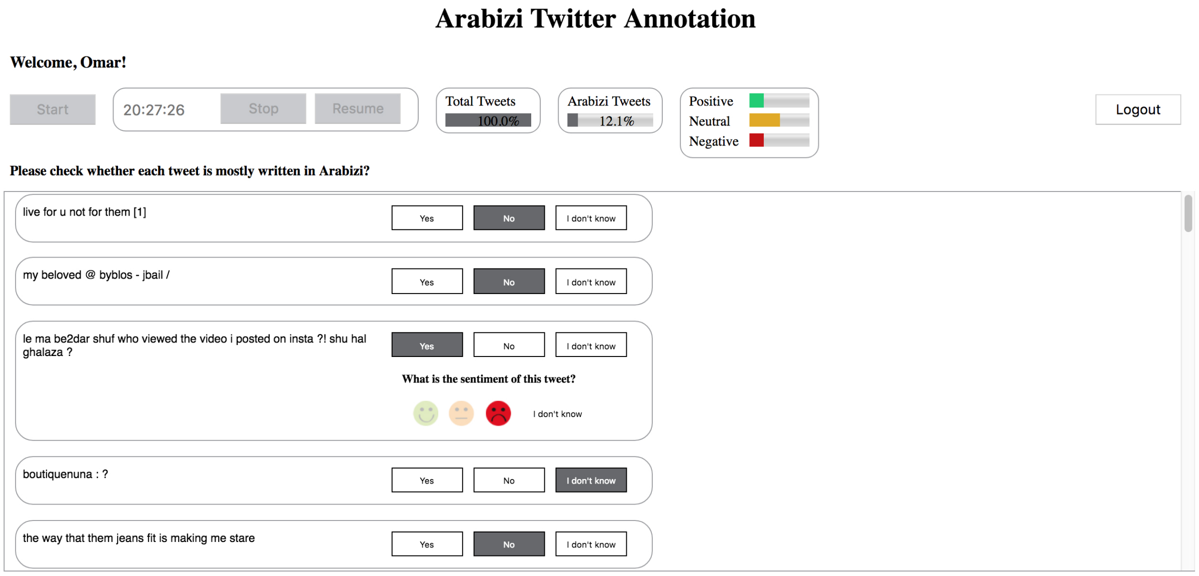
We created an Arabizi corpus of 1M Facebook public comments collected from 49 popular and active Lebanese pages[4]. The pages vary in genre such as, news, comedy, and politics. We used this corpus (in Section 5.2) to create a word embeddings space to discover inflectional and orthographic forms of SenZi's sentiment words.

Collection: We wrote a script that uses Facebook API to iterate over all posts (texts, images, and videos) in a public page and extract all the comments and replies from every post. It collects all Latin script comments and replies in reverse chronological order up to the very first post posted by the page. As we extracted the comments and their replies, we skipped comments that contain Arabic text. We ran the script over the 49 public pages in 2017 resulting in a 2.2M Latin script Facebook comments.

Preprocessing: We removed the URLs, mentions, and media attachments and deleted duplicated comments and comments that lack an alphabet, reducing the comments to 2.1M.

Identification: We used the trained Arabizi identifier (from Section 4.2) to identify the Arabizi text, obtaining a corpus of 1M Arabizi Facebook comments.

[4] The list of pages can be found at the project's webpage.



20:27:26

Total Tweets 100.0%

Arabizi Tweets 12.1%

Please check whether each tweet is mostly written in Arabizi?

live for u not for them [1] — Yes [✓ No] I don't know

my beloved @ byblos - jbail / — Yes [✓ No] I don't know

le ma be2dar shuf who viewed the video i posted on insta ?! shu hal ghalaza ? — [✓ Yes] No I don't know

What is the sentiment of this tweet? — 🙂 😐 [✓ ☹] I don't know

boutiquenuna : ? — Yes No [✓ I don't know]

the way that them jeans fit is making me stare — Yes [✓ No] I don't know

Figure 1: Annotation Platform

5 SenZi

This section presents the pipeline of building SenZi. It was built in two phases:

1. Lexicon Generation: Using existing resources to generate an initial list of Arabizi sentiment words.
2. Lexicon Expansion: Expanding this sentiment word list using the created Facebook corpus (from Section 4.3).

5.1 Lexicon Generation

Resources: We started with two English sentiment lexicons and one Lebanese dialect word list as seeds to build SenZi. We chose two of the most common English sentiment lexicons in the literature: Hiu and Liu[5] (2K positive and 4.8K negative) and the MPQA[6] (2.7K positive and 4.9K negative) (Wilson et al., 2005). LivingArabic is a list of 7.1K Lebanese dialect words compiled by the Living Arabic project[7]. We generated the Lebanese Arabizi sentiment words in five steps:

1. Combine the existing English lexicons.
2. Translate to Arabic.
3. Select the dialectal sentiment words.
4. Combine the resulting Arabic lexicons.
5. Transliterate to Arabizi.

5.1.1 Combination: English Lexicons

We took the union of Hiu Liu and MPQA to have a list of 2.7K positive and 5.1K negative words. We call this list HL-MPQA.

5.1.2 Translation

We used an online dictionary *bab.la*[8] to translate HL-MPQA to MSA. We wrote a script that inputs every word from HL-MPQA into *bab.la* and copies the single-word translations keeping the multi-word expressions for a future work. We generated 4.2K positive and 5.2K negative unique MSA words. We call this list HL-MPQA-Ar.

5.1.3 Selection

HL-MPQA-Ar: Since we aimed to create a Lebanese dialect lexicon, we needed to filter HL-MPQA-Ar from terms that are not common to the Lebanese dialect. We asked a Lebanese graduate student to select the dialectal sentiment words. The student selected 537 positive and 1K negative dialectal terms.

LivingArabic: We assigned an annotation task to three undergraduate Lebanese students to select the sentiment words from LivingArabic. The students selected 531, 672, and 1K sentiment words. We took 732 words (179 positive and 553 negative) where at least two students had agreed on the sentiment.

[6] https://mpqa.cs.pitt.edu/lexicons/subj_lexicon

[7] http://www.livingarabic.com

[8] https://bab.la

5.1.4 Combination: Arabic Lexicons

We took the union of the selected dialectal words from HL-MPQA-Ar and the selected sentiment words from LivingArabic to have a list of 607 positive and 1.4K negative Arabic words.

5.1.5 Transliteration

We asked the Lebanese graduate student to transliterate the resulting dialectal Arabic words to Arabizi. This marked the first version of SenZi, consisting of 2K Arabizi words (607 positive and 1.4K negative).

5.2 Lexicon Expansion

As mentioned in Section 2, Arabizi inherits the rich morphology of Arabic and introduces an inconsistent orthography causing a high degree of lexical sparsity. We addressed this challenge by expanding SenZi automatically to cover a range of inflectional and orthographic forms for each sentiment word.

We created a word vector space by training a word embeddings fastText skipgram model (Bojanowski et al., 2016) on the 1M Arabizi FB comments corpus (from Section 4.3). We retrieved a vector of nearest word neighbours for every SenZi word. Then, we matched the inflectional and orthographic forms from the retrieved vector with the SenZi word automatically. We learned heuristically that a retrieved Arabizi word is a form of a SenZi word if it contains the same sequence of consonant letters of that SenZi word. We maximised the inflectional and orthographic forms from the retrieved vector by normalising its words lightly to stay consistent with the words of SenZi. We ran this expansion twice, recursively.

5.2.1 First Expansion:

1. Retrieve a vector of 50 nearest word neighbors for each SenZi word.
2. Normalise the orthography of these words:
   - Replace *8, 5* and *ch* with *gh, kh* and *sh.*
   - Remove repeated letters (exaggeration).
3. Take the nearest word neighbors (in their original form, before normalisation) that contain the same consonant letter sequence of the SenZi word.

For example, the consonant letter sequence *tyb* from the word *tayab* / *cute* or *tasty* matched 30 inflectional and orthographic forms such as, *atyab, atyabak, atyabo, 2tyab, tayoub, taybe, tayoubi, taybeee, taybin,* and *tayoubin,*.

We note that applying this technique against all words in the corpus would match many irrelevant words because most Arabic words stem from triliteral words, but in this case we are limited with the nearest word neighbors, i.e., words that are semantically related.

This expanded SenZi to 12.3K words (5.1K positive and 7.2K negative).

5.2.2 Second Expansion:

1. Retrieve a vector of 50 nearest word neighbors for each *new* word.
2. Normalise the orthography of these words.
3. Take the nearest word neighbors that contain the same consonant letter sequence of the *original* SenZi word (not the new word).

For example, the word *atyabak* was retrieved in the first expansion of the word *tayab*. In the second expansion we match the consonant letter sequence *tyb* of the original word *tayab* with the word neighbors of the newly retrieved word *atyabak*. This further expanded *tayab* with two new inflectional forms of *atyabak* in two different orthographies *atyabek, atyabik, atyabkon,* and *atyabkoun* / *cute-singular-feminine* and *cute-plural* in the second person perspective.

We cleaned SenZi by deleting duplicates of words and words that occurred in both the positive and negative lists. This further expanded SenZi to 24.6K words (11.3K positive and 13.3K negative).

6 Evaluation

This section describes the sentiment analysis approach and results and presents a manual error analysis.

6.1 Evaluation Setup and Results

We followed the evaluation method of AraSenti, an Arabic sentiment lexicon proposed by (Al-Twairesh et al., 2016), to evaluate SenZi. we applied a 2-class sentiment classification using a simple lexicon-based approach. We evaluated SenZi before and after the expansion against the SA Dataset (from Section 4.1) which consists of 800 positive and 800 negative tweets.

We created a list of 10 negators and expanded it to 170 words[9] using the same lexicon expansion technique. We classified a sentiment word in its opposite sentiment class if it is preceded by a

[9] List of negators available at the project's webpage.

negator. However, the negator ما *ma* acts as an intensifier in some cases. For example, the *ma* in *ma ajmala! / How beautiful-she/it-is!* precedes an inflection of *jamil / pretty* that begins with a glottal stop أ *2* or *a*, we therefore exempted this negator from negation if followed by a glottal stop.

We matched the positive and negative words in the tweets with SenZi and classified the tweet *positive* if the positive matches were greater than the negative matches, *negative* if the negative matches were greater than the positive matches, and *no sentiment* otherwise. Since this is a 2-class classification and the dataset is balanced, we classifed tweets with *no sentiment* as *positive* or *negative* randomly. The average results are presented in Table 4.

Table 4: SenZi Evaluation
Lexicon-Based Classification

	R	P	F	A
SenZi Original	0.56	0.59	0.57	0.58
SenZi 1st Expansion	0.74	0.64	0.69	0.67
SenZi 2nd Expansion	0.79	0.66	0.72	0.69

Enriching SenZi with inflectional and orthographic forms pushed the F1-score by a solid 0.15 over the baseline. This implies that the word forms and variants play a significant role in sentiment analysis for Arabizi.

6.2 Error Analysis

We provide a detailed error analysis for the lexicon-based classification using the best version of SenZi (2nd expansion) in classifying 800 positive and 800 negative tweets (SA Dataset from Section 4.1). The confusion matrix of this classification is presented in Table 5.

Table 5: Confusion Matrix
Lexicon-Based Classification

Actual	Classified		
	Positive	Negative	No Sentiment
Positive	55%	3%	42%
Negative	13%	39%	48%

Most of the error (45%) lies in not determining a sentiment class for the tweets. As such, we extracted a sample of 100 positive and 100 negative tweets that were wrongly classified for a manual assessment. We checked all the words in the sample whether matched or missed by SenZi. The challenges that impact the performance of the lexicon-based approach and their percentages are presented in Table 6 followed by a small discussion for each challenge.

Sentiment form not in the lexicon: The main factor for not classifying sentiment tweets was due to lexical sparsity, the same challenge that we addressed in this paper. Although we expanded SenZi from 2K to 24.6K words with an increase of 0.23 in recall, it still did not match 38% of inflectional and orthographic forms of SenZi's sentiment words.

Sentiment word is in English: Although the Twitter dataset was annotated as mostly Arabizi, 12% of the unclassified sentiment words are written in English. Sentiment words in English appeared in the positive set slightly more than the negative set with expressions like *my love, miss you, happy birthday, best wishes,* and *good luck* over cursing and swearing in the negative set. Borrowing is also common in Arabizi e.g., *luvik* and *missik* for *love-you-feminine* and *miss-you-feminine* in the second person perspective.

Neutral word classified: The drawback of the automatic expansion of words is a decrease in precision with 14% wrong classification of neutral words in this case.

Multi-word expressions and sarcasm: Many common multi-word expressions that express sentiment or sarcasm lack sentiment words, hence bypass a simple lexicon-based approach. For example, *to2bor albe / burry my heart* expresses love or *ras kbeer / big head* means stubborn.

No sentiment words: 9% of the unclassified tweets lack sentiment words with a higher tendency in the negative class. For example, the translated negative tweet *mom woke me up 30 minutes ago saying common common you have to give your sister a ride, guess who is still waiting?* or the positive *lets listen to keaton henson and eat shawarma*. This is an open problem in the literature of sentiment analysis (Liu, 2012).

Sentiment word not in the lexicon: SenZi did not match 6% of the unclassified sentiment words.

Word Ambiguity: We identified 5% of the wrongly classified words as ambiguous. As mentioned previously (in Section 2.2), word ambiguity is one of the Arabizi NLP challenges generated by the transcription of Arabic in Latin script.

Wrong negation: Classifying negated sentiment words accurately requires more effort than

Table 6: Challenges of Arabizi Sentiment Analysis

	Sentiment form not in the lexicon	Sentiment word is in English	Neutral word classified	Multiword expressions or sarcasm	No sentiment words	Sentiment word not in the lexicon	Word ambiguity	Wrong negation
Positive	37.5%	15%	12.5%	11%	5%	8%	5%	3%
Negative	39%	10%	15.5%	10%	12%	4%	5%	4%

negating sentiment words that are preceded by a negator. A negator may precede or succeed a sentiment word by several words and it may only diminish the sentiment in some cases.

7 Discussion

In this work we focused on an area that has not been explored thoroughly in the literature of sentiment analysis. Arabizi has been proven to be a prominent way of texting on social media among the Arab youth yet there are no public resources to analyse sentiment from this script.

We provided a rigorous explanation of the linguistic challenges for analysing Arabizi text. We created SenZi, the first Lebanese Arabizi sentiment lexicon. We addressed the high degree of lexical sparsity by enriching SenZi with different inflectional and orthographic forms using word embeddings. We achieved an F1-score of 0.72 using a lexicon-based sentiment classification approach.

To the best of our knowledge, there are no other Levant dialect Arabizi datasets or sentiment lexicons to compare our work with. As such, we provided a detailed error analysis to point out the cases that bypassed SenZi.

The annotations carried out to create SenZi and the datasets took place at different times between 2016 and 2018. We tried our best to keep three annotators per task, but in a few cases we had one annotator at hand. However, we tested the annotators with test sets for credibility.

Word embeddings proved to be an excellent technique to expand SenZi, yet 38% of the unmatched sentiment words are forms of SenZi words. Next, we will explore cross-lingual word embeddings with Arabic for further expansion.

Arabizi is a code-switched language, with English appearing the most in Arabizi text from Lebanon. We plan to add English sentiment words to SenZi carefully to handle codeswitching.

Nevertheless, this work is one of the very first attempts to create and evaluate NLP resources for Arabizi sentiment analysis. We created a new sentiment lexicon consisting of 11.3K positive and 13.3K negative words, a sentiment-annotated dataset of 3.4K tweets, and a Facebook corpus of 1M comments. All resources and detailed description are made public and freely accessible on the project's webpage[10].

8 Conclusion

We presented SenZi, the first sentiment analysis lexicon for the Lebanese dialect Arabizi. We built it by translating, annotating, and transliterating other resources to have an initial set of 2K sentiment words. We expanded it to 24.6K sentiment words by importing inflectional and orthographic forms using word embeddings. We evaluated it using a lexicon-based sentiment analysis, achieving an F1-score of 0.72. We finally presented a detailed error analysis to pinpoint its limitations and the challenges that impact the lexicon-based approach for Arabizi sentiment analysis.

Abstract

Semantic change detection (i.e., identifying words whose meaning has changed over time) started emerging as a growing area of research over the past decade, with important downstream applications in natural language processing, historical linguistics and computational social science. However, several obstacles make progress in the domain slow and difficult. These pertain primarily to the lack of well-established gold standard datasets, resources to study the problem at a fine-grained temporal resolution, and quantitative evaluation approaches. In this work, we aim to mitigate these issues by (a) releasing a new labelled dataset of more than 47K word vectors trained on the UK Web Archive over a short time-frame (2000-2013); (b) proposing a variant of Procrustes alignment to detect words that have undergone semantic shift; and (c) introducing a rank-based approach for evaluation purposes. Through extensive numerical experiments and validation, we illustrate the effectiveness of our approach against competitive baselines. Finally, we also make our resources publicly available to further enable research in the domain.

1 Introduction

Semantic change detection is the task of identifying words whose lexical meaning has changed over time. Detecting this temporal variation enables historical and social scientists to study cultural shifts over time (Michel et al., 2011), but it can also have important implications on the performance of models in various NLP tasks, such as sentiment analysis (Lukeš and Søgaard, 2018).

While early theoretical work on semantic change dates back to the previous century (Bloomfield, 1933), the recent availability of historical datasets has made the computational study of the task feasible (Sandhaus, 2008; Michel et al., 2011; Davies, 2012). Past work has demonstrated that semantic change can manifest over decades (Cook and Stevenson, 2010; Mihalcea and Nastase, 2012), years (Yao et al., 2018; Basile and McGillivray, 2018), or even months and weeks (Kulkarni et al., 2015; Tsakalidis et al., 2018).

However, important gaps make progress in the field slow. In particular, there is a relative lack of labelled datasets to study the task over a short time-frame, since most known instances of semantic change took place over centuries or decades. Furthermore, the evaluation of a semantic change detection model is typically performed by manually inspecting a few examples, which can result in unreliable or even non-measurable performance. Finally, on a methodological front, a common practice to measure the semantic shift of words between consecutive time periods is to calculate their displacement error that results from "aligning" word vector representations across these time periods (Hamilton et al., 2016). However, a subset of these words may have actually undergone semantic change and thus trying to align their representations across time is counter-intuitive for the task of semantic change detection, and – importantly – can result in drop in performance. To this end, our work makes the following contributions:

- We release a new dataset for semantic change detection, comprised of word vector representations trained on yearly time intervals of the UK Web Archive (>20TB), along with a list of words with known semantic change, as provided by the Oxford English Dictionary.
- We propose a variant of Procrustes alignment

Proceedings of Recent Advances in Natural Language Processing, pages 1212–1221,
Varna, Bulgaria, Sep 2–4 2019.

for semantic shift detection, trained on an extremely small number of "anchor words" whose meaning is "stable" across time.

- We illustrate the effectiveness of our approach through extensive experimentation, by also proposing the employment of rank-based metrics for evaluation purposes.

2 Related Work

Early work on semantic change detection relied primarily on the comparison of word frequency and co-occurrence patterns between words at different time intervals (Sagi et al., 2009; Cook and Stevenson, 2010; Gulordava and Baroni, 2011), most often representing a single word based on its context (Mihalcea and Nastase, 2012; Jatowt and Duh, 2014; Basile and McGillivray, 2018). Recently, word embeddings have become the common practice for constructing word representations in NLP (Mikolov et al., 2013). A typical process followed in the context of semantic change is to learn the representations of a word over different time intervals and then compute its shift, by employing some distance metric over the resulting representations (Kim et al., 2014; Hamilton et al., 2016; Del Tredici et al., 2018).

A key issue that results from this process is that the comparison of the same word across different time periods becomes impossible, due to the stochastic process of generating the word vectors (e.g., word2vec). To accommodate that, Kim et al. (2014) proposed the initialisation of the word embeddings at time $t+1$ based on the resulting word representations at time t. Kulkarni et al. (2015) learned a linear mapping between the word representations of the nearest neighbours of a word at different time periods. Hamilton et al. (2016) employed Orthogonal Procrustes (Schönemann, 1966) to map the resulting word representations of the whole vocabulary at time t to their corresponding ones at time $t+1$. Another strand of work focuses on generating diachronic word embeddings (Kutuzov et al., 2018), aiming to learn word representations across time (Bamler and Mandt, 2017; Rosenfeld and Erk, 2018; Yao et al., 2018; Rudolph and Blei, 2018). However, these are often hard and slow to train under a massive dataset, such as the UK Web Archive. Similarly, the approach by Kim et al. (2014) does not allow for parallel processing of massive historical collections, since the word vectors at time $t+1$ need to be initialised based on the resulting representations at t. Our work is more closely related to Hamilton et al. (2016). However, aligning the vectors of the whole vocabulary at different times can be noisy and is counter-intuitive for the task of semantic change detection. To mitigate this effect, we propose to learn the alignment based only on a few "stable" (from a semantic point of view) words and apply the same transformation to the full vocabulary, leading to more appropriate alignment and, therefore, to more effective detection of semantically shifted words.

Regardless of the methodological approach, an open issue is the evaluation method of such a model. Owed to the lack of large-scale ground-truth datasets, past work has performed the evaluation either on the basis of detecting only a few word cases of semantic change (Cook and Stevenson, 2010; Gulordava and Baroni, 2011; Del Tredici et al., 2018) or by creating an artificial task, such as word epoch disambiguation (Mihalcea and Nastase, 2012). In this work, we propose instead a rank-based approach that can be employed for the evaluation of a semantic change detection model, even with a few positive examples of words whose lexical semantics have changed.

For more information on semantic change detection, the reader is referred to Tang (2018).

3 Methodology

3.1 Task Definition

Let $[W^{(0)}, ..., W^{(|T|)}]$ be word representations of a common (intersected) vocabulary of $|V|$ terms across $|T|$ consecutive time intervals given by $\{[t, t+1], t \in \{0, \ldots, T-1\}\}$, where each t maps to a given year. Our goal is to *find the words whose meaning has changed the most over each of the consecutive time intervals* $[t, t+1]$ (e.g., between [2000, 2001], [2001, 2002], etc.).

Clear cases of words that have undergone semantic change are difficult to find in a short time period. Furthermore, it has been recently demonstrated that semantic shift is a gradual process and not a sudden and distinctive phenomenon (Rosenfeld and Erk, 2018). Therefore, here we treat our task as a *word ranking problem*, where our aim is to rank the words based on their semantic shift. Importantly, this also enables us to validate the performance of our models in a more robust way as compared to treating the task as a classification problem, since in the latter case the precision score

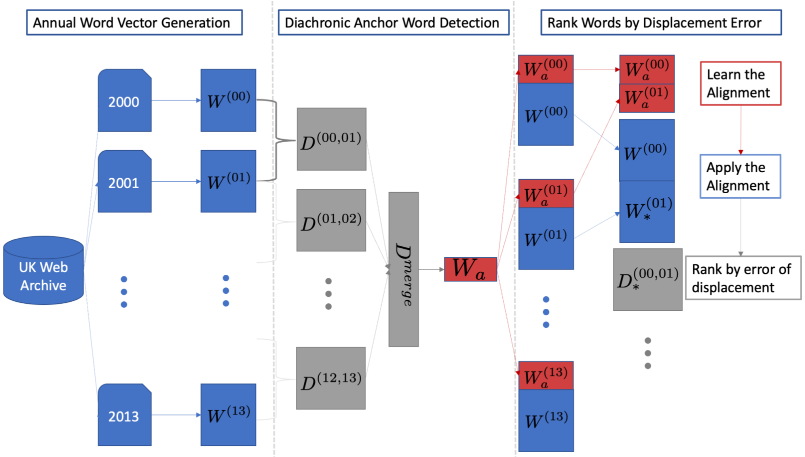

Figure 1: After constructing the word vectors on an annual basis, we learn their pairwise alignments of the resulting word vectors $\{W^{(t)}, W^{(t+1)}\}$. We rank the words based on their average displacement errors across all pairwise alignments in D^{merge} and select the k most stable words as our diachronic anchors W_a. Finally, we learn the alignment of $W_a^{(t+1)}$ based on $W_a^{(t)}$, and apply the same transformation to $W^{(t+1)}$ based on $W^{(t)}$. The words whose meaning has changed the most within $[t, t+1]$ are the ones with the largest displacement error in $D_*^{(t,t+1)}$.

of the positive (semantically shifted) class can be highly biased due to the small number of words belonging to it.

3.2 Our Approach

Figure 1 provides an overview of our approach for ranking the words based on their semantic shift levels. Given some word representations $\{W^{(t)}, W^{(t+1)}\}$ across two consecutive years (see section 4), our goal is to find an optimal way to align $W^{(t+1)}$ based on $W^{(t)}$, so that we can then compute the semantic shift level of a word by means of some distance metric. Typically, this alignment between $W^{(t+1)}$ and $W^{(t)}$ is performed on the complete vocabulary (Hamilton et al., 2016). This implies that the representation of words that have undergone semantic shift are still used as an input to the alignment algorithm, which can result into noisy pairwise alignments (Lubin et al., 2019).

To mitigate this issue, inspired by recent work in word translation (Conneau et al., 2017), we propose the use of a small number of *"anchor words"* to learn the optimal alignment between word representations at two consecutive time periods. Anchor words are defined as words whose lexical semantics remain static over two consecutive time periods. Similarly, *"diachronic anchor words"* correspond to those whose representations remain static across multiple and consecutive time intervals. The detection of these words can lead to more appropriate pairwise alignments of the word vectors, thus facilitating the task of finding semantically shifted words in a more robust fashion.

Anchor Words We formulate our approach on aligning the word vectors $\{W^{(t)}, W^{(t+1)}\}$ across consecutive time periods $[t, t+1]$ on the basis of the Orthogonal Procrustes problem (Schönemann, 1966). Besides past work on semantic change (Hamilton et al., 2016), this approach has been employed in related NLP tasks, such as word translation (Conneau et al., 2017; Ruder et al., 2018). In our case, it finds the optimal transformation of $W^{(t+1)}$ that best aligns it with $W^{(t)}$, by:

$$R = \underset{\Omega;\Omega^T\Omega=I}{\operatorname{argmin}} \left\| W^{(t)}\Omega - W^{(t+1)} \right\|_F. \quad (1)$$

The solution to Eq. 1 can be found via singular value decomposition: $R = UV^T$, where $U\Sigma V^T = SVD(W^{(t+1)}W^{(t)T})$. In our work, we ensure that $W^{(t+1)}$ and $W^{(t)}$ are centered at the origin and that $tr(W^{(t)}W^{(t)T}) = tr(W^{(t+1)}W^{(t+1)T}) = 1$. Finally, we transform $W^{(t+1)}$ as: $W_*^{(t+1)} = W^{(t+1)}R^Ts$, where $s = \sum\Sigma$. We measure the displacement error matrix $D^{(t,t+1)}$ using the cosine distance over the resulting representations $\{W^{(t)}, W_*^{(t+1)}\}$. The k anchor words across $[t, t+1]$ correspond to the k words of $D^{(t,t+1)}$ with the lowest cosine distance (where one can vary the "stability" threshold of the anchor words by varying k).

Diachronic Anchor Words The sets of the detected anchor words may vary between consecutive pairwise time intervals $\{[t, t+1], [t+1, t+2], ...\}$. This contrasts with our intuition of aligning the word vectors based on a few static (from a lexical semantic point of view) words. An intuitive way to accommodate this is to use words that are static throughout a longer period of time. Therefore, to detect "diachronic anchor words", we first perform all of the pairwise alignments and calculate the cosine distances of the words as before. We then concatenate these distances in a $|W|$-by-$|T|$ matrix D^{merge}. The diachronic anchor words correspond to the k words with the lowest average cosine distance in D^{merge}. In Figure 1, we denote their representations as W_a.

Semantic Change Detection We can now use a two-fold process to align the word vectors of two consecutive years $[t, t+1]$: first, we use Procrustes to learn the alignment of $W_a^{(t+1)}$ based on $W_a^{(t)}$, where $W_a^{(i)}$ corresponds to the vector representations of the diachronic anchor words at the time period i. Then, the learned transformation is applied to the representations of the complete vocabulary $W^{(t+1)}$, which are transformed into $W_*^{(t+1)}$. This way, we map the word representations at $t+1$ to the corresponding ones at t in a more robust way. Finally, we calculate the cosine distance matrix $D_*^{(t,t+1)}$ between the word representations in $W^{(t)}$ and $W_*^{(t+1)}$, where lower ranks indicate the index of a word with a higher level of semantic shift. The process is repeated for every pair of consecutive years, by keeping the same set of k diachronic anchor words for each alignment.

4 Data

We employ two datasets in our analysis: (a) the UK Web Domain Dataset 1996-2013 (JISC-UK) is used to learn word representations over different time periods (section 4.1); (b) the Oxford English Dictionary (OED) is used to refine our vocabulary and to build our ground truth – i.e., words that have changed their meaning over time (section 4.2).

4.1 JISC-UK Dataset

The UK Web Domain Dataset 1996-2013 (JISC-UK) contains textual information published in UK-based websites over the time period 1996-2013, thus facilitating the task of semantic change detection in a short-term and fine-grained temporal resolution (Basile and McGillivray, 2018).

Word Vectors Generation The dataset was processed based on previous work by Basile and McGillivray (2018), resulting in over 20TB of textual data. Instead of generating a single vector representation of a word across all years (e.g., by using Temporal Random Indexing (Basile and McGillivray, 2018)), we treated the concatenated content that was published within each year as a single (annual) document $D^{(t)}$, $t \in \{2000, ..., 2013\}$[1]. Following most of the past approaches on semantic change (Kim et al., 2014; Hamilton et al., 2016), we generated word representations by training $|T+1|$ `word2vec` models $m^{(t)}$ (one per year), using Skip-Gram with Negative Sampling and excluding all words appearing less than 1,000 times within a year. Each model was trained for five epochs, using a window size of five words. Finally, we represent every word in year t as a 100-dimensional vector $w_i^{(t)}$, and the resulting matrix of all words as $W^{(t)}$. The resulting vocabulary size per year is shown in Figure 2.

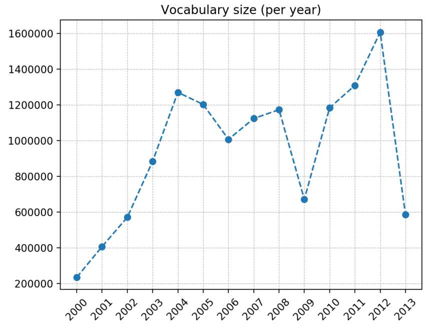

Figure 2: Vocabulary size per year (till May '13), excluding words appearing less than 1,000 times.

4.2 Oxford English Dictionary

The Oxford English Dictionary (OED) is one of the largest dictionaries and the most authoritative historical dictionary for the English language. It records over 250K lemmata along with their definitions, including the year in which each sense was first introduced in the language.

Ground Truth We consider the lemmata that are single words and with definitions whose first appearance in OED is recorded between 2001 and

[1] We excluded the years 1996-1999 owed to the data sparsity observed for these years.

2013 as our ground truth (218 words). Arguably, we expect there to be cases of words whose meaning has changed over time but are not recorded in the OED – i.e., the precision rate of our ground truth is not guaranteed to be 100%. However, this does not affect much our evaluation, since we are not treating our task as a classification problem, but are instead interested in ranking words with known semantic shift in an appropriate manner compared to more semantically stable words (i.e., we are interested in having high recall score of our ground truth, which is guaranteed by the OED).

4.3 Resulting Dataset

As opposed to early work studying the change in word frequency over time to detect semantic change (Michel et al., 2011), here we are interested in detecting words that have undergone semantic change based purely on their context. Therefore, to avoid any bias towards words that have appeared at a certain point in time (e.g., "facebook"), we focus strictly on the words that appear every year, yielding a vocabulary of 168,362 unique words. Finally, we filter out any word that does not appear in OED, due to the lack of ground truth for these words. The resulting dataset that is employed in our modelling is composed of **47,886** unique words that are present in OED and appear at least 1,000 times in every single year between 2000 and 2013, out of which **65** are marked by OED as words that have gained a new meaning after the year 2000[2].

4.4 Empirical Evidence of Semantic Change

Before presenting our experiments, it is important to get some insights on whether (a) semantic change actually occurs in such a limited time period and (b) that our ground-truth showcases this shift, in a qualitative manner.

We begin our analysis by leveraging Procrustes alignment in all possible year-to-year combinations and measure the sum of squared errors of each of the respective alignments. We try this approach on both (a) the intersected vocabulary (approximately 168K words) and (b) the resulting vocabulary by keeping only the words that are mapped to an OED entry (approximately 48K words, see section 4.3).

The results of this process are illustrated in Figure 3. We plot three heatmaps for each case, so that we see if there is an influence stemming from relatively rarely appearing words (when the threshold is set to 1,000). The results demonstrate that the further we move away from the diagonal, the higher the error becomes – note that this is picked up even though there is no notion of "time" in the alignments – indicating that there is a gradual/temporal shift in the meaning of the words, as captured by the context they appear in.

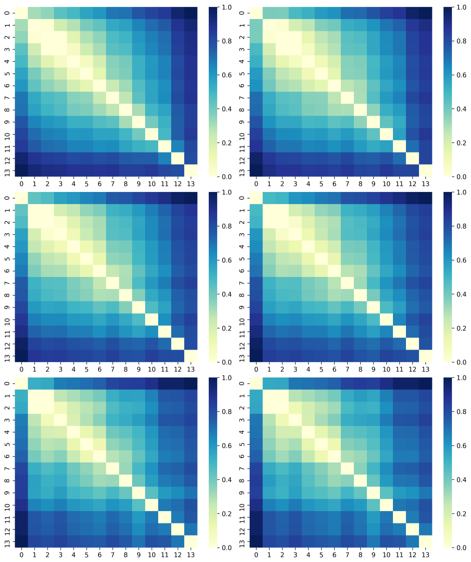

Figure 3: Normalised sum squared errors when aligning the word vectors across different years (2000-2013), using the complete vocabulary (left) and the its intersection with the OED dictionary (right), with different minimum frequency thresholds: 1K (top), 10K (middle) and 100K (bottom).

To further validate the notion of semantic change with respect to our ground truth, we take a closer look at the 65 semantically shifted words that are used in our experiments. The five closest neighbours (by means of cosine similarity) of eight of these words in the years 2000 and 2013 are shown in Figure 4, along with the shift level, measured for each word w and its neighbour n as $cos(w^{(13)}, n^{(13)}) - cos(w^{(00)}, n^{(00)})$. Figure 5 shows the temporal shift in the meaning of the same words from their top-100 neighbours in 2000, using a 3-year moving averaging filter. Both figures demonstrate that the semantic change of our ground-truth is captured through our representations. However, it is also demonstrated that semantic shift is a gradual process and its level may vary across different words. In what follows, we examine the extent to which we can capture this effect using our approach presented in section 3.2.

[2] The resulting dataset is available through: https://github.com/adtsakal/Semantic_Change

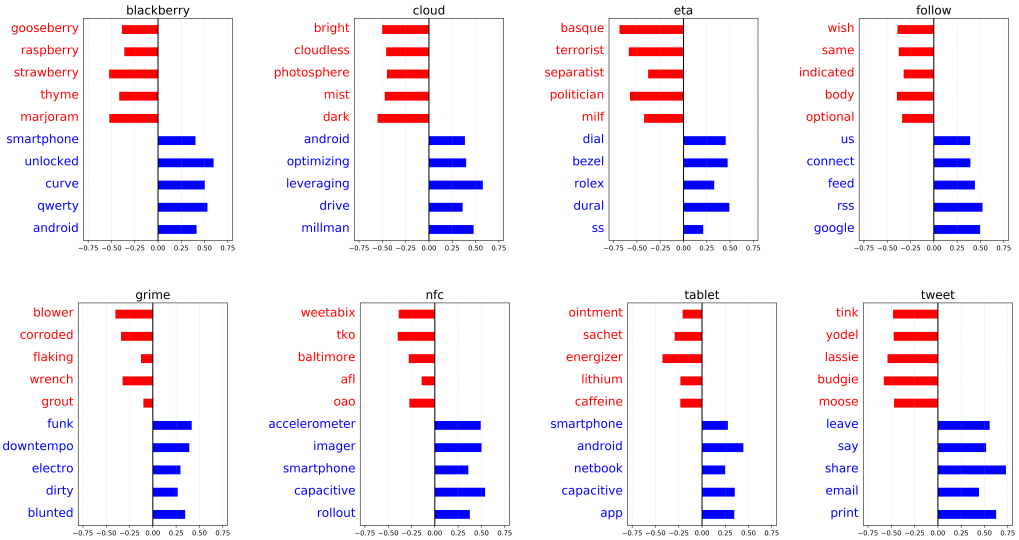

Figure 4: Closest neighbours of words that have undergone semantic shift, at two years (2000, 2013). The bar indicates the shift level of each word towards (away from) each of its neighbours in 2013 (2000).

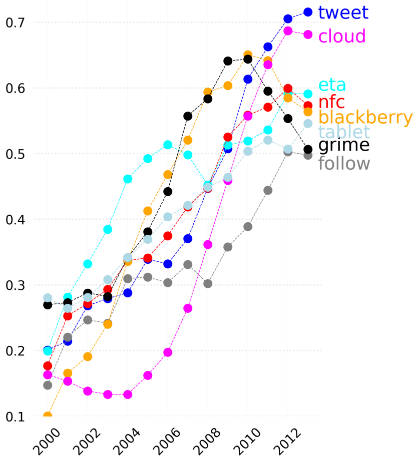

Figure 5: Cosine distance over time between four semantically shifted words (as marked by OED) and their top-100 neighbours in the year 2000.

5 Experiments

5.1 Task Formulation

Given the vector representations of all words across consecutive pairs of years (i.e., {[2000, 2001], ..., [2012, 2013]}), *our aim is to rank the words* based on their respective displacement errors that result after each pairwise alignment. Similarly to past work, we assume that the words corresponding to the highest displacement are those whose semantics has changed the most (Kim et al., 2014; Hamilton et al., 2016). The displacement of a word in a certain interval of a pair of years is calculated on the basis of the cosine distance between its resulting vectors on the first and the second year. Our task is performed on every pair of consecutive years separately.

5.2 Data Split

Experiment 1 We split our data into two sets: (a) in our training set we use most of our data to learn the alignment of the word representations across two different years, by ensuring that none of the 65 words denoted by the OED as words with altered meaning falls in this set (i.e., all of them are considered “static”); (b) we use the rest of our data for evaluation purposes (see next subsection), by ensuring that we include the 65 “changed” words in this set. We experiment with different percentage splits between training and evaluation sets (evaluation set size: [10%, ..., 50%]). This enables us to study the effect of the training set size and the number of diachronic anchor words (see 5.4 below) that are needed to detect semantic change effectively. Due to the small number of “changed” words in the evaluation set, for each percentage split, we perform 40 runs with random splits of the “static” words into the two sets.

Experiment 2 Here we use the complete set of word representations to learn the alignments across the different time intervals, disregarding the split into train/evaluation sets. This enables us to get clearer insights on the performance of the models under a complete setting and study the effect of diachronic anchor words in more detail.

5.3 Evaluation

We propose an alternative, rank-based metric, which can yield robust comparisons across different models, even with a relatively small number of labelled words. Given the final word rankings of an algorithm when applied on a certain pair of years, we denote *the average relative rank of a word whose meaning has changed* (as denoted by the OED) as μ-rank. The value of a single word for this metric lie within the $[0, 1]$ interval, with lower values indicating a better rank produced by the model. The μ-rank of a model is calculated for each of the 13 pairs of years independently and all the results are averaged across the 40 runs, yielding a vector of rank 13. Finally, we consider the average μ-rank score of this vector as our evaluation metric. For all of the models used in Experiment 1, the μ-rank is calculated based on the evaluation set.

5.4 Models

Baselines Our first vanilla approach ($\boldsymbol{PROCR_{100}}$) ranks the words by means of their respective displacement errors (i.e., cosine distance), by learning a single transformation across the whole dataset (Hamilton et al., 2016). For Experiment 1, we also include a second approach ($\boldsymbol{PROCR_{90}}$) which similarly learns the transformation based on the training set and then applies it to the evaluation set.

Our Models We employ two models based on the notion of anchor words: for a given pair of years, $\boldsymbol{PROCR_k}$ first learns an optimal alignment based on the full training set (similarly to $PROCR_{90}$) and then selects the k words with the lowest displacement error of this set to serve as "anchor" words, in order to learn a new alignment based strictly on them; this new transformation is then applied in the evaluation set to yield the final word rankings. This implies that the anchor words are not necessarily the same across all pairs of years. $\boldsymbol{PROCR_{kt}}$ operates in a similar fashion, albeit resolving this drawback through the use of diachronic anchor words: it first learns all of the alignments across the different pairs of years ({[2000, 2001], ..., [2012, 2013]}) and then it selects the k words with the lowest average displacement error across time; finally, it ranks the words in the evaluation set by learning a single transformation for every pair of years based strictly on these anchor words. For both of our models, we experiment with a varying value for k, measured as a % of the size of our training set in Experiment 1. For Experiment 2, we fix k to be the optimal number of words found in Experiment 1.

6 Results

Experiment 1 The results of our models and the baselines are presented in Figure 6. We provide one chart for each evaluation set percentage of the data that was used in our experiments, averaged over the 40 randomised splits we performed.

It becomes apparent that the anchor-based approaches perform clearly better (i.e., they have consistently lower average μ-rank) than those based on the alignment of all of the words – either of the training set, in $\boldsymbol{PROCR_{90}}$, or of both sets, in $\boldsymbol{PROCR_{100}}$. This is because the alignments of the former are based on the representations of words that are indeed stable over time. As we have empirically demonstrated in the previous section, semantic change is a gradual process; thus, aligning words whose representations are not stable across time results into noisy alignments that fail to capture the semantic change of words effectively.

The comparison between the anchor ($\boldsymbol{PROCR_k}$) and diachronic anchor ($\boldsymbol{PROCR_{kt}}$) approaches indicates that the latter performs consistently better. We find that using a very small number of anchor words (0.1% of the training set) yields much better results in almost all cases. Depending on the size of the evaluation set, this number of words ranges from 43 (in the case of 10%) down to 28 words (in the case of 40%). When we further increase the size of the evaluation set (thus decreasing the size of the training set) to 50% of our dataset, we find that using 1% (239) of the words in the training set as anchor words yields slightly better results than using 0.1%. This is because some of the anchor words are placed within the evaluation set, thus the alignment is learned based on weaker anchors, yielding poorer performance. Having a large training set to extract the (diachronic) anchor words from and learn the optimal alignments between their representations across different years is sufficient to overcome this issue.

Finally, while the proposed models outperform the standard practices found in related work, we observe that their performance is still relatively poor: a semantically shifted word is expected to be

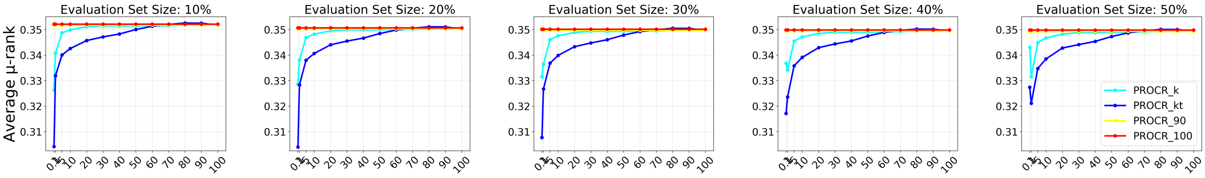

Figure 6: Average μ-rank in Experiment 1 across all runs, using different % of anchor words (x-axis).

ranked close to the top-30% of all of the competing words, with respect to its semantic shift level. This indicates that the task of semantic change detection is rather challenging. Incorporating the temporal dimension of the task is a promising direction for future research in this perspective.

Experiment 2 We present the results when we employ the full dataset to learn the alignments of the $\boldsymbol{PROCR_{100}}$, $\boldsymbol{PROCR_k}$ and $\boldsymbol{PROCR_{kt}}$ models. We fix the percentage of (diachronic) anchor words to be the 47 most stable words (i.e., the top-0.1%). The results are provided in Figure 7 in a per-year basis. $\boldsymbol{PROCR_{kt}}$ performs better on average μ-rank terms (29.48±3.67) against $\boldsymbol{PROCR_k}$ (32.68±4.93) and $\boldsymbol{PROCR_{100}}$ (35.08±4.71), demonstrating again the effectiveness of the alignment based on the diachronic anchor words.

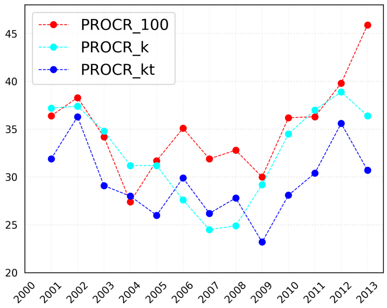

Figure 7: μ-rank of the three models on an annual basis in Experiment 2.

To shed light into the difference between the performance of models employing the anchor and the diachronic anchor words, we calculate the number of anchor words that belong to the set of the diachronic anchors, per year. On average, we find that only 16% (st.dev.: 5.9%) of the annually detected anchor words belong to the latter set. Throughout the pairwise alignments, there are overall 434 unique anchor words detected, from an overall possible of 611. This is owed to the "noisy" selection of anchor words. In Experiment 1, we have demonstrated that aligning the word vectors based on a very small number of anchors performs better. However, the accurate selection of such a small proportion of words can be rather challenging and can vary a lot over consecutive time intervals, due to the noisy nature of the word representations and the alignments themselves. By selecting diachronic anchor words, we are able to filter out this noise, thus yielding more accurate word alignments and tracking the semantic shift of words through time in a more robust way.

7 Conclusion and Future Work

We have introduced a new labelled dataset for semantic change detection. Approaching our task as a word ranking problem, we have proposed an approach to align word representations across different points in time on the basis of a few stable words across time. Through extensive experimentation, we have demonstrated that our approach yields better performance compared to current practices that are based on aligning word representations at different points in time.

An extension to our work is the incorporation of Generalised Procrustes Alignment (Gower, 1975). This will allow us to align the word representations across all years simultaneously and observe the trajectory of each word through time. Furthermore, in our exploratory analysis, we have qualitatively demonstrated that semantic change is a gradual process. Therefore, incorporating the temporal dimension of the task in our approach is a major direction for future work. In particular, we plan to incorporate temporal approaches that are well-suited for the task, such as temporal word clustering and change point detection. Finally, by making our resources publicly available, we hope to facilitate further research in the domain.

Abstract

Cross-lingual word embedding models learn a shared vector space for two or more languages so that words with similar meaning are represented by similar vectors regardless of their language. Although the existing models achieve high performance on pairs of morphologically simple languages, they perform very poorly on morphologically rich languages such as Turkish and Finnish. In this paper, we propose a morpheme-based model in order to increase the performance of cross-lingual word embeddings on morphologically rich languages. Our model includes a simple extension which enables us to exploit morphemes for cross-lingual mapping. We applied our model for the Turkish-Finnish language pair on the bilingual word translation task. Results show that our model outperforms the baseline models by 2% in the nearest neighbour ranking.

1 Introduction

Cross-lingual word embeddings (CLEs) have drawn a lot of attention in recent times. CLE models learn vectors of words in two or more languages and represent them in a shared cross-lingual word embedding space, where words with similar meaning have similar vectors, independent of their language. Most popular approaches for CLEs are mapping-based approaches which are also called offline approaches. These kinds of approaches require only pre-trained monolingual embeddings and a small seed dictionary so that the CLE model learns a mapping that minimizes the distance between word pairs in the seed dictionary to align the pre-trained embedding spaces.

CLE models enable multi-lingual modeling which has direct applications on cross-lingual tasks such as unsupervised machine translation (Lample et al., 2017), and cross-lingual transfer for downstream NLP tasks and low-resource languages. Document classification (Klementiev et al., 2012), information retrieval (Vulić and Moens, 2015), dependency parsing (Guo et al., 2015), and sequence labelling (Zhang et al., 2016) are examples of downstream NLP tasks in which CLEs serve as a source of cross-lingual knowledge.

Although the existing models achieve high performance, agglutinative languages, such as Turkish, Finnish and Estonian, pose a challenge to learn cross-lingual word embeddings due to three main reasons. First, with respect to the monolingual aspects, morphological complexity causes high sparsity which decreases the quality of monolingual embedding spaces (Cao and Rei, 2016; Üstün et al., 2018). Second, in the context of CLEs, the rich morphology causes inaccurate mappings especially for complex words because the existing CLE models cannot access the sub-word level information to align complex words with the correct morphological counterparts. Søgaard et al. (2018) shows that the existing CLE models underperform on rich morphological complexity. On the bilingual dictionary induction task, while the baseline method achieves 82.62% score on English-Spanish, it performs very poorly on English-Finnish (28.01%), English-Estonian (31.45%) and English-Turkish (39.22%). In the Estonian-Finnish dictionary induction experiment in which both languages are morphologically complex, the baseline model performs even worse (24.35%). Last, in addition to this limitation, word-based CLE models are also unable to map an inflected word in the morphologically complex language to a counterpart which corresponds to a phrase in a language with simple morphology.

In this study, we propose a morphologically-sensitive cross-lingual word embedding model[1] in order to overcome the second limitation. We build a cross-lingual model to learn the morpheme representations in the source languages so that a word can be represented through its morphemes in the target space. We design a supervised learning setting as in the baseline model that contains a small bilingual dictionary consisting of morphologically complex word pairs. We perform experiments on Turkish and Finnish as a pair of morphologically complex languages and compare our approach with the baseline models.

2 The Morpheme-Based Alignment Model

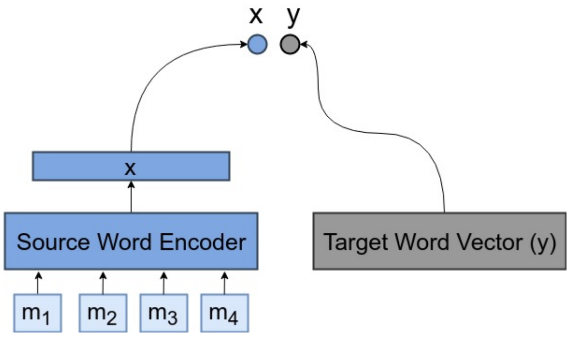

Figure 1: Morpheme-based cross-lingual alignment model that contains a source side word encoder for morphemes. The encoder is trained to learn morpheme representations in the target space

Baselines In this paper, we consider two baseline models. As the first baseline, we employ a simple projection-based CLE method which learns a mapping between embedding spaces by solving the Procrustes problem (Smith et al., 2017; Artetxe et al., 2016). This method first learns a linear transformation matrix to minimize the distance between vectors of word pairs in a seed dictionary by imposing the orthogonality constraint (Gower et al., 2004) and then it uses this matrix to transform the source language embedding space to represent both languages in a shared embedding space. The baseline method is denoted by Procrustes in this paper.

As the second baseline, we use relaxed cross-domain similarity local scaling (RCSLS) (Joulin et al., 2018). RCSLS optimizes the transformation matrix by maximizing the cross-domain similarity local scaling (CSLS) score, instead of minimizing the distance between word pairs in the training dictionary. CSLS is a modification of cosine similarity commonly used in information retrieval. In this way, RCSLS relaxes the orthogonality constraint used in Procrustes according to a retrieval criterion.

Note that for the both baseline models and our model, we use fastText (Bojanowski et al., 2017) to generate monolingual word embeddings. Fasttext represents words as sequence of character n-grams but in many cases this is suboptimal since not all character n-grams are morphemes (Üstün et al., 2018). Besides that the aim of this study is to incorporate morphology into cross-lingual training, whereas fastText is designed for monolingual training.

Morpheme-based Model In the morpheme-based model, we extend the projection-based baseline (Procrustes) in order to exploit sub-word (morpheme) level information for the cross-lingual mapping. Our model starts by splitting all words in the source language into morphemes by using a morphological analyzer. A vector is then computed for each generated morpheme, by using fastText (Bojanowski et al., 2017), as fastText is able to generate a vector for any sub-word since it is based on character n-gram representations.

After the resulting morpheme vectors are inserted into the source vector space, we apply a linear transformation based on the seed dictionary by using the Procrustes method to initialize source and target side vectors in a shared embedding space. Then, our model learns an encoder that encodes each word as a morpheme sequence and transforms them by aligning to their counterparts in the target language. In this way, the resulting encoder learns to represent source side morphemes in the target embedding space.

The model architecture is given in Figure 1. In the figure, x denotes the fixed length word representation generated by the word encoder through morphemes and y represents the target side word embedding. The source encoder is trained to mimic target word embeddings in the bilingual dictionary by minimizing the loss function:

$$L_{align} = dist(x, y) - \lambda(dist(x_c, y) + dist(x, y_c))$$

where (x, y) corresponds to the source and target word embeddings, (x_c, y_c) is a contrastive

[1] Code available at: https://bitbucket.org/ahmetustunn/morphology-sensitive-cle

term. λ[2] controls the effect of the negative samples in the alignment loss. We use the *cosine* similarity for the distance measure.

For the encoder model, following (Conneau et al., 2017a), we use bidirectional LSTMs with max pooling. It encodes the words in both the forward and the backward direction to capture unidirectional information, then it combines the resulting numbers to form a fixed-size vector by selecting the maximum value over each dimension of the hidden units. Figure 2 shows the encoder model. In the figure, each word vector u is computed from morphemes m_n through the bidirectional LSTM encoder.

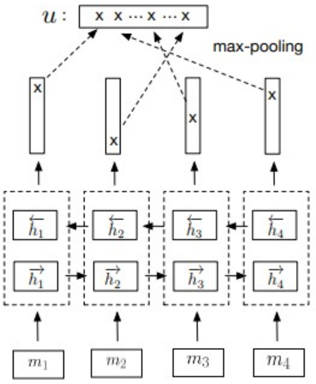

Figure 2: An overview of the word encoder which is used for the source language. It consists of bidirectional LSTMs and a max pooling layer. The inputs of the encoder are the morpheme sequences for each word

3 Morphologically Sensitive Bilingual Lexicon

In order to build a bilingual dictionary for the Turkish and Finnish word pairs, we use the MUSE dataset (Conneau et al., 2017b). Since the MUSE bilingual lexicon consists of translations to or from English for these two languages, we use the intersection of their translation to English. These bilingual lexicons are built with an automatic translation system and the dictionaries handle well the polysemy of words. However, the dictionaries mostly consist of morphologically simple word pairs since English is used as a pivot language.

Considering the morphological variations in these languages, we enriched the dictionary with morphologically complex word pairs. To this end, we first create a lookup table for the lemmas, their inflections and the corresponding morphological features for both languages by using the Universal Dependency Treebanks (Nivre et al., 2016) and the Universal Morphology (Sylak-Glassman, 2016) project.[3] Each word pair in the dictionary is then searched in these lookup tables to list their inflections. The inflected word forms which have the same morphological features for a pair are then added to the bilingual dictionary. Table 1 shows the inflected wordforms found in lookup table for the seed pair *gölge-varjo*.[4] The morphological features that occur in both languages are given in Table 2.

Turkish	Finnish	
gölgem	varjoni	`N;SG;PSS1S`
gölgenin	varjojen	`N;SG;GEN`
gölgelerin	varjoja	`N;PL;PSS2S`
gölgelerde	varjoissa	`N;ESS;PLS`

Table 1: The inflected wordforms with the same morphological features for the word pair *gölge-varjo* which mean *shadow*

Attribute	Morphological Classes
Number	Sing, Plu
Polarity	Neg, Pos
Person	{Pss1,Pss2,Pss3}+{Sg,Pl}
Case	{in,on,at}+{Ess,Abl}, Gen, Prt
Tense	Pst, Prs, Imp
Agreement	P1,P2,P3
Voice	Pass
Mood	Ind, Imp, Cond

Table 2: Morphological features which are common in both Turkish and Finnish

The training dictionary comprises the first 5000 Turkish words and their Finnish counterparts while the test set is composed of the following 1500 word pairs in the lexicon.

4 Experiments

We compare our morpheme-based model with Procrustes (Smith et al., 2017; Artetxe et al., 2016) and relaxed cross-domain similarity local scaling (RCSLS) (Joulin et al., 2018), as explained in Section 2.

[2] Following Conneau et al. (2018), we set λ to 0.25

[3] During the preprocessing step, the default morphological features which are language specific are removed from the datasets.

[4] Both words mean *shadow* in English

Model	NN	CSLS
Turkish-Finnish (TR-FI)		
Procrustes	16.54	17.89
RCSLS	18.26	**21.06**
Our model	**20.35**	20.40
TR-FI on English		
Procrustes	12.72	14.89
RCSLS	15.10	17.05

Table 3: Bilingual word translation performance of the models at P@1 (%). First three rows show the results after training with Turkish-Finnish morphologically sensitive seed dictionary. The last two rows present the results when English is used as a pivot language.

Evaluation Task In order to evaluate the models, we used the bilingual word translation task. Bilingual word translation has become the standard evaluation task for mapping-based CLE models. Given a shared embedding space which is learned by a CLE model, the task is to translate source language words to the target language by retrieving a word in the target language. As the retrieval criterion, either nearest neighbor search (NN) or cross-domain local scaling (CSLS) can be used.

Implementation Details Our evaluation comprises Turkish and Finnish which are both morphologically complex languages. We use the l_2-normalized fastText word and morpheme vectors (Bojanowski et al., 2017) trained on Wikipedia for these languages. We initialize source side embeddings with a linear transformation defined by a Procrustes operation based on the seed dictionary. In order to split words into morphemes, we use the Zemberek toolkit (Akın and Akın, 2007)[5] for Turkish and the Omorfi project (Pirinen, 2015)[6] for Finnish. Both morphological analyzers are rule-based and run with high accuracy. All models are trained with the same seed dictionary and evaluated on the same test set. We evaluated the model by the scores of precision at rank 1 (P@1) so that the results can be morphologically sensitive.

5 Results

Table 3 shows the results on the bilingual word translation performance of the models for the Turkish-Finnish language pair. According to the CSLS scores, RCSLS (Joulin et al., 2018) outperforms our models by a slight margin (0.66%). This is expected because the RCSLS model is explicitly designed to maximize the CSLS objective which causes better performance on the bilingual word translation task according to the CSLS score. However, according to nearest neighbor ranking, our model displays the strongest performance compared to Procrustes and RCSLS with a 2.09% score difference. Table 5 show examples of the nearest neighbour predictions of different models including our model.

We also run Procrustes and RCSLS on the Turkish-English and Finnish-English language pairs so that all three languages share the monolingual English embedding space. We use the MUSE (Conneau et al., 2017b) training dictionaries for both language pairs. In this setting, both Procrustes and RCSLS perform worse on Turkish-Finnish bilingual word translation suggesting that a third language (as a pivot language) does not provide benefit for word translation across morphologically rich language pairs even if it has high-quality word vectors. As our model requires the translations of inflected (morphologically complex) words in the target language, we can not run our model on Turkish-English or Finnish-English pairs because the translations mostly correspond to phrases instead of words.

Model	Spearman
Morph2Vec (Üstün et al., 2018)	**52.90**
Our model	42.05
Fasttext (Bojanowski et al., 2017)	20.80

Table 4: The comparison of the Spearman correlation between human judgments and the word similarities obtained by computing the cosine similarity between the learned word embeddings for Turkish.

Monolingual Impact Similar to the RCSLS, our model changes the cosine distance between word vectors in the same language, that is, it also has an impact on the monolingual embedding space. We evaluate this impact on the Turkish morphologically complex wordlist (Üstün et al., 2018). Results are given in the Table 4.

The Morph2Vec model (Üstün et al., 2018) learns a morpheme-based encoder which is monolingually trained on the large Turkish wordlist which consists of 100K unique words. Although our model is trained on 5K Turkish-Finnish word

2	aileler	perhe *(a family)*	**perheet** ***(families)***	**perheet** ***(families)***
3	zamanımız	aikani *(my time)*	aikani *(my time)*	**aikamme** ***(our time)***
4	acemilerden	aloittelijoilla *(in the beginners)*	aloittelijasta *(from the beginner)*	**aloittelijoilta** ***(from the beginners)***
5	makineler	**koneet** ***(machines)***	**koneet** ***(machines)***	koneissa *(in machines)*

Table 5: Examples comparing the translations of different models which also includes the glosses in English. Bolding indicates the correct translation. In Examples 1-4, our model predicts correct word considering the morphological structure but in the Example 5, our model gives wrong translation.

pairs, it improves the monolingual quality of Turkish word vectors for morphologically complex words. The reason behind this impact is that our model also changes the cosine similarity among Turkish word vectors according to morphologically sensitive cross-lingual signals, during the cross-lingual transformation. However, the Morph2Vec model still outperforms our model by a high margin. The results demonstrate that even if training a morpheme-based encoder on cross-lingual word pairs improves the monolingual embedding quality, the same training strategy still performs substantially better on a monolingual wordlist.

Error Analysis Here we study the errors produced by our model on Turkish-Finnish word pairs. Although our model is motivated by morphology, a small portion of the wrong translations is caused by the prediction of wrong inflections of a correct root word. The model translates the Turkish word *santralin* (*of the power plant*) as *voimalaa* (*in the power plant*) instead of *voimalan*. However, the majority of errors have incorrectly translated root words with correct inflections. These observations can suggest two shortcomings. Firstly, our model over-focuses on morphemes so that in some cases it lost the meaning of the content word. Secondly, especially for the distant language pair, some morphological features have different meanings which depend on the sentence syntax and contextual meaning, even if they have the same label. This issue could be alleviated by modeling and processing sentence-level context.

Limitations Similar to the baseline models, the main limitation of our model is that it can not generate multi-word expressions such as phrases on the target side, although our model is able to represent a sequence of strings in the source encoder. However, a morphologically complex word in the source language such as Turkish or Finnish, in most cases corresponds to a phrase, containing more than one word, in morphologically simple target languages such as English. For this reason, our model does not have any direct benefit for the morphologically simple languages and this issue will be the focus of follow-up studies.

Another limitation is that, our model requires a morphological segmenter to split words into morphemes. A simple solution for this could be to employ an unsupervised morphological segmenter which is commonly used in the literature such as Morfessor (Creutz and Lagus, 2005).

6 Conclusion

In this work, we extend the simple mapping-based cross-lingual embedding (CLE) model to learn a morphology-sensitive transformation between embedding spaces for morphologically rich language pairs. We start with the baseline transformation to initialize the source and target embedding spaces and then our model learns an encoder based on morphological segments in the source side and their counterparts in the target space. Thus, the transition matrix which is computed to produce a shared cross-lingual embedding space, is learned through morpheme representations and their composition in the source language.

We evaluated our model on the bilingual word translation task and compare our results with Procrustes and RCSLS (Joulin et al., 2018) scores. Results show that our morpheme-based cross-lingual embeddings model learns slightly better alignments for complex word pairs for languages having rich morphology compared to the baseline models. In this work, we have made the first step towards the comprehensive evaluation of CLE models according to the morphology of languages, however, our evaluation is limited to the bilingual word translation task. For further analysis, we are planning to evaluate our model on other language pairs which consists of both morphologically complex and simple languages and on downstream NLP tasks such as POS tagging and dependency parsing.

Abstract

We propose a multi-task deep-learning approach for estimating the check-worthiness of claims in political debates. Given a political debate, such as the 2016 US Presidential and Vice-Presidential ones, the task is to predict which statements in the debate should be prioritized for fact-checking. While different fact-checking organizations would naturally make different choices when analyzing the same debate, we show that it pays to learn from multiple sources simultaneously (PolitiFact, FactCheck, ABC, CNN, NPR, NYT, Chicago Tribune, The Guardian, and Washington Post) in a multi-task learning setup, even when a particular source is chosen as a target to imitate. Our evaluation shows state-of-the-art results on a standard dataset for the task of check-worthiness prediction.

1 Introduction

Recent years have seen the explosion of fake news, rumors, false claims, distorted facts, half-true statements, and propaganda, which are spreading primarily in social media, but also via standard news broadcasters. This trend became particularly evident during the 2016 US Presidential campaign, which was the turning point that attracted wide public attention to the problem. By then, a number of organizations, e.g., FactCheck[1] and Snopes[2] among many others, launched fact-checking initiatives. Yet, this proved to be a very demanding manual effort, and only a relatively small number of claims could be fact-checked. Thus, it is important to prioritize what to check.

The task of detecting check-worthy claims has been recognized as an important stage in the process of fully automatic fact-checking. According to Vlachos and Riedel (2014) this is a multi-step process that (*i*) extracts statements to be fact-checked, (*ii*) constructs appropriate questions, (*iii*) obtains the answers from relevant sources, and (*iv*) reaches a verdict using these answers. Hassan et al. (2015a) presented a similar vision, and in a follow up work they made check-worthiness an integral part of an end-to-end fact-checking system Hassan et al. (2017).

Here, we approach the problem of mimicking the selection strategy of several renowned fact-checking organizations such as PolitiFact, FactCheck, ABC, CNN, NPR, NYT, Chicago Tribune, The Guardian, and The Washington Post. An important characteristic of this setup is that, perhaps due to editorial policies, fact-checking organizations often select different claims for the same text, with little overlap in their choices (see Tables 1 and 2). Yet, it has been previously shown that it might be beneficial to learn from the union of the selections by multiple fact-checking organizations (Gencheva et al., 2017). Thus, we propose a multi-task deep learning framework, in which we try to predict the choice of each and every fact-checking organization simultaneously. We show that, even when the goal is to mimic the choice of one particular fact-checking organization, it is beneficial to leverage on the choices by multiple such organizations. The evaluation results on a standard dataset show state-of-the-art results.

The remainder of this paper is organized as follows. Section 2 provides an overview of related work. Section 3 describes the used dataset. Section 4 describes our method and features. Section 5 presents the experiments and the evaluation results. Finally, Section 7 concludes and points to some possible directions for future work.

2 Related Work

The proliferation of false information has attracted a lot of research interest recently. This includes challenging the truthiness of news (Brill, 2001; Hardalov et al., 2016; Potthast et al., 2018), of news sources (Baly et al., 2018, 2019), and of social media posts (Canini et al., 2011; Castillo et al., 2011; Zubiaga et al., 2016), as well as studying credibility, influence, bias, and propaganda (Ba et al., 2016; Chen et al., 2013; Mihaylov et al., 2015; Kulkarni et al., 2018; Baly et al., 2018; Mihaylov et al., 2018; Barrón-Cedeño et al., 2019; Da San Martino et al., 2019; Zhang et al., 2019).

