When $d = 2$, the weights $\alpha_{2,k,i}$ for every H_k are calculated on the basis of how likely x_k becomes the 2nd-order parent of x_i. Here, d-th-order refers to the distance between x_k and x_i. For example, suppose there are two different paths connecting two nodes, and that their distances are both 2, illustrated by the path colored blue and red in Figure 2. The module multiplies the weights of the edges on each path, $\alpha_{1,2,3} \times \alpha_{1,3,4}$ for the red path and $\alpha_{1,2,1} \times \alpha_{1,1,4}$ for the blue path, and then the module sums the multiplied values;

[1] We use the plural form "parents" here because how likely a sentence becomes the parent of x_i is represented as a probability distribution in our model and multiple parents can be considered.

$\alpha_{2,2,4} = \alpha_{1,2,3} \times \alpha_{1,3,4} + \alpha_{1,2,1} \times \alpha_{1,1,4}$. We consider $\alpha_{2,2,4}$ to be the probability of x_2 being the 2nd-order parent of x_4. Then, the module uses the value as the weight and outputs the weighted sum vector $\gamma_{2,4}$.

When $d > 2$, the module recursively calculates the weight $\alpha_{d,k,i}$ by using the previously calculated weight $\alpha_{d-1,k,i}$ as shown in the next section.

Step3: Selective Attention Module Once weighted sum vectors $\gamma_{d,i}$ have been obtained taking into account the d-th-order parents of x_i, this module calculates the weights of each order d to select a suitable order. The module again calculates the weights for every order d and generates a weighted sum vector Ω_i.

5.1 Formulation of Attention Modules

Here, we describe the formulation of each attention module. The Parent Attention Module calculates the probability of x_k being the parents of x_i for all combinations of k and i where $k \neq i$:

$$\begin{aligned} p(k|i, \mathbf{H}) &= softmax(g(k,i)), \\ g(k,i) &= v_a^{\mathrm{T}} \tanh(U_a \cdot H_k + W_a H_i), \end{aligned} \tag{3}$$

where v_a, U_a and W_a are weight matrices.

The Recursive Attention Module recursively calculates the probability of x_k being the d-th-order parents of x_i:

$$\alpha_{d,k,i} = \begin{cases} p(k|i, \mathbf{H}) & (d = 1), \\ \sum_{l=0}^{N} \alpha_{d-1,k,l} \times \alpha_{1,l,i} & (d > 1). \end{cases} \tag{4}$$

Furthermore, in a discourse dependency tree, ROOT should not have any parent, and a sentence should not depend on itself. To satisfy these constraints, we impose the following on $\alpha_{1,k,i}$:

$$\alpha_{1,k,i} = \begin{cases} 1 & (k = 0, i = 0), \\ 0 & (k = i, i \neq 0). \end{cases} \tag{5}$$

The first equation constrains the ROOT node not to have any parent sentence. The second constraint ensures that a sentence does not depend on itself.

The calculated probabilities $\alpha_{d,k,i}$ are then used to weigh the vectors in $\mathbf{H}$, and the weighted sum vector $\gamma_{d,i}$ is generated as:

$$\gamma_{d,i} = \textstyle\sum_{k=0}^{N} \alpha_{d,k,i} H_k. \tag{6}$$

Once the weighted sum vector $\gamma_{d,i}$ is obtained for each order d, the Selective Attention Module calculates the weights $\beta_{d,i}$ for each $\gamma_{d,i}$ to find a suitable order:

$$\beta_{d,i} = softmax(\mathbf{W}_\beta [H_i; s_i; K]), \tag{7}$$

where $\mathbf{W}_\beta$ is a weight matrix. The attention vector is obtained as a weighted sum of $\gamma_{d,t}$:

$$\Omega_i = \textstyle\sum_d \beta_{d,i} \gamma_{d,i}. \tag{8}$$

Finally, the output layer receives the concatenated vector of H_i and Ω_i:

$$p(y_i|\mathbf{x}, \theta) = softmax(\mathbf{W}_o tanh(\mathbf{W}_{c'}[H_i; s_t; K; \Omega_i])). \tag{9}$$

5.2 Objective

The training updates the parameters to maximize both the label probability and 1st-order attention distribution $\alpha_{1,k,l}$. Specifically, we use the following loss function for optimization:

$$-\log p(\mathbf{y}|\mathbf{x}) - \lambda \cdot \textstyle\sum_{k=1}^{N} \sum_{i=1}^{N} E_{k,i} \log \alpha_{1,k,i}. \tag{10}$$

In this equation, $E_{k,i}$ is 1 if the edge from x_k to x_i exists in the training instance. Thus, all the parameters are updated to reproduce the correct labels and edges appearing in the training data D. λ is a parameter to control the priority of the output labels or the edges given by an RST parser.

6 Experiments

Data and Preprocessing: We used two different datasets for the experiments; the DailyMail dataset for training and evaluation, and the DUC2002 test set[2] only for evaluation.

The DailyMail dataset (Hermann et al., 2015) consists of news articles extracted from Daily Mail Online[3] and their "story highlights" created by human writers. Nallapati et al. (2016) regarded the highlights as human-generated abstractive summaries. For training extractive summarization models, we need to annotate sentences with binary labels for sentence extraction. To do this, Cheng and Lapata (2016) used a rule-based approach considering the similarity between the original document and extracted sentences. On the other hand, Nallapati et al. (2017) proposed a simple heuristic for labeling sentences to be included in the summary by maximizing the ROUGE scores, using the highlights as reference summaries. We used the latter scheme to annotate the binary labels for sentence extraction.

As a preprocessing, we applied the HILDA parser (Hernault et al., 2010) to annotate RST-based discourse information for all the documents. The RST trees were then converted into dependency structures by using the method described in Hirao et al. (2013). The parser requires the features extracted from word surfaces and the information on paragraph boundaries. However,

[2] https://www-nlpir.nist.gov/projects/duc/guidelines/2002.html

[3] http://www.dailymail.co.uk/

the preprocessed DailyMail dataset[4] provided by Cheng and Lapata (2016) and commonly used for summarization tasks was not suitable for our use. The dataset is anonymized; all named entities were replaced by the special token `@entity`, and paragraph boundaries were deleted. Therefore, we used the non-anonymized version of the dataset provided by Hermann et al. (2015). We obtained 196,557 training documents, 12,147 validation documents and 10,396 test documents from the DailyMail dataset.

The DUC2002 test set consists of 116 pairs of source documents and their extractive summaries, and 567 pairs of source documents and their abstractive summaries. We used the dataset for evaluation on out-of-domain data.

Compared Models: We compared our models with various baseline models. `DIS w/ PAR` is our model with the model parameter $\lambda > 0$. With this setting, all the parameters are tuned to reproduce the correct labels and the edges given by the RST parser. `DIS fixed` is the discourse-aware model with the attention vector $\Omega_t = H_{t-1}$. Thus, this model always treats the preceding sentence as the parent. `DIS w/o PAR` is the model with the model parameter $\lambda = 0$. Note that the objective function in this model does not take into account the RST annotations given by the RST parser. Thus, all the discourse structures are learned to reproduce the correct sentence labels without the information from the parser.

We compared the above models with the model without any discourse-aware attention mechanisms (`no-attn`) to verify the effectiveness of our attention mechanisms. `Lead-3` is a common baseline to select the first three sentences. `SummaRuNNer` is a well-known RNN-based summarizer by Nallapati et al. (2017). This model uses some types of information that we do not use, such as the similarity between the source document and the target sentence, and the novelty score of the target sentence, while our approach incorporates the information on the parent sentence of the target sentence. `NeuralSum` is also a neural network-based summarizer which uses convolutional neural networks in the encoder. `Refresh` is a state-of-the-art method using reinforcement learning (Narayan et al., 2018) [5].

In addition to the above methods, we compared our models with previously reported performances on the DUC2002 test set. `LREG` is a feature-rich logistic regression based approach used as a baseline in Cheng and Lapata (2016). `ILP` is a phrase-based extraction system proposed by Woodsend and Lapata (2010). The approach extracts the phrases and recombines them subject to the constraints in the ILP such as length, coverage or grammaticality. Both `TGRAPH` (Parveen et al., 2015) and `URANK` (Wan, 2010) are graph-based sentence extraction approaches, that perform well on the DUC2002 corpus.

Evaluation Metrics: We conducted both automatic evaluation and human evaluation. In automatic evaluation, we adopted ROUGE scores (Lin, 2004). We specifically calculated ROUGE-1, ROUGE-2 and ROUGE-L by using the Pyrouge library[6]. The highlights in the Dailymail dataset were treated as reference summaries when we calculated the scores. We used three length constraints; 75 bytes, 275 bytes (Nallapati et al., 2017; Cheng and Lapata, 2016) and the bytes of reference summaries. We truncated generated summaries in the middle to conform to the length constraints. We adopted the last constraint to evaluate whether a model can include sufficient information within the ideal summary length. For the evaluation on out-of-domain data, we report the ROUGE scores on the DUC2002 abstractive and extractive test sets. Our models are trained on the DailyMail dataset and tested on DUC2002.

We additionally carried out human evaluation because ROUGE scores cannot capture the coherence, though our attention modules are designed to improve the coherence of summaries. We used Amazon Mechanical Turk to conduct human evaluation. Specifically, randomly selected 100 documents and their four summaries generated by `DIS w/ PAR`, `Lead-3`, `no-attn`, and `SummaRuNNer` were shown to the workers. Five workers were asked to rate each summary on a 1-5 scale in terms of coherence and informativeness. The instruction shown to the workers follows the DUC quality question[7].

Training Details: We used Adam (Kingma and Ba, 2015) for the optimizer, where the learning rate was set to 0.001. In accordance with the model parameters used in Nallapati et al. (2017),

[4] `http://homepages.inf.ed.ac.uk/mlap/index.php?page=resources`

[5] We used the implementation provided by the authors.

[6] The options for the Rouge script were "-a -c 95 -m -n 2 -b 75" and "-a -c 95 -m -n 2 -b 275".

[7] `https://duc.nist.gov/duc2007/quality-questions.txt`

we limited the vocabulary size of the input to 150,000 and replaced the out-of-vocabulary words with the token UNK. The size of the mini-batch was set to 8. We used the size of 100 for hidden layers in the LSTMs and 300 for word embeddings, which were initialized with pre-trained embeddings, word2vec-slim. Note that the previous researches (Nallapati et al., 2017; Cheng and Lapata, 2016) also used pre-trained embeddings. We filtered the training instances consisting of 50 or more sentences in the source document, following Nallapati et al. (2017). The parameter λ of all the discourse-aware models was tuned on the validation set. We tried the following values for λ: 0.01, 0.1, 1.0, 2.0, 5.0 and 10.0.

7 Results and Discussion

ROUGE scores on DailyMail dataset: Table 1 shows the ROUGE scores evaluated on the DailyMail test set. For fair comparison, we also re-trained the baseline models by using our non-anonymized dataset.

DIS w/o PAR achieved better ROUGE scores than no-attn in all variations of length constraint except for ROUGE-L score on the setting with $d = \{1, 2\}$. Furthermore, we obtained better scores for DIS fixed than DIS w/o PAR. Incorporating the simple discourse information which treats the preceding sentence as the parent in the objective function improved the performance. Exploiting the discourse information given by the RST parser (DIS w/ PAR) further improved the scores in most settings. These observations suggest that discourse information is useful in RNN-based summarizers.

In the setting with the length constraint of 75 bytes, we observed a statistically significant difference between DIS w/ PAR and other neural network-based models (SummaRuNNer , Refresh and NeuralSum) on the settings with $d = \{1, 2\}$ and $d = \{1, 2, 3\}$. We also observed the similar tendency in the setting with the length constraint of reference summaries. Furthermore, we did not observe a statistically significant difference between DIS w/ PAR and SummaRuNNer in the setting with the length constraint of 275 bytes. Those facts would suggest that our models achieve a performance similar to the other baseline models in the setting with longer length constraints, and can perform better with shorter length constraints.

ROUGE scores on DUC2002 dataset: The results are shown in Table 2. Neural network-based approaches achieved similar scores on the abstractive test set because the length constraint is long; specifically it was set to 100-words. However, graph-based approaches (TGRAPH and URANK) performed better than the neural network-based approaches. As reported in Nallapati et al. (2017), neural network-based approaches suffer the difficulties in achieving high performance on out-of-domain data due to its high capability to fit in-domain data. Another possible reason might be the method for creating the binary labels for the training dataset. The binary decisions on the training dataset were made to maximize the ROUGE-F scores. Thus, the labels are strongly affected by the length of reference summaries in the DailyMail dataset. Since the average length of the reference summaries in the DUC test set is longer than the average length in the DailyMail dataset, the models trained on the DailyMail dataset might face difficulties. Our proposed models achieved the significantly better performances among the neural network-based approaches on the extractive test sets, which are for the settings with shorter length constraints (50 and 100 words) .

Human Evaluation: Table 3 shows the results. DIS w/ PAR were evaluated better than no-attn and SummaRuNNer in terms of coherence in the settings with all the different length constraints. These differences are statistically significant with the sign test ($p < 0.05$). Thus, human evaluation also supports the effectiveness of incorporating discourse information. Lead-3 is inherently strong in terms of coherence because this model is constrained to extract consecutive sentences while other models possibly extract non-consecutive ones. It was evaluated better in the setting with 75 bytes length constraint.

Analysis: Table 4 shows an example of the source document and outputs of two models; the sentences selected by our model are colored red and those selected by SummaRuNNer are blue, and those selected by both are purple. In this example, $S7$ elaborates $S6$. Our summarizer successfully extracted $S6$, that made the output summary more similar to the gold summary.

8 Conclusion

We presented a hierarchical attention network that captures the discourse dependency structure of the

Document:

S1: Bayern Munich is interested in Chelsea defender Branislav Ivanovic but are unlikely to make a move until Jan.

S2: The Serbia captain has yet to open talks over a new contract at Chelsea and his current deal runs out in 2016.

S3: Chelsea defender Branislav Ivanovic could be targeted by Bayern Munich in the January transfer window.

S4: Bayern like Ivanovic but don't expect Chelsea to sell yet they know he will be free to talk to foreign clubs from Jan.

S5: Paris Saint-germain will make a 7million offer for Chelsea goalkeeper Petr Cech this summer.