Research was facilitated by shared tasks such as the SemEval 2017 and 2019 tasks on Rumor Detection (Derczynski et al., 2017; Gorrell et al., 2019), the CLEF 2018 and 2019 CheckThat! labs (Nakov et al., 2018; Elsayed et al., 2019b,a), which featured tasks on automatic identification (Atanasova et al., 2018, 2019) and verification (Barrón-Cedeño et al., 2018; Hasanain et al., 2019) of claims in political debates, the FEVER 2018 and 2019 task on Fact Extraction and VERification (Thorne et al., 2018), and the SemEval 2019 task on Fact-Checking in Community Question Answering Forums (Mihaylova et al., 2019), among others.

The interested reader can learn more about "fake news" from the overview by Shu et al. (2017), which adopted a data mining perspective and focused on social media. Another recent survey (Thorne and Vlachos, 2018) took a fact-checking perspective on "fake news" and related problems. Yet another survey was performed by Li et al. (2016), and it covered truth discovery in general. Moreover, there were two recent articles in *Science*: Lazer et al. (2018) offered a general overview and discussion on the science of "fake news", while Vosoughi et al. (2018) focused on the proliferation of true and false news online.

The first work to target check-worthiness estimation, i.e., predicting which sentences in a given input text should be prioritized for fact-checking, was the ClaimBuster system (Hassan et al., 2015b). It is trained on data that was manually annotated by students, professors, and journalists, where each sentence was marked as *non-factual*, *unimportant factual*, or *check-worthy factual*. The system used an SVM classifier and features such as sentiment, TF.IDF representations, part-of-speech tags, and named entities.

In our previous work (Gencheva et al., 2017; Jaradat et al., 2018), we used debates from the 2016 US Presidential Campaign and fact-checking reports by professional journalists; we use this same dataset here. Beside most of the features borrowed from ClaimBuster, our model paid special attention to the context of each sentence. This includes whether it is part of a long intervention by one of the debate participants and its position within such an intervention. We predicted both (*i*) whether any of the fact-checking organizations would select the target sentence, and also (*ii*) whether a specific fact-checking organization would select it. There was also a lab on fact-checking at CLEF 2018 and 2019 (Atanasova et al., 2018, 2019), which was partially based on a variant of this data, but it focused on one fact-checking organization, unlike our multi-source setup here.

Patwari et al. (2017) also focused on the 2016 US Election campaign. Their setup asks to predict whether any of the fact-checking organizations would select the target sentence. They used a boosting-like model that takes SVMs focusing on different clusters of the dataset and the final outcome is considered as that coming from the most confident classifier. The features considered range from LDA topic-modeling to part-of-speech (POS) tuples and bag-of-words representations.

Other claim monitoring tools include FactWatcher (Hassan et al., 2014) and DisputeFinder (Ennals et al., 2010b). FactWatcher classifies claims as situational facts, one-of-the-few, or prominent streaks. It checks whether a new text triggers some of the three types of claims, treating the sentences in the text as sequential data. DisputeFinder mines the Web for already-verified claims. Both maintain a growing database of facts and known claims.

Beyond the document context, it has been proposed to mine check-worthy claims on the Web. For example, Ennals et al. (2010a) searched for linguistic cues of disagreement between the author of a statement and what is believed, e.g., "*falsely claimed that X*". The claims matching the patterns would then go through a classifier. This procedure can be used to acquire a dataset of disputed claims.

Given a set of disputed claims, Ennals et al. (2010b) looked for new claims on the Web that entail the ones that have already been collected. Thus, the task can be reduced to recognizing textual entailment (Dagan et al., 2009).

de Marneffe et al. (2008) also looked for contradictions in text. They tried to classify the contradictions that can be found in a piece of text in two categories —those occurring via antonymy, negation, and date/number mismatch, and those arising from different world knowledge and lexical contrasts. The features that are selected for the task of contradiction detection include polarity, numbers, dates and time, antonymy, factivity, modality, structural, and relational features.

Finally, Le et al. (2016) used deep learning. They argued that the top terms in claim vs. non-claim sentences are highly overlapping in content, which is a problem for bag-of-words approaches. Thus, they used a Convolutional Neural Network, where each word is represented by its embedding and each named entity is replaced by its tag, e.g., *person*, *organization*, *location*.

Unlike the above work, we mimic the selection strategy of *one* specific fact-checking organization by learning to jointly predict the selection choices by *multiple* such organizations.

3 Data

In our experiments, we used the CW-USPD-2016 dataset from our previous work (Gencheva et al., 2017), which can be found on GitHub.[3] It is derived from transcripts of the 2016 US Presidential campaign, and includes one Vice-Presidential and three Presidential debates, all of which were fact-checked by the following nine reputable fact-checking organizations: PolitiFact, FactCheck, ABC, CNN, NPR, NYT, Chicago Tribune, The Guardian, and The Washington Post.

Overall, there are four debates with a total of 5,415 sentences. A sentence is considered check-worthy with respect to a source if that source has chosen to fact-check it. Overall, a total of 880 sentences were fact-checked by at least one source, 191 were selected by two or more sources, 100 by three or more, and only one sentence was chosen by all nine sources, as Table 1 shows. Table 2 shows an example: interventions by Hillary Clinton and Donald Trump from the first US presidential debate. This reflects the disparities in check-worthiness selection criteria. More details about the dataset can be found in (Gencheva et al., 2017).

Selected by # Sources	Number of Sentences	Cumulative Sum
9	1	1
8	6	7
7	5	12
6	19	31
5	26	57
4	40	97
3	100	197
2	191	388
1	**492**	**880**

Table 1: Agreement between the fact-checkers: sentences selected by 1, 2, . . ., 9 of them.

4 Our Multi-Task Learning Model

We approach the task of check-worthiness prediction as a multi-source learning problem, using different sources of annotation over the same training dataset. Thus, we can learn to mimic the selection strategy of each of the individual sources.

Figure 1 shows the architecture of our neural multi-task learning model which, given an input sentence in the context of a political debate, predicts whether each of the nine individual sources (tasks) would have selected it, and whether at least one of them would, which is the special *task ANY*.

The input to our neural network consists of various domain-specific features that have been previously shown to work well for the task of check-worthiness prediction. In particular, from (Hassan et al., 2015b), we adopt TF.IDF-weighted bag of words, part-of-speech tags, the presence of named entities, sentiment scores, and sentence length (in number of tokens). Moreover, from (Gencheva et al., 2017), we further adopt *lexicon features*, e.g., for bias (Recasens et al., 2013), for sentiment (Liu et al., 2005), for assertiveness (Hooper, 1974), and for subjectivity; *structural features*, e.g., for location of the sentence within the debate/intervention; LDA topics (Blei et al., 2003); word embeddings, pretrained on Google News (Mikolov et al., 2013); and discourse relations with respect to the neighboring sentences (Joty et al., 2015). See (Hassan et al., 2015b; Gencheva et al., 2017) for more details about each of these feature types.

After the input layer, comes a hidden layer that is shared between all tasks. It is followed by ten parallel task-specific hidden layers. During training, in the process of backpropagation, each task modifies the weights of its own task-specific layer and also of the shared layer.

[3] http://github.com/pgencheva/claim-rank

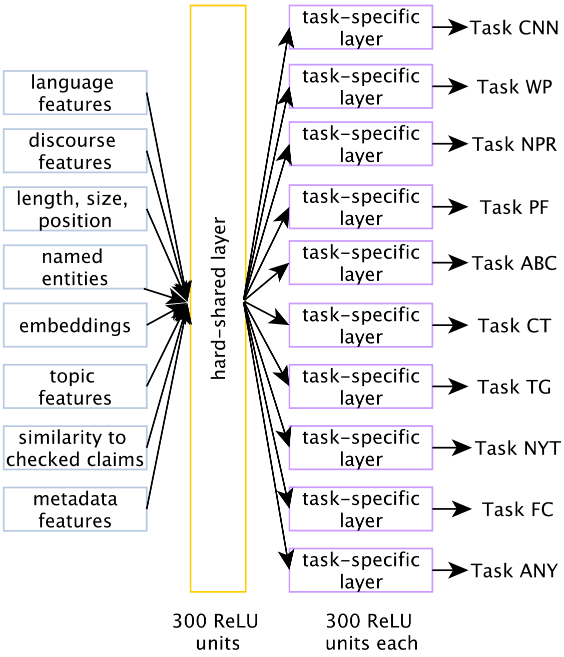

Figure 1: The architecture of our neural multi-task learning model, predicting whether each of the nine individual fact-checking organizations (tasks) would consider this sentence check-worthy and one cumulative source: *task ANY*.

Finally, each task-specific layer is followed by an output layer: a single sigmoid unit that provides the prediction of whether the utterance was fact-checked by the corresponding source. Eventually, we make use of the probability of the prediction to prioritize claims for fact-checking. This kind of neural network architecture for multi-task learning is known in the literature as *hard parameter sharing* (Caruana, 1993), and it can greatly reduce the risk of overfitting.

5 Experiments and Evaluation

As the CW-USPD-2016 corpus contains four debates, we perform 4-fold cross-validation, where each time we leave one debate out for testing, and we train on the remaining three debates. Moreover, in order to stabilize the results, we repeat each experiment three times with different random seeds and we report the average over these three reruns of the system.[4]

In our neural model, we used ReLU units and a shared layer of size 300. For training, we used Stochastic Gradient Descent with Nesterov momentum,[5] iterating for 100 epochs.

Recall that our main objective is to prioritize the claims that should be selected for manual fact-checking, which is best achieved by proposing a ranked list of claims. Thus, we have a ranking task, for which we use suitable information retrieval evaluation measures. In particular, we adopt Mean Average Precision (MAP) as our primary evaluation measure. We further report R-Precision, or R-Pr, and precision at k, or P@k,[6] for $k = \{5, 10, 20, 50\}$. Note that 50 is the approximate number of claims checked by most of the sources for each debate (the exception being PolitiFact, with up to 99 checked claims).

Table 3 presents the evaluation results comparing three models. The first one is a single-task model *singleton* where a separate neural network is trained for each source. The other two are multi-task learning models: *multi* predicts labels for each of the nine tasks, one for each fact-checker, and *multi+any* predicts labels for each of the nine tasks (one for each fact-checker), and also for *task ANY* (as shown in Figure 1). We further compare to the online version of ClaimBuster (Hassan et al., 2015b) and to the *singleton* results reported in (Gencheva et al., 2017) (on the same dataset, with the same cross-validation).[7]

We can see in Table 3 that our *singleton* is comparable and even slightly better than the *singleton* model in (Gencheva et al., 2017), and both outperform the online version of ClaimBuster (Hassan et al., 2015a). We further see that limiting our singleton system to ClaimBuster's features yields a sizable drop in performance. Moreover, for most sources, multi-task learning improves over the singleton models. The results of the multi-task variations that improve over the single baseline are boldfaced. The improvements are consistent across the evaluation measures, but they vary largely depending on the fact-checking source and the evaluation measure.

[4] Having multiple reruns is a standard procedure to stabilize an optimization algorithm that is sensitive to the random seed, e.g., this strategy has been argued for when using MERT for tuning hyper-parameters in Statistical Machine Translation (Foster and Kuhn, 2009).

[5] Using Adam optimizer was faster, converging after only 30 epochs, but it yielded slightly worse results.

[6] See (Buckley and Voorhees, 2000) for a discussion on these evaluation measures.

[7] Note that we could not compare to (Patwari et al., 2017) directly as they used a different dataset. However, they use a small set of basic features that overlap with those of ClaimBuster (Hassan et al., 2015b) to a large extent, and thus we expect that they would perform similarly to ClaimBuster.

Speaker	Total	CT	ABC	CNN	WP	NPR	PF	TG	NYT	FC	Text
Clinton	0	0	0	0	0	0	0	0	0	0	So we're now on the precipice of having a potentially much better economy, but the last thing we need to do is to go back to the policies that failed us in the first place.
Clinton	6	1	1	0	0	1	1	0	1	1	Independent experts have looked at what I've proposed and looked at what Donald's proposed, and basically they've said this, that if his tax plan, which would blow up the debt by over $5 trillion and would in some instances disadvantage middle-class families compared to the wealthy, were to go into effect, we would lose 3.5 million jobs and maybe have another recession.
Clinton	1	1	0	0	0	0	0	0	0	0	They've looked at my plans and they've said, OK, if we can do this, and I intend to get it done, we will have 10 million more new jobs, because we will be making investments where we can grow the economy.
Clinton	0	0	0	0	0	0	0	0	0	0	Take clean energy.
Clinton	0	0	0	0	0	0	0	0	0	0	Some country is going to be the clean- energy superpower of the 21st century.
Clinton	6	1	1	1	1	0	0	1	0	1	Donald thinks that climate change is a hoax perpetrated by the Chinese.
Clinton	0	0	0	0	0	0	0	0	0	0	I think it's real.
Trump	5	1	1	0	1	1	1	0	0	0	I did not.

Table 2: Excerpt from the transcript of the first US 2016 Presidential Debate, annotated by nine sources: Chicago Tribune, ABC News, CNN, Washington Post, NPR, PolitiFact, The Guardian, The New York Times and Factcheck.org. Whether the media fact-checked the claim or not is indicated by a 1 or 0, respectively. The blue sentences are considered as positive in the *any* setting.

One notable exception is NYT, for which the single-task learning shows the highest scores. We hypothesize that the network has found some distinctive features of NYT, which make it easy to predict. These relations are blurred when we try to optimize for multiple tasks at once. However, it is important to state that removing NYT from the learning targets worsens the results for the other sources, i.e. it carries some important relations that are worth modeling.

Table 4 presents the same results but averaged over the nine sources. The first section in Table 4 shows the results for the online version of ClaimBuster (Hassan et al., 2015b), and for the *singleton* and the *task ANY* results in (Gencheva et al., 2017). We can see that our *singleton* model is comparable to the *singleton* and *any* models in (Gencheva et al., 2017), and our multi-task learning models consistently improve over them for all evaluation measures in all but one case.

It is common in neural networks to try to implicitly learn the representations based on word embeddings. We include this as a baseline in the second section in Table 4. The performance of the model that only uses embeddings is in general poor, which suggests that complex feature modeling is necessary for this task; including features that go beyond the current-sentence level. Further feature analysis is included in Table 6.

The third section of Table 4 presents the results for the models of this paper. Again, we can see that multi-task learning yields sizeable improvement over the single-task learning baseline for all evaluation measures.

Another conclusion that can be drawn from this table is that including the task *task ANY* (i.e., whether any of the nine media would select a target) does not help to improve the multi-task model. This is probably due to the fact that this information is already contained in the multi-task model with nine sources.

The last section in Table 4 presents two additional variants of the model: the single-task learning *any* system —which trains on the union of the selected sentences by all nine fact-checkers to predict the target fact-checker only—, and the system *singleton+any* that predicts labels for two tasks: (*i*) for the target fact-checker, and (*ii*) for *task ANY*. We can see that *any* performs comparably to the *singleton* baseline, thus being clearly inferior than the multi-task learning variants. Finally, *singleton+any* is also better than the single-task learning variants, but it falls short compared to the other multi-task learning variants. Including output units for all nine individual media seems crucial for getting advantage of the multi-task learning, i.e., considering only an extra output prediction node for the *task ANY* problem is not enough.

Table 4: Evaluation results averaged over nine fact-checking organizations (see Table 3 for the unrolled results). We compare multi-task learning to three *singleton* baselines; the improvements are shown in bold. The first section compares to the online version of ClaimBuster (Hassan et al., 2015b), as well as to *singleton* and to *task ANY* results in (Gencheva et al., 2017). The improvements over the latter are underlined. The last section shows the results for two more baselines: *any* and *singleton+any* .

6 Discussion

In this section, we provide deeper insight into the peculiar characteristics of the multi-task model.

Error Analysis First, we perform comparative error analysis, showing both examples of improvement of the proposed *multi* model with respect to the *singleton* as well as some cases where the former fails. The results are shown in Table 5. The first four rows are true positive claims, which were misclassified by the *singleton* model, but were correctly classified by the *multi-task* one. As we can see, the claims were selected for fact-checking by many organizations: between six and eight. This reflects that these instances were certainly check-worthy and the multi-task model correctly spotted them. The observation holds for a prevailing number of all of the new true positives. This is a natural consequence of our neural architecture, where all sources share a hidden layer and tend to learn from the selection criteria of the other sources as well.

Two types of false positive errors occur in rows 5–8. Rows 5 and 6 are predicted by multiple sources that reinforce one another for the wrong guess. We can attribute this to the specifics of the multi-task architecture. On the one hand, the shared layer helps a medium to learn from the selection process of other media. On the other hand, it begins to make more mistakes on claims selected by more media.

N	Type	Tgt	#	Sentence
1	TP	CT	8	**Trump** ▸ It's gone, $6 billion.
2	TP	WP	8	**Trump** ▸ I was against – I was against the war in Iraq.
3	TP	TG	6	**Trump** ▸ You ran the State Department, $6 billion was either stolen.
4	TP	NYT	6	**Pence** ▸ Less than 10 cents on the dollar of the Clinton Foundation has gone to charitable causes.
5	FP	CT	4	**Trump** ▸ Wrong.
6	FP	CT	3	**Trump** ▸ In Chicago, they've had thousands of shootings, thousands since January 1st.
7	FP	CNN	0	**Clinton** ▸ Donald has said he's in favor of defending Planned Parenthood.
8	FP	WP	0	**Trump** ▸ I never met Putin.
9	FN	FC	6	**Clinton** ▸ Donald thinks that climate change is a hoax perpetrated by the Chinese.
10	FN	NYT	4	**Pence** ▸ And Iraq has been overrun by ISIS, because Hillary Clinton failed to renegotiate...
11	FN	NPR	1	**Trump** ▸ China should go into North Korea.
12	FN	NPR	1	**Trump** ▸ We have no growth in this country.

Table 5: Sentences with prediction type (for the *multi* model, with respect to the target medium), the target medium, and total number of media that selected this sentence (#).

On the contrary, rows 7 and 8 show claims that are not check-worthy for any source, but exhibit features such as named entities and negations that typically suggest that the claim might be check-worthy. Finally, rows 9–12 are false negative instances. We have two claims that were fact-checked by several media and two selected by one medium only. The first group indicates that some tasks might try to learn their own features, while the second group shows a possible down side of the multi-task model.

Feature Importance Next, we conduct feature ablation experiments to determine which of the feature groups are most important for the final multi-task model. For this purpose, we remove one feature group at a time from the *multi* model.

Table 6 shows that without the Embedding features the performance of the model drops significantly. They were also the best features in the *singletonG* model of Gencheva et al. (2017). Metadata features are the second most important for the model. An interesting observation is that some of the best-preforming features from *singletonG* are the least contributing to the multi-task model. Such features are *Sim. to prev.* (similarity to previously fact-checked claims), and the linguistic features.

Feature	MAP	R-Pr	P@5	P@10	P@20	P@50

Table 6: Ablation experiments: removing a feature group from the *multi* model, using all nine tasks.

Source Ablation Figure 2 shows ablation results with the *multi* model. A cell at row r and column c shows the performance difference for target c when excluding the target r at training time. For example, in the first row we run the *multi* model neglecting CT in the set of targets. Negative values indicate that removing target r worsens the MAP of target c. Conversely, positive values indicate that removing target r improves MAP for target c. We can observe that the MAP of ABC has dropped by .008, meaning that ABC finds beneficial information from sharing a layer with the CT target. On the contrary, the target FC improves after removing CT, pointing out the presence of conflicts in the learning phase of the shared layer. The largest decrease in MAP is observed in PF after removing CNN, NYT, and NPR. On the other hand, the most significant increase in MAP is in WP after removing NPR and CNN.

7 Conclusion and Future Work

We have presented a multi-task learning approach for estimating the check-worthiness of claims in political debates, and we have further demonstrated its effectiveness experimentally, pushing the state of the art.

In future work, we plan to experiment with more debates. We further plan to go beyond debates, i.e., to general news articles. Moreover, we would like to apply our approach to other languages for which multiple check-worthiness annotations of the same dataset are available.

We plan to try information sources such as the Web (Popat et al., 2017), as well as tweets and temporal information (Ma et al., 2016). We also want to explore other multi-task learning options, e.g., as described in (Ruder, 2017).

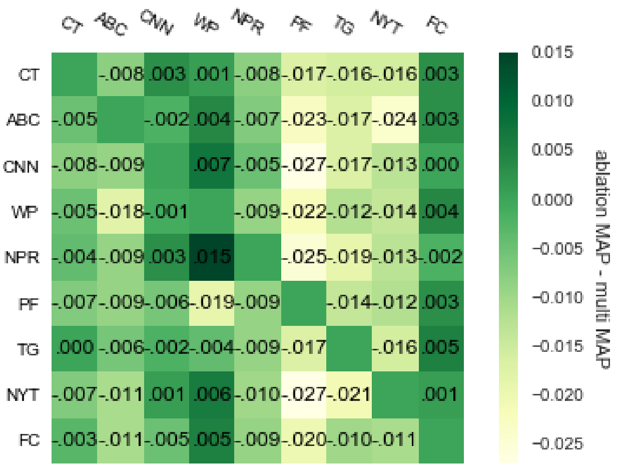

Figure 2: Ablation experiment with the *multi* model. Each row is an experiment removing one target. Each column is the MAP *difference* with respect to the *multi* model for the corresponding target.

It would be interesting to investigate the reasons why the NYT source does not benefit from the multi-task architecture. In order to adapt to this situation with a single model, we plan to experiment with a network with *soft parameter sharing*, e.g., as in (Duong et al., 2015). For example, we could create a chain of layers that back-propagate to the input using only single task targets and then add an auxiliary layer that is shared between the tasks on the side. In this way, the model would be able to turn off the multi-task learning completely for some of the sources. However, training such kind of model might require significantly more training data; semi-supervised training might be a possible solution.

Acknowledgments

We would like to thank the anonymous reviewer, whose constructive feedback has helped us improve the quality of this paper.

This work is part of the Tanbih project,[8] which aims to limit the effect of “fake news”, propaganda and media bias by making users aware of what they are reading. The project is developed in collaboration between the Qatar Computing Research Institute (QCRI), HBKU and the MIT Computer Science and Artificial Intelligence Laboratory (CSAIL).

Abstract

This paper presents an approach for prediction of results for sport events. Usually the sport forecasting approaches are based on structured data. We test the hypothesis that the sports results can be predicted by using natural language processing and machine learning techniques applied over interviews with the players shortly before the sport events. The proposed method uses deep learning contextual models, applied over unstructured textual documents. Several experiments were performed for interviews with players in individual sports like boxing, martial arts, and tennis. The results from the conducted experiment confirmed our initial assumption that an interview from a sportsman before a match contains information that can be used for prediction the outcome from it. Furthermore, the results provide strong evidence in support of our research hypothesis, that is, we can predict the outcome from a sport match analyzing an interview, given before it.

1 Introduction

1.1 Motivation

The problem of predicting sports results is very challenging and is widely explored in artificial intelligence (AI) (McCabe and Trevathan, 2008). This task requires application of complex algorithms over a huge variety of heterogeneous types of features. Classical decisions are based on statistical and probability models. The AI techniques used to solve this task are based on machine learning (Keshtkar Langaroudi and Yamaghani, 2019) and data mining (Haghighat et al., 2013). This is due to the lack of large datasets with previous results for players and games. Sport is a very dynamic area and players are active for a relatively short period of time. There are also limitations to the predictability of sports outcomes data over a long period of time.

Team sports are more difficult to predict because different team members are selected to play games and even during the game several changes are made to the team, several penalties and injuries to the players that can have a huge impact on the end result. Such predictions in sports rely on many features and time models over a long period of time. In this way, we are able to tackle the task of predicting sports results only in individual sports, such as tennis, boxing, mixed martial arts (MMA) and etc.

1.2 Related Works and Methods

The task of prediction of the sport results can be solved as a classification problem. Naïve Bayes (NB) (McCallum et al., 1998) is the simplest method of classification. It can show good results even for small sets of training data, as is the case with the sports prediction task. The main drawback of the approach is the assumption of attribute independence. Joseph et al (Joseph et al., 2006) presents an application of NB to predict football scores from a database of 76 matches with 30 attributes. The overall average percentage of correct NB learner estimates is 47.86% for the entire database. For a subset of season 1, both with train and test settings from the same season, accuracy increases to 81.58%.

Support Vector Machines (SVM) (Cortes and Vapnik, 1995) are linear classifiers that, like NB classifiers, do not require a large set of training data, making them an appropriate method for predicting sports outcomes. Igiri (Igiri, 2015) presents experimental football prediction results

Proceedings of Recent Advances in Natural Language Processing, pages 1240–1246,
Varna, Bulgaria, Sep 2–4 2019.

with an accuracy of 53.3%. The dataset is based on the English Premier League, with 38 attributes, data for 16 matches in a training set and 15 matches in a test set.

Logistic Regression (Dreiseitl and Ohno-Machado, 2002) can handle the latter problem when the size of the feature space is larger than the size of the training set.

K-nearest neighbour (kNN) (Cunningham and Delany, 2007) A classifier is a proximity classifier that uses distance-based measures for the classification task. Joseph et al (Joseph et al., 2006) presents a kNN application for predicting football scores with an overall average accuracy of 50.58%. They report the highest accuracy of 97.37% for a subset where both training and test sets contain data from the same season.

Other classic classification methods are Random forest, Decision trees, and Rule-based classification. Lock and Nettleton (Lock and Nettleton, 2014) also propose a Random Forest-based approach to predicting winners in the National Football League. Joseph et al.(Joseph et al., 2006) report experiment results for classification for predicting football scores with an overall average accuracy of 45.77% and a maximum accuracy of 78.95%.

Artificial neural networks (ANNs), deep learning, and transfer training are the current preferred approaches to the classification task as they show very high accuracy for large training datasets. An example of applying ANN in predicting football results is presented in (Arabzad et al., 2014) for a set of 2,068 match results records.

The successful application of the classification techniques in tweets for football prediction was presented by (Kampakis and Adamides, 2014) and (Sinha et al., 2013). The model has been learned from about 2 million posts by Tweeter. The maximum accuracy reported for classification is 74.7% (Kampakis and Adamides, 2014).

1.3 Research Hypotheses

We assume that an interview by a sportsman shortly before the match contains information that can be used to predict the outcome of it. In order to extract this information, we first need to understand what the interviewee specifically says about the outcome of the match. Furthermore, this information can be shaded. In addition, we need to capture information that is relevant to the match, but is expressed in a semi-explicit or implicit way, such as health conditions, confidence, psyche, etc. Therefore, we formulate the following research hypothesis: We can predict the outcome of a sport match by analyzing a given pre-match interview using modern NLP and ML methods. To test this hypothesis, we developed the following experiments. First, we learned a model for predicting the outcome of a match without thinking about the interview, using only the available player data such as rank, score in the previous match and ages. We then learned a model for predicting math score solely based on an NLP interview analysis.

2 The Dataset

2.1 Data Collection

For the purpose of our study we collected 50 articles with interviews, in Bulgarian language, conducted with sportsmen shortly before their matches. Interviews are collected online manually and include only individual sports - Boxing, Mixed martial arts (MMA) and Tennis. The idea is to determine if information from them could serve to guess the outcome of the upcoming match - win or lose. For these interviews, we also collected some additional structured data from the official sports rankings, as follows: **Sport** (Boxing:MMA:Tennis – 21:5:24), **Sex** (M:F – 47:3), **IntRank** (Rank of the interviewee), **OppRank** (Rank of the opponent), **IntAge** (Age of the interviewee), **OppAge** (Age of the opponent), **PrevMatch** (The result in the previous match with the same opponent: *W* (The interviewee wins), *L* (The interviewee loses), *N* (There isn't a previous match)) and **Result** (Whether the interviewee *Wins* or *Loses* the match - 56%:44%).

There are no missing values. All structured data and interviews are publicly available[1].

2.2 Data Preprocessing

2.2.1 Structured Data Preprocessing

There is a significant difference in the presentation of player rank and calculations for different sports. For example, tennis rank is a singular number, unlike boxing rank and MMA players are usually presented as a triple ”win – lose – draw”. So, some sort of rank data format was merged. In addition, two derived attributes were added to represent the difference in age and rank of players:

[1] https://github.com/BorisVelichkov/paper

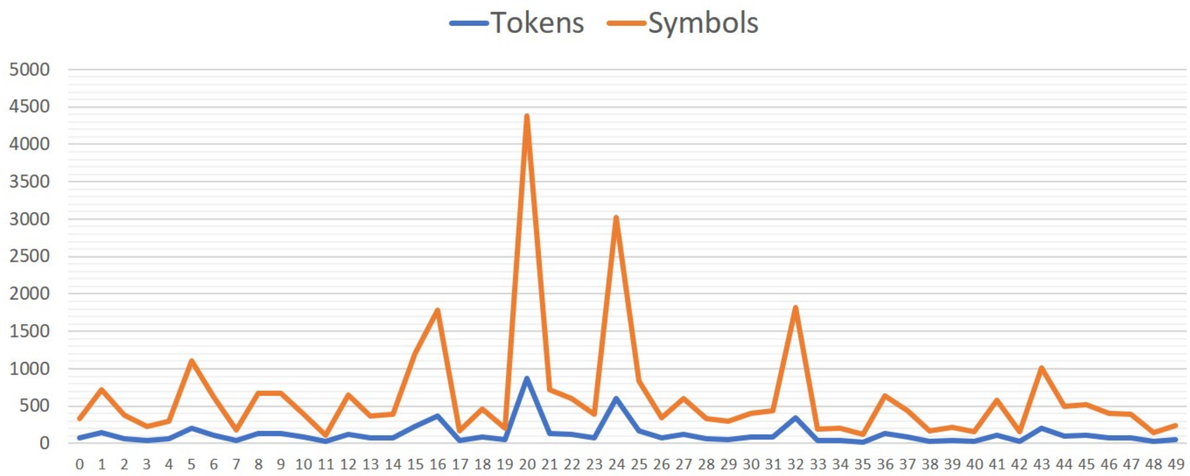

Figure 1: The number of tokens and symbols in the interviews

DiffRank and **DiffAge**. Finally, all data were normalized using a min-max normalization approach.

2.2.2 Unstructured Data Preprocessing

Initial data cleaning and preprocessing was performed. From interviews were removed reporters' comments, leaving only sportsman's quotes/replies. All data are labeled in two categories ”win” and ”lose”, depending on whether the interviewee wins or loses the match discussed in the interview.

Some additional text transformations are applied to the texts for text vectorization. The basic transformations consist of the following steps:

- tokenization - the collection contains 7,799 tokens from 1,469 types;
- all words are converted to lower case;
- all non-Cyrillic words and symbols are removed;
- all punctuation marks are removed;
- all numbers are removed;
- a stemmer is applied - we used the stemmer for Bulgarian language - Bulstem (Nakov, 2003), that provides 3 types of context stemming rules. Based on this, three different datasets are formed, for which we will refer as ”Stem 1”, ”Stem 2” and ”Stem 3”.
- and finally text vectorization based on TFIDF is applied.

The number of words and characters for each interview is shown in Figure 1. The average number of words and characters for interview is respectively 124.52 and 623.8.

3 Experiments

The main purpose of the conducted experiments is to test the assumption that an interview by a sportsman before a match contains information that can be used to predict the outcome of it. Furthermore we would like to explore whether modern pre-trained contextualization models such us a Word2vec (Mikolov et al., 2013) and BERT (Devlin et al., 2018) could help in this task. We also explored how feature selection can affect the accuracy of model building prediction using machine learning (ML) algorithms. Feature selection seems to be an important preprocessing step for many ML algorithms, especially when the attribute space is large, but the examples shown are scarce.

In the experiment we use the following supervised ML algorithms: k-Nearest Neighbors, Support Vector Machines (v-SVM, RBF kernel), Stochastic gradient descent (Squared loss regression, Squared & insensitive classification, Elastic Net regularization, Inverse scaling learning rate), Random Forest (5 trees, 4 attributes per split), Neural Networks (ReLu, 20 hidden layers, Adam solver), Naïve Classifier and Logistic Regression (Regularization type – Ridge L2). Most of the algorithms' parameters are on its default value. The initial setup of some of them was made for structural data so that the algorithms would show their best performance on it. It then remains unchanged throughout the remaining experiments.

For all experiment we used 10-fold cross-validation for models' prediction evaluation.

3.1 Experiments with Structured Data

In the first experiments, we used a structured data set just to learn models that could predict the outcome of the matches. In our general setup of experiments, the prediction accuracy of these models will serve as a baseline for the performance of models learned on an unstructured dataset. The very baseline of the dataset is the prediction of the majority class - 56%.

Model	Accuracy
kNN	0.60
SVM	0.64
SGD	0.60
Random Forest	0.62
Neural Network	**0.66**
Naïve Bayes	0.56
Logistic Regression	0.58

Table 1: Performance of employed ML algorithm using structured data only.

Table 1 presents the experiment results with structured data. The average forecast accuracy is 61%, which is slightly higher than the baseline. Our main goal is not to compare the accuracy achieved with different ML algorithms, but we can mention that algorithms that build more sophisticated models, such as ANN, SVM, and Random Forest, achieve slightly higher accuracy.

3.2 Experiments with Unstructured Data

In the second group of experiments the employed ML algorithms are used on unstructured datasets.

3.2.1 Topic Models

This experiment is based on topic models that have been chosen as a more advanced method than the BOW and TFIDF, as an attempt to capture the basic semantics of the interviews. We experimented with several Topic Modeling Techniques for pre-selected limit 20 for topics sets: Hierarchical Dirichlet Process (HDP) (Teh et al., 2005), Latent Dirichlet Allocation (LDA) (Blei et al., 2003), and Latent Semantic Indexing (LDI) (Hofmann, 2017). The result from experiments are presented in Table 4. We can see that model performance is about the same as that learned on structural data, and HDP slightly outperforms the other two algorithms in this task.

Model	HDP	LDA	LSI
SVM	0.62	0.36	0.58
Random Forest	0.60	**0.60**	0.48
Neural Network	**0.64**	0.56	0.50
NaïveBayes	0.62	0.62	**0.54**

Table 2: Average accuracy of used machine learning algorithms on unstructured data using Topic models HDA, LDA and LSI

3.2.2 Features Selection

To reduce the space dimensionality after text vectorization are applied several features selection techniques. The approach combines the results from the following 6 features selection techniques (Yang and Pedersen, 1997), (Shardlow, 2016), (Saeys et al., 2007):

- Filter methods: (1) χ^2 and (2) Pearson Correlation;
- Wrapper methods: (3) Recursive feature elimination with Logistic Regression;
- Embedded methods: (4) Logistics Regression L1; (5) Random Forest, and (6) LightGBM (Gradient Boosting Machines).

The features, selected from all 6 methods as appropriate, form the first set of features called ”Top 1 features”. Features that are selected through 5 of the 6 appropriate methods form the second feature set, called the ”Top 2 Features”. These two feature categories help to create datasets with filtered features. As a result, there are 3 versions for each dataset: ”All features”, ”Top 1 & Top 2 features” and ”Top 1 features”.

We experimented with the 3 stemmers available. We found no significant effect on the prediction accuracy of the selected stemmer for this task.

Most of the Top 1 features include words that describe in some way the player's condition (“форма” - form, “способен” - ability, “специал” - specialty, “силен” - strong, “здрав” - solid), player expectations and attitudes (“чувств” - feel, “участва” - involved, “нокаутира” - knocked out, “постижени” - achieved, “получи” - received, “оценява” - evaluated, “вярвам” - believe, “вълнува” - excite, “край” - end), information about the training process (“треньор” - trainer, “тренировъч” - training) and many others that are difficult to summarize as a specific category (“деца” - children, “взето” - taken, “софия”

- sofia, and etc.). Interesting is the presence of the words “бокс” - box and “боксов” - boxing in these features because they are describing one exact sport - boxing. 42% of interviews are about boxing matches. Top 2 features include words that are related to pre-match preparation (“подготвя” - prepares, “план” - plan, “процес” - process) and its outcome (“видим” - visible, “обрат” - turning point, “доказва” - proves).

Using feature selection we can reduce features to average 4.80% features with Top 1 features and average 7.49% features with Top 1 & Top 2 features, see Table 3.

Features	Stem 1	Stem 2	Stem 3
All Features	1281	1350	1453
Top 1 Features	65	64	67
Top 2 Features	36	40	34

Table 3: Number of features for Top 1, Top 2 and all features on unstructured data

Model	Stem 1	Stem 2	Stem 3

Naïve Bayes	0.78	0.88	0.82
Logistic Regression	0.84	**0.90**	0.86

Table 5: Accuracy of prediction for the employed ML algorithm on unstructured data with Top 1 & Top 2 features

Experiments with datasets with feature selection in above described setup (Top 1 & Top 2 features) shows surprisingly good accuracy of prediction, see Table 5. Further reducing the size of feature space (Top 1 features) results in even better forecasting accuracy, see Table 6. Given the large number of features and the relatively small training data set, such an improvement after the selection of features is not unexpected. All experiments were performed with the same parameter settings for ML algorithms as those for the structured dataset.

Model	Stem 1	Stem 2	Stem 3
kNN	0.62	0.62	0.62
SVM	**0.96**	**0.94**	**0.92**
SGD	0.94	0.82	**0.92**

3.2.3 Employing BERT Pre-trained Models

For the text/unstructured dataset, we also used the Google’s pre-trained model BERT (deep bidirectional transformers for language understanding) (Devlin et al., 2018). It has been trained on English Wikipedia and the BookCorpus. For this study we used two of the models: the first one is the default one - *“bert_uncased_L-12_H-768_A-12”*: the second model we used is the Multilingual one - *“bert_multi_cased_L-12_H-768_A-12”*. For our experiments the raw text format is used as an input.

Table 7 presents the results of the experiments performed. We can see that the BERT default model performs significantly better than the multilingual BERT model - over 20 %. At the moment we do not have explanation to such difference. An interesting observation is that the accuracy varies very much across the folds from 0% to 100%. Therefor we run 10 times 10-fold cross validation on random selected folds.

In the context of our main research hypothesis, the two BERT models achieved greater accuracy than the models learned from structured data. This is further evidence that strongly supports our main hypothesis that sportsmen interviews contains information (mostly implicitly presented) that modern NLP techniques and pre-trained models can capture and use it to predict the outcome of a match with very high altitude accuracy.

3.3 Discussion

The results of the experiments performed on structured data alone show that we can build a model

BERT model	Average Accuracy
Default BERT	**0.92**
Multilingual BERT	0.70

Table 7: Performance of BERT models on interviews in Bulgarian language

that achieves a prediction accuracy of 66%. This is significantly above the accuracy of the majority class prediction baseline , which is 56%.

Model based on interviews' content only, achieves an maximum accuracy of 64% for the topic models and 62% for all features. This confirms our initial assumption that the content of the sportsman's interview given before the match contains information that can be used to predict the outcome of the match. In addition, it provides evidence to support our research hypothesis that using modern NLP and ML methods, we can build a classifier that "understands" the text, even possibly caching implicit signals in the text related to the outcome of the match. The interviews show the sportsman's current attitude towards the match and his/her current physical and mental form for the next match. The text contains many moods and shows the sportsman's willingness and readiness to win.

In comparison with our basic model, based on structure data only, we can see that the model build on interviews only, provides approximately the same accuracy. Finally, using feature selection that allows to be captured more significant words for the interviews context, we achieve accuracy 96% for SVM model and Top 1 features, which is an increase in comparison to the previous results. This provides evidence to support the hypothesis that the interview text contains some implicit signals that current NLP methods are able to extract, and that cannot be extracted from structured data.

4 Conclusions

The results of the experiment confirmed our initial assumption that the pre-match sportsman's interview contain information that could be used to predict the outcome of the match. In addition, the results provide strong evidence to support our research hypothesis, that is, we can predict the outcome of a sport match by analyzing an interview given before it using modern NLP and ML methods. More generally, the result of the experiment provides some evidence that current NLP methods are quite cable to "understand" the meaning of text at an almost human level. For feature work we plan to collect a bigger corpora of interviews and conduct further experiments to provide more solid evidences about our research hypotheses and to explore the problem in more details. We also plan to make experiments for collective sports and to combine information from several player interviews, because for such sports is not clear how individual player performance can contribute to the overall match result.

Abstract

We describe a novel system for automatic extraction of typological linguistic information from descriptive grammars of natural languages, applying the theory of frame semantics in the form of frame-semantic parsing. The current proof-of-concept system covers a few selected linguistic features, but the methodology is general and can be extended not only to other typological features but also to descriptive grammars written in languages other than English. Such a system is expected to be a useful assistance for automatic curation of typological databases which otherwise are built manually, a very labor and time consuming as well as cognitively taxing enterprise.

1 Introduction

There are more than 7,000 living languages in the world and grammatical descriptions[1] are available for some 4,000 of these (Seifart et al., 2017). A central concern of the academic discipline of linguistics is to classify languages along different dimensions. The subbranch of linguistics which deals with classification and comparison of languages based on their structural and functional characteristics is known as *linguistic typology* (or *typological linguistics*. In addition to comparing the world's languages, practitioners of linguistic typology aim to explore the distribution of various structural and functional patterns among languages and to explain them in historical and/or universal terms. (Song, 2010)

To achieve its goals, typological linguistics has relied largely on manual reading of available descriptive material about languages for the extraction of pertinent feature values for comparison of these across languages. For example, in their sentence structure, different languages favor different word orders (e.g. subject-object-verb, verb-object-subject, or object-verb-subject, etc). If word order is to be used as one structural feature for language comparison, the word order of all the languages to be compared has to be found out manually by reading available material on those languages. This is doable, if the scope of comparison is to be limited to a few features spanning across a few languages. If one aims to extend the scope from a few to a few hundred features spanning across thousands of languages, the manual reading and comparison strategy seems simply unfeasible. With the availability of large amounts of digital data, and the recent advances in natural language processing, automatic extraction of typological features from grammatical descriptions seems a plausible task.

There have already been a few attempts to automatically extract typological and other linguistic information from descriptive grammars (Virk et al., 2017; Borin et al., 2018). In these studies, the authors have reported simple pattern matching and syntactic parsing based approaches, and have shown that their strategy is useful, yielding reasonable precision and recall values. Even though simple pattern matching based systems are easy to comprehend, implement, and maintain, they require a deep understanding of the rules/patterns which may not be very obvious in certain cases. Further, such systems are heuristics based and also require a large manual effort (Chiticariu et al., 2013). For these reasons the pattern-matching based systems are becoming a less and

[1] Grammatical descriptions are plain text descriptions of various phonological, morphological, and syntactic characteristics of languages.

Proceedings of Recent Advances in Natural Language Processing, pages 1247–1256,
Varna, Bulgaria, Sep 2–4 2019.

less attractive choice and machine learning and big-data based approaches are taking their place.

In this paper, we report a novel methodology and a system for automatic extraction of typological information from descriptive grammars. The system is based on the theory of frame semantics and frame-semantic parsing, and employs a machine learning based approach. Using a set of domain-specific semantic frames, a handful of descriptive grammars are manually annotated with linguistic frames and their associated frame elements. Using these annotations as training data, machine learning models are trained and tested, which are then used to automatically annotate new descriptive grammars. The annotations are subsequently converted into typological feature values using a small rule based module, hence resulting in automatic extraction of typological feature values from descriptive grammars.

Section 2 describes frame semantics, FrameNet, and frame-semantic parsing as a theoretical background, followed by a brief introduction to the the linguistic domain FrameNet (Section 3). The development of a parser for the linguistic domain is outlined in Section 4, leading to a description of the system for automatic extraction of typological features (Section 5).

2 Frame Semantics, FrameNet, and Frame-Semantic Parsing

2.1 Frame Semantics

Frame semantics is a theory of meaning in language introduced by Charles Filmore (Fillmore, 1976, 1977, 1982). The theory is based on the notion that meanings of words can be best understood when studied in connection with the situations to which they belong, and/or in which they may occur.

The backbone of the theory is a conceptual structure called a *semantic frame*, which is a script-like description of a prototypical situation, an event, an object, or a relation. As an example, consider a real life scenario of robbery – a situation in which someone (a perpetrator) wrongs a victim by taking something (goods) from him/her. A structured representation of such a situation is called a *semantic frame*. The participants of the situation (i.e. the perpetrator, the victim, the goods, time, place, manner) are called *frame elements*. Some of the them (the perpetrator, the victim, and the goods) are necessary for the situation to make sense and are called *core frame elements*. Others like the place where the robbery took place, the manner in which it took place are called *non-core frame elements* (see Ruppenhofer et al., 2016 for details). Now, with the availability of a structured representation of the robbery situation, words like *hold up, mug, ransack, rifle, rob, stick up* can be better understood and analyzed.

2.2 FrameNet

The development of a lexico-semantic resource – FrameNet (Baker et al., 1998) – based on the theory of frame semantics was initiated in 1998 for English. In this lexical resource, generally referred to as simply FrameNet or Berkeley FrameNet (BFN), each of the semantic frames has a set of associated words (or *triggers*) which can evoke that particular semantic frame. The linguistic expressions for participants, props, and other characteristic elements of the situations (called *frame elements*) are also identified for each frame. In addition, each semantic frame is accompanied by example sentences taken from naturally occurring natural language text, annotated with triggers, frame elements and other linguistic information.

In the context of deploying FrameNets in NLP applications, BFN and other FrameNets have often been criticized for their limited coverage. A solution to this problem is to develop domain-specific (sublanguage) FrameNets to complement the corresponding general-language FrameNets for particular NLP tasks. In the literature we find such initiatives covering various domains, e.g.: (1) a FrameNet to cover medical terminology (Borin et al., 2007); (2) *Kicktionary*,[2] a soccer language FrameNet; (3) the *Copa 2014* project, covering the domains of soccer, tourism and the World Cup in Brazilian Portuguese, English and Spanish (Torrent et al., 2014).

Because of their perceived usefulness for a variety of purposes, general-language FrameNets have also been developed for a number of other languages including Chinese, French, German, Hebrew, Korean, Italian, Japanese, Portuguese, Spanish, and Swedish.

2.3 Frame-Semantic Parsing

In addition to the annotated examples, FrameNets are also often accompanied by varying amounts of frame-annotated natural running text intended

[2] http://www.kicktionary.de/

both to illustrate particular semantic-frame usages and to demonstrate the utility of frame semantics as a model of meaning in language. One of the uses of such annotated text is to develop automatic frame-semantic parsers, which in turn have proved useful in a number of natural language processing tasks including question answering (Shen and Lapata, 2007), coreference resolution (Ponzetto and Strube, 2006), paraphrase extraction (Hasegawa et al., 2011), machine translation (Wu and Fung, 2009), and information extraction (Surdeanu et al., 2003).

Frame-semantic parsing necessarily involves three basic steps. These are frame identification, frame element identification, and frame-element classification. Consider the annotated sentence shown in Figure 1 to better understand those basic steps of the frame semantic parsing. If the annotation shown is to be done automatically, the first step would be to consider each word of the sentence and check if it evokes a particular frame or not, and disambiguate in case if the candidate word evokes more than one frame. As a result, the word *agrees* (shown in bold) will be recognized as a lexical unit triggering the AGREEMENT frame. This is the frame identification task. Having identified the frame-triggering lexical units and the triggered frame, the next steps are to identify the text segments filling various semantic roles (i.e. frame elements) of the triggered frame. For this task, each word (or combination of words) in the sentence needs to checked for whether it expresses a frame element or not. This is the frame-element identification task. When a particular word or word-combination has been recognized as a frame element, it should be labeled next i.e. frame-element classification. So the frame-element identification and classification tasks will label the text segment *The genitive* as 'Participant_1', *sometimes* as 'Frequency', *noun* as 'Participant_2', *in gender* as 'Grammatical_Category' and *Gondi* as the 'Reference_Language'.

All of these three steps can be formulated as supervised machine learning classification tasks. Gildea and Jurafsky (2002) were the first to report their experiments with an automatic frame-semantic parsing system, and since then there have been a number of studies (Johansson and Nugues, 2008; Swayamdipta et al., 2017; Kabbach et al., 2018) and a shared task (Surdeanu et al., 2008) devoted to exploring and improving the task of frame-semantic parsing.

3 LingFN – a FrameNet for the Linguistic Domain

Linguistics has established a rich set of domain-specific terms and concepts such as *verbs*, *nouns*, *determiners*, *inflection*, *agreement*, *affixation*, etc. Inspired by other domain-specific FrameNets (mentioned in Section 2.2), the development of a FrameNet for the linguistic domain (LingFN) has been previously reported (Malm et al., 2018). LingFN contains two types of frames: the *filler frames* and the *eventful frames*. The former are to cover simple linguistic terms such as *noun*, *verb*, etc. mostly referring to the morpho-syntactic linguistic categories, and the later type covers linguistic processes such as *inflection*, *agreement*, *affixation* etc. Based on the empirical investigations of the usage of those terms and concepts in a large collection of domain-specific data, both types of frames were constructed. Consider again Figure 1 which also shows the structure of the AGREEMENT frame – an eventful of frame. In the linguistic domain, agreement is a phenomenon in which words of a particular morphological category (e.g. nouns) agree with another morphological category for a particular grammatical category (gender, number, etc.). The structure shown in Figure 1 was developed based on the investigations of the usage of the word *agree* within the linguistic corpora. See Malm et al. (2018) for a detailed description of the procedure followed to design frames together with annotated example sentences given to show the realization of those frames in the linguistic domain data.

The current version of LingFN contains a total of 100 frames, 32 frame elements, 360 lexical units, and around 2,800 annotated examples.

For the study reported in this paper, we have restricted ourselves to the frames outlined in Table 1 in addition to the AGREEMENT frame above. These frames will prove useful while automatically extracting values of certain typological feature as will be elaborated in Section 5.

4 The LingFN Parser

This section describes the development of an automatic parser based on LingFN. Treating it as a

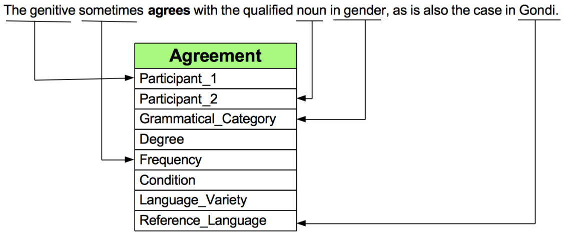

Figure 1: The structure of the AGREEMENT frame

supervised machine learning task, we describe the production of training data, feature selection and training data generation, and the training and testing of machine learning models in the following subsections.

4.1 Data Annotation

A set of 66 grammatical descriptions from the classical *Linguistic Survey of India* (LSI; Grierson, 1903–1927)[3] were annotated with the frames from LingFN described in Section 3.[4]

An online annotation tool from the Brazilian FrameNet Brasil project[5] was used. The annotation process was a collective effort and a number of data annotators were involved in this step. Each data annotator was responsible for 6 documents, and the length of each document is between 90 and 255 sentences. The task for each annotator was to go through the sentences of each document, identify each lexical unit and record the frame triggered by it. Once the frame has been identified, the next task was to identify and label the text segments (if present) of the sentence indicating the frame elements of the frame. Figure 2 shows a screenshot from the web tool used for annotation. As can be seen, the tool provides a layered view with the sentence to be annotated appearing in the top layer. This is followed by two layers, one for the frame and the other for frame elements annotation, for each of the triggered frames. The screenshot shows the annotation of the sentence *the verb agrees in number and gender with the subject* with two frames i.e. the frame VERBAL triggered by the lexical units *verb* (shown in black) with an empty FE layer (since there is no FE to be annotated in the sentence for this frame) and the frame AGREEMENT triggered by the lexical unit *agrees*. The FE layer for the AGREEMENT frame contains the annotations 'Participant_1' (in red) referring to text-segment *the verb*, 'Participant_2' (in blue) referring to the text segment *the subject*, and 'Grammatical_Category' (in green) referring to the text segment *in number and gender*.

1	**Frame Name:** AFFIXATION
	Definition: A frame to capture the phenomena of affixation in linguistics, which is the process of adding a morpheme — or affix— to a word to create either a different form of that word or a new word with a different meaning
	Frame Elements: Stem, Affix, Language_Variety, Reference_Language, Location Frequency, Manner, Purpose, Condition, Position, Degree
	Example Annotation: [An n]$_{\text{Morpheme\_one}}$ is [often]$_{\text{Frequency}}$ [infixed]$_{\text{LU}}$ [after the first vowel of a word]$_{\text{Morphosyntactic\_position}}$, the vowel being also repeated after n .
2	**Frame Name:** SEQUENCE
	Definition: A frame to capture the ordering information of various morphological or syntactical categories
	Frame Elements: Entity_1, Entity_2, Order, Language_Variety, Entities, Condition, Frequency, Reference_Language, Certainty, Data, Data_Translation
	Example Annotation: [Adjectives]$_{\text{Entity\_1}}$ in [Garo]$_{\text{Language\_Variety}}$, [as in Kacha ri]$_{\text{Reference\_Language}}$, [generally]$_{\text{Frequency}}$ [[follow]$_{\text{Order}}$]$_{\text{LU}}$ [the noun they qualify]$_{\text{Entity\_2}}$
3	**Frame Name:** CREATION
	Definition: A frame to capture the phenomena of creation of a morphological or syntactic category from another morphological or syntactic category
	Frame Elements: Created_Entity, Created_From, Process, Degree, Certainty , Language_Variety, Reference_Language, Data, Data_Translation, Condition
	Example Annotation: [Adverbs]$_{\text{formed\_Entity}}$ are often separate words , but are also [frequently]$_{\text{Degree}}$ [formed]$_{\text{LU}}$ from [the corresponding adjective]$_{\text{formed\_From}}$ [by adding hui or ui]$_{\text{Process}}$.

Table 1: Targeted frames

Table 2 shows some statistics of the produced annotated data. Further details, such as inter-annotator agreement, etc., are beyond the scope of

[3] The LSI presents a comprehensive survey of the languages spoken in South Asia conducted in the late nineteenth and the early twentieth century by the British government. It has descriptions of various phonological, morphological, and grammatical features of about 723 linguistic varieties spoken in the nineteenth-century British-controlled India (modern Pakistan, India, Bangladesh, and parts of Burma).

[4] There, we also mentioned that we have restricted ourselves to a few frames for the study reported in this paper, but it is worth mentioning that the data was annotated with the full set of LingFN frames.

this paper, and will be reported on in a separate publication.

4.2 Feature Selection and Training Data Generation

To train machine learning based classification models, the first task is to define a useful set of features, and then compute the feature values from the training data. The area of frame-semantic parsing is well researched meaning that a set of suitable features both for the frame-element identification and frame-element classification tasks have previously been explored (Johansson and Nugues, 2008; Das et al., 2014). Since our objective in this work is not to improve frame-semantic parsing, but rather to show how frame-semantic parsing can be exploited to extract linguistic features from descriptive grammars, we have opted to use the same feature set as described by Johansson and Nugues (2008).

While a detailed explanation of the features can be found in Johansson and Nugues (2008), Table 5 lists *15* features used for training both the frame-element identification and frame-element classification models. The procedure for generating the training instances and computing the features values is as follows: Each sentence of the training data set was parsed using the Stanford constituency parser (Manning et al., 2014) resulting into parse trees as shown in Figure 3. Each node of the tree is then taken as one training instance and the required feature values are computed. The features values given in the last column of Table 5 were computed for the NP node referring to *the qualified nouns* (the one enclosed within the dotted area) as the argument node (i.e. the frame-element node) and with *agree* as the target word (i.e. frame triggering word). When computing for the whole tree, if a given argument node has been annotated as a frame element in the annotation the computed feature vector will get 'Y' as its class label, and 'N' otherwise resulting into the type of training instances shown in Table 3, and making it a binary classification task.

For the frame-element classification task, the objective is not to learn whether an argument node is a frame element or not, but rather to learn the frame-element label for all the annotated nodes (a multi-class classification task). The training data for the frame-element classification task was generated by going through all the nodes in the parse tree (as above), but this time only keeping those nodes which have been annotated as frame elements together with their label. Table 4 below shows a few instances from the generated frame-element classification data set.

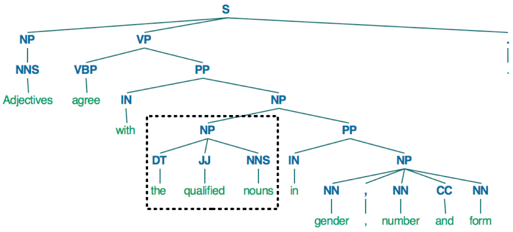

Figure 3: Example parse tree

The described procedure resulted into a set of 197,313 training instances for the frame-element identification task, and 11,904 training instances for the frame-element classification task. After removal of duplicates, 81,878 instances were left. Out of these, 76,036 (92.86%) were labeled 'Y', and the remaining 5,842 (7.14%) were labeled 'N'.

After removing duplicates, 5,855 cases were available for the frame-element classification task, covering 49 different classes of frame elements.

For the frame identification task, a simple dictionary lookup based approach was preferred at this stage simply because there are not many frames in the LingFN, indicating that frame disambiguation is rarely required. In future, we intend to train model for this task as well.

4.3 Data Representation

All of the variables in both of the datasets are the same, except that they differ on the possible set of values for the target variable, *label*. However, in either case, together with the target, all of the variables are categorical.

target_lemma	target_pos	arg_word	arg_word_pos	right_word	right_word_pos	left_word	left_word_pos	parent_word	parent_word_pos	c_subcat	phrase_type	position	fes_list	gov_cat	label

11	c_subcat	Subcategorization frame corresponding to the phrase structure rule used to expand the phrase around the target	VP- >VBP PP
12	phrase_type	Phrase type of the argument node	NP
13	position	Position of the argument w.r.t target word	
14	fes_list	List of frame elements of the triggered frame	(Participant_1, Participant_2, Grammatical_Category, Degree, Frequency, Language_Variety, Reference_Language, Condition)
15	gov_cat	The governing category either S or VP	VP

Table 5: Feature set

In order to achieve best performance while performing machine learning modeling, the right choice of data representation technique for categorical data is very important. The main reason is that there are a limited number of machine learning algorithms that can be directly applied to categorical data. On the other hand, if we can turn them into numerical variables, starting from basic Decision Trees, Naïve Bayes, Support Vector Machines, Logistic Regression, Random Forest, to Multi-layer Perceptron (Deep Learning), almost all of the machine learning algorithms can be applied. There are plenty of techniques to transform categorical values to numerical data. One such technique is one-hot encoding. The basic strategy is to convert each category level (value) of the categorical variable into a new variable, and assign the value *1* to this new variable wherever the corresponding categorical variable equals this level, and *0* otherwise. This is done for all category levels of the variable being encoded except one, which will be redundant (applies when all other associated variables equal zero) and can be any category level. The key is to always create one fewer binary variables than the number of categories. The new binary variables together replace the original categorical variable. The new variables are sometimes termed *dummy variables*, and the approach is also called *Dummy Variables Encoding*. This encoding has the benefit of not weighting a value improperly, but does have the downside of adding more variables to the dataset.

4.4 Model Training

Successful encoding makes the dataset ready to be used for applying machine learning algorithms. We experimented with different machine learning models. A comparison of the machine learning models chosen for binary classification (frame-element identification) and multiclass classification (frame-element classification) tasks for our datasets has been performed. Tables 6 and 7 provide a comparison of various evaluation metrics using average scores of 5-fold cross validation) respectively for the frame-element identification and classification tasks.

Model	Accuracy	Precision	Recall	F_score
Decision Tree	0.926	0.712	0.664	0.921
Logistic Regression	0.936	0.797	0.609	0.922
Naïve Bayes	0.658	0.552	0.686	0.741
Support Vector Machine	0.929	0.465	0.5	0.895

Table 6: Model comparison for the frame-element identification dataset using one hot encoding

Model	Accuracy	Precision	Recall	F_score
Decision Tree	0.789	0.56	0.542	0.786
Logistic Regression	0.817	0.619	0.545	0.808
Naïve Bayes	0.528	0.481	0.489	0.537
Support Vector Machine	0.465	0.019	0.04	0.295

Table 7: Model comparison for the frame-element classification dataset using one hot encoding

The best performing logistic regression models were selected and used in the typological feature extraction system described in the next section.

5 Topological Feature Extraction System

Figure 4 shows the complete architecture of the typological feature extraction system. As shown (the middle part within dotted area), the system takes a descriptive grammar in raw form and annotate it with LingFN frames using the pre-trained models both for the frame-element identification and frame-element classification tasks (i.e. the part above the dotted area). The annotated data is further processed with a simple rule based module to convert those annotations to typological feature values (i.e. the part below the dotted area). Lets take an example to explain this part in particular, and the overall purpose of such a system in general.

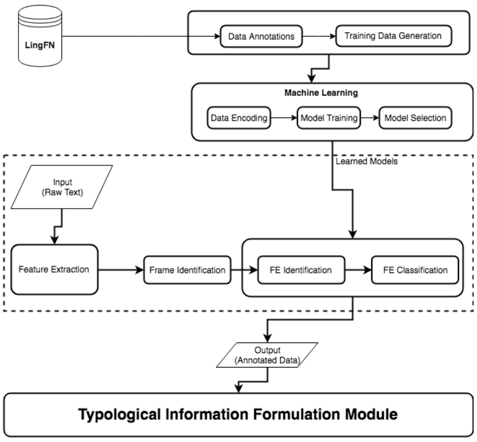

Figure 4: System architecture

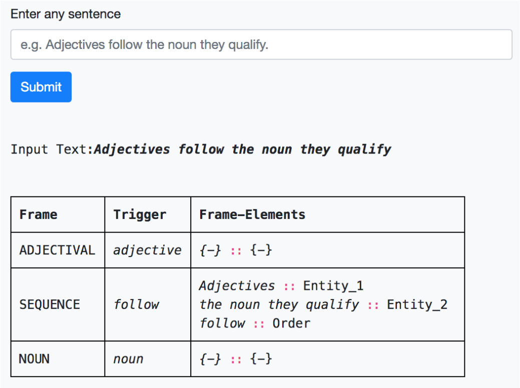
Suppose we are interested in finding an answer to the question "What is the order of adjective and noun in the noun phrase" for the Siyin[6] language. The LSI data set contains a grammatical description of this language, and one of the sentences in that description is *The adjectives follow the noun they qualify*. Automatic parsing of this sentence using the developed LingFN parser will result into the annotations shown in Figure 5 (a screenshot from the web demo of the parser).



Input Text:***Adjectives follow the noun they qualify***

Frame	Trigger	Frame-Elements
ADJECTIVAL	*adjective*	*{-}* :: {-}
SEQUENCE	*follow*	*Adjectives* :: Entity_1 *the noun they qualify* :: Entity_2 *follow* :: Order
NOUN	*noun*	*{-}* :: {-}

Figure 5: Automatic frame annotation

This parse contains the answer to the above asked question. However, the typological databases often record answers in a specific format. For example, the answer to the above question could be required to be of one of these values 'NA', 'AN', or 'Both' meaning that the order is 'Adjective-Noun', 'Noun-Adjective', or 'Both' respectively. If required, the above given parse information can be converted into specific feature values using a simple rule-based module such as given below (only a part of the full module is shown). The module simply checks the contents of different frame elements to formulate the feature value.

Using the same sort of procedure and the frames mentioned in Section 3, we have targeted to extract and formulate values for some of the typological features given in the Grambank[7] and other typological databases. A few of these features are given below.

- Can an adnominal property word agree with the noun in gender/noun class?
- Can an article agree with the noun in gender/noun class?
- Can an article agree with the noun in number?
- Can the relative clause precede the noun?

[6] A Tibeto-Burman language spoken in southern Tedim township, Chin State, Burma. Also known as Siyin Chin and Sizang Chin, ISO 639-3: csy

[7] A typological database: https://github.com/clld/grambank.

Algorithm 1 Extract adjective noun order

```
procedure ExtractAdjective-NounOrder(parse)
    for <every frame in parse> do
        if $frame = SEQUENCE$ then
            $NA \leftarrow False$
            $AN \leftarrow False$
            $Both \leftarrow False$
            if $'adjective' \in Entity\_1 \wedge' noun' \in Entity\_2$ then
                if $Frequency \in [sometimes, usually, mostly, often]$ then
                    $Both \leftarrow True$
                else if $order = follow$ then
                    $AN \leftarrow True$
                else if $order = precede$ then
                    $NA \leftarrow True$
                end if
            end if
        end if
    end for
end procedure
```

- Can the relative clause follow the noun?
- Order of Adjective and Noun.
- Order of Subject, Object and Verb.
- Order of Numeral and Noun.
- Order of Relative Clause and Noun.

It is worth mentioning that the same methodology can be used to extract values for various other typological features from the descriptive grammars. This will require designing suitable frames, annotating the data and re-training models. Further, the methodology can be extended to descriptive grammars written in languages other than English.

6 Conclusions and Future Work

We have presented a novel system for automatic extraction of typological features from descriptive grammars based on the theory of frame semantics and frame-semantic parsing. We have presented the methodology, set up the machinery and architecture, and shown the working of this machinery for extraction of feature values of an example typological feature. The methodology is scalable and can easily be extended not only to other features but also to the descriptive grammars written in other natural languages. This is required because there are many grammatical descriptions written in languages other than English (German, French, Spanish, and Russian are among them).

The system we report is expected to be a useful assistance for the development of typological databases, which otherwise are built manually. Manual curation of typological databases is very time and labor consuming, as well as cognitively taxing, thus making the scope of studies based on such databases very limited. We hope with the automatic extraction of typological databases, the scope of studies in typological and other related areas can be broaden further.

The current version of LingFN provides a very limited number of eventful frames restricting us to target only a few typological features. There are 195 typological features listed in Grambank. In the future, we would like to build more frames, annotate more grammars, and automatically extract values for as many as possible features of the Grambank.

In conclusion, the current study can be considered as a proof of concept. In the future, we plan to extend the system and evaluate it against existing manually curated typological databases to compute measures such as precision and recall. Further, the extraction of typological features is just a case study, the automatically annotated grammars are envisioned to be equally useful in other linguistic subdisciplines, in particular the related areas of genetic and areal linguistics. In the future, we also have plans to show the usefulness of the annotated descriptions in these and other related areas.