S6: The 32-year-old is poised to leave Stamford Bridge and wants to play for a champions league.

S7: Contender PSG are set to make a 7million bid for Ivanovic's Chelse a team-mate Petr Cech in the summer.

Gold Summary:

Branislav Ivanovic's contract at Chelsea expires at the end of next season.The 31-year-old has yet to open
talks over a new deal at Stanford bridge. Petrcech is poised to leave Chelsea at the end of the season

Table 4: Example of the extracted sentences. The sentences in bold are included in our summary. The sentences colored red were selected by our model, blue were by SummaRuNNer and purple were by both models.

source document. The experiments showed that incorporating discourse information into RNN-based extractive summarizers improves coherence and informativeness evaluated by human judges in addition to ROUGE scores. Our models outperformed or achieved competitive performances against the state-of-the-art methods. Improving the performance on out-of-domain data will be one of our future directions.

Semi-Supervised Induction of POS-Tag Lexicons with Tree Models

Abstract

We approach the problem of POS tagging of morphologically rich languages in a setting where only a small amount of labeled training data is available. We show that a bigram HMM tagger benefits from re-training on a larger untagged text using Baum-Welch estimation. Most importantly, this estimation can be significantly improved by pre-guessing tags for OOV words based on morphological criteria. We consider two models for this task: a character-based recurrent neural network, which guesses the tag from the string form of the word, and a recently proposed graph-based model of morphological transformations. In the latter, the unknown POS tags can be modeled as latent variables in a way very similar to Hidden Markov Tree models and an analogue of the Forward-Backward algorithm can be formulated, which enables us to compute expected values over unknown taggings. We evaluate both the quality of the induced tag lexicon and its impact on the HMM's tagging accuracy. In both tasks, the graph-based morphology model performs significantly better than the RNN predictor. This confirms the intuition that morphologically related words provide useful information about an unknown word's POS tag.

1 Introduction

Part-of-speech tagging is nowadays commonly thought of as a solved problem, with accuracy scores easily achieving 95% or more. However, such results are typically reported for English or other resource-rich European languages, for which large amounts of high-quality training data are available. Those languages also tend to have a simple morphology and utilize small to mid-sized tagsets. However, for many other languages, the reality is different: training data are expensive or not available, more fine-grained tagsets are needed and complex morphology accounts for large numbers of OOV words in corpora. (Straka and Straková, 2017) present a contemporary evaluation of state-of-the-art POS tagging for a very wide variety of languages. The scores for tagging with UPOS[1] tagset lie below 90% for many languages. The lack of sufficient amounts of training data is undoubtedly one of the main reasons for such results.

In this paper, we attempt to improve the POS tagging in a setting where only a small amount of labeled training data is available, as well as a significantly larger corpus of unlabeled text. We train a bigram Hidden Markov Model on the labeled part of the corpus and subsequently apply Baum-Welch estimation on the unlabeled part. Additionally, we use the labeled part to train a morphology model in an unsupervised setting. The key idea is to extend the tagger's lexicon with words occurring in the unlabeled part before the Baum-Welch estimation and to pre-guess their possible tags using the morphology model.

The choice of a bigram HMM for tagging is clearly suboptimal. However, our objective here is an initial proof-of-concept demonstrating that tagging in low-resource settings can benefit from unsupervised morphology. The choice of an HMM is dictated by the fact that it is easy to implement, well interpretable in its workings, possible to train on unlabeled data (using the Baum-Welch algorithm) and that it is possible to extend an exist-

[1] The tagset used in the Universal Dependencies project. It is very coarse-grained, containing e.g. only a single tag for nouns and verbs, respectively.

ing model with new vocabulary without complete re-training. Furthermore, the closely related trigram HMMs used to be state-of-the-art for a long time and are still used in popular tools like HunPos (Halácsy et al., 2007; Megyesi, 2009). Transferring this result to state-of-the-art tagging methods remains a topic for further work.

2 Related Work

2.1 Morphology-Based Induction of POS Lexicons

The idea of guessing possible tags for out-of-vocabulary words based on automatically induced morphological rules was proposed already by (Mikheev, 1997). He introduces a probabilistic model of string transformations, followed by a statistical significance analysis, which learns the correspondence between string patterns and POS tags. A related problem is learning morphological paradigms from inflection tables (Durrett and DeNero, 2013; Ahlberg et al., 2014). Here, complete paradigm tables of annotated word forms are used to learn string transformations between different forms, which are subsequently applied to unknown words to derive their possible tags.

Recently, (Faruqui et al., 2016) approached a task very similar to ours using a graph-based model. Without explicitly modeling morphology, they model structural similarities between words, like a regular affix change or sharing a common affix, as graph edges. They use a discriminative model of label propagation through edges which is similar to the Ising model of intermolecular forces. The induced lexicons are evaluated directly, as well as on how they improve a morphosyntactic tagger and a dependency parser.

2.2 Hidden Markov Tree Models

Hidden Markov Tree (HMT) models are a generalization of Hidden Markov Models, in which every node can have multiple descendents. They were introduced in the context of signal processing by (Crouse et al., 1998; Durand et al., 2004), together with an analogue of the well-known forward-backward algorithm. They remain relatively unknown in the field of language processing – the only mentions that we are aware of are (Žabokrtský and Popel, 2009) and (Kondo et al., 2013).

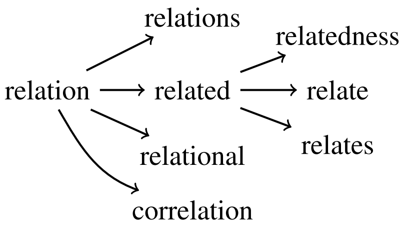

Figure 1: An example tree of word derivations. Edge labels are omitted for better readability. (reproduced from: (Sumalvico, 2017))

3 The Graph Model of Morphology

As a model of morphology suitable for unsupervised training, we use the graph-based model introduced by (Janicki, 2015), which is based on the Whole Word Morphology approach (Ford et al., 1997; Neuvel and Fulop, 2002). It expresses morphological relationships amongst words as a graph, in which words are vertices and morphologically related words are connected with an edge. A concrete morphological analysis of a set of related words is a tree, in which directed edges denote morphological derivation (Fig. 1). In general, the analysis of a vocabulary is a forest, i.e. a set of such trees.[2]

Every edge in the graph is an instance of a *morphological rule*, which describes a pattern applied to whole words. For example, the rule responsible for the pair (*relation*, *related*) might have the following form:

$$/X\text{ion}/ \rightarrow /X\text{ed}/ \qquad (1)$$

In this notation, X is a wildcard that can be instantiated with any string and a pattern between slashes refers to a whole word in its surface form. The rules may also include context: $/X\text{tion}/ \rightarrow /X\text{ted}/$ would be a possible alternative to (1). As there are multiple possible rules that can describe a relationship between a pair of words, the graph edges are defined as triplets of source word, target word and rule.

(Janicki, 2015) introduced a generative probabilistic model for trees such as the one depicted in Fig. 1. It assumes that the roots of the trees are

[2] It is important to point out that such trees are only an intermediary means in determining the strength of morphological relationship between string-similar words. The inference is always based on large samples of trees and finding the ‘right’ tree, i.e. the one that is consistent with linguistic analysis, is not the goal of the model.

generated independently from a distribution over arbitrary strings, called ρ. Furthermore, every rule r has a fixed probability θ_r of being applied to generate a new word. The probability of the whole forest is defined as follows:

$$Pr(V, E|R, \theta_R) \propto \prod_{v \in V_0} \rho(v) \\ \times \prod_{v \in V} \prod_{r \in R} \prod_{v' \in r(v)} \begin{cases} \theta_r & \text{if } \langle v, v', r \rangle \in E, \\ 1 - \theta_r & \text{if } \langle v, v', r \rangle \notin E \end{cases} \tag{2}$$

V denotes the set of vertices (words) and E the set of (labeled) edges of the graph. R denotes the set of rules and θ_R the vector of probabilities θ_r for the rules from R. Furthermore, $V_0 \subseteq V$ denotes the set of root nodes of the graph and $r(v)$ the set of words that can be derived from word v by application of rule r. Note that the latter might be an empty set if the context on the left-hand side of the rule is not matched. Each possible derivation from $r(v)$ corresponds to a Bernoulli variable with probability θ_r.

(Sumalvico, 2017) describes an unsupervised fitting procedure for this model using Monte Carlo Expectation Maximization algorithm. The computation involves drawing large samples of graphs from the conditional distribution $Pr(E|V, R, \theta_R)$ using a Metropolis-Hastings sampler.

4 Computing POS-Tags

We now turn to applying the model introduced in the previous section to the task of semi-supervised POS tag lexicon induction. The idea is to train a model of morphology on a labeled vocabulary (coming from a tagged corpus) and apply this model to infer the tags for another vocabulary.

The underlying intuition is that morphological relationships between words can give hints about their POS tags and inflectional forms, which are not visible in the isolated forms. For example, consider the following German[3] words: *Fichten* 'spruce.N.PL', *richten* 'judge.V.INF', *rechten* 'right.ADJ.NOM.PL.DEF'.[4] Phonetically and orthographically they are very similar and all include an inflectional suffix *-en*, which is highly ambiguous in German. The knowledge that German nouns are always capitalized does not provide much of a clue, because words belonging to any other part-of-speech may also occur capitalized. Even worse, many further similar words are ambiguous in their meaning and part-of-speech, e.g. *Dichten* ('density.N.PL' or capitalized 'dense.ADJ.NOM.PL.DEF' or 'compose (e.g. a poem).V.INF'), *schlichten* ('simple.ADJ.NOM.PL.DEF' or 'mediate.V.INF').

It is much easier to reason about possible tags for those words if we take into account morphologically related words. For example, we might observe words like *richtet* or *richtete*, which together with *richten* look unambiguously like a verb paradigm. Similarly, the occurrence of a form like *rechtes* can convince us that *rechten* is an adjective, because verbs do not take the suffix *-es*. For ambiguous forms, we will likely find parts of different paradigms, for example *schlichtet* (verb) and *schlichtes* (adjective), which will allow us to notice the ambiguity. Of course, in order to conduct such analysis, we have to know which affix configurations are characteristic for which part of speech. This is the part that we are going to learn from labeled data.

4.1 Applying Tagged Rules to Untagged Words

Let us assume that we have learned a morphology model on tagged data. Now we are presented with a new set of words, possibly containing many words not present in the original training set. In this section, we will show how the trained model can be applied to derive guesses for tags in the new vocabulary. The approach follows the idea sketched in the previous section: the tag of the word will be determined by the neighboring words, together with the knowledge about the morphology contained in tagged rules.

To illustrate the approach with a minimal example, let us assume that our tagset consists of only three tags: NN, VVINF and VVFIN, and that the untagged vocabulary consists of the German words *machen*, *mache*, *macht*. We compute the edge probabilities for every edge that is possible according to the model, under every tagging. For example, the model might consist of the rules and parameters listed in Table 1.

Using those values, we can reason about the possible taggings based on an untagged graph.

[3] It is very difficult to find plausible examples of this phenomenon in English due to its small inflection and very productive zero-affix derivation.

[4] All cited words are ambiguous in their inflectional form (but not part-of-speech). The glosses shown here are picked as examples.

r	θ_r
$/X\text{en}/_{\text{NN}} \rightarrow /X\text{e}/_{\text{NN}}$	0.3
$/X\text{en}/_{\text{VVINF}} \rightarrow /X\text{e}/_{\text{VVFIN}}$	0.01
$/X\text{en}/_{\text{VVINF}} \rightarrow /X\text{t}/_{\text{VVFIN}}$	0.2

Table 1: An example model learnt from a tagged vocabulary.

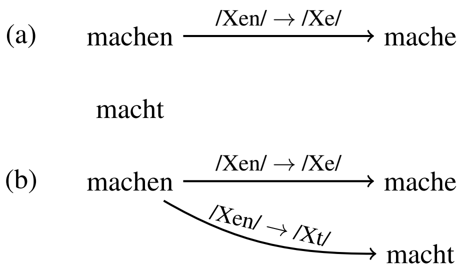

Figure 2: Two possible morphology graphs corresponding to the words *machen*, *mache*, *macht*. What does each of them tell us about the possible tags of those words according to Table 1?

Consider the two graphs shown in Fig. 2. What does each of them say about the possible taggings?

Graph 2a is consistent with either $\{machen_{\text{NN}}, mache_{\text{NN}}\}$ or $\{machen_{\text{VVINF}}, mache_{\text{VVFIN}}\}$, since the only edge in this graph is possible with both labelings. Note that the edge containing noun labels has much higher probability, so this graph suggests a strong preference for the noun hypothesis. It does not say anything about the possible tags of *macht*. On the other hand, the only tagging consistent with the graph 2b is $\{machen_{\text{VVINF}}, mache_{\text{VVFIN}}, macht_{\text{VVFIN}}\}$, since the edge between *machen* and *macht* is only possible if *machen* is a verb infinitive. It is important to notice that adding an edge between *machen* and *macht* diametrically changed the possible taggings for *mache*, although it is not touched by the edge in question. This illustrates how the graph model captures dependencies between the tags across a whole paradigm, although the edge probabilities are local.

Moving on to formalize the above introduction, let the tag of word v be denoted by a random variable T_v. We will be interested in the expected probability of a word v obtaining tag t, given an untagged vocabulary and a tagged morphology model. We call this value $\tau_{v,t}$ and define it as follows:

$$\tau_{v,t} = \mathbb{E}_{E|V,R,\theta}\mathbb{E}_{T|V,E,R,\theta}\delta_{T_v,t} \qquad (3)$$

$\delta_{x,y}$ denotes the Kronecker delta. Thus, we take the expectation over all possible graphs for the given vocabulary, and then over all possible taggings for a fixed graph. The inner expectation can be computed exactly by a variant of Forward-Backward algorithm introduced in Sec. 4.2. In order to approximate the outer expectation, we use Markov Chain Monte Carlo sampling over untagged graphs as described by (Sumalvico, 2017). However, the sampling algorithm will need some modifications, as contrary to the original approach, the edge probabilities are not independent of the graph structure. We describe those modifications in Sec. 4.3. Finally, the computed values of $\tau_{v,t}$ will be fed to an already pre-trained HMM to provide it with guesses for the tags of unknown words, before it is reestimated on untagged text. This procedure is described in detail in Sec. 4.4.

4.2 The Forward-Backward Algorithm for Trees[5]

In order to compute $\tau_{v,t} = \mathbb{E}_{T|V,E,R,\theta}\delta_{T_v,t}$ for a fixed graph (V, E), let us recall the well-known Forward-Backward algorithm used for Hidden Markov Models.[6] The HMMs employed for POS tagging operate on sentences, which are linear sequences of words (Fig. 3). The summing over all possible tag sequences is tackled by introducing the so-called *forward probability* (usually written as α) and *backward probability* (β). The forward probability $\alpha_{v,t}$ of a node v with tag t is the joint probability of v and all its predecessors *and* v having tag t, while the backward probability $\beta_{v,t}$ is the probability of all successors of v onwards *provided that* v has tag t. The product of the two is the probability of the whole sequence *and* v having tag t.

The concepts of *successor* and *predecessor* can be applied to a tree model as well (Fig. 4). In this case, $\beta_{v,t}$ is the probability of the subtree rooted in v provided that v has tag t, and $\alpha_{v,t}$ is the probability of the rest of the tree *and* v having tag t. Note that $\alpha_{v,t}$ involves not only the path leading

[5] The algorithm presented in this section is similar, but not identical, to the one presented by (Crouse et al., 1998). The underlying models differ slightly.

[6] See for example (Manning and Schütze, 1999) or (Jelinek, 1997) for an introduction to HMMs and the Forward-Backward algorithm.

$$v_1 \to v_2 \to v_3 \to v_4 \to v_5 \to v_6 \to v_7 \to v_8 \to v_9$$

Figure 3: The Forward-Backward computation for a linear sequence in an HMM. $\alpha_{v_6,t} = P(v_1, \ldots, v_6, T_6 = t)$, whereas $\beta_{v_6,t} = P(v_7, v_8, v_9 | T_6 = t)$.

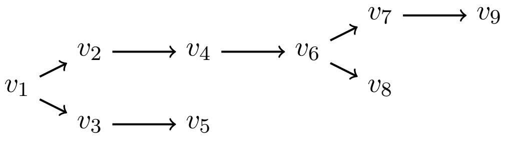

Figure 4: The Forward-Backward computation for a tree. Also here, $\alpha_{v_6,t} = P(v_1, \ldots, v_6, T_6 = t)$ and $\beta_{v_6,t} = P(v_7, v_8, v_9 | T_6 = t)$.

from root to v, but also all side branches sprouting from this path.

We will now derive recursive formulas for forward and backward probabilities for the tree case. For this purpose, we assign a *transition matrix* to each graph edge. For each possible tagging of the source and target node, the transition matrix contains a value $\frac{\theta_r}{1-\theta_r}$, where r is the corresponding tagged rule. Continuing the example from 4.1, the probabilities in Table 1 yield the following transition matrix:

$$T^{(\text{machen},\text{mache},/X\text{en}/\to/X\text{e}/)} =$$

$$\begin{array}{c c} & \begin{array}{ccc} \text{NN} & \text{VVINF} & \text{VVFIN} \end{array} \\ \begin{array}{c} \text{NN} \\ \text{VVINF} \\ \text{VVFIN} \end{array} & \begin{pmatrix} \frac{0.3}{1-0.3} & 0 & 0 \\ 0 & 0 & \frac{0.01}{1-0.01} \\ 0 & 0 & 0 \end{pmatrix} \end{array} \tag{4}$$

Furthermore, let $\lambda_{v,t}$ denote the probability that the node v with tag t is a leaf, i.e. it contains no outgoing edges. Then:

$$\lambda_{v,t} = \prod_{r \in R} \prod_{(v',t') \in r(v,t)} (1 - \theta_r) \tag{5}$$

It is trivial to see that for leaf nodes, $\beta_v = \lambda_v$. For a non-leaf node v, we multiply λ_v by the terms $\frac{\theta_r}{1-\theta_r}$ for each outgoing edge, summed over every possible tagging. In the matrix and vector notation, this corresponds to the following formula:[7]

$$\beta_v = \lambda_v * \prod_{(v,v',r) \in out_{\mathcal{G}}(v)} T^{(v,v',r)} \beta_{v'} \tag{6}$$

$out_{\mathcal{G}}(v)$ denotes the set of outgoing edges of node v. In order to compute the forward probability of a non-root node v, let us assume that it is derived by the edge (v', v, r). In addition to the forward probability of v' (the parent of v) and the edge deriving v, we also take into account the side branches, i.e. all subtrees rooted in children of v' other than v. The resulting formula is as follows:

$$\alpha_v = \alpha_{v'} * \prod_{\substack{(v',v'',r') \in out_{\mathcal{G}}(v') \\ v'' \neq v}} T^{(v',v'',r')} \beta_{v''} \cdot T^{(v',v,r)} \tag{7}$$

The last remaining issue is the forward probability of root nodes. The generative model defined by (2) contains a distribution $\rho(\cdot)$ over arbitrary strings, from which the string forms of the root nodes are chosen. In the tagged case, we augment this distribution to $\rho(v,t) = \rho_{\text{string}}(v)\rho_{\text{tag}}(t\ |v)$. As in (Sumalvico, 2017)'s experiments, we use a simple character-level unigram model for $\rho_{\text{string}}(\cdot)$. In order to model the distribution $\rho_{\text{tag}}(t|v)$, which predicts a word's tag from its string form, we use a character-level recurrent neural network. Note that the forward probability of root nodes is equal to their probability according to the root model, i.e. $\alpha_{v,t} = \rho(v,t)$.

4.3 Modifications to the Sampling Algorithm

In order to approximate the expected value over possible graphs given a vocabulary, we use the Metropolis-Hastings sampler proposed by (Sumalvico, 2017). The algorithm computes each new graph by proposing a small change in the previous graph. The possible moves are: adding or deleting a single edge, exchanging an edge for another one with the same target node and the so-called 'flip' move. The latter simultaneosly exchanges two edges for two others and is designed as a way to prevent the creation of a cycle while adding an edge. The algorithm subsequently computes an acceptance probability from the probabilities of the changed edges and decides whether to accept the proposed graph as a new sample point.

As we have seen in the analysis of Fig. 2, adding an edge typically has consequences for the whole subtree, in which the edge is added. The values τ_v for all nodes in the subtree may change, which in turn changes the probability of all edges in the subtree. This behavior constitutes a significant difference compared to the original sampling algorithm, in which the edge probabilities were independent of the graph structure and the cost of a

[7] Asterisk denotes element-wise multiplication, while dot or no symbol denotes the dot product.

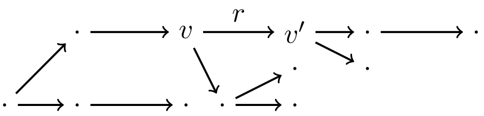

Figure 5: Adding or removing the edge (v, v', r).

change could be easily computed from the cost of added and removed edges. However, we can use the forward and backward probabilities to score the changes.

Observe that for every node v, the value $\sum_t \alpha_{v,t}\beta_{v,t}$ is the probability of whole subtree, to which v belongs. This property – being able to compute the probability of a whole subgraph using the values of a single node – is crucial in evaluating the sampler moves.

Adding or removing a single edge. Consider the graph in Fig. 5, to which the edge (v, v', r) is supposed to be added. Without this edge, we have two separate trees with a total probability expressed by $(\sum_t \alpha_{v,t}\beta_{v,t})(\sum_t \alpha_{v',t}\beta_{v',t})$. After adding this edge, we obtain a single tree. As v obtains a new child node, β_v will change. Let β'_v denote the new value, which can be computed as follows:

$$\beta'_v = \beta_v * T^{(v,v',r)}\beta_{v'} \tag{8}$$

Note that neither α_v nor $\beta_{v'}$ is affected by adding this edge. The probability of the new tree is simply $\sum_t \alpha_{v,t}\beta'_{v,t}$. If the move is accepted, the β values of all nodes on the path from the root to v have to be updated, as well as the α values of all nodes except for this path.

Deleting an edge involves a very similar computation. In this case, the probability of the graph before deletion is $\sum_t \alpha_{v,t}\beta_{v,t}$, whereas the probability after deletion is $(\sum_t \alpha_{v,t}\beta'_{v,t})(\sum_t \rho_{v',t}\beta_{v,t})$. Here, $\beta'_{v,t}$ is the updated backward probability of v excluding the deleted edge.

Other moves. When exchanging a single edge to another one with the same target node, we already need to be careful, as two distinct cases arise: either the change takes place within one tree, or it involves two separate trees. If we proceeded as in the previous paragraph, those cases would require different formulas. Instead of conducting such a detailed analysis of the changes, we apply a more general approach that covers the 'flip' moves as well.

First, we group all edges that are to be changed (added or deleted) according to the tree, to which they belong (more specifically, according to the root of the tree, to which the edge's source node currently belongs). In each tree, we look for a minimum subtree that contains all the changes (Fig. 6). We build a copy of this subtree with all changes applied and recompute the forward probability for its root and the backward probabilities for the whole subtree. Finally, we use the (newly computed) forward and backward probability of the subtree root to determine the probability of the whole tree after changes.

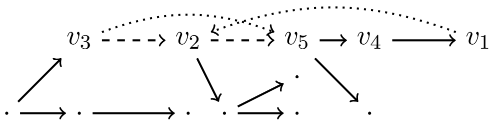

Figure 6: In case of a 'flip' move, the smallest subtree containing all changes is the one rooted in v_3. The deleted edges are dashed, while the newly added edges are dotted. In order to obtain the new β_{v_3}, we recompute the backward probabilities in the whole subtree. α_{v_3} is not affected by the changes. (The node labels are consistent with the definition in (Sumalvico, 2017).)

4.4 Extending an HMM with New Vocabulary

The vectors τ_v obtained from the sampling approach sketched in the previous subsections provide us with a morphologically motivated POS-tag distribution for words from the untagged corpus. We augment the HMM's emission probability matrix with those values for previously unseen words.[8]

5 Experiments

5.1 Experiment Setup

We conducted evaluation experiments for 9 languages: Ancient Greek (GRC), German (DEU), Finnish (FIN), Gothic (GOT), Latin (LAT), Latvian (LAV), Polish (POL), Romanian (RON) and Russian (RUS), using the Universal Dependencies[9] corpora. Each corpus is randomly split into

[8] The values τ_v are conditional probabilities of a tag given word, while the emission probabilities of an HMM are probabilities of a word given tag. We use the Bayes' formula to convert the former to the latter. We obtain the marginal probabilities of tags during the HMM pre-training and assume equal frequencies for unseen words.

Table 2: Different setups of the HMM tagger used in the tagging experiment.

training, development and testing dataset in proportions 10%:80%:10%. An HMM tagger is fitted to the (labeled) training data using ML estimation. The training dataset is also used to learn tagged morphological rules. Then, we remove the labels from the development corpus and re-estimate the HMM on this corpus using Baum-Welch algorithm. This step is performed in several configurations: either with or without vocabulary extension. In the latter case, all types occurring in the development corpus, but not known to the HMM (i.e. not occurring in the training corpus) are added to the vocabulary before the estimation. Finally, the tagging accuracy is assessed on the testing dataset. The details of the possible configurations are shown in Table 2.

For each corpus, two kinds of datasets are prepared: with *coarse-grained* and *fine-grained* tags. In the former case, the UPOS tagset is used, which amounts to around 15 tags for every language. In the latter, all inflectional information provided by the corpus annotation is additionally included, which results in several hundred different tags (depending on the language). For example, in the Latin corpus, we have tokens like `beati<ADJ>` in the coarse-grained and `beati<ADJ><NOM><POS><MASC><PLUR>` in the fine-grained case.

The morphology-based tag guessing approach developed in the previous sections is compared to the guesses made only based on the word's string form. The latter are provided by the distribution $\rho_{\text{tag}}(\cdot)$, i.e. a character-based recurrent neural network, mentioned at the end of Sec. 4.2.

5.2 Evaluation Measures

Two kinds of evaluation are performed: *lexicon* and *tagging* evaluation. In the first case, the quality of tag guesses for unknown words, τ_v, is measured directly. It is desirable for those values to not only predict the correct tag for unambiguous words, but also to handle ambiguity correctly, which means providing probabilities that correspond to the expected frequency of a word with the certain tag. We derive the gold standard data from the labels in the development set using the following formula:

$$\hat{\tau}_{v,t} = \frac{n_{v,t}}{\sum_{t'} n_{v,t'}} \qquad (9)$$

with $n_{v,t}$ being the number of occurrences of word v with tag t in the development set. This way, true ambiguities (with roughly equal frequency of different taggings) are treated differently than rare taggings, which may result from tagging errors or some obscure, infrequent meanings. The accuracy is computed as follows:

$$accuracy = \frac{1}{|V|} \sum_{v \in V} \sum_{t} \min\{\tau_{v,t}, \hat{\tau}_{v,t}\} \qquad (10)$$

It is intentionally a very demanding measure: it achieves 100% for a given word only if the probability mass is distributed exactly according to the corpus frequency of the tagging variants, which is virtually impossible for ambiguous words. Hence, low scores according to this measure are not surprising and do not necessarily represent a bad-quality tagging. We decided for this measure, because it is easier to interpret than e.g. KL-divergence.

In the tagging evaluation, we evaluate the impact of providing tag guesses on a real POS-tagging task. The evaluation measure used there is the standard accuracy, i.e. the percentage of correctly tagged tokens.

5.3 Results

Table 3 shows the results of the lexicon evaluation. The figures show clearly that the morphology-based method outperforms the RNN in predicting possible tags for a given word type. Probably the most important reason for that is that the RNN always makes unsharp predictions – it never attributes the whole probability mass to a single tag. On the other hand, the graph-based morphology model often makes unambiguous predictions

because of the absence of rules allowing for alternatives (a phenomenon illustrated in Fig. 2). Thus, the latter achieves better scores especially on correctly tagged unambiguous words.

The comparison of tagging accuracies is shown in Tables 4 and 5. The columns correspond to the tagger configurations explained in Table 2. In general, a rise of the score from left to right is to be expected.