Abstract

Natural language inference (NLI) is a key part of natural language understanding. The NLI task is defined as a decision problem whether a given sentence – hypothesis – can be inferred from a given text. Typically, we deal with a text consisting of just a single premise/single sentence, which is called a single premise entailment (SPE) task. Recently, a derived task of NLI from multiple premises (MPE) was introduced together with the first annotated corpus and corresponding several strong baselines. Nevertheless, the further development in MPE field requires accessibility of huge amounts of annotated data. In this paper we introduce a novel method for rapid deriving of MPE corpora from an existing NLI (SPE) annotated data that does not require any additional annotation work. This proposed approach is based on using an open information extraction system. We demonstrate the application of the method on a well known SNLI corpus. Over the obtained corpus, we provide the first evaluations as well as we state a strong baseline.

1 Introduction

Natural language inference (NLI), formerly known as recognizing textual entailment (RTE) task – as a part of natural language understanding (NLU) – belongs to one of the most prominent problems in NLP for more than ten years. Generally, the NLI task is to classify the relationship between a given text and a given hypothesis: whether the hypothesis can be inferred from the text. The task is typically formulated in a "sentence-pair setting", i. e., the text is just a single sentence. According to (Lai et al., 2017), we refer this setting as a *single premise entailment* (SPE for short). Current state-of-the-art approaches are based on deep learning and/or ensemble methods. Over the years, solid resources for supervised learning for SPE were developed. In contrast, problems related to NLI and/or problems derived from NLI, like relation inference (Levy and Dagan, 2016), question entailment (Abacha and Demner-Fushman, 2016), partial/facet entailment (Levy et al., 2013) and (Nielsen et al., 2009), and others, are strongly under-resourced. For further development in these fields, this fact may be limiting.

Recently, a task of NLI from multiple premises was proposed in (Lai et al., 2017) – the idea is based on relaxing the common assumption that the premise is just a single sentence. Again, according to this paper, we will call this derived of NLI task *multiple premises entailment* (MPE for short). Similarly to other mentioned entailment tasks, MPE is also under-resourced: to best of our knowledge, there exists only one annotated corpus (introduced in the original paper) for MPE.

The main aim of this work is to describe a novel method of preparing MPE annotated corpora from existing NLI SPE ones. It is based on using open information extraction systems and on several plausible assumptions. Then we apply the proposed method on a concrete corpus and provide the first evaluation and we state a strong baseline for MPE task on this obtained corpus.

2 Preliminaries and Related Work

In this section we are going to put MPE task in context, describe briefly the notion of open IE and recall two entailment tasks where textual tuples play a certain role.

2.1 NLI Task and Notable Corpora for NLI

There exist several definitions of NLI or, formerly, RTE task. Indeed, the differences among them are rather subtle and have no real consequences for NLP. For completeness, we provide the original definition from (Dagan et al., 2005): "*We say that T entails H if humans reading T would typically infer that H is most likely true.*" The deep insight into the nature of NLI from the logical and philosophical point of view is provided in (Korman et al., 2018).

Originally, RTE was proposed as a binary decision task (entailment/non-entailment). Later, the 3-way task (entailment/neutral/contradiction) became more frequent.

Nowadays, there exists a number of annotated corpora for the NLI task. At the beginning of RTE investigations, it was a collection of RTE corpora created for Pascal/NIST/SemEval challenges. A comprehensive overview of older RTE corpora is provided in (Bentivogli et al., 2017).

A massive development in the field of NLI using deep learning approaches was started after the release of the Stanford NLI corpus (Bowman et al., 2015), probably the most widely used annotated corpus for NLI, containing approx. 570K of annotated sentence text-hypothesis pairs. This corpus was later followed by MultiGenre NLI corpus – MultiNLI (Williams et al., 2018) – of a comparable size, but with a wider range of genres, including spoken language, newspapers, 9/11 etc. Both of these corpora were constructed in a similar way: given a sentence/premise, the annotators were asked to write a sentence that is entailed by the premise, a sentence that is contradictory to the premise, and a sentence neutral w. r. t. the premise, i. e., such that its truth value is independent to the truth value of the premise. According to the classification presented in the paper (Poliak et al., 2018), these two corpora belong to the *human elicited* category. The paper also provides a comprehensive analyses of SNLI, MultiNLI as well as an overview of more recent and specific NLI corpora.

2.2 Natural Language Inference from Multiple Premises

As already mentioned, the novel NLI task that is based on inference over multiple premises was recently introduced in (Lai et al., 2017). Given four premise sentences and one hypothesis sentence, the task is to label this premises-hypothesis pair in a standard 3-way manner – entailment, neutral, or contradiction.

This work was inspired by the *Approximate entailment task* (Young et al., 2014), that arises from processing the image captions – the task is to decide whether a brief caption h (the hypothesis) can describe the same image as a set of captions $P = \{P_1, \ldots, P_N\}$ known to describe the same image (the premises).

The (only one) MPE corpus[1] introduced in the paper (Lai et al., 2017) was created upon the FLICKR30K dataset (Plummer et al., 2015). Hypotheses were generated in by simplifying either a fifth caption describing the same image or a caption corresponding to a different image and given the standard 3-way tags (Poliak et al., 2018). The simplification process relies on the denotation graph (Young et al., 2014) – it is based on normalization and reduction rules (e. g. lemmatization, dropping modifiers and prepositional phrases, replacing nouns with their hypernyms, extracting noun phrases), see (Lai et al., 2017). Each hypothesis has at most 50% overlap with the words in its corresponding premises. The MPE corpus contains 8000 items in the training set, 1000 items in the development set and 1000 in the test set.

To provide a better idea about the corpus, here is an example of positive (entailment) item taken again from (Lai et al., 2017):

Premises:

1. *Two girls sitting down and looking at a book.*
2. *A couple laughs together as they read a book on a train.*
3. *Two travelers on a train or bus reading a book together.*
4. *A woman wearing glasses and a brown beanie next to a girl with long brown hair holding a book.*

Hypothesis: *Women smiling.*
Label: ⇒ ENTAILMENT

In the paper, the authors also investigate the relation between MPE and the standard (SPE) entailment. In this particular MPE task/corpus, each premise consists of four independently written sentences and, using crowdsourcing, single-premise entailment labels for each individual

[1] https://github.com/aylai/MultiPremiseEntailment/tree/master/data/MPE

single-premise-hypothesis pair in the DEV dataset were obtained. Based on these individual labels, it has been shown that majority voting strategies as well as more sophisticated rule based approaches over single labels to obtain the final MPE label do not lead to sufficient results, hence MPE cannot be trivially reduced to multiple SPE tasks.

2.3 Information Extraction (IE) and Open Information Extraction (Open IE)

Information extraction is generally a process of transforming an unstructured textual information into a structured representation in the form of relational phrase and its arguments, usually `(arg1 ; rel-phrase; arg2)`, see (Niklaus et al., 2018). Information extraction deals with a predefined relation vocabulary.

In contrast, in *open information extraction* introduced by (Banko et al., 2007), this assumption is relaxed, i. e., we do not require a fixed vocabulary of relations. Open information extraction systems extract textual n-tuples that represent basic propositions asserted by a sentence (Stanovsky et al., 2018). An example of a result of open IE process taken again from (Stanovsky et al., 2018):

INPUT: *Mercury filling, particularly prevalent in the USA, was banned in the EU, partly because it causes antibiotic resistance.*

OUTPUT:

- `(mercury filling; particularly prevalent; in the USA)`
- `(mercury filling; causes; antibiotic resistance)`
- `(mercury filling; was banned; in the EU; partly because it causes antibiotic resistance)`

2.4 Relational Entailment/Relation Inference

Open information extraction over particular parts of an NLI corpus (hypotheses) was already exploited in (Víta, 2018) in order to obtain "sentence-textual tuple" entailment pairs when introducing a task of *relational entailment*. This task can be employed for checking facts in open knowledge bases, i. e., sets of extracted tuples, see (Mausam, 2016).

Another entailment task based on relational tuples, was introduced by Levy et al. in (Levy and Dagan, 2016) together with a new annotation method for collecting data (on relation inference) in context: the inference task was transformed into simple factoid question answering. The resulting annotated corpus has a form of "textual triple-textual triple plus entailment label".

Indeed, in both cases, textual tuples are a "subject of entailment" – in the final corpus, the tuples are inputs for the entailment decision. In this paper we are going exploit open IE in a different way – to create certain sentences.

3 Methods

In this section we are going to describe a general method of constructing an MPE corpus from a given single premise entailment corpus using an open IE system and also its evaluation. Concrete implementation details are provided in the next section.

3.1 Creating MPE Corpus from SPE One

The main idea of this proposed approach is based on the following observations:

- From longer sentences, it is usually possible to extract multiple textual n-tuples.
- Results of open IE systems is naturally interpretable when reading from left to right (Stanovsky et al., 2018), hence they correspond with sentences.
- The entailment label in an SPE task can be used even for tasks where premise is represented in a "semantically equivalent form".

In order to provide a compact notation, we introduce the following convention: let us denote a set of word types contained in a sentence or a textual n-tuple t by a symbol $||t||$. Let $e(s)$ be a set of textual n-tuples extracted by an open IE system from a sentence s and, finally, let $s(t)$ be a string obtained from a textual n-tuple t by removing auxiliary symbols (brackets and semicolons) – this refers to the second observation: we assume that $s(t)$ can be treated as a sentence – it is a subject of further investigations.

Given a premise P and a hypothesis H and a corresponding entailment label L, we transform this P-H pair into a set of multiple premises $M(P) = \{s(t) \mid t \in e(P)\}$ accompanied with the unchanged hypothesis H a s well as unchanged label L, iff the following conditions hold:

1. $|e(P)| > 1$, i. e., we are interested only in such cases, when more than one tuple is extracted from a given premise,

2. $(\cup_{t \in e(P)} ||t||) \setminus \{$"and"$\} = ||P||$, i. e., each word of the premise is contained in at least one extracted tuple (except "and"),

3. $\forall t \in e(P), ||H|| \not\subseteq ||t||$, i. e., we do not allow situations, where the hypothesis is a shortening of some of the considered tuples,

4. $\forall t, u \in e(P), t \neq u, ||t|| \not\subseteq ||u||$ and $||u|| \not\subseteq ||t||$.

The first condition is obvious. The second one ensures that the information contained in the set of extracted tuples is the same as in the original premise under the natural assumption that a content of a sentence can be fully represented by a set of textual n-tuples for sufficiently high n. By the third condition we want to avoid cases of trivial entailment from one of the multiple premises. The last condition excludes situations when the result $M(P)$ set contains "inclusion sentences" like: `Three men standing on grass` and `Three men standing on grass by the water looking at something on a table.`

The procedure of generating the MPE corpus from an existing NLI one is now straightforward: for each $P - H - L$ triple of NLI corpus check the conditions 3.1 for P, $e(P)$ and H – if satisfied, the obtained $M(P)$-H-L item is added into MPE corpus being created. These items can be further filtered according to different intentions, e. g., we want to deal with items having at least k premises or at most m premises, for instance. Obviously, the quality of the annotation of the original SPE corpus hardly influences the quality of the obtained MPE corpus.

Unlike the MPE corpus from (Lai et al., 2017) where all entailment items contain a set of a *fixed number* of premises (4), we will generally obtain sets of *variable number* of premises.

Reducing the number of trivial inferences by limiting lexical overlap In order to reduce the number of items where the inferences can be done trivially, we may set up a threshold for lexical overlap and consider only such items that the fraction of the number of hypothesis tokens that appear in at least one premise and the number of hypothesis tokens after stopwords removal is lower or equal to a given threshold.

Remark The process can also produce positive (entailment) items where not all premises in the $M(P)$ set take part in the entailment of the hypothesis, i. e., one or more of the premises involved together with the hypothesis form a neutral pair/pairs. This phenomenon will be a subject of further investigations. Nevertheless, in real situations, it is natural to deal with it, as well as with premises such that one extends information provided by another, thus not fulfilling condition 4.

According to (Poliak et al., 2018) again, our proposed corpus can be classified as *automatically recast*, i. e., a corpus that was automatically generated from an existing dataset constructed for a different NLP task and the labeling was done with no or a little manual work. In such cases, some properties of the source corpora may be also transferred into the recasts.

3.2 Quality Evaluation of Our Corpus

NLI corpora are prone to contain several types of *annotation artifacts* (Gururangan et al., 2018). For example, a negation can indicate a contradiction label, mainly in human elicited corpora. Using "generic" words such as "animal" or "instrument" is often typical for the entailment label thanks to common annotators' strategies.

In order to obtain a better insight into the characteristics of the obtained corpus, we are going to investigate the role of occurrence of certain single words in hypotheses when predicting labels and the role of the hypothesis-context relation as well as appearance of different (annotators') patterns.

3.3 Lexical Biases

At first, we are going to focus on words that are strongly indicative of each inference class. In (Gururangan et al., 2018), the authors use pointwise mutual information (PMI) for all words and classes in the training set:

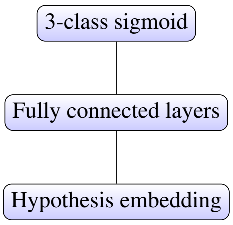
$$PMI(word, class) = \log \frac{p(word, class)}{p(word, .)p(., class)}.$$

The authors use add-100 smoothing to emphasize word-class correlation and select Top 5 words in each class.

In (Poliak et al., 2018), a conditional probability was used:

$$p(l|w) = \frac{count(w, l)}{count(w)}.$$

Figure 1: Overall architecture of the simple hypothesis-only classifier



Then they analogously select Top words for each class (label) l. If $p(l|w)$ is highly skewed across labels, there exists the potential for a predictive bias (Poliak et al., 2018). In this paper, we are going to use this second approach.

3.4 Hypothesis-Only Approach

Annotation artifacts in NLI corpora are common, since annotators, mainly in human elicited corpora development, have different strategies and patterns for generating hypotheses. There are also artifacts that arise from the "hypothesis-context" relation. To model the degree of annotation artifact existence, a classifier that uses only hypotheses for predicting the entailment classes can be trained. In other words, the classifier completely ignoring the information contained in the premise(s) is used.

In (Poliak et al., 2018), the authors call this approach "hypothesis-only" and they used a modified `InferSent` model (Conneau et al., 2017).

In (Gururangan et al., 2018), `fastText` (Joulin et al., 2017), bag-of-words and bigram based model was used, there it is called "premise-oblivious text classifier".

A general architecture of a hypothesis-only classifier is depicted in Figure 1.

Since the outstanding results of BERT model in SPE NLI task[2], we use BERT (Devlin et al., 2018) embeddings.

4 Results and Discussion

The proposed approach for MPE corpus development can be generally used on any single premise NLI annotated corpus in a language where a suitable open IE system is available. To demonstrate it on a concrete dataset, we have chosen the already mentioned SNLI corpus.

4.1 MPE(SNLI) Corpus

As an input for our approach, the training dataset of SNLI was used. From 150.736 *unique* texts/premises, 229.428 n-tuples were extracted, i. e., 1.522 n-tuples per sentence in average. The extraction process was performed by Open IE 5.0[3] (Mausam, 2016). Additional labels provided by the system (like `L:` for location) were removed.

For premise-hypothesis-GoldLabel items of SNLI train, we follow the list of requirements in subsection 3.1. The SNLI corpus contains appox. 2% of items without GoldLabel (marked "-") (Bowman et al., 2015). Even if P-H-L item with L ="-" meets the requirements, it is not added to the corpus being created. Hence the corpus contains only three common labels (entailment, neutral, contradiction) – the number of such items was 96.

Moreover, we set-up a threshold for a lexical overlap according to (Lai et al., 2017) to be equal to 0.5.

The obtained dataset contains 45.622 items. It was then randomly split into train/dev/test datasets containing 32.000, 7.000 and 6.622 items, respectively. Although the SNLI corpus is roughly balanced between the three classes, our corpus contains slightly higher fraction of contradiction labels, mainly because of application of the lexical overlap threshold – high lexical overlap typically indicates the entailment class.

To provide a better idea about the proposed corpus, we provide an example of each label – the premises are syntactically transformed (from t to $s(t)$ in our notation): from textual tuples into sentences, i. e. brackets and semicolons are removed, the first letter is capitalized.

Example 1
Premises:

1. *A white dog with his tongue out is in the snow.*
2. *A brown dog with his tongue out is in the snow.*
3. *A black dog with his tongue out is in the snow.*

Hypothesis: *There are animals outdoors.*
Label: ⇒ ENTAILMENT

Example 2
Premises:

[2] See state-of-the-art results on SciTail corpus: `https://leaderboard.allenai.org/scitail/submissions/public`

[3] `https://github.com/dair-iitd/OpenIE-standalone`

1. *3 women posing for a picture.*
2. *3 women are sitting down.*

Hypothesis: *The women are smiling.*
Label: ⇒ NEUTRAL

Example 3
Premises:

1. *A baby has food on his face.*
2. *A baby eats.*

Hypothesis: *Baby playing with a dog.*
Label: ⇒ CONTRADICTION

The distribution of labels in the corpus is provided in Table 1.

Table 1: Distribution of labels in MPE(SNLI)

	Train	**Dev**	**Test**
entailment	0.231	0.235	0.231
neutral	0.361	0.362	0.372
contradiction	0.407	0.403	0.396

As already mentioned, we do not require the same number of premises in each corpus item, the distribution of number of premises in the corpus is also provided, see Table 2.

Table 2: Number of premises in MPE(SNLI)

# prem.	2	3	4	5	≥ 6
# items	37765	5013	2294	253	297

4.2 MPE(SNLI) Lexical Biases

In order to select the most characteristic words for each entailment label, we used the conditional probability of a word w w. r. t. the label l. Since there are extremely discriminative words having a very low frequency, we focus only on words that appear at least five times in the training dataset. Table 3, Table 4, and Table 5 present Top 5 words for each class in MPE(SNLI) corpus (training): entailment, neutral, and contradiction respectively together with corresponding values of conditional probability.

These results correspond with our intuition, if we consider the fact that the source of SNLI sentences are mainly photo captions and the fact that the original SNLI corpus was human elicited. Using lexical items that refer to "general" words like *object, similar, multicolored* matches common strategies and patterns when creating entailment pairs. We can also note that the first item in the "contradiction list" is linked to negation. Investigations of annotation strategies and patterns can be a part of the future work.

Table 3: Cond. prob.: l = "entailment"

w	$p(l\|w)$
similar	0.875
facial	0.857
multicolored	0.857
object	0.848
least	0.840

Table 4: Cond. prob.: l = "neutral"

w	$p(l\|w)$
favorite	0.976
tired	0.964
first	0.940
tips	0.9385
tour	0.933

Table 5: Cond. prob.: l = "contradiction"

w	$p(l\|w)$
nobody	0.994
naked	0.971
quietly	0.968
cats	0.938
napping	0.931

4.3 Hypothesis-Only Classifier

Sentence (hypothesis) BERT embeddings were computed using `BERT-as-a-service` application (Xiao, 2018). We have used a pretrained BERT model[4] (12-layer, 768-hidden, 12-heads, 110M parameters). Each hypothesis was encoded as a 768-dimensional vector. The optimal dimension ($d = 100$) of the single hidden layer was obtained by a grid search.

The achieved accuracy reached **0.671** on the test dataset, highly above the majority baseline that equals **0.396**. This result indicates a notable

[4] https://storage.googleapis.com/bert_models/2018_10_18/uncased_L-12_H-768_A-12.zip

presence of annotation artifacts in MPE(SNLI) corpus. Nevertheless, approximately the same accuracy was obtained on the test set of the original SNLI single premise corpus using premise-oblivious `fastText` classifier. We may conclude that proposed corpus achieves a comparable level of annotation artifacts occurrence.

4.4 Conclusion

We have proposed a method of exploiting an open information extraction system for transforming a NLI single premise corpus into a multiple premises entailment (MPE) setting. The method was then applied on SNLI training data and an annotated MPE(SNLI) corpus was obtained. The final corpus will be available at: https://github.com/martinvita/openIE-MPE

4.5 Future Work

This work presents the first steps in creating corpora for MPE task using open IE with a particular application on SNLI data. The further work on the proposed MPE(SNLI) corpus will include extending investigations outlined in this paper, e. g. obtaining deeper insight into lexical bias or investigations about individual entailment classification between hypotheses and individual premises – "elements of M(P)" etc. as a natural continuation of the work.

The keystone of the further work are the investigations of relations among the members of the premise set $M(P)$ together with the development of the entire MPE task . According to our intuition, the MPE should be significantly more difficult than SPE task in the sense that the entailment judgement should be based on a fusion of information contained in the premises. This is also a natural step after the initial work (Lai et al., 2017) – approving the importance of the MPE task.

Both the quality and quantity of extracted tuples – hence also the number of premises and items in the MPE corpus – are strongly influenced by the functionality and quality of the open information extraction system used. Comparing results/outputs of different open IE systems is another prospective field of study.

As we have seen from examples provided in the text, the proposed process led to the MPE corpus with a variable number of premises whereas in the first MPE corpus (Lai et al., 2017), each item contains preciously four premises. In order to prepare a formally compatible corpus, we are interested also in "normalizing" the number of premises using various techniques, e. g. a paraphrase generation for cases when we have less premises than needed, and concatenation in cases when the number of premises exceeds the required number.

Obviously, the proposed process does not rely on certain properties of SNLI, hence it can be straightforwardly applied to other corpora, (e. g. MultiNLI, SciTail etc.), even to NLI single-premise corpora in different languages where open IE tools are available. SNLI is prone to several biases (that are transferred to MPE corpus), thus we can expect the result obtained by applying our procedure on other corpora can lead to more valuable and inspiring results.

A general task when having MPE corpora of suitable quality and volume, is the development of classifiers for MPE task based on different architectures, i. e., general development in MPE field as well as further study on the mutual relationship between the SPE NLI and the MPE NLI task.

Remark Finally, it should be noticed that MPE task is related to NLI with external/background knowledge, which seems to be a promising direction in the field of NLU (Jiang et al., 2018). Having a premise-hypothesis pair and an external/background knowledge that can be formalized in the form of sentences, we can generally add these sentences as additional premises. The key question is obviously the process of selection/recommendation of relevant sentences to become these new additional premises. Clearly, the number of premises needs to be limited. This observation illustrates the importance of the MPE task in the entire NLU field.

Towards Adaptive Text Summarization:
How Does Compression Rate Affect Summary Readability of L2 Texts?

Abstract

This paper addresses the problem of readability of automatically generated summaries in the context of second language learning. For this we experimented with a new corpus of level-annotated simplified English texts. The texts were summarized using a total of 7 extractive and abstractive summarization systems with compression rates of 20%, 40%, 60% and 80%. We analyzed the generated summaries in terms of lexical, syntactic and length-based features of readability, and concluded that summary complexity depends on the compression rate, summarization technique and the nature of the summarized corpus. Our experiments demonstrate the importance of choosing appropriate summarization techniques that align with users needs and language proficiency.

1 Introduction

It is often the case that people, at some point in their lives, are incapable of benefiting from available information due to various aspects of text complexity resulting from domain-specific terminology and grammatical structure complexity. The literature has identified specific instances of this, such as: diabetes patients with no medical training who try to make sense of recent scientific advances in the treatment of the disease (Ong et al., 2008); elderly people forced to embrace the technical terminology of the digital age when using computers and mobile phones (Li and Perkins, 2007); parents trying to decipher the latest slang words used by their teenage children (Vizgirdaite, 2009); people with different degrees of learning difficulties such as aphasia (Carroll et al., 1998), dyslexia (Rello et al., 2012) or autism (Štajner et al., 2012); and, second languag (L2) learners trying to infer the meaning of idioms from the literal meaning of their constituents (Charteris-Black, 2002).

Extensive research has been carried out in the field of automatic text simplification and text enrichment (Rello et al., 2014; Aranzabe et al., 2012; Woodsend and Lapata, 2011; Thomas and Anderson, 2012; Barbu et al., 2015). But only a few studies integrate them into other applications of natural language processing (NLP), such as, for example, in text summarization for the purpose of improving readability. Text summarization is not considered to be primarily a simplification task. However, it becomes useful when long documents are involved as it aims to reduce text processing time and thus to access quicker the main concepts of the document. In this context most of the studies apply text simplification to reduce redundant or less important information and to increase the informativeness of extractive summaries, but not their readability (Jing, 2000). Lloret et al. (2019) point out that summaries are rarely evaluated for readability. But text summarization can clearly benefit from readability assessment to better serve its purpose of saving reading time and to avoid the generation of incomprehensible summaries. We take this idea further and suggest that to maintain an optimal level of summary complexity and to adapt it in a personalized way according to user needs and language proficiency, the summarization aproach needs to identify and integrate the necessary degree of simplification.

This paper presents the initial study of ongoing research on the development of an abstractive text summarization approach that can adapt generated summaries to user language proficiency and cognitive abilities. In this study, we rely on the fact that texts for L2 learners are written in a well-structured manner with clear style. Unlike first language texts, these texts, in addition to their semantic readability features, include a broader range of syntactic features, thereby providing an

Proceedings of Recent Advances in Natural Language Processing, pages 1265–1274,
Varna, Bulgaria, Sep 2–4 2019.

overall richer set of readability metrics for examination (Heilman et al., 2007). Once identified these features can be used to measure variation in readability of automatically generated summaries.

For this purpose we harvested a corpus of texts for L2 learners of English that are classified into 7 levels according to language proficiency . This dataset provides an appropriate setup to explore the distribution of different readability characteristics across the levels and to study how these characteristics change when summarization is applied.

The main contributions of this paper are:

- we experiment with a new dataset of graded L2 learner texts that can be used both for text simplification and text summarization tasks;
- we test a number of summarization approaches on this corpus and demonstrate that compression rate always affects the complexity of generated summaries;
- we show that the domain of the corpus affects the results;
- we prove that the complexity of generated summaries varies depending on the summarization technique and the readability metric.

2 Related work

The present study spans two fields of NLP: text summarization and readability assessment as a part of the text simplification process.

Only a few studies address the problem of how text summarization affects summary readability. Petersen and Ostendorf (2007) are among the first to point out that text summarization techniques alone do not control the degree of readability of generated summaries because sentences with challenging vocabulary and complex grammatical structures may be chosen. Lloret et al. (2019) further explore this idea, showing that text summarization does not maintain the same degree of text complexity as the original document. However, based on their experiments with a corpus of unsimplified newswire documents for native speakers DUC 2002[1] and contrary to the observation of Petersen and Ostendorf (2007), they conclude that on some readability metrics the summaries generated with the compression rate of 20% score better and are easier to comprehend than the original texts. For their experiments Lloret et al. (2019) used a total of 9 lexical and length-based readability features and a modular extractive text summarization approach that allowed the testing of how anaphora resolution, word sense disambiguation and textual entailment affect the readability of summaries.

Only a handful of text summarization methods so far have integrated readability assessment to select not only the most informative, but also the most comprehensible sentences. Nandhini and Balasundaram (2014) designed one of such approaches. They represent each document as a set of 4 informative features (sentence position, title similarity, etc.) and 5 readability features (word length, sentence length, etc.) and treat summarization as an optimization problem to maximize the average informative score of the summary and to improve its readability. However, their set of readability features is small and they do not study the relative importance of each feature with respect to the corpus or the target language proficiency level.

In recent years, several studies appeared that address readability assessment and text simplification for L2 learners. Vajjala and Lučić (2018) compiled the OneStopEnglish corpus of simplified level-annotated news articles for L2 learners with comparable texts across all levels. Xia et al. (2016) trained a machine learning algorithm for readability assessment on past Cambridge English Exam papers. Their set of readability features includes data from English Vocabulary Profile, an online vocabulary resource with integrated grading scale based on the Common European Framework of Reference for Languages (CEFR) (Council of Europe, 2001).

Our study has been inspired by the aforementioned research and further expands on the idea of Lloret et al. (2019) by experimenting with a graded simplified corpus of texts for L2 learners of English, adding vocabulary-based and syntactic families of readability features, including an abstractive summarization system and testing these metrics with 4 different compression rates.

3 Data

The goal of this paper is to provide an initial analysis on how automatic text summarization affects readability for L2 learners with the long term goal of integrating these findings into an abstractive text summarization approach capable of adapting generated summaries to user language proficiency, knowledge and cognitive abilities. This requires a

Table 1: Statistics for the BNE corpus

corpus of simplified texts that are adapted to different reading proficiency levels and also include the original source documents. To the best of our knowledge there is no such freely available level-annotated corpus of learner's materials that can also be used for text summarization.

Motivated by this fact we harvested a corpus of texts for English learners from Breaking News English website[2]. Breaking News English (BNE) is a website with different resources for English language teachers created and maintained since November 2004 by an experienced ESL/EFL teacher Sean Banville[3]. This website was nominated for a British Council ELTons award in the category "Innovation in Learner Resources" in 2014. We obtained permission from the author to use it for research purposes. The site contains materials classified into seven levels from 0 to 6 that roughly correspond to CEFR grading scale, comprising levels from A2 to C2 (see Table 3). A new lesson, containing quizzes, reading and listening activities, appears every two days. The main component of each lesson is a piece of news from 120 to 250 words long, depending on the level. Texts cover a broad range of topics, but try to avoid more emotive and sensitive ones (Banville, 2005). As the vocabulary difficulty depends on the topic, each news article topic is assigned to one of two groups, representing linguistic levels 0 to 3 or 4 to 6, respectively. The grading process is the following: first, the author manually creates a text for level 3 or 6 and then makes the easier levels by reducing sentence length, simplifying grammar, introducing easier vocabulary and avoiding idioms. We will revisit this grading policy in Section 4.2, as it affects readability statistics of the corpus.

The distinguishing features of this resource are:

- each text is available at different levels of complexity.
- each text can be considered as a summary of a set of news articles that can be extracted from the provided URLs.

As mentioned in Section 2 the OneStopEnglish corpus (Vajjala and Lučić, 2018) is a similar resource for readability assessment that contains the same texts rewritten for elementary, intermediate or advanced reading proficiency levels. However, given the 7 levels from the BNE dataset we expect to be able to identify the more subtle readability differences between them. Going forward, with access to the original news articles via URLs, we will be able to develop and test an adaptive multi-document summarization approach on this corpus.

The BNE website has been evolving since its creation in 2004, thereby level annotation is available only starting from July 2013. We harvested all the suitable data, but for this initial research we used a subset from March 2016 to January 2019, resulting in 1,754 news articles in total and 250/251 articles for each of the 7 levels. Table 1 shows further statistics of the corpus where *CEFR* and *Difficulty* rows reflect grading information provided on the resource's website.

To contrast BNE's website CEFR level annotation with the CEFR annotation of other state-of-the-art resources, we evaluated our corpus with the readability assessment method developed by Xia et al. (2016) and trained on past Cambridge English Exam papers and on the set of 100 additionally annotated news articles. The row *% of docs* illustrates how many texts were identified by this method as belonging to the indicated CEFR level.

4 Readability

4.1 Features

The most recent research on readability assessment uses machine learning based approaches in combination with a broad set of linguistic features. Such sets of features are usually organized into families that share similar linguistic properties. They typically include length-based, syntactic, lexico-semantic and discourse-based features, among others. Experiments show that different families, or even individual features, affect the accuracy of the classifier in a different manner (Xia et al., 2016).

[2] https://breakingnewsenglish.com/

[3] https://www.linkedin.com/in/seanbanville/

Following previous research on assessing readability of summaries by Lloret et al. (2019), we selected the same set of 9 readability features. However, after detailed analysis of the set and the revision of other research in readability assessment of L2 texts, we added further lexical and syntactic features (Xia et al., 2016; Heilman et al., 2007). The rationale for this was twofold. First, experiments show that these families of features significantly improve performance of classifiers and therefore help to correctly identify the grade of text complexity (Pitler and Nenkova, 2008). Second, the initial set of readability metrics would not be capable of grasping grammatical and vocabulary changes that are an integral part of second language acquisition. To cover these aspects of text complexity we added 12 more features[4] including the revised Dale-Chall formula (Chall and Dale, 1995). This formula calculates the proportion of words that do not belong to the list of 3,000 familiar words. Some studies view this formula as a simplified version of a language model (Collins-Thompson and Callan, 2004). The complete set of 21 features, by families, is described below.

Traditional Features This family includes superficial length-based features and traditional readability formulas that are easy to compute, but provide a competitive baseline.

- Flesch Reading Ease (FRE) (Flesch, 1948)
- Avg. Word Length (AWL)
- Mean Length of a Sentence (MLS)
- Avg. Number of Sentences (ANS)
- Avg. Text Length in Tokens (ANT)

Lexical Features Our final feature set does not include discourse features, although 4 already integrated features from the original feature set of Lloret et al. (2019) based on noun and proper noun ratios may be related to the entity-density features, which could cast some light on the discourse properties of the corpus (Feng et al., 2009).

- Word variation index (OVIX) is a variety of type-token ratio measure (Hultman and Westman, 1977)
- Revised Dale-Chall formula (DC)
- Proper Noun Ratio (PNR)
- Avg. Number of Unique Proper Nouns (uPNR)
- Noun Ratio (NR)
- Pronoun Ratio (PR)

Syntactic Features Heilman et al. (2007) emphasize that grammatical features may play a more important role in readability assessment for the L2 learners than for the native speakers. Following their example, we calculate the last 4 features in this family on a per word basis.

- Parse Tree Depth (PTD)
- Noun Phrase Ratio (NPR)
- Verb Phrase Ratio (VPR)
- Adjective Phrase Ratio (ADJPR)
- Adverbial Phrase Ratio (ADVPR)
- Avg. number of SBARs per sentence (SBAR)
- Ratio of Passive Voice constructions (PV)
- Avg. number of Relative Clauses (RC)
- Past Participles (VBN)
- Modal verbs (MD)

4.2 BNE Readability Statistics

In Section 3 we explained how Sean Banville manually creates the news articles for each complexity level. His grading scheme does not correspond one-to-one to other established classifications, such as for example CEFR level annotation. To analyze how readability varies across the 7 levels, we extracted statistics from the BNE corpus for each of the 21 features. Table 2 contains average values by level for each of the selected readability measures and Table 3 Pearson correlation coefficient.

Length-based readability features reveal irregularities in the size of articles between levels 3 and 4 when the more complex topic replaces the easier one. One can observe that the average number of tokens and sentences per article, as well as the mean sentence length (ANS, ANT, MLS) gradually increase from level 0 to level 3, but then in level 4 decrease almost to the values of level 1, again increasing and surpassing previous values up until level 6. It affects FRE formula and introduces the same irregularity in its values. These size differences are intended by the author. Indeed, he states on his website that levels 4 and 5 texts are shorter than levels 2 and 3 respectively. Average word length is the only length-based feature that grows linearly and slightly smooths out the values of FRE.

This tendency in length-based features also affects syntactic features, since more complex syntactic constructions tend to contain more words. Considering these findings, none of the discussed features in isolation, except for AWL, could be

Table 2: Readability statistics for the BNE corpus

used to correctly identify the level of a BNE document. Among lexical features, we want to point out the OVIX and the DC metrics that together with the AWL suggest that the best approach to automatically assess complexity of this corpus may involve a statistical language model.

Based on the values of Pearson correlation coefficient we reduced our readability set to 3 features including FRE, DC and PTD - one feature per family - as the most reliable readability indicators for the given corpus (see Table 3). Since average sentence length is one of the components of FRE, we included FRE and not MSL in this set, even though it has a higher correlation coefficient. We will use this reduced set in the next experiments.

5 Summarization Methods

For this research we considered 7 state-of-the-art methods with different summarization techniques that include graph-based and frequency-based methods, methods that implement language models, incorporate such heuristics as word sense disambiguation and anaphora resolution and involve abstractive text summarization. Implementations of 2 of them were obtained from the authors (ExL19, AbL15), while the remaining 5 were provided by the sumy framework[5]. Each

method is described in more detail below.

Luhn's classical technique was one of the first summarization algorithms ranking sentences on word and phrase frequencies (Luhn, 1958). It weighs each sentence according to the number of significant words it contains ignoring high frequency common words from a stop word list.

SumBasic (Nenkova and Vanderwende, 2005) is another frequency-based summarizer that incorporates context information. It assumes that distribution of words in a human summary is similar to that of the original text. The authors reported that it outperformed many of the DUC 2004 systems, so it is frequently used in the literature as a baseline summarizer.

KLSum (Haghighi and Vanderwende, 2009) uses Kullback-Leibler divergence to measure the similarity between a sentence and the language model of the document and selects a set of sentences such that the distribution of words in the selected sentences is as similar as possible to the overall distribution of words in the document.

ExL19[6] Lloret et al. (2019) designed a modular extractive text summarization approach based on frequencies. For this experiment we selected the combination that includes anaphora resolution, word sense disambiguation and textual entailment, scoring sentences on concept frequencies.

LexRank (Erkan and Radev, 2004) is a graph-based approach that uses cosine similarity of TF–IDF vectors to calculate pairwise similarity between two sentences. The final score of each sentence is the sum of the weights of all the edges connected to it. The sentences are ranked by applying PageRank to the resulting graph.

TextRank (Mihalcea and Tarau, 2004) is another graph-based approach that uses PageRank to rank the sentences. In the case of TextRank, the similarity between two sentences is calculated as the number of words they have in common normalized by sentence length. In contrast to LexRank, TextRank recursively changes the weights of the sentences incorporating in this manner how all the sentences in the graph relate to each other.

AbL15 (Lloret et al., 2015) is an abstractive text summarization approach that incorporates the stages of text interpretation, transformation and summary generation. Each text passes through the process of syntactic simplification that splits complex sentences into shorter ones. Subsequently, the system extracts subject-verb-object triplets, identifies named entities and head nouns in nouns phrases, and supplies all this information to the summarizer. The summarizer scores each sentence representation based on the extracted information. In the final step the system translates each sentence into its surface representation and selects the highest rated sentences with respect to the maximum allowed summary size.

6 Results

The final setup of our experiment includes: 7 summarization methods (Luhn, SumBasic, ExL19, LexRank, TextRank, KLSum, AbL15); 4 compression rates (20%, 40%, 60% & 80%); and, 3 readability metrics (FRE, DC and PTD). To evaluate how much readability of generated summaries ($sread$) differs from that of the original documents ($oread$) we calculated for each document *i* the percent deviation (*PD*)

$$PD_i = \frac{(sread_i - oread_i)}{oread_i} * 100 \qquad (1)$$

and then averaged it across the entire set. This value can be both negative and positive and indicates whether the summary is more or less complex than the original text.

Another way to assess the summarizer's performance on readability is to calculate the average absolute deviation from the original text's complexity, in other words from 0. With this information we can determine the degree to which the summaries, independently from being more complex or simple, differ from the original documents across all the compression rates. Although the complexity of a system may vary across all the compression rates, their average variation may be very small.

$$AAD_s = \frac{\sum_{n=1}^{4} |PD_n - 0|}{4} \qquad (2)$$

where AAD_s is the average absolute deviation of a given system s and PD_n is its percent deviation for the compression rate n.

6.1 Length-based readability results

Table 4 shows how selected text summarization methods affect length-based readability features. FRE measure depends on the number of tokens per

[6] We will refer to the systems developed by Lloret et al. using ExL19 for extractive and AbL15 for the abstractive one.

%compression	Luhn	SumBasic	KLSum	ExL19	LexRank	TextRank	AbL15
20	-12.36%	12.68%	-8.80%	-4.82%	-1.67%	-7.20%	-12.36%
40	-5.24%	9.16%	4.68%	-3.74%	2.25%	-2.51%	-3.38%
60	-1.53%	6.94%	8.04%	-1.41%	3.45%	-0.59%	4.32%
80	0.95%	4.85%	7.63%	0.19%	3.81%	1.35%	10.16%
Avg. abs. dev.	5.02%	8.41%	7.29%	2.54%	2.80%	2.91%	7.56%

Table 4: Flesch Reading Ease statistics

%compression	Luhn	SumBasic	KLSum	ExL19	LexRank	TextRank	AbL15
20	6.98%	-5.25%	2.06%	9.67%	2.01%	3.30%	10.65%
40	4.69%	-3.29%	-3.60%	7.72%	0.68%	2.34%	6.62%
60	2.73%	-2.58%	-4.37%	6.03%	-0.52%	1.60%	2.91%
80	0.76%	-1.62%	-3.59%	4.28%	-0.79%	0.48%	0.05%
Avg. abs. dev.	3.79%	3.18%	3.41%	6.93%	1.00%	1.93%	5.06%

Table 5: Dale-Chall statistics

sentence and syllables per words; the higher the score, the easier is the text. Thus when the percent deviation is negative, the summary is less comprehensible than the original text. This occurs across almost all of the settings where the summary comprises only 20% of the original text. The only exception is SumBasic that, with higher compression rates[7], tends to select shorter words and shorter sentences. For this readability feature SumBasic simplifies summaries across all the compression rates. However, other frequency-based summarization systems show a different tendency: Luhn and ExL19 tend to generate more complex summaries with longer words and sentences for almost all the compression rates. Graph-based approach TextRank shows the same tendency. In turn, KLSum and AbL15 for higher compression rates generate more complex summaries and for the lower compression rates more simple ones. The degree of difficulty for compression rate 20% is almost the same as the degree of simplification for 80% rate. For example, consider AbL15 that for 20% rate generated 12.36% more complex summaries, while for 80% rate 10.16% more simple.

The overall average degree of deviation from the readability of the original document also needs to be taken into account. ExL19 has the lowest average absolute deviation. It generates summaries with closest complexity to the original (2.54%) across all the compression rates.

Contrary to the findings of Lloret et al. (2019), who showed that for the DUC 2002 corpus, ExL19 generated more comprehensible summaries with respect to FRE, for the BNE corpus, ExL19 tends to select longer words and sentences. We believe the variation in original document complexity is what causes this difference because the BNE coprus contains texts simplified for L2 learners ranging mostly from A2 to B2 CEFR levels, whereas DUC 2002 is comprised of unsimplified newswire documents that are instrinsically more complex. This may indicate that present analysis of selected summarization systems and their impact on readability cannot be extended to other domains beyond L2 learner materials, since the performance of any summarizer depends on the corpus.

6.2 Lexical readability results

Lexical complexity of summaries was evaluated with the help of Dale-Chall formula; lower values of this metric indicate easier to comprehend summaries. Results in Table 5 show that in this evaluation SumBasic again simplifies summaries across all the compression rates. KLSum reveals similar values, except for the setting with 20% compression rate. Luhn, ExL19 and AbL15 include sentences with high percentage of complex words in summaries. In terms of lexical complexity, summarizers based on graphs (LexRank and TextRank) demonstrate the lowest average absolute deviation across all the compression rates and thus maintain lexical complexity of summaries that are closest to the original documents. For the length-based readability metric, graph-based approaches were also among the most similar.

6.3 Syntactic readability results

Parse tree depth statistics can be found in Table 6. For this feature as well, higher values indicate

[7] Under "higher compression rates" we understand shorter summaries; in our study compression rate of 20% is the highest

%compression	Luhn	SumBasic	KLSum	ExL19	LexRank	TextRank	AbL15
20	3.13%	-6.38%	11.37%	-13.86%	3.47%	7.87%	-15.21%
40	3.03%	-3.70%	0.05%	-8.06%	0.71%	5.50%	-16.63%
60	2.33%	-2.48%	-2.01%	-4.78%	-0.20%	4.02%	-19.87%
80	1.13%	-1.02%	-1.73%	-2.53%	-0.17%	2.46%	-23.10%

Table 6: Parse tree depth statistics.

summaries with more complex syntactic constructions and negative percent of deviation indicates that the respective system selects syntactically less complex sentences. For this feature SumBasic again simplifies summaries with respect to the original documents; and graph-based LexRank, by maintaining the lowest average absolute deviation, preserves the original text complexity. For parse tree depth and the other two readability features, KLSum tends to simplify summaries on lower compression rates, but for the compression rate of 20% it generates more complex summaries. Due to the integrated syntactic simplification step, abstractive system AbL15 generates sentences with shorter parse trees across all the settings. It also displays the highest average absolute deviation to the original values. Extractive system ExL19 reveals a similar tendency, namely, while selecting more complex sentences in terms of lexical complexity, it tends to include syntactically more simple sentences in summaries.

7 Conclusion and Future Work

In this paper we experimented with a new dataset of level-annotated L2 learner texts that can be used both for text simplification and text summarization tasks. We analyzed its syntactic, lexical and length-based readability features and evaluated its level annotation with a machine learning system trained on data annotated by Cambridge exam annotators.

We further conducted a novel analysis on how different extractive and abstractive summarization techniques at different compression rates affect readability of simplified L2 learner texts. Our experiments showed how this impact varied depending on the system used: 1) frequency-based system SumBasic consistently simplified summaries with respect to the original texts across all the compression rates, and thus may be considered a competitive baseline, not only in terms of recall but also readability; 2) graph-based approaches, especially LexRank, tended to maintain the same complexity as the original document; 3) Luhn's classical frequency-based method generated more complex summaries; 4) KLSum method based on Kullback-Leibler divergence produced complex summaries at higher compression rates, while simplifying them at lower compression rates; 5) integration of anaphora resolution, textual entailment and word-sense disambiguation led to syntactically more simple, but lexically more complex summaries; 6) abstractive summarizer AbL15 oversimplified syntactic structures and maintained at the same time a high complexity of lexical readability component. Hence no common pattern among the summarization approaches was identified with respect to the effect of compression rate on readability.

This work has provided an insight on the behaviour of different summarization approaches and permitted the discovery of a necessary dataset, as well as the analysis of the dataset's readability. These findings can be viewed as the first important step for designing a summarization system aimed at people with different levels of language proficiency. Future lines of research will consider integrating second language acquisition and discourse readability metrics.

Acknowledgments

This research work has been partially funded by the University of Alicante (Spain), Generalitat Valenciana and the Spanish Government through the projects SIIA (PROMETEU/2018/089), LIVING-LANG (RTI2018-094653-B-C22), INTEGER (RTI2018-094649-B-I00) and Red iGLN (TIN2017-90773-REDT). We would also like to thank Ekaterina Kochmar from the University of Cambridge for her help with the readability assessment of the BNE corpus, as well as Sean Banville for the permission to use his website materials and the valuable insights on the process of their creation.

Abstract

In this paper we describe how an abstractive text summarization method improved the informativeness of automatic summaries by integrating syntactic text simplification, subject-verb-object concept frequency scoring and a set of rules that transform text into its semantic representation. We analyzed the impact of each component of our approach on the quality of generated summaries and tested it on DUC 2002 dataset. Our experiments showed that our approach outperformed other state-of-the-art abstractive methods while maintaining acceptable linguistic quality and redundancy rate.

1 Introduction

Rapid growth of digital information increases the need for automatic text summarization methods that can digest large amounts of textual data, such as scientific articles, blogs and news articles to extract concise and relevant information from them. Text summarization methods can be classified into abstractive and extractive ones (Nenkova and McKeown, 2012). Extractive methods compose summaries from the most salient sentences of the original document. In contrast, abstractive methods generate novel or partially novel text using such techniques as sentence compression, fusion, calculation of path scores in graphs or, natural language generation tools such as SimpleNLG (Gupta and Gupta, 2018). They involve an intermediate step of deep linguistic analysis and an abstract semantic representation of the data. Extractive techniques have been intensively researched for over half a century and, according to some studies, “have more or less achieved their peak performance” (Mehta, 2016).

Over the past few years interest in the field of text summarization has shifted towards abstractive methods and quickly produced a large variety of approaches. Gupta and Gupta (2018) classify them broadly into methods based on the structure, semantics and deep learning with neural networks.

The main advantage of semantic-based approaches over deep learning ones lies in their independence from a large training corpus. Most of the available datasets for deep learning belong to the domain of news text that further restricts the application of these methods to other domains. However, semantic-based approaches rely on a parser to transform text to its semantic representation and, therefore, a poor parser performance will reduce the quality of generated summaries. Another limitation of the deep learning methods comes from the fact that they rely on statistical co-occurrence of words and are prone to semantic and grammatical errors. This is something that a reliable parser could help to avoid.

Structure-based methods, such as template and ontology based ones reveal other weaknesses. Template-based methods lack diversity. At the same time, ontology based ones rely on a time-consuming task of creating an ontology by a human expert. However, they provide highly coherent summaries and can handle uncertainties respectively. Semantic-based approaches that rely on handcrafted rules to transform text into semantic representation may be criticized for the same reason related to the human effort and time required to solve the laborious task of creating transformation rules.

It becomes clear that each abstractive approach can reliably handle only some aspects of the summarization process while revealing weaknesses in the remaining ones. Thus far, none of the approaches has been capable of offering a broad-based solution. Research in this field is mak-

Proceedings of Recent Advances in Natural Language Processing, pages 1275–1284,
Varna, Bulgaria, Sep 2–4 2019.

ing headway, each time with more elaborate algorithms and combining techniques from a number of different methods. However, Chen et al. (2016) have shown via their analysis of the reading comprehension task – another natural language processing task that requires interpretation of the text – that a straightforward approach designed around a small set of carefully selected features can obtain high, state-of-the-art accuracy.

Therefore, this study has a threefold objective. First, to design a broad-based abstractive text summarization method. Second, to evaluate whether the proposed method is capable of delivering concise and informative summaries while maintaining above-average linguistic quality and redundancy rate. Third, to compare it against other state-of-the-art abstractive methods.

The approach that we propose in this work falls into the previously mentioned semantic-based group of abstractive summarization approaches and has been inspired by the ideas of Genest and Lapalme (2011) and Lloret et al. (2015). Our contribution takes their abstractive models one step further by scoring abstract information representation without taking into account its surface representation. The proposed method incorporates syntactic text simplification, subject-verb-object concept frequency scoring, and a set of rules that transform text into its semantic representation.

This paper is structured as follows: Section 2 discusses related semantic-based abstractive summarization approaches. Section 3 describes in detail the architecture of our method. Evaluation methods and results are presented in Section 4. Section 5 describes the effect of individual components of our approach upon the quality of generated summaries. Section 6 provides a summary of the conclusions and areas for future work.

2 Related Work

All the methods in the semantic-based abstractive summarization group include the initial step of converting texts into an abstract semantic representation. For example, Genest and Lapalme (2011) introduced the concept of information item that was defined as a smallest element of coherent information and represented as a dated and located subject-verb-object triplet. Lloret et al. (2015) also base their concept representation on subject-verb-object triplets. Alshaina et al. (2017) use predicate-argument structure as their underlying information representation and extract a number of features from it that are later used for ranking. Li (2015) define the concept of Basic Semantic Unit (BSU) where each BSU is an actor-action-receiver triplet with its obligatory arguments, namely, actor and receiver of the action. The BSUs are used to construct a BSU semantic link network representation for each text.

Abstract Meaning Representation (AMR) graphs is the most recent approach to abstract semantic representation of texts (Vilca and Cabezudo, 2017). AMR nodes are represented by either words or PropBank[1] frames, and edges define relationships between them. Both the AMR graph representation and the subject-verb-object (SVO) representation depend on the efficiency of the parser. However, AMR graphs also rely on PropBank framework whose limitations pose additional constraints on AMR graphs. Furthermore, the problem of text generation from AMR graphs is still a challenge and it has not yet been solved (Li, 2015).

The summarization method based on BSUs proposed by Li (2015) overcomes the limitation of text generation faced by AMR graphs, and produces informative, coherent and compact summaries. However, as the authors state, the BSU network cannot yet handle data that express opinions rather than facts and actions, since these cases involve verbs that lack meaningful actions, such as ’be’, and the underlying representation of actor-action-receiver cannot be appropriately computed.

Alshaina et al. (2017) use K-means and agglomerative hierarchical clustering algorithms to group similar predicate-argument structures (PAS) based on semantic similarity measures, and to eventually select the most representative PAS based on a weighted set of 12 features. The PAS proposed by this approach are classified into simple and complex ones. Complex PAS are derived from sentences with multiple verbs, otherwise they are considered to be simple. Nested PAS are eliminated. One of the features that determines whether to include a PAS into the summary or not is the ”number of verbs and nouns” that gives preference to complex PAS as crucial to summary generation.

Lloret et al. (2015) propose an abstractive semantic-based approach to ultra-concise opinion summarization. It involves a syntactic sentence simplification in the preprocessing step and

[1] https://propbank.github.io/

semantic representation based on subject-verb-object triplets. Their scoring heuristics relies on subject-verb-object term frequencies.

The approaches closest to ours are those of Lloret et al. (2015); Genest and Lapalme (2011, 2010). However, the difference between them is twofold. First, the aforementioned systems use term or document frequencies for scoring. We integrate word sense disambiguation to identify similarities between subject-verb-object triplets on the conceptual level that allows us to introduce concept frequencies for scoring. Second, the architecture of our approach is characterized by a higher level of abstraction. Namely, our approach scores abstractive concepts represented in the form of enriched subject-verb-object triplets and not their surface representation. Their surface representation is integrated in the final step when all the triplets have already been assigned their score.

Unlike the approach of Alshaina et al. (2017) who give preference to sentences with more than one verb, our approach integrates syntactic sentence simplification in the preprocessing step in order to split complex sentences into simpler ones and ideally reduce syntactic structure to a single main verb. This allows us to generate various subject-verb-object triplets from a single sentence and to manipulate them in a more precise manner.

3 Abstractive Summarization Framework

The architecture of our proposed abstractive text summarization approach is illustrated in Figure 1. This section describes the role and the implementation of each of its components.

Simplification. We begin by applying syntactic simplification to the original document as a pre-processing step. Simplification targets only complex sentences, splitting their syntactic trees into simpler ones. Each newly created sentence is a fully grammatical construction that, not always but in most cases, contains one main verb and covers one single concept[2]. In the next stages our method generates an information item from each simplified sentence. Simplifying the syntactic structure of the input text allows us to have fewer, less recursive and less error-prone rules for information item extraction. And capturing as many concepts as possible benefits the process of information item selection: only the most salient bits of information are selected while the irrelevant ones are discarded. We use the Factual Statement Extractor to carry out the simplification task (Heilman and Smith, 2010).

Analysis. In this stage, we perform a linguistic analysis decomposing each supplied simplified sentence into lemmas, stems, parts of speech, senses, named entities, syntactic roles and noun phrases. This is done mainly with the help of Stanford CoreNLP (Manning et al., 2014). Additionally we use Porter stemmer for stemming (Porter, 1997), Freeling for word sense disambiguation (Padró and Stanilovsky, 2012) and Java DOM parser for noun phrase chunking.

Information Items Generation. Once the data have been analyzed we proceed to build an abstract representation of each of the sentences. We adopt the same naming convention as Genest and Lapalme (2011) and refer to them as information items (`InIts`). At the core of each `InIt` lies the main verb of the sentence accompanied by its subject and object, if they are present. Contrary to Genest and Lapalme (2011) we do not incorporate any manual rules to reject candidate `InIts`. However, a small portion of them will be lost during the surface realization stage if SimpleNLG fails to generate a sentence from an `InIt`. It happens at most to 1-2 simplified sentences per document. Preserving all `InIts` may introduce a higher rate of grammatically incorrect sentences due to the incorrect sentence parses[3]. However, since no clear pattern between syntactic linguistic phenomena and incorrect parses was observed, we could not discard such cases. Additionally, we extend the core subject-verb-object structure to include open clausal complements and prepositional phrases. Since the Stanford CoreNLP configuration that we used implements Universal Dependencies [4] for dependency parsing, our rules for transforming text into `InIts` are also designed around this annotation scheme. We implemented 5 transformation rules:

1. `ccomp` rule retains a clausal complement of a verb or adjective, rejecting the initial part. *He says that [you like to swim].*
2. `subject` and `verb` rule identifies them in the remaining sentence. It also handles copula and passive voice.

[2] Table 9 provides an example of a simplified sentence.

[3] Common mistakes provoked by this decision can be found in Section 4.2.

[4] https://universaldependencies.org/

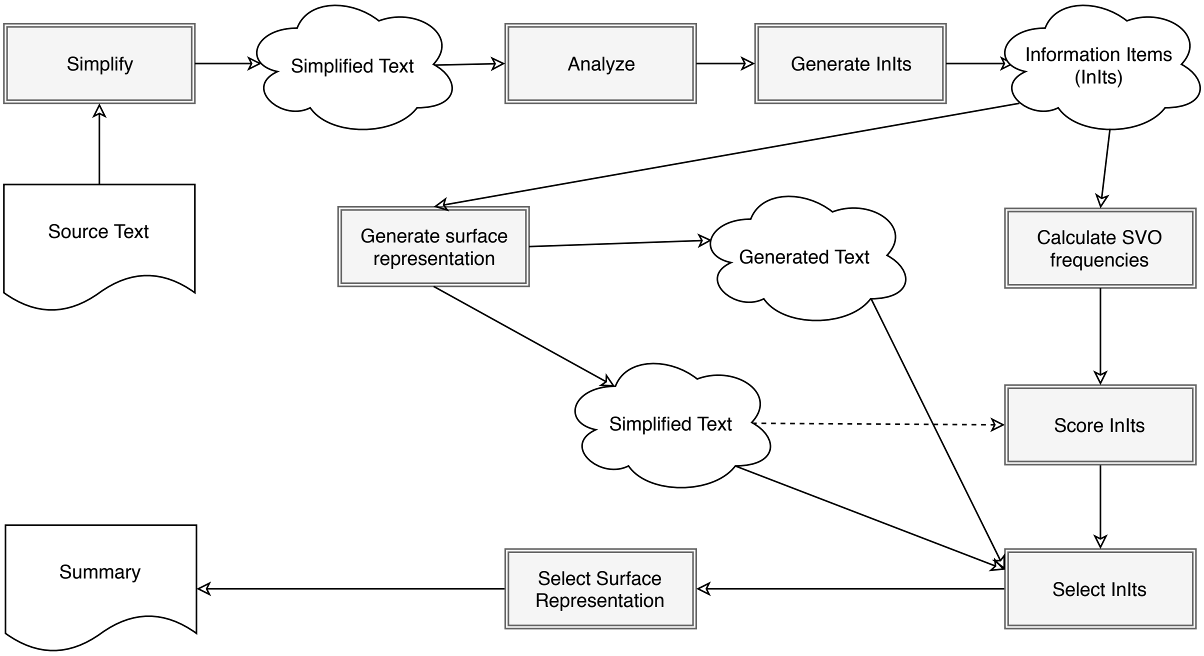

Figure 1: Our Abstractive Summarization Framework.

3. `direct` and `indirect object` rule sets corresponding objects if they exist.
4. `xcomp` rule handles open clausal complements of verbs and adjective. *She looks [very beautiful]. I consider him [a fool]. He tried [to run].*
5. `pp` rule identifies remaining prepositional phrases. *They talked [about London].*

All the `InIts` are stored internally as an ordered list.

Calculation of frequencies. In this stage we analyze `InIts` and calculate concept frequencies of all the verb, subject and object phrase heads of the input. For the purpose of evaluating effectiveness of concept frequencies, we also incorporated their term frequency scoring for comparative purposes. Our scoring strategy is based on the idea that there is "a very strong correlation between concepts of topic and subject in English." (Foley, 1994). And it has also been shown in previous research on text summarization that subjects, verbs and objects play a crucial role in content selection and cannot be dropped (Harabagiu and Lacatusu, 2010). Along with the SVO frequencies we also calculate term frequencies of named entities that represent subject or object phrase heads.

Information Items Scoring. Unlike the approaches of Genest and Lapalme (2011); Lloret et al. (2015) in our approach, `InIt` scoring and surface realization are independent from each other. We apply extracted SVO and named entity head frequencies from the previous step to score `InIts` directly. This gives us the flexibility to choose which parts of `InIts` to use for scoring. Our scoring is based on the idea that `InIts` that cover the main topic of the document contain the most frequent SVO concepts and named entities in any of their components. Given the flexibility to work with `InIts` directly and not the raw text, we experimented with scoring on SVO components and also combined them with open clausal complements and prepositional phrases. While scoring, we calculate matches not only between candidate noun phrase heads, but other phrase constituents es well.

For testing purposes we also integrate a modification of this step that, instead of scoring `InIts` directly, applies SVO and named entity frequencies to the simplified text. This configuration is indicated with the dashed arrow in Figure 1. It allows us to compare how much information is lost during the transformation and generation stages.

Text Generation. We generate sentences from `InIts` with the help of SimpleNLG realization engine (Gatt and Reiter, 2009). The order of text generation rules is defined mainly by functionalities of SimpleNLG and follows these steps:

- generate a noun phrase (NP) to represent the subject if present;
- generate the main verb;

- generate an NP to represent direct object if present;
- generate an NP for indirect object if present;
- generate prepositional phrases
- generate open clausal complements if present (xcomp transformation rule); and,
- assemble all the components and generate the verb phrase (VP).

We do not do any other modifications apart from syntactic simplification of long sentences in the preprocessing step of our approach. This means, for example, that we do not convert passive constructions into active ones. However, since we always use the same order for the text generation rules, the original order of constituents may be changed, i.e. prepositional phrases will always be generated after subject, verb or objects, despite the fact that in the original sentence they may be in a different position. Generated sentences play no role in InIts scoring or InIt selection. They remain on hold until the selection of InIts and surface representation stage.

Information Items Selection. At this stage, we inspect all the InIts and reject the ones with empty text representation generated by SimpleNLG.

Selection of Surface Representation. For all the remaining ranked InIts, starting from the highest ranked one, we add each InIt's surface representation to the final summary until the maximum allowed size has been reached. Once we reach it we reorder sentences to preserve the original order of simplified sentences that each InIt originated from and deliver the summary. For surface representation our approach allows the selection of either a representation generated with SimpleNLG or the simplified sentence. In this final stage we do not integrate additional date or location information as Genest and Lapalme (2011), but if an InIt contained them among its prepositional phrases, they are included into the generated sentence by SimpleNLG.

4 Evaluation

Our approach is evaluated on DUC 2002 dataset for the single document summarization task[5]. After discarding duplicates, the dataset consists of 530 newswire articles. Each article is accompanied by one or more manually created abstractive model summaries of approximately 100 words.

At this development phase, our approach generates summaries operating exclusively with the words present in the original text. However, as a result of the syntactic simplification, they are likely to be reorganized into shorter sentences. Moreover, some of the words are ordered differently or not included into generated sentences as a consequence of the implemented translation and surface realization rules. These operations create summaries that go beyond the literal extraction of original text fragments.

We evaluate the content selection part of our approach with ROUGE toolkit and use human evaluation to assess the linguistic quality of generated summaries as described in Sections 4.1 and 4.2 respectively.

4.1 Informativeness

Following the example of recent works on abstractive text summarization we used ROUGE toolkit (Lin, 2004) to evaluate generated summaries (Vilca and Cabezudo, 2017; Hsu et al., 2018). ROUGE-1 and ROUGE-2 are used to assess informativeness and together with ROUGE-SU4 they have been found to correlate well with human judgement. The longest common subsequence ROUGE-L is used to assess fluency. We compared our summaries to the human summaries provided for DUC 2002 corpus, and each text can be evaluated against at least 2 of them.

We also calculated average pairwise ROUGE values for human summaries to identify the highest score that an abstractive summary can obtain with ROUGE (see Table 1).

The selected baseline was implemented with the help of our method such that each original text passes through all the stages specified in Section 3, including sentence simplification and surface realization stages but avoiding the SVO and named entity scoring. To produce the baseline summary we applied tf-scoring to such regenerated sentences. This ensures that the baseline is an abstractive summary only differing in the scoring method.

We compared our approach to two state-of-the-art approaches for abstractive text summarization of a different nature: 1) Vilca and Cabezudo's (2017) approach based on AMR graphs and Rhetorical Structure Theory; and, 2) the approach proposed by Hsu et al. (2018) based on deep learning and combines abstractive and extractive components. To compare our approach with the latter

one, we used their abstractive model pre-trained on CNN/Daily Mail dataset of newswire articles.

Table 1 shows that our approach outperforms both the abstractive baseline and the approach of Hsu et al. (2018) on all the ROUGE metrics. It also outperforms Vilca and Cabezudo's (2017) approach on 3 of the 4 metrics.

To illustrate how our approach and the approach of Hsu et al. (2018) modify original sentences, we contrast an extractive term-frequency based summary with the abstractive summaries generated by both of the approaches (see Table 2). For convenience, the common chunks between the summaries are numbered and surrounded by square brackets, while the unique chunks are italicized.

Our approach: [More than 4,000 workers at a coal mine in the southern city of Jastrzebie went to demand legalization of Solidarity and higher wages on strike]^{1}. [Workers on the overnight shift at the Manifest Lipcowy mine stayed outside the mine shaft]^{2}. [The miners are demanding the legalization of Solidarity]^{4}. *The workers are calling for higher wages and better working conditions. The workers are requesting two lawyers and two economists. Workers at the Rudna copper mine near the city of Wroclaw staged a protest rally.*[Workers at factories around the northern port of Gdansk joined striking shipyard workers.]^{5}.
Extractive TF summary: *Solidarity spokeswoman Katarzyna Ketrzynska said* [[workers on the overnight shift at the Manifest Lipcowy mine stayed outside the mine shaft]^{2} all night and were joined by workers arriving for the morning shift]^{3}. *The strike began at noon today, according to Katrzynska. She said* [the miners are demanding the legalization of Solidarity]^{4} *and reinstatement of workers fired for union activities. Three members of Solidarity were barred Saturday from working. On Aug. 16, 1980,* [workers at factories around the northern port of Gdansk joined striking shipyard workers]^{5} *to form Solidarity, the first and only independent trade federation in the Soviet bloc.*
Hsu'18: [more than 4,000 workers at a coal mine in the southern city of jastrzebie went on strike today to demand legalization of solidarity and higher wages]^{1}. [[workers on the overnight shift at the manifest lipcowy mine stayed outside the mine shaft]^{2} all night and were joined by workers arriving for the morning shift]^{3}.

Table 2: An comparison of abstractive summaries with an extractive summary.

Grammaticality: 1. TAS **gave not** details of Gorbachev 's suggestion. 2. Six bodies were *founded* in the hull of the ferry by Police. 3. The Lone Star Statuette *were* built by Chicago 's Creative House Promotions.
Redundancy: 1. Martin Nelson was another meteorologist at the center *at center*. 2. Dullah Omar was an activist and family friend of the Mandelas *of Mandelas*. 3. A resolution promises reforms. A resolution promises reforms.
Completeness: 1. A quake of 6 on the scale is capable. 2. Reunification mishandled. 3. Arthur Andersen wanted.

Table 3: Examples of some of the mistakes produced by our approach.