The difference between columns 1 and 2 illustrates the influence of reestimating the trained model on unlabeled data without adding the OOV words to the vocabulary. Interestingly, this results in an improvement in case of the coarse-grained tagset, but in a decline when using the fine-grained tagset, both significant. However, adding the OOV words from the development set to the vocabulary, even with randomly initialized probabilities (column 3), further improves the accuracy (with a few exceptions), so that the result is consistently better than column 1. Column 4 introduces intrinsic tag guessing as initial probabilities for newly added words, rather than random values. This results in a further improvement, especially significant for Finnish, Ancient Greek and Latvian (both coarse-grained and fine-grained).

The most important comparison in this evaluation is between column 4 and 5. This illustrates the benefit of using extrinsic tag guessing (column 5), rather than intrinsic. This results in a consistent improvement, ranging from very slight to significant. The most significant improvements are shown in bold. Finally, column 6 displays what one might expect to be the upper bound on the accuracy: the one that would be achieved if tags were guessed perfectly (i.e. as $\hat{\tau}_v$). Surprisingly, it is not always the highest value in a row. It looks as if taking into account some wrong taggings during Baum-Welch estimation could accidentally improve the estimation, because the wrong tag might *also* have occurred in the given context. This seems especially plausible for cases like common and proper nouns, which are often confused.

5.4 Discussion

Although the results speak consistently in favor of using morphology-based tag guessing, as well as using tag guessing at all, the benefits are somewhat less clear than one could expect. Especially in the case of fine-grained tags, our expectation was that, due to the discrete nature of morphological rules, at least the tags of unambiguous words would be identified mostly correctly. This was supposed to greatly improve the Baum-Welch estimation, as instead of considering many hundred possible tags, the correct one is already known, which turns the estimation into almost supervised learning. However, we had underestimated the impact of the small size of training corpus on the morphology component. Most fine-grained tags are very rare, so many morphological rules related to such forms are not learnt.

Word Sense Disambiguation Based on Constrained Random Walks in Linked Semantic Networks

Arkadiusz Janz, Maciej Piasecki
Wrocław University of Science and Technology, Poland
{arkadiusz.janz|maciej.piasecki}@pwr.edu.pl

Abstract

Word Sense Disambiguation remains a challenging NLP task. Due to the lack of annotated training data, especially for rare senses, the supervised approaches are usually designed for specific subdomains limited to a narrow subset of identified senses. Recent advances in this area have shown that knowledge-based approaches are more scalable and obtain more promising results in all-words WSD scenarios. In this work we present a faster WSD algorithm based on the Monte Carlo approximation of sense probabilities given a context using constrained random walks over linked semantic networks. We show that the local semantic relatedness is mostly sufficient to successfully identify correct senses when an extensive knowledge base and a proper weighting scheme are used. The proposed methods are evaluated on English (SenseEval, SemEval) and Polish (Składnica, KPWr) datasets.

1 Introduction

Semantic analysis is the process of understanding the underlying meaning in text. Building a rich semantic representation is a crucial element of modern Natural Language Processing NLP. It allows us to build comprehensive text representations in order to analyse the underlying text meaning more effectively. Semantic information helps us to resolve the issue of textual ambiguity. The main aim of semantic analysis is to differentiate texts which use the same vocabulary yet present different ideas about the same topic. One of the most important building blocks of semantic analysis is *word sense disambiguation* (WSD). WSD aims at solving the problem of lexical ambiguity, i.e. two or more meanings being represented by one word e.g. English words *space*, *shape*, or Polish words *tło* (background color, a context or an incidental music) *wnętrze* (a room, a soul or a set). This lexical ambiguity is still an open issue for semantic analysis due to the lack of required training data and the computational power required to process the growing number of possible classes. The task of word sense disambiguation is usually solved by mapping words onto their senses given a particular sense inventory.

WSD can be performed in a supervised way, i.e. on the basis of the annotated lexical meanings in training texts, or in an unsupervised way, i.e. sense induction from texts.

Supervised machine learning approaches can achieve a very good performance when trained on a large training data annotated with good inter-annotator agreement and well designed features.

However, it is difficult to acquire large training data for WSD because training data is usually manually annotated and manual annotation is labour-intensive and thus costly[1]. Semi-automatic approaches on the other hand often result in lower quality data blurred with statistical noise.

Thus, the best performing supervised approaches to WSD task are usually limited to a specific narrow subset of training vocabulary. Moreover, supervised approaches are strongly connected with the underlying domain of the training data. Sense induction methods require only large amounts of text, but representative in relation to all word senses. However, senses induced automatically are mostly difficult to be matched against dictionaries or other word sense inventories created manually. Thus, semi-supervised methods based on lexical knowledge bases describing word senses, e.g. wordnets, offer a poten-

[1] It is barely possible to scale it up to a couple of dozens of thousands words well described according to all its senses

Proceedings of Recent Advances in Natural Language Processing, pages 516–525,
Varna, Bulgaria, Sep 2–4 2019.

tially good compromise. Such methods can cover, at least potentially, all word senses described in a lexical knowledge base. Very large wordnets describing more than 100,000 words (lemmas) and their senses by hundreds of lexico-semantic relation instances have been constructed for several languages, including the English and Polish language. A large and dense network of relations seems to be a good basis for mapping word occurrences in texts onto their senses.

An enormous amount of semantic data appeared on the Web in recent years. With the growth of resources joining the Linked Open Data collection the available semantic information becomes a very important knowledge source for WSD tasks.

Semi-supervised methods are very often based on the idea of mapping texts onto the wordnet graph of lexico-semantic relations as the initial activation of the graph nodes. Next a recursive spreading activation method, mostly based on PageRank (Page et al., 1998) is applied. However, as seen in the following paragraphs, such methods raise problems with efficiency.

In this paper we explore Monte Carlo methods based on a random walk algorithm for the task of Word Sense Disambiguation. We show that the lexical knowledge base with its expansions and the way they are exploited has a strong impact on WSD performance and the proposed method allows for the efficient utilisation of large lexical knowledge bases. The presented solutions are evaluated on popular Polish and English benchmark datasets.

2 Related Work

The first group of approaches is based on supervised machine learning algorithms. The researchers have adapted many different ML methods for WSD task. One can find the classical NLP approaches based on feature engineering and popular classification algorithms e.g. decision trees, decision lists, Naive Bayes solutions, kNN, adaptive boosting, as well as more modern approaches using Deep Learning with LSTM, biLSTM and more sophisticated variants of neural architectures. The main issue is that most of the words are strongly imbalanced in terms of their sense distribution, thus, due to the lack of required training data, the supervised approaches present a lower recall in all-words WSD setting.

The knowledge-based solutions use the structural properties of existing sense inventories e.g. wordnets.

One of the first solutions to WSD task for Polish (Baś et al., 2008) was mainly focused on supervised approaches. The authors trained the classifiers on a relatively small dataset for a preselected, annotated vocabulary. Later works were focused mainly on WSD methods close to sense induction from text corpora, e.g. (Broda and Piasecki, 2011).

Weakly supervised WSD approaches are usually based on sense inventories and their semantic structure describing senses. The main assumption is that the words being a part of a text can be mapped onto their potential senses existing in a given sense inventory, mainly the synsets existing in a wordnet. The senses activate local subgraphs of wordnet's semantic structure to activate meanings possibly being relevant to a given text fragment. As the initial activation is sparse a kind of spreading activation algorithm is next applied in order to recursively concentrate this information in some "hot" areas and identify word senses located in them or close to them. The identified synsets should be the most likely senses for words in the text. There are several parameters to set in this general scheme: the initial activation (coming from the text words), spreading activation algorithm (topology and relations) and identification of association between "hot" areas and senses to be selected. Various methods following this scheme were proposed.

Weakly supervised WSD methods are mostly based on the recursive PageRank algorithm (Page et al., 1998) for spreading activation. Mihalcea et al. (2004) proposed application of the original PageRank to WSD called Static PageRank.

PageRank algorithm (henceforth PR) is an iterative method for ranking nodes in the graph G. In WSD the nodes in G represent synsets and the edges of G correspond to wordnet relations (linking synsets, and in some wordnets also linking specific word senses).

(Agirre and Soroa, 2009; Agirre et al., 2014) proposed a modified version called Personalised PageRank (PPR) in which the values in $\mathbf{v}$, called personalised vector, depend on the textual context of the disambiguated word. The non-zero score values are assigned to those nodes which are contextually supported. In PPR all words from the context are disambiguated at once. The $\mathbf{v}$ values are equal to:

$$\mathbf{v}[i] = \frac{1}{\frac{CS}{NS(i)}}, \quad i = 1, 2, ..., N \qquad (1)$$

where CS is the number of different lemmas in the context, $NS(i)$ – the number of synsets sharing the same context lemma with the synset i.

In addition a modified version of PPR called *Personalised PageRank Word-to-Word* (PPR_W2W) was also presented by (Agirre and Soroa, 2009; Stevenson et al., 2012), in which a word to be disambiguated is excluded from the occurrence contexts, i.e. all synsets of this word have initial scores in $\mathbf{v}$ set to zero. Thus, PPR_W2W cannot be run once for all ambiguous words in the context. The vector $\mathbf{v}$ must be initialised individually for each ambiguous word in the context – this is a disadvantage of PPR_W2W. A potential advantage is the removal of the effect of mutual amplification of the closely connected senses of the word being disambiguated. All PR-based WSD algorithms showed good performance that is increasing with the enlargement and enrichment of the knowledge base. However, with larger graphs the time of processing increases non-linearly causing a significant drop in efficiency. The problem is especially visible in the case of PPR_W2W in which the algorithm must be restarted several times per context.

In (Kędzia et al., 2014), PR-based WSD algorithm for Polish was presented and run with the help of plWordNet 2.1. The graph consisted of synsets linked by edges representing a selected subset of the synset relations. Next several versions of the PR-based algorithms, namely Static PR, PPR and PPR_W2W was applied to Polish texts and plWordNet 2.2 in (Kędzia et al., 2015). The achieved precision (on *KPWr*) was in the range 42.79%-50.73% for nouns and 29.79%-32.94% for verbs. PPR_W2W produced the best results. Different variants of combining plWordNet with the *Suggested Upper Merged Ontology* (SUMO) (Pease, 2011) on the basis of the mapping constructed in (Kędzia and Piasecki, 2014). All three PR-based algorithm were evaluated. A slight improvement of the precision for nouns up to 50.89% for PPR_W2W could be observed when the two joined graphs were treated as one large graph.

In (Pershina et al., 2015) the authors presented a graph-based algorithm using random walks algorithm for named entity disambiguation. The motivation for their work was the fact that PR-based methods mainly rely on global coherence, but the methods should utilise the local similarity more effectively.

3 Knowledge Base

The general sense inventory for all-words WSD is usually created on the basis of a wordnet. Wordnets can be presented as graphs with nodes representing word senses or synsets (but also with two types of nodes) and edges expressing the structure of the lexico-semantic relations described in a given wordnet. The methods based on lexical knowledge bases usually explore the lexico-semantic relations represented by a wordnet to disambiguate the words given the context.

Most wordnet relations are paradigmatic, but for WSD we also need syntagmatic relations, rarely covered by wordnets, because the plain wordnet structure might be insufficient to successfully disambiguate a text. As the large public sources like Linked Open Data are available, we can try to apply them for the expansion of the lexical knowledge base. They may also contain Named Entities which can be very important for WSD, e.g. helping to identify the narrow semantic context.

More formally, a *lexical knowledge base* is a graph $G(V, E)$ consisting of nodes and edges, where $V = \{v_1, v_2, ..., v_N\}$ represents a set of concepts (modelling lexical meanings) and $E = \{e_1, e_2, ..., e_M\}$ a set of edges corresponding to lexico-semantic associations linking these concepts.

3.1 Existing Knowledge Bases

In literature, we can find many attempts to combine Princeton WordNet with resources of many types to obtain a better knowledge base for WSD.

UKB lexical knowledge base, e.g. (Agirre and Soroa, 2009), consists of Princeton WordNet 3.0 or eXtended WordNet (Harabagiu et al., 1999) which was expanded by introducing links extracted from SemCor, manually disambiguated glosses from Princeton WordNet Gloss Corpus, and Wikipedia.

BabelNet (Navigli and Ponzetto, 2012) was initially created by linking the largest multilingual Web encyclopedia, i.e. Wikipedia, with the most popular computational semantic lexicon, i.e., WordNet. Later it was expanded with a number of resources:

- OmegaWiki, a large collaborative multilingual dictionary (January 2017 dump);
- Wiktionary, a collaborative project to produce a free-content multilingual dictionary (February 2018 dump);
- Wikidata, a free knowledge base that can be read and edited by humans and machines alike (February 2018 dump);
- Wikiquote, a free online compendium of sourced quotations from notable people and creative works in every language (March 2015 dump);
- VerbNet (Kippera et al., 2006), a Class-Based Verb Lexicon (version 3.2);
- Microsoft Terminology, a collection of terminologies that can be used to develop localised versions of applications (July 2015 dumps);
- GeoNames, a free geographical database covering all countries and containing over eight million place names (April 2015 dump);
- FrameNet (Ruppenhofer et al., 2016), a lexical database of English that is both human- and machine-readable (version 1.6);
- Open Multilingual WordNet (Bond and Foster, 2013), a collection of wordnets available in different languages.

The mappings provided by BabelNet (especially the links between synsets and Wikipedia pages) were built semi-automatically. We chose to manually map synsets of plWordNet by lexicographers instead of use the semi-automatic mappings provided by BabelNet to have more control over the accuracy of our results.

3.2 Presented Knowledge Base

For the work presented here, two knowledge graphs were built on the basis of the two largest wordnets, namely *plWordNet 3.2* (Maziarz et al., 2016) for Polish, and *Princeton WordNet 3.1* (Fellbaum, 1998) for English. They are mutually mapped on each other as a result of the laborious work of bilingual lexicographers.

3.3 Expansions

The initial performance of the algorithms can be moderate when the knowledge-base is limited only to the plain wordnet structure. We can significantly improve the overall performance by introducing new semantic links to the basis knowledge graph. In this work we expanded the ideas presented in (Agirre and Soroa, 2009), (Agirre et al., 2018) and (Moro et al., 2014). Following the procedure presented in (Agirre et al., 2018) we extended the structure of our knowledge graph by including the links extracted from the the Princeton WordNet Gloss Corpus[2] including manually disambiguated glosses.