4.2 Human Evaluation

For our preliminary human evaluation of generated summaries, we used the statistical formula to calculate the correct size of a representative sample that was proposed by Pita-Fernández (1996) and successfully applied to different NLP tasks (Vázquez et al., 2010; Lloret et al., 2019). For DUC 2002 dataset, a representative sample consists of 77 documents that we randomly chose from the corpus. They were evaluated according to the following criteria based on the DUC guidelines, but adapted to the specific task and errors:

- *grammaticality* - grammatical correctness of the summary (i.e. number agreement);
- *non-redundancy* - no unnecessary repetitions; and,
- *completeness* - completeness of grammatical construction (i.e. a missing direct object of a transitive verb).

The generated abstractive summaries were assessed on a five-point Likert scale by 3 external annotators without any knowledge about how the summaries were produced. A grammatically correct, non-redundant and complete summary would receive a score of 5-5-5 respectively. The results in Table 4 show that the summaries produced by our approach scored above the average on the three criteria.

Measure	**Score**
Grammaticality	3.60
Non-redundancy	3.71
Completeness	3.81

Table 4: Average scores for human evaluation.

Table 3 shows examples of such mistakes. Upon closer inspection we detected that the completeness errors are often caused by incorrect parses. Some of the grammatical errors are produced by SimpleNLG, whereas others refer to the cases not covered by information item extraction rules. Contrary to our predictions, the non-redundancy rate was above the average. The overall linguistic quality looks promising and reveals areas for improvement. However, there is a need for a deeper evaluation that is planned for future work.

5 Further Experiments and Discussion

In this section we analyze the impact of each of the components of our method on the informativeness of generated summaries.

5.1 Syntactic Constituents

We experimented with different configurations of our scoring module to test whether the subject, verb and object are enough for the scoring, or should be extended with open clausal complements and prepositional phrases to improve its performance. For this purpose we applied the scoring in three different contexts: exclusively SVO (SVO); the SVO extended with clausal complements (SVO+xComp); and, the SVO+xComp extended with prepositional phrases (SVO+xComp+PPs). This means that the scoring module checked occurrences of the most frequent SVO elements only in subject-object-object triplets or in the extended structures. The results in Table 5 show that there is some improvement in performance when additional syntactic components are included. We believe that this improvement may increase as the corpus increases, since a larger corpus will contain more cases of open clausal complements and prepositional phrases.

	R-1	R-2	R-L
SVO	0.4064	0.1522	0.3756
SVO xComp	0.4078	0.1523	0.3765
SVO xComp PPs	0.4102	0.1544	0.3776

Table 5: ROUGE scores for syntactic components

5.2 Generation and Recall

Another experimental setup addresses the question of how much important information is lost during the generation stage. As described in Section 3, we integrated a setting (signaled with the dashed arrow in Figure 1) that, instead of scoring InIts, applied the SVO frequencies to the simplified text and delivered it in the final summary. This setting overcomes two possible limitations of our approach: it also scores the parts of the sentence that are not included into an InIt and provides more text for the future recall evaluation with ROUGE. Results in Table 6 show a slight improvement over the InIt-based scoring, but the difference is not as high as we expected. We may conclude that our InIt extraction rules capture most of the information, and surface realization rules generate sufficient material for the ROUGE evaluation.

	R-1	R-2	R-L
InIt	0.4102	0.1544	0.3776
Simpl. text	0.4181	0.1668	0.3797

Table 6: ROUGE evaluation of text-based scoring

5.3 Effect of Concept Frequency Scoring

Word sense disambiguation and the resulting concept scoring should positively affect InIt selection as well. Table 7 shows that in this setting the difference between term and concept frequencies is almost non-existent. We believe that if we integrate the entire noun phrase when calculating SVO frequencies and not only the noun phrase head, it may lead to a more significant difference.

	R-1	R-2	R-L
SVO cf	0.4102	0.1544	0.3776
SVO tf	0.4100	0.1545	0.3777

Table 7: ROUGE scores for concept and term frequency scoring.

5.4 Simplification and Recall

Our motivation behind the integration of a syntactic simplification module was to reach a greater degree of concept granularity that would allow us to select only the most salient InIts while discarding the less relevant ones. We tested our approach both with and without simplification. The results revealed in Table 8 indicate that working with original text yields a slightly better recall.

Close inspection showed that our simplification module generates syntactically more simple sentences, but introduces more repetitions that are

	R-1	R-2	R-L
Simplified	0.4102	0.1544	0.3776
Original	0.4169	0.1588	0.3803

Table 8: ROUGE scores for simplification test.

picked up by the SVO and named entity scoring. Consider the example in Table 9:

Original sentence: Greek marine archaeologists focus on locating and surveying historic wrecks scattered around the Aegean and rarely carry out excavations.
Simplified: 1. Greek marine archaeologists focus on locating. 2. Greek marine archaeologists focus on surveying historic wrecks scattered around the Aegean. 3. Greek marine archaeologists carry out excavations.
Simplified summary: 1. Greek marine archaeologists focus. 2. Greek marine archaeologists carry out excavations.
Original summary: not included

Table 9: Simplification example.

When we split a long sentence into several shorter ones with the repeated subject, the scoring module gives them more importance by considering the repeated subject to be the topic of the document. If some of these split sentences are included in the final summary, the repeated subject noun phrase takes summary space that otherwise could be occupied by a different phrase. On the other hand if the subject of such a split phrase is the true topic of the document, our method generates a very topic-focused summary. We hypothesize that scoring should be performed on the original subject-verb-object distribution of the document so as to avoid scoring for repeated subjects.

5.5 Summary Readability

Readability is rarely studied in detail in the context of automatic text summarization. Our summarization approach integrates syntactic simplification that results in syntactically simpler summaries and concept frequency scoring that may yield summaries with richer vocabulary when compared to term frequency based ones. To assess readability of generated summaries we calculated their Flesch Reading Ease (FRE), Dale-Chall (DC) and depth of the parse tree (PTD) scores. These three metrics give us a quick but complete assessment of the length, vocabulary and syntactic complexity-based readability aspects. Higher FRE and lower PTD and DC values correspond more comprehensible texts.

Results in Table 10 show that human summaries include longer sentences and words, and are also more concept dense than the original texts. Human summaries also tend to consist of syntactically less complex sentences. Unlike human summaries, our approach generates more comprehensible texts in terms of sentence and word length. As expected, syntactic sentence simplification positively affects the parse tree depth metric. However, it also generates summaries with greater lexical density.

	FRE	**DC**	**PTD**
Ours	50.74	10.56	8.30
Human	42.76	10.45	10.51
Original	43.51	10.13	11.48

Table 10: Readability metrics for different methods.

6 Conclusions and Future Work

This paper presents a broad-based abstractive text summarization method that outperforms other state-of-the-art abstractive approaches while maintaining acceptable linguistic quality and redundancy rate. Our approach is based on the set of syntactic rules that transform text into its semantic representation as well as the combination of subject-verb-object concept frequency and named entity frequency for scoring.

The results show that some aspects of the proposed approach require improvement. Integration of the entire subject and object noun phrases for the calculation of frequencies may increase informativeness of the generated summaries. Coreference resolution and sentence fusion may help to lower the degree of redundancy introduced through the syntactic sentence simplification.

In future work, we plan to integrate these improvements and to evaluate our method on other datasets such as CNN/Daily Mail dataset. First, a larger dataset can provide more insights on the relative importance of open clausal complements, prepositional phrases and concept frequency for information item rating. Second, it will allow us to gauge the weaknesses and strengths of our approach, which is based on the concept of information items and handcrafted syntactic transformation rules, via a comparative analysis with state-of-the-art deep learning and semantic graph approaches.

Abstract

Given many recent advanced embedding models, selecting pre-trained word embedding (a.k.a., word representation) models best fit for a specific downstream task is non-trivial. In this paper, we propose a systematic approach, called *ETNLP*, for extracting, evaluating, and visualizing multiple sets of pre-trained word embeddings to determine which embeddings should be used in a downstream task.

We demonstrate the effectiveness of the proposed approach on our pre-trained word embedding models in Vietnamese to select which models are suitable for a named entity recognition (NER) task. Specifically, we create a large Vietnamese word analogy list to evaluate and select the pre-trained embedding models for the task. We then utilize the selected embeddings for the NER task and achieve the new state-of-the-art results on the task benchmark dataset. We also apply the approach to another downstream task of privacy-guaranteed embedding selection, and show that it helps users quickly select the most suitable embeddings. In addition, we create an open-source system using the proposed systematic approach to facilitate similar studies on other NLP tasks. The source code and data are available at `https://github.com/vietnlp/etnlp`.

1 Introduction

Word embedding, also known as word representation, represents a word as a vector capturing both syntactic and semantic information, so that the words with similar meanings should have similar vectors (Levy and Goldberg, 2014). Although, the classical embedding models, such as Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), fastText (Bojanowski et al., 2017), have been shown to help improve the performance of existing models in a variety of Natural Language Processing (NLP) tasks like parsing (Bansal et al., 2014), topic modeling (Nguyen et al., 2015), and document classification (Taddy, 2015; Vu et al., 2018b). Each word is associated with a single vector leading to a challenge on using the vector across linguistic contexts (Peters et al., 2018). To handle the problem, recently, contextual embeddings (e.g., ELMO of Peters et al. (2018), BERT of Devlin et al. (2018)) have been proposed and help existing models achieve new state-of-the-art results on many NLP tasks. Different from non-contextual embeddings, ELMO and BERT can capture different latent syntactic-semantic information of the same word based on its contextual uses. Therefore, for completeness, in this paper, we incorporate both classical embeddings (i.e., Word2Vec, fastText) and contextual embeddings (i.e., ELMO, BERT) to evaluate their performances on NLP downstream tasks.

Given the fact that there are many different types of word embedding models, we argue that having a systematic pipeline to evaluate, extract, and visualize word embeddings for a downstream NLP task, is important but non-trivial. However, to our knowledge, there is no single comprehensive pipeline (or toolkit) which can perform all the tasks of evaluation, extraction, and visualization. For example, the recent framework called *flair* (Akbik et al., 2018) is used for training and stacking multiple embeddings but does not provide the whole pipeline of extraction, evaluation and visualization.

In this paper, we propose *ETNLP*, a systematic pipeline to extract, evaluate and visualize the pre-trained embeddings on a specific downstream NLP task (hereafter ETNLP pipeline). The ETNLP pipeline consists of three main components which are *extractor*, *evaluator*, and *visualizer*. Based on the vocabulary set within a downstream task, the extractor will extract a subset of word embeddings for the set to run evaluation

Proceedings of Recent Advances in Natural Language Processing, pages 1285–1294,
Varna, Bulgaria, Sep 2–4 2019.

and visualization. The results from both *evaluator* and *visualizer* will help researchers quickly select which embedding models should be used for the downstream NLP task. On the one hand, the *evaluator* gives a concrete comparison between multiple sets of word embeddings. While, on the other hand, the *visualizer* will give the sense on what type of information each set of embeddings preserves given the constraint of the vocabulary size of the downstream task. We detail the three main components as follows.

- **Extractor** extracts a subset of pre-trained embeddings based on the vocabulary size of a downstream task. Moreover, given multiple sets of pre-trained embeddings, how do we get the advantage from a few or all of them? For instance, if people want to use the character embedding to handle the out-of-vocabulary (OOV) problem in Word2Vec model, they have to implement their own extractor to combine two different sets of embeddings. It is more complicated when they want to evaluate the performance of either each set of embeddings separately or the combination of the two sets. The provided **extractor** module in ETNLP will fulfill those needs seamlessly to elaborate this process in NLP applications.

- **Evaluator** evaluates the pre-trained embeddings for a downstream task. Specifically, given multiple sets of pre-trained embeddings, how do we choose the embeddings which will potentially work best for a specific downstream task (e.g., NER)? Mikolov et al. (2013) presented a large benchmark for embedding evaluation based on a series of analogies. However, the benchmark is only for English and there is no publicly available *large* benchmark for low resource languages like Vietnamese (Vu et al., 2014). Therefore, we propose a new evaluation metric for the word analogy task in Section 3.

- **Visualizer** visualizes the embedding space of multiple sets of word embeddings. When having a new set of word embeddings, we need to get a sense of what kinds of information (e.g., syntactic or semantic) the model does preserve. We specifically want to get samples from the embedding set to see what is the semantic similarity between different words. To fulfill this requirement, we design two different visualization strategies to explore the embedding space: (1) side-by-side visualization and (2) interactive visualization.

The side-by-side visualization helps users compare the qualities of the word similarity list between multiple embeddings (see figure 5). It allows researchers to "zoom-out" and see at the overview level what is the main difference between multiple embeddings. Moreover, it can visualize large embeddings up to the memory size of the running system. Regarding implementation, we implemented this visualization from scratch running on a lightweight webserver called Flask (`flask.pocoo.org`).

For the interactive visualization, it helps researchers "zoom-in" each embedding space to explore how each word is similar to the others. To do this, the well-known Embedding Projector (`projector.tensorflow.org`) is employed to explore the embedding space interactively. Unlike the side-by-side visualization, this interactive visualization can only visualize up to a certain amount of embedding vectors as long as the tensor graph is less than 2GB. This is a big limitation of the interactive visualization approach, which we plan to improve in the near future. Finally, it is worth to mention that the visualization module is dynamic and it does not require to change any codes when users want to visualize multiple pre-trained word embeddings.

To demonstrate the effectiveness of the ETNLP pipeline, we employ it to a use case in Vietnamese. Evaluating pre-trained embeddings in Vietnamese is a challenge as there is no publicly available *large*[1] lexical resource similar to the word analogy list in English to evaluate the performance of pre-trained embeddings. Moreover, different from English where all word analogy records consist of a single syllable in one record (e.g., grandfather | grandmother | king | queen), in Vietnamese, there are many cases where only words formulated by multiple syllables can represent a word analogy record (e.g., ông nội | bà ngoại | vua | nữ_hoàng).

We propose a large word analogy list in Vietnamese which can handle the problems. Having that word analogy list constructed, we utilize different embedding models, namely Word2Vec, fastText, ELMO and BERT on Vietnamese Wikipedia data to generate different sets of word embeddings. We then utilize the word analogy list to select suitable sets of embeddings for the named entity recognition (NER) task in Vietnamese. We achieve

[1] There are a couple of available datasets (Nguyen et al., 2018b). But the datasets are small containing only 400 words.

the new state-of-the-art results on VLSP 2016[2], a Vietnamese benchmark dataset for the NER task.

Here are our key contributions in this work:

- Propose a systematic pipeline (ETNLP) to evaluate, extract, and visualize multiple sets of word embeddings on a downstream task.

- Release a large word analogy list in Vietnamese for evaluating multiple word embeddings.

- Train and release multiple sets of word embeddings for NLP tasks in Vietnamese, wherein, their effectiveness is verified through new state-of-the-art results on a NER task in Vietnamese.

The rest of this paper is organized as follows. Section 2 describes how different embedding models are trained. Section 3 shows how to use ETNLP to extract, evaluate, and visualize word embeddings. Section 4 explains how the word embeddings are selected for the NER task using the word analogy task. Section 5 concludes the paper followed by future work.

2 Embedding Models

This section details the word embedding models incorporated in our systematic pipeline.

- **Word2Vec (W2V)** (Mikolov et al., 2013): a widely used method in NLP for generating word embeddings.

- **W2V_C2V**: the Word2Vec (W2V) model faces the OOV issue on unseen text, therefore, we provide a character2vec (C2V) (Kim et al., 2015) embedding for unseen words. When the C2V is not available, it can be easily calculated from a W2V model by averaging all vectors where a character occurred. Our experiments further confirm this averaging approach is efficient.

- **fastText** (Bojanowski et al., 2016): it associates embeddings with character-based n-grams, and a word is represented as the summation of the representations of its character-based n-grams. Based on this design, fastText attempts to capture morphological information to induce word embeddings, and hence, deals better with OOV words.

Visualization of Embedding Space

Figure 1: General process of the ETNLP pipeline where $\mathcal{S}$ is the set of extracted embeddings for Evaluation and Visualization of multiple embeddings on a downstream NLP task.

- **ELMO** (Peters et al., 2018): a model generates embeddings for a word based on the context it appears. Thus, we choose the contexts where the word appears in the training corpus to generate embeddings for each of its occurrences. Then the final embedding vector is the average of all its context embeddings.

- **BERT_{Base, Large}** (Devlin et al., 2018): BERT makes use of Transformer, an attention mechanism that learns contextual relations between words (or sub-words) in a text. Different from ELMO, the directional models, which reads the text input sequentially (left-to-right or right-to-left), the Transformer encoder reads the entire sequence of words simultaneously. It, therefore, is considered bidirectional. This characteristic allows the model to learn the context of a word based on all of its surroundings (left and right of the word). BERT comes with two configurations called BERT_Base (12 layers) and BERT_Large (24 layers). To get the embedding vector of a word, we average all vectors of its subwords. Regarding contexts, similar to the ELMO model above, we choose the contexts where the word appears in the training corpus.

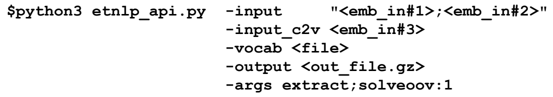
3 Systematic Pipeline

Figure 1 shows the general process of the ETNLP pipeline. The four main processes of ETNLP are very simple to call from either the command-line or the Python API.

- **Pre-processing:** since we use Word2Vec (W2V) format as the standard format for the whole process of ETNLP, we provide a pre-processing tool for converting different embedding formats to the W2V format.

- **Extractor:** to extract embedding vectors at word level for the specific target NLP task (i.e., NER task in our case). For instance, the popular implementation of Reimers and Gurevych (2017) on the sequence tagging task allows users to set location for the word embeddings. The format of the

[2] http://vlsp.org.vn/vlsp2016/eval/ner



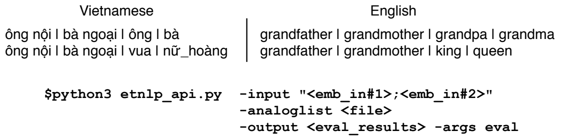
```
$python3 etnlp_api.py  -input      "<emb_in#1>;<emb_in#2>"
                       -input_c2v <emb_in#3>
                       -vocab <file>
                       -output <out_file.gz>
                       -args extract;solveoov:1
```

Figure 2: Run *extractor* to export single or multiple embeddings for NLP tasks.

file is text-based, i.e., each line contains the embedding of a word. The file then is compressed in .gz format. Figure 2 shows a command-line to extract multiple embeddings for an NLP task. The argument "-vocab" is the location to a vocabulary list of the target NLP task (i.e., the NER task) which is extracted from the task training data. The option "solveoov:1" informs the *extractor* to use Character2Vec (C2V) embedding to solve OOV words in the first embedding "<emb_in#1>". The "-input_c2v" can be omitted if users wish to simply extract embeddings from the embedding list given after the "-input_embs" argument. Output of this phase is a set of embeddings $\mathcal{S}$ to run on the next evaluation phase.

- **Evaluator** evaluates multiple sets of embeddings (i.e., $\mathcal{S}$) on the word analogy task. Based on the performance of each set of embeddings in $\mathcal{S}$, we can decide what embeddings are used in the target NLP task. To do this evaluation, users have to set the location of the word embeddings and the word analogy list. For more convenience to represent the compound words, we use " | " to separate different part of a word analogy record instead of space as in the English word analogy list. Figure 3 shows an example of two records in the word analogy in Vietnamese (on the left) and their translation (on the right). The lower part shows a command-line to evaluate multiple sets of word embeddings on this task. Regarding this *evaluator*, it is worth to note that with a huge number of possible linguistic relations (and different objectives, e.g., modeling syntactic vs. semantic properties), no embedding model is able to hold all related words close in the vector space. Therefore, only one testing schema (i.e., word analogy test) is not enough to evaluate multiple pre-trained embeddings. Thus, ETNLP is designed with the capability to be easily plugged in more tests, which makes *evaluator* more robust. However, in this paper, our experimental results showed that, word analogy task is sufficient to select good embeddings for the NER task in Vietnamese.