The Suggested Upper Merged Ontology (SUMO) (Pease, 2011) is a formal representation of concepts, organised into hierarchies of classes and subclasses, which is widely used for semantic analysis in NLP. The lexical senses of PWN 3.0 and plWordNet 3.2 have been mapped onto their equivalent concepts of SUMO. The mapping procedure for plWordNet was based on interlingual links existing between plWordNet and PWN (Maziarz et al., 2016) and the initial mapping of PWN senses to SUMO ontology (Kędzia and Piasecki, 2014). We used the structure of SUMO ontology as a more general semantic description for lexical senses existing in wordnet. The semantic structure of our knowledge base was extended with concepts and links existing in the SUMO ontology by attaching the concepts to corresponding synsets and linking them with SUMO relations.

Wikipedia has opened many new opportunities for semantic analysis. The structure of Wikipedia has been used as a knowledge-base for the task of named entity disambiguation (NED), but also adapted for WSD. Graph-based approaches for computing semantic relatedness and disambiguation can be improved by using the semantic information contained in Wikipedia and expand the underlying knowledge base e.g. a wordnet. For this work we decided to add the links extracted from Wikipedia by using the mapping of lexical senses to equivalent Wikipedia articles. For every mapped synset we added new semantic links by analysing the content of the page and extracting monosemous words. The lexical senses of monosemous words were linked to mapped synset.

[2] http://wordnetcode.princeton.edu/glosstag.shtml

4 Methods

The main drawback of PageRank-based methods is that to compute the score of a sense given the context they have to compute the features with respect to the global structure of a given knowledge graph. This means the PageRank values have to be computed for every single node in the graph. To avoid this issue we use only the local approximation of PageRank as it was presented in (Avrachenkov et al., 2007).

4.1 PageRank Based Methods

The computational complexity of Personalised PageRank (PPR) is still a limiting factor for fast, real time WSD of large textual data. The naive algorithm for computing PageRank values requires to iterate over the entire graph. The most popular approach to compute PPR scores is the Power Iteration method (Berkhin, 2005), where the score is defined in a recursive way taking into account the global information. Recently the methods of local approximation of PageRank scores have received a lot of attention, especially in the case of dynamic graphs where the structure of the graph changes in time.

Let $G = (V, E)$ be a graph where V is a set of nodes and E represents a set of edges. The overall number of nodes and edges is N and M, respectively. We can define the adjacency matrix $A_{N \times N}$ of the graph G as $A_{N \times N} = [a_{ij}]$, $i \in \{1, 2, ..., N\}, j \in \{1, 2, ..., N\}$, where the values a_{ij} are representing links existing in the graph, where $a_{ij} = 1$ if there is an edge pointing from node v_i to v_j, otherwise $a_{ij} = 0$. A Markov transition matrix P can be defined as $P_{N \times N} = [p_{ij}]$ with p_{ij} values being normalised by the number of outgoing links (from node v_i) $p_{ij} = \frac{1}{d_i}$ if $a_{ij} = 1$, otherwise $p_{ij} = 0$. The graph might also contain dangling nodes without any outgoing links. To handle these cases p_{ij} values for dangling nodes are usually replaced by a constant $\frac{1}{N}$, which means adding a link to every node in the graph. The static PageRank can be interpreted then as a stationary distribution π of a Markov chain with final transition matrix $\widetilde{P}$ (Google's matrix):

$$\widetilde{P} = cP + (1 - c)\frac{1}{N}R \tag{2}$$

The matrix R consists of entries being equal to one. The value $c \in (0, 1)$ is the probability that the random walk follows a link according to distribution P instead of performing a random jump (usually $c = 0.85$). The $\pi = \pi\widetilde{P}$ represents a vector of PageRank scores for nodes of a given graph.

We can also show, that the final PageRank distribution π can be then defined as shown in (3), which directly follows from (2).

$$\pi = \frac{1 - c}{n} \sum_{k=0}^{\infty} c^k P^k \tag{3}$$

One of the first attempts to compute a local approximation of PageRank scores, namely (Fogaras et al., 2005), was based on the property presented in (3) which leads us to Monte Carlo methods. The authors in (Avrachenkov et al., 2007) proved that we can easily approximate PageRank values using random walks with restarts. Let the random walk start from a randomly chosen page and terminate with the probability $(1 - c)$. The random walk runs over the graph and makes the transitions according to transition matrix P with probability c. Let π_j be the final PageRank score for node j in the graph G. So, the initial PageRank formula (2) can be replaced with its rough estimate. We can show that using the properties of equation (3) we can also transform the Personalised PageRank formula and compute a rough estimate of its scores (Avrachenkov et al., 2010) with equation (4).

$$\hat{\pi_j}(s) = (1 - c)\frac{1}{m} \sum_{r=1}^{m} N_j(s, r) \tag{4}$$

A seed of initial nodes s is used to perform random walks over the graph, where c is the probability that the random walks terminates, m represents the overall number of required random walks, $N_j(s, r)$ is the number of random walks ending for node j, starting from seed node s in r-th random walk. The nodes representing a seed are usually randomly sampled from the graph.

This leads us to the following algorithm of PPR computation:

1. Simulate m runs of the random walks initiated at a node s.

2. Evaluate π_j as a fraction of m random walks which end at node $j \in \{1, 2, ..., n\}$.

The Monte Carlo approaches are based on random sampling, thus, we may obtain slightly different results for every run, especially when the number of the required iterations is too small to obtain faster progress of convergence giving a narrow confidence interval for estimated parameter. The unnecessary randomness can be avoided by initiating the random walk from each node in the same way, rather than jumping to random nodes over the graph. The accuracy of our estimate can be also improved by using variance reduction techniques e.g. by using Common Random Numbers approach (Clark, 1990).

4.2 Our Method

The initial idea was to approximate personalised PageRank value using random walk methods over semantic graphs, thus, we adopted the idea presented in (Fogaras et al., 2005) and (Pershina et al., 2015). The methods are usually based on random walk algorithm where the main assumption is that the local properties of senses are sufficient to accurately disambiguate the texts. This assumption allows us to reduce processing time of the algorithm when working with large lexical knowledge bases.

The underlying lexical knowledge base is a crucial element of a WSD method and it has a great impact on its performance. The algorithms and their properties presented in Sec. 4.1 were an inspiration for further work on disambiguation algorithms using large semantic networks.

The properties of personalised PageRank algorithm can be a limiting factor for WSD performance. The main issue is that in some specific cases a large node degree does not indicate a high significance, especially when the underlying knowledge base is a heterogenous graph constructed from different semantic resources (ontologies, dictionaries, wordnets). Adding or removing certain links can change the PageRank scores of the target nodes. The main problem is that not all of the links are correct, and to protect PageRank scores against incorrect links we can manipulate the importance of the links by using a heuristic weighting schema. We can also manipulate our seed to make the PPR algorithm more robust to textual noise. Since we are interested only in the importance of our personalisation nodes (representing senses of words for a given context), the initial seed for PPR computation is limited to a set of personalised nodes (usually a set of senses representing the words in a small textual window).

Simulate m random walks of length $L \sim Geom(p)$ starting from each seed node s. The seed consists of the nodes (synsets) representing all of available senses for the words from a given disambiguation context. The importance score γ_j for a given node j is the total number of visits to node j divided by the total number of visited nodes.

$$\hat{\gamma_j}(s) = \frac{1}{m}\sum_{r=1}^{m}(1-c)[N_j(s,r)+R_j(s,r)] \quad (5)$$

$$\hat{\gamma_j}(\boldsymbol{s}) = \frac{1}{m}\sum_{s\in\boldsymbol{s}}\sum_{r=1}^{m}(1-c)[N_j(s,r)+R_j(s,r)] \quad (6)$$

The parameter m denotes the overall number of performed random walks. The expected length of a single random walk is expressed as a geometric distribution $Geom(c)$, usually initialized with the value of parameter c (eq. (4)). To reduce the randomness effects we generate the lengths of walks only once, for all of our seed nodes, which is similar to the variance reduction with Common Random Numbers (Clark, 1990).

$R_j(s,r)$ represents the overall number of random resets, where the decision of a random jump to the starting node s is distributed according to $Bernoulli(p)$. The parameter p is dependent on the smoothed similarity score between usage example and a context.

We can compute a more accurate score estimate by using the recursive property of PageRank formula and averaging the scores of the neighbours. The recomputed final score for a single node j can be defined as:

$$\hat{\gamma_j}(\boldsymbol{s}) = (1-c)\frac{1}{|O(j)|}\sum_{v\in O(j)}\hat{\gamma_v}(\boldsymbol{s}) \quad (7)$$

In (7), the set $O(j)$ represents the neighbourhood of a single personalisation node j and $\hat{\gamma_v}(\boldsymbol{s})$ is a scoring function computed for neighbour v in $O(j)$.

In (Agirre and Soroa, 2009) and (Agirre et al., 2018) the authors proved that the sense frequency is a strong signal for accurate WSD. To make our methods comparable we decided to use the same source of sense frequency, namely SemCor corpus. Following the idea presented in (Agirre et al., 2018), the final score of a synset is computed as a linear combination of its normalised sense frequency and graph-based scores.

5 Evaluation

The proposed method incorporates several expansions to improve the overall performance of WSD. For the evaluation of WSD in English we utilised available semantic resources: i) manually disambiguated glosses, ii) synsets linked to Wikipedia, iii) the knowledge extracted from SemCor corpus.

In the case of Polish language the available semantic resources are limited. The glosses and usage examples for Polish senses were not disambiguated, thus, the synsets were linked only with the senses of monosemous words appearing in their glosses or usage examples. In the case of Wikipedia-based expansion we used a different mapping – the Polish synsets were partially linked to Wikipedia in a manual process (around 50,000 of synsets were mapped to Polish Wikipedia). We also translated the links by using interlingual synonymy links between Polish and English (enWordNet) parts of plWordNet.

5.1 Datasets

In the experimental part we evaluate our methods on the English dataset described in (Raganato et al., 2017) and the Polish dataset presented in (Kędzia et al., 2015). The former dataset consists of the five standard English texts prepared for Senseval and SemEval competitions for all-words WSD task. A sense inventory for the gold standard annotations was built on a basis of Princeton WordNet 3.0 which makes it approximately compatible with our knowledge-base, i.e. built on extended Princeton WordNet 3.1 in the case of English and plWordNet 3.2 (mapped to WordNet 3.1 and via it to SUMO) in the case of Polish. As we use WordNet 3.1 some small discrepancies can influence the results of the comparison with the test datasets, but they should not have significant impact on the outcome of the comparison.

Regarding the dataset for Polish only partially sense-annotated corpora exist. *Składnica* is a manually annotated dependency treebank with 13,035 sentences written Polish. The updated version of the semantic annotation in *Składnica* was based on plWordNet 3.2.

The *Polish Corpus of Wrocław University of Technology* (henceforth KPWr) consists of 1,127 documents manually annotated with the plWordNet 2.1 senses. The annotation was limited to a pre-selected set of words representing different cases of homonymy and polysemy. The original dataset consisted of 74 words in total, including 45 nouns and 29 verbs. The overall number of annotated word occurrences was 5,148 with 3,219 noun occurrences and 1,929 verb ones. Since there is a small inconsistency between senses used in the annotation and produced by WSD methods, i.e. coming from plWordNet 3.2, we decided to exclude from it 473 word occurrences for which the appropriate sense does not exist any more in our WSD model.

5.2 Experimental Setting

To accomplish a satisfactory convergence and obtain a small variance of final accuracy we adapted a following set of parameters for our experimental part: the transition probability $c = 0.3$, the overall number of random walks per node $rw\_iter = 1000$, the importance of sense frequencies on the final score $\alpha = 0.5$, and $(1-\alpha)$ for the importance of random walk-based scores. For a Polish dataset we did not use sense frequencies since there are no sense-tagged corpora available to compute the frequencies. The resultant performance (tables tab. 1 and tab. 2) was computed 10 times and averaged.

6 Results

Table 1. presents the final peformance for English dataset. The proposed method and introduced knowledge base expansions mostly outperformed a very strong most frequent sense (MSF) baseline. The method achieved the results being on the comparable level with other weakly supervised baseline methods, namely UKB (Agirre et al., 2018), Babelfy (Moro et al., 2014), and WoSeDon (Kędzia et al., 2015). Table 2. shows the average disambiguation time per context. As it was expected, the Monte Carlo approach provides better time efficiency (PPR vs PPRMC) and a comparable performance to power iteration method. The best results were achieved by mixing all available sources of semantic knowledge: the links extracted from disambiguated glosses, Wikipedia pages, SemCor texts and the links provided by SUMO ontology. The same tendency was observed for Polish dataset (table 3) – the best performance was noted for a mixed setting. The performance obtained for this dataset was also on a comparable level with the approaches based on power iteration method proposed in (Kędzia et al., 2015). PPRMC-1 uses a knowledge graph of synsets only. PPRMC-2 expands the model of

Table 3: Averaged precision of PPRMC for Polish datasets computed for nouns (N) and verbs (V) separately. A comparison with knowledge-based solution presented in (Kędzia et al., 2015) adapted to the structure of plWordNet 3.2.

PPRMC-1 with links to monosemous words extracted from glosses – in case of Polish glosses, or to disambiguated senses – in case of English glosses. PPRMC-3 adds the links to monosemous words extracted from Wikipedia, and PPRMC-4 introduces additional semantic links from SUMO ontology.

7 Conclusions

Weakly supervised Word Sense Disambiguation (WSD) methods express very good coverage that is only limited by the coverage of the underlying knowledge base used to define word senses and provide a basis for their disambiguation. However, very good results are obtained only when a rich and large knowledge base is utilised. In such a case, PPR-based WSD methods become slow that limits their applicability. We have shown that an estimation of the PPR algorithm on the basis of the Monte Carlo scheme can preserve most of the quality of the method while gaining a lot in terms of the efficiency of computation. We proposed a WSD tool[3] that achieves the performance comparable to the state-of-the-art among the weakly supervised methods, but it is 4-5 times faster. In addition, the efficiency of the proposed tool does not deteriorate so quickly with the increasing complexity of the knowledge base. The proposed method also offers an opportunity to balance between accuracy and processing speed by selecting the number of random walks.

Abstract

Extracting features and writing styles from short text messages is always a challenge. Short messages, like tweets, do not have enough data to perform statistical authorship attribution. Besides, the vocabulary used in these texts is sometimes improvised or misspelled. Therefore, in this paper, we propose combining four feature extraction techniques namely character n-grams, word n-grams, Flexible Patterns and a new sub-word embedding using the skip-gram model. Our system uses a Multi-Layer Perceptron to utilize these features from tweets to analyze short text messages. This proposed system achieves 85% accuracy, which is a considerable improvement over previous systems.

1 Introduction

One of the most challenging problems in text analysis is identifying the author of a micro-text, i.e. short text messages. Most of the data created on social media applications whether a Tweet, Facebook comment or text on a messaging application is a micro text. A micro or short text message could be a tweet or a comment which is around 140 characters or less. In general, text analysis and natural language processing approaches employ statistical feature extraction techniques such as term frequency, inverse document frequency and a bag of words. Due to the feature extraction process being statistical in nature, all these techniques require a certain amount of data to use them effectively for determining patterns or perform authorship attribution. Thus, having short text messages such as tweets which is around 140 characters or less makes it difficult to identify the patterns on a given text and make predictions about the author.

Shrestha et al. (2017) used a convolutional neural network (CNN) architecture using character embeddings instead of word embeddings for short texts. With this approach they showed less than five percent improvement on previous researches (Qian et al., 2015; Schwartz et al., 2013) in this area. In this paper, we start by implementing a simpler approach; combining the two consecutive records from the same author to train our model and then apply the feature known as Flexible patterns (Schwartz et al., 2013) after modifying the existing method and finally introducing our new feature based on the word vector approach (Bojanowski et al., 2017).

The paper is organized in the following sections. Section 2 represents related works. In section 3 we define our model architecture followed by the dataset and the feature extraction techniques. Section 4 shows the results of our approach compared with previous works. Lastly, in section 5, we discuss conclusion and future work.

2 Related Works

In short-text analysis, one of the earlier works by Layton et al. (2010) aims to identify the author based on the data collected from micro-blogging websites like Twitter. The authors create author profiles using character level n-grams. They find the frequency of the most common n-grams in an author profile and assume that text from the same author would have a similar pattern. This approach is further extended by Schwartz et al. (2013); they use two more features namely word n-grams and a Hyponyms acquisition technique (Hearst, 1992) called Flexible patterns along with character n-grams. They then input a combination of these features into a linear SVM and ten-fold cross validation is applied to evaluate the model.

Proceedings of Recent Advances in Natural Language Processing, pages 526–533,
Varna, Bulgaria, Sep 2–4 2019.

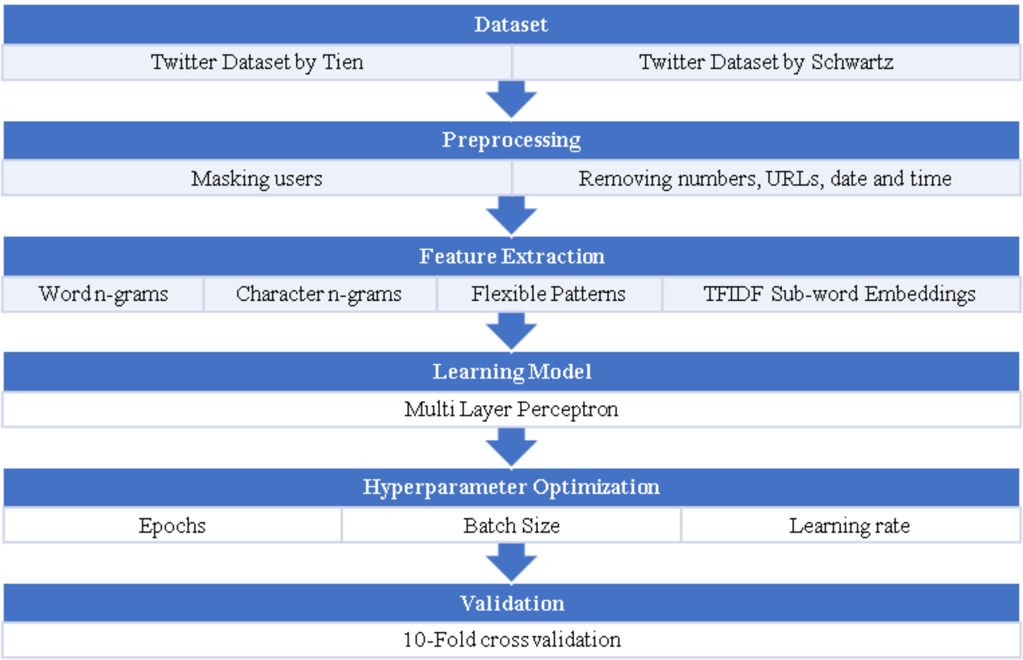

Figure 1: Overview of the proposed system

One of the first deep learning approaches by Rhodes (2015) used word embeddings and a convolutional neural network. Skip-gram method with negative sampling is used for word vectorization from the Google news dataset while using random initialization for unseen words. Furthermore, the convolutional neural network was based on a similar model (Collobert et al., 2011) for language processing, where the activation function is changed to rectified linear units and introducing dropouts. Finally, it demonstrated that the system performs well on longer text sequences.

Shrestha et al. (2017) makes use of a similar architecture; a convolutional neural network (CNN) using character embeddings instead of word embeddings for short texts. The CNN model takes character unigram or bigram as an input that passes through the character embedding layer before feeding it to the convolutional layer. Similar datasets and evaluation criteria as Schwartz et al. (2013) are used to determine the performance of the system. This approach increases the overall accuracy to approximately 76%. Even though the results are better than all previous researches there is a scope for further improvement.

A more recent study on this field (Phan and Zincir-Heywood, 2018) used word embeddings and the neural network to identify the authors of short text messages. They used the three different datasets namely Reuters Corpora (RCVI) (Lewis et al., 2004), Enron dataset (Klimt and Yang, 2004), and Twitter dataset (Yilu et al., 2016). The RCVI is used to train the embeddings which in turn generated the high-level features from the other two corpora by concatenating the vector of means and standard deviations. They then used the feed forward neural network to identify the authors.Therefor, in this work, we also used the same five authors (*Ashley_Nunn75, bradshaw1984, shawnevans81 , terrymarvin63, and WhieRose65*) from the twitter dataset that they used to test our proposed system.

3 Methodology

In this section, we describe our proposed approach and the features we used to train our system. Figure 1 shows an overview of our system in which we worked on two datasets: one by Schwartz et al. (2013) and the other one by Yilu et al. (2016). Section 3.1 explains more about the data.

We carried our pre-processing on the data before preforming feature extraction. There are a total of four features that are obtained from the text namely word n-grams, character n-grams, flexible patterns and word embeddings. An n-gram (section 3.2) is a sequence of n words where n is a positive integer. For example, in the phrase - *”This is a sentence”* -, a word unigram would be - *”This”, ”is”, ”a”* - and a word bigram would be *”this is”, ”is a”, ”a sentence”* - and so on. On the other hand, character n-grams are similar to word n-grams except, they are a sequence of characters. For instance, if we use the previous example, ”This is a sentence”, a character unigram would be - *”T”, ”h”, ”i”, ”s”* - and a character bigram would be - *”th”, ”hi”, ”is”*.

In section 3.3 we define Flexible patterns, explain the existing method and our new approach to create them. The idea behind flexible patterns is that some users tend to use the same sequence of words in their writing style and only change a few keywords called content words (CW). For example, the flexible pattern of the following phrases; *”I read the paper today”* and *”I drove the car yesterday”* is *”I CW the CW CW”*. The words *read, paper, today, drove, car* and *yesterday* are replaced by the word *CW* based on the pre-defined condition. Therefore, masking some words, would create a pattern and separate the texts of some users from other users. We modified the existing approach (Schwartz et al., 2013) to make it suitable for smaller datasets and also to make it easier to implement.

Next, we talked about the word embeddings (Mikolov et al., 2013) feature set in section 3.4. We used the skip-gram technique to create the 300-dimensional vector representation of our data and used that to create the embeddings by combining them using the weights obtained by using TF-IDF.

Later we analyzed (section 3.5) all the models we used and the reason for choosing a Multi-Layer Perceptron (MLP) architecture (Gillian, 2014). We also explained the architecture of our MLP model and the parameters we used to further optimize. Lastly, in section 4 we will compare the results of our approach to both datasets.

3.1 Datasets

To compare our results with the previously mentioned approaches, we used the same dataset that Schwartz et al. (2013) used. The dataset contains a total of 7000 authors, out of which we selected 50 authors at random, where each author has 1000 tweets. We masked the username (@user), numbers, links, date and time from the texts to minimize the bias and noise in the data. We also changed all of the letter characters to lowercase and employ word stemming to reduce the size of the vocabulary used.

Before extracting features and feeding data into the MLP, we concatenated sets of two adjacent records. For example, the first text is combined with the second, the third with the fourth and so forth. Though the initial number of records remains the same, combining the original texts enables us to have a larger sequence, which achieves better accuracy even with the earlier approaches of feature extraction (Schwartz et al., 2013; Shrestha et al., 2017). The larger sequence also helps us to achieve more meaningful patterns which is not otherwise possible.

We also applied the above approach on a different dataset (Yilu et al., 2016) used in Phan and Zincir-Heywood (2018). We used the same 5 authors (users) as they did, with 2000 tweets each. In that paper (Phan and Zincir-Heywood, 2018), the names of the tagged users in a tweet were not masked. However, we masked them, i.e. whenever we encounter a tagged user - *@user* - we change it to a specific word preventing our system from overfitting.

3.2 Word and Character N-Grams

Both word and character n-grams were extracted from the datasets used. For the value of *n* in n-grams and the minimum occurrence of each n-gram, we used the same parameters as used by Schwartz et al. (2013) for comparison purposes. We also took into consideration the maximum occurrence of the n-grams. For example, a pattern including prepositions (as shown in 1 below) or a masked username (as shown in 2 below) are very common in tweets.

1. *for a*
2. *<User> I*

This is even more common in character n-grams. For this reason, we kept the upper limit of the n-grams to 0.9, which means we do not consider any word or character n-grams that appear in more than 90 percent of the documents. This further helps us identify the unique writing style of an author.

We restricted each feature to a maximum of 50,000 in our experiments where each author had 1000 tweets. To assign weights to the n-grams, we used the term frequency-inverse document frequency (TF-IDF) weighted scheme.

TF-IDF (Manning et al., 2008) calculates the importance of the word based on how frequently it appeared in a text, which was then balanced by the frequency of the word in the entire corpus.

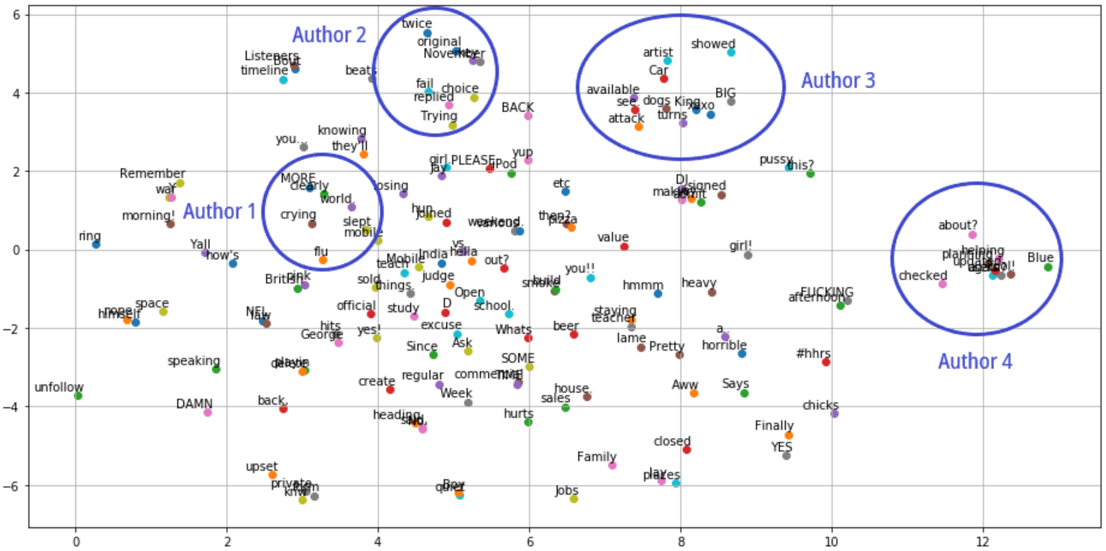

Figure 2: Skip-Gram word embeddings

In a text document d, the frequency of term t is: $tf_{t,d} = f_{t,d}$. This shows the total number of times (frequency count) the term occurs in the document, whereas the inverse document frequency is: $idf(_{t,d}) = log\frac{N}{t \in D}$, where $\hat{N}$ is the total number of documents D in the corpus. Moreover, we employed sub-linear scaling to the TF-IDF by taking the log of the term frequency, Eq.1.

$$wf_{t,d} = \begin{cases} 1 + logtf_{td}, & \text{if } tf_{td} = 1 \\ 0, & \text{otherwise} \end{cases} \tag{1}$$

3.3 Flexible Patterns

Flexible patterns are a branch of word n-grams, where each word is either a high-frequency word or a content word and some words can be both (Schwartz et al., 2013). For a corpus size s if a word appears more than $10^{-4} \times s$ times it is a High-Frequency Word (HFW) and if it appears less than $10^{-3} \times s$ times it is a Common Word (CW). Also, the previous method takes into consideration that flexible patterns start/end with an HFW and there can be no consecutive HFWs.

The problem with this approach is that it does not work with a smaller corpus. For a corpus where the value of s is 1000, no word is a CW. Thus, to overcome this limitation, Eq.2 is used to calculate the CW for a bigger corpus. Therefore in a corpus with a vocabulary size n, the CW is calculated as the common log of the threshold for CW is selected as twice of log of s which are total number of words in the training dataset vocabulary. This method is based on the various experiments we carried out to choose the optimum number.

$$CW \leqslant 2 \times log_{10}n \tag{2}$$

After replacing all the CWs in the corpus, we then used the same approach as we did for word n-grams. Then we applied the TF-IDF weighted scheme to those flexible n-grams before inputting them into the model.