- **Visualizer:** to visualize given word embeddings in the argument "-input_embs" in both zoom-out (the side-by-side visualization) and zoom-in (the interactive visualization) manners. For the zoom-out, users type a word that they want to compare the similar words in different embedding models (see Figure 5). For the zoom-in, after the executions, embedding vectors are transformed to tensors to visualize with the Embedding Projector. Each word embedding will be set to different local port from which, users can explore the embedding space using a Web browser. Figure 6 shows an example of the interactive visualization of "Hà_Nội"$_{Hanoi}$ using ELMO embeddings. See Figure 4 for an example command-line.



```

Figure 4: Run *visualizer* to explore given pre-trained embedding models.

4 Evaluations: A Use-Case in Vietnamese

4.1 Training Word Embeddings

We trained embedding models detailed in Section 2 on the Wikipedia dump in Vietnamese[3]. We then apply sentence tokenization and word segmentation provided by VnCoreNLP (Vu et al., 2018a; Nguyen et al., 2018a) to pre-process all documents. It is noted that, for BERT model, we have to (1) format the data differently for the next sentence prediction task; and (2) use SentencePiece (Kudo and Richardson, 2018) to tokenize the data for learning the pre-trained embedding. It is worth

Table 1: Evaluation results of different word embeddings on the Word Analogy Task. P-value column shows significance test results using Paired *t*-tests. '*' means significant (p-value < 0.05) to the rest.

Figure 5: Side-by-side visualization for the word “heo $_{\textbf{pig}}$” with multiple embeddings. From this visualization, we get the sense that W2V_C2V, ELMO, and Bert_Base mainly capture the categorical information (i.e., “heo $_{\textbf{pig}}$” is surrounded by names of other animals, e.g., "bò $_{\textbf{cow}}$", "trâu $_{\textbf{buffalo}}$") while “FastText“ captures both categorical information (i.e., surrounded by names of other animals) and related verbs to “pig” such as “xào $_{\textbf{frying}}$”, “nướng $_{\textbf{grill}}$”. Bert_Large, on the other hand, does not converge well due to the short training steps mentioned in section 4, therefore, many irrelevant words (e.g., “cốc $_{\textbf{cup}}$”, “dịu $_{\textbf{floppy}}$”) are surrounded the input word “heo $_{\textbf{pig}}$”, “keo$_{\textbf{glue}}$”.

Table 2: Example of five types of semantic and four (out of nine) types of syntactic questions in the word analogy list. “NOT AVAILABLE“ means that the syntactic phenomena do not apply in Vietnamese in comparison to the list of Mikolov et al. (2013).

	Type of relationship	Word Pair 1	Word Pair 2
Semantic	capital-common-countries	Athens | Hy_Lạp $_{\text{Greek}}$	| Baghdad | Irac
	capital-world	Abuja | Nigeria	| Thổ Nhĩ Kỳ $_{\text{Turkey}}$ | Turkey
	currency	Algeria | dinar	| Canada | đô la $_{\text{dollar}}$
	city-in-zone	Hòa Bình $_{\text{Hoa Binh}}$ | Tây Bắc Bộ $_{\text{West North}}$	| Hà Giang $_{\text{Ha Giang}}$ | Đông Bắc Bộ $_{\text{East Northern}}$
	family	cậu bé $_{\text{boy}}$ | cô gái $_{\text{girl}}$	| anh trai $_{\text{brother}}$ | em gái $_{\text{sister}}$
Syntactic	gram1-adjective-to-adverb	NOT AVAILABLE	
	gram2-opposite	chấp nhận được $_{\text{acceptable}}$ | không thể chấp nhận $_{\text{unacceptable}}$	| nhận thức $_{\text{aware}}$ | không biết $_{\text{unaware}}$
	gram3-comparative	tệ $_{\text{bad}}$ | tệ hơn $_{\text{worse}}$	| lớn $_{\text{big}}$ | lớn hơn $_{\text{bigger}}$
	gram4-superlative	lớn $_{\text{big}}$ | lớn nhất $_{\text{biggest}}$	| sáng $_{\text{bright}}$ | sáng nhất $_{\text{brightest}}$
	gram5-present-participle	NOT AVAILABLE	
	gram6-nationality-adjective	Albania | Tiếng Albania $_{\text{Albanian}}$	| Argentina | Tiếng Argentina $_{\text{Argentinean}}$
	gram7-past-tense	NOT AVAILABLE	
	gram8-plural-nouns	NOT AVAILABLE	
	gram9-plural-verbs	NOT AVAILABLE	

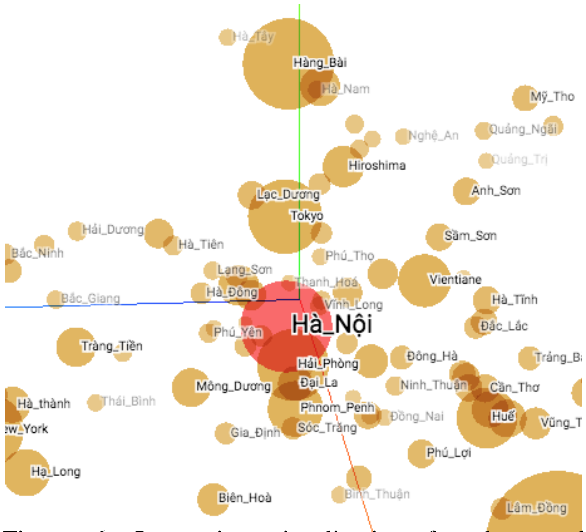

Figure 6: Interactive visualization for the word "Hà_Nội" with ELMO embeddings where near "Hà_Nội" are the names of many other cities in Vietnam (e.g., "Hải_Phòng$_{\textbf{Hai Phong}}$" as well as capital of other countries (e.g., Tokyo).

Table 3: Grid search for hyper-parameters.

Hyper-parameter	Search Space		
cemb dim (char embedding)	50	100	500
drpt (dropout rate)	0.3	0.5	0.7
lstm-s (LSTM size)	50	100	500
lrate (learning rate)	0.0005	0.001	0.005

noting that due to the limitation in computing resources, we can only run BERT_Base for 900,000 update steps and BERT_Large for 60,000 update steps. We, therefore, do not report the result of BERT_Large for a fair comparison. We also create *MULTI* embeddings by concatenating four sets of embeddings (i.e., W2V_C2V, fastText, ELMO and BERT_Base) [4].

4.2 Dataset

The named entity recognition (NER) shared task at the 2016 VLSP workshop provides a dataset of 16,861 manually annotated sentences for training and development, and a set of 2,831 manually annotated sentences for test, with four NER labels PER, LOC, ORG, and MISC. The data was published in 2016 and recently reported in Nguyen et al. (2019). It is a standard benchmark on the NER task and has been used in (Vu et al., 2018a; Dong and Nguyen, 2018). It is noted that, in the original dataset, each word representing a full personal name are separated into syllables that constitute the word. Because this annotation scheme results in an unrealistic scenario for a pipeline evaluation (Vu et al., 2018a), therefore, we tested on a "modified" VLSP 2016 corpus where we merge contiguous syllables constituting a full name to form a word. This similar setup was also used in (Vu et al., 2018a; Dong and Nguyen, 2018), the current state-of-the-art approaches.

4.3 Word Analogy Task

To measure the quality of different sets of embeddings in Vietnamese, similar to Mikolov et al. (2013), we define a word analogy list consisting of 9,802 word analogy records. To create the list, we selected suitable categories from the English word analogy list and then translated them to Vietnamese. We also added customized categories which are suitable for Vietnamese (e.g., cities and their zones in Vietnam). Different from (Mikolov et al., 2013), five categories: "Adjective to adverb", "Present Participle", "Past tense", "Plural nouns", "Plural verbs" were not used to be translated in Vietnamese since the same syntactic phenomena does not exist in Vietnamese. Table 2 shows the list of categories and their examples of the constructed word analogy list in Vietnamese. Since most of this process is automatically done, it can be applied easily to other languages. To know which set of word embeddings potentially works better for a target downstream task, we limit the vocabulary of the embeddings similar to vocabulary of the task (i.e., the NER task). Thus, only 3,135 word analogy records are being evaluated for the NER dataset (Section 4.2).

Regarding the evaluation metric, Mikolov et al. (2013) used accuracy metric to measure the quality of word embeddings on the task in which only when the expected word is on top of the prediction list, then the model gets +1 for true positive count. However, this is not a well-suited metric in low resource languages where training corpus is relatively small, i.e., 233M tokens in Vietnamese Wiki compared to 6B tokens in Google News corpus. Therefore, we change to use mean average precision (MAP) metric to measure quality of the word analogy task. MAP is widely used in information retrieval to evaluate results based on the top$K$ returned results (Vu et al., 2019). We use MAP@10 in this paper. Table 1 shows evaluation results of different sets of embeddings on the word analogy task. The *evaluator* of ETNLP also shows P-value using the paired t-tests on the raw

[4] We do not use W2V here because W2V_C2V is W2V with the use of character embedding to deal with OOV.

Table 4: Performance of the NER task using different embedding models. The $MULTI_{WC\_F\_E\_B}$ is the concatenation of four embeddings: W2V_C2V, fastText, ELMO, and Bert_Base. “wemb dim” is the dimension of the embedding model. VnCoreNLP* means we retrain the VnCoreNLP with our pre-trained embeddings.

	F1	wemb dim	cemb dim	drpt	lstm-s	lrate
BiLC3 (Ma and Hovy, 2016)	88.28	300	-	-	-	-
VNER (Dong and Nguyen, 2018)	89.58	300	300	0.6	-	0.001
VnCoreNLP (Vu et al., 2018a)	88.55	300	-	-	-	-
VnCoreNLP (*)	**91.30**	1024	-	-	-	-
BiLC3 + W2V	*89.01*	300	50	0.5	100	0.0005
BiLC3 + BERT-Base	*88.26*	768	500	0.3	100	0.0005
BiLC3 + W2V_C2V	*89.46*	300	100	0.5	500	0.0005
BiLC3 + fastText	89.65	300	500	0.3	100	0.001
BiLC3 + ELMO	89.67	1024	100	0.7	500	0.0005
BiLC3 + $MULTI_{WC\_F\_E\_B}$	**91.09**	2392	100	0.7	100	0.001

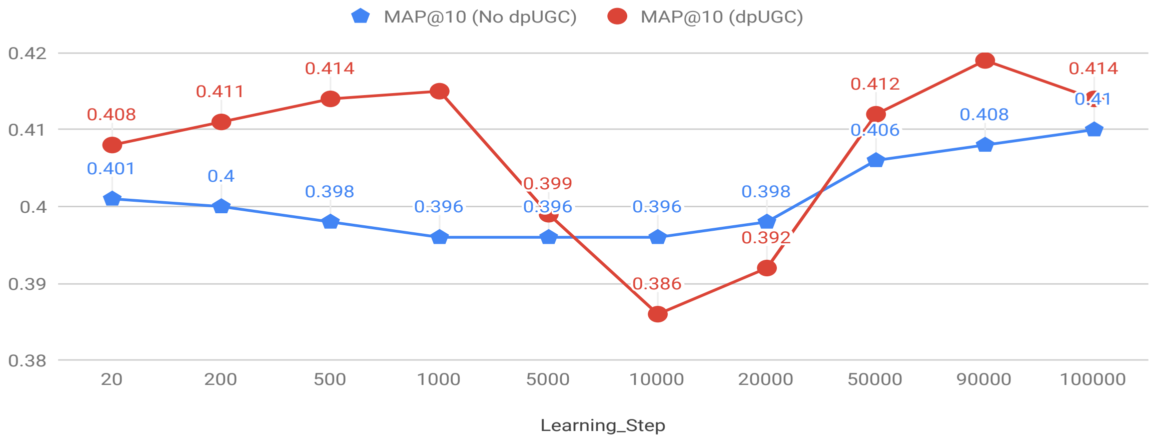

Figure 7: Evaluation results of different word embeddings trained using **dpUGC** and **No dpUGC** (i.e., one option in dpUGC to train embeddings without privacy guarantee for comparison) on the Word Analogy Task.

MAP@10 scores (i.e., before averaging) between different sets of embeddings. The P-values (Table 1) show that the performances of the top three sets of word embeddings (i.e., fastText, ELMO, and MULTI), are significantly better than the remainders but there is no significant difference between the three. Therefore, these sets of embeddings will be selected for NER task.

4.4 NER Task

Model: We apply the current most well-known neural network architecture for NER task of Ma and Hovy (2016) with no modification in its architecture, namely, *BiLSTM-CRF+CNN-char (BiLC3)*. Only in the embedding layer, a different set of word embeddings is used to evaluate their effectiveness. Regarding experiments, we perform a grid search for hyper-parameters and select the best parameters on the validation set to run on the test set. Table 3 presents the value ranges we used to search for the best hyper-parameters. We also follow the same setting as in (Vu et al., 2018a) to use the *last* 2000 records in the training data as the validation set. Moreover, due to the availability of the VnCoreNLP code, we also retrain their model with our pre-trained embeddings (*VnCoreNLP**).

Main Results: Table 4 shows the results of NER task using different word embeddings. It clearly shows that, by using the pre-trained embeddings on Vietnamese Wikipedia data, we can achieve the new state-of-the-art results on the task. The reason might be that FastText, ELMO and MULTI can handle OOV words as well as capture better the context of the words. Moreover, learning the embeddings from a formal dataset like Wikipedia is beneficial for the NER task. This also verified the fact that using our pre-trained embeddings on VnCoreNLP helps significantly boost its performance. Table 4 also shows the F1 scores of W2V, W2V_C2V and BERT_Base embeddings which are worse than three *selected* embeddings

Table 5: P-values of the paired t-tests between embeddings obtained using dpUGC at different learning step (Emb@L). "-" denotes values of these entries in the upper triangular matrix are the values of the transposed entries in the lower triangular matrix. P-values in **bold font** are statistical significance at the level of 0.05.

Emb@L	20	200	500	1000	5000	10000	20000	50000	90K	100K
20	1	-	-	-	-	-	-	-	-	-
200	0.0578	1	-	-	-	-	-	-	-	-
500	**0.0074**	0.1809	1	-	-	-	-	-	-	-
1000	**0.0053**	0.169	0.9031	1	-	-	-	-	-	-
5000	**0.0178**	**0.0009**	6.992	1.6242	1	-	-	-	-	-
10000	2.543	6.9872	2.25867	9.3987	**0.001**	1	-	-	-	-
20000	**0.0016**	**0.0001**	1.757	9.6053	0.112	0.1819	1	-	-	-
50000	0.5077	0.9023	0.73137	0.7003	**0.031**	5.0673	**0.0001**	1	-	-
90K	0.1205	0.2878	0.5127	0.5323	**0.0049**	2.4211	**0.0001**	0.2688	1	-
100K	0.3777	0.6822	0.9932	0.9764	**0.0357**	8.2638	**0.0019**	0.7274	0.2758	1

(i.e., fastText, ELMO and MULTI). This might indicate that using word analogy to select embeddings for downstream NLP tasks is sensible.

4.5 Privacy-Guaranteed Embedding Selection Task

In this section, we show how to apply ETNLP to another downstream task of privacy-guaranteed embedding selection. Vu et al. (2019) introduced dpUGC to guarantee privacy for word embeddings. The main intuition behind dpUGC is that, when the embedding is trained on very sensitive text corpus (e.g., medical text data), it has to guarantee privacy at the highest level to prevent privacy leakage. However, among many embeddings at different learning steps of dpUGC, how to choose a suitable embedding to achieve a good trade-off between data privacy and data utility is a key challenge. To this end, we propose to apply ETNLP into this scenario to select good embeddings for knowledge sharing using dpUGC.

Similar to Vu et al. (2019), we trained 20 different embeddings from 10 different learning steps while training on the same Vietnamese Wikipedia dataset as used in Section 4.1 with (dpUGC) and without privacy-guarantee (No dpUGC) to evaluate their performances. Figure 7 shows that the pre-trained embedding at learning_step 1000 (Emb@1000) seems to be a good word embedding candidate to have a good trade-off between privacy guarantee and data utility. Emb@1000 was in favor because of two reasons. Firstly, in training privacy-guaranteed embeddings, we try to stop as early as possible since the more training steps we run, the higher privacy we have to sacrifice (Vu et al., 2019). Secondly, its performance in the Word Analogy Task was more or less similar to the other good embedding at the learning step 90K (i.e., Emb@90K). In fact, from Table 5 we know that the performance between Emb@1000 and Emb@90K learning steps are not significant difference. Therefore, selecting the pre-trained embedding at the learning step 1000 is the best option for privacy-guaranteed embedding using dpUGC. In summary, in this task, we showed how ETNLP can be used to select a good word embedding candidate for privacy-guaranteed knowledge sharing. Normally, this selection process is very time consuming, however, it is much easier with ETNLP since it allows users to import multiple embeddings for running evaluations.

5 Conclusions

We have presented a new systematic pipeline, ETNLP, for extracting, evaluating and visualizing multiple pre-trained embeddings on a specific downstream task. The ETNLP pipeline was designed with three principles in mind: (1) easy to apply on any language processing task, (2) better performance, and (3) be able to handle unknown vocabulary in real-world data (i.e., using C2V (char to vec)). The evaluation of the approach in (1) Vietnamese NER task and (2) privacy-guaranteed embedding selection task showed its effectiveness.

In the future, we plan to support more embeddings in different languages, especially in low resource languages. We will also support new ways to explore the embedding spaces including at phrase and subword levels.

Abstract

In this paper we present a morpho-syntactic tagger dedicated to Computer-mediated Communication texts in Polish. Its construction is based on an expanded RNN-based neural network adapted to the work on noisy texts. Among several techniques, the tagger utilises fastText embedding vectors, sequential character embedding vectors, and Brown clustering for the coarse-grained representation of sentence structures. In addition a set of manually written rules was proposed for post-processing. The system was trained to disambiguate descriptions of words in relation to Parts of Speech tags together with the full morphological information in terms of values for the different grammatical categories. We present also evaluation of several model variants on the gold standard annotated CMC data, comparison to the state-of-the-art taggers for Polish and error analysis. The proposed tagger shows significantly better results in this domain and demonstrates the viability of adaptation.

1 Introduction

Morpho-syntactic disambiguation (called also morpho-syntactic tagging) is an important pre-processing step in many text processing pipelines (e.g. terminology and information extraction), especially in the case of highly inflected languages where tagging is tightly correlated with lemmatisation. Work on the development of programs for morpho-syntactic disambiguaters, henceforth *taggers*, has been concentrated on texts written in the standard language, i.e. containing only small percentage free of jargon, extra-linguistic elements like codes or symbols, etc. Computer-mediated communication (CMC) texts, especially texts from different kinds of social media, are written in language that often is significantly different from the standard language, see Sec. 3. While in the case of texts in a standard language, a state-of-the-art tagger reaches near 95% of accuracy in disambiguation, taggers for CMC texts express much lower accuracy. Moreover, much fewer works are devoted to tagging CMC texts than text of the standard language, while the problem of processing CMC texts is continuously growing in importance and numbers of applications. Thus, the fast growth of social media requires appropriate adaptation, or even expansion, of the tagging methods, to serve growing interest and requirements in the processing of texts of such kinds. According to our best knowledge, a morpho-syntactic tagger dedicated to CMC texts in the Polish language has not been yet developed or at least made publicly available. The goal of this work is a far going adaptation of a tagger for the standard Polish to the demands of CMC texts in Polish.

In the rest of the paper, first solutions for tagging the standard Polish language and CMC texts in general are discussed. Next, we analyse characteristic features of CMC texts on the basis of a collected CMC corpus. A tagger model is proposed. Finally, we presented evaluation of the tagger and discuss perspectives for its further development.

2 Related Works

The construction of our CMC tagger has been inspired by a tagger for the Polish language that won the PolEval competition (Kobyliński and Ogrodniczuk, 2017) in 2017 that is called *Toygger* (Krasnowska-Kieraś, 2017). *Toygger* is based on a recursive neural network – a bidirectional LSTM. Recursive layers extract features based on an input

Proceedings of Recent Advances in Natural Language Processing, pages 1295–1303,
Varna, Bulgaria, Sep 2–4 2019.

vector encoding morphological information and including embedded vectors. The extracted features are next transferred to separated non-linear layers, where each represents a different part of the morpho-syntactic tag. In Sec. 4 we propose several expansions to this model which are aimed at providing better handling of noisy texts. Aside from Toygger, another tagger – *KRNNT* (Wróbel, 2017), also based on a bidirectional LSTM network, achieved very good results in the PolEval contest. The main difference between these two is in the encoding of the input text and features generated for it. Toygger uses text encoded as a sequence of embedding vectors in combination with information from the morphological analysis performed with the morpho-syntactic analyser *Morfeusz2* (Kieraś and Woliński, 2017), and KRNNT uses information from the morphological analysis from Maca (Radziszewski and Śniatowski, 2011) (that is also employing *Morfeusz* inside) in combination with predetermined features based on a set of features from the *Concraft* (Waszczuk, 2012) tool.

In a similar way, complex systems such as dependency parser *COMBO* (Rybak and Wróblewska, 2018), in their internal taggers began to use LSTM networks with similar architecture to the stand-alone taggers mentioned above. Inside the COMBO system the tagger component obtains the features extracted from a bidirectional LSTM layer and passes them through a fully connected network with one hidden layer with a softmax activation function. That network predicts a universal part-of-speech tag and a tagset specific tag (for instance a grammatical class in the case of a tagset for Polish). The morphological features have similar networks for each feature type.

Apart from the systems created for the Polish language, several solutions were proposed for other Slavic languages or even highly inflected languages in general. The winning solution of the competition organised at the VarDial 2018 conference (Zampieri et al., 2018) was a system based on a bidirectional LSTM network, which instead of classifying words with morpho-syntactic tags generates the tags in a character per character way and uses a different type of a recursive network (Silfverberg and Drobac, 2018) for this purpose. The way the network is trained ensures that a tag that has never occurred in the training data is not generated. Such a manner of getting replies from networks allows also words, which are concatenated together from several morphemes, to have a 'multi-part' tag, i.e. a cluster of several tags *per se*. This solution was inspired by the Sequence-to-Sequence architecture. It also shows the positive effect of combining embedding vectors for words and characters, which is confirmed by other works from this genre, such as (Plank et al., 2016). Another work in this field is (Ljubešić, 2018), which compares a tagger model based on Conditional Random Fields with a model based on a recursive neural network in disambiguation of Slovene, Serbian and Croatian CMC texts. The differences between the two models are small (about 0.02), which leads to the conclusion that both methods are worth considering in further research. However, a comparative study in (Östling, 2018) shows that better results are achieved with good manual processing of features than with extending and deepening the architecture.

Apart from CRF-based models, the other methods presented here do not pay attention to both sides of the context. Using a bidirectional LSTM layers does bring information about the context, but only before the word (or after the word when looking from the other direction) and the method of combining the results of these two directions does not guarantee focusing on both sides of context in the same degree. Therefore, our solution proposes to add to the network information about the context from the Brown clustering algorithm. Here, we were inspired by another work about tagger adaptation (Ljubešić et al., 2017).

3 Computer-Mediated Communication Corpus

Computer-mediated communication (CMC) texts are part of user-generated content (UGC) data. Due to the nature of this kind of data, the texts commonly include many mistakes and problematic phenomena. A linguistic analysis of the data as well as the results of similar research (see e.g (Pluwak et al., 2016)) helped us to define distinctive features, which are related to various text levels such as: notation (e.g. lack of diacritics, spelling mistakes, typos, omissions of capital letters, incorrectly connected or disconnected segments, lack of or poor punctuation), morphology and syntax (e.g. incorrect word endings, token repetition, lack of phrase elements), or lexical issues (e.g. emojis and special characters, internet slang, characters replacements, abbreviated forms, URL addresses, hashtags, mentions). Most of these phenomena require specific solutions in annotation guidelines. Since the available data in Polish is based on the sources of a different nature – they are mostly edited and officially published texts (Przepiórkowski et al., 2012) – there was a need to create a CMC corpus manually annotated with morphological information.

The *Corpus of the Colloquial Polish Language*[1] (CCPL) used in all experiments presented in this paper consists of 7,561 documents (402,810 tokens). All the source texts were posted by users on online social media platforms, so they have the characteristics of user-generated content (UGC). The texts include opinions, tweets, comments, social media posts and chat utterances.

The whole corpus was manually annotated with morphological information and next morphosyntactically disambiguated by the team of professional linguists from the Wrocław University of Science and Technology. The inter-annotator agreement for various pairs of annotators was calculated. The results ranged from 0.91 to 0.97.

4 Tagger Model

4.1 Data and Preprocessing

National Corpus of Polish (NCP) as the basic training data, and only in some experiments we expanded the training data with annotated texts from social media coming from CCPL, see Section 5. This subcorpus of NCP contains a bit above 1.2 million of manually annotated and disambiguated tokens from different sources. It is commonly used as training-testing data set for a tagging task in Polish language. For the test data set we used CCPL, which is described in Section 5.1.

We have decided not to apply text normalisation before tagging process in order to save as much information as possible from the text structure which can be helpful in next stages of processing like sentiment recognition. Many of the methods proposed in literature are based on a process: normalisation followed by tagger application. Thus, a comparison of our solution with them is difficult, as the text tagged is different. Therefore we do not handle segmentation problems in our tagging system. To deal with typos and lack of diacritics we focus on character representation together with suffix representation and choose to use the *fastText* embedding (Bojanowski et al., 2017), because it is based on the n-gram based subword word representation. In addition, we obtained cluster information to get better representation of contexts for similar words. We applied the Brown Clustering algorithm (Brown et al., 1992) to group words on the basis of the one million subcorpus of NCP (Przepiórkowski et al., 2012) (this is the same data set which is used as training data). The Brown Clustering is a method of hierarchical clustering of words based on their contexts. We assumed that words belonging to the same clusters have the same probability of the contextual occurrence under the condition of the occurrence of preceding and following words. In principle, we want to achieve good results in spite of processing noisy textual data, due to the knowledge of their structure on the coarse-grained description level based on Brown clusters of words. We assume that such representation helps to determine to which group of words an unknown or broken word may belong to. Other elements of CMC texts are emoticons, URL and e-mail addresses, hashtags and user mentions. We handle these cases with handwritten rules.

In several experiments, see Section 5, the evaluation of the whole tagging process was performed on the entire CCPL corpus, because it was not involved in training in those cases.

4.2 Input Text Representation

In order to improve the tagger ability to generalise over the training data, we used a representation based on distributional vector models. An input vector for a word from the processed sentence is constructed as a concatenation of several subvectors representing different properties of a word:

1. a morphological information vector,
2. a suffix character embedding vector,
3. a suffix index in the set of known suffixes,
4. a suffix embedding vector,
5. a word embedding vector from a *fastText*-based model,
6. a whole word character embedding,
7. a Brown cluster embedding vector.

The morphological information vector expresses jointly information collected from all tags

[1] http://hdl.handle.net/11321/637

that are possible for a given token according to the morphological analysis (in the case of unknown words, the full vector is set). Sets of possible tags are represented as a sequence of bits: every single bit of each vector represents a possible grammatical class or a value of some grammatical category (an attribute), e.g. case, number gender etc. For instance for the Polish word *jedzenie* 'food' we obtain a vector with two bits set for the two grammatical classes: *noun* (*jedzenie* as 'food') and *gerund* (*jedzenie* 'eating'), bits for the *nominal* and *accusative* genders, one bit for the *singular* number, one for the *m3* gender etc. The morphological vector is intended to be a kind of regularisation constraining the tagging process and to make the tagger decisions compatible with the morphological analyser.

The suffix character embedding vector – the part 2 – is trained during the time of learning by using an additional small (64 hidden units) biLSTM network to represent suffixes as character sequences. In all experiments, we set the size of a suffix to 3, based on the results published in the (Krasnowska-Kieraś, 2017) (who tested experimentally 4 and 5, too) and our previous experiments. This vector is aimed at recognition of different suffixes (carrying important morphological information) and their similarity.

The suffix index (3) and suffix embedding vector (4) represent also suffixes, but on the level of suffixes as tokens, not sequences of characters. Concerning the former, a set of known suffixes is first extracted from the learning data. Next each recognised suffix is represented by its index during training and testing. In the case of the latter, for suffixes as tokens their vector embeddings are trained during learning the sequential tagging task. During testing and application for each known suffix its embedding vector representation is searched for in the look-up table layer. By introducing these two components we want to emphasise the presences of more frequent suffixes that often express more specific morpho-syntactic information.

The fifth part is a word embedding vector for the whole token obtained from *fastText* model. We use a *fastText* model for Polish that was trained on a very large corpus of Polish (Kocoń, 2018). This vector introduced lexical element to the representation, but due to the nature of the distributional model, words of similar distribution receive similar vectors. Moreover, *fastText* (a subword distributional model) assigns also vectors to unknown words on the basis of n-gram structure.

The sixth part is a character embedding for whole words. Similar to suffix character embedding in part 2, it is learned during the training the whole tagger and has similar architecture. The most significant difference is that it takes whole words at the input, not just suffixes.

The last component (7) is an embedding vector for the Brown cluster of the given word. In a similar way to the suffix embedding vector, vector embeddings for Brown clusters are trained during learning the tagger. If the word does not appear in any cluster, it receives a cluster index for Out of Vocabulary (OOV) words. During testing and application the vectors are read from the look-up table layer. Brown clusters offer a coarse-grained representation of the input sequence that helps to analyse OOV words.

4.3 Network and Processing

The core part of the tagger is a deep neural network. The input vector is a sequence of the combined word vectors. It is sent to two bidirectional LSTM layers with 512 hidden units each. 50% dropout is applied to both LSTM layers. The goal of these layers is to calculate features for each word of the input sentence. Next, these features are used to feed down separated layers. These separated layers are *softmax layers*. The first one is dedicated to the grammatical class and the rest (13) to the 13 different grammatical categories (morphological attributes). The whole network is trained with the help of the *RMSprop optimizer* (Tieleman and Hinton, 2012) and the *Categorical Cross Entropy loss function*.

Due to the variability of CMC texts the main processing by the neural network is supplemented by deterministic post-processing which is performed in three steps:

1. verification of the correctness of a predicted tag,
2. final tag selection,
3. rule-based error detection and correction.

Concerning the first, the correctness of the predicted tag is checked in relation to the set of all possible tags proposed by the morphological analysis. Checking correctness of predicted tag is simple task. On the basis of the predicted grammatical class we verify if the attributes obtain values

number	accuracy
No clusters	85.21%
500	85.46%
750	85.44%
1000	85.44%
1250	85.31%
1500	85.23%
1750	**85.48**%
2000	85.36%

Table 1: Influence of the number of clusters on the tagger strict accuracy.

specified for this grammatical class. In the case of the lack of a tag exactly matching the predicted one among the tags obtained from the morphological analysis, for the final tag selection, we choose a tag that is in the minimal Levenshtein distance of its form to the form of the predicted tag, i.e. the predicted tags are somehow mapped onto tags available from the morphological analysis (in the case of out-of-vocabulary words the full set of tags is assumed as the result of the morphological analysis).

In order to improve an automatic tagging process, we developed and applied several rules. They specify morphological interpretations for selected words directly encountered in text. This concerns, in particular, emojis or internet addresses. In some cases a rule covers only the first characters which serve to identify the relevant word form, e.g. it was not possible to list all URL addresses but the rule using the expression [*if 'https://' in w*] could be applied to all word forms that begin with *https://*).

A morphological interpretation for several word forms (or types of word forms) were assigned irrespective of the interpretation automatically predicted by the tagger. An example of such a general rule is given below:

$if\,'https://'\,in\,w\,or\,'http://'\,in\,w:$

$corrected\_tag =' subst:sg:nom:m3'$

The results of the first attempt to error analysis were the basis for drawing up also specific rules for the word forms tagged initially with specific morphological information, e.g.

$if\ (w\ ==\ 'jak'\ or\ w\ ==\ 'tak')$

$and\ predicted\_tag\ ==\ 'adv:pos':$

$corrected\_tag\ =\ 'adv'$

settings	accuracy
SCE(128) + SE(64)	86.09%
SCE(128) + SE(64) + CLE(64)	*87.06%*
SCE(128) + SE(64) + CLE(64) + R	**87.87**%
CE(128) + SE(64) + CLE(64) + R	87.39%
CE(128) + SCE(128) + CLE(64) + R	87.67%

5 Evaluation

5.1 Experiments

In our research, we focused on two main aspects

- determining the best number of Brown clusters,
- and selecting the best possible configuration of the input vector components.

In all experiments the input vector included the components representing the morphological analyses and the *fastText* based representation of words. The *fastText* component vector size was fixed to 300 elements.

First, we performed tests to find the best number of the Brown clusters. The results of these experiments are shown in Table 1. The performance of the tagger is measured in the *strict accuracy*, i.e. only the assigned tags that completely, in relation to all its components, match the tag from the manual annotation are treated as correct solutions. The results show that the addition of clustering, regardless of its size, improves the tagging accuracy. Finally, we set the number of clusters to 1,750 in accordance with the best result obtained during the first experiments.

Next, we performed several experiments that were aimed at investigating the influence of the different joint vector components on the tagger accuracy. The results of the most important ones are presented in Table 2 where the shortcuts mean:

SCE – suffix characters embedding,

SE – suffix embedding,

CE – character embedding,

CLE – clustering embedding,

R – postprocessing rules.

The numbers in the round brackets remind about the size of the given vector component. In Table 2 the performance of the tagger is measured, like above, in the *strict accuracy*. The results show that suffix characters embedding brings the most benefits. This is consistent with the intuition, that in the case of words that are blured by noise inside them and OOV words their suffix can tell us most about their morphology. Also, adding rule-based post-processing to the tagger output increased its final accuracy.

On the basis of the experiments, for the final version of the system we chose the input vector consisting of the following components: morphological information, suffix characters embedding, suffix embedding, fastText embedding and clustering embedding for 1,750 clusters.

After selecting the network architecture parameters, we made an additional experiment. Using cross-validation we conducted a test during which we trained the tagger on the two combined data sets, namely: the manually annotated part of NCP and a subset of the manually annotated part of CCPL (i.e. the training folds). The manually annotated CCPL subcorpus was divided into five parts further on referred to as *folds*. The sub-models during the cross-validation process were trained on an NCP with four folds from CCPL and the sub-model was tested on the fifth fold from CCPL. Our tagger tested in this way achieved an average accuracy of 90.14%.

Finally, we compared the version of our CMC Tagger trained on the combined NCP and four folds of CCPL with the two taggers for Polish treated as a baseline, namely:

- *MorphoDiTa-pl* (Piasecki and Walentynowicz, 2017) is accessible at `http://ws.clarin-pl.eu/tager.shtml` and its source code at `https://github.com/ufal/morphodita`.

- *Toygger*, already mentioned, originally trained on NCP with *word2vec* embedding and suffix information feature, with 20 epochs.

The results of the tests done on the folds of CCPL are presented in Table 3.

Tagger	Accuracy (strong)
CMC Tagger	**90.14%**
MorphoDiTa	81.32%
Toygger	86.12%

Table 3: Strong accuracy (identical morphosyntactic class and values of grammatical categories) measured on CCPL corpus.

5.2 Results

We performed detailed linguistic error analysis. It covered the word forms differently tagged by human annotator and morphological tagger. 600 word forms most frequently judged inconsistently (3,675 error instances) were analysed. Among them several error types can be distinguished that mainly correspond to grammatical categories incorrectly recognised and every tuple (word form – human annotator tag – automatically ascribed tag) was assigned to one of the categories presented in Table 4.

The most common error concerned grammatical class. The most frequently confused classes are: adverb – particle-adverb (174 of 3,675 error instances) and coordinating conjunction – particle-adverb (90 instances). The word that appeared to be most difficult to judge was *to* (‘this’, ‘then’, ‘to be’, adverb) (263 error instances), which could be interpreted as adjective, predicative, noun, particle-adverb or subordinating conjunction depending on the context. Tagger had also problems with emojis correct recognition (177 instances).

Generally, the issues described above concern parts of speech that are very often the source of confusion for human annotators. Furthermore, the distribution of tagger errors is very similar to the observed distribution of inconsistencies in manual CCPL tagging. This shows that the mistakes are related to the difficult cases in general. A few use cases from the test dataset are presented below.

In the original, the fragment of sentence looks as follows:
“*[...] a mu sie nie spodoba i po wezystkm.*”
Correctly (without typing errors) this sentence would look like this:
“*[...] a mu się nie spodoba i po wszystkim.*”
(English: “*and he will not like it, and this is all.*”).

The CMC Tagger output for this sentence is shown in Table 5. Our tagger for the word *sie* (reciprocal participle *się* but written without diacritics) wrongly chose adjective as the grammatical class. This problem originated from the morphological analysis. Word form *sie* exists in the dictionary and the tagger could not recognise it

object of inconsistency	percent
number of assigned categories	4.71%
base	6.80%
grammatical class	31.16%
case	14.45%
number	2.29%
gender	22.42%
rection	4.60%
person	1.41%
aspect	0.33%
human error	9.31%
other	2.53%

as a corrupted form of *się*, which is a reflexive pronoun or reciprocal participle (an component of a compound verb). The form *wezystkm* (i.e. in its proper form: *wszystkim* 'everything'/'all of them(case:dative)') is an unknown (OOV) word for the morphological analyser, but our tagger made only a small mistake in the gender attribute – it should be neutral.

In the case of a sentence that is grammatically constructed correctly, like the one in Table 6, our tagger works quite well. This sentence in English looks as follows: "In crediting the car purchase all went very smoothly and quite decent repayments.".

Form	Tag

6 Conclusions

We presented that standard approaches to morpho-syntactic disambiguation must be adapted to specific domains of non-standard texts, like CMC and User Generated Content texts, e.g. including social media texts. Thus, we proposed significant expansions to the state-of-the-art tagger for Polish, namely *Toygger*, that resulted in large gain in performance in CMC texts, as measured on the manually annotated gold standard for this domain. In the proposed expansions we focused on the representation and appropriate encoding in the input vector the information about: suffix types, better word embedding models (i.e. taking into account the sub-word level) and word clusters generated on the basis of standard text, but enabling coarse-grained text representation.

In future we want to focus on improving the usage of the morpho-syntactic information, e.g. in a form of partial recognition of possible dependencies. We plan to expand morphological vectors with the representation of the manually written constraints. We also want to work on semi-automatic extraction of contextual post-processing rules for improvement of the tagger performance. At the same time we want research how to expand representation of words on character level to get better recognition of noisy elements in text. An important challenge is handling of the segmentation in a correct way or applying a more advanced normalisation process before tagging. The tagger is available on the open licence from: http://hdl.handle.net/11321/634.

Abstract

The paper presents an evaluation of word embedding models in clustering of texts in the Polish language. Authors verified six different embedding models, starting from widely used word2vec, across fastText with character n-grams embedding, to deep learning-based ELMo and BERT. Moreover, four standardisation methods, three distance measures and four clustering methods were evaluated. The analysis was performed on two corpora of texts in Polish classified into subjects. The Adjusted Mutual Information (AMI) metric was used to verify the quality of clustering results. The performed experiments show that Skipgram models with n-grams character embedding, built on KGR10 corpus and provided by Clarin-PL, outperforms other publicly available models for Polish. Moreover, presented results suggest that Yeo–Johnson transformation for document vectors standardisation and Agglomerative Clustering with a cosine distance should be used for grouping of text documents.

1 Introduction

A number of digital repositories of texts enlarge each year. The variety of tools for natural language processing and the quality of their performance are growing steadily. That opens possibilities for automatic categorisation of text documents in terms of the subject areas in any digital collection of documents. It is also an important problem for researchers from different areas of the humanities and social science (Eder et al., 2017).

Commonly used methods rely on representing documents with feature vectors and using clustering algorithm (Hastie et al., 2009) to assign documents to some groups. The classical feature vectors are based on the bag-of-words technique (Harris, 1954). Components of these vectors represent frequencies (weighted) of occurrences of words/terms in individual documents. The contemporary state-of-the-art technique is word2vec (Le and Mikolov, 2014), where individual words are represented by high-dimensional feature vectors trained on large text corpora. This technique is constantly being improved. This is demonstrated by the most recent propositions of algorithms like ELMo (Peters et al., 2018) or BERT (Devlin et al., 2018). Choosing the most useful clustering algorithm is not a trivial task since there is a large number of them. Just to mention the most popular ones like K-means (K.Jain, 2009), Agglomerative Hierarchical Clustering (Day and Edelsbrunner, 1984) and Spectral Clustering (Ng et al., 2002). Moreover, the results of clustering are strongly dependent on the chosen distance measure and the used method of an input data standardisation. The entire workflow, described above, expresses many factors which can influence results of the text exploration. It is difficult to control them and thus, might lead to unpredictable outcomes of the experiment. It becomes challenging for texts in an inflected language such as Polish.

The main aim of this research is the evaluation of clustering accuracy on documents in Polish, using publicly available word embedding models. We conducted our experiments to answer the following research questions: What is the best method (i.e. the word2vec model, standardisation method, distance metric and clustering algorithm) for subject grouping texts in Polish? The experiments were performed on two corpora with texts assigned to subject groups. We analysed the quality of results (defined by AMI metric (Romano et al., 2016)) in a function of method options.

Proceedings of Recent Advances in Natural Language Processing, pages 1304–1311,
Varna, Bulgaria, Sep 2–4 2019.

Some works studied the quality of word2vec models for Polish (Piasecki et al., 2018; Mykowiecka et al., 2017; Kocon and Gawor, 2019), but they focus on single words, not on an application of the word embeddings to represent whole documents for a clustering purpose.

The paper is structured as follows. In Section 2, we describe in details word embedding techniques and list the models examined in the work. Next, we provide technicalities about the methods we compared and finally in Section 4 we present test corpora used in the study as well as results of the comparative study.

2 Word Embeddings

2.1 Techniques of Word Embedding

Word embedding is an approach of text analysis based on the assumption that individual words can be represented by high-dimensional feature vectors. It is based on the hypothesis that relationships (distances) between vector representations of words can be related to semantic similarities of words. The models are built on large text corpora by observing co-occurrence of words in similar contexts. One of the most popular technique, *word2vec*, is based on neural networks (Le and Mikolov, 2014). The authors proposed two approaches: CBOW and Skipgram. In the first one, the aim is to predict a word based on context words. The Skipgram model does the opposite task, it predicts context words from a given word. In the classical word2vec (Le and Mikolov, 2014) technique each word (form from the text) is represented by a distinct vector, which might be a problem for a language with large vocabularies and rich inflexion like Polish is. The first solution to this problem was to build models based on word lemmas (Mykowiecka et al., 2017), however, such a technique requires a morphological analysis of all texts in a training corpus. Next, in (Bojanowski et al., 2017) authors extend the Skipgram model by building a vector representation of character n-grams and constructing the word representation as the sum of the character n-grams embeddings (for n-grams appearing in the word). It could decree the model size and allows to generate word embedding for words not seen in a training corpus.

The next step forward was introducing (Grave et al., 2018) the extension of the original CBOW model (Le and Mikolov, 2014) with position weights and subword information (character n-grams).

The newest approaches are inspired by deep-learning algorithms. In a recently introduced ELMo (Peters et al., 2018), word embeddings are defined by the internal states of a deep bidirectional LTSM language model (biLSTM), which is trained on a large text corpus. What is important, ELMo looks at the whole sentence before assigning an embedding to each word in it. Therefore, the embeddings are sentence aware and could solve a problem of polysemous words (words with multiple meanings). Another approach similar to ELMo is BERT (Devlin et al., 2018). It is also a bidirectional representation, but it is jointly built on both the left and the right context. The available BERT models[1] are multilingual and pre-trained on two unsupervised tasks: masked language modelling and next sentence prediction.

Word embeddings can be simply used to generate feature vectors for document clustering by averaging vector representations of individual words occurring in a document. This approach is known as *doc2vec* and used for example in fastText (Joulin et al., 2017) algorithm. In the case of BERT, we get sentence embeddings, but the approach used for word models can be repeated here as well (as an average of sentence embeddings).

2.2 Available Models for Polish

There are two groups working on publicly available word embedding models for Polish: IPI PAN[2] and Clarin-PL[3]. The IPI PAN provides[4] a set of more than 100 CBOW and Skipgram models generated from data consisting of National Corpus of Polish (NKJP) (Przepiorkowski et al., 2012) and Wikipedia (Wiki). Some of them are generated only for lemmas, others of words from texts (forms). For tests we have selected the Skipgram model (i.e. *nkjp+wiki-forms-all-300-skipg-hs-50*). The model was generated by gensim tool[5]. It assigns a distinct vector to each word.

The Clarin-PL provides[6] 16 models generated by fastText software[7] on larger than in a previous case corpus (Kocon and Gawor, 2019). They are joint models of words and character n-grams

[7] https://fasttext.cc/

able to produce vectors for unknown words (Bojanowski et al., 2017). For tests, we have selected two Skipgram models based on forms (*KGR10*) and lemmas (*KGR10_lemma*). The second group of sources of word2vec models for Polish are web pages of word embedding tools like fastText, ELMo and BERT. They were trained on Polish Common Crawl and Wikipedia. However, the BERT model was trained on many languages in parallel. The details on used models are summarised in Table 1.

3 Methods

3.1 Metrics and Clustering

A distance measure needs to distinguish contrasting samples. Sometimes that contrast is well defined, and we know what kind of behaviour we require from the chosen function. In natural language processing commonly used function is a cosine distance as i.e. it does not distinguish documents, described as a vector of most frequently occurred words in the corpus, that have a linear dependence between features. It also works well with sparse high-dimensional space and is less *noisy* than euclidean (Kriegel H-P., 2012). Models we want to compare have different properties, so relevant distance function is even less obvious. In our work we decided to focus on *cosine*, *Bray–Curtis* and *Euclidean distance*.

We also tried few different variations of them but the results were not significantly different.

In order to group data, we decided to use following methods (mind that two of them use only Euclidean distance or L_k norm in general, because otherwise algorithms may stop converging).

1. *K-means* (K.Jain, 2009) algorithm is a classic method that assigns labels to the data, basing on a distance to the nearest centroid. Centroids are moved iteratively until all clusters stabilise.

2. *Agglomerative hierarchical clustering (AC)* (Day and Edelsbrunner, 1984) is a method that iteratively joins subgroups basing on a *linkage criterion*. In this paper, we present result for the average linkage clustering.

3. *Spectral clustering (SC)* (Ng et al., 2002) is based on the Laplacian matrix of the similarity graph and its eigenvectors. The least significant eigenvectors create new, lower dimensional space that is used with a *K-means* algorithm.

4. *Expectation–maximisation (EM)* (Bilmes et al., 1998) is used to estimate parameters in statistical models, Gaussian mixture model in our example. Gaussian mixture model assumes that data is generated from a finite number of Gaussian distributions.

3.2 Standardisation

Standardisation of input data is usually necessary, because many machine learning algorithms requires features to have a normal distribution and, probably more important in clustering algorithms, a similar scale. In our work, we decided to use following methods:

Table 2: Symbols description

X	feature vector (column of the input matrix)
$\overline{X}$	mean value of the feature
X_{min}, X_{max}	minimal/maximal value of the feature
$x_i, \hat{x}_i$	new/old value of the feature of i-th sample
σ	standard deviation of the feature
λ	power parameter that is estimated through maximum likelihood

1. Min–Max scaling - the most popular way of scaling data. Returned values are in range from 0 to 1:

$$\hat{x}_i = \frac{x_i - X_{min}}{X_{max} - X_{min}}$$

2. Z-score normalisation - one of the classic method of standardisation. It results in a distribution with a standard deviation equal to 1:

$$\hat{x}_i = \frac{x_i - \overline{X}}{\sigma}$$

3. Yeo–Johnson transformation - a member of power transform functions that allows negative values of input (Yeo and Johnson, 2000):

$$\hat{x}_i = \begin{cases} \frac{(x_i+1)^\lambda - 1}{\lambda}, & \text{if } \lambda \neq 0, x \geq 0 \\ \log(x_i + 1), & \text{if } \lambda = 0, x \geq 0 \\ -\frac{(-x_i+1)^(2-\lambda)-1}{2-\lambda}, & \text{if } \lambda \neq 2, x < 0 \\ -\log(-x_i + 1), & \text{if } \lambda = 2, x < 0 \end{cases}$$

bert	BERT	multilingual forms, sentences	BERT	768	github.com/google-research/bert

3.3 Quality Metrics

Evaluation of clustering quality may be performed in two different ways: with external knowledge of sample membership or without it. The first way is usually better if we have already labelled data and using supervised learning is none of our options. For example, we know that the clustering problem we want to solve concerns similar data we have labelled, which is a case in this work. We compare how different vector representation of documents, which have an assigned label to it, can be clustered.

There are plenty of clustering quality measures that have a different interpretations, like *purity*, *V-measure* or *Rand Index* (Amigo et al., 2009). In our work, we decided to use corrected for a chance measures where the result does not increase with several clusters for randomly chosen labels. Two most common metrics are *Adjusted Rand Index* (ARI) and *Adjusted Mutual Information* (AMI) (Vinh et al., 2010). According to (Romano et al., 2016) AMI is better suited to our problem as documents types are often unbalanced. It gives more weight to a clustering solutions with purer small groups than to minor mistakes in bigger ones.

Adjusted mutual information score is one of the information theoretically based measures. It is based on mutual information (MI) which comes naturally from entropy.

Table 3: Symbols description

X, Y	set of classes/clusters
H	Entropy
MI	mutual information
NMI	normalized mutual information
AMI	adjusted mutual information
x_i, y_i	i-th element of X/Y (class or cluster)
$P(x_i), P(y_i)$	probability of the document being in i-th class or cluster
$P(x_i\hat{y}_j)$	intersection of $P(x_i)$ and $P(y_j)$
$E(MI)$	expected value of MI

$$H(X) = \sum_i P(x_i) \log \frac{1}{P(x_i)}$$

$$MI(X,Y) = \sum_i \sum_j P(x_i \cap y_j) \log \frac{P(x_i \cap y_j)}{P(x_i)P(y_i)}$$

The problem with mutual information is that the maximum is reached not only when labels from one set (clusters) matches perfectly those from the other (classes), but also when they are further subdivided. The simple solution for that is to normalise MI by mean of entropy of X and Y:

$$NMI(X,Y) = \frac{MI(X,Y)}{(H(X) + H(Y))/2}$$

Normalised mutual information can be further improved by subtracting expected value of MI from nominator and denominator:

$$AMI(X,Y) = \frac{MI(X,Y) - E(MI)}{(H(X) + H(Y)/2 - E(MI)}$$

This is what is called ”corrected for a chance”. The general form of AMI was proposed in (Hubert and Arabie, 1985).

4 Experiments

4.1 Data Sets

We performed tests on two collections of text documents in Polish: $Press$ and $Rewievs$. The first corpus ($Press$) comprises Polish press news. It is a complete, high quality and well defined data set. The texts were assigned by press agency to five subject categories. All the subject groups are well separable from each other and each group contains a reasonably large number of members. In the study (Walkowiak and Malak, 2018), the authors reported 95.5% accuracy achieved on this data set in supervised classification. There are ca. $6,500$ documents in total in this corpus.

The second corpus (*Reviews*) consists of reviews of scientific works from 21 different science areas. The achieved accuracy on this data set by fastText (Joulin et al., 2017) in supervised classification was 90.7% (after division 2:1 for training and testing). There are ca. $10,500$ documents in this corpus.

4.2 Idea

The goal of our experiments was to find the best performing word embedding model in a clustering problem. In order to do that, first, we checked how standardisation affects results and picked one of the methods to use it in further tests. Then we compared several models using different clustering approaches with and without standardisation. In order to generate feature vectors for documents (doc2vec) we averaged word/sentence embeddings for every text in the dataset.

4.3 Choosing the Standardisation Method

We performed our first experiment as follows: having the documents $d_i \in D$ represented as doc2vec vectors from KGR10_lemma model, we performed several tests to evaluate the quality measure (AMI) of multiple clustering algorithms with different distance functions. The results are given in the Figure 1 and Figure 2. It can be observed that for EM, K-means and SC standardisation does not significantly improve the results. What is more, for Euclidean distance, data scaling may blur the distances between points and worsen the quality of the solution. On the other hand, usage of standardisation methods with Agglomerative Clustering (AC) algorithm improves obtained results. It is not surprising as the linkage method strongly depends on variance especially when using a cosine distance. On average (the average height of the AMI score) the best method of standardisation turned out to be Yeo–Johnson transformation, so we used it in subsequent experiments.

4.4 Model Comparison

In order to compare how the chosen model affects quality, we performed multiple tests, similar to the previously conducted. They were evaluating the quality measure due to used doc2vec representations, generated from models described in Section 2. The results of clusterisation of the original data can be observed in figures 3 and 5 alongside with the results of standardised vectors with Yeo–Johnson transformation in figures 4 and 6. It can be noticed that standardisation has minor influence on Spectral Clustering (SC). It either slightly improves or does not deteriorate results. The only exception is Euclidean distance where standardisation can blur and therefore worsen the score. It is clearly visible for Agglomerative Clustering (AC) which, after standardisation and with a cosine or a Bray–Courtis distance, works best. Using standardised version of K-means algorithm with any of proposed models is rather not suitable since standardisation does not necessarily increase the score, however this classic approach is usable with the given problem, especially that it strongly depends on centroids which usually are quite useful. We expected that standardisation will have a positive influence on Gaussian mixture model (EM) which assumes data is generated from some number of Gaussian distributions and standardisation should make that data more Gaussian-like. It is probably the case with those models that have higher score in figures 4 and 6 than in figures 3 and 5, but it is not a rule.

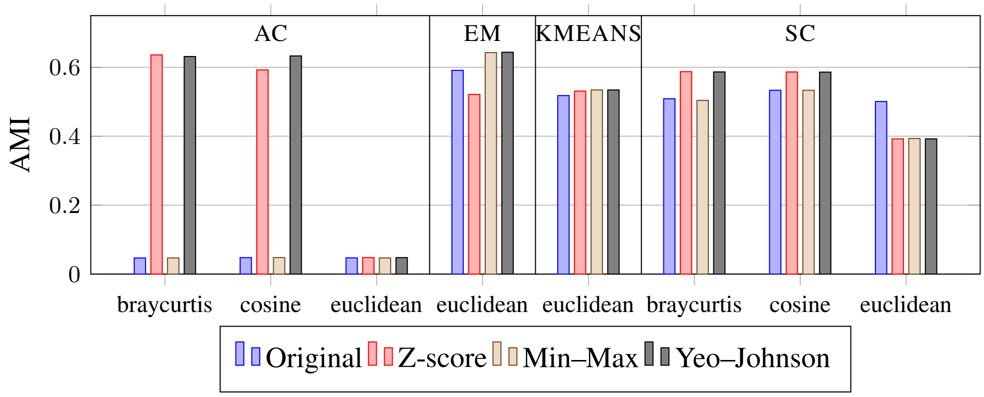

Figure 1: Standarization - PRESS

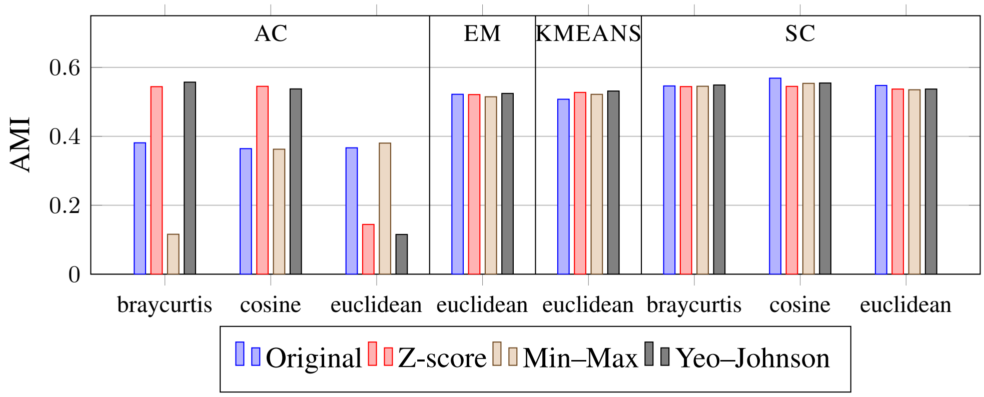

Figure 2: Standarization - REVIEWS

5 Conclusion

As a conclusion, we would like to recommend using Yeo–Johnson transformation to standardise doc2vec embedding and if a task is to group documents, Agglomerative Clustering (AC) with a cosine distance. For researchers who deal with Polish datasets, we strongly recommend using KGR10_lemma or KGR10 word2vec models (Kocon and Gawor, 2019)[9]. First of them gives better results but the second one (only slightly worse) is much faster in a usage, since it does not require a time consuming lemmatization of texts. We are now working on implementing the best selected workflow as a part of WebSty (Eder et al., 2017), an online tool[10] aimed for researchers in humanities and social science working with texts in Polish.

Although, that ELMo and BERT perform great in many tasks in NLP our results show otherwise. Two factors can be responsible for this. First, we used already trained models downloaded from the addresses shown in Table. 1. As they might not be the best quality for the Polish language, we currently training our own model to verify this hypothesis. The second reason may be that both BERT and ELMo do not work well with the discussed problem. It is hard to find any article dealing with document clustering problem using those methods.

We plan to test other methods of composing document vectors, i.e. representing documents by several concatenated vectors. We want to test two approaches. One is based on a division of documents into parts and generating doc2vec for each part. And the second, based on clustering of word embeddings into a predefined number of groups and using centroids as elements of final document vectors.

The work was funded by the Polish Ministry of Science and Higher Education within CLARIN-PL Research Infrastructure.

Bigger versus Similar: Selecting a Background Corpus for First Story Detection Based on Distributional Similarity

Fei Wang and **Robert J. Ross** and **John D. Kelleher**

Abstract

The current state of the art for First Story Detection (FSD) are nearest neighbour-based models with traditional term vector representations; however, one challenge faced by FSD models is that the document representation is usually defined by the vocabulary and term frequency from a background corpus. Consequently, the ideal background corpus should arguably be both large-scale to ensure adequate term coverage, and similar to the target domain in terms of the language distribution. However, given these two factors cannot always be mutually satisfied, in this paper we examine whether the distributional similarity of common terms is more important than the scale of common terms for FSD. As a basis for our analysis we propose a set of metrics to quantitatively measure the scale of common terms and the distributional similarity between corpora. Using these metrics we rank different background corpora relative to a target corpus. We also apply models based on different background corpora to the FSD task. Our results show that term distributional similarity is more predictive of good FSD performance than the scale of common terms; and, thus we demonstrate that a smaller recent domain-related corpus will be more suitable than a very large-scale general corpus for FSD.

1 Introduction

Given a stream of documents about news events in a chronological order, the goal of First Story Detection (FSD) is to identify the very first story for each event. Each story is processed in sequence, and a decision is made for a given candidate document on whether or not it discusses an event that has not been seen in previous documents; crucially this decision is made after processing the candidate document but before processing any subsequent documents (Allan et al., 1998; Yang et al., 1998). The decision making process for each incoming document is normally based on a novelty score; namely, if the novelty score of a new document is higher than a given threshold, we say it is a first story.

Hundreds of FSD models have been proposed in prior research, and the nearest neighbour-based models, in which the novelty score is defined as the distance from the new story to the closest existing story, remain the state of the art (Wang et al., 2018). In the implementation of nearest neighbour-based FSD models, the first step is to represent each story with a sound document representation. Even though many deep learning-based document representations have been shown to achieve very good results in a range of NLP (Natural Language Processing) tasks (Goldberg, 2017), the dominant document representation model for FSD remains the traditional term vector models in which each feature represents a term in the vocabulary (Brants et al., 2003; Petrović et al., 2010; Wang et al., 2018; Kannan et al., 2018).

The majority of machine learning research assumes that the data used for building a model and making inference are sampled from the same distribution, i.e., the data generation process is stationary. However, because of its online characteristic, one challenge faced by FSD models is that the system's vocabulary (and hence document representation) cannot be derived from a target corpus, but must instead be defined by the vocabulary of a background corpus. The resultant potential difference between the background and target corpus demonstrates a non-stationary characteristic

Proceedings of Recent Advances in Natural Language Processing, pages 1312–1320,
Varna, Bulgaria, Sep 2–4 2019.

of FSD. To mitigate for potential differences between background and target data, the ideal background corpus should be both large-scale, so as to ensure an adequate number of common terms between it and the documents in the target stream (i.e., minimize *unknown* words), and similar in the sense of language distribution. In many cases, these two factors cannot be satisfied at the same time, and thus the emphasis has to be placed on the more informative one of the two, which leads to a question of "bigger or similar?". To the best of our knowledge however, there is little research addressing this question empirically, and no metrics have been proposed for the quantitative comparison of the scale and similarity between background corpora relative to a target corpus.

In this paper we examine whether the distributional similarity of common terms between corpora (background and target story stream) is more important than the scale of common terms for FSD. As a basis for our analysis we propose a set of metrics to quantitatively measure the scale of common terms and the distributional similarity between corpora. Using these metrics we rank different background corpora relative to a target FSD corpus. Finally, we apply the models based on different background corpora to the FSD task to determine the relative utility of different assumptions about the background corpus. Our contributions are thus two-fold: an investigation of background corpus similarity versus scale, and a metrics framework for making such an investigation.

2 First Story Detection

FSD as a challenge was initially defined within the Topic Detection and Tracking (TDT) competition series (Yang et al., 1998; Allan et al., 2000b); and was considered to be the most difficult challenge in all five TDT tasks (Allan et al., 2000a). Since then, the need for accurate FSD models has been greatly strengthened by the proliferation of digital content, and social media streams in particular. One of the challenges of FSD is the undefinable characteristic of a first story. We can never know what the next first story will look like; instead, we only know that it must be different to existing stories to some degree. Therefore, we normally consider FSD as an unsupervised learning application, and hence attempt to define and make use of a novelty score in a similar fashion to how novelty-style metrics are defined in other unsupervised learning applications (Wang et al., 2017).

Based on different definitions of novelty scores, it has been proposed that there are three categories of FSD models (Wang et al., 2018): Point-to-Point (P2P) models, Point-to-Cluster (P2C) models, and Point-to-All (P2A) models. P2P models, in which the novelty score is defined as the distance from the incoming story to an existing story, are normally nearest neighbour-based (Yang et al., 1998; Allan et al., 2000b), or approximate nearest neighbour-based (Brants et al., 2003; Petrović et al., 2010, 2012; Moran et al., 2016; Kannan et al., 2018). In P2C models or P2A models, the novelty score is defined respectively as the distance from the new story to a cluster of existing stories (also can be considered as the distance to an existing event), or to all the existing stories. The former is usually clustering-based (Yang et al., 1998; Allan et al., 2000b; Li et al., 2017), and the latter uses all the existing data to build a system, and applies this system to the incoming story to generate a novelty score (Schölkopf et al., 2001; Wurzer et al., 2015). Based on previous literature and research on FSD, it has been shown that nearest neighbour-based P2P models perform the best among all these three categories of FSD models (Wang et al., 2018).

2.1 Term Vector Models for First Story Detection

As presented above, the novelty score in a P2P model is calculated by comparing the incoming story to previous stories and then finding its (approximate) nearest neighbour and the corresponding closest distance. When implementing a P2P model, the first step is to convert the raw stories to document representation vectors that can be fed into the detection model; this is then followed by the quantitative comparisons between these document representations. The state of the art document representation model for P2P FSD models remains the traditional term vector models, due, in part, to their specificity of terms (Wang et al., 2018). In a term vector model, each feature (dimension) represents a term in the vocabulary, so the dimensionality of each vector is generally the same length as the corpus vocabulary.

TF-IDF is the most well-known term vector model and also the most effective one used for FSD (Brants et al., 2003; Petrović et al., 2010; Kannan et al., 2018). A TF-IDF weight is calculated for each term in a document vector as the product of the TF (term frequency) and IDF (inverse document frequency) components. The TF component captures the number of times a term was encountered in the document, while the IDF component discounts the term weights that are very common in the corpus such that these are judged to have little information relevant to the distinction of documents. A TF-IDF model always stores a vocabulary as well as an IDF dictionary in which the key is each term while the value is the corresponding IDF component for that term. When applying a TF-IDF model, it is necessary to use some corpus to build the vocabulary and the IDF dictionary before calculating the TF-IDF weight for each term in a document using some specific scheme. A widely-applied TF-IDF weighting scheme is shown as follows:

$$tf\text{-}idf(t,d) = tf(t,d) \times idf(t) \tag{1}$$

$$idf(t) = log\frac{N}{df(t)} \tag{2}$$

where $tf(t,d)$ represents the TF component, that is just the number of times the term t occurs in document d, and $idf(t)$ represents the IDF component, in which N denotes the total number of documents and $df(t)$ refers to the number of documents that contain the term t.

In the context of FSD, the labelled target corpus is always unavailable before detection because of the online characteristic of FSD, and thus a background corpus is required to build the TF-IDF model, i.e., the vocabulary and the IDF dictionary in the model. As shown in Fig. 1, we assume that a TF-IDF model is built with a background Corpus B and is applied to the FSD task for a target Corpus T. Set 2 is the overlapping term set that contains the terms common to both Corpus B and T, and Set 1 and 3 contain the terms that only exist in Corpus B or T respectively. Consequently, Set 1 and 2 constitute all terms in Corpus B, while Set 2 and 3 constitute all terms in Corpus T.

2.2 Set Overlap and FSD Modelling

In a pre-built TF-IDF model, all the terms in the vocabulary are from the background Corpus B, i.e., the terms used to generate the term vector space are those from Set 1 and 2, while those terms in Set 3 will not appear in the TF-IDF model at all. In other words, the terms in Set 3 are all the *unknown* terms with respect to the TF-IDF model. However, when the TF-IDF model is applied to FSD, all the documents to be analysed will be from the target Corpus T, which means that all the terms in Set 1 will not appear at all in the process of FSD; as a result the TF components for these terms are always zero and thus all the final TF-IDF weights of these will always be zero as well. It should be noted that we can look at all the terms of the target corpus here because we are now doing the analysis. However, during the real FSD we will never know whether a term from the background corpus appears in the target corpus or not. Therefore, we have to keep all the terms in Set 1 and 2 that are from the background corpus, even though the weights of all the terms in Set 1 are always zero.

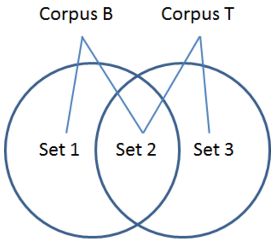

Figure 1: Term Sets within a Background Corpus B and a Target Corpus T

The comparison between TF-IDF representations is usually based on cosine distance calculations for FSD (Allan et al., 2000b; Brants et al., 2003). For such calculations, all representation vectors are normalised so that the cosine distance is not sensitive to the specific weighting schemes (Allan et al., 2000b). To clarify, given an incoming story represented by $\vec{a}$ and an existing story represented by $\vec{b}$, the cosine distance between them is defined as:

$$cosine\_distance(\vec{a}, \vec{b}) = 1 - \frac{\vec{a} \cdot \vec{b}}{|\vec{a}|\left|\vec{b}\right|} \tag{3}$$

According to the definition of cosine distance, in each document vector the terms whose weights are always zero do not have any effect on the result of calculation, so they can be ignored when we analyse the calculation. Hence, the valid terms that make sense for FSD are only those in Set 2, which are the common terms in both the background and target corpus. Given this, the effectiveness of the TF-IDF model only depends on Set 2, and specifically, two factors of Set 2: the scale and the distributional similarity between the background and target corpus. The scale describes the number of common terms between the corpora. The larger the scale of Set 2, the more informative terms are taken into account. The distributional similarity of two corpora refers to similarity of the frequencies of common terms. As the IDF components of these common terms are calculated only based on the background corpus, the more similar the background corpus is to the target corpus in terms of the language distribution, the better the generated weights can represent the common terms for FSD in the target corpus.

Therefore, the ideal background corpus for FSD should be both large-scale and similar in frequency distribution to the assumed target corpus. However, in many cases, these two factors cannot always be satisfied at the same time, and so it can be useful to determine which of these factors is more predictive of good FSD performance.

3 Quantitatively Measuring Background Corpus Suitability

To propose a method for evaluating the relative importance of the quantity of shared terms versus the similarity of language distributions between a background and target corpus, in this section we outline a set of quantitative metrics to make pairwise comparisons between different background corpora relative to the target FSD corpus.

3.1 Measuring the Scale of Common Terms

As shown earlier in Fig. 1, the scale of common terms relative to the target Corpus T can be quantitatively measured using the proportion of common terms of Set 2 relative to all the terms of Corpus T; we refer to this as the overlapping rate of the background Corpus B relative to the target Corpus T. Given any specific target corpus, the bigger the overlapping rate is for a background corpus, the more informative terms are available to be taken into account, and hence the less unknown terms occur in the FSD process.

3.2 Measuring the Distributional Similarity

While measuring the scale of common terms is relatively straightforward, the assessment of distributional similarity is somewhat more involved.

As we focus on the TF-IDF model, the distribution similarity between corpora should be based on the document frequencies. If we order the terms by document frequency for different corpora, each term will likely have a different rank within each corpus. Moreover, if we only look at the ranks of common terms in both corpora (i.e., the terms in Set 2 shown in Fig. 1), it is possible to measure the dissimilarity between two corpora based on their different lists of term ranks.

Before making rank based similarity measurements, some preparation is required. Firstly, the common terms in both corpora (background and target corpus) are extracted as the basis for the comparisons. For each corpus, these common terms are ordered in a descending order based on their document frequencies calculated with only this corpus, and then each term is assigned an index from 1 to n, where n is the number of common terms that are being taken into account. For different corpora, the order of terms will be different, as well as the index of each term. If there are no terms with the same document frequency in an ordered term list, the index of each term can be reasonably considered as its rank in this corpus. However, the fact is that many terms have the same document frequency in a corpus, so they should have the same rank. Instead of assigning different ranks to the neighbouring terms with the same document frequency, we implement some extra operations to make their ranks the same. Specifically, for the terms with the same document frequency, i.e., the terms with indices from i to j, we assign the same average rank $\frac{i+j}{2}$ to all of these, such that this does not affect the rank of any other term. If from the 1^{st} to the 4^{th} terms in the ordered term list have the same document frequency, all of them will be assigned a rank $(1 + 4)/2 = 2.5$.

After pre-processing, we count the number of inversions and calculate the distance between two ordered same-length term lists to present the dissimilarity between these two corpora:

1 **Inversion count** If the order of two different terms in one corpus is not the same as that in the other corpus, e.g., in one corpus, term X has a rank smaller than term Y, while in the other corpus, term X has a rank larger or equal to term Y, we call this situation an inversion. The inversion count metric is defined as the count of all the inversions between two different ordered rank lists.

2 **Manhattan distance** To calculate the dissimilarity between two same-length rank lists we

subtract the rank of each term in one list from the rank of the same term in the other list and sum the absolute value of each of these differences (Kelleher et al., 2015).

As both these dissimilarity metrics show the degree to which a background corpus is different from the target corpus, we expect that the greater the metric the worse the subsequent model is expected to perform on the FSD task. We only evaluate the distributional similarity based on the frequency ranks of the common terms, rather than the quantitative frequency values, because the comparisons based on the quantitative frequency values usually lead to more emphasis on the terms with high frequency values, which should be avoided. It is worth noting that in real use both of these metrics are normalised to between 0 and 1 by being divided by n^2, where n is the length of the rank lists, i.e, the number of common terms. The calculation of these two metrics requires time complexity of $O(n^2)$ and $O(n)$ respectively.

3.3 Comparison between Two Background Corpora Relative to a Target Corpus

With the metrics proposed above, we can make comparisons between different background corpora relative to a target FSD corpus. For the comparison of the scale of common terms, the overlapping rate can be applied to multiple background corpora to rank them based on their rate values. However, the situation for the comparison of the distributional similarity is more involved.

As explained in their definitions, both two dissimilarity metrics proposed above are calculated based on the common terms of a background corpus and a target corpus. If we want to compare among multiple background corpora relative to a target corpus, the calculation should be based on the common terms of all the background and target corpus to ensure the rank list for each background corpus in the same length[1]. The situation of two background corpora and a target corpus is depicted in Fig. 2, in which the calculation of dissimilarity metrics would be based on Common Set. Generally, the common terms shared by the three corpora will be less than those shared by only any two of them. For each background corpus, the terms used for the comparison (i.e., the terms in Common Set) will be less than those used in FSD (i.e., the terms in Common Set and Set 1 for Corpus B1, and the terms in Common Set and Set 2 for Corpus B2). This will lead to errors in the measures and comparisons, and the more background corpora are being compared, the greater the errors will be. In order to limit this kind of error, we restrict to pairwise comparison between background corpora so that the number of terms used for comparisons are relatively large in comparison to the terms used in FSD.

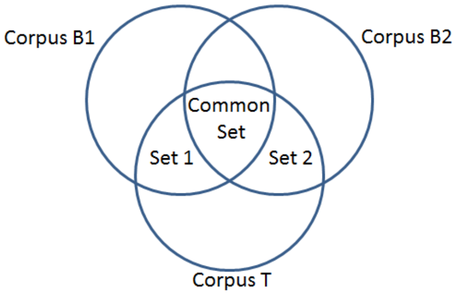

Figure 2: Common Set among two Background Corpora B1 and B2 and a Target Corpus T

4 Experiment Design

In this section, we present our experiments for comparing the scale of common terms and the distributional similarity between different background corpora relative to a target FSD corpus, and apply the models based on different background corpora to the FSD task in an attempt to determine which factor is more predictive of good FSD performance.

4.1 Corpora Used in the Experiments

The target corpus we use for FSD detection is the standard $TDT5$ corpus[2]; the contents of which are newswire stories generated from April to September 2003. The background corpora we are making use of for the current investigation are subsets of $COHA$ (Corpus of Historical American English) (Davies, 2012) and $COCA$ (The Corpus of Contemporary American English) (Davies, 2010). The former covers comprehensive historical English documents from 1810 to 2009 in different domains such as news, fiction, academia

[1] We also tried designing metrics that can be generated based on different terms, i.e., for each background corpus using the terms shared only by the target corpus and itself, rather than common terms shared by all corpora, but we failed because we could not find any valid method to normalise the metrics generated based on different numbers of terms.

[2] https://catalog.ldc.upenn.edu/LDC2006T18

and so on, and the latter is similar to $COHA$ in themes but focuses only on the contemporary contents from 1990 to present. The numbers of documents in $TDT5$, $COHA$ and $COCA$ are about 278,000, 115,000 and 190,000 respectively. As mentioned we make use of subsets of $COHA$ and $COCA$; specifically we mostly include data that predates 2003, i.e., the year of $TDT5$ collection, unless otherwise stated.

In order to answer our underlying research question, i.e., whether bigger or similar background corpora provide the clearer benefit, we carried-out three sets of experiments. In the first set, comparisons are made between $COCA$ and $COHA$ with the assumption that a contemporary corpus will be more similar to the target corpus than a historical one. The second set of experiments supplement the first set and focus on corpus temporality. Comparisons are made between two subsets of the entire COCA corpus - $COCA$ and $COCA\_After\_2003$ that respectively include only the documents before and after 2003, the year when the target corpus was collected. We assume that a corpus with future data is more similar to a target corpus than that with prior data only[3]. The last set of experiments establish comparisons between two subsets of $COCA$ - $COCA\_News$ and $COCA\_Except\_News$, in which $COCA\_News$ contains only the documents in the domain of news, which is the same as the domain of the target TDT5 corpus, while $COCA\_Except\_News$ contains the documents in other domains except news. We also assume that the domain-related corpus is more similar to the target corpus than those in different domains.

4.2 Metric Calculation

In the implementation, we apply all the metrics to each corpus mentioned above, and then make comparisons in each pair of background corpora. In addition, for the comparison of corpus similarity, we examine whether the two proposed metrics, inversion count and Manhattan distance, are consistent with each other in deciding which corpus in each pair is more similar to the target corpus, i.e., whether two metric values for a corpus are both smaller or greater than those for the other corpus in the comparison pair. We also verify whether the results of comparisons correspond with our assumptions about corpus similarity in Sect. 4.1.

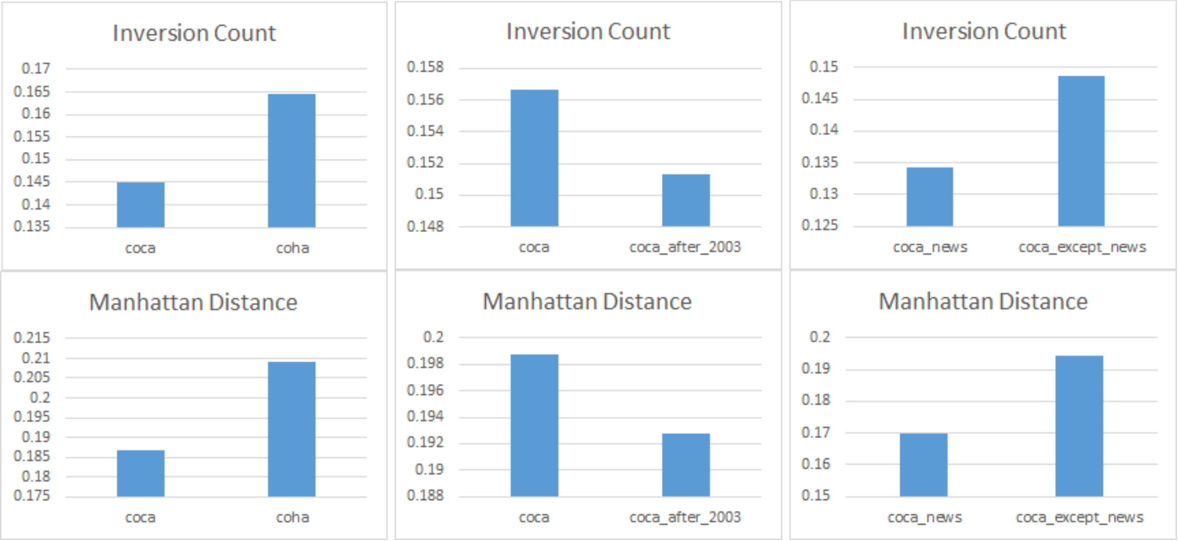
4.3 FSD Evaluation

Following background corpus metric calculation, we build TF-IDF models based on the background corpora being compared and apply these models to the FSD task.

The implementation of FSD is based on the nearest neighbour algorithm with the TF-IDF representations we described in Sect. 2.1. We also adopt the cosine distance as the dissimilarity measure between document representations. In order to reduce the effect of useless terms and different term forms, for both the background and target corpus we remove terms with very high and very low document frequency (stop words and typos), and stem all terms. Aligning with previous research (Yang et al., 1998), comparisons are only implemented with the 2000 most recent stories for each incoming story. The output of each FSD model is a list of novelty scores for each document in the target corpus TDT5. Based on these outputs, the standard evaluation method for FSD is to apply multiple thresholds to sweep through all the novelty scores. For each threshold, a missing rate and a false alarm rate are calculated, and then for all thresholds, the missing and false alarm rates are used to generate a DET (Detection Error Tradeoff) curve (Martin et al., 1997), which shows the trade-off between the false alarm error and the missing error in the detection results. The closer the DET curve is to the zero point, the better the FSD model is said to perform. It happens sometimes for the evaluation with DET curves that many curves are in a tangle – making it is difficult to figure out visually which model performs better. Therefore, we calculate Area Under Curve (AUC) for each FSD model, and the model with the lowest AUC is judged to be best.

In order to achieve more comprehensive results for this evaluation, we implement tests for set variants. Specifically, for each set of experiments, we make comparisons not only between the two background corpora being evaluated, but also between each corpus and the union of both corpora; for example for $COCA$ vs. $COHA$, we not only implement the comparison between $COCA$ and $COHA$, but also between $COCA$ and $COCA + COHA$ and between $COHA$ and $COCA + COHA$, where $COCA + COHA$ is the union of $COCA$ and $COHA$. In this way, we

[3] In real FSD, future data is always unavailable. This set of experiments are only for the use of analysis.



(a) Metric Results for $COCA$ vs. $COHA$

(b) Metric Results for $COCA$ vs. $COCA\_After\_2003$

(c) Metric Results for $COCA\_News$ vs. $COCA\_Except\_News$

Figure 3: Comparisons of Corpus Dissimilarity

have six more comparison results that can be used for the evaluation of the relations between background corpus and model performance for FSD.

5 Results & Analysis

We first look at the comparisons between corpora before looking at FSD performance for different background corpora.

5.1 Results of the Comparisons of Corpus Dissimilarity

We applied the two metrics, inversion count and Manhattan distance, to the three sets of comparisons: $COCA$ vs. $COHA$, $COCA$ vs. $COCA\_After\_2003$ and $COCA\_News$ vs. $COCA\_Except\_News$. The results are shown in Fig. 3. We find firstly that in all comparison sets that the results of the two evaluation metrics are consistent with each other, i.e., the metric values for $COCA$ are both smaller than $COHA$, but greater than $COCA\_After\_2003$, and those for $COCA\_News$ are both smaller than $COCA\_Except\_News$. Secondly, we also find that these comparison results all correspond with our assumptions that more recent domain-related corpora are more similar to the target corpus. Given this, we conclude that both metrics are effective for the comparison of the distributional similarity between background corpora relative to the target corpus, and for the sake of simplicity, we judge Manhattan distance as the most useful metric due to its ease of calculation and interpretation.

5.2 Results of the Relations between Background Corpus and Model Performance for First Story Detection

Results are shown in Table 1, 2 and 3, where the values of the overlapping rates and Manhattan distances are the values for one corresponding background corpus relative to the target corpus. The cells in bold indicate the better results in the comparisons of the scale of common terms and the common term distributional similarity between each pair of background corpora, as well as the better FSD performance. We find that all corpora that are more similar (in terms of term distributions) to the target corpus lead to better performance in FSD, except in the case of very similar performance between $COCA$ and $COCA + COHA$. However, it is worth noting that only six in nine corpora that have a larger scale of common terms correspond with better FSD performance while the other three do not. For example, in Table 3 although the corpus $COCA$ has the much larger scale of common terms, the FSD performance based on it is still worse than that based on $COCA\_News$, because $COCA\_News$ is more similar to the target corpus in terms of language distribution.

Based on these results, it can be argued that term distributional similarity is more predictive of

	coca vs. coha		**coca vs. coca+coha**		**coha vs. coca+coha**

Table 3: Comparisons between $COCA\_News$ and $COCA\_Except\_News$

good FSD performance than the scale of common terms; and, thus we can give general guidance to the selection of background corpus for FSD that a smaller recent domain-related corpus will be more suitable than a very large-scale general corpus for FSD. Of course, our research is directed only at the general situations, as the interpretations do not include extreme situations such as extremely large or small scale of common terms. It is also worth noting that we are purposefully focusing here on the case of a static background corpus and not on the case of updates being made to the TF-IDF model as the FSD process unfolds.

6 Conclusion

We conclude with a highlight of our three main contributions. We proposed a set of metrics for the quantitative evaluation of the scale of common terms and the term distributional similarity of a background corpus relative to a target corpus, and a pairwise comparison scheme between two different background corpora. We also applied the proposed metrics and comparison scheme to the comparisons between background corpora relative to the target FSD corpus, and our results indicate that term distributional similarity is more predictive of good FSD performance than the scale of common terms. Finally, we answered the research question of whether bigger or similar corpus are more useful for FSD by showing that a smaller recent domain-related corpus will be more suitable than a very large-scale general corpus for FSD.

Abstract

The goal of this paper is to use all available Polish language data sets to seek the best possible performance in supervised sentiment analysis of short texts. We use text collections with labeled sentiment such as tweets, movie reviews and a sentiment treebank, in three comparison modes. In the first, we examine the performance of models trained and tested on the same text collection using standard cross-validation (in-domain). In the second we train models on all available data except the given test collection, which we use for testing (one vs rest cross-domain). In the third, we train a model on one data set and apply it to another one (one vs one cross-domain). We compare wide range of methods including machine learning on bag-of-words representation, bidirectional recurrent neural networks as well as the most recent pre-trained architectures ELMO and BERT. We formulate conclusions as to cross-domain and in-domain performance of each method. Unsurprisingly, BERT turned out to be a strong performer, especially in the cross-domain setting. What is surprising however, is solid performance of the relatively simple multinomial Naive Bayes classifier, which performed equally well as BERT on several data sets.

1 Introduction

Automated sentiment analysis usually involves training machine learning or deep learning models in supervised fashion. Typically, studies involve one data type and report high accuracy. For example, the seminal machine learning studies on IMDB movie reviews of (Pang et al., 2002) indicated accuracy over 80%. Recently, the accuracy of a deep learning system reported on this data set exceeded 95% (Howard and Ruder, 2018). Similarly, sentence-level sentiment predictions exceeded 95% accuracy on binary version of the popular Stanford Sentiment Treebank (abbreviated as SST-2) (Liu et al., 2019).

However, multiple studies indicate that the models trained on such data sets are in fact very far from being applicable universally. Machine and deep learning models tend to fit to specific type of texts and language. When applied to different language types in terms of both style and vocabulary, the performance drops sharply. This issue is often explored under the name of domain dependency or data set dependency. Several methods have been proposed to address it, such as for example (Selmer et al., 2013). In another stream of related studies, authors considered the task of cross-domain sentiment analysis: adaptation of a model to target domain or text type that is different from the domain or text type that the model was trained on. Examples include (Peng et al., 2018).

The goal of this article is to evaluate and compare supervised techniques of sentiment analysis of short texts using all available resources in the Polish language. We utilize three generations of machine learning:

- machine learning models using bag-of-words vector representations, algorithms such as Naive Bayes and Support Vector Machines,
- recurrent deep neural networks based on LSTM with and without pre-trained word embeddings,
- finally the most recent generation of deep neural networks, pre-trained on language modeling tasks (BERT and ELMO).

Proceedings of Recent Advances in Natural Language Processing, pages 1321–1327,
Varna, Bulgaria, Sep 2–4 2019.

The questions that our paper addresses are: (1) to what extent is each of the method usable for training a universal sentiment analysis model (how well it performs in cross-domain setting) and (2) how good it is for predicting sentiment within the same text type it has been trained on (how well it performs in in-domain setting).

The motivation for a universal classifier might not be obvious at first, as clearly the best performance is achieved by in-domain classification (Twitter may need tweet classifier, Facebook needs posts classifier, IMDB needs review classifier, and so on). However, universal character of sentiment classification models allows for better performance in cases when source data distribution is different than target data distribution. This happens on every day basis, for instance Twitter posts change their topic over time and optimum performance requires new train sets to match the newest data. These issues are well-known to machine learning community and explored under topics of domain adaptation, dataset shift and semantic drift. Ability to apply the model universally to various data types is a great advantage from the practical point of view.

Our intention is to focus on supervised learning. Specifically, this means working on collections of short texts such as single sentences, tweets or short reviews with labeled sentiments. The goal of our task is to classify sentiment of the whole written utterance (as for example, a sentence, review or tweet) into three classes: as positive, neutral or negative.

When computing sentiment we rely only only on learning from provided text examples and do not use any resource which might help in sentiment predictions such as a sentiment dictionary.

The paper is organized as follows: Section 2 contains a description of sentiment datasets, Section 3 describes the methods used for sentiment prediction. Section 4 describes the results obtained in our experiments. Finally, Section 5 contains conclusions and a discussion of possible future work.

2 Data Sets

The experiments described in this paper are based on several resources with manually labeled sentiment. The texts in our experiments are "short": tweets do not exceed 140 characters, Treebank sentences are arbitrarily long in terms of tokens but syntactically and semantically correct, reviews contain from 1 to 3 sentences.

2.1 Polish Sentiment Treebank (TW)

The first resource is Polish language dependency treebank with sentiment annotations ("Treebank Wydźwięku" abbreviated as TW). It is available to download [1]. Similar to Stanford's Sentiment Treebank (SST) (Socher et al., 2013), Treebank Wydźwięku (TW) was intended to study compositional phenomena in sentiment analysis. There are several notable differences between the two:

- Dependency trees (TW) instead of constituency binary parse tress (SST),
- 3-class sentiment (TW) instead of 5-class (SST),
- Open-domain (TW) instead of one domain of movie reviews (SST).

In TW, overall sentiment of each sentence corresponds to the sentiment of its root. Sentences in this data set often contain mixed sentiment, even opposite polarities: one part may be positive and the other negative. This makes the task of predicting overall sentiment more difficult.

2.1.1 TW Version 1.0

Initial version of the TW treebank contained sentences from Składnica Treebank[2] (part referred to as **sklad**) and sentences from two types of product reviews: perfumes and clothes (part called **rev**).

The first release of the treebank was published as a part of Task 2: Sentiment analysis in PolEval 2017 campaign on evaluation of natural language processing tools for Polish. In this competition, submitted tools competed against one another within certain tasks selected by organisers, using provided data. Solutions were evaluated according to common procedures.

The intended use of the treebank was as follows: given a set of syntactic dependency trees, the goal was to provide the correct sentiment for each subtree (phrase). Phrases correspond to sub-trees of dependency parse tree. Annotations assign sentiment values to whole phrases (and in some cases, sentences), regardless of their type. The PolEval

[1] http://zil.ipipan.waw.pl/TreebankWydzwieku

[2] http://zil.ipipan.waw.pl/Sk%C5%82adnica

part of the treebank and related evaluation script may be freely downloaded[3].

Three systems participated in the tasks, all of them based on TreeLSTM (Tai et al., 2015). The description of systems and evaluation methodology can be found in (Wawer and Ogrodniczuk, 2017). Due to different nature of these tasks (computing sentiment of each sub-phrase and each sentence vs sentiment of sentences only) the results of these systems are not directly comparable to results reported in our paper.

2.1.2 TW Version 2.0

In August 2018, a new batch of sentences has been added to TW. It contains following new parts:

- Test (evaluation) sentences from PolEval 2017 sentiment task (part called **polevaltest**),
- 2 x 500 sentences collected from various web sources, mostly difficult, mixed sentiments and negative ones (parts called **neg** and **jun18**).

To our best knowledge, our paper is the first to describe and use the new version of this resource.

2.2 Twitter Data

This data set contains one thousand Polish language tweets, gathered and manually labeled as to their sentiment during the TrendMiner project[4]. Many tweets are related to publicly discussed events, some of them originate from politicians, journalists and public figures. Many of them are tweets of simple Twitter users, including teenagers. Overall, the dataset appears to be a fairly representative sample of communication occurring on Twitter in the Polish language. Due to Twitter's policy it can not be made publicly downloadable.

2.3 Movie Reviews

This data set consists of one thousand manually collected movie reviews from Polish website: http://www.filmweb.pl. Most of them are very short texts (1-2 sentences), the rest is a collection of reviews containing up to 5 sentences. Each review has a corresponding numeric score (number of stars) from 1 to 10, assigned by the review's author. Each category (number of stars) has exactly one hundred reviews.

All scores were re-scaled into three categories: stars from 1 to 3 were re-scaled into negative category (-1), stars from 4 to 6 into neutral (0), stars 7 to 10 into positive (1).

What should be noted, however, is that the reviews very often contain spelling mistakes, words with omitted Polish diactric marks, often contain slang or sarcasm. All that makes them problematic for automated analysis.

2.4 Label Frequencies

Most of the datasets are not balanced in terms of sentiment label distributions. Twitter data set contains mostly neutral texts (tweets). Filmweb's balance is nearly perfect, as only the positive class has slight advantage in terms of frequency. Also TW's balance is far from perfect distribution between three sentiment classes as most sentences are neutral. Some pieces of TW treebank have been deliberately created to address imbalance issues in the sentiment treebank, such as for example part of the data called neg in TW 2.0, which contains many negative sentences.

Table 1 presents sentiment label distribution in each of the data set.

Table 1: Distribution of sentiment classes in each data set

file	-1	0	1	all
jun18-TW	59	240	202	501
neg-TW	252	245	3	500

rev-TW.	7	868	90	965
sklad-TW	3	230	2	235
twitter	80	854	66	1000
filmweb	300	300	400	1000

3 Machine and Deep Learning Methods

3.1 Bag-of-Words and Machine Learning

Machine learning methods described in this subsection used bag-of-words text representations. We converted text to word vectors using word-level unigram vectorizer with TF-IDF weights.

We have focused on two machine learning algorithms: Naive Bayes and Support Vector Machines.

[3] http://2017.poleval.pl/index.php/tasks/

[4] https://cordis.europa.eu/project/rcn/100752/factsheet/en

Multinomial Naive Bayes (NB) Classifier is a well-known supervised machine-learning algorithm with an assumption of independence among predictors.

Support Vector Machine (SVM) is also a well-known supervised machine learning algorithm. We used linear kernels and implementation from the liblinear library[5].

3.2 LSTM Neural Network (NN)

We used two approaches to implement the first layer of the neural network.

In the first approach we used untrained, random initialized embedding layer that uses 32 length vectors to represent each word. This method is marked as NN in the results.

In the second approach we changed this layer to pre-trained word2vec 100-dimensional word embeddings for Polish[6]. The embeddings were generated using gensim package (Řehůřek and Sojka, 2010) with skip-gram model architecture for two large text corpora: The National Corpus of Polish[7] and Polish edition of Wikipedia. We marked this approach as NN+E subsequently.

The structure of the neural network was as follows: word embedding layer, LSTM layer with 100 memory units, two Dense layers: the first with 100 neurons, the second with 3 output values, one for each class, with dropout regularization between them. As an output layer we used the softmax activation function.

3.3 ELMO

In one of the approaches we used ELMo method (Peters et al., 2018) to represent texts. ELMo, as it's authors put it, is a deep contextualized word representation that models both (1) characteristics of word use (e.g., syntax and semantics), and (2) how these uses vary across linguistic contexts (i.e., to model polysemy). These word vectors are extracted from states of a deep bidirectional language model, which is pre-trained on a large text corpus. We used the ELMO implementation and models described in (Che et al., 2018). The model was trained on Polish language Wikipedia.

ELMO, although currently often superseded by other alternatives, contributed to state-of-the-art results in multiple natural language processing tasks such as question answering or paraphrase detection.

To obtain ELMO representation of each text, we computed average vector from 3 neural network layers, which resulted in a vector of 512 numbers. In the second step, these vectors were used to classify sentiment of an input text. Here, we experimented with multiple well-known machine learning methods such as Logistic Regression (LR), Random Forest (RF) with 200 trees and Support Vector Machine classifier (SVC) with a linear kernel. Each of these variants is subsequently marked as ELMO-LR, ELMO-RF and ELMO-SVC.

3.4 BERT

BERT is an example of the newest generation of pre-trained neural networks based on transformer architecture (Devlin et al., 2018). BERT acronym stands for Bidirectional Encoder Representations from Transformers, also obtained state-of-the-art results on multiple NLP tasks such as natural language inference and question answering. BERT model comes pre-trained on a very large corpus of unlabeled data, can be subsequently fine-tuned to a task with a limited amount of data such as sentiment analysis.

In our experiments we used smaller version of BERT. It contains 110M parameters and has support for 104 languages, 12 layers, the size of each hidden layer is 768, 12 self-attention heads (bert-base-multilingual-cased). We set maximum sequence length parameter to 128, which is enough to cover several sentences, and tested 3 and 4 training epochs. We tested BERT in a scenario which adds a sequence classification head on top. BERT Transformer is pre-trained, the sequence classification head is only initialized and has to be trained.

4 Results

This section illustrates the results of three experimental modes tested in our paper.

4.1 In-Domain

In the first mode (in-domain), we examine the performance of models trained and tested on the same text collection using standard cross-validation. On one hand, the performance of in-domain is driven up by lexical and structural similarity: training data are likely to be similar to test data in terms of vocabulary and syntactic structures. On the other,

Table 3: One vs rest cross-domain accuracy

models do not utilize information contained in other available data sets.

The results of this mode are presented in Table 2. The best results were achieved by BERT (two treebank datasets: jun18 and neg) and SVC classifier (treebank dataset sklad, twitter and filmweb). Except for filmweb data set with over 30% discrepancy between the best and worst methods, the differences between methods were not large, usually did not exceed several percents.

On the whole TW sentiment treebank (marked as all-TW) the surprising winer was Naive Bayes, that managed to outperform other methods including BERT by a small margin.

4.2 One vs Rest Cross-Domain

In the second mode (one vs rest cross-domain) we train models on all available data except the given test collection, which we use as a test set. In this mode, models did not have a chance to learn from data similar to test data (maybe except some parts of TW treebank which may be considered similar). However, can utilize and possibly benefit from information contained in all other data sets available. Table 3 presents the results of one vs rest cross-domain experiments. In this mode, the best performers were BERT (the best results for 5 out 7 data sets) and surprisingly, Naive Bayes algorithm (best performance for 4 out of 7). Recurrent neural networks (NN) did not manage to reach state-of-the-art results, however it is easy to notice strong positive influence of pre-trained word2vec word embeddings (NN+E), with accuracy gains from several to as much as twenty percentage points in the case of twitter. One can also note that the performance of ELMO with Random Forest (ELMO+RF) is significantly better than the two other ELMO variants we tested.

4.3 One vs One Cross-Domain

	all-TW	tweets	filmweb
all-TW	-	70.4%	15.3%
tweets	85.4%	-	30.6%
filmweb	30%	30%	-

Table 4: One vs one cross-domain accuracy of BERT method

	all-TW	tweets	filmweb
all-TW	-	67.9%	32.1%
tweets	79.1%	-	37%
filmweb	38.9%	30.5%	-

Table 5: One vs one cross-domain accuracy of NB method

In the third mode (one vs one cross-domain), we train a model on one data set and apply it to another one, repeating for each combination. In this mode we tested only the highest performing methods, such as BERT and Multinomial Naive Bayes. In this experiment we merged all sub-parts of the sentiment treebank (jun18, neg, polevaltest, rev, sklad) into one data set presented as TW. It consists of 2500 sentences.

Table 4 contains one vs one results for BERT classifier. Rows refer to test data sets and columns to train data sets. As we can see, the accuracy of 85.4% on tweets with models trained on TW is high and identical to SVC of in-domain 5-fold cross-validation and also identical to BERT in one vs rest mode. The performance on filmweb indicates that the models did not start to learn effectively. Training on filmweb did not help the performance on TW treebank (only 15.3%). Since filmweb dataset is reasonable in size and balanced, we can only hypothesize that the language is too different.

Table 5 contains one vs one results for Naive Bayes classifier. As before, rows refer to test data sets and columns to train data sets. In some cases Naive Bayes outperformed BERT. It was the case with training on filmweb movie reviews, models trained on this data set performed better than BERT both on tweets and on sentiment treebank TW. Also in the scenario of training on TW and testing on filmweb, Naive Bayes turned out to be better.

5 Conclusions and Future Work

The main point of this paper was to use all available Polish language data sets to seek the best possible performance in supervised sentiment analysis of short texts. We compared three generations of methods: machine learning with bag-of-words representation, recurrent neural networks (with and without pre-trained word embeddings) and finally deep neural networks pre-trained on language modeling task, including the newest transformer architecture BERT.

In sentiment classification, data available at training time is often different from data we intend to analyze in production environments. Ideally, classifiers should be capable of predicting sentiment on multiple types of data, covering various topics and texts of varied length without the need of re-training. In practice, achieving the best possible performance requires training or re-training on data very similar to those we intend to analyze.

To explore the limits of this approach we experimented with cross-domain setting in which we train the model on one text type and apply it to another text type (one vs one cross-domain). We confirmed that this setting poses a problem often leading to substantial performance degradation.

Using several sentiment-labeled data sets as training data may in theory improve classifier's accuracy and robustness. In our paper we investigated possible benefits from training models on data less similar to the test set (cross-domain one-vs-rest mode) and compared this to model training on smaller amounts of highly similar data (in-domain, models trained on the same type of data).

We found that for some data sets (TW treebank sub-sets, twitter) the results are comparable for cross-domain and in-domain setting, while for movie reviews in-domain setting turned out to be almost 30% better. Here, similar training data played a more significant role than using other less similar data sets to learn from. The best-performing in-domain method turned out to be somewhat old SVC with simple bag-of-words representation.

BERT, transformer-based neural network with pre-training, turned out to benefit from large amounts of less similar data, with top performance in one-vs-rest cross-domain setting. Interestingly, multinomial Naive Bayes method turned out to perform on a very similar level with far less model parameters, which may be a viable alternative in more speed oriented environments without GPU processors.

Some of the issues raised in this paper are worth pursuing in further work. The first problem is the amount of pre-training and architecture changes needed to reach acceptable cross-domain performance. Apparently, this problem has still not been solved and more efforts are needed to reach high accuracy.

The second problem worth investigating is the matter of how suitable are sentiment treebanks, designed for experiments on within-sentence compositional sentiment phenomena (for example, studying sentiment propagation in sentence structure or mixed sentiments) for predicting single label of sentence-level sentiment. As a part of this future study, we intend to compare the performance of Tree-LSTM methods such as those reported in PolEval 2017 (Wawer and Ogrodniczuk, 2017) on sentence-level sentiment with methods reported in our work.

Abstract

Gold standard corpora and competitive evaluations play a key role in benchmarking named entity linking (NEL) performance and driving the development of more sophisticated NEL systems.

The quality of the used corpora and the used evaluation metrics are crucial in this process. We, therefore, assess the quality of three popular evaluation corpora, identifying four major issues which affect these gold standards: (i) the use of different annotation styles, (ii) incorrect and missing annotations, (iii) Knowledge Base evolution, (iv) and differences in annotating co-occurrences. This paper addresses these issues by formalizing NEL annotations and corpus versioning which allows standardizing corpus creation, supports corpus evolution, and paves the way for the use of lenses to automatically transform between different corpus configurations. In addition, the use of clearly defined scoring rules and evaluation metrics ensures a better comparability of evaluation results.

1 Introduction

Named Entity Linking (NEL) systems identify mentions of named entities and link them to Knowledge Bases (KBs) (Ji et al., 2017). Their evaluation heavily depends upon annotated gold standards and competitions such as TAC-KBP (Ji et al., 2017) or Open Knowledge Extraction (Nuzzolese et al., 2016) which help drive research and advance the state of the art. Knowledge Bases, annotation guidelines and gold standards, NEL tools, as well as the evaluation systems themselves, were found to introduce errors into NEL evaluations (Braşoveanu et al., 2018). The most critical issues are related to corpora quality due to wrong, partial or insufficient annotations (van Erp et al., 2016; Jha et al., 2017). Annotation guidelines used to produce a gold standard come with different rules for describing whether the annotation systems should take into account overlapping mentions, co-references or general concepts mentioned in a KB (Rosales-Méndez et al., 2018). These guidelines are domain-specific and often depend on the application and task-specific context. Semantic search, for instance, would not require co-references, but they are relevant for relation extraction tasks (Rosales-Méndez et al., 2018).

The mentioned issues can be approached from various angles. General improvements such as a clear definition for NEL will affect multiple components of a NEL system. More specific suggestions, such as KB refinements typically affect only corpora that link entities to that particular KB. In all these cases the objective should be improving the quality and transparency of both the corpus and the evaluation processes.

A serious issue with current NEL evaluations is the lack of flexibility during the evaluation process which forces NEL systems to adapt to the used evaluation corpora. For example, if a KB has more name variants (e.g., Bobby Kennedy and RFK for Robert F. Kennedy) than the corpus annotators have considered, NEL systems able to correctly detect these name variants will be penalized since they do not occur in the corpus and are, therefore, considered errors. This paper, therefore, suggests solutions such as lenses (Section 3) and corpus versioning (Section 4.2) to address this issue. In particular, our main contribution is describing the innovations that can be applied at a corpus and evaluation systems level in order to create more flexible and expressive evaluations.

Proceedings of Recent Advances in Natural Language Processing, pages 1328–1337,
Varna, Bulgaria, Sep 2–4 2019.

The rest of the paper is organized as follows: Section 2 describes related work; Section 3 collects empirical evidence for common issues with NEL corpora and provides a concise problem description; Section 4 presents our approach towards building flexible evaluation systems; whereas the final section discusses the conclusions.

2 Related Work

An early analysis on the effect entity overlap between different data sets, confusability (the number of meanings a surface form can take) and dominance in several data sets was performed in (van Erp et al., 2016). Most current gold standards are known to suffer from *annotation mistakes*, *lack of updates* (typically due to the fact that there are no clear updating guidelines or funds for this operation), *popularity bias* (tools return most popular candidates), *small volume* (only several hundred examples), and are typically focused on a small set of languages (Ngomo et al., 2018).

Early methods to improve the quality and speed of human annotations have included: dynamic sentence selection in combination with iterative pre-annotation and qualitative checks (Tsuruoka et al., 2008) or crowdsourcing (Sabou et al., 2014); whereas more recent techniques include hypergraphs in order to highlight various name variants (Katiyar and Cardie, 2018). Several recent linguistic-driven techniques for improving gold standard quality discussed in (Sakor et al., 2018) include effect of capitalization, of implicit/explicit entities, of number of words or hidden relations. Automatically generated benchmarks like those provided with BENGAL (Ngomo et al., 2018) can help improve annotation speed, but only if deployed together with advanced debugging and error analysis tools, as otherwise there will be a risk of increasing bias.

A set of KB improvements can also be devised to aid domain experts and NEL systems in identifying mentions of named entities. KBs, for example, can be used to expand upon the number of name variants from a corpus by including multiple annotations for each entity to cover cases of embeddings, overlap and extensions (Odoni et al., 2018). At the named entity disambiguation level, such techniques include collecting all name variants from multiple Knowledge Graphs (Ehrmann et al., 2016) or using hypergraphs and multi-layer bi-LSTMS to detect the nested entities (Katiyar and Cardie, 2018).

The lack of parallel language corpora like Europarl (Koehn, 2005) for NEL (except for some smaller corpora like MeanTime (Minard et al., 2016)) is another serious issue that is rarely discussed, though such corpora are available for NER (Agerri et al., 2018).

3 Lenses and Corpus Quality

Today's NEL evaluation tools automatically compare the performance of multiple NEL systems on various data sets using a wide variety of experiments (e.g., NER - Named Entity Recognition, Entity Typing, D2KB - matching entity mentions to certain KB, etc) and indicators (e.g., precision, recall, F1, accuracy, etc). GERBIL (Röder et al., 2018) and its extensions (Waitelonis et al., 2019) were designed to support multiple experiment types using black box evaluation techniques. The neleval system (Hachey et al., 2014) based on the TAC-KBP guidelines provides primary error explanations. As an alternative, visual evaluation systems such as Orbis (Odoni et al., 2018) and VEX (Heinzerling and Strube, 2015), also allow close inspection of the evaluation results and help designers improve system performance. Upon analyzing these packages, we came to the conclusion that none of them provides suitable tools for handling multiple annotation styles and updating gold standards. Therefore, reuse of old gold standards can lead to problematic results (e.g., entities declared NIL in the gold can currently exist in the current KB version and can be retrieved by annotator tools) or even unfair evaluations (e.g., tools that use an old KB should not be compared with those who use the latest updates).

We think NEL systems should be evaluated against both updated gold standards and KBs, therefore we suggest the application of lenses over the existing data, i.e. transformations between different KB versions (e.g., DBpedia 2015-10 and DBpedia 2017-10), KBs (e.g., DBpedia and Wikidata) and annotation styles (e.g., always take the longest strings or only annotate non-NIL entities). The following section presents an analysis of three popular NEL corpora, discusses different use case for lenses and the corresponding transformation rules that are required to transfer corpora from one representation to the other.

3.1 Corpus Quality

Creating high quality gold standard data is a difficult task due to: (i) *incomplete annotation rules* - i.e. cases that have not been properly covered in the annotation rules; (ii) *errors* - present on multiple levels, from human or automated annotation errors, to process errors (e.g., errors in the annotation guidelines) or KB errors; as well as (iii) *decay* - KBs used for the annotation might become obsolete or outdated, forcing the corpus maintainer to consider KB evolution or even KB migration.

In order to understand the extent to which a corpus may require updating, we have analyzed several well-known corpora from our field: (i) *OKE2016 Task 1* (Nuzzolese et al., 2016) - focuses on short biographical sentences extracted from Wikipedia; (ii) *Reuters128* (Röder et al., 2014) - a set of texts extracted from the classic Reuters corpora; and (iii) the English partition of the *MeanTime* (Minard et al., 2016) corpus that covers events extraction.

Table 1 illustrates several attributes related to the number of entities in a corpus that directly reflect *incomplete annotation rules*, *errors* and *decay*: (i) the number of original annotations; (ii) the number of NIL annotations at publication date; (iii) updated NIL counts which indicate the impact of KB evolution; (iv) count of potential overlaps within the original annotations that need to be handled according to the used annotation guidelines; (v) potential missing entities based on the annotation the guideline (if such a document exists).

Empty columns (marked with -) were not filled due to lack of available data or guideline. Counts from rows (i) and (ii) were taken directly from the corpora; row (iii) count was estimated based on SPARQL queries that aim at linking NIL entities to the KB; and counts for columns (iv) and (v) were estimated based on annotating samples from each data set.

Two annotators have independently annotated a quarter of the documents that have been selected using random sampling. Only the entities mentioned in the article or guideline related to a data set were used for the respective counts (e.g., Reuters128 was only annotated with Person (PER), Organization (ORG) and Location (LOC) based on (Röder et al., 2014)). The analysis only considers NIL entities that were marked as such (e.g., NIL or similar designation). Consequently, the OKE 2016 counts shows no NIL entities, since they were not included in the original dataset. The updated NIL counts are obtained by using SPARQL queries that determine whether NIL entities have become available in new KB versions.

Table 2 examples were extracted from the Reuters128 corpus and illustrate (i) missing and wrong groundings, (ii) KB evolution, and (iii) surface forms deviations due to different annotation rules.

Overlaps tend to appear in cases related to LOC and ORG entities. Quite often, an overlap is identified in long names such as *Chattanooga State Technical College* or *City University of New York Graduate Center*. In similar cases a surface form expansion that will contain the longest possible string should correctly match the entity from the gold standard. Complicated cases like the following: *Loyola's University in Belgium, Economics* (from OKE2016) can be interpreted in multiple ways. This example can either be rendered as (i) one long entity that corresponds to the whole string; (ii) one entity that describes the University (*Loyola's University in Belgium*); (iii) two entities (*Loyola's University* and Belgium); (iv) two entities again (*Loyola's University in Belgium* and a string *Economics*); even (v) three entities (*Loyola's University* and *Belgium* and *Economics*). The phrasing of the examined sentence suggests that the fourth version is the correct one. Without a thorough text analysis such instances are extremely difficult to disambiguate for both humans and machines.

Even if we leave aside difficult cases that typically show a low inter-rater agreement such as *Potential Overlap* (Table 1, row iv; e.g., agreement of 0.40 for Reuters128) or *confusability* (van Erp et al., 2016), there are still many mentions that are not spotted in the original corpus such as those from the *Missing Entities Guideline* (Table 1, row v) for which experts also exhibit better inter-rater agreements (e.g., 0.61 for Reuters128).

These findings suggest that the methods and processes used for annotating documents need to be updated. Applying lenses would be one of the methods that could address some of the mentioned shortcomings, as they would help both accounting for multiple points of views when annotating, as well as for KB evolution. Such lenses coupled with well-defined metrics for measuring NEL performance are key towards reliably assessing a system's performance and driving its development.

No	Rule	OKE2016	Reuters128	MeanTime
i	Original Annotation ALL	176	880	853
ii	Original NIL Only	-	230	554
iii	Updated NIL Count	-	175	465
iv	Potential Overlap	84	104	221
v	Missing Entities Guideline	76	180	272

Table 1: Estimated entity counts based on different criteria in three corpora. All data sets are in English.

surface	gold link	correct link	error
[Volkswagen AG] **[VOWG.F]**, [VW], is due ...	NIL	dbr:Volkswagen	Missing Annotation
bid for **[Avondale Mills]** ...	NIL	dbr:Avondale_Mills	KB evolution
[The Chicago Mercantile Exchange], **[CME]**, said ...	dbr:CME_Group	dbr:Chicago _Mercantile_Exchange	Incorrect Link
... of **[Salem**, Ore.]	dbr:Salem,_Oregon	dbr:Salem,_Oregon	Different surface form

Table 2: Examples of dataset errors. Gold entity spans are marked by parentheses. Errors are presented in bold. Abbreviations or tickers should be separate entities. Locations can include states.

3.2 Context-Specific and Application-Specific Transformation Rules for Lenses

A named entity linking system links a mention $m_{[s_i]}^{e_i,KB}$ or $m_{[x_i,y_i]}^{e_i,KB}$ of a named entity with surface form s_i within a document d to the corresponding entity e_i in a knowledge base KB. The variable x_i indicates the mention's start position within the document and y_i the corresponding end position.

Mentions may overlap and the specification of the knowledge base KB can be omitted, if it is not relevant for the application (e.g. if we do not consider different KB versions in the given use case).

The system distinguishes between

1. $m_{[s_i]}^{e_i,KB}$ surface forms s_i that were linked to an entity e_i within a knowledge base KB,
2. $m_{[s_i]}^{nil}$ mentions of Named Entities (NEs) that are not available in the KB and, therefore, are not linked (i.e. NIL entities), and
3. $m_{[s_i]}^{\emptyset}$ candidate mentions with surface form s_i that do not refer to a named entity.

3.2.1 Different Annotation Styles

Annotation styles specify rules that aid annotators in assessing if (i) a candidate mention should be considered a mention of a named entity, and (ii) the extent of the corresponding surface form.

Although a trivial design decision for isolated mentions, the consistent handling of nested mentions requires more thought. For instance, the text snippet *University of Western Australia Cricket Club* may contain, dependent on the applied annotation rule, up to four overlapping mentions (*Australia*, *Western Australia*, *University of Western Australia*, *University of Western Australia Cricket Club*). In addition, annotation styles might be entity type specific even within a single corpus.

We consider the following three annotation styles, as illustrated based on the annotation of the text snippet *Vienna, VA*:

1. *∅MIN* disregards overlapping entities and tries to extract the minimum number of entities: $m_{\text{[Vienna, VA]}}^{dbr:Vienna,\_Virginia}$, i.e. links the snippet to the *Vienna, Virginia* DBpedia entity.
2. The annotation style *∅MAX*, in contrast, extracts the maximum number of entities from a given text snippet: $m_{\text{[Vienna]}}^{dbr:Vienna,\_Virginia}$, $m_{\text{[VA]}}^{dbr:Virginia}$
3. The style *OMAX* allows for overlaps and, again, extracts the maximum number of entities: $m_{\text{[Vienna, VA]}}^{dbr:Vienna,\_Virginia}$, $m_{\text{[VA]}}^{dbr:Virginia}$

The presented rules only consider borderline cases, even though combinations of them can also be used within a corpus. For instance, a corpus might use the *OMAX* rule for LOC entities but apply *∅MIN* for all other entity types, therefore only yielding $m_{\text{[ETH Zurich]}}^{dbr:ETH\_Zurich}$ rather than

$m^{dbr:ETH\_Zurich}_{\text{[ETH Zurich]}}$ and $m^{dbr:Zurich}_{\text{[Zurich]}}$ for the text snippet *ETH Zurich.*

Table 3 outlines transformation rules between different annotation styles.

3.2.2 Knowledge Base Evolution

Lenses are also able to capture KB evolution, i.e. the case where a KB evolves due to changes or extended coverage of the underlying domain. Changes to the KB may

1. introduce new entities (e.g. the company Alphabet Inc. in October 2015),
2. lead to the deletion of entities that are no longer considered relevant, or
3. drive the introduction of a more fine grained or coarser mapping for existing entities.

Table 4 introduces the corresponding transformation rules. Newly introduced entities may enable the grounding of *NIL* entities to the extended knowledge base. The removal of an entity, in contrast, may transform an existing grounding to a *NIL* entity since the corresponding KB entity is no longer available. Finally, changes in granularity may either lead to the introduction of additional entities, or to the deletion of links to the KB.

3.2.3 Knowledge Base Migration

KB migration is the case in which a corpus that has been initially annotated with one KB is used to evaluate a component that links mentions to another KB. Many well maintained knowledge bases such as DBpedia, GeoNames and Wikidata contain links to indicate equivalent entities (e.g., *owl:sameAs*, *skos:exactMatch*, etc). These links and techniques such as ontology alignment may be used to automatize the transformation of a mentions $m^{e_i,KB}_{[x_i,y_i]}$ within a KB (KB) to the corresponding mention $m^{e_i,KB'}_{[x_i,y_i]}$ in the target KB (KB'). KB migration draws at the same set of transformation rules as the KB evolution use case.

3.2.4 Co-references

Co-references play a crucial role in natural language processing tasks such as relation extraction. A co-reference is a mention with surface form s'_i that refers to the same entities e_{ij} as other mentions $m^{e_{ij}}_{[s_{ij}]}$ within the document. Its surface form often contains prepositions or noun-phrases that on their own do not provide enough context to determine the referred entities e_{ij}. For anaphora and cataphora the co-reference $m^{e_i,KB}_{[s_i]}$ points to a single entity, for split antecedents the co-reference refers to multiple NEs. For instance, in the text: *"Berlin, Rome and Paris are capitals of European countries. These cities are also popular tourist destinations."* the surface form *These cities* refers to three previous named entities and is, therefore, annotated as $m^{dbr:Berlin}_{\text{[These cities]}}$, $m^{dbr:Rome}_{\text{[These cities]}}$ and $m^{dbr:Paris}_{\text{[These cities]}}$. Systems and corpora that do not support co-reference resolution, therefore, consider co-references as candidate mentions $m^{\emptyset}_{[s_i]}$ that do not link to any named entity.

3.3 Limitations of Corpus Transformation with Lenses

The rules outlined in the previous section can be used to translate between different corpus representations. Translations from expressive representations to less expressive ones can be done automatically and exposed to users as lenses. For example, a transformation from the OMAX to the ∅MIN annotation style, from a corpus with annotated co-references to a corpus which does not considers them, and the KB migration use case for NIL entities may be performed automatically.

Otherwise, corpus versioning (Section 4.2) is required to record any changes added by manual or semi-automatic processes.

4 Method

This section discusses options for improving corpus quality by (i) introducing semi-automatic tools that support corpus creation and evaluation by automatically spotting violations of the annotation style and suspicious entities (Section 4.1), and (ii) suggesting guidelines for versioning corpora ensuring that improvements and extensions are incorporated in a meaningful and backward compatible way (Section 4.2).

4.1 Corpus Analysis Tools

Software developers frequently use static code analysis tools such as pylint[1], findbugs[2] and checkstyle[3] as part of the build pipeline to enforce coding style guidelines and to spot potential bugs in an early stage.

[1] www.pylint.org

[2] findbugs.sourceforge.net

[3] checkstyle.sourceforge.net/

Table 3: Lense transformation rules between different annotation styles.

Annotation style	∅MIN	∅MAX	OMAX
Corpus entity	$m^{e_1,KB}_{[x1,y1]}$	$m^{e_1,KB}_{[x1,y11]}, \dots, m^{e_n,KB}_{[x1n,y1]}$	$m^{e_1,KB}_{[x1,y1]}, \dots, m^{e_n,KB}_{[x1,y1]}$
Transformation to			
∅MIN	$m^{e_1,KB}_{[x1,y1]}$	$m^{e_1,KB}_{[x1,y1]}$	$m^{e_1,KB}_{[x1,y1]}$
∅MAX	$m^{e_1,KB}_{[x1,y11]}, \dots, m^{e_n,KB}_{[x1n,y1]}$	$m^{e_1,KB}_{[x1,y11]}, \dots, m^{e_n,KB}_{[x1n,y1]}$	$m^{e_1,KB}_{[x1,y11]}, \dots, m^{e_n,KB}_{[x1n,y1]}$
OMAX	$m^{e_1,KB}_{[x1,y1]}, \dots, m^{e_n,KB}_{[x1,y1]}$	$m^{e_1,KB}_{[x1,y1]}, \dots, m^{e_n,KB}_{[x1,y1]}$	$m^{e_1,KB}_{[x1,y1]}, \dots, m^{e_n,KB}_{[x1,y1]}$

Table 4: Lense transformation rules for knowledge base evolution and knowledge base migration.

Task	new entity	deleted entity	more fine grained entity mapping	coarser entity mapping
Corpus entity	$m^{nil,KB}_{[x_i,y_i]}$	$m^{e_i,KB}_{[x_i,y_i]}$	$m^{e_i,KB}_{[x_i,y_i]}$	$m^{e_{i1}}_{[x_{i1},y_{i1}]}, \dots, m^{e_{in},KB}_{[x_{in},y_{in}]}$
Transformation	$m^{e_i,KB'}_{[x_i,y_i]}$	$m^{nil,KB'}_{[x_i,y_i]}$	$m^{e_{i1},KB'}_{[x_{i1},y_{i1}]}, \dots, m^{e_{in},KB'}_{[x_{in},y_{in}]}$	$m^{e_i,KB'}_{[x_i,y_i]}$

We strongly believe that similar tools could be highly beneficial for aiding researchers in the creation and validation of NLP corpora, by

1. automatically locating violations of annotation styles (e.g. overlaps in case of a non-overlapping annotation style).

2. drawing upon POS tagging and dependency parsing for marking unusual annotations such as NEs that do not contain a noun to flag potentially incorrect annotations.

4.2 Corpus Versioning

Even corpora that are frequently used in NEL evaluation suffer from quality issues (see Table 1). Although addressing these issues is important, backward compatibility of refined corpora is key to their usefulness since it ensures that results can be compared to previously published work.

We, therefore, suggest corpus versioning to promote the improvement of corpora. Publishing multiple corpus versions will enable researchers to run evaluations against these versions and, therefore, provides means to compare the gathered results to other work.

Corpus versioning is needed for cases where an automatic translation to the desired gold standard representation via lenses is not feasible:

- addressing data quality issues and mistakes in the original corpus,

- the linking of *NIL* entities to a knowledge base entity due to knowledge base evolution or knowledge base migration, and

- a new more expressive annotation style.

Versioning should enable researchers to address these issues while ensuring

- a clear relation to the original corpus that makes comparison with previous versions feasible;

- support for multiple versions and version trees that have been contributed by different people and organizations (Figure 1)

- that corpus metadata provides (i) information on the relations between different corpus versions, (ii) easily traceable contributions, (iii) credits for contributors, and (iv) easy re-use of refined corpora for further evaluations;

- easily accessible corpus versions, e.g. by uploading them to research data platforms and providing a digital object identifier (DOI) for each version, so that researchers can easily cite, locate and re-use corpora.

Table 5: Lense transformation rules for co-reference resolution.

Task	single co-reference	split antecedents
Corpus entity	$m^{e_i}_{[s'_i]}$	$m_{[s'_i}]^{e_{i1}}, \dots m_{[s'_i}]^{e_{in}}$
No co-reference resolution	$m^{\emptyset}_{[s'_i]}$	$m^{\emptyset}_{[s'_i]}$

Table 6: Suggested corpus metadata

Metadata	Description	Example
corpus_name	A name that identifies the corpus.	OKE2018
corpus_url	The corpus archive URL.	http://github.com/fhgr/oke2016-dbpedia-2019-02-01_v1.zip
creator	A comma-separated list of persons or organizations that created the corpus.	Sue May <sue@myorg.edu>
date	The corpus's publishing date.	2019-05-30
description	A description of the current corpus version.	Adapted OKE2016 to DBpedia 2019-02-01 and integrated bug fixes from 2018-03-07.
final	Is it usable for official evaluations?	false
parent_corpus_url	The URL of the parent corpus (if any)	http://github.com/fhgr/oke2016-dbpedia-2018-09-03_v2.zip
considers_corpus_url	A list of URLs pointing to related corpus versions.	http://github.com/sue/oke2016-dbpedia-fixes-2018-03-07.zip
annotation_style	A list of annotation styles per supported named entity type.	PER: NOMIN, GEO: OMAX, ORG: OMIN
annotators_per_document	Number of annotators per document.	3
annotator_agreement	Inter-rater-agreement between annotators computed using the Fleiss' kappa.	0.61

The key here is making evaluations easier to replicate and increase the benefit they provide to the community. Currently evaluations are often tightly designed to a specific context such as a competition or an application domain. These kinds of results are helpful for determining the best performing system under tight restrictions, but they unnecessarily restrict the scope of the evaluation. For instance, such results do not provide information on how systems cope with different annotation rules, settings and use cases. Automatically performing evaluations with all available lenses, corpus versions and scoring rules (Section 4.3) could address this issue. Scientists could still publish the results for their particular application context in the research paper but would in addition provide a DOI to the full results that cover also settings for which their system hasn't been optimized. Ultimately such an approach would improve the usefulness of evaluations since it would provide (i) much more context on the strengths and weaknesses of NEL systems, and (ii) broader insights into the effects of the suggested methods and design decisions.

4.2.1 Publishing a Corpus Version

We recommend a standardized directory structure for publishing corpora that contains:

1. a `corpus` directory containing all corpus data and annotations in the NIF format.
2. a `METADATA.yaml` file that describes the corpus based on the metadata introduced in Table 6.
3. a `README.md` file which provides additional unstructured information.

Popular version control services such as github and gitlab offer a release feature that automatically

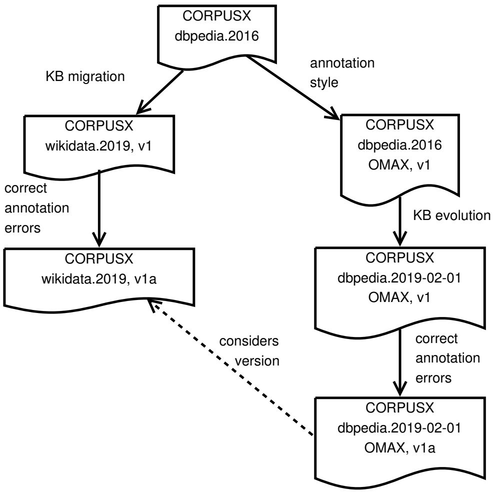

Figure 1: Common corpus versioning use cases.

publishes an archive of the released repository version which can be used to publish a certain corpus version. Another option would be publishing corpus versions in research data repositories such as zenodo.org which also provide a DOI and bibliographical metadata to data artifacts.

4.3 Scoring Rules

Scoring rules outline the conditions under which a gold standard corpus mention $m^c := m^{e_c,KB}_{[x_c,y_c]}$ and a mention returned by the NEL system $m^s := m^{e_s,KB}_{[x_s,y_s]}$ are considered equivalent to each other. The following three scoring rules are frequently used in NEL evaluations:

1. perfect match $\mathcal{P}$ - the entities refer to the same KB entity e_i, and the exactly same surface form s_i.

2. contained match $\mathcal{C}$ - both entities refer to the same KB entity e_i and the surface form of the mention returned by the NEL system m^s is contained in the surface form of the corpus mention m^c, i.e. $x^s_i \geq x^c_i$ and $y^s_i \leq y^c_i$.

3. overlapping match $\mathcal{O}$ - this case is equivalent to the contained match but further relaxes the restrictions on the surface form, so that even an overlap (i.e. $y^s_i \geq x^c_i$ and $x^s_i \leq y^c_i$) between entities is considered a valid match.

The used scoring rule have a significant impact on the computation of the NEL system's performance metrics such as precision and recall.

5 Conclusion

This paper discusses approaches for addressing the issues of corpus quality and the comparability of evaluations that have been performed with these corpora, together with associated annotations[4]. We discuss (i) factors that seriously affect the accuracy of evaluation corpora such as different annotation styles, missing and wrong annotations, KB evolution and co-reference handling.

In addition we also shed light on the issue of KB migration, which is relevant if the evaluation corpus and the NEL system use different KBs. Afterwards we (ii) introduce a formalization that captures these factors, and (iii) present transformation rules between different corpus configurations.

These transformation rules that expose different corpus configurations as lenses in conjunction with corpus analysis tools and corpus versioning are key towards improving corpus quality. Well-defined scoring rules and evaluation metrics are further steps towards standardizing evaluations and improving their validity and reproducibility.

Future research will focus on (i) applying these guidelines to the NEL evaluation of annotation of TV-related content in the ReTV project[5] so that results can be compared and evolved in the future if need be,(ii) the creation of tools that support corpus creation and evaluation processes, (iii) adding support for corpus versioning and the parallel analysis of multiple corpus versions to evaluation tools such as Orbis (Odoni et al., 2018) and GERBIL (Röder et al., 2018), and (iii) proving a research data infrastructure for publishing evaluation corpora and evaluations that have been performed on these corpora.

Abstract

We propose a method for non-projective dependency parsing by incrementally predicting a set of edges. Since the edges do not have a pre-specified order, we propose a set-based learning method. Our method blends graph, transition, and easy-first parsing, including a prior state of the parser as a special case. The proposed transition-based method successfully parses near the state of the art on both projective and non-projective languages, without assuming a certain parsing order.

1 Introduction

Dependency parsing methods can be categorized as graph-based and transition-based. Typical graph-based methods support non-projective parsing, but introduce independence assumptions and rely on external decoding algorithms. Conversely, transition-based methods model joint dependencies, but without modification are typically limited to projective parses.

There are two recent exceptions of interest here. (Ma et al., 2018) developed the Stack-Pointer parser, a transition-based, non-projective parser that maintains a stack populated in a top-down, depth-first manner, and uses a pointer network to determine the dependent of the stack's top node, resulting in a transition sequence of length $2n-1$. Recently, (Fernández-González and Gómez-Rodrguez, 2019) developed a variant of the Stack-Pointer parser which parses in n steps by traversing the sentence left-to-right, selecting the *head* of the current node in the traversal, while incrementally checking for, and prohibiting, cycles.

We take inspiration from both graph-based and transition-based approaches by viewing parsing as sequential graph generation. In this view, a graph is incrementally built by adding edges to an edge set. No distinction between projective and non-projective trees is necessary. Since edges do not have a pre-specified order, we propose a set-based learning method. Like (Fernández-González and Gómez-Rodrguez, 2019), our parser runs in n steps. However, our learning method and transitions do not impose a left-to-right parsing order, allowing easy-first (Tsuruoka and Tsujii, 2005; Goldberg and Elhadad, 2010) behavior. Experimentally, we find that the proposed method can yield a sequential parser with preferred, input-dependent generation orders and performance gains over strong one-step methods.[1]

2 Graph Dependency Parser

Given a sentence $x = x_1, \ldots, x_N$, a dependency parser constructs a graph $G = (V, E)$ with $V = (x_0, x_1, \ldots, x_N)$ and $E = \{(i,j)_1, \ldots (i,j)_N\}$, where x_0 is a special root node, and $E \subset \mathcal{E}$ forms a dependency tree.[2]

We describe a family of sequential graph-based dependency parsers. A parser in this family generates a *sequence* of graphs where V is fixed and $E = \bigcup_{t=1}^{T} E_t$:

$$H^{\text{enc}} = f_{\text{enc}}(x_0, \ldots x_N) \quad (1)$$

$$H_t^{\text{head}}, H_t^{\text{dep}} = f_{\text{V}}(H^{\text{enc}}, E_{<t}, h_{t-1}) \quad (2)$$

$$S_t = f_{\text{E}}(H_t^{\text{head}}, H_t^{\text{dep}}, S_{t-1}) \quad (3)$$

$$E_t = f_{\text{dec}}(S_t, E_{<t}). \quad (4)$$

Steps (2-4) run for $T \le N$ time-steps. At each time-step, first f_V generates head and dependent

[1] Code will be made available at https://github.com/wellecks/nonmonotonic_parsing.

[2] See properties (1-5) in Appendix A.

representations for each vertex, $H_t^{\cdot} \in \mathbb{R}^{V \times d_H}$, based on vertex representations $H^{\text{enc}} \in \mathbb{R}^{V \times d}$, previously predicted edges $E_{<t}$, and a recurrent state $h_{t-1} \in \mathbb{R}^d$. Then f_E computes a score for every possible edge, $S_t \in \mathbb{R}^{V \times V}$, and the scores are used by f_{dec} to predict a set of edges E_t.

This general sequential family includes the biaffine parser of (Dozat and Manning, 2017) as a one-step special case, as well as a recurrent variant which we discuss below.

2.1 Biaffine One-Step

The Biaffine parser of (Dozat and Manning, 2017) is a one-step variant, implementing steps (1-4) using a bidirectional LSTM, head and dependent neural networks, a biaffine scorer, and a maximum spanning tree decoder, respectively:

$$\begin{aligned} H^{\text{enc}} &= \text{BiLSTM}(x_1, \ldots, x_N) \\ H^{\text{head}}, H^{\text{dep}} &= \text{MLP}^{\text{h}}(H^{\text{enc}}), \text{MLP}^{\text{d}}(H^{\text{enc}}) \\ S &= \text{BiAffine}(H^{\text{head}}, H^{\text{dep}}) \\ E &= \text{MST}(S), \end{aligned}$$

where each row of scores $S^{(i)}$ is interpreted as a distribution over i's potential head nodes:

$$p((j \rightarrow i)|x) \propto \text{softmax}_j(S^{(i)}),$$

and $\text{MST}(\cdot)$ is an off-the-shelf maximum-spanning-tree algorithm. This model assumes conditional independence of the edges.

2.2 Recurrent Weight

We propose a variant which iteratively adjusts a distribution over edges at each step, based on the predictions so far. A recurrent function generates a weight matrix W which is used to form vertex embeddings and in turn adjust edge scores.

Specifically, we first obtain an initial score matrix S_0 using the biaffine one-step parser (2.1), and initialize a recurrent hidden state h_0 using a linear transformation of f_{enc}'s final hidden state. Then f_V is defined as:

$$\begin{aligned} W, h_t &= \text{LSTM}(f_{\text{emb}}(E_{t-1}), h_{t-1}) \\ H_t^{\text{head}} &= \text{emb}_h(0, \ldots, N)W \\ H_t^{\text{dep}} &= \text{emb}_d(0, \ldots, N)W, \end{aligned}$$

and $f_{\text{E}}(H_t^{\text{head}}, H_t^{\text{dep}}, S_{t-1})$ is defined as:

$$\begin{aligned} S_t^{\Delta} &= \text{BiAffine}(H_t^{\text{head}}, H_t^{\text{dep}}) \\ S_t &= S_{t-1} + S_t^{\Delta}, \end{aligned}$$

where t ranges from 1 to N, $W \in \mathbb{R}^{d_{\text{emb}} \times d_H}$, and each $\text{emb}_{(\cdot)} : \mathbb{N} \rightarrow \mathbb{R}^{d_{\text{emb}}}$ is a learned embedding layer, yielding $\text{emb}_{(\cdot)}(0, \ldots, N)$ in $\mathbb{R}^{V \times d_{\text{emb}}}$. We use a bidirectional LSTM as f_{enc}.

The scores at each step yield a distribution over all $V \times V$ edges, which we denote by π:

$$\pi((i \rightarrow j)|E_{<t}, x) \propto \text{softmax}(\text{flatten}(S_t)). \quad (5)$$

Unlike the one-step model, this recurrent model can predict edges based on past predictions.

Inference We must ensure the incrementally decoded edges $E = \bigcup_{t=1}^{T} E_t$ form a valid dependency tree. To do so, we choose f_{dec} to be a decoder which greedily selects valid edges,

$$E_t = f_{\text{valid}}(S_t, E_{<t}),$$

which we refer to as the **valid decoder**, detailed in Appendix A. We only predict one edge per step ($|E_t| = 1$), leaving the setting of multiple predictions per step as future work.

Embedding Edges We embed a predicted edge $E_t = \{(\widehat{i, j})\}$ as:

$$\begin{aligned} f_{\text{emb}}(E_t) &= e_{\text{edge}}; e_{\text{head}}; e_{\text{dependent}} \\ e_{\text{edge}} &= W_e H_{(i)}^{\text{enc}} - W_e H_{(j)}^{\text{enc}} \\ e_{\text{head}} &= \text{emb}_h(i) \\ e_{\text{dependent}} &= \text{emb}_d(j), \end{aligned}$$

where $H_{(\cdot)}^{\text{enc}} \in \mathbb{R}^d$ are row vectors, $W_e \in \mathbb{R}^{d_e \times d}$ is a learned weight matrix, $\text{emb}_{(\cdot)}$ are learned embedding layers, and ; is concatenation.

Future Work The proposed method does not specifically require a BiLSTM encoder, LSTM, or the BiAffine function. For instance, f_{V} could use a Transformer (Vaswani et al., 2017) to output states that are linearly transformed into H^{head} and H^{dep}. Additionally, partial graphs $(V, E_{<t})$ might be embedded using neural networks specifically designed for graphs (Gilmer et al., 2017). Finally, predicting edge sets of size greater than 1 could potentially be achieved using a partially-autoregressive model, trained with a 'masked

edges' objective, similar to recent work in machine translation with conditional masked language models (Ghazvininejad et al., 2019). Each call to f_V would involve a separate forward pass which calls a Transformer f_{enc}. The partial tree is encoded via non-masked inputs to f_{enc}. f_{E} corresponds to having V outputs, each a distribution over V edges. The multi-step decoder (Appendix A) might be used at test time.

3 Learning

In this paper, we restrict to the case of predicting a single edge $\widehat{(i,j)}$ per step, so that the recurrent weight model generates a sequence of edges with the goal of matching a target edge set, i.e. $\bigcup_{t=1}^{N} \widehat{(i,j)}_t = E$. Since the target edges E are a set, the model's generation order is not determined *a priori*. As a result, we propose to use a learning method that does not require a pre-specified generation order and allows the model to learn input-dependent orderings.

Our proposed method is based on the multiset loss (Welleck et al., 2018) and its recent extensions for non-monotonic generation (Welleck et al., 2019). The method is motivated from the perspective of learning-to-search (Daumé III et al., 2009; Chang et al., 2015), which involves learning a *policy* π_θ that mimics an *oracle policy* π^*. The policy maps *states* to distributions over *actions*.

For the proposed graph parser, an action is an edge $(i, j) \in \mathcal{E}$, and a state s_t is an input sentence x along with the edges predicted so far, $\hat{E}_{<t}$. The policy is a conditional distribution over $\mathcal{E}$,

$$\pi_\theta((i,j)|\hat{E}_{<t}, x),$$

such as the distribution in equation (5).

Learning consists of minimizing a cost, computed by first sampling states from a *roll-in* policy π^{in}, then using a *roll-out policy* π^{out} to estimate cost-to-go for all actions at the sampled states. Formally, we minimize the following objective with respect to θ:

$$\mathbb{E}_{x\sim\mathcal{D}}\mathbb{E}_{s_1,\ldots,s_{|x|}\sim\pi^{\text{in}}}\mathcal{C}(\pi_\theta, \pi^{\text{out}}, s_t). \tag{6}$$

This objective involves sampling a sentence x from a dataset, sampling a sequence of edges from the roll-in policy, then computing a cost $\mathcal{C}$ at each of the resulting states. We now describe our choices of $\mathcal{C}$, π^{out}, π^*, and π^{in}, and evaluate them later in the experiments (4).

3.1 Cost Function and Roll-Out

Following (Welleck et al., 2018, 2019) we use a KL-divergence cost:

$$\mathcal{C}(\pi_\theta, \pi^{\text{out}}, s) = D_{\text{KL}}(\pi^{\text{out}}(\cdot|s)||\pi_\theta(\cdot|s)). \tag{7}$$

We use the oracle π^* as the roll-out π^{out}.

3.2 Oracle

Based on the free labels set in (Welleck et al., 2018), we first define a *free edge set* containing the un-predicted target edges at time t:

$$E^t_{\text{free}} = E \setminus \bigcup_{t'=1}^{t-1} \widehat{(i,j)}_{t'}, \tag{8}$$

where $E^0_{\text{free}} = E$. We then construct a family of oracle policies that place non-zero probability mass only on free edges:

$$\pi^*((i,j)|E^t_{\text{free}}) = \begin{cases} p_{ij} & (i,j) \in E^t_{\text{free}} \\ 0 & \text{otherwise.} \end{cases} \tag{9}$$

We now describe several oracles by varying how p_{ij} is defined.

Uniform This oracle treats each permutation of the target edge set as equally likely by assigning a uniform probability to each free edge:

$$\pi^*_{\text{unif}}((i,j)|E^t_{\text{free}}) = \begin{cases} \frac{1}{|E^t_{\text{free}}|} & (i,j) \in E^t_{\text{free}} \\ 0 & \text{otherwise.} \end{cases}$$

Coaching Motivated by (He et al., 2012; Welleck et al., 2019), we define a coaching oracle which weights free edges by π_θ:

$$\pi^*_{\text{coaching}}((i,j)|E^t_{\text{free}}) \propto \pi^*_{\text{unif}}(\cdot|E^t_{\text{free}})\pi_\theta(\cdot|E_{<t}, X).$$

This oracle prefers certain edge permutations over others, reinforcing π_θ's preferences. The coaching and uniform oracles can be mixed to ensure each free edge receives probability mass:

$$\beta\pi^*_{\text{unif}} + (1-\beta)\pi^*_{\text{coaching}}, \tag{10}$$

where $\beta \in [0, 1]$.

Annealed Coaching This oracle begins with the uniform oracle, then anneals towards the coaching oracle as training progresses by annealing the β term in (10). This may prevent the coaching oracle from reinforcing sub-optimal permutations early in training.

Linearized This oracle uses a deterministic function to linearize an edge set E into a sequence E_{seq}. The oracle selects the t'th element of E_{seq} at time t with probability 1. We linearize an edge set in increasing edge-index order: (i_1, j_1) precedes (i_2, j_2) if $(i_1, j_1) < (i_2, j_2)$. This oracle serves as a baseline that is analogous to the fixed generation orders used in conventional parsers.

3.3 Roll-In

The roll-in policy determines the state distribution that π_θ is trained on, which can address the mismatch between training and testing state distributions (Ross et al., 2011; Chang et al., 2015) or narrow the set of training trajectories. We evaluate several alternatives:

1. **uniform** $(i, j) \sim \pi^*_{\text{unif}}$
2. **coaching** $(i, j) \sim \pi_\theta \odot \pi^*_{\text{unif}}$
3. **valid-policy** $(i, j) \sim \text{valid}(\pi_\theta)$

where valid(π_θ) is the set of edges that keeps the predicted tree as a valid dependency tree. The coaching and valid-policy roll-ins choose edge permutations that are preferred by the policy, with valid-policy resembling test-time behavior.

4 Experiments

In Experiments 4.1 and 4.2 we evaluate on English, German, Chinese, and Ancient Greek since they vary with respect to projectivity, size, and performance in (Qi et al., 2018). Based on these development set results, we then test our strongest model on a large suite of languages (4.3).

Experimental Setup Experiments are done using datasets from the CoNLL 2018 Shared Task (Zeman et al., 2018). We build our implementation from the open-source version of (Qi et al., 2018)[3], and use their experimental setup (e.g. pre-processing, data-loading, pre-trained vectors, evaluation) which follows the shared task setup. Our model uses the same encoder from (Qi et al., 2018). For the (Qi et al., 2018) baseline, we use their pretrained models[4] and evaluation script. For the (Dozat and Manning, 2017) baseline, we use the (Qi et al., 2018) implementation with auxiliary outputs and losses disabled, and train with the default hyper-parameters and training script. For our models only, we changed the learning rate schedule (and model-specific hyper-parameters), after observing diverging loss in preliminary experiments with the default learning rate. Our models did not require the additional AMSGrad technique used in (Qi et al., 2018). We evaluate validation UAS every 2k steps (vs. 100 for the baseline). Models are trained for up to 100k steps, and the model with the highest validation unlabeled attachment score (UAS) is saved.

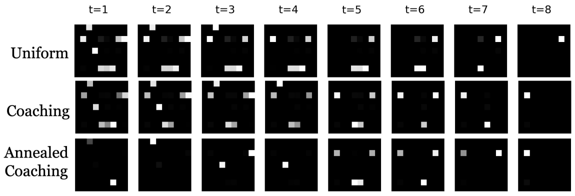

Figure 1: Per-step edge distributions from recurrent weight models trained with the given oracle.

4.1 Multi-Step Learning

In this experiment we evaluate the sequential aspect of the proposed recurrent model by comparing it with one-step baselines. We compare against a baseline ('One-Step') that simply uses the first step's score matrix S_0 from the recurrent weight model and minimizes (6) for one time-step using a uniform oracle. At test time the valid decoder uses S_0 for all timesteps. We also compare against the biaffine one-step model of (Dozat and Manning, 2017) which uses Chu-Liu-Edmonds maximum spanning tree decoding instead of valid decoding. Since we only evaluate UAS, we disable its edge label output and loss. Finally, we compare against (Qi et al., 2018) which is based on (Dozat and Manning, 2017) plus auxiliary losses for length and linearization prediction.

Results are shown in Table 1, including results for

Qi et al. (2018)	92.11	89.46	81.35	86.73
One-Step	91.74	91.07	79.60	86.61
Recurrent (U)	91.92	91.02	79.15	86.69
Recurrent (C)	91.99	91.19	79.93	86.77

Table 1: Development set UAS for single vs. multi-step methods. (U) is uniform oracle and roll-in, (C) is coaching with greedy valid roll-in ($\beta = 0.5$). D & M (2017) is an abbreviation for (Dozat and Manning, 2017).

a recurrent model trained with coaching ('Recurrent (C)') using a mixture (eq. 10) with $\beta = 0.5$. The one-step baseline is strong, even outperforming the uniform recurrent variant on some languages. The recurrent weight model with coaching, however, outperforms the one-step and (Dozat and Manning, 2017) baselines on all four languages. Adding in auxiliary losses to the (Dozat and Manning, 2017) model yields improved UAS as seen in the (Qi et al., 2018) performance, suggesting that our proposed recurrent model might be improved further with auxiliary losses.

Temporal Distribution Adjustment Figure 1 shows per-step edge distributions on an eight-edge example. The recurrent weight variants learned to adjust their distributions over time based on past predictions. The model trained with the uniform oracle has a decreasing number of high probability edges per step since it aims to place equal mass on each free edge $(i, j) \in \hat{E}^t_{\text{free}}$. The model trained with coaching learned to prefer certain free edges over others, but with $\beta = 0.5$ the uniform term in the loss still encourages placing mass on multiple edges per step. By annealing β, however, the coaching model exhibits vastly different behavior than the uniform-trained policy. The low entropy distributions at early steps followed by higher entropy distributions later on (e.g. $t \in \{5, 6\}$) may indicate easy-first behavior.

4.2 Oracle and Roll-In Choice

In this experiment, we study the effects of varying the oracle and roll-in distributions. Table (2) shows results on German, analyzed below. Models trained with coaching (C) use a mixture with $\beta = 0.5$, after observing lower UAS in preliminary experiments with lower β. The π^*_{coach} and $\pi^{\text{valid}}_\theta$ roll-ins use a mixture with $\beta = 0.5$ and greedy decoding, which generally outperformed stochastic sampling.

Oracle	Roll-in	UAS	Loss
Linear	π^*_{linear}	81.03	0.04
U	π^*_{unif}	91.02	0.35
C	π^*_{unif}	91.04	0.17
U	π^*_{coach}	90.93	0.45
C	π^*_{coach}	91.17	0.33
CA	π^*_{coach}	90.89	0.34
U	$\pi^{\text{valid}}_\theta$	90.99	0.51
C	$\pi^{\text{valid}}_\theta$	**91.19**	0.31
CA	$\pi^{\text{valid}}_\theta$	90.91	0.30

Table 2: Varying oracle and roll-in policies on German. (U), (C), (A) refer to uniform, coaching, and annealing, respectively. The π^*_{coach} and $\pi^{\text{valid}}_\theta$ roll-ins are mixtures with a uniform oracle, with $\beta = 0.5$ for coaching (C), and β linearly annealed by 0.02 every 2000 steps for annealing (CA).

Set-Based Learning The model trained with the linearized oracle (UAS 81.03), which teaches the model to adhere to a pre-specified generation order, significantly under-performs the set-based models (UAS $\geq$ 90.89), which do not have a pre-specified generation order and can in principle learn strategies such as easy-first.

Coaching Models trained with coaching (C, UAS $\geq$ 91.04) had higher UAS and lower loss than models trained with the uniform oracle (U, UAS $\leq$ 91.02), for all roll-in methods. This suggests that for the proposed model, weighting free edges in the loss based on the model's distribution is more effective than a uniform weighting.

Annealing the β parameter generally did not further improve UAS (CA vs. C), possibly due to the annealing schedule or overfitting; despite lower losses with annealing, eventually validation UAS *decreased* as training progressed.

Roll-In With the coaching oracle (C), the choice of roll-in impacted UAS, with coaching roll-in (π^*_{coach}, 91.17) and valid roll-in ($\pi^{\text{valid}}_\theta, 91.19$) achieving higher UAS than uniform oracle roll-in ($\pi^*_{\text{unif}}, 91.04$). This suggests that when using coaching, narrowing the set of training trajectories

to those preferred by the policy may be more effective than sampling uniformly from the set of all correct trajectories. Based on these results, we use the coaching oracle and valid roll-in for training our final model in the next experiment.

4.3 CoNLL 2018 Comparison

In this experiment, we evaluate our best model on a diverse set of multi-lingual datasets. We use the CoNLL 2018 shared task datasets that have at least 200k examples, along with the four datasets used in the previous experiments. We train a recurrent weight model for each dataset using the coaching oracle and valid roll-in. We compare against (Qi et al., 2018) which placed highly in the CoNLL 2018 competition, reporting test UAS evaluated using their pre-trained models.

Table 3 shows the results on the 19 datasets from 17 different languages. The proposed model trained with coaching achieves a higher UAS than the Qi et al. (2018) model on 12 of the 19 datasets, plus two ties.

5 Related Work

Transition-based dependency parsing has a rich history, with methods generally varying by the choice of transition system and feature representation. Traditional stack-based arc-standard and arc-eager (Yamada and Matsumoto, 2003; Nivre, 2003) transition systems only parse projectively, requiring additional operations for pseudo-non-projectivity (Gómez-Rodríguez et al., 2014) or projectivity (Nivre, 2009), while list-based non-projective systems have been developed (Nivre, 2008). Recent variations assume a generation order such as top-down (Ma et al., 2018) or left-to-right (Fernández-González and Gómez-Rodrguez, 2019). Other recent models focus on unsupervised settings (Kim et al., 2019). Our focus here is a non-projective transition system and learning method which does not assume a particular generation order.

A separate thread of research in sequential modeling has demonstrated that generation order can affect performance (Vinyals et al., 2015), both in tasks with set-structured outputs such as objects (Welleck et al., 2017, 2018) or graphs (Li et al., 2018), and in sequential tasks such as language modeling (Ford et al., 2018). Developing models with relaxed or learned generation orders has picked up recent interest (Welleck et al., 2018, 2019; Gu et al., 2019; Stern et al., 2019). We investigate this for dependency parsing, framing the problem as sequential set generation without a pre-specified order.

Finally, our work is inspired by techniques for improving upon maximum likelihood training through error exploration and dynamic oracles (Goldberg and Nivre, 2012, 2013), and related techniques in imitation learning for structured prediction (Daumé III et al., 2009; Ross et al., 2011; He et al., 2012; Goodman et al., 2016). In particular, our formulation is closely related to the framework of (Chang et al., 2015), where our oracle can be seen as an optimal roll-out policy which computes action costs without explicit roll-outs.

6 Conclusion

We described a family of dependency parsers which construct a dependency tree by generating a sequence of edge sets, and a learning method that does not presuppose a generation order. Experimentally, we found that a 'coaching' method, which weights actions in the loss according to the model, improves parsing accuracy compared to a uniform weighting and allows the parser to learn preferred, input-dependent generation orders. The model's sequential aspect, along with the coaching method and training on a state distribution which resembles the model's own behavior, yielded improvements in unlabeled dependency parsing over strong one-step baselines.

A Sequential Valid Decoder

We wish to sequentially sample $E_1, E_2, \dots, E_T$ from score matrices $S_1, S_2, \dots, S_T$, respectively, such that $E = \bigcup_t E_t$ is a dependency tree. A dependency tree must satisfy:

1. The root node has no incoming edges.
2. Each non-root node has exactly one incoming edge.
3. There are no duplicate edges.
4. There are no self-loops.
5. There are no cycles.

We first consider predicting one edge per step $|E_t| = 1$, then address the case $|E_t| \geq 1$.

One Edge Per Step Let $x = x_0, x_1, \dots, x_N$ where x_0 is a root node. We define a function $f_{\text{valid}}(S_t, E_{<t}) \rightarrow (i, j)$ which chooses the highest scoring edge (i, j) such that $E_{<t} \cup \{(i, j)\}$ is a dependency tree, given edges $E_{<t}$ and scores S_t. We represent $E_{<t}$ as an adjacency matrix $A_{<t}$, and implement $f_{\text{valid}}(S_t, A_{<t})$ by masking S_t to yield scores $\tilde{S}$ that satisfy (1-5) as follows:

1. $\tilde{S}_{\cdot,0} = -\infty$
2. $A_{i,j} = 1$ implies $\tilde{S}_{\cdot,j} = -\infty$
3. $A_{i,j} = 1$ implies $\tilde{S}_{i,j} = -\infty$
4. $\tilde{S}_{i,i} = -\infty$ for all i
5. $R_{i,j} = 1$ implies $\tilde{S}_{j,i} = -\infty$, where $R \in \{0, 1\}^{N \times N}$ is the reachability matrix (transitive closure) of A. That is, $R_{i,j} = 1$ when there is a directed path from i to j. [5]

The selected edge is then $\arg\max_{(i,j)} \tilde{S}_{i,j}$.

A full tree is decoded by calling f_{valid} for T steps, using the current step scores S_t and an adjacency matrix $A_{<t} = \bigcup_{t'=1}^{t-1} \{(i, j)_{t'}\}$.

Multiple Edges Per Step To decode multiple edges per step, i.e. $|E_t| \geq 1$, we propose to repeatedly call f_{valid}, adding the returned edge to the adjacency matrix after each call, and stopping once the returned edge's score is below a pre-defined threshold τ.

[5] The reachability matrix R can be computed with batched matrix multiplication as $\sum_{k=1}^{t} A^k$ where t is the maximum path length; other methods could potentially improve speed.

Term-Based Extraction of Medical Information: Pre-Operative Patient Education Use Case

Martin Wolf[1], **Volha Petukhova**[2] **and Dietrich Klakow**[2]
Computational Linguistics[1], Spoken Language Systems[2], Saarland University, Germany

{v.petukhova;dietrich.klakow}@lsv.uni-saarland.de

Abstract

The processing of medical information is not a trivial task for medical non-experts. The paper presents an artificial assistant designed to facilitate a reliable access to medical online contents. Interactions are modelled as doctor-patient Question Answering sessions within a pre-operative patient education scenario where the system addresses patient's information needs explaining medical events and procedures. This implies an accurate medical information extraction from and reasoning with available medical knowledge and large amounts of unstructured multilingual online data. Bridging the gap between medical knowledge and data, we explore a language-agnostic approach to medical concepts mining from the standard terminologies, and the data-driven collection of the corresponding seed terms in a distant supervision setting for German. Experimenting with different terminologies, features and term matching strategies, we achieved a promising F-score of 0.91 on the medical term extraction task. The concepts and terms are used to search and retrieve definitions from the verified online free resources. The proof-of-concept definition retrieval system is designed and evaluated showing promising results, acceptable by humans in 92% of cases.

1 Introduction

Nowadays, digital online services possess the dominant role delivering widely accessible applications at limited costs. For instance, recent technological advances make the provision of various eHealth services feasible. Using these applications, patients can stay informed searching content outside hospital business hours in a more convenient manner. A doctor, who conducts 120,000 - 160,000 interviews in the course of a 40-year career (Lipkin et al., 1995), meets then 'competent' patients who understand their medical needs and potential consequences of medical decisions. In the healthcare sector, language barriers and domain complexity may result in poor understanding of diagnosis, low compliance with recommendations, a significantly greater likelihood of a serious medical event and lower patient satisfaction (Bonacruz Kazzi and Cooper, 2003; Cohen et al., 2005; Pitkin Derose et al., 2009). The mainstream online services are therefore required to be reliable, accessible and to account for the diversity in individual needs, educational backgrounds, personal preferences, cognitive and physical limitations.

This paper addresses the needs in the reliable access to verified multilingual complex medical information. As a use case, we simulate pre-operative Question Answering (QA) sessions between doctors and patients. As a core part of these medical encounters, Patient Education Forms (PEFs) need to be filled in and the patient's informed consent signed. It is of chief importance that the forms are properly understood, medical procedures and risks are explained. PEFs contain many medical terms including those in Latin and as abbreviations. These terms have to be detected and corresponding definitions retrieved from available electronic medical documents. Although a number of biomedical entities recognition systems (Zhang and Elhadad, 2013; Björne et al., 2013; Sahu and Anand, 2017) and medical resources exist (Gurulingappa et al., 2010; Ohta et al., 2012), they are mostly built for English. We explore a language-agnostic approach to medical concepts mining based on the existing

Proceedings of Recent Advances in Natural Language Processing, pages 1346–1355,
Varna, Bulgaria, Sep 2–4 2019.

de-facto standard terminologies and dictionaries, and the collection of the corresponding German seed terms in a distant supervision setting. The extracted concepts and terms are used to search and retrieve definitions from the verified online free text sources. The proof-of-concept definition retrieval system is designed and evaluated.

The paper is structured as follows. In Section 2, we provide an overview of the state-of-the-art in Biomedical Named Entity Recognition (BM-NER). In Section 3, we discuss the conceptual design of a medical domain. Section 4 defines the medical term extraction task, assesses various resources for medical information extraction and presents the overall QA system architecture. Section 5 proposes the experimental design by specifying the collected and simulated data, and discusses the obtained results. Finally, Section 6 summarizes our findings and outlines directions for the future research and development.

2 Biomedical Named Entity Recognition

In 1995, the 6th Message Understanding Conference (MUC-6) focused on the Information Extraction (IE) from unstructured textual data (Grishman and Sundheim, 1996) and defined the Named Entity Recognition and Classification (NERC) task, see (Nadeau and Sekine, 2007) for a comprehensive overview. The relevant entities comprised names of persons, organizations and locations defined as ENAMEX (Entity Name Expression), extended later with TIMEX (Time Expressions) and NUMEX (Numerical Expressions).

In the early 2000s, the interest in bioinformatics lead to enriching the categories with concepts from biomedical domains focusing on the recognition of biological and genetic terms, disease and drug names and other medical or clinical entities (Settles, 2004; Shen et al., 2003). Biomedical named entity recognition is a key step in biomedical language processing.

Early (BM-)NER approaches were largely *rule-based* detecting entities based on the observed contextual and orthographic patterns. Such systems are especially useful if no or little training examples are available (Sekine and Nobata, 2004), are often straightforward to implement, suited for the entity classes or domains where the regularities in orthography or morphology can be exploited, and have other important advantages (Chiticariu et al., 2013). Although they achieve a rather high precision, recall is often low as the rule sets are rarely exhaustive. `AbGene` system of Tanabe and Wilbur (2002) uses a POS tagger extended to include gene and protein names as tag types. The system was trained on the manually labelled biomedical text. In its second iteration, it applies manually defined post-processing rules.

Another successful approach underlies the so-called *dictionary-based* systems. Here, the decision whether an entity is of an interest is made by matching against the entries in a dictionary, i.e. gazetteer or word list. To expand the coverage, linguistic methods (e.g. stemming or lemmatization), as well as fuzzy or exact matching strategies are used. `cTakes` of Savova et al. (2010) is an open-source information extraction tool from Electronic Health Records (EHR) which NER component is based on a dictionary look-up approach.

Dictionaries are also used supplementary to *machine learning* approaches (Tsuruoka and Tsujii, 2003), which are particularly useful if there is a high variability in entities observed. *Supervised* models like Hidden Markov Models (Zhou and Su, 2002), Support Vector Machines (Björne et al., 2013), Conditional Random Fields (Settles, 2004) and Neural Networks (Sahu and Anand, 2017) are reported to show the state-of-the-art performance. These approaches rely on large amounts of the annotated training data. To perform BM-NER some resources are created: the NCBI Disease Corpus (Doğan et al., 2014), the GENIA corpus (Kim et al., 2003) for molecular biology, the i2b2[1] corpus of clinical notes. The data for languages other than English is still an issue. Techniques which allow to automatically generate labelled training data like bootstrapping and distant supervision (Mintz et al., 2009) methods are proposed to build models in *semi-supervised* or *weakly supervised* way. For example, Dembowski et al. (2017) extract word lists from Wikipedia to label the data for an NER model training. The trained classifier outperforms the simple dictionary baseline.

Unsupervised approaches do not require any labelled training data, but rely on external resources like knowledge-bases or semantic nets (Alfonseca and Manandhar, 2002), lexical patterns (Evans and Street, 2003), and distributional semantics. Zhang and Elhadad (2013) applied a distributional semantics method to clinical notes and biological texts. The final system yields competitive results

on the i2b2 biomedical dataset of clinical notes and the GENIA corpus of biological literature, and outperforms the dictionary-matching baseline. This approach incorporates the collection of *seed terms*. The seed term sets are gathered from external terminologies and grouped into entity classes that represent the domain the best. For a QA application, it means that the classes of domain-specific semantic concepts can be used to generate signature vectors and the semantic similarity with the signature vectors of the answer candidates can be computed for retrieval and ranking. The concept classes can be also translated into the Expected Answer Types (EATs) to query the structured or unstructured data to retrieve an answer in a supervised or rule-based way.

3 Conceptual Domain Modelling

To facilitate an accurate information extraction from and reasoning with large amounts of (un-)structured data, it is important to specify and model real world entities and relations between them. This knowledge is often represented as ontologies, terminologies with semantic concepts groupings and taxonomic relations between them, and semantic networks. In many knowledge-based QA systems, high level semantic representations are used to query databases or other types of structured data. For example, Wilensky et al. (1988) developed the *Berkeley Unix Consultant*, for the domain related to the UNIX operating system where questions are analysed and transformed into an internal representation which are used to generate hypothesis about the user's information needs. A knowledge-based QA system as used by Apple Siri[2] and Wolfram Alpha[3] also first builds a query representation and then maps it to structured data like ontologies, gazeteers, etc. The Watson a DeepQA system of IBM Research (Ferrucci et al., 2010) incorporates content acquisition, question analysis, hypothesis generation, etc. Inside the hypotheses generation, it relies on NE detection, triple store and reverse dictionary look-up to generate candidate answers.

Alternative approaches advocate that intelligent behaviour is a result of the processing of stimuli rather than symbols. Sub-symbolic modelling is based on uninterpreted input and distributed representations by dynamic connection weights, e.g. Artificial Neural Networks comprise interconnected networks of simple processing units. In QA, so-called Neural Question Answering currently dominates the field, see e.g. (Weston et al., 2015). Based on neural network models, the systems involve relatively small pipeline, but require a significant amount of annotated data.

Recently, a number of approaches have been devised proposing a combination of symbolic and sub-symbolic processing. It has been shown that fundamental to human cognitive abilities is the capacity to process *concepts* which emerge from a distributed connectionist representation at a lower level where stimuli are processed, and are combined to form symbolic structures at the highest level to support understanding and reasoning, see e.g. (Gärdenfors, 2004). For a QA system, it implies that questions understanding and answers retrieval can be modelled at a higher level of semantic abstraction mining key concepts from available

[2] http://www.apple.com/ios/siri/
[3] www.wolframalpha.com

(e.g. medical) taxonomies, mapping them to (parts of) EATs, which on their turn can be used to perform data-driven entity recognition and semantic relation classification tasks.

Over the past few years, the community proposed different approaches to generate taxonomies which range from flat lists of mutually exclusive categories to hierarchical taxonomies with coarse categories subdivided into fine-grained classes. For example, Srihari and Li (1999) used the defined MUC NER categories to derive their taxonomy. Kim et al. (2001) created a taxonomy for semantic categorization of questions and candidate answers based on the WordNet categories. Chuang and Chien (2003) clustered queries with similar information needs into groups. Hereby, higher ranked results from web search engines were used as features to create multi-way trees via hierarchical clustering.

Chilton et al. (2013) applied crowdsourcing techniques to generate taxonomies based on three Human Intelligence Tasks (HITs) where different groups of participants: (1) generate a category for each shown item; (2) decide which items and the generated categories fit the best; and (3) decide for each category whether an item fits in it or not.

The conceptual complexity of medical domains, can make it difficult for users of information systems to comprehend and interact with the knowledge embedded in those systems (Wickens et al., 1998). To give an example, the Unified Medical Language System (UMLS)[4] integrates over 2 million names for 900 000 concepts from more than 60 families of biomedical vocabularies, as well as 12 million relations among these concepts. The UMLS semantic network reduces the complexity of this construct by grouping concepts according to the semantic types that have been assigned to them McCray et al. (2001). Medical knowledge bases, ontologies, standard terminologies and lexicons can facilitate many NLP and AI tasks, and are exploited in this work.

4 Methodology

4.1 Medical Term Extraction: The EAT Taxonomy and Seed Terms

Ideally, doctors want to meet competent patients who understand their medical needs and potential consequences of medical decisions, so that doctors can be sure that the patient's consent is well-informed. It is a common practice nowadays that before meeting a doctor who will plan an operative medical procedures, patients often have to fill in Patient Education Forms (PEF) to understand procedures and risks involved, and ask their doctors more precise and in-depth questions. To model system's QA behaviour for our use case, the reference PEF[5] was analysed to extract the domain-specific semantic concepts and grouped them into 14 categories using the UMLS semantic network. The form consists of 1,886 tokens, from which 448 tokens (261 unique tokens) were identified as medical entities. Thus, in theory a patient can ask 261 question to the system requesting additional information or explanation. The resulted taxonomy (Table 1) was used to annotate 64 PEFs in German, cluster dictionary terms and to define the EAT to classify questions and retrieve definitions for the system's answers.

Table 2: Overview of the assessed medical online resources. (+ stands for 'yes', – for 'no', and (+) for 'partially'. see Section 4.2

The semantic categories were populated with relevant seed terms. For this, the dictionary was created using a medical word list available on Wiktionary[6]. We first matched the PEFs seed terms to the lexicon entries using dictions (i.e. case, number), lemma, and/or stem, and enriched it further with synonyms, hyponyms, and hypernyms using the Wiktionary relations.

To improve the coverage of the proposed term set, we augmented the list with entities from available online unstructured medical data in a distant supervision setting. The classifiers, Naive Bayes (NB) and Multinominal Naive Bayes (MNB), were trained operating on different types of lexical and linguistic (e.g. words, lemmas, stems and as-

signed POS tags), orthographic (e.g. capitalization information and word length), morphological (e.g. inflections) and contextual features where preceding and following words as well there POS tags are encoded as bi- and tri-grams.

4.2 Resources for Definition Retrieval

Users of medical QA systems want to get medical information which is accurate, not misleading or fake. The verified sources, in our view, need to fulfil the following criteria:

1. **Trustworthiness**: the resource is accepted as medical information source;
2. **Availability**: the resource is distributed under non-exclusive license agreements with no costs associated with its use;
3. **Accessibility**: the resource can be crawled from the website or there are APIs available.

For example, the **Pschyrembel**[7] is the most referred clinical German database. Although there exists a free online test version, a license is required for a complete access. The website can not be crawled. Pschyrembel is an excellent source for medical terminology even for laymen, since the definitions are very well explained and concise, include synonyms and an English translation.

Wikipedia[8] and **Wiktionary**[9], published by the *Wikimedia Foundation*[10], are freely available databases. Generally, the Wikimedia databases are good information sources, however can not be considered as trusted medical resources. Both resources are available in many different languages enabling terms alignment and translation. Wiktionary definitions are mostly one-sentence short explanations capturing the term meaning in general, whereas Wikipedia often provides long and detailed descriptions of multiple related aspects. There are interfaces available to access the data.

Other surveyed medical resources are **Roche Lexikon Medizin**[11] for German and **MedlinePlus**[12] of the *US National Institute of Health* for English. However, their trustworthiness comes with a price, see Table 2 for a comparison.

Dataset	#texts	#tokens	#NE
Training set

Full training dataset	6,929	4,072,668	263,568
Test set			
PEF	1	1,886	448

Table 3: Training and test datasets.

4.3 QA System Architecture

The designed QA system consists of three core modules performing pre/post-processing, term extraction and definition retrieval. A general overview of the system is depicted in Figure 1.

Patient's input and available resources are *preprocessed*, e.g. tokenized, segmented; language models and (multilingual) word embeddings are computed. As output, vectors representing questions and documents are generated.

The next step is concerned with medical entities recognition. The *medical term extractor* exists in two versions (Section 5.2.1). The dictionary-based (DB) extractor annotates tokens depending on their presence in the dictionary. The module takes different parameters specific for the matching process such as word, dictions, lemma, stem, and case-(in-)sensitive matching. The machine learning (ML) classifier operates on the computed features discussed above, applies the trained prediction models and extracts the relevant entities.

To query online resources either unstructured online contents or available medical knowledge bases, queries are formulated containing the EAT concepts extended with the collected (multilingual) seed terms. The expanded queries are also transformed into the signature vectors to measure the semantic similarity with the previously computed document vectors. Multiple *definitions* can be *retrieved* and ranked. For the generation of system's answers, definitions can be summarized (Hardy et al., 2002), simplified or lexically/syntactically adapted, see e.g. (Wang et al., 2016).

5 Experiments

5.1 Data

The data used in our IE experiments is of two types: (1) dictionaries, and (2) medical free texts as training and test data for classifiers.

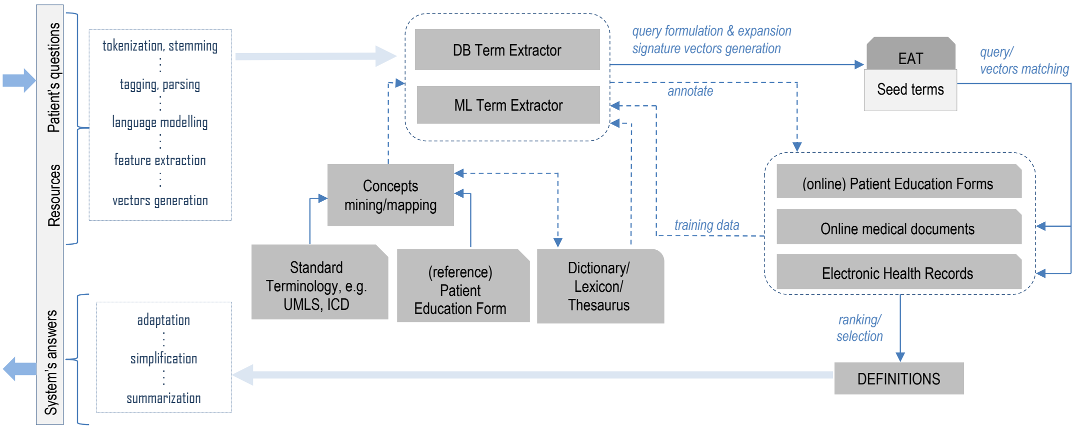

Figure 1: Proposed QA system architecture. From left to right: patient's questions and available medical documents are processed. Medical terms are extracted using available concepts taxonomies, terminologies, medical dictionaries and are learned from the annotated data. Concepts and terms are mapped to the EAT to formulate and expand the query. Signature vectors for questions and answer candidates are computed. The verified (un-)structured data/knowledge sources are queried to retrieve definitions which are ranked and post-processed before returning to the patient.

Dictionary comprises the initial word list of 2,035 Wiktionary medical term entries.[13] The word list covers different fields of medical work from general medicine to dentistry, and contains a mix of Latin and German names of medical procedures, tools and events. We augmented this list with the Wiktionary technical terms[14] and Wikipedia medical terms[15]. The resulting cleaned term list comprises 12,711 terms, see Table 4.

Table 4: Results of word list experiments. Here and in the further Tables, P stands for precision, R - for recall, F1 - for F-scores. *differs significantly from the baseline obtained on the smallest word list according to the McNemar's test, $\alpha < 0.05$

The **training data** consists of the 64 online PEFs and 6,865 Wikipedia articles[16] extracted with the Wikipedia term list. The test data as described above was constructed from a single PEF, see Table 3 for details.

5.2 Results

5.2.1 Medical NE Recognition

We conducted: (1) the dictionary-based, and (2) machine learning NER experiments. For evaluation, the standard metrics of precision, recall, and F-scores were used. The McNemar's tests were performed to measure statistical significance (McNemar, 1947).[17]

Relation depth: synonym,hypernym,hyponym	P	R	F1
0,0,0	0.92	0.31	0.47
0,0,1	0.93	0.41	0.57*
1,1,1	0.85	0.48	**0.61***
1,1,2	0.85	0.48	**0.61***
3,2,2	0.63	0.48	0.55*
2,2,3	0.76	0.48	0.59*
3,1,1	0.63	0.48	0.55*

Table 5: Results of the dictionary-based experiments: the assessment of the relation depth levels. *differs significantly from the baseline 0,0,0 setting according to the McNemar's test, $\alpha < 0.05$

Dictionary-based (DB) term recognition experiments were performed in two steps. First, the dictionary was gradually expanded to improve its coverage. We evaluated the performance using the word lists compiled from *Wiktionary* medical terms and technical medical terms, *Wikipedia* medical terms and combinations of those. Further, we experimented with the depth of Wik-

Table 6: Results of the **dictionary-based** experiments assessing of various matching strategies with relation depth 1,1,1 (best results) and the **classification** performance. *differs significantly from the baseline according to the McNemar's test, $\alpha < 0.05$

tionary *synonyms*, *hypernyms* and *hyponyms* relations. For example, a depth of 2 in the hypernym relation means that the hypernym of the word, and the hypernym of the hypernym is added to the dictionary.

Subsequently, different matching strategies were tested tuning parameters like *lemma*, *stem* and different *inflections* types and combinations of those. The matching was also conducted in *case-sensitive* and *case-insensitive* setting.

From the results presented in Table 4 can be observed that larger dictionaries result in a better system performance in terms of higher F-scores. The expanded dictionary coverage leads to a higher recall, as more relevant terms can be found. The precision, by contrast, drops slightly when larger dictionaries are used, due to the larger amount of false positives. For our use case, we assume that the system's acceptance will depend on its ability to explain as many terms as possible than missing many relevant of them.

In the second set of experiments, we assessed the impact of the relation depth on the term extraction performance. As Table 5 shows that encoding the relation information of 1,1,1 and 1,1,2 types resulted in the best performance (F-scores of 0.611). We concluded that recall increases with the increased relation depth. Deeper relations, however, generate more out-of-domain terms causing the precision drop. For example, the further up the hypernym relation gets, the more general the terms become. Considering synonyms of all word senses introduce further noise in the training data, e.g. the German word 'Nase / nose' is also a fish and the synonym list does not only contain 'Riechorgan / olfactory organ' or 'Zinken / beak', but also 'Näsling / common nase', which is a kind of carp and is unlikely to occur in PEFs.

Features	P	R	F1
word	0.875	0.879	0.876
+POS	0.876	0.880	0.877
+Suffix	0.879	0.882	0.879*
+Prefix	**0.882**	**0.885**	**0.883***
+nextBigramPOS	0.877	0.880	0.877
+prevBigramPOS	0.879	0.882	0.880*
Best features	**0.909**	**0.909**	**0.909***

Table 7: Classification performance on different feature sets. Note: only features that improved the previously obtained results are reported here. *differs significantly from the word baseline according to the McNemar's test, $\alpha < 0.05$

In the final dictionary experiments, we assessed the impact of the word-based matching strategies. The experiments showed that using lemmas and case-insensitive strategies yielded the best results. The best overall F-score of 0.726 was achieved using the complete Wikipedia and Wiktionary word list, a relation depth set to 1,1,1 for synonyms, hypernyms, and hyponyms respectively, lemmatising and ignoring capitalizations in the input. The performance of the best dictionary-based extractor outperforms the Wiktionary medical baseline by broad margins, compare Tables 4 and 6.

For our **machine learning** (ML) experiments, we generated the training data using the distant supervision approach and the best version of the dictionary-based extractor. The MNB classifier outperformed the NB classifier by broad margins, achieving F-scores of 0.85 comparing to 0.65, consider two last rows of Table 6.

Finally, the impact of different feature combinations on the classifier performance was evaluated. For this, each feature was tested individually in combination with the *word* feature. Results showed that only few features contributed to the improvement of the overall classification performance, see Table 7 for an overview. The best feature combination was found to be a combination of word features and POS information of previous, current and next word, as well as the morphological information concerning prefixes and suffixes.

Our experiments showed that the built classifiers outperformed the dictionary-based extractors. The overall F-scores improvement of 0.183 was achieved. More importantly, the recall was drastically improved from 0.236 (dictionary baseline)

and from 0.673 (best dictionary-based system) to 0.909 of the best classification model. Table 8 summarizes the key experimental results.

5.2.2 Definition Retrieval

The proof-of-concept definition retrieval was implemented using Wiktionary and Wikipedia resources that contain clear understandable definitions and are available in many different languages. The methods developed for German and English can be used for many other languages.

On a technical note, the Wikipedia and Wiktionary APIs are available to retrieve the summary part of the corresponding Wikipedia article, and the sense of Wiktionary. **Coverage** of the reference PEF medical terms and the **quality** of the retrieved definitions were evaluated.

Both resources covered 51.3% of the annotated PEF terms: 47.5% for Wikipedia and 51.0% for Wiktionary. The retrieved definitions were evaluated on their acceptability: whether the definition is *correct*, *clear* and *sufficient*. The evaluation was performed by three human raters. Out of the 133 Wiktionary definitions, 123 (92.4%) definitions were evaluated as acceptable: wording and sentence structure were simple, i.e. not containing other complex terminology and more than one subordinate clause. The retrieved Wikipedia definitions were, by contrast, evaluated as less acceptable: multi-sentence definitions are frequent with complex sentence structures using other medical expressions. The assessment results for the definition coverage and quality from the respective sources can be found in Table 9.

6 Conclusions and Future Work

In this paper, we addressed medical terms and definitions extraction simulating Patient Education QA sessions. We assessed two core methods to medical terms extraction: based on the standard medical terminologies and available dictionaries, and applying a machine-learning approach to extract German seed terms in a distant supervision setting expanding the system's coverage. We also proposed criteria to test and select medical resources for a QA application. A proof-of-concept definition retrieval systems was implemented and evaluated. The work contributes to a closed-domain QA system design to facilitate access to verified multilingual medical information.

The baseline DB and ML-based extraction techniques are assessed considering various dictionaries/datasets sizes, word matching strategies and different feature combinations. The distant supervision is a viable method to overcome the shortage of manually annotated monolingual data and can be successfully applied to automatically and productively generate large sets of the annotated multilingual seed terms. The proposed term-based information extraction opens perspectives for multi- and cross-lingual QA application design. The concepts categories populated with terms in multiple languages enable cross-lingual mappings. If the language is available on Wiktionary, the relational connections can be used as well.

Our future work will pursue multiple goals. To improve the quality, a larger annotated corpus for German will be collected. Larger data sets will also allow to train machine learning classifiers on noisy labelled data. Different search and retrieval methods will be explored, i.e. based on machine translation, cross-lingual language models and multilingual embeddings. In particular, we are interested in training new neural networks in multi- and cross-lingual term extraction and definition retrieval settings. We also plan to invest into the adaptation and simplification of the retrieved definitions where the complex medical terms will be translated into common terms. This can be achieved in a dictionary-based setting augmenting seed terms collections, but also defining the task as a machine translation one.

A Survey of the Perceived Text Adaptation Needs of Adults with Autism

Victoria Yaneva, Constantin Orăsan, Le An Ha and Natalia Ponomareva
Research Institute in Information and Language Processing,
University of Wolverhampton, UK
{v.yaneva, c.orasan, ha.l.a, n.ponomareva}@wlv.ac.uk

Abstract

NLP approaches to automatic text adaptation often rely on user-need guidelines which are generic and do not account for the differences between various types of target groups. One such group are adults with high-functioning autism, who are usually able to read long sentences and comprehend difficult words but whose comprehension may be impeded by other linguistic constructions. This is especially challenging for real-world user-generated texts such as product reviews, which cannot be controlled editorially and are thus in a stronger need of automatic adaptation. To address this problem, we present a mixed-methods survey conducted with 24 adult web-users diagnosed with autism and an age-matched control group of 33 neurotypical participants. The aim of the survey is to identify whether the group with autism experiences any barriers when reading online reviews, what these potential barriers are, and what NLP methods would be best suited to improve the accessibility of online reviews for people with autism. The group with autism consistently reported significantly greater difficulties with understanding online product reviews compared to the control group and identified issues related to text length, poor topic organisation, identifying the intention of the author, trustworthiness, and the use of irony, sarcasm and exaggeration.

1 Introduction

The aim of automatic text adaptation (also known as automatic text simplification) is to make the meaning of texts more accessible to specific target groups such as language learners or people with cognitive disabilities. To achieve this, the development of automatic systems is driven by guidelines that describe the needs of the target group, but very often these guidelines are generic. For example, one of the most authoritative sources of such guidelines for people with cognitive disabilities, the *European Guidelines for the Production of Easy-to-Read Information* (Freyhoff et al., 1998), lists requirements that fit the profile of people with moderate to severe comprehension deficits, but not those of more highly able individuals. As a result, the majority of text simplification strategies aim to reduce sentence and word complexity, while approaches to other aspects of text adaptation (e.g. clarifying the opinion of the author or strengthening the text organization) receive less attention.

In this paper we address this issue by providing insight into the needs of a specific subgroup, people with high-functioning autism, who are known to be able to read and comprehend complex texts, but may struggle with specific aspects of their comprehension. For example, readers with high-functioning autism are usually able to cope with the meaning of complex words but are known to struggle with non-literal language or with combining the meaning of individual text components into a meaningful whole (see Section 2).

These difficulties are particularly challenging when interacting with texts that were not controlled editorially and may create barriers for people with autism to interact with the web, make informed decisions, and being an active part of the economy. One such type of text is the user feedback on goods and services, which is increasingly used to guide decision making in many aspects of life, from travel, entertainment, and shopping to education, social care, and policy making (Eynon and Margetts, 2007). This feedback usually comprises numerical ratings and written reviews submitted by users. A survey of online shoppers in the UK showed that product reviews have the greatest influence on purchasing decisions, greater than that of expert reviews or advice from friends (Fretwell et al., 2013). Unlike other types of Web content, whose accessibility can be controlled editorially, product reviews in user feedback are produced spontaneously by a large, dynamic, and heterogeneous population of writers. Unsurprisingly, this feedback, which represents a large proportion of content available on the Web, is of varying levels of accessibility.

The paper presents a mixed-methods survey conducted with 24 adult web-users diagnosed with autism and an age-matched control group of 33 neurotypical participants. The aim of the survey was to identify whether the group with autism: i) experienced any barriers when reading online reviews, ii) what these potential barriers were, and iii) what automatic methods would be best suited to improve the accessibility of online reviews for people with autism. To the best of our knowledge, this is the first time when the perception of online product reviews has been investigated in terms of its accessibility for people with autism.

The next section presents information on the reading difficulties of people with autism.

2 Background

2.1 Autism Spectrum Disorder and Reading

Autism Spectrum Disorder (ASD) is a developmental disorder with neural origin characterised by impairment in communication and social interaction (American Psychiatric Association, 2013) and is known to affect about 1 in 100 people in the UK (Brugha et al., 2011). Language comprehension difficulties in autism cover phenomena such as *difficulties in syntax processing of long sentences* (Whyte et al., 2014), *resolving ambiguity in meaning* (Happe, F., and Frith, U, 2006), and *identifying pronoun referents* (O'Connor and Klein, 2004), as well as having difficulties in *figurative language comprehension* and *making pragmatic inferences* (MacKay and Shaw, 2004). These difficulties, together with the specific cognitive profile of individuals with autism (e.g., differences in the Theory of Mind (Baron-Cohen, 2000)) may lead to secondary issues such as challenges with identifying author intent and subtler nuances of meaning. In addition, web users with autism have been consistently shown to have different information searching strategies when processing web pages (Eraslan et al., 2017; Yaneva et al., 2018; Eraslan et al., 2019; Yaneva et al., 2019), which relate to differences in visual attention. As a result of these difficulties, information contained in online user feedback can be less accessible for people with autism.

2.2 Automatic Text Adaptation for Adults with Autism

In terms of systems aimed at making text more accessible for autistic individuals who are fairly able, the *OpenBook* tool[1] is the most comprehensive existing system to date. The tool provides semi-automatic conversion of text documents by reducing syntactic complexity and disambiguating meaning by resolving pronominal reference, performing word sense disambiguation and detecting conventional metaphors (Evans et al., 2014; Orăsan et al., 2018), with some initial efforts towards concept substitutions for images (Barbu et al., 2015). As part of the research project, the tool was evaluated together with end-users with ASD who were shown to find the adapted texts more accessible than the originals. Nevertheless, a major impediment for the automatic evaluation of such systems is the limited amount of user-evaluated data. To the best of our knowledge, the only available resources containing a limited amount of such data are the ASD corpus (Yaneva et al., 2016a; Yaneva, 2016), followed by a corpus of easy-to-read documents that were specifically developed for people with cognitive disabilities (Yaneva et al., 2016b) [2]. Constrained by these limitations, some approaches propose to automatically evaluate text simplification systems for people with autism in terms the change in readability of the generated sentences (Evans et al., 2014; Štajner and Saggion, 2013), the incorporation of user-evaluated data into larger corpora (Yaneva et al., 2017), or the use of corpora containing texts for children and language-learners (Štajner et al., 2014). Therefore, very little is known about the perceptions of adults with high-functioning autism on the usefulness of specific simplification strategies.

In the following sections we present a survey on the perceptions of adults with high-functioning autism on the accessibility of user reviews.

3 Data Collection

This section presents the way the survey responses were collected.

[1] http://www.openbooktool.net/

[2] Note, however, that the latter is not targeted at readers with high-functioning autism

Question	Possible Answers
1. Do you read online reviews to determine whether a product or service is good or bad?	a) Every time b) Very often c) Sometimes d) Rarely e) Never
2. How many product reviews do you read before coming to a decision?	a) None b) Less than 10 c) Between 10 and 20 d) More than 20 e) Most of the available reviews
3. In general, do you find understanding product reviews:	a) Very easy b) Easy c) Medium d) Difficult e) Very difficult
4. In general, how do you find understanding whether the author approves or disapproves of the described product?	a) Very easy b) Easy c) Medium d) Difficult e) difficult
5. Have you ever felt confused about the meaning of an online review because the author used irony or sarcasm?	a) Very often b) Often c) Sometimes d) Rarely e) Never
6. Do you think that having a summary of the main points of all reviews would be:	a) Very helpful b) Helpful c) Moderately helpful d) Not very helpful e) Not helpful at all
7. Do you feel that there are certain barriers for you with regards to understanding product reviews?	a) Most of the time b) Often c) Sometimes d) Rarely e) Never
8. Do you have any recommendations about improving online reviews? Please type your answer in the box below.	(open ended question)

Table 1: List of the survey questions and their possible answers

3.1 Survey Structure

The questions and their possible answers are presented in Table 1. The survey was designed in such a way as to collect information on four main subjects. The first subject was whether or not the participants had any interest in and/or experience with reading online reviews, as well as whether the two groups read a similar amount of surveys before reaching a decision (Q1 and Q2). The second subject was whether or not the participants felt that they experienced any barriers when reading online reviews. This was assessed through two separate questions positioned at different places in the survey. The first question was formulated as a question about rating their experience with understanding the reviews (Q3), while the second one directly asked whether they experienced any barriers (Q7). Collecting responses relevant to this subject using two separate types of questions allowed assessing the consistency of the answers between the two. The third subject consisted of structured questions about specific barriers that were both: i) suggested by the literature as potential obstacles for this target population and ii) had corresponding NLP applications developed for these domains (e.g. opinion mining, figurative language identification and text summarization) (Q4, Q5 and Q6). Finally, the last subject was the recommendations that participants had on improving the accessibility of online reviews (Q8), which simultaneously revealed other frustrations that they had which we not accounted for in the structured questions. This was an open-ended question, the responses to which were coded into categories during the analysis stage.

3.2 Participants

A total of 57 participants took part in the survey, of whom 24 had a formal clinical diagnosis of autism and 33 were neurotypical control-group participants. All participants from both groups were native speakers of English, with the exception of 1 ASD participant who was native in Romanian and Hungarian but fluent in English. We screened the participants for other conditions affecting reading such as dyslexia and aphasia. None of the control-group participants had any of these conditions and 2 of the ASD participants had been diagnosed with dyslexia. The mean age in years of the ASD group was m = 40.08 (SD = 14.09). Number of years spent in formal education were m = 17.4 (SD = 3.26). 18 out of the 24 participants responded to the question “When did you receive your diagnosis?”. A total of 7 cases were diagnosed before 2013 following the diagnostic criteria outlined in the DSM-IV. The remaining 11 cases were diagnosed after 2013 following the diagnostic criteria in the DSM-5. The mean age in years of the Control group was m = 40.38 (SD = 10.89) and number of years spent in formal education were m = 16.39 (SD = 3.11).

3.3 Recruitment Channels

The majority of the participants with autism were recruited through a UK charity organisation (N = 17). Another 3 participants were recruited through the Student Enabling Centre at the University of Wolverhampton and the remaining 4 participants were recruited through peer-support groups for people with autism on Facebook. All control-group participants were recruited through snowball sampling.

3.4 Survey Administration

All participants completed an online version of the survey. All control-group participants and four ASD-participants were sent a survey link through Survey Monkey[3]. The rest of the ASD participants (N = 20) took part in a larger online reading comprehension experiment and completed the survey as an attachment to that experiment. The questions and their presentation was identical in both platforms.

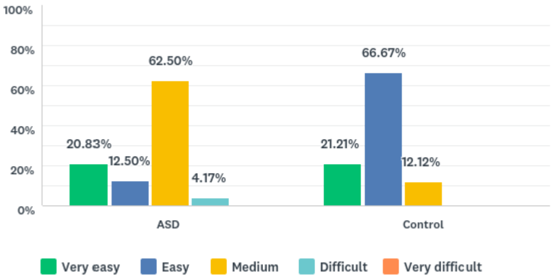
First, all participants read an information sheet and ticked “Yes” to a question asking for their informed consent to take part in the research. After that the participants were asked for their age in years, number of years spent in formal education and whether or not they had been diagnosed with any of the following: Autism Spectrum Disorder, Dyslexia, Aphasia. If they ticked “Yes” to any of these they were required to state the year in which they had received their formal diagnosis. Another answer options was “No”, in which case the participant was assigned to the Control group. The next question assessed whether or not the participant was a native speaker of English. If not, they were required to state their level of fluency in English and their mother tongue. Once information about the demographic characteristics of the participants was collected, they proceeded to answering 7 multiple-choice questions and one open-ended question related to online product reviews.

4 Results

This section presents the main results from each question of the survey.

Q1: Do you read online reviews to determine whether a product or service is good or bad? All participants who took part in the survey had experience with reading online reviews for products and services. An equal number of ASD-group participants chose the answer options *Sometimes* (33.33%, N = 8) and *Very often* (33.33%, N = 8). Another 7 participants chose the option *Every time* (29.17%, N = 7) and only 1 participant chose the option *Rarely* (4.17%, N = 1). More than half of the control-group participants said they read online reviews *Very often* (54.55%, N = 18) or *Every time* (15.15%, N = 5). Nine control participants said they read reviews *Sometimes* (27.27%, N = 9) and one participant selected the option *Rarely* (3.03%, N = 1).

Figure 1: In general, do you find understanding product reviews:



Q2: How many product reviews do you read before coming to a decision? The majority of the participants from both groups indicated that they read less than 10 reviews before coming to a decision. The answer distribution for the ASD group was 65.22% (N = 15) for the option *Less than 10*, 21.74% (N = 5) for the option *Between 10 and 20*, and 8.7% (N = 2) for the option *More than 20*. One participant had selected the answer *Most of the available reviews* (4.35%, N = 1). For the Control group, 69.7% (N = 23) of the participants chose *Less than 10*, 24.24% (N = 8) chose *Between 10 and 20*, 3.03% (N = 1) chose *Most of the available reviews*, and, surprisingly, 3.03% (N = 1) chose *None*. The answer of this last participant contradicts the results from the previous question where no participant chose the option *Never*.

Q3:In general, do you find understanding product reviews ... There was a statistically significant association between the perceived level of understanding and the group type, where the participants with ASD reported greater difficulty with understanding product reviews ($\chi^2(3) = 21.25$, $p < 0.0001$). The answer distributions are presented in Figure 1.

Q4: In general, how do you find understanding whether the author approves or disapproves of the described product? Similar to the previous question, there was a statistically significant association between the perceived understanding of the author’s opinion and the group type, where the participants with ASD reported greater difficulty with understanding what the opinion was ($\chi^2(3) = 11.94$, $p = 0.008$). The answer distribution for the two groups is presented in Figure 2.

[3] https://www.surveymonkey.com

Figure 2: In general, how do you find understanding whether the author approves or disapproves of the described product?

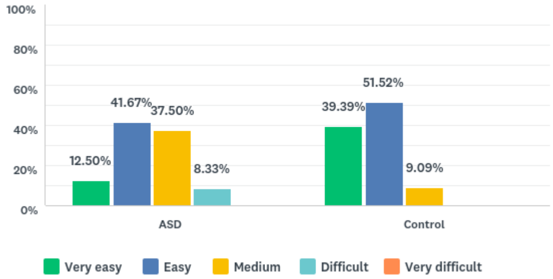


Figure 3: Have you ever felt confused about the meaning of an online review because the author used irony or sarcasm?

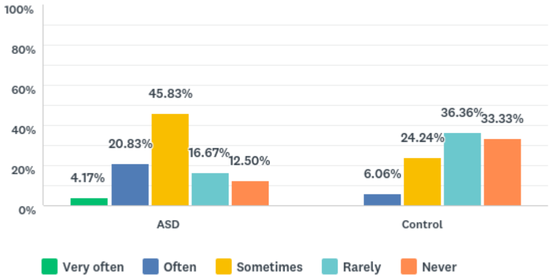
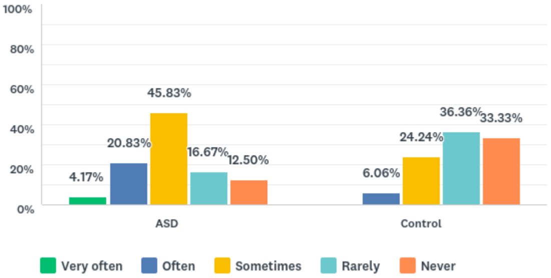


Q5: Have you ever felt confused about the meaning of an online review because the author used irony or sarcasm? The answers to this question were very diverse, however, there was a statistically significant association between the group type and the selected answers ($\chi^2(4) = 10.16$, *p*= 0.038). While 33.33% (N = 11) of the control group said that they had never felt confused by irony or sarcasm in online reviews, this corresponded to only 12.5% (N = 3) of the ASD group. The rest of the answer distributions are presented in Figure 3.

Q6: Do you think that having a summary of the main points of all reviews would be ... Large proportions of both groups[4] reported that they find the idea of summary of the main points of all reviews either *Very helpful* (36.36%, N = 8 of the ASD group and 45.45%, N = 15 of the Control group) or *Helpful* (45.45%, N = 10 of the ASD group and 39.39%, N = 13 of the Control group). *Moderately helpful* and *Not very helpful* were selected by an equal number of people from both groups, namely 9.09%, N = 2 of the ASD group and 6.06%, N =2 of the Controls. Finally, one participant from the Control group selected the option *Not helpful at all* (3.03%, N =1). There were no significant differences between the opinions of the two groups ($\chi^2(4) = 1.37$, *p*= 0.848).

Figure 4: Do you feel that there are certain barriers for you with regards to understanding product reviews?



Q7: Do you feel that there are certain barriers for you with regards to understanding product reviews? Analysis of the responses to this question revealed that the participants with autism significantly more often felt that there are barriers to their comprehension of online reviews[5] ($\chi^2(3) = 12.92$, *p*= 0.005). The percentages for each answer option are presented in Figure 4.

Q8: Do you have any recommendations about improving online reviews? The answers to this open-ended question were manually coded. The responses of the ASD participants were grouped into the two main categories below.

Category 1: Issues related to language and presentation.

- **Text length:** Long reviews were identified as the most confusing ones by the participants with autism and they would often give up on them because of information overload, e.g. “I don’t like those really long reviews as I can’t take it in”.

- **Organisation:** Another demand was for the information to be better organised: “I would rather have numbers and star ratings to support any language.”; “Subheadings for what to review; i.e. cost, appearance, functionality etc.”; “Bullet points or a summary of the review at the top of the review would be brilliant”, and “Having the positive and negatives in a table would be really helpful for me”.

[4] Two participants from the ASD group did not give an answer to this question

[5] One person with autism did not give an answer to this question.

Category 2: Issues related to interpretation

- **Trustworthiness:** Another general issue was anxiety over not being able to decide which reviews are truthful and which ones might be biased or should not be taken seriously. "I would also like to know who the reviewers are and their bias! I find it difficult to trust unknown sources."

- **Focus on facts instead of emotion:** There was a clear preference for facts to avoid confusion: "Stating facts rather than how it made you feel".

- **Exaggeration:** Although this was mentioned by only one participant, they explained at length that reviews containing exaggeration and jokes were very confusing for them.

The responses of the control group were mostly related to better organisation and the inclusion of summaries and subheadings.

5 Discussion

The results from the survey revealed two important points: i) that the ASD group does perceive reviews as being more challenging to comprehend, confirming the need for adaptation efforts in this domain and ii) the specific aspects in which they find the reviews challenging, together with recommendations for their improvement.

First, participants with and without autism alike had a similar disposition towards reading product reviews and the amount of reviews they read before coming to a decision (less than 10). However, the group with autism consistently perceived online product reviews as being more difficult to understand compared to the control group (Q3). Furthermore, significantly more people from the ASD group felt that there were certain barriers to understanding product reviews compared to the control-group participants (Q7), which was a control question that assessed similar information as Q3 (general understanding of product reviews). Formulating this query in two different ways gave consistent results about the perceived difficulty of online reviews for people with autism, which was significantly higher compared to controls.

With regards to specific aspects of the reviews that were potentially challenging, there were significant between-group differences in terms of the understanding of the author's opinion of the product (Q4) and the use of irony and sarcasm (Q5). This suggests that adaptation strategies related to *sentiment analysis* or *opinion mining*, together with *figurative language identification* would be suitable for this domain and target population. Both groups felt strongly in favour of having a summary of the main points of all reviews (Q6), indicating that *text summarisation* would also be helpful for improving accessibility.

The open-ended question revealed even more aspects that need to be improved, including the length of the text, the lack of consistent structure and the use of exaggeration (Q8). Again, summarisation and *topic modeling* could help improve the structure of the reviews and potentially present them as a populated table of characteristics that has a consistent structure. An interesting addition was the issue with trusting the reviews. While relevant to all, this may be particularly challenging for individuals on the spectrum due to overall comprehension issues. Therefore, another application that would be particularly helpful for this group of web users would be the *detection of fake reviews*. While less applicable to a broad type of texts, detecting fake reviews or posts is also relevant to improving the accessibility of social media by making it a safer space.

It is important to note that these results reflect the *perceived* experiences of the participants rather than their actual processing of product reviews. It is therefore possible that the results from evaluation studies of specific text adaptation strategies may point out to different outcomes. Nevertheless, the perceived experiences of the target group should always be taken into consideration when developing technical solutions and gaining insight into what these are is the first step towards making the web more accessible.

6 Conclusion

We conducted a survey with 24 participants with high-functioning autism and 33 neurotypical control participants on their experiences with reading online product reviews. The results showed that both groups were interested in reading reviews before making a purchasing decision but that the ASD group perceived comprehending the reviews to be significantly more challenging. Appropriate strategies for making the reviews more accessible were clarifying the opinion of the author, identifying any figurative language and summarising the main points of the review, together with enhancing the way the information is structured, as well as flagging reviews that are not trustworthy.

Abstract

In this paper, we present a two-level morphological analyzer for Turkish which consists of five main components: finite state transducer, rule engine for suffixation, lexicon, trie data structure, and LRU cache. We use Java language to implement finite state machine logic and rule engine, Xml language to describe the finite state transducer rules of the Turkish language, which makes the morphological analyzer both easily extendible and easily applicable to other languages. Empowered with a comprehensive lexicon of 54,000 bare-forms including 19,000 proper nouns, our morphological analyzer is amongst the most reliable analyzers produced so far. The analyzer is compared with Turkish morphological analyzers in the literature. By using LRU cache and a trie data structure, the system can analyze 100,000 words per second, which enables users to analyze huge corpora in a few hours.

1 Introduction

Morphological analysis is one of the key components of computational language processing, especially in morphologically rich languages. After some preprocessing stages such as stripping nontextual parts from the corpus and sentence segmentation, the first and foremost stage in computational analysis of the text is morphological analysis, that is dividing the words into constituent morphemes.

In this study, we deal with the morphology of Turkish, which is a textbook example for an agglutinative language. In Turkish, a word in its surface form contains 3 to 4 morphemes on the average (Sak, 2011), and these morphemes can have a semantic and/or syntactic content. Not only a surface form can have a multimorpheme structure in Turkish, but also has multi morphological analyses.

In this paper, we will present a new morphological analyzer, which is (i) open: The latest version of source codes, the lexicon, and the morphotactic rule engine are all available on the Internet[1], (ii) extendible: One of the disadvantages of other morphological analyzers is that their lexicons are fixed or unmodifiable, which prevents to add new bare-forms to the morphological analyzer. In our morphological analyzer, the lexicon is in text form and is easily modifiable, (iii) fast: Morphological analysis is one of the core components of any NLP process. It must be very fast to handle huge corpora. Compared to other morphological analyzers, our analyzer is capable of analyzing hundreds of thousands words per second, which makes it one of the fastest Turkish morphological analyzers available.

2 Turkish Morphology

In linguistics, the term *morphology* refers to the study of the internal structure of words. Each word is assumed to consist of one or more *morphemes*, which can be defined as the smallest linguistic unit having a particular meaning or grammatical function. One can come across morphologically simplex words, i.e. *roots*, as well as morphologically complex ones, such as compounds or affixed forms.

(1) Batı-lı-laş-tır-ıl-ama-yan-lar-dan-mış-ız
west-With-Make-Caus-Pass-Neg.Abil-Nom-Pl-Abl-Evid-A3Pl
'It appears that we are among the ones that cannot be westernized.'

[1] https://github.com/olcaytaner/TurkishMorphologicalAnalysis

The morphemes that constitute a word combine in a (more or less) strict order. Most morphologically complex words are in the ”ROOT-SUFFIX1-SUFFIX2-. . .” structure. Affixes have two types: (i) derivational affixes, which change the meaning and sometimes also the grammatical category of the base they are attached to, and (ii) inflectional affixes serving particular grammatical functions. In general, derivational suffixes precede inflectional ones. The order of derivational suffixes is reflected on the meaning of the derived form. For instance, consider the combination of the noun göz ‘eye’ with two derivational suffixes -lIK and -CI: Even though the same three morphemes are used, the meaning of a word like göz-cü-lük ‘scouting’ is clearly different from that of göz-lük-çü ‘optician’.

Owing to its morphological properties, in Turkish, the problem of parsing and disambiguation constitutes a major challenge, as not only content words in their base forms but also functional morphemes may be the source of ambiguity. While certain affixes have clear functions/meanings, there exist others, for which the meaning can only be determined within a context. In fact, only a few derivational suffixes (which are productively used for word-formation) are semantically transparent and some derived forms are no longer considered to be compositional in that their meaning cannot be predicted from the morphemes they contain.

2.1 Allomorphy

Linguists speak of underlying representations (UR) of morphemes, which is the representation of a form in the mental lexicon, and surface representations of morphs, which concerns their exact pronunciation. While some morphemes may be realized in a single way, others have several allomorphs, i.e. phonetic variants. There are, in general, two major kinds of allomorphy with respect to their source: (i) phonologically conditioned, and (ii) morphologically or lexically conditioned.

2.1.1 Phonologically-Conditioned Allomorphy

Turkish has a rich inventory of phonological rules affecting the pronunciation of morphemes and dictating what a well-formed word in Turkish may look (or rather sound) like. There are restrictions concerning the distribution of vowel segments (V), consonants segments (Cs) or their co-occurrence. For instance, the nature of consonant clusters is highly restricted. Due to the rules dictating the so-called Vowel-Alternation, an epenthetic high vowel is inserted to break up a disallowed sequence of consonants. Morphology must respect the rules of phonology, and therefore, for instance, an impermissible cluster cannot be formed through morphological operations – an epenthetic vowel comes to rescue as in (Table 1(b)), as opposed to (Table 1(a)).

a. kedi ‘cat’ + 1st person Poss = kedim ‘my cat’
b. ev ‘house’ + 1st person Poss = evim ‘my house’

Table 1: Example cases showing how morphology must respect the rules of phonology.

UR	Bare-form	Accu.	Plural
a. akl ‘mind’	a.kıl	ak.l-ı	a.kıl-lar
b. sırr ‘secret’	sır	sır.r-ı	sır-lar

Table 2: Example words whose underlying representation ends in an impermissible cluster or a geminate.

Bare-form	Accu.	Dative	Plural
a. kas ‘muscle’	kas-ı	kas-a	kas-lar
b. kasa ‘safe’	kasa-yı	kasa-ya	kasa-lar

Table 3: Example Turkish words which do not contain two successive vowels.

There are some words in Turkish whose underlying representation ends in an impermissible cluster or a geminate. In the former case, vowel epenthesis takes place (Table 2(a)) whereas words of the latter kind undergo degemination (Table 2(b)), unless they are followed by a vowel which results in the resyllabification of the second consonant in the cluster (‘.’ indicates syllable boundary in the examples below).

There are also restrictions on neighboring vowels. Typically, Turkish words do not contain two successive vowels, except for some loanwords. Therefore, if a vowel-initial suffix is attached to a vowel-final word, a consonant (typically ‘y’) emerges to avoid a VV sequence, as demonstrated in (Table 3(b)).

A further phonological operation in Turkish is Vowel Harmony, which requires any vowel to agree in backness and any high vowel to agree in rounding with the preceding vowel. Respecting the rules dictating harmony, suffixes in Turkish have various allomorphs. Turkish vowel harmony

Bare-form	Accusative	Plural
a. at ‘horse’	at-ı	at-lar
b. et ‘meat’	et-i	et-ler
c. saat ‘hour, clock’	saat-i	saat-ler

Table 4: Example Turkish words which obey/does not obey vowel harmony while taking suffixes.

Bare-form	Past
kal ‘stay’	kal-dı ‘She/he/it stayed’

Table 5: Example Turkish cases with consonant harmony.

UR	Bare-form	Accu.	Plural
a. kitab ‘book’	kitap	kitab-ı	kitap-lar
b. top ‘ball’	top	top-u	top-lar

Table 6: Example Turkish words with word-final devoicing.

operates regularly on suffixes with a very few exceptions consisting of non-alternating suffixes, the most productive of which being the progressive suffix –(I)yor (e.g. when attached to git ‘to go’, we get gidiyor ‘s/he goes’, instead of *gidiyör or *gidiyir) and some words which take a front-vowel suffix even though their last vowel is back (Table 4)).

Other than Vowel Harmony, there is also Consonant Harmony in Turkish according to which oral stops and affricates agree in voicing with the preceding segment. Hence, a suffix, such as the past tense morpheme –DI, has up to 8 allomorphs when both consonant and vowel harmonies are applicable (Table 5)).

Another process relating to the voicing properties of consonants is called ‘word-final devoicing’, according to which word-final obstruents must be voiceless. Words, or rather morphemes, that are affected by this process have a voiced obstruent in the final position in their UR (as in Table 6(a)), which gets devoiced unless a vowel-initial suffix follows.

A further alternation targets the word- or rather morpheme-final ‘k’s. Dubbed ‘k-alternation’ in the literature, this process results in the replacement of morpheme-final ‘k’s with ‘ğ’ (which phonologically means a lengthening of the vowel preceding it) when they are followed by a vowel-initial suffix. K-alternation may affect roots (as in köpek ‘dog’ + ACC = köpeği instead of *köpeki) as well as suffixes (as in göz ‘eye’ + lIK + ACC forming gözlüğü instead of *gözlükü).

a. dur ‘stop, stand’ → dur-ur	bil ‘know’ → bil-ir
b. kur ‘set up’ → kur-ar	sil ‘wipe’ → sil-er

Table 7: Examples of unpredictable allomorphy.

a. it ‘push’ → it-tir	bit ‘end’ → bit-ir
b. bak ‘look’ → bak-tır	ak ‘flow, leak’ → ak-ıt

Table 8: Examples of unpredictable allomorphy for the causative suffix.

The list of phonological processes presented in this section covers some of the most frequently occurring alternations, yet it is not exhaustive. For one, there are also processes that do not have any reflection on orthography, such as alternations on vowel length. There are several others which have a narrower distribution, such as vowel reduction occurring in verbs ending in a vowel.

2.1.2 Morphologically or Lexically Conditioned Allomorphy

The crucial difference between phonologically conditioned allomorphy from other types of allomorphy is that in the former case, the alternations are predictable and apply regularly, while in the latter case the phonological features, by themselves, are not sufficient to define the environment in which the change takes place. Among the suffixes having several allomorphs, which cannot be accounted for by phonological premises only, is the aorist. While some of its forms are phonologically conditioned and thus predictable, others (Table 7(a) vs. Table 7(b)) are unpredictable from the phonological shape of the base they are attached to. A similar allomorphy is found for the causative suffix, as demonstrated in Table 8.

2.2 Inflectional Categories

Inflectional markers encode grammatical information and are category-selective. For instance, (i) Number (Singular vs. Plural); (ii) Case (nominative, accusative, dative, locative, ablative, genitive, comitative); and (iii) Possessive are encoded by inflectional suffixes (or the lack of them) on nominal stems.

Inflectional suffixes attached to verbal stems encode (i) Tense/Aspect/Modality (such as Past, Future, Aorist, Progressive, Evidential, Optative, Conditional, Ability/Possibility, Obligative etc.); (ii) Agreement (person & number); (iii) Voice (Passive, causative, reflexive, reciprocal); and (iv) Polarity (Affirmative vs. Negative).

Due to spatial restrictions, only a brief overview of morphological processes in Turkish is presented in this paper. For further information on the linguistic structure of Turkish in general, and on Turkish morphology in particular, the reader is referred to (Lewis, 1967), (Kornfilt, 1997), (Underhill, 1976), (Göksel and Kerslake, 2005), and (Erguvanlı, 2015).

3 Related Work

3.1 Available Resources

There exist several morphological analyzer resources in the Turkish NLP literature. In this section, we aim at analyzing currently available resources in terms of their usage, technology, structure, availability, and extendibility. Table 9 shows a comparison table of such resources along with our utility. Publicly unavailable resources such as widely known KIMMO-based (Karttunen et al., 1983) analyzer (Oflazer, 1994) were decidedly left out of scope of this study.

Sak et al. (2008) released the Finite-State Morphological Parser (SakMP) which uses AT&T FSM parser (Mohri, 1997). Although it is not publicly available, authors provide compiled Linux library (*.so file) upon requests. As it does not depend on any external components on runtime, researchers can call the services through the command line or Python scripting without making any installations on Linux systems. Since it is delivered as a single compiled file, its lexicon, suffixation rules and the transducer is not extendible for researchers.

TRMorph (Çöltekin, 2010) is another morphological analyzer implementation which is built upon an existing FST engine. Its latest version[2] (2.0 pre-release) uses Foma FST compiler (Hulden, 2009) which is basically a C compiler converting regular expressions to finite automata and transducers. TRMorph's lexicon files are in a raw text file format which makes them easily updatable for the researcher. It has a special regular expression based syntax (through *.xfst files) that enable researchers to update suffixation rules in compile time. Once the output file (*.fst) compiled for the platform, it can be queried with the help of Foma executables through the command line or Python scripts. The author has also introduced a web service integration with the WebLicht environment (Hinrichs et al., 2010) which allows serving TRMorph's functionality through the web interfaces (Çöltekin, 2015).

Similarly, ITU Turkish NLP Web Service (ITUWS) (Eryiğit, 2014) offers a publicly available[3] NLP user interface[4] and a web service for Turkish language which covers common tools such as tokenizer, morphological analyzer/disambiguator and dependency parser. ITUWS requires an access token on http requests in order authenticate researchers to web services. According to their paper, ITUWS wraps the morphological analyzer tool ITUMORPH (Şahin, 2013)(Şahin et al., 2013) which depends on another external tool HFST (Lindén et al., 2009) for its FST implementation. Since ITUWS is a web service-based resource, it is not suitable for tasks that require millions of analyses. Another downside of the web service-based model is the researcher could not modify any of its components such as lexicon, suffixes, and suffixation rules.

Lastly, Zemberek[5] is a popular open-source NLP framework which includes tools for Turkish such as morphological analyzer/disambiguator, tokenizer, and spell checker. It has been using as a spelling checking extension for LibreOffice[6] and the Turkish national Linux Distribution Pardus.[7] Although the project is still actively developed and maintained, its original paper is quite outdated (Akın and Akın, 2007). In documentation pages, authors note that the latest version of the library almost written from the scratch. While the original goal of the project was to abstract language specific components form the parser to support all Turkic languages (e.g., Turkmen, Azeri, Uzbek), its current focus seems on the Turkish language only. Unlike the generally accepted approach in the literature, Zemberek does not use a FST for morphological parsing. Whereas it allows developers to easily modify the lexicon through text files and the API, updating the suffixation and morphotactic rules require recompilation because of they are represented in the core Java code.

4 Core Components

Our morphological analyzer consists of five main components, namely, a lexicon, a finite state trans-

ducer, a rule engine for suffixation, a trie data structure, and a least recently used (LRU) cache.

4.1 Lexicon

For the purposes of the present study, we will assume all idiosyncratic information to be encoded in the lexicon. While phonologically conditioned allomorphy will be dealt with by the transducer, other types of allomorphy (including the ones discussed in Section 2.1.2), all exceptional forms to otherwise regular processes, as well as words formed through derivation (except for the few transparently compositional derivational suffixes) are considered to be included in the lexicon.

Table 10 shows 10 example words taken from our lexicon, where the lexicon is sorted alphabetically. Each line in the lexicon consists of the bare-form and a set of attributes separated by white space.

4.1.1 Bare-Forms

The bare-forms in the lexicon consists of nouns, adjectives, verbs, adverbs, shortcuts, etc. Each bare-form appears the same in the lexicon except verbs. Since the bare-forms of the verbs in Turkish do not have the infinitive affix 'mAk', our lexicon includes all verbs without the infinitive affix. For instance, in Table 10, verbs 'abanmak' and 'abartmak' appear as 'aban' and 'abart' respectively.

Since our morphological analyzer must support all types of texts, the bare-forms with diacritics are included in two forms, with and without diacritics. For example, noun 'rüzgâr' appear both as 'rüzgâr' and 'rüzgar'.

Special markers are included as bare-forms such as <doc>, <s>, etc.

Some compound words are included in their affixed form. For instance, 'acemlalesi' appears as it is, but not as 'acemlale'.

Foreign words, especially proper noun foreign words, are included, so that the system can easily recognize them as proper nouns. In Table 10, the words 'abbott', 'abbigail' are example foreign proper nouns. Including foreign proper nouns, there are 19,000 proper nouns in our lexicon.

From derivational suffixes, we only include words which has taken -lI, -sIz, -CI, -lIk, and -CIlIk derivational affixes. In Table 10, the bare-forms 'abacı', 'abdallık', 'abdestli' and 'abdestlilik', are included, since they have taken one or more derivational affixes listed above.

abacı CL_ISIM	aban CL_FIIL F5PR
abart CL_FIIL F5PR	abbott IS_OA
abbigail IS_OA	abdallık CL_ISIM IS_SD
abdestli IS_ADJ	abdestlilik CL_ISIM IS_SD
rüzgar CL_ISIM	rüzgâr CL_FIIL CL_ISIM

Table 10: 10 example words from our lexicon.

4.1.2 Attributes

Each bare-form has a set of attributes give in Table 11. For instance, in Table 10, 'abacı' is a noun, therefore, it includes CL_ISIM attribute. Similarly, 'abdestli' is an adjective, which includes IS_ADJ attribute. If the bare-form has homonyms with different part of speech tags, all corresponding attributes are included.

4.2 Finite State Transducer

Given a possible bare-form, depending on the possible part of speech(es) of that bare-form, the finite state transducer (FST) starts with one or more initial state. FST is responsible from state transitions, where at each transition FST (i) changes from one state to another state, (ii) appends a suffix to the current surface form to generate a new surface form, (iii) produces an output, which is the current morphological analysis of the current surface form. After a set of transitions, the current surface form will be equal to the word, for which morphological analysis sought, and if also the current state is a final state, FST will output current morphological analysis as a possible mor-

Name	Purpose
CL_ISIM, CL_FIIL, ...	Part of speech tag(s)
IS_OA	Proper noun
IS_DUP	Part of a duplicate form
IS_KIS	Abbreviation, which does not obey vowel harmony while taking suffixes.
IS_UU, IS_UUU	Does not obey vowel harmony while taking suffixes.
IS_BILEŞ	A portmanteau word in affixed form, such as 'adamotu'
IS_B_SI	A portmanteau word ending with 'sı', such as 'acemlalesi'
IS_CA	Already in a plural form, therefore can not take plural suffixes such as 'ler' or 'lar'.
IS_ST	The second consonant undergoes a resyllabification.
IS_UD, IS_UDD, F_UD	Includes vowel epenthesis.
IS_KG	Ends with a 'k', and when it is followed by a vowel-initial suffix, the final 'k' is replaced with a 'g'.
IS_SD, IS_SDD, F_SD	Final consonant gets devoiced during vowel-initial suffixation.
F_GUD, F_GUDO	The verb bare-form includes vowel reduction.
F1P1, F1P1-NO-REF, ...	A verb, and depending on this attribute, the verb can (or can not) take causative suffix, factitive suffix, passive suffix etc.

Table 11: Attributes of the bare-forms

phological analysis. Depending on the number of initial states, the number of possible paths FST has sought, FST can output one or more possible morphological analyses.

In our morphological analyzer, FST is encoded in an xml file. Table 12 shows three example states from our Turkish FST xml file. <state> tag shows the properties of a state including; **name** of the state, if the state is a **start** state, if the state is a **final** state, the **pos** (part of speech) of the state if the state is a start state.

<to> tag shows the properties of state transitions from the current state including; **name** of the next state, **output** of the transducer while doing this transition, if the transition changes the part of the speech, **pos** of the produced surface form.

<with> tag has a text showing the suffix to append to the current surface form in this current state. **null** transitions are shown with '0' suffix. Similar to the <to> tag, <with> tag may have **output** of the transducer while doing this transition; if the transition changes the part of the speech, **pos** of the produced surface form.

In Table 12, first state is the *ConjunctionRoot* state, which shows the initial state for conjunctions. Since in Turkish conjunctions can not take suffixes, it is also a final state with no additional transitions. Second state is the *VerbalRoot(F4PW)* state, which shows the initial state for a specific class of verbs. These verbs can take a reciprocal suffix 'Hs', a causative suffix 't', a passive suffix 'n', and null passive suffix. Third state is the *NominalRootPlural* state, which shows the initial state for root nouns already in plural form. Since they are already in plural form, the morphological outputs always start with 'A3PL' and depending on the possesive suffix, the person of the possessive is determined.