3.4 TF-IDF Weighted Word Embeddings

Word embedding (Mikolov et al., 2013) is a semantic parsing technique used to create the vector representation of a text in a smaller dimensional space compared to the classic Bag of words approach (Zhang et al., 2010). The idea behind word embedding is that semantically similar words should be close to each other. That is, in an n-dimensional space, the angle between the similar words should be close to zero. There are two types of methods to achieve this; namely, Continuous Bag of Words (CBOW) and Skip-Gram methods (Mikolov et al., 2013). While CBOW predicts the target words by taking the context word as input, Skip-gram predicts the probability of the context words using the target words.

We used the word embedding approach from Bojanowski et al. (2017), which is based on the assumption that tweets contain several words, including, but not limited to, hashtags that are rare and sparsely occur in a corpus. To address this sparsity issue, each word is represented by the sum of the vector representations of its n-grams. Having a dictionary as size D and a word w belongs to this dictionary having $D_w \subset \{1, ..., D\}$, the set of n-grams appearing in w. Associating a vector representation of z_d to each n-gram d, the scoring function for w can be represented by Eq.3:

$$s(w,c) = \sum_{d \in D_w} z_d^T v_c \tag{3}$$

For the value of n, we chose $2 \leqslant n \leqslant 6$. Empirically, instead of using pre-trained embedding, we trained it on our corpus with a 300-dimension vector space. We constructed the embedding using the Skip Gram approach which works better for a smaller amount of data and is preferable when there are a greater number of rare words in the corpus (Schwartz et al., 2013). Figure 2 shows the created vector representation from the dataset.

Using t-distributed Stochastic Neighbor Embedding technique (Maaten and Hinton, 2008), we visualized the 300-dimensional data in a two-dimensional space (Figure 2). This shows that words which are used in the same context are grouped closer to each other. The idea behind this approach is that a particular author would use the same combination of words in his/her tweets and therefore, they should be close to each other.

Before using this as an input feature for our model, we weighted the embedding of each word in a text with the IDF value of that word. The resulting dimension is the same as the dimension of each word, which in our case is 300. Ultimately, we calculated the mean of the words to keep the dimensionality of the entire text the same as our vector space. Having a text of size T and words w where $T_w \subset \{1, ..., T\}$, the TF-IDF weighted embedding feature $f(w)$ of a word w_T is given by using Eq.4:

$$f(w) = \frac{\sum_{w \in T_w} idf(w_T) \times emb(w_T)}{T} \tag{4}$$

4 Experiments and Results

As shown in Figure 1, four different machine learning algorithms are employed at the learning phase of the proposed system in this work. We implemented SVM, Naive Bayes, Random Forest (Decision Trees) and MLP classifiers using the Scikit-Learn Python machine learning library (Pedregosa et al., 2011). As discussed earlier, the goal is to classify micro-text. In doing so, we aim to choose the most suitable classifier using the extracted features proposed in the previous section. To this end, we employed the same small dataset used in Phan and Zincir-Heywood (2018). Table 1 shows the 10-fold cross validation accuracy of the four classifiers on that dataset for the 5 authors previously mentioned, where 2000 tweets are used for each author. In this case, our system (Table 1) achieves more than 99% 10-fold cross-validation accuracy which is 15% more than the best result reported in Phan and Zincir-Heywood (2018). Moreover, Figure 3 (confusion matrix) demonstrates that these results are not biased to any specific author in the dataset used. Additionally, Table 2 shows how the 10-fold cross-validation accuracy improved the proposed MLP classifier as the different feature extraction techniques are used, where the first three columns show the accuracy of the combination of extraction techniques and the last column is the best test results given in Phan and Zincir-Heywood (2018).

authors. Figure 4 presents the overview of the proposed MLP model. The number of nodes in the input layer depend on the size of the input feature. *None* represents that the dimension is variable, and in this case, it is *86121*. Then, there is a dense layer, which is a fully connected layer, where each input node is connected to each output node. In the proposed model, there are two Dense layers. One is a hidden layer of 1000 nodes and the other is the output layer of 50 nodes, which corresponds to 50 authors. This can be changed depending on the number of authors (output classes). Inbetween the two dense layers, there is a dropout layer for regularization.

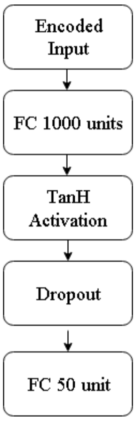

Figure 4: Overview of the proposed model using a Multi-Layer Perceptron as the classifier with one hidden layer and a dropout layer

The input layer of the MLP model depends on the number of features, which increases as the number of tweets increases to train the model. There is only one hidden layer with 1000 nodes. It should be noted, that increasing the hidden layers did not improve the validation accuracy in our experiments. The Tanh activation function (Weisstein, 2002) is used for the hidden layer. The last layer consists of the same number of nodes as the number of authors where the SoftMax activation function (Nwankpa et al., 2018) is used. Furthermore, we have a 30% dropout after the hidden layer to prevent overfitting. In the proposed system, ADAM (Kingma and Ba, 2014) is adapted as the optimization algorithm with a learning rate of 0.001. We divided the data into batches of 64 and trained our model for a maximum of 40 epochs. Figure 5 and Figure 6 show the number of epochs vs loss, and the number of epochs vs accuracy graphs for training and validation data, respectively. These results show that both the loss and accuracy are optimal at around 40 epochs.

Table 3: Accuracy for 50 users with 1000 tweets each

In the following experiments, we incrementally applied all three feature extraction techniques using the MLP classifier and observed the improvements compared to the previous research results (see Section 2). To this end, we first combined the subsequent tweets and applied the approach presented by Schwartz et al. (2013), then we improved that method to calculate flexible patterns and their effect on the accuracy of the system. Last but not the least, we built weighted TF-IDF embeddings and combined them with the improved flexible patterns to form the combined set of features as input into the proposed MLP model. Ten-fold cross-validation approach was used to evaluate the performance of the proposed system. We evaluated the proposed system on the same dataset as used by Schwartz et al. (2013); Shrestha et al. (2017), where the dataset consisted of 50 authors, each having 1000 tweets.

Columns 1-3, in Table 3, shows the results of all three feature extraction techniques used with

#	TFIDF Emb.	Mod. flex	Joining rec.	CNN-C	SCH	Char	LSTM-2
500	**.791**	.76	.748	.724	.672	.655	.597

100	**.648**	.619	.608	.617	.565	.517	.438
50	**.589**	.563	.53	.562	.505	.466	.364

Table 4: Accuracy for 50 users from 500 to 50 tweets for each

the MLP, and columns 4-7 represents the results from the previous works on the same dataset. Our results are mutually inclusive, and the results are built upon combining all the feature extraction techniques. For example, we used the weighted TF-IDF embeddings in combination with the flexible patterns.

CNN-C, shown in Table 3, represents the best result obtained by Shrestha et al. (2017) where a convolutional neural network architecture is proposed using character n-grams, specifically unigrams and bigrams as input. The convolutional model used was a three-level architecture with the input layer as the character embedding layer, a convolutional module, and finally, a dense layer with a Softmax activation function for classification. The unigram model performed well on the smaller dataset. Alternatively, the bigram model had better accuracy on the bigger dataset.

SCH, shown in Table 3, represents the best result obtained by Schwartz et al. (2013). They used a linear SVM for classification and their model was a combination of word and character n-grams along with a new feature set called flexible patterns (see section 3.3), which is modified and used in our system as well.

Char, shown in Table 3, represents one of the systems used by Shrestha et al. (2017) in which they compared the performance of their system based on the earlier character n-gram approaches (Layton et al., 2010; Schwartz et al., 2013) and proposed a logistic regression model that employed character n-grams of sizes two to four.

LSTM-2, shown in Table 3, represents the state-of-the-art LSTM model based on the success of previous implementations (Tai et al., 2015; Tang et al., 2015). This model was also used with bigrams as input to evaluate the performance of those systems, with respect to other models on the same dataset.

Introducing the concatenation of the consecutive records enables the accuracy of the proposed system to be improved by 5% compared to the previous approaches. Then applying the flexible patterns, further improved the accuracy by approximately 2%. Finally, implementing the weighted TF-IDF word embedding, and combining it with all the other features increases the accuracy of the proposed system to approximately 85%, Table 3.

In Table 4, we also compared the proposed system's accuracy to other approaches as we reduced the number of tweets from 500 to 50 for each author (50). After reducing the number of tweets, the proposed system still outperformed all the other previous approaches and performed well even when the dataset became as small as 50 tweets per author.

5 Conclusion and Future Work

In this paper, we explored a feature extraction technique that was based on a word embedding model weighted by TF-IDF. We also worked on modifying and improving the existing implementation of flexible patterns and proposed a neural network architecture that makes use of a combination of these features to perform authorship attribution. Our model outperformed all the existing systems based on similar testing criteria and using the same datasets. Since we trained our embeddings from scratch our system performs equally well, irrespective of the language.

With the success of word embeddings, we look forward to working upon new word embedding techniques such as Elmo (Peters et al., 2018) and Bert (Devlin et al., 2018), which are based on the context of a word in a corpus. Alongside that, we are also interested to improve our neural network architecture using transfer learning models such as ULMFit (Howard and Ruder, 2018).

Abstract

This paper describes a novel, syntax-based system for automatic detection and resolution of Noun Phrase Ellipsis (NPE) in English. The system takes in free input English text, detects the site of nominal elision, and if present, selects potential antecedent candidates. The rules are built using the syntactic information on ellipsis and its antecedent discussed in previous theoretical linguistics literature on NPE. Additionally, we prepare a curated dataset of 337 sentences from well-known, reliable sources, containing positive and negative samples of NPE. We split this dataset into two parts, and use one part to refine our rules and the other to test the performance of our final system. We get an F1-score of 76.47% for detection and 70.27% for NPE resolution on the testset. To the best of our knowledge, ours is the first system that detects and resolves NPE in English. The curated dataset used for this task, albeit small, covers a wide variety of NPE cases and will be made public for future work.

1 Introduction

Nominal Ellipsis or Noun Phrase Ellipsis (NPE, henceforth) is a type of ellipsis in linguists wherein the sub-parts of a nominal projection are elided, with the remaining projection pronounced in the overt syntax. For example in the sentence presented in (1), the noun *chairs* is elided at the position marked by [e].

1. There are three **chairs** in the living room and two [e] in the hall.

The full meaning of such a sentence can only be understood when we reconstruct the meaning of the elided part from the antecedent, which can be present in the linguistic context as in (1) or has to be retrieved from real world knowledge as in (2), where *Mary's* actually means *Mary's place*.

2. We are all partying at Mary's [e].

All world languages use some or the other mechanism to elide redundant information and, hence, ellipses is fairly pervasive in natural language, more so in conversational settings (Langacker, 1999). While human interlocutors effectively resolve and disambiguate any elided information in a sentence based on context and cognitive commonsense extension (Chen, 2016), the realization of the complexity of processing of ellipsis becomes evident when it poses a serious challenge for computational systems involved in natural language understanding.

The approaches that handle ellipsis in both theoretical linguistics and NLP are largely classified as syntactic, semantic and pragmatic (Merchant, 2010). For the current paper, we present a system that automatically detects and resolves NPE in English using a syntax-driven approach.

2 Previous Work

The syntax and semantics of the ellipsis phenomenon has been thoroughly studied in theoretical linguistics (Halliday and Hasan, 1976; Dalrymple et al., 1991; Lobeck, 1995; Lappin, 1996; Hardt, 1999; Johnson, 2001; Merchant, 2004; Frazier, 2008; Chung et al., 2010; Merchant, 2010; Rouveret, 2012; Gunther, 2011; van Craenenbroeck and Merchant, 2013; Park, 2017), in cognitive linguistics (Kim et al., 2019), and in language acquisition studies (Hyams et al., 2017; Lindenbergh et al., 2015; Goksun et al., 2010; Wijnen et al., 2003). In the context of NLP, most of the work on handling ellipsis has been done on Verb Phrase Ellipsis (VPE) and related phenomenon, for instance the preparation of annotated corpus for analysis of VPE (Bos and Spenader, 2011), the detection of VPE in Penn treebank (Hardt, 1997), the domain independent detection and resolution

Proceedings of Recent Advances in Natural Language Processing, pages 534–540,
Varna, Bulgaria, Sep 2–4 2019.

of VPE using machine learning (Nielsen, 2003) and parsed text (Nielsen, 2004), using linguistic principles (McShane and Babkin, 2016), with sentence trimming methods (McShane et al., 2015), reconstruction of sentences with gapping using improved parsing techniques that encode elided material dependencies (Schuster et al., 2018), etc.

There are no known systems that handle NPE detection and resolution in English. However, on a related linguistic phenomenon called one-anaphora or one-substitution, in which the elided noun is replaced by an overt pro-form, there is a thorough data-driven investigation (Gardiner, 2003) and machine-learning methods that use heuristics proposed in this study (Ng et al., 2005). Another phenomenon similar to NPE is zero-anaphora, which has been thoroughly studied in some pro drop languages such as Chinese (Yeh and Chen, 2019a,b) and Japanese (Iida et al., 2007; Asao et al., 2018; Chen, 2016). Zero-anaphora does not occur in English, although there is some evidence of the phenomenon being used to achieve certain interactional functions in ordinary conversational settings by English speakers (Oh, 2005). There are also proposed heuristics for determining antecedents of pronominal words (Lappin and Leass, 1994; Kennedy and Boguraev, 1996). In the present paper, we do not deal with one-anaphora, zero anaphora or pronominals, and restrict our focus to NPE.

3 Task Description

Resolution of ellipsis comprises two tasks - detection of the elided material and antecedent selection. In some cases, reference resolution might also be necessary (Liu et al., 2016; Nielsen, 2003). For example, in (3), the common sense interpretation is that Sam loves his girlfriend. But it could also lead to a sloppy reading where it means Sam loves John's girlfriend.

3. John **loves his girlfriend**. Sam does [e] too.

Note that (3) presents an example of VPE as the verb along with its predicate are elided. In this paper, we focus only on the first two tasks, i.e. detection of NPE and antecedent selection.