```
<state name="ConjunctionRoot" start="yes"
 final ="yes" pos="CONJ">
</state>
<state name="VerbalRoot(F4PW)" start="yes"
 final ="no" pos="VERB">
    <to name="Reciprocal" output="RECIP">
        <with>Hs</with>
    </to>
    <to name="PassiveHn">
        <with>0</with>
    </to>
</state>
<state name="NominalRootPlural" start="yes"
 final ="no" pos="NOUN">
    <to name="Possessive">
        <with output="A3PL+PNON">0</with>
        <with output="A3PL+P1SG">Hm</with>
        <with output="A3PL+P2SG">Hn</with>
        <with output="A3PL+P1PL">HmHz</with>
        <with output="A3PL+P2PL">HnHz</with>
    </to>
</state>
```

Table 12: Example states from Turkish FST.

4.3 Morphotactic Rule Engine

Given the FST and a possible transition, the rule engine's job is to apply morphotactical rules to append the suffix (in the transition) to the current surface form to produce the suffixed surface form.

When the suffixes are appended to the bare-form, for the categorical exceptional cases, rule engine uses the attributes of the bare-forms given in Section 4.1.2. So, for example, if the bare-form is 'saat', and since it has an attribute IS_UU, when the accusative suffix is appended to that word, we get the surface form 'saati' (Table 4c)).

The most important function of morphotactic rule engine is to solve allomorphic cases, that is phonetic realization of metamorphemes such as 'Hs'. There are a total of four allomorphs defined in our FST. The allomorphs, the metamorphemes which use those allomorphs, and their possible phonetic realizations are given in Table 13).

There are also well known exceptions in the application of morphotactical rules, for example, when the pronouns 'bu', 'şu', 'o' get the suf-

A.morph	M.morpheme	Real.
D	DA, DAn, DH, DHk	d, t
A	Ar, CA, cAsHnA, DA	a, e
C	CA, CH, CHk	c, ç
H	cAsHnA, CH, CHk, DH	ı, i, u, ü

Table 13: Allomorphs defined in our FST and some of the metamorphemes and their realizations.

fix ‘ylA’, the surface form is not ‘buyla’, ‘şuyla’, ‘oyla’; but ‘bununla’, ‘şununla’, ‘onunla’. Another example is, when the pronoun ‘ben’ gets the suffix ‘ya’, the surface form is not ‘bene’ but ‘bana’. The engine must also handle these kind of irregularities.

4.4 Trie Data Structure

One of the most important tasks of a morphological analyzer is to guess possible bare-forms given a surface form. The speed of the analyzer mainly depends on the number of initial bare-forms it starts with. When extraneous bare-forms are present, FST deals with unnecessary morphotactics and / or phonetic realizations, which decreases the speed of the analyzer significantly.

The naive approach of taking the k ($1 \leq k \leq$ length of the surface form) leftmost characters as possible bare-forms does not work well, since there are many irregularities. For instance, if the word ‘ahenk’ takes an accusative suffix, ‘k’ is replaced with ‘g’, resulting in the word ‘ahengi’. In this case, we can not get the bare-form ‘ahenk’ by taking any leftmost characters of the word ‘ahengi’.

To overcome these irregularities and also to accelerate the search for the bare-forms, we use a trie data structure in our morphological analyzer, and store all words in our lexicon in that data structure. For the regular words, we only store that word in our trie, whereas for irregular words we store both the original form and some prefix of that word. Let s^k represent the leftmost k characters of a string s, $s[m]$ represent the m'th character of a string s, and l represent the length of string s. The irregular cases occur, when the bare-form has one of the following attributes.

In these cases, we insert token t into the trie. Figure 1 shows the above cases on a trie data structure. After inserting all of the lexicon into the trie, we are ready for searching the candidate bare-forms of a given surface form. We just traverse the trie and select matched words in the trie as candidate bare-forms.

Attribute	t	Example
IS_BILEŞ	s^{l-1}	ademot
IS_B_SI	s^{l-2}	acemlale
IS_UD, IS_UDD, F_UD	$s^{l-2} + s[l] + s[l-1]$	aklı
IS_KG	s^{l-1} + ‘g’	aheng
IS_SD, IS_SDD, F_SD	s^{l-1} + (‘b’ $\mid$ ‘c’ $\mid$ ‘d’ $\mid$ ‘ğ’)	açlığ
F_GUD, F_GUDO	s^{l-1}	açıkl

Table 14: Tokens to be inserted for the selected attributes.

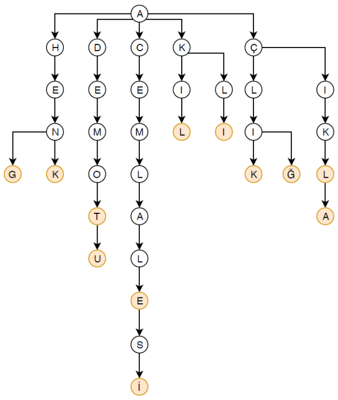

Figure 1: An example trie in our analyzer.

4.5 LRU Cache

The speed of a morphological analyzer is usually calculated on large corpora. These corpora contains millions (sometimes billions) of surface forms and as expected include many surface forms repeatedly. Since the morphological analyses of a surface form does not depend on the neighboring words, one can safely assume that, once we have extracted the morphological analyses of a word, we do not need to reextract those analyses. We can just look up the analyses of that surface form from a cache.

The idea of caching items for fast retrieval goes back nearly to the beginning of the computer science. We also use that idea and use a LRU cache for storing morphological analyses of surface forms. Before analyzing a surface form, we first look up to the cache, and if there is an hit, we just take the analyses from the cache. If there is a miss, we analyze the surface form and put the morphological analyses of that surface form in the LRU cache. As can be expected, the speed of the caching mechanism surely depends on the size of the cache. In our experiments, our cache contains up to 100K (sometimes 1M) surface forms.

5 Evaluation

5.1 Functional Evaluation

The main motivation behind our functional experiments is to test our morphological analyzer's parsing capability against known suffixation cases based on our own lexicon entries and their attributes described in the section 4.1.2. To achieve this, first, we synthetically generated test cases for 14 attributes by applying suffixes to bare-forms using our FST as a word generator. Then reversely, we tried to analyze the generated words using the same engine. After fixing some incorrectly generated cases manually, we ended up with 28,900 generated test cases in total. Lastly, we ran generated test cases on all available morphological analyzers. Table 15 shows the *passed case counts* of 14 group of test cases for each morphological analyzer. Our analyzer successfully parsed generated tests cases with 99.36% accuracy.

Test oracles for test cases slightly differ based on their group of attributes. For instance, IS_OA group test cases check whether the parser successfully yields any analysis which contains the given proper noun. This is the most simple group of test cases where its success depends heavily on the existence of such proper nouns in lexicons. Another example from group IS_UU has the test oracle ”$saat \mid saatler$” meaning that at least one analysis (e.g., ”saat+NOUN+A3PL+PNON+NOM”) of the second string ‘saatler’ should contain the first string ‘saat’ as a bare-form. All analyzers have marked as ’passed’ in this specific test case. One last special test oracle example is the IS_BI_SI attribute. This time the test oracle marks the case as passed even if the last two characters of the parsed bare-form does not match the given bare-form. This special oracle resolves the falsely failed cases caused by the incompatible bare-form structures of different analyzers as in the example of ”$geceyarısı \mid geceyarıları$” where the parsed bare-form of the second string can be accepted for both ‘geceyarı’ or ‘geceyarısı’. In this study, our test oracles do not check for any special tags (i.e., POS, MTAG) or suffixes while marking the test case as passed or not. We leave the test cases with more advanced oracles for future work.

Groups	Cases	Ours	Zemb.	TRMo.	SakMP	ITUWS
F_GUD	1,367	1,366	1,324	337	1,261	1,333

	100%	**99.36%**	69.61%	63.26%	62.71%	-

Table 15: The number of passed test cases on functional evaluations, grouped by attributes.

	Ours		**TRMorph**		**Zemberek**	
Corpus (words)	Dur.	Par.	Dur.	Par.	Dur.	Par.
Milliyet (810K)	22 sec	1.2M	39 sec	-	17 sec	1.6M
Gazete (19M)	219 sec	37M	950 sec	-	330 sec	47M
BounC. (433M)	24 min	839M	161 min	-	72 min	1.1B

Table 16: Durations (Dur.) and parse counts (Par.)

5.2 Performance Evaluation

For the performance comparison, we used three corpora in different sizes: Milliyet (Hakkani-Tür et al., 2002), BounCorpus (Sak et al., 2008), and our corpus Gazete. All datasets are constructed from daily news websites. We excluded ITUWS and SakMP from the experiments. Since their usage models and platform (web service-based and Linux) is different, it would not yield comparable results with others. Table 16 shows final durations and number of analyses/parses of our performance tests. Number of returning parses vary depending on the authors' design choices for morphological analysis process. Parse counts are not related with the execution performances.

Our performance experiments show that our analyzer can analyze a big corpus with 37.2 million sentences in 24 minutes. Compared to the other analyzers, our tool's built-in cache mechanism leverages the memory efficiently which leads to the reduction of the analysis times.

6 Conclusion

In this paper, we have presented common challenges of morphological analysis task for Turkish caused by the rich morphology of the language. Then we extensively explained the internal structure of our open-source morphological analyzer toolkit which is designed to deal with such challenges. Finally, we analyzed the currently available morphological analyzer resources in the Turkish literature and reported the functional and performance-wise comparisons we have made.

Self-Attention Networks for Intent Detection

Sevinj Yolchuyeva, Géza Németh, Bálint Gyires-Tóth

Abstract

Self-attention networks (SAN) have shown promising performance in various Natural Language Processing (NLP) scenarios, especially in machine translation. One of the main points of SANs is the strength of capturing long-range and multi-scale dependencies from the data. In this paper, we present a novel intent detection system which is based on a self-attention network and a Bi-LSTM. Our approach shows improvement by using a transformer model and deep averaging network-based universal sentence encoder compared to previous solutions. We evaluate the system on Snips, Smart Speaker, Smart Lights, and ATIS datasets by different evaluation metrics. The performance of the proposed model is compared with LSTM with the same datasets.

1 Introduction and Related Work

Spoken dialogue systems are agents that are intended to help users to access information efficiently by speech interactions (Liu, et al., 2006). In doing so, spoken dialogue systems categorize most of the major fields of spoken language technology, including speech recognition and speech synthesis, language processing, and dialogue system (McTear, 2002). There are different areas of research in the field of spoken dialogue systems. Spoken language understanding (SLU) is one of the essential components of spoken dialogue systems, and it aims to form a semantic frame that captures the semantics of user utterances or queries. Intent detection is one of the main tasks of SLU system. It can be treated as a semantic utterance classification task; since the dialogue system is created to answer a limited range of questions, there is a predefined finite set of intents (Balodis and Deksne, 2019). This task focuses on classifying the user's intent and extracting semantic concepts as constraints for natural language. For example, the utterance "Switch off the garage lights" is related to switching the light off, as shown in Table 1.

Table 1. Example of utterance and a corresponding intent label.

Utterance	**Intent**
Switch off the garage lights.	SwitchLightOff
Get the room brighter, please.	IncreaseBrightness
Skip this song and go on to the next one.	NextSong

Intent detection has been an ongoing field of research in SLU, and similar to most NLP tasks, there are two main approaches to identify the intent of an utterance: rule-based and statistical methods (Hashemi, et al., 2016). The rule-based systems use predefined rules to match new utterances to their intents, and these rules need to be carefully engineered by human experts. Thus, the advancement of these systems requires a huge amount of human effort.

Statistical models, like conditional random field (CRF) and Support Vector Machines, were investigated for this task (Mendoza and Zamora, 2009; Chen et al., 2018). Another important task of SLU is slot filling, which can be formulated as a sequence labelling task. The combination of intent detection and slot filling models was investigated (Mendoza and Zamora, 2009; Kim, 2016).

Furthermore, neural network-based models have also been investigated by (Liu, 2017). Convolutional neural networks (CNN) were applied for classifying intents in (Hashemi, et al., 2016). The combination of CNN and the triangular CRF model (TriCRF) was proposed for the intent labels and the slot filling in (Kim, et al. 2016). During

Proceedings of Recent Advances in Natural Language Processing, pages 1373–1379,
Varna, Bulgaria, Sep 2–4 2019.

training, the features are learned through CNN layers and shared by the intent detection and slot filling tasks. With this approach, for intent detection, the error on the ATIS dataset was 5.91%, and F1-score was 95.42% for slot filling.

In recent years, neural network-based solutions and word embeddings have gained growing popularity for intent detection (Balodis and Deksne, 2019; Kim, et al. 2016). The enriching word embeddings with semantic lexicons can be helpful intent detection, and it is combined with bidirectional LSTM in (Kim, et al., 2016).

The encoder-decoder neural architectures have achieved remarkable success in various tasks (e.g., speech recognition, text-to-speech synthesis and machine translation). This type of networks has also been enhanced with attention mechanism (Xu, et al., 2015; Luong, et al., 2015). Those models have also been used for intent detection and other SLU tasks (Liu and Lane, 2016; Schumann and Angkititrakul, 2018). The combination of attention-based encoder-decoder architecture and alignment-based methods was studied in (Liu and Lane, 2016) for joint intent detection and slot filling.

Self-attention networks (SANs) have shown outstanding performance in various NLP tasks, such as machine translation (Vaswani et al. 2017), and sentiment analysis (Letarte, et al., 2018) stance classification (Xu, et al., 2018; Raheja and Tetreault 2019). It is a special attention mechanism for selecting specific parts of an input sequence by relating its elements at different positions (Vaswani et al. 2017). With a well-designed architecture, SANs are capable of multi-scale modelling. Inspired by (Xu, et al., 2018), we propose the Self-Attention Network (SAN) architecture for intent detection. In our approach, the self-attention is applied to utterances (input), and it is combined with Bi-LSTM (or LSTM). For evaluation, we used Natural Language Understanding benchmark dataset (Snips) (Goo, et al., 2018), Smart Speaker and Smart Lights dataset (Saade, et al., 2018), and ATIS (Hemphill, et al., 1990). We show the effectiveness of this approach in different experimental settings. The application of pre-trained Word2vec (Mikolov, et al., 2013), and FastText (Bojanowski, et al., 2017) embeddings also helps to get competitive results. The remaining part of the paper is organized as follows. In Section 2, we introduce word embedding methods. Section 3 presents the proposed approach. In Section 4, we describe the datasets, which were used in this work and discuss the experimental setup and the results.

2 Word Embedding

Word embeddings map the words to vectors of real numbers. This approach has been widely used as the inputs to neural network-based models for NLP tasks. Word embedding models can be trained with several different tools, such as Word2vec (skip-gram and continuous bag-of-words (CBOW)) (Mikolov, et al., 2013), GloVe (Pennington, et al., 2014), FastText (Bojanowski, et al., 2017). Continuous Bag-of-Words (CBOW) and Continuous Skip-gram models are both powerful techniques for creating word vectors. FastText is one of the recent advances in word embedding algorithms. The main contribution of FastText is to introduce the idea of modular embeddings, which computes a vector for sub-word components, usually n-grams, instead of computing an embedded vector per word. These n-grams are later combined by a simple composition function to compute the final word embeddings. In pre-trained word embedding models, the word embedding tool is trained on large corpora of texts in the given language and highly useful in different NLP tasks. One of the latest embedding methods is Universal Sentence Encoder models (Cer, et al., 2018), which is a form of transfer learning. In (Cer, et al., 2018), it was introduced two encoding models. One of them is based on a Transformer model (TM) and the other one is based on Deep Averaging Network (DAN). They are pre-trained on a large corpus and can be used in a variety of tasks (sentimental analysis, classification, etc.). Both models take a word, sentence or a paragraph as input and generate a 512-dimensional output vector. The transformer-based encoder model targets high accuracy at the cost of greater model complexity and resource consumption (Cer, et al., 2018). But DAN targets performance efficient inference with slightly reduced accuracy.

In this work, we used 300-dimension Word2vec and FastText word embeddings, which were pre-trained on the English Wikipedia corpus. We also investigated TM and DAN based universal encoder models, and each embedding is combined LSTM and Bi-LSTM.

3 Proposed Model

In this section, we introduce two models for intent detection:

1. SAN and LSTM (SAN + LSTM)
2. SAN and Bi-LSTM (SAN + Bi-LSTM)

Both proposed models encode each word to its embedding first. We carried out experiments with different embeddings, as discussed in Section 4.3. As the next step, the contextual information in the input sentences (utterances) is encoded. In the first model, LSTM, in the second one, a Bi-LSTM was used to capture the left and right contexts of each word in the input. In the second model, Bi-LSTM combines two unidirectional LSTM layers that process the input from left-to-right and right-to-left, respectively. Both models are followed by the SAN (see Figure 1), which is based on an attention mechanism for selecting specific parts of a sequence by relating its elements at different positions (Vaswani, et al., 2017). In our work, we only perform input-input attention with self-attention. By using the self-attention, the semantics of the entire utterance can be extracted, and it can be helpful for the better classified. To score attention weight vectors we applied the method of (Xu, et al., 2018).

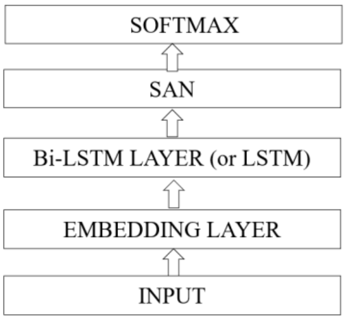

Figure 1. The architecture of the proposed model.

The goal of training is to minimize the loss function. For this purpose, we use multi-class cross-entropy loss,

$$J = -\sum_i \sum_j y_j^i log\hat{y}_j^i + \gamma\|\theta\|^2 \qquad (1)$$

where i is the index of utterance and j is the index of the intent label. γ is the L_2 regularization coefficient and θ is the parameter set. y_j^i is the ground-truth label indicator for i-th utterance, and $\hat{y}_j^i$ is the predicted probability output of i-th utterance. At the output of the network, softmax function was used to predict probabilities.

4 Experiments

4.1. Dataset

We used Natural Language Understanding benchmark dataset (Snips) (Goo, et al., 2018), Spoken Language Understanding research datasets (Saade, et al., 2018) and Airline Travel Information System (ATIS) dataset (Hemphill, et al., 1990). Snips is a balanced dataset and collected from the Snips personal voice assistant; the number of samples for each intent is approximately the same. The training set contains 13,084 utterances, the test and validation (development set) set consist of 700 - 700 utterances. Vocabulary size is 11,241 and intent types are 7, as shown in Table 2.

Table 2. The intent labels and the number of utterances in each label in Snips.

Type of intent	**Number**
PlayMusic	1914
GetWeather	1896
BookRestaurant	1881
RateBook	1876
SearchScreeningEvent	1851
SearchCreativeWork	1847
AddToPlaylist	1818

Smart Lights has 6 intents allowing to turn on or off the light or change its brightness or colour, as shown in Table 3. It has a vocabulary size of approximately 400 words. Smart Speaker dataset has 9 intents and vocabulary size is approximately 1,270. The number of utterances in each intent label is presented in Table 4. In these two datasets, we have split the data into 90 % training and 10% test sets. The validation dataset consists of 10% proportion of the training set.

Table 3. The intent labels and the number of utterances in each label in Smart Lights.

Type of intent	**Number**
Decrease Brightness	296
Increase Brightness	296
Set Light Brightness	296
Set Light Color	306
Switch Light Off	299
Switch Light On	278

Table 4. The intent labels and the number of utterances in each label in Smart Speaker.

Type of intent	Number
GetInfos	199
NextSong	200
PlayMusic	1508
PreviousSong	199
ResumeMusic	200
SpeakerInterrupt	172
VolumeDown	215
VolumeSet	100
VolumeUp	260

ATIS contains audio recordings of people making flight reservations. The training set contains 4,478 utterances, the test set contains 893 utterances; 500 utterances were used as development set. The intent types in ATIS are unbalanced. For example, the intent atis_flight equals about 73.8 % of the training data, while the number of some intents were less than 10.

4.2 Training setup

Data preprocessing may include data normalization, tokenization, lower-casing, removal of punctuation, grammar correction, feature extraction etc., by depending on the task and given dataset. We have done tokenization, have removed punctuation and have converted the numbers to words for all investigated datasets. The word embeddings are initialized with the pretrained 300-dimension Word2Vec or FastText word vectors and these are fixed during training. We also investigated TA and DAN Universal Encoder model-based utterance vectors. The number of units in LSTM and Bi-LSTM is 64.

The L2-regularization coefficient λ in the loss is 0.01.

ADAM (Kingma and Ba, 2015) is used as the optimizer, with a learning rate of 0.001, and with the baseline values of β1, β2 and ε (0.9, 0.999 and 1e-08, respectively). The batch size is 16, the number of epochs is 25.

4.3 Evaluation and Results

We evaluated the performance of the models by accuracy, precision, recall, F1-score. The results are presented in Table 5.

By micro and macro averaged, overall F1-scores were computed, and their average was used (Sokolova and Lapalme, 2009). In Table 5, the first column describes the proposed models, and other columns show the overall accuracy and F1-score for each dataset.

For all datasets, SAN + Bi-LSTM consequently have shown better results than SAN + LSTM, as expected. For Snips, the accuracy of FastText + SAN +Bi-LSTM and TM +SAN +Bi-LSTM is almost the same. The result of Word2Vec + SAN + Bi-LSTM, FastText + SAN + Bi-LSTM, and TM + SAN + Bi-LSTM is almost the same for Smart Speaker. The lowest accuracy score for Smart Lights was produced by DAN + SAN + LSTM, which is 90.2%. The highest accuracy score for ATIS was produced by TM + SAN + Bi-LSTM, which is 96.81. This result is comparable with (Goo, et al., 2018; Hakkani-Tür, et al., 2016). We observed that TM based universal encoder can help to improve accuracy.

Furthermore, Figure 2 and Figure 3 show the confusion matrix of Smart Lights and Snips test dataset by using DAN and TM universal encoder vectors with SAN + Bi-LSTM. SAN + Bi-LSTM based DAN correctly classified 30 intents labels out of 31 for SetLightBrightness and 29 tokens out of 30 for SwitchLightOff, which is the same in SAN + Bi-LSTM based TM.

Table 5. Result of proposed models

Model	Snips		Smart Lights		Smart Speaker		ATIS	
	Acc(%)	F1-s.	Acc (%)	F1-s.	Acc(%)	F1-s.	Acc(%)	F1-s.
Word2Vec + SAN + LSTM	94.2	0.94	91.8	0.90	94.9	0.94	93.93	0.92
FastText + SAN + LSTM	94.6	0.94	92.1	0.92	95.1	0.95	94.51	0.94
DAN + SAN + LSTM	94.1	0.94	90.2	0.90	91.7	0.90	93.56	0.93
TM + SAN + LSTM	94.2	0.94	93.6	0.93	94.2	0.93	94.81	0.94
Word2Vec+SAN+Bi-LSTM	95.6	0.96	93.8	0.94	97.7	0.98	94.49	0.93
FastText + SAN + Bi-LSTM	96.1	0.96	93.4	0.92	97.7	0.97	95.77	0.94
DAN + SAN + Bi-LSTM	94.2	0.94	93.2	0.93	94.7	0.95	94.91	0.93
TM + SAN + Bi-LSTM	96.5	0.97	96.6	0.97	97.7	0.98	96.81	0.95

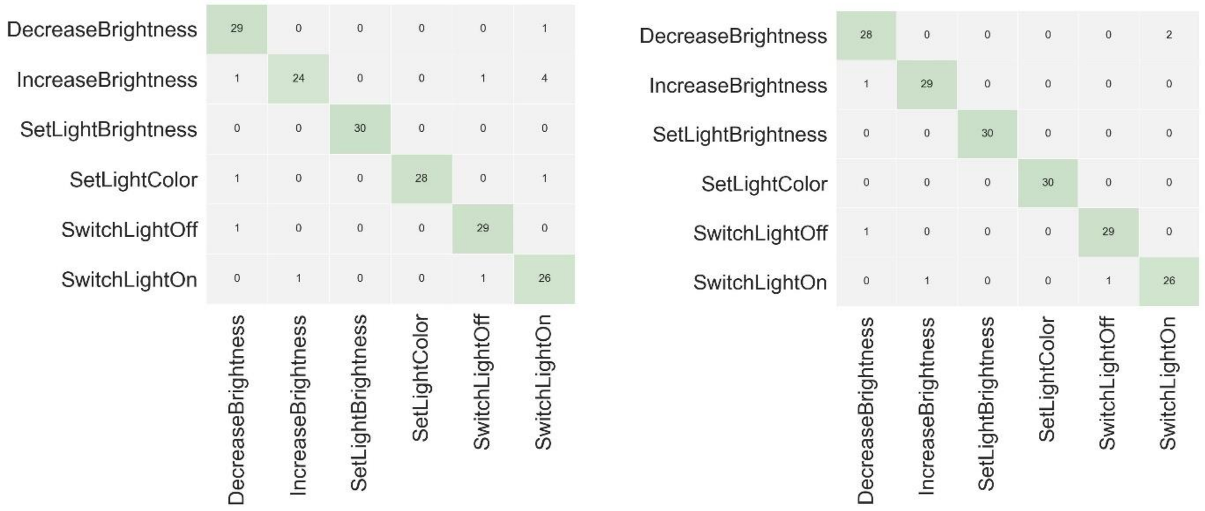

Figure 2. Confusion matrix of Smart Light test dataset by using DAN and TM Universal encoder vectors with SAN + Bi-LSTM.

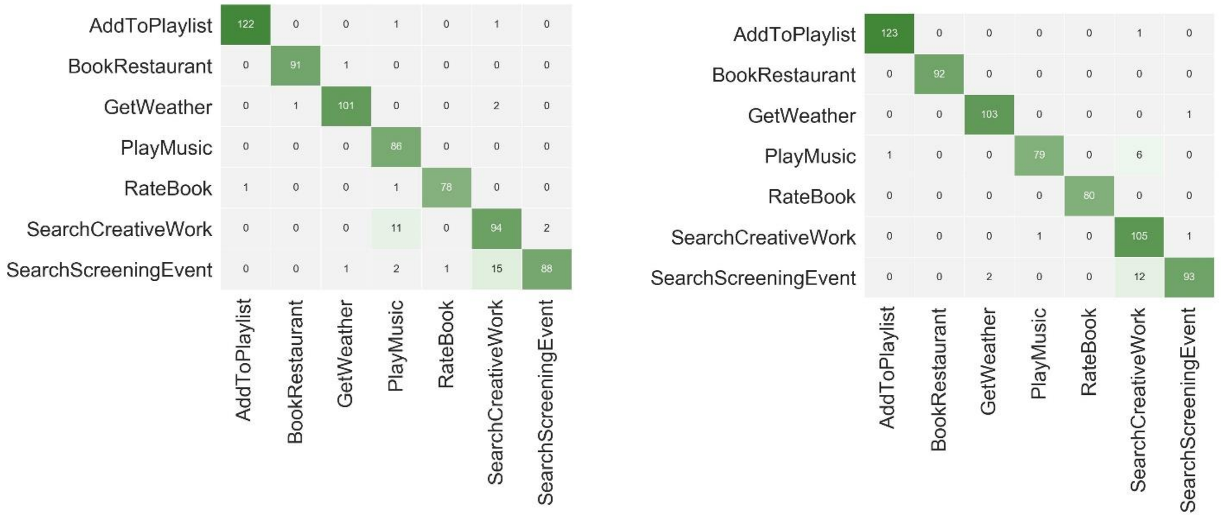

Figure 3. Confusion matrix of Snips test dataset by using DAN and TM Universal encoder vectors with SAN + Bi-LSTM.

The intent of IncreaseBrightness was predicted correctly in case of 24 out of 30, while 4 intent labels were misclassified to the SwitchLightOn by SAN + Bi-LSTM based DAN.

For Snips, SAN + Bi-LSTM based DAN correctly classified 88 intent labels out of 105 SearchScreeningEvent, while the TM-based approach classified 93 intent labels correctly. The AddToPlaylist, GetWeather, RateBook labels achieved almost the same accuracy from both models. SearchCreativeWork intent labels were better predicted by TM based SAN + Bi-LSTM.

As reasons for the misclassification are that some words can belong to both intent classes, depending on the context, and the size of training data is not large enough.

Conclusion

In this paper, the combination of SAN and Bi-LSTM for intent detection were proposed. 300-dimensional Word2Vec and FastText embeddings pretrained on English Wikipedia were used as word representations. Utterance vectors of DAN and TM based Universal sentence encoders were investigated. The results were evaluated with the help of accuracy and confusion matrices. Experiments were also carried out with SAN + LSTM, however, the accuracy was worse than with SAN + Bi-LSTM.

Generally, comparison of these models shows that SAN + Bi-LSTM with TM embeddings performs better than other models on all the investigated datasets. In the future, we would like to carry out more comprehensive analysis and investigate other attention mechanisms such as directional self-attention and bi-directional block self-attention (Shen, et al., 2018) for this task.

Abstract

Short-text classification is a challenging task, due to the sparsity and high dimensionality of the feature space. In this study, we aim to analyze and classify Turkish tweets based on their topics. Social media jargon and the agglutinative structure of the Turkish language makes this classification task even harder. As far as we know, this is the first study that uses a Transformer Encoder for short text classification in Turkish. The model is trained in a weakly supervised manner, where the training data set has been labeled automatically. Our results on the test set, which has been manually labeled, show that performing morphological analysis improves the classification performance of the traditional machine learning algorithms Random Forest, Naive Bayes, and Support Vector Machines. Still, the proposed approach achieves an F-score of 89.3% outperforming those algorithms by at least 5 points.

1 Introduction

Short-text usage is increasing day by day and we encounter short-text messages on many social media platforms in different forms such as tweets, Facebook status posts, or microblog entries. Twitter is one of the most widely used platforms, where a huge amount of short-texts are produced. More than 500 million tweets are posted on a typical day (Aslam, 2018). People use Twitter in order to produce and reach information faster about the topic they are interested in. Therefore, tweet classification becomes an important task to improve tweet filtering and tweet recommendation.

Traditional machine learning algorithms such as K-Nearest Neighbor, Support Vector Machines (SVM), and Naive Bayes have been widely used for text classification tasks and accuracy levels of over 80% have been reported in the literature for various data sets (Kadhim, 2019). However, obtaining a similar level of success for short-text classification is difficult, since short-texts contain smaller number of words compared to lengthy texts, which makes classifying them effectively a challenging task (Taksa et al., 2007). While a number of studies have been conducted for short-text classification, most of them have addressed the task of English tweet classification (Batool et al., 2013; Selvaperumal & Suruliandi, 2014).

In this paper, we tackle the task of Turkish tweet classification. The grammatical and syntactic features of the Turkish language pose additional challenges for short-text classification. The agglutinative nature of Turkish results in a high number of different word surface forms, since a root word can take many different derivational and inflectional affixes. This leads to the data sparseness problem. We propose a Transformer-Encoder based model for Turkish topic-based tweet classification and compare it with the traditional machine learning algorithms Naive Bayes, SVM, and Random Forest. The results show that morphological analysis enhances the performance of the traditional classification algorithms. However, the Transformer-Encoder model achieves the best F-score performance, even without any morphological analysis. Another contribution of this study is the constructed Turkish tweet data set on nine different topics. The tweet IDs and the corresponding topics are made available for future studies. [1]

The rest of this paper is organized as follows: in Section 2, we give a review of the related work

[*] Equal contribution

Proceedings of Recent Advances in Natural Language Processing, pages 1380–1387,
Varna, Bulgaria, Sep 2–4 2019.

on short-text classification, especially for Turkish. In Section 3, the data set creation and the steps of tweet preprocessing are explained in detail. Section 4 describes the proposed Transformer Encoder model and its usage. The experimental results and error analysis are presented in Section 5. Finally, Section 6 includes the conclusion and future works.

2 Related Work

Traditional text classification methods based on the BoW (Bag of words) model (Harris, 1954) suffer from high dimensionality and sparse feature sets, particularly in short-texts. Other limitations of BoW based models are that semantic features are not captured, the positions of the words in the text are not considered, and the words are assumed to be independent from each other.

In order to overcome the weaknesses of BoW, Latent Dirichlet Allocation (LDA) (Blei et al., 2003), where the terms are mapped to distributional representations based on latent topics within documents, has been used for building classifiers that deal with short and sparse text (Phan et al., 2008; Song et al., 2014).

One of the most commonly used algorithms for short text classification is Naive Bayes, which is based on word occurrence and class priors. For example, Kiritchenko & Matwin (2011) used this algorithm on an email dataset and Kim et al. (2006) offered powerful techniques for improving text classification by Naive Bayes. Sriram et al. (2010) extracted different features from short-texts and used these with Naive Bayes to classify them.

Support Vector Machine (SVM) is another commonly used algorithm in short text classification studies. Pointing to the weaknesses of the BoW approach, different kernels have been developed for SVM such as semantic kernels that use TF-IDF (Salton & Buckley, 1988) and its variants that apply different term weighting functions on the term incidence matrix. Wang & Manning (2012) showed that Naive Bayes obtains higher scores than SVM for short-text sentiment classification tasks and the combination of SVM and Naive Bayes outperforms SVM and Naive Bayes for some of the datasets that they used. More relevant to our study, Lee et al. (2011) used SVM for text-based classification of trending topics under 18 classes and reached 61.76% accuracy. They obtained 65.36% accuracy with Multinomial Naive Bayes.

The advances of deep learning in NLP led to the use of Artificial Neural Network (ANN) based models in recent studies. Convolutional Neural Networks (CNNs) and Dynamic CNNs have been applied to text classificatioon and promising results have been obtained (Kim, 2014; Kalchbrenner et al., 2014). In a recent study, Le & Mikolov (2014) successfully added sequential information by using Recurrent and Convolutional Neural Networks for sequential short-text classification.

In this study, we address the task of Turkish short text classification. Turkish is an agglutinative language, which may result in the same word to map to different features when it takes different inflectional affixes or suffixes. Possessive pronouns, tenses, and auxiliary verbs can be encoded as affixes of the words. For this reason, a word may have many different forms and this poses challenges for classical term weighting methods to construct strong relations between the text and its topic. Most prior work on Turkish short text classification is on sentiment analysis. Demirci (2014) used Naive Bayes, SVM and k Nearest Neighbor (kNN) for emotion analysis on Turkish tweets and obtained accuracy levels of up to 69.9%. Similarly, Yelmen et al. (2018) showed that SVM reaches 80% accuracy for sentiment classification of Turkish tweets for GSM operators, whereas an Artificial Neural Network (ANN) results in slightly lower performance. Türkmenoğlu & Tantuğ (2014) compared lexicon based sentiment analysis and machine learning based sentiment analysis on tweet and movie review datasets and concluded that the machine learning based algorithms SVM, Naive Bayes, and decision trees achieve better scores. Yıldırım et al. (2014) combined lexicon and machine learning based methods to improve sentiment analysis of Turkish tweets.

Unlike prior studies on Turkish short text classification that address the task of sentiment analysis, we tackle the task of topic-based tweet classification and create a Turkish tweet data set for nine different topics. We propose using Transformer Encoder architecture for Turkish short-text classification. Transformer Encoder is a recently proposed model that offers a better understanding of the language structure by protecting the semantic values and meanings of word sequences (Vaswani et al., 2017). Furthermore, the positions of the terms in text are taken into account and the terms are not assumed to be independent from each other by using a contextual word embedding representation.

3 Dataset

In this section, we briefly explain how we created the dataset and the main steps of data preprocessing, as well as the importance of lemmatization on Turkish short-text classification.

3.1 Dataset Creation

The dataset includes 164,549 Turkish tweets, written by 74 different users until February 2019. These tweets are retrieved from the users' profiles, who are known experts in their areas and mostly write tweets on the subjects of their expertise. The tweets of each user are automatically labelled with the topic of expertise of the user. The dataset contains nine topics, namely politics, economics & investment, health, technology & informatics, history, literature & film, sports, education & personal growth, and magazine. The selection of topics was made in a similar way the news sites categorise their content.

We observed that some of the tweets of a user could be mislabeled, since a user may also tweet about topics different than his/her area of expertise, which results in noise. In order to ensure that most of the tweets are related to their assigned topics, we selected a random sample of tweets and manually checked the percentage of the correctly labelled ones. The percentage of the correctly labelled tweets was around 80%. That is, the training dataset contains around 20% noise (i.e., incorrectly labeled tweets). We randomly selected 10% of the dataset as a test set. In order to report reliable results, we manually verified and corrected the labels of the test set.

3.2 Data Preprocessing

Preprocessing Turkish sentences is quite different from the English ones, since Turkish is an agglutinative language and we may encounter words in many different forms. In addition, tweets come with their own difficulties when they are used in natural language processing. They contain hashtags, mentions, emojis, and links which make tokenization difficult. To overcome those challenges we follow three main steps for preprocessing as described in the following subsections.

3.2.1 Data Cleaning

Users use some adhoc pattern such as hashtags, mentions, the link of website they want to refer to, and emojis in tweets.In our work, we are only interested in lexical terms in tweets. Hence, we drop the hashtags, mentions, links, emojis, numbers, and punctuations. On the other hand, hashtags can be quite useful when deciding the topic of a tweet. There are some studies to split hashtags (Çelebi & Özgür, 2018) into meaningful words in English. However, it is left as an open future work for Turkish hashtags.

Some tweets contain only response to a tweet like "greetings", "thank you", "okay", or "congratulations" for good news etc. When we examine the tweets which have less than 4 words, nearly all of these tweets are examples of such tweets. These tweets are removed from the dataset, since they are not about any specific topic.

In addition, when we examined the tweets with retweet and like statistics that are significantly different from the others, we discovered that those tweets are mostly retweets of campaigns or calling for help. For this reason, we filtered this type of tweets from the dataset.

3.2.2 Language Identification

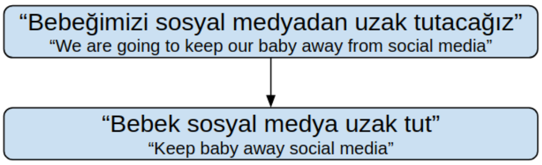
In Twitter, users sometimes write and retweet tweets in languages different from their native language. When we analysed our dataset, we observed that the languages used by users are Turkish, English, Arabic, French, and German. For filtering non-Turkish tweets, we used the language identification model in (Lui & Baldwin, 2012).

After the dataset cleaning and language-based filtering steps, the training set contains 119,778 tweets and the test set contains 3050 tweets.

3.2.3 Lemmatization

The goal of lemmatization is to find the lemmas of the words by removing the prefixes, suffixes, and other types of affixes based on morphological analysis. This process is harder for the Turkish language, since it has more types of affixes than English.

In the Naive Bayes model, the frequency of a word is prominent for scoring the importance of the word for each class. Therefore, finding the correct lemmas of the words is a useful transformation to classify tweets correctly. Lemmatization is also important for the SVM classifier, in order to compute the similarity between the instances in the training set, as well as the support vectors and the test instances in the classification step more accurately. Yıldırım et al. (2014) showed the positive impact of morphological analysis for the sentiment analysis of Turkish tweets. Therefore, in order to increase the success of the Naive Bayes and SVM models, we use a lemmatization model (Sak et al., 2008) which is trained by nearly one million Turkish sentences. An example tweet and its lemmatized version are shown in Figure 1. The effects of lemmatization on the success of Turkish tweet classification are presented in Section 5.



"Bebeğimizi sosyal medyadan uzak tutacağız"
"We are going to keep our baby away from social media"
"Bebek sosyal medya uzak tut"
"Keep baby away social media"

Figure 1: A sample tweet from the dataset and its lemmatized from.

4 Model Description

In this section, the main components of the proposed model are presented. First, the general structure of the input embeddings is explained. Then, the architecture of the Transformer Encoder model is described in detail.

4.1 Input Embeddings

One of the most widely used and robust word embedding models, word2vec, was proposed by Mikolov et al. (2013). Besides word embeddings, sentence embeddings (Logeswaran & Lee, 2018) and paragraph embeddings (Le & Mikolov, 2014) were studied in order to represent larger text snippets correctly and classify documents accordingly. Aiming to construct the word embeddings based on the context of each word, Peters et al. (2018) offered a new word embedding representation model named as ELMo. ELMo tries to keep the contextual features in word embedding representations so that the polysemy and homonymy problems are alleviated.

In our study, pretrained contextual word embedding representations of Turkish words (Devlin et al., 2019) are used. They are obtained by using the bidirectional approach with masked language model (Taylor, 1953) in training. Hence, the representation of each word contains the information of the left and right words in their own context. Moreover, in order to account for the word order in text, positional embeddings (Vaswani et al., 2017) are used and combined with the word embeddings. When using the input embeddings, they are fed into the Transformer Encoder by matching each word in the input tweet with the longest token in the vocabulary of the pretrained contextual word embeddings. An example from the dataset is shown in Figure 2.

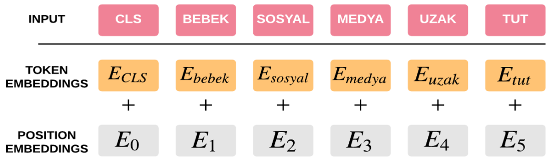


Figure 2: Input embeddings representation.

4.2 Transformer Encoder

This model is based on the Transformer architecture (Vaswani et al., 2017), which contains self-attention layers. What we aim to find in this architecture is reaching the importance of every word in tweets by training the query and key matrices of the attention layers. Hence, the attention score is calculated for every word in a tweet in order to determine its usefulness for each class. Lots of different attention patterns are obtained with multi-head self attention layers, which enable the model to decide which attention score is significant among the pairs of the terms in the tweet.

In general, the transformer architecture is constructed by combining the layers of multi self-attention heads, Dropout, Layer Normalization, and 2 fully-connected layers, respectively. A pictorial representation of this Transformer architecture is shown as a grey block in Figure 3.

In the general architecture of the Transformer Encoder, Layer Normalization and Dropout layers are applied to the contextual word embeddings, into which positional information is added before it enters into the Transformer. In the Transformer, multi-head self attention layers are used as we mentioned above. After the Transformer obtains the attention score matrices containing the score of every word with different attention patterns, these inter-layer features are connected into 2 fully-connected layers in order to reach the combination of different attention scores of the terms. Then, the class prediction of the tweet is found after passing the pooler, dropout, and the last fully-

Model	Accuracy	Precision	Recall	F1-Score
Random Forest (Baseline)	65.0	64.9	64.5	64.5
Random Forest + Lemmatization	71.1	70.9	70.9	70.7
Random Forest + Lemmatization + TF-IDF	69.9	69.8	69.6	69.6
Naive Bayes	82.7	82.4	82.4	82.6
Naive Bayes + Lemmatization	85.0	84.8	84.7	84.9
Naive Bayes + Lemmatization + TF-IDF	85.4	85.3	85.4	85.2
SVM	78.6	78.2	78.3	78.1
SVM + Lemmatization	80.3	80.3	80.2	80.1
SVM + Lemmatization + TF-IDF	84.4	84.2	84.3	84.2
Transformer Encoder + Input Embeddings	**89.4**	**89.3**	**89.4**	**89.3**

Table 1: Comparison of the models' scores over the manually labeled test set.

connected layer. The class probabilities are calculated by using the Softmax classifier. The general architecture of the model is shown in Figure 3.

5 Experiments

We compared the performance of the Transformer Encoder model with three different baseline models, which are widely used in the area of short-text classification: Naive Bayes, SVM and Random Forest. The parameters of the models are tuned using cross-validation over the training set and the performance results are reported over the manually labeled test set (Table 1).

In the training phase of the Transformer Encoder, 10 epochs are run on the dataset. Batch size of training data is selected as 8 due to computational constraints. Maximum sequence length is 128, learning rate is equal to 2e-5, and the number of attention heads is equal to 12 in our configuration.

For Naive Bayes, SVM and Random Forest the most frequent 15000 words are selected as the features to represent the data. We also experimented with using the most frequent 10000, 20000, and 25000 words, however, the results in the cross-validation experiments were lower. So, we report the results with 15000 words over the test set. We also investigated the effect of lemmatization and TF-IDF weighting on the baseline models.

5.1 Comparison Results

The results of the compared models over the test set are shown in Table 1. Naive Bayes, Random Forest, and SVM obtain better scores when morphological analysis is performed.

However, in spite of these improvements, the proposed Transformer Encoder model achieves the highest scores in all metrics for tweet classification even though it does not use the morphological analysis. These results point out that using pretrained word embeddings, which are trained on large datasets, with a Transformer Encoder architecture is more effective than using morphological analysis and TF-IDF based term weighting with the traditional machine learning algorithms Random Forest, Naive Bayes, and SVM for Turkish short text classification.

5.2 Error Analysis

Figure 4 shows the confusion matrix for the Transformer Encoder model over the test set.

	T1	T2	T3	T4	T5	T6	T7	T8	T9
T1	283	18	2	3	12	0	4	12	7
T2	22	246	8	1	11	21	5	9	2
T3	1	1	258	0	14	1	2	1	7
T4	3	2	3	371	3	3	4	1	3
T5	9	18	5	2	280	0	9	13	6
T6	0	3	2	1	0	354	0	0	4
T7	4	6	5	1	5	2	300	2	1
T8	8	2	2	0	12	1	2	274	0
T9	2	4	1	0	3	1	0	0	362

Figure 4: Confusion matrix for the Transformer Encoder. The names of the topics (from T1 to T9) are literature & film, education & personal growth, economy & investment, magazine, politics, health, sport, history, and technology & informatics, respectively.

It is observed that most of the errors are caused by the proximity of the topics like politics and history or literature & film and education & personal growth. The main reason is that there are many common words which are frequently used in close topics. In many cases, it is hard to differentiate a tweet about recent history from a tweet about politics. Similarly, an expression from a novel can be similar to an expression written by an educator. For example[1], the topic of the tweet "*Bachmann is so right, the real death of a man is not from diseases, but from what another man does to him.*" is predicted by the Transformer Encoder model as education & personal growth, whereas its correct label is literature & film. As another misclassified example the topic of the tweet "*The Lausanne Treaty debate should be discussed in public.*" is predicted as politics, whereas this tweet is in the scope of the recent history.

6 Conclusion and Future Works

We proposed using a Transformer Encoder architecture with contextual word embeddings and positional embeddings for Turkish short text classification. In addition, we compiled a dataset of Turkish tweets for topic-based classification. The training set has been labeled automatically using a weakly supervised approach, whereas the test set has been manually labeled for reliable evaluation. Our results demonstrate that the Transformer Encoder model outperforms the widely used machine learning models for topic-based Turkish tweet classification. Also, this study shows the importance of morphological analysis for Turkish short-text classification with the widely used machine learning algorithms SVM, Naive Bayes, and Random Forest. It is interesting to note that, the Transformer Encoder model is able to outperform these algorithms, even though it does not involve a morphological analysis step.

One of the areas of usage of this study is guiding Twitter users and making easier for them to find correct accounts to follow. Twitter is one of the most used social media platforms in the world in order to get news and learn about what people think (Riquelme & Gonzlez-Cantergiani, 2016). Users may prefer Twitter for getting breaking news or reading about a social event. Therefore, it is necessary to find the correct people to follow and be aware of the popular and informative tweets. By using our model, Turkish tweets can be categorized and the most relevant ones can be suggested to users according to their interests, which would lead to saving time and manual effort.

Multilingual Dynamic Topic Model

Elaine Zosa and **Mark Granroth-Wilding**
Department of Computer Science

Helsinki, Finland
firstname.lastname@helsinki.fi

1 Abstract

Dynamic topic models (DTMs) capture the evolution of topics and trends in time series data. Current DTMs are applicable only to monolingual datasets. In this paper we present the multilingual dynamic topic model (ML-DTM), a novel topic model that combines DTM with an existing multilingual topic modeling method to capture cross-lingual topics that evolve across time. We present results of this model on a parallel German-English corpus of news articles and a comparable corpus of Finnish and Swedish news articles. We demonstrate the capability of ML-DTM to track significant events related to a topic and show that it finds distinct topics and performs as well as existing multilingual topic models in aligning cross-lingual topics.

2 Introduction

Dynamic topic models (DTMs, Blei and Lafferty, 2006) capture themes or topics discussed in a set of time-stamped documents and how the words related to these topics change in prominence over time. Other topic models have been proposed that aim to model time series data (Wang and McCallum, 2006; Wei et al., 2007; Hall et al., 2008). These models can be used to explore historical document collections to study historical trends, language changes (Frermann and Lapata, 2016) and track the emergence and evolution of certain subjects (Hall et al., 2008; Yang et al., 2011).

With the internet becoming more multilingual it is increasingly important to build cross-lingual tools to bridge different linguistic groups online. Fortunately, large multilingual datasets such as Wikipedia, the Europarl parallel corpus (Koehn, 2005) and other datasets assembled from crawling the web (Van Gael and Zhu, 2007) are also becoming widely available to researchers. This has led to the development of several multilingual topic models to infer topics from multilingual datasets. Examples include the polylingual topic model (PLTM, Mimno et al., 2009), multilingual topic model for unaligned text (MuTo, Boyd-Graber and Blei, 2009), and JointLDA (Jagarlamudi and Daumé, 2010). What is currently lacking are topic models for multilingual time-stamped data that can model historical and linguistic changes in a specific context. Digitalization efforts in libraries and archives, such as the Europeana collections[1], have made available online historical document collections from different European countries. Collections such as these are valuable resources for comparing historical trends in different countries. However, scholars and other interested parties may not possess the linguistic skills necessary to explore such data and would benefit from tools to automatically discover connections across linguistic boundaries.

In this paper, we present the multilingual dynamic topic model (ML-DTM), a novel topic model that captures dynamic topics from broadly topically aligned multilingual datasets. We extend a DTM inference method by Bhadury et al. (2016) to train this model.

In the following sections, we give a broad review of related work, discuss existing *dynamic* and *multilingual* topic models in more detail, and then give a description of our proposed combined model. We then demonstrate usage of this model on a parallel dataset and a comparable dataset of news articles and present our results. We show that this novel topic model learns aligned bilingual topics as demonstrated by the cosine similarities of learned vector representations of named entities. Table 1 summarizes the notations used in this paper. Code is available at: `https://github.com/ezosa/multilingual_dtm`.

Symbol	Description
α	parameter for θ
β	hyperparameter for ϕ
ψ	hyperparameter for θ
θ	distribution of topics over a document
ϕ	distribution of words over a topic
D	set of documents
W_d	words in document d
N_d	number of words in document d, or $\|W_d\|$
Z_d	topic assignments of words in document d
K	number of topics
T	number of time slices
L	number of languages in the dataset
V	words in a vocabulary for language

Table 1: Summary of notations.

3 Related Work

Topic models capture themes inherent in document collections through the co-occurence patterns of the words in documents. Latent Dirichlet Allocation (LDA, Blei et al., 2003) is a popular method for inferring these themes or topics. It is generative document model where a document is described by a mixture of different topics and each topic is a probability distribution over the words in the vocabulary. In a document collection we can only observe the *words* in a document. Therefore, training a model involves inferring these latent variables through approximate inference methods.

In the case of documents with timestamps covering some time interval, such as news articles, we might want to capture *dynamic* co-occurence patterns that evolve through time. Dynamic Topic Model (DTM, Blei and Lafferty, 2006) divides time into discrete slices and chains parameters from each slice in order to infer topics that are aligned across time. DTM gives us a set of topic-term distributions that evolve from one time slice to the next. There are also other topic models for time-series data such as the Continuous Dynamic Topic Model (cDTM, Wang et al., 2008), a version of DTM that does not explicitly discretize time intervals. Dynamic Mixture Model (DMM, Wei et al., 2007) captures the evolution of documents across time and Topics over Time (TOT, Wang and McCallum, 2006) is a method that models the prominence of topics over time.

A limitation of LDA, as well as these dynamic models, is that it is not applicable to multilingual data. LDA captures co-occurences of words in documents and words from different languages would rarely, if ever, occur in the same document regardless of their semantics, as demonstrated by experiments on the Europarl corpus (Jagarlamudi and Daumé, 2010; Boyd-Graber and Blei, 2009). Multilingual topic models are developed to capture cross-lingual topics from multilingual datasets.

Polylingual Topic Model (PLTM, Mimno et al., 2009) is a multilingual topic model that extends LDA for an aligned multilingual corpus. Instead of running topic inference on individual documents as in LDA, PLTM infers topics for *tuples* of documents, where each document in the tuple is in a different language. PLTM assumes that the documents of a tuple discuss the same subject broadly and therefore share the same document-topic distribution.

Other topic models for multilingual data include Multilingual Topic Model for Unaligned Text (MuTo, Boyd-Graber and Blei, 2009) and JointLDA (Jagarlamudi and Daumé, 2010). MuTo attempts to match words between languages in the corpus and samples topic assignments for these matchings. JointLDA is a multilingual model that does not require an aligned corpus but requires a bilingual dictionary and uses concepts, instead of words, to infer topics where concepts can be entries in the bilingual dictionary.

In this work we will focus on DTM and PLTM because we want to capture topic evolution in multilingual settings without using additional lexical resources such as dictionaries.

3.1 Dynamic Topic Model

LDA uses Dirichlet and multinomial distributions for inferring both topic-term distributions ϕ and document-topic distributions θ. The conjugacy of these distributions allow ϕ and θ to be integrated out leaving us only with the posterior distribution for topic-term assignments Z, which we can sample through Gibbs sampling (Griffiths and Steyvers, 2004). Inference in DTM, however, is

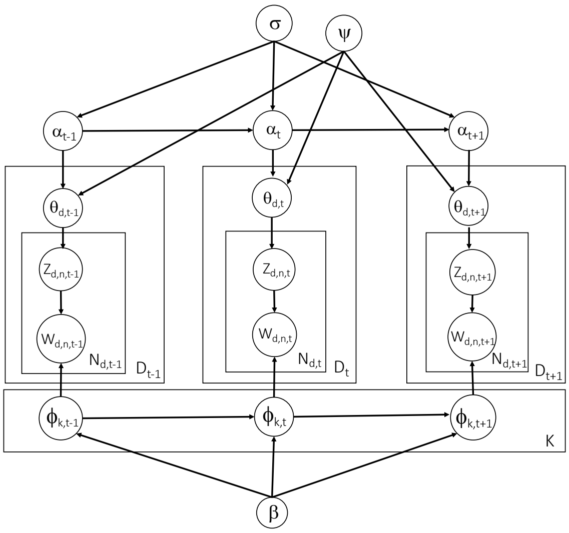

Figure 1: DTM for three time slices as shown in Bhadury et al. (2016).

more complicated due to the non-conjugacy of the distributions used in the model. Blei and Lafferty (2006) use variational Kalman filtering for topic inference, which does not scale well for a large number of topics and documents and large numbers of time slices (Bhadury et al., 2016; Wang et al., 2008). Bhadury et al. (2016) developed a method for inferring the posterior distributions of DTM with Gibbs sampling. In their method, the parameters α, θ, ϕ and Z are re-sampled during every iteration of the sampler.

The document-topic proportions θ, sampled for each document in each time slice, and the topic-term distributions ϕ, sampled for each topic in each time slice, are updated using Stochastic Gradient Langevin Dynamics (SGLD, Welling and Teh, 2011) which is based on Stochastic Gradient Descent (SGD). Figure 1 shows the plate diagram for DTM from Bhadury et al. (2016).

3.2 Polylingual Topic Model

The polylingual topic model (PLTM, Mimno et al., 2009) is an extension of LDA that infers topics from an aligned multilingual corpus composed of document tuples. Tuples are composed of documents in different languages that are thematically aligned, meaning that they discuss the subject in broadly similar ways. For instance, a news article in German and another article in English that report on the same event can compose a tuple.

Inference on PLTM can be done via Gibbs sampling where the topic assignment of each term $z^l_{d,n}$ is resampled during every iteration. Following Vulić et al. (2015), we provide the update formulae for the bilingual case for brevity. The update formulae for documents in languages x and y are:

$$P(z^x_{d,n}=k|z^x,z^y,w^x,w^y,\alpha,\beta)\propto \frac{m^x_{d,k}-1+m^y_{d,k}+\alpha}{\sum_{i=1}^K m^x_{d,i}-1+\sum_{i=1}^K m^y_{d,i}+K\alpha}\cdot \frac{v^x_{k,w_{d,n}}-1+\beta}{\sum_{i=1}^{|V^x|}v^x_{k,w_{d,i}}-1+|V^x|\beta} \qquad (1)$$

$$P(z^y_{d,n}=k|z^y,z^x,w^y,w^x,\alpha,\beta)\propto \frac{m^y_{d,k}-1+m^x_{d,k}+\alpha}{\sum_{i=1}^K m^y_{d,i}-1+\sum_{i=1}^K m^x_{d,i}+K\alpha}\cdot \frac{v^y_{k,w_{d,n}}-1+\beta}{\sum_{i=1}^{|V^y|}v^y_{k,w_{d,i}}-1+|V^y|\beta} \qquad (2)$$

where $m^x_{d,k}$ is the number of times topic k has been assigned to a word in document d written in language x and $v^x_{k,w_{d,n}}$ is the number of times word $w_{d,n}$, that is, the word at position n in document d, has been assigned to topic k. $|V^x|$ is the vocabulary size of language x. The first part of these formulae links the two languages together and is language-independent while the second part is language-specific.

Figure 2 shows the graphical representation of PLTM for l languages.

4 Multilingual Dynamic Topic Model

Here we combine the above *dynamic* and *polylingual* models to produce a *Multilingual Dynamic Topic Model* (ML-DTM). Figure 3 shows the diagram of ML-DTM for two languages and three time slices. Although we show only the bilingual case here for brevity, the model is applicable for any number of languages.

The inference method of Bhadury et al. (2016) was originally motivated by the need to speed up DTM inference for very large datsets. We apply it here to the combined ML-DTM model. We propose the following posterior conditional distribution for $\theta_{x,t}$ where x is a tuple index in the dataset:

$$p(\theta_{x,t}|\alpha_t,Z_{x,t})\propto \mathcal{N}(\theta_{x,t}|\alpha_t,\psi^2 I)\times \prod_{l=1}^{L}\prod_{n=1}^{N_{d_l,t}} Mult(Z_{d_l,n,t}|\pi(\theta_{x,t})) \qquad (3)$$

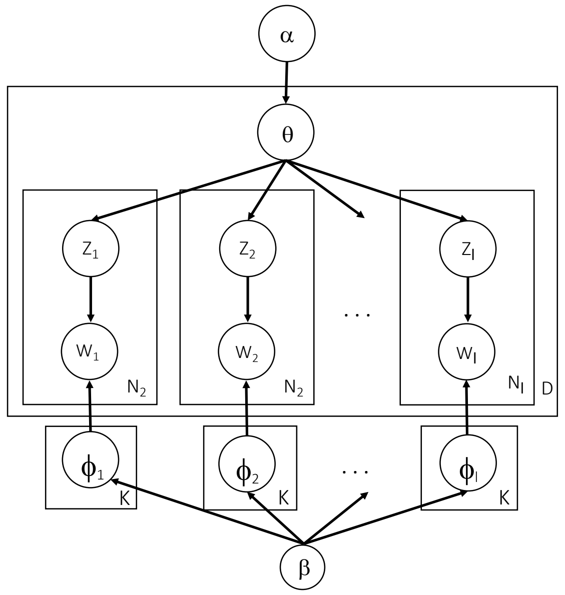

Figure 2: Polylingual topic model for l languages of Mimno et al. (2009).

Following Bhadury et al. (2016), the update equation to evaluate the gradient of $\theta^k_{x,t}$ becomes:

$$\nabla_{\theta^k_{x,t}} \log p(\theta_{x,t}|\alpha_t, Z_{x,t}) = \frac{-1}{\psi^2}(\theta^k_{x,t} - \alpha^k_t) + \sum_{l=1}^{L} C^k_{d_l,t} - \left(N_{d_l,t} \times \frac{\exp(\theta^k_{x,t})}{\sum_j \exp(\theta^j_{x,t})}\right) \quad (4)$$

where $Z_{x,t}$ are the topic assignments for the words in the documents in tuple x at time slice t; $C^k_{d_l,t}$ is the number of times topic k has been assigned to a word in document d_l at time t; and $N_{d_l,t}$ is the length of document d_l at time t.

Instead of evaluating $\theta_{d,t}$ for a single document as in monolingual DTM, we compute $\theta_{x,t}$ for a document *tuple*. The second term in (4) links the languages together by summing up the counts of each document in the tuple.

The equation for evaluating the gradient of the topic-term distributions $\phi_{k,t}$ is the same as in the original paper except that we compute separate distributions for each language since every language has a different vocabulary. This means that for each time slice, instead of updating K different ϕs (one for each topic), we will need to update $K \cdot L$ ϕs. Table 2 shows the dimensions of the parameters to be estimated.

Finally, the topic assignment $Z_{d_l,n,t}$ is sampled as in the original paper:

$$P(Z_{d_l,n,t} = k|\theta_{x,t}, \phi^{w_l}_{k,t}) \propto exp(\theta^k_{x,t})exp(\phi^{w_l}_{k,t}) \quad (5)$$

where w_l is a word from the vocabulary of language l.

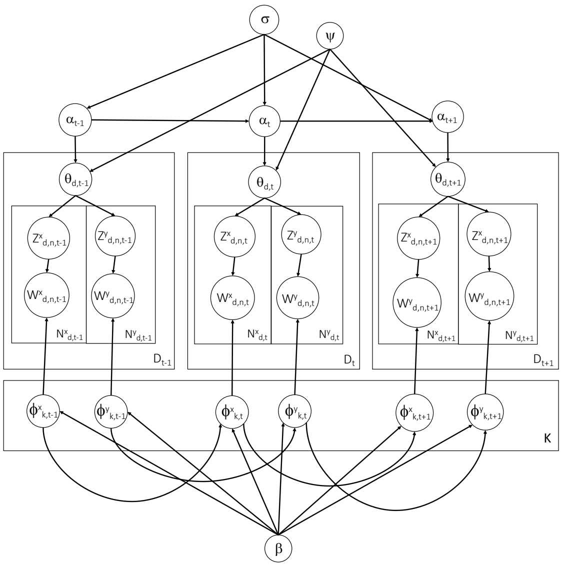

Figure 3: ML-DTM for two languages and three time slices.

Parameter	Dimension
α	$K \times T$
θ	$D^t \times K \times T$
ϕ	$\lvert V^l \rvert \times L \times K \times T$

Table 2: Dimensions of the sampled parameters in the multilingual dynamic topic model (ML-DTM). D^t is the number of document tuples in a dataset.

5 Evaluation

5.1 Datasets

We ran experiments on ML-DTM with two kinds of data: a parallel dataset and a thematically-comparable one.

The DE-NEWS parallel dataset consists of German news articles from August 1996 to January 2000 with English translations done by human volunteers[2]. This dataset covers 42 months with an average of 200 articles per month. Since this is a parallel corpus there is no need to align the articles.

[2] http://homepages.inf.ed.ac.uk/pkoehn/publications/de-news/

For the comparable dataset, we use the YLE news dataset which consists of Finnish and Swedish articles from the Finnish broadcaster YLE, covering news in Finland from January 2012 to December 2018[3]. The Finnish and Swedish articles are written separately and are not direct translations of each other. We use existing methods for aligning comparable news articles (Utiyama and Isahara, 2003; Vu et al., 2009). Specifically, we create an aligned corpus by pairing a Finnish article with a Swedish article published within a two-day window and sharing three or more named entities. We want to have a one-to-one alignment in our dataset such that no article is duplicated, so we pair a Finnish article with the first Swedish article encountered in the dataset that fits the above criteria and remove the paired articles from the unaligned dataset. The unaligned dataset has a total of 604,297 Finnish articles and 228,473 Swedish articles and the final aligned dataset consists of 123,818 articles covering 84 months. A script for aligning articles using the method described is provided in the Github project associated with this work.

We tokenized, lemmatized (using WordNetLemmatizer for German and English and LAS (Mäkelä, 2016) for Finnish and Swedish) and removed stopwords for these two datasets and then used the 5,000 most frequent words of each language as the vocabulary for that language.

5.2 Cross-Lingual Alignment

We compare the cross-lingual alignment of topics of ML-DTM and PLTM by evaluating the similarity of the learned vector representations of named entities (NEs) that appear in both languages of the same dataset. This method is suggested by Vulić et al. (2015) on the basis that NEs tend to be spelled in the same way in different languages and can be expected to have a similar association with topics across languages. The K-dimensional vector of a NE w for language s is thus:

$$vec(w_s) = [P(z_1|w_s), P(z_2|w_s), ..., P(z_K|w_s)] \tag{6}$$

Under an assumption of a uniform prior over topics, this vector can be computed as:

$$\begin{aligned} P(z_k|w_s) &\propto \frac{P(w_s|z_k)}{P(w_s)} \\ &= \frac{\phi_{l,z_k,w_s}}{Norm_{\phi_{s,\cdot,w_s}}} \end{aligned} \tag{7}$$

$$Norm_{\phi_{s,\cdot,w_s}} = \sum_{k=1}^{K} \phi_{s,z_k,w_s} \tag{8}$$

$$vec(w_s) = \frac{[\phi_{l,z_1,w_s}, \phi_{l,z_2,w_s}, ..., \phi_{l,z_K,w_s}]}{Norm_{\phi_{s,\cdot,w_s}}} \tag{9}$$

We then take the cosine similarities between the L different vector representations of the NE (for both datasets, $L = 2$).

We evaluate the cosine similarities of NEs that occur five or more times in each time slice. To make the comparison between PLTM and ML-DTM, we train one ML-DTM model on three time slices for 10 topics and three separate PLTM models for each time slice, also capturing 10 topics. We set $\alpha = 1.0$ and $\beta = 0.08$ for PLTM and $\alpha = 0.5$ and $\beta = 0.5$ for ML-DTM for both datasets, which achieved the best results of a small range of values tried. We did not, for now, perform more extensive optimisation of hyperparameters.

5.3 Topic Diversity

We also measure the *diversity* of the topics ML-DTM finds by computing the Jensen-Shannon (JS) divergence of every topic pair for each time slice for each language and averaging the divergences. Wang and McCallum (2006) used this method, though with KL divergence. It is desirable for the model to find topics that are as distinct as possible from each other.

We compare the diversity of the topics found by ML-DTM, trained as in the previous section, with the topics found by DTM. To make this comparison we train separate DTM models for each language in our two datasets, giving us four different models and compare the divergences of the topics found by these models with their ML-DTM counterparts. We use the Gensim implementation of DTM[4] where we set the chain variance to 0.1 and leave other parameters to be inferred during training. We train both ML-DTM and DTM on 10 time slices for 10 topics.

6 Results and Discussion

Tables 3 and 4 show the average cosine similarity between NEs for each language in the DE-NEWS and YLE datasets, respectively. In the DE-NEWS data (Table 3), PLTM outperforms ML-DTM in the first time slice but ML-DTM performs better on the succeeding time slices. This is an encouraging result, considering that the parameters of ML-DTM at time slice t are estimated from adjacent time slices, adding a large degree of complexity to the model, whereas PLTM estimates parameters based on the current time slice only (PLTM has no concept of time).

For the YLE dataset (Table 4), ML-DTM shows an improvement in the first time and third slices and comparable performance in the second. The comparable nature of this dataset makes aligning NEs a more challenging task for both models. One way to improve performance on this task might be to use stricter criteria in aligning the dataset, such as pairing articles only if they were published on the same day or if they share more named entities.

We compare topic diversity of the topics found by DTM and ML-DTM. Tables 5 and 6 show the average JS divergence of every topic pair for five time slices in the DE-NEWS and YLE datasets, respectively. ML-DTM consistently learns more diverse topics than DTM for both datasets.

In Figure 4, we show the evolution of one topic found by ML-DTM trained on DE-NEWS. We show the top words of a topic about labor unions for the first eight months of the dataset. The English and German words are not exact translations of each other but we see similar or related words and NEs in each time slice. For instance, in August 1996 'employer' and 'arbeitgeber' both appear, as does 'einzelhandel' and 'retail'. In Sept 1996, 'kohl' is the top term for both languages (referring to former German chancellor Helmut Kohl). There are cases where German terms have no direct translation in English but an equivalent concept appears in the English topic. This is the case with 'lohnfortzahlung' (sick-leave pay) where the terms 'sick' and 'pay' appear on the English side; and 'steuerreform' (tax reform) where 'reform' appears on the English side as well.

A named entity, 'thyssen', appears in March 1997 in both languages but not in other months. This is because of an event that happened around mid-March where the German steel company Thyssen was being bought by competitor Krupp-Hoesch (also a top term in the German topic) prompting concerns about job losses[5].

Figure 5 shows the first six months of a topic about political news from the YLE dataset. The first two months has terms related to presidential elections. This refers to the Finnish presidential election in 2012, where rounds of voting took place in January and February 2012[6]. These time slices also mention the two candidates in the runoff election, Sauli Niinistö and

Table 6: Topic diversity comparison between DTM and ML-DTM: average JS divergences of each topic pair for five months of the YLE dataset for Finnish and Swedish.

Pekka Haavisto. Sauli Niinistö eventually won the election which explains why the next time slices ceases to mention Pekka Haavisto while 'niinistö' is still a prominent term. After March 2012, the topic stops talking about presidential elections and moves on to other political news. This gives us an insight into how the model can track significant events, such as high-profile elections, related to a topic. Another example is May 2012, where Greece ('kreikka' in Finnish, 'grekland' in Swedish) suddenly becomes a prominent term for both languages due to the Greek legislative elections which took place on 6 May 2012. The term 'syyria'/'syrien' appears in May and June, corresponding to the beginning of the Syrian Civil War.

Figure 6 shows the posterior probabilities of some terms related to the presidential elections ('niinistö'), Greece ('kreikka' or 'grekland') and Syria ('syyria' or 'syrien') in the political news topic for both languages. We see the rise and fall of the prominence of the terms according to their relevance in the news.

7 Conclusions and Future Work

In this paper we present a novel topic model, the *multilingual dynamic topic model* (ML-DTM), that combines dynamic topic modeling (DTM) and polylingual topic modeling (PLTM) to infer dynamic topics from aligned multilingual data. ML-DTM uses an extension of the DTM inference method of Bhadury et al. (2016) to aligned multilingual data.

significant events regarding a topic through sudden changes in the prominent terms of the topic. This same method can also detect approximately when the event emerged and when it ended.

In a further experiment, we compared ML-DTM to the monolingual DTM, showing that ML-DTM achieves a consistently higher topic diversity within a single language.

We plan to run further experiments with ML-DTM using noisy datasets, such as historical news data where OCR errors might affect upstream tasks such as tokenization and lemmatization. We also plan to use named-entity recognition to improve our model such that named entities are treated as distinct items in the model's vocabulary, allowing us to track mentions of an entity across time slices and languages.

Historical news data covering a longer time span (several decades or more) would also enable us to study the changes in the use of words in a language and compare these changes with other languages. Historical news data from different regions would enable us to compare the way certain historical events were discussed in these places.

Abstract

We present an open-source, wide-coverage context-free grammar (CFG) for Icelandic, and an accompanying parsing system. The grammar has over 5,600 nonterminals, 4,600 terminals and 19,000 productions in fully expanded form, with feature agreement constraints for case, gender, number and person. The parsing system consists of an enhanced Earley-based parser and a mechanism to select best-scoring parse trees from shared packed parse forests. Our parsing system is able to parse about 90% of all sentences in articles published on the main Icelandic news websites. Preliminary evaluation with *evalb* shows an F-measure of 71.90% on parsed sentences. Our system demonstrates that parsing a morphologically rich language using a wide-coverage CFG can be practical.

1 Introduction

A CFG consists of a set of production rules that recursively describe how the strings of the underlying language can be derived. A parser for a natural language CFG checks whether a sentence can be derived by the CFG, and if so, assigns a syntactic structure (one or more parse trees) to the sentence. Well-known general parsing algorithms for CFGs include the (bottom-up) CYK algorithm (Younger, 1967) and the (top-down) Earley algorithm (Earley, 1970).

Various textbooks on Natural Language Processing (NLP) contain toy CFGs (for English, in most cases, e.g. (Jurafsky and Martin, 2009; Ljunglöf and Wirén, 2010)), but very few papers in recent literature describe hand-crafted natural language CFGs and parsers for them (we discuss a couple of them in Section 2). The reason is that the development of wide-coverage hand-crafted CFGs has been viewed as a challenging and time-consuming task (Briscoe et al., 1987; Hindle, 1989; Kinyon and Prolo, 2002), and that common phenomena, like agreement and inflection, have been considered complicated to describe using a CFG (Ljunglöf and Wirén, 2010). The processor and memory requirements of fully general parsing algorithms that can handle ambiguous grammars, being of worst-case cubic order (Younger, 1967; Scott, 2008), have also been seen as prohibitive. Beyond parsing, hand-crafted CFGs can be used *inter alia* to check and correct grammar in text (see Section 3).

Several treebanks have been developed for various languages during the past 25 years or so, e.g. (Marcus et al., 1993; Brants et al., 2004; Rögnvaldsson et al., 2012). Thus, instead of developing a CFG for a given language and a parser for the grammar, the more common approach has been to induce a probabilistic CFG (PCFG) from a treebank, and to train a probabilistic parser on the PCFG (Cahill, 2008). However, creating a high-quality treebank is a labor-intensive task, and, indeed, in many aspects similar to the process of manually crafting a grammar (Xia, 2001). Moreover, attempts to apply probabilistic parsing to morphologically rich languages (MRLs) have in many cases yielded unsatisfactory results, as complex word structure and flexible word order cause data sparseness in the probabilistic model (Tsarfaty et al., 2013).

In this paper, we present the development of an open-source, wide-coverage CFG for Icelandic, an MRL in the Germanic language family. We also present a parsing system, based on an enhanced Earley parser, that performs Part-of-Speech (PoS) tagging and parsing in a combined algorithm, and is able to cope with the large CFG and high levels of ambiguity associated with an MRL. It uses heuristics to return a single best scoring tree from the (often very large) packed parse forest for a sentence.

This paper is organized as follows: We discuss related work in Section 2 and the motivation for our work in Section 3. Tokenization and Out-of-Vocabulary words are discussed in Sections 4 and 5, respectively. We describe the development of the CFG in Section 6 and the parsing system in Section 7. The system is demonstrated in Section 8 and an evaluation is presented in Section 9. Finally, we conclude in Section 10.

2 Related Work

As discussed in Section 1, it is difficult to find published work from recent years describing the development of wide-coverage natural language CFGs and parsers for them. Here, we mention a couple of papers that we are aware of.

A CFG for English, developed over several years, is part of the GATE (General Architecture for Text Engineering) system, developed at the University of Sheffield (Gaizauskas et al., 2005). The CFG was specifically developed to complement a general purpose bottom-up chart parser called SUPPLE for feature-based CFGs, i.e. a CFG augmented with features in order to enforce agreement.

Abbas (2016) describes an extended Earley algorithm for parsing Urdu, an MRL. The parser uses a CFG extracted from a small treebank of 1,400 sentences (in comparison, the Penn Treebank (Marcus et al., 1993) contains 40,000 sentences). The small size of the treebank is, presumably, the main reason for not training a probabilistic parser. Moreover, the author mentions that it is hard to achieve good parsing results with probabilistic parsers for an MRL, without explicit encoding of linguistic information.

Before the work presented in this paper, no full parser existed for Icelandic. On the other hand, a shallow parser, *IceParser*, has been developed for the language (Loftsson and Rögnvaldsson, 2007). IceParser is an incremental finite-state parser, which annotates both constituent structure and syntactic functions, given PoS tagged input. The annotation scheme was designed in the project.

One Icelandic treebank, *The Icelandic Parsed Historical Corpus (IcePaHC)*, has been developed (Rögnvaldsson et al., 2012). It consists of one million words of historical texts, from the late 12^{th} century to the present, with about 10% being modern Icelandic. The annotation scheme follows the Penn Treebank style. IcePaHC has been used to train a probabilistic parser in a project aimed at improving the parsing accuracy of a related language, Faroese (Ingason et al., 2014).

3 Motivation

An initial primary goal of our project was to be able to extract information from text on Icelandic websites, such as associating person names with titles, and named entities with their definitions, irrespective of the grammatical forms that such associations may take in the text. As the project evolved, a secondary goal became to leverage the CFG and the parser to check and correct grammar, by adding specially annotated grammar rules and parser configurations for common error constructs. Finally, as our corpus of automatically parsed sentence trees grew to an order of millions, it became the basis of a follow-on project, beyond the scope of this paper, to train a deep neural network to parse Icelandic text.

4 Tokenization and Annotation

One of the catalysts for the project was the availability of the *Database of Modern Icelandic Inflection* (DMII) (Bjarnadóttir, 2012)[1]. DMII is a database that maps over 6 million lexical entries, 2.8 million unique word forms, to lemmas as well as PoS tags (word categories and morphological features).

The first phase of our project involved writing a tokenizer that uses data from the DMII to annotate each word token of a sentence with the set of its possible lemmas and corresponding PoS tag profile (possible PoS tags). In Icelandic, even common words such as *á* are highly ambiguous; *á* can mean *own* (verb), *female sheep* (noun), *river* (noun), or *on* (preposition), and can also occur as an adverb and an exclamation – our system associates it with 14 different PoS tags. This again means that the token for *á*, and indeed most word tokens, can match several different terminals in the CFG.

The tokenizer greedily recognizes certain multi-token spans, such as dates and adverbial multi-

[1] The DMII is available for download at http://bin.arnastofnun.is/dmii/.

word idioms, and coalesces them into single compound tokens. This makes the parsing stage more efficient and reduces ambiguity.

5 Out-of-Vocabulary Words

Compounding in Icelandic is very productive, and thus out-of-vocabulary (OOV) words, i.e. word forms that are not present in the DMII, are frequently encountered. We handle this by implementing a de-compounding algorithm, on top of a *Directed Acyclic Word Graph* comprising all word forms in the DMII, that maps each OOV word to a minimal sequence of prefixes followed by the longest possible suffix. This suffix is then used as a proxy for the compound word when looking up its PoS tags in the DMII.[2]

If the de-compounding algorithm is unable to make sense of a word, e.g. a foreign word, spelling error, or previously unseen named entity, its token is assumed to represent a neutral gender, singular noun that matches noun terminals in any of the four cases.

6 Context-Free Grammar

Once we had designed the mechanism for token-to-terminal matching (further described in Section 6.1), we proceeded to write out the nonterminals and productions of our CFG in an iterative fashion. Initially, a kernel of core nonterminals and productions for basic sentence structures and simple forms of noun, verb, prepositional and adverbial phrases was created.[3] This small CFG was then used to parse a starting reference set of typical texts selected from news articles. In each iteration, the most significant gaps in the CFG were identified and a round of improvements was applied. The set of reference texts was gradually expanded as the CFG coverage increased. This cycle is still ongoing, albeit of course with diminishing returns.

A web-based graphical user interface (GUI) was developed at an early stage in the project (see Section 8). The GUI provides an overview of news articles where sentences that the system fails to parse are clearly identified, and allows inspection of parse trees in graphical format. Having a visual way to identify problem areas and assess the system's performance facilitated the iterative cycle.

Our CFG for Icelandic is defined in a text file, presently about 5,800 lines including comments, written in a superset of Enhanced Backus-Naur Format (EBNF). This superset is our own implementation which facilitates automatic expansion of production rules (as discussed in Section 6.2). Apart from the CFG itself, the file contains annotation pragmas, such as priority scores for nonterminals (further discussed in Section 7.2). The total effort to date on the construction of the CFG is on the order of 2–3 man years.

6.1 Terminals

Our CFG allows three types of terminals:

- **Literal terminals**: Terminals of the form `"text"` match tokens with that text only (case-insensitive). This terminal form is, for example, used for various types of conjunctions.

- **Lemma terminals**: Terminals of the form `'lemma:category'_var1_var2...` match tokens having at least one PoS tag matching the indicated word category with the given lemma, optionally also agreeing with the specified variants (see Section 6.2). As an example, `'hafa:vb'_sg` (*hafa* being the infinitive of the verb *to have*) matches any singular form (`_sg`) of the verb, including *hef* (*[I] have*), *hafðir* (*[you] had*) and *hefur* (*[she] has*). This terminal form is, for example, used for auxiliary verbs in complex verb constructions.

- **Lookup terminals**: Terminals of the form `category_var1_var2...` match tokens having at least one PoS tag with the indicated word category that agrees with all of the specified variants, if any. As an example, `no_neut_sg_nom` matches any word token that has a PoS tag that identifies it as a noun (`no`), neutral (`_neut`), singular (`_sg`), nominative case (`_nom`). A word token such as *veður* (meaning *weather*) would match the terminal `no_neut_sg_nom`, but the same token also has a PoS tag indicating a verb (meaning *(he) wades*) and would thus also match the terminal `vb_sg_p3` that specifies a singular, third person verb.

[2] An example is *menntamálaráðherra*, (the minister of matters of education), composed of *mennta-mála-ráð-herra*, i.e. three prefixes and the suffix noun *herra*, from which the inflection of the compound word is derived.

[3] The general outlines of such a kernel would be similar for most languages in the Germanic family.

Feature	Variant	Values
Gender	`/gender`	`_masc, _fem, _neut`
Number	`/number`	`_sg, _pl`
Case	`/case`	`_nom, _acc, _dat, _gen`
Person	`/person`	`_p1, _p2, _p3`

Table 1: The major variants used in our CFG for Icelandic.

6.2 Variants and Feature Agreement

Describing nontrivial, potentially long-distance feature agreement in CFGs has been considered a challenge. In our grammar, we use automatic expansion of macro-like constructs, called *variants*, for this purpose. Variants are defined for the morphological features for which agreement is required within the productions of a nonterminal. They can be applied to both nonterminals and terminals. Table 1 shows the major variants used in our CFG for Icelandic.

Terminals with variants can only match word tokens that have at least one PoS tag that matches all of the variants. If a terminal has, e.g., an accusative case variant (`_acc`), it can only match word tokens that have a PoS tag indicating the accusative in the DMII.

As a simplified (and anglicized) example of how feature agreement is specified in the CFG, consider the following fragment:

```
NounPhrase ->
  Determiner/case/number/gender?
  Noun/case/number/gender
Determiner/case/number/gender ->
  det/case/number/gender
Noun/case/number/gender ->
  no/case/number/gender
```

Here, the nonterminal `NounPhrase` is defined as an optional `Determiner` having case, number and gender variants (`/case/number/gender`), followed by a mandatory `Noun` nonterminal, again with case, number and gender variants that agree in each expansion with the ones in the `Determiner`. The production for `Determiner` consists of a single terminal, `det/case/number/gender`, which matches word tokens having a PoS tag with the `det` category, inflected in accordance with the variants. The same applies to the production for `Noun`, which contains a single `no` terminal matching any noun that agrees with the features specified by the variants.

When the CFG is parsed, the variants are expanded as macros having each of their feature values in turn. The fragment above is expanded from three production rules to a total of 3 rules * 4 cases * 2 numbers * 3 genders = 72 expanded rules in the grammar. They include:

```
NounPhrase ->
    Determiner_nom_sg_masc? Noun_nom_sg_masc
  | Determiner_nom_sg_fem? Noun_nom_sg_fem
  | Determiner_nom_sg_neut? Noun_nom_sg_neut
...[21 generated productions omitted]...
Determiner_nom_sg_masc -> det_nom_sg_masc
Determiner_nom_sg_fem -> det_nom_sg_fem
Determiner_nom_sg_neut -> det_nom_sg_neut
...[21 generated productions omitted]...
Noun_nom_sg_masc -> no_nom_sg_masc
Noun_nom_sg_fem -> no_nom_sg_fem
Noun_nom_sg_neut -> no_nom_sg_neut
...[21 generated productions omitted]...
```

7 Parsing System

7.1 Earley-Based Parser

Parsing algorithms for natural language text can be evaluated on a number of criteria. They need to be able to parse all well-formed CFGs, including (heavily) ambiguous ones. A direct relationship between the produced parse forests and the original, unmodified CFG is a desirable feature. Last, but not least, the parsing performance in terms of time and space must be good enough for real-world applications.

The Earley (1970) algorithm handles all CFGs and, when extended from its original recognizer form to a full parser, returns parse trees that correspond directly to the original grammar (i.e. not requiring any *ex ante* transformation of the CFG). However, performance has been seen as a problem when parsing heavily ambiguous sentences, with both time and space requirements being worst-case cubic ($O(N^3)$) in the sentence length *N*.

Tomita (1986) described *Shared Packed Parse Forests* (SPPFs), a data structure that avoids redundancy when generating and storing parse trees for ambiguous token spans. Tomita's parser was a Generalized LR parser of worst-case unbounded polynomial order. Later, Scott (2008) and Scott and Johnstone (2010) presented an Earley-based parser which produces a binarized SPPF representation of all derivations of a sentence in worst-case cubic time. This parser meets all of the above mentioned criteria.

We implemented the Earley-Scott-Johnstone algorithm in C++ and found it to perform well enough for parsing natural language text according to our highly complex and ambiguous CFG for Icelandic.[4]

[4] Our system takes just over 1 second of wall-clock time

7.2 Disambiguation

The parser produces a binarized SPPF that includes all possible derivations of a sentence. A typical ambiguity factor is around 1.8, meaning that a sentence of N tokens typically has around 1.8^N different parse trees.

A nonterminal node in the SPPF may have more than one family of children if there are multiple derivations of that nonterminal for the same token span. Note that a single packed subtree may occur within multiple parse trees in a forest, by virtue of the packing mechanism.

Once the parse forest has been derived, bottom-up scoring heuristics are applied in a disambiguation step to find a single "best" parse tree. We begin the disambiguation process at the terminal (bottom) level of the SPPF, by assigning a score to each token-terminal match based on the probability of that match. For instance, the word *ekki* can be both an adverb (meaning *not*) and a noun (meaning *sob*, as in crying). The former meaning is much more common than the latter one, and thus a match of *ekki* to a noun terminal gets a relatively lower score, while a match of *ekki* to an adverb terminal gets a relatively higher score. The scores are heuristically defined and hand-tuned by us.

The scores assigned at the terminal level are summed up as they percolate upwards in the SPPF, and further adjusted at nonterminal nodes. In the CFG specification, scores can be assigned to nonterminals using pragmas. More common grammatical constructs have positive scores, while less common or exceptional ones have negative scores.

When the traversal encounters an ambiguous nonterminal node with multiple families of children, the accumulated scores of the families are compared. The family (subtree) with the highest score "wins" and is retained, while the other families are pruned from the tree. At the root (top) nonterminal, a single highest-scoring tree remains and is returned. It is at this point that the PoS tag for each word token is finally determined.

7.3 Attachment of Prepositions

There is, however, one exception to the general case described in the last subsection: The mechanism for attaching prepositional phrases (PPs) to verb or noun phrases. This well-known problem manifests itself in ambiguous sentences such as: *Ég las blaðið í gær* (*I read the paper yesterday / I read yesterday's paper*); should the PP *í gær* (*yesterday*) be attached to the verb *las* (*read*) or to the noun *blaðið* (*the paper*)? The problem is not perfectly solvable since the correct attachment may depend on semantics. We approximate a solution by augmenting our database of almost 7,300 verbs with a hand-crafted list of prepositions that are commonly attached to each verb. For example, with the verb *tala*, meaning *talk*, we associate the preposition *við/acc* (meaning *to/accusative*), indicating that the preposition *við*, when governing an object in the accusative case, is commonly attached to the verb *tala*.

Recall that our parser generates an SPPF representing all possible parse trees, including ones where PPs are attached to verbs and ones where they are attached to nouns. We want to selectively boost the score of subtrees where a PP (such as *við/acc*) is attached to a verb phrase (VP) with a matching verb (such as *tala*). This makes such subtrees more likely to "win" in the disambiguation and tree pruning process, vs. subtrees where the same PP is attached to a noun or to a non-matching verb.

In order for this to work correctly, we must partially unpack the parse forest. Specifically, PP nodes are unpacked (cloned) to become independent children of any ambiguous parent nonterminal nodes up to and including the enclosing VP node. This is done in a special top-down preprocessing pass before the main disambiguation scoring and pruning pass. During the scoring pass, we keep track of current VP scopes (such as the scope of *tala*) and assign scores to preposition terminal nodes (such as *við*) depending on whether the preposition matches an enclosing verb. Since the PP nodes have been unpacked, they can have different scores in different subtrees and can be independently pruned from the forest, which the SPPF structure would otherwise not allow.

8 Demonstration

Our system is open and available both as a public website[5] and as a GNU GPLv3-licensed Python package for NLP researchers and developers.[6]

to parse, disambiguate and process a typical 22-sentence news article from the web, on a quad-core Intel® i7 based GNU/Linux server.

[5] `https://greynir.is` (only in Icelandic).

[6] The source code for the CFG and the parsing system, written in Python 3 and C++, is available at `https://github.com/mideind/ReynirPackage`.

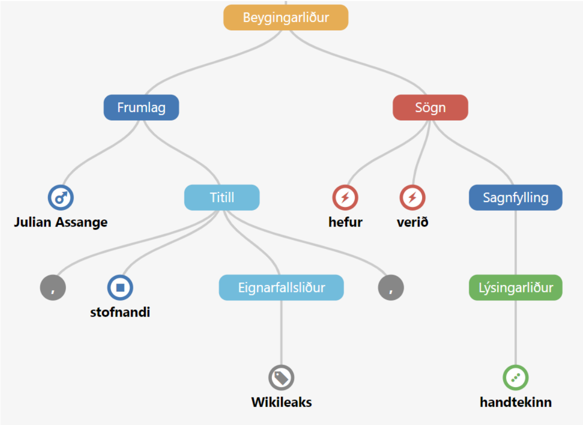

Figure 1: A part of a simplified parse tree, as displayed on the `greynir.is` website. The sentence is *Julian Assange, founder of Wikileaks, has been arrested*. (*Beygingarliður*, *Frumlag*, *Eignarfallsliður*, *Sögn*, *Sagnfylling*, *Lýsingarliður*) = (*IP*, *Subject*, *Possessive Phrase*, *VP*, *Predicative Complement*, *Adjective Phrase*).

The website is refreshed every 30 minutes with new articles from the major Icelandic news outlets. The news articles can be browsed, and parse trees for individual sentences can be viewed in a graphical format by clicking on them (see Figure 1). Sentences that the system is not able to parse are marked in red. The system shows the names and titles of people who have been mentioned in recent news articles, the definitions of named entities, and geographical locations that occur in recent news. This information is picked up from tokens and parse trees.

Apart from browsing news articles, users are able to enter their own text and have it parsed and checked by the system. As with news articles, the parse tree of a user-entered sentence can be displayed by clicking on the sentence.

9 Evaluation

On the basis of the current CFG, our parser is able to derive at least one parse tree from about 90% of sentences in our database of 8.7 million sentences extracted from news articles. The remaining 10% are divided between sentences in languages other than Icelandic, number-oriented text in currently unparsable format such as sports results and data tables, sentences containing severe spelling or grammar errors, and valid sentences which our CFG does not yet cover.

Recall	**Precision**	**F-measure**	**Average Crossing**
`71.15%`	`72.67%`	`71.90%`	`4.18`

Table 2: *evalb* results for 78 hand-annotated sentences.

To estimate the accuracy of our CFG and the parser, we hand-annotated 80 randomly selected sentences from news articles using a simplified, syntactically bracketed annotation scheme similar to that of the Penn Treebank. The trees output from our parser were converted from their internal representation, corresponding directly to the CFG, to the simplified scheme via a set of mapping rules. Spelling and grammar errors were corrected before parsing. Results for this small test corpus, using the *evalb* tool (Sekine and Collins, 2013), are shown in Table 2.

Out of 80 sentences, two could not be parsed as they contain syntactic structures not presently covered by the CFG. Out of 1,444 word tokens, 66 (4.6%) were OOV of which the de-compounding algorithm handles 35.

Many errors are caused by wrong attachment of PPs and subclauses, or when NPs from phrases or clauses deeper in the tree are erroneously attached as objects of verbs in the main clause, instead of correctly identifying a complement clause or PP as the object.

Both error types affect all intermediate levels in the tree, and thus lower *evalb*'s reported scores severely. We continue to work on our grammar and our parsing system to address these errors, as well as developing a gold standard of parsed news text for more accurate evaluation.

10 Conclusion

We have presented a system consisting of an open-source, wide-coverage CFG for Icelandic, and an accompanying parser. Our system demonstrates that it is practical to develop a wide-coverage CFG for an MRL, such as Icelandic, with a parsing system that performs well enough for real-world use cases. Such a system can be used *inter alia* for information extraction from news websites, grammar correction, and to generate dependency annotated corpora as well as treebanks for training deep neural network-based parsers.