4 Dataset Preparation

There are no dedicated linguistic resources or datasets for the analysis of NPE in English. However, there are many well-known corpora that contain annotated instances of NPE. One such resource is the Universal Dependency (UD) tree-

No.	Syntactic Category	Examples
	Can License NPE	
1.	Cardinal Numbers	I read three **chapters** from this book and Mary read [$_{NP}$ four [e]].
2.	Ordinal Numbers	Mary got first **position** in the university and John got [$_{NP}$ second [e]].
3.	Demonstrative Determiners (Plural)	Of all the **candidates** that applied for the job, [$_{NP}$ these [e]] got selected.
4.	Quantifiers (Not all)	Some **students** love physics and [$_{NP}$ some [e]] don't.
5.	Superlative Adjectives	He is the funniest **guy** here. And also [$_{NP}$ the weirdest [e]].
6.	Noun Possessives	That big **car** standing over there is [$_{NP}$ Joey's [e].
7.	Pronoun Possessives	John is reading my **book** and I am reading [$_{NP}$ his [e]].
8.	Interrogative Determiners	I don't know which **pages** to read and [$_{NP}$ which [e]] to ignore.
	Cannot License NPE	
1.	Adjectives	* I have a big **house** and she has [$_{NP}$ a small [e]].
2.	Demonstrative Determiners (Singular)	* That **pen** belongs to Mary and [$_{NP}$ this [e]] belongs to John.
3.	Articles	* I really liked that **house** and I know you liked [$_{NP}$ the [e]] too.
4.	Quantifiers (Not all)	* There are 50 **students** in my class and [$_{NP}$ every [e]] went to see the movie.

Table 1: Syntactic categories that can and cannot license NPE in English, with examples for each category.

bank (Silveira et al., 2014) for English that contains example sentences for different types of ellipsis such as VPE, NPE, etc. The UD treebank marks NPE by raising the dependents of the elided noun to the position of head in cases where the dependents are overtly marked. Through a simple search for noun dependents that are given the status of noun heads, we get a total of 146 cases of NPE in 120 sentences from the UD treebank. There is another comparatively small corpus called the ParCorFull: a Parallel Corpus Annotated with Full Coreference (Lapshinova-Koltunski et al., 2018) that is dedicated to anaphora. This corpus targets anaphora, but deals partly with NPE cases as well, marking them with a nom-ellipsis tag. A simple search for this tag gives us 5 sentences containing 5 NPE cases. We also pick a total of 80 sentences containing 83 cases of NPE from linguistic textbooks on ellipsis (Lobeck, 1995; Saito et al., 2008; Menzel, 2017; Kim et al., 2019; Corver and van Koppen, 2011) to cover even the infrequently occurring cases. Finally, we randomly pick 132 sentences that do not contain NPE from UD treebank, ParCOrFull and the same linguistic textbooks. Some of these negative samples of NPE contain sentences with ellipsis other than NPE, such as VPE.

In total, we curate a small dataset of 337 sentences, of which 205 sentences have 234 instances of NPE (some sentences contain more than one instance of NPE) and the remaining 132 sentences without NPE. This dataset, albeit small, covers a wide variety of the cases of NPE discussed in the ellipsis literature and will be useful for future work. Since the focus of this paper is on presenting a system for detection and resolution of ellipsis, we do not undertake the formidable task of preparation of annotation guidelines and performing annotation to prepare a Gold dataset in this paper. However, this could be an important future work considering the limited available resources for the analysis of NPE.

To fine tune our rules, we only need positive samples of NPE. However, for testing, it is important to use both positive and negative samples. We split our dataset into two parts. For fine tuning the rules, we randomly pick 140 out of the 205 positive sentences (roughly 70%), containing a total of 158 NPE instances. The remaining 65 sentences (roughly 30%) contain 76 NPE instances and are included in the testset along with the 132 sentences without NPE. Hence, our testset has 76 positive and 132 negative samples.

5 System Overview

Our system is divided into two parts. An input sentence is fed into the NPE detection system that decides whether an NPE is present or not. If an NPE is detected, it sends the sentence to the Resolution system where a potential antecedent is selected. The output of the complete system is either a decision that there is no ellipsis present in the sentence or an ellipsis site marked along with its antecedent.

5.1 NPE Detection

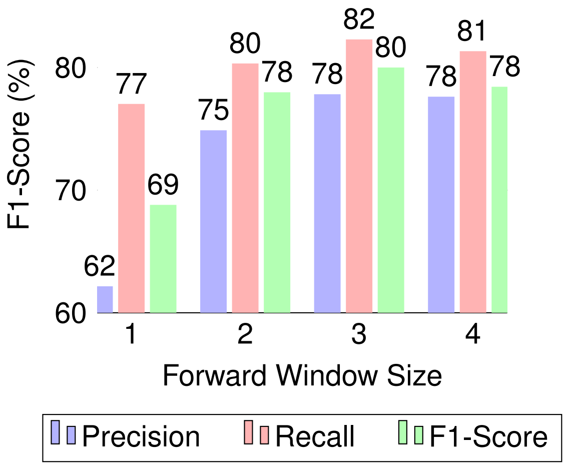
For the task of NPE detection, we exploit a very useful syntactic feature, which is the presence of overt remnants of the noun phrase at the ellipsis site. In case of NPE in English, these trigger words are often determiners and modifiers of the elided noun. These are also known as licensors of ellipsis. In the examples presented in (1) and (2), the licensors of elided noun are the cardinal number *two* and possessive proper noun *Mary's* respectively. We use these remnants or noun modifiers present at the ellipsis site as cues to locate the elided noun.

An interesting feature about these license of NPE in English is that they can only belong to certain syntactic categories. These include cardinal and ordinal numbers, plural demonstrative determiners, possessives, adjectives, quantifiers, and a certain types of determiners. Table 1 provides examples from each of these categories, along with examples of syntactic categories that cannot license NPEs in English. Hence, the idea is to use the syntactic environment of the nominal ellipsis site to perform detection. Linguistically, our approach is similar to detection of VPE by using auxiliary and modal verbs as cues (McShane and Babkin, 2016), as VPE in English are licensed by auxiliary and modal verbs.

5.1.1 Look for Pre-Modifiers and Determiners

NPE detection is carried out in two steps. In the first step, the input sentence is parsed using the state-of-the-art spaCy parser (Honnibal and Johnson, 2015) and using the Part-of-Speech (POS) tags, we check for the presence of nominal modifiers and determiners from the aforementioned syntactic categories that can potentially license an

Figure 1: F1-score corresponding to different window sizes for searching nouns.



NPE. If the system detects POS tags corresponding to any such category, it proceeds to the second step.

5.1.2 Filter Using Syntactic Features

In this step, the system decides if the selected noun modifier is a licensor of an elided noun or not. This decision is taken using the following syntactic features:

(a) Search for Noun Heads

This simple feature looks for a noun word after the selected noun modifier. We check nouns in a forward search window of 3 words. This window is forward because in English noun heads follow their dependents. If there is no noun present in the next 3 words, the system marks the modifier in question as a licensor. The optimum size of the window as 3 is obtained after experimentation with different window sizes on the 100 sentences from the curated dataset. Figure 1 presents the results of experiments done with different forward window sizes searching for noun heads after noun dependents.

(b) Check for Noun Modifiers as Verbal Arguments

The feature looks for verbs with the selected noun modifiers as the main argument. This is because, many times, spaCy raises a noun modifier to the position of a head in the absence of its noun head, which confirms the presence of an elided noun.

(c) Check for Punctuation

We first check for a simple feature that checks for noun modifiers close to punctuation marks. Since a punctuation can indicate a sentential or phrasal break, this could indicate the absence of a noun head for the given noun modifier in the sentence or noun phrase respectively.

(d) Check for Prepositions

We check if the selected noun modifier is immediately followed by a preposition as that would indicate the beginning of a new (prepositional) phrase and imply that the noun modifier in the given noun phrase does not have a noun head overtly present.

(e) Check for Verbs and Auxiliaries

We also check if the selected noun modifier is immediately followed by a verb or auxiliary verb as that would indicate the end of the given noun phrase immediately after the noun modifier.

5.2 NPE Resolution

Ellipses can be resolved textually when their antecedents are present in the same text as in (1). Such cases of ellipsis are called *endophoric*. However, not all ellipses can be recovered or inferred from a co-text. It is also possible that the antecedent of a given ellipsis is present outside the given text. For example, consider a speaker pointing towards pencils in a shop and uttering a sentence such as (4).

4. Give me three [e].

Using visual context, the shopkeeper can easily resolve the ellipsis in this sentence as *three pencils*. Such cases of ellipses are called *exophoric* or situational as they need situational context to resolve. Since we are only limited to text processing at this stage in the current paper, we only focus on resolving NPE that have textual antecedents.

5.2.1 Ellipsis-Antecedent Environment

It is shown that clauses that are linked by an ellipsis-antecedent relation often have similar syntactic structure and priming effects (Xiang et al., 2014). Further, there is evidence that parallelism in discourse can be applied to resolve possible readings for VPE and possibly other ellipsis and reference phenomenon (Hobbs and Kehler, 1997). This becomes our motivation to resolve NPE.

(a) Match POS tags of the Licensor with other Noun Modifiers

The syntactic environment of the an NPE comprises the remnants left in the noun phrase. One simple way to see structural parallelism between the syntactic environment of antecedent and that of ellipsis to locate antecedents is through matching the syntactic category information. From the detection task, we already have the POS tag information of the licensor of the NPE. In the first step of antecedent selection, the system checks for other noun phrases in the sentence that contain the modifiers with the same POS tag as that of the licensor of the NPE.

(b) Select Antecedent

If a POS tag matching the licensor of the NPE (detected in the NPE detection task) is found in the sentence, the system outputs the noun that the modifier with the same tag modifies as the antecedent of the NPE. If there are more than one such modifiers found, the system selects the one nearest to the NPE as distance generally has a role to play in anaphora and coreference resolution tasks (Lappin, 1996).

6 Results

Simply looking for nouns in the context of the noun modifiers gives a poor F1-score of 64.20%. Addition of only the feature that checks for noun modifiers raised as verbal arguments results into an increased in F1-score by 10.25%. Addition of only the punctuation feature after auxiliary and modal verbs resulted into an increase in accuracy by 3% for VPE detection task (Nielsen, 2004). However, in our task, this resulted into a drop in accuracy by 0.05%. Hence, we excluded this feature from the final system. Addition of only the feature that checks for prepositions immediately following the noun modifier results into an increase in F1-score by 13.73%. Finally, addition of only the feature that checks for verbs and auxiliaries that immediately follow the noun modifier gives an increase in F1-score by 11.46%. These features are independent of each other and do not follow any hierarchy.

The final system together with only the significantly important features is tested on the testset containing 76 positive and 132 negative samples of NPE. The detection system is able to correctly detect 65 instances of NPE out of 76. It also rightly predicts 113 out of 132 negative samples as not containing any NPE. It fails to detect 11 positive cases and falsely detects 29 others. This gives us a final precision of 69.15%, a recall of 85.53% and an F1-score 76.47%. Out of the 65 NPE cases detected by the system, 41 have a textual antecedent and the remaining 24 are exophoric and need extra-linguistic context to resolve. Our system is able to select a potential antecedent for 37 of these from the text, of which 32 are correct predictions. The system fails to select any antecedent for the 9 cases. This gives us a final precision of 78.79%, a recall of 63.41% and an F1-score 70.27%. See table 2 for precision, recall and F1-score values for the NPE detection and resolution tasks on the testset.

One of the main reasons of the low accuracy of our system is wrong POS tags generated for sentences with missing or incomplete information as in the case of ellipses (Menzel, 2017). Secondly, although, licensors of NPE and modifiers of the antecedent indeed show similarity in terms of syntactic category information, this might not always be the case.

5. The books were new, and all six [e] were on syntax.

For example in (5), the NPE licensor is a cardinal number, but antecedent *books* has the definitive article in its Noun Phrase.

7 Conclusion & Future Work

This paper described a syntax-based system for automatic detection of NPE in English. The sys-

Task	Positive Samples	Negative Samples	Precision	Recall	F1-Score
Detection	76	132	69.15%	85.53%	76.47%
Resolution	65	29	78.79%	63.41%	70.27%

Table 2: Performance of NPE detection and resolution systems on the testset.

tem takes in free English text and exploits syntactic constraints on the licensors of NPE to mark the site of ellipsis and syntactic parallelism between antecedent-ellipsis syntactic environments to select potential antecedents. Evaluated on a testset containing both positive and negative NPE samples, the system achieves an F1-score of 76.47% on the detection task and 70.27% on the resolution task. Although these numbers are not high, they can be useful as baselines for future work in this direction. NLP research on ellipsis and NPE in particular suffers from a scarcity of resources. While a rule-based system such as ours does not need sizable data for training, with more language resources available in future, machine learning methods can also be used.

Abstract

Researchers in Computational Linguistics build models of similarity and test them against human judgments. Although there are many empirical studies of the computational models of similarity for the English language, the similarity for other languages is less explored. In this study we are chiefly interested in two aspects. In the first place we want to know how much of the human similarity is grounded in the visual perception. To answer this question two neural computer vision models are used and their correlation with the human derived similarity scores is computed. In the second place we investigate if language influences the similarity computation. To this purpose diverse computational models trained on Estonian resources are evaluated against human judgments.

1 Introduction

Various disciplines and research communities are interested in the study of similarity: Philosophy, Psychology, Computational Linguistics, Semantic Web and the Linked Data communities, to name a few. For example, to integrate heterogeneous semantic resources the Linked Data and Semantic Web communities estimate the degree of similarities between the concepts in these resources (Euzenat and Shvaiko, 2013; Harispe et al., 2015).

In Computational Linguistics researchers build computational models of similarity. To test them, the correlation between the human similarity scores and the scores assigned by the computational models is calculated. It is assumed that the best computational models predict better the human judge scores.

However, earlier studies of similarity suffered from a drawback: they do not distinguish between the relations of similarity and association. In psychology, for example, the distinction between these two notions is well understood. The association between two concepts is defined as the propensity of a subject to activate a representation of the second concept when the first concept is presented. In contrast, the similarity is defined as the proximity of two mental representations. In the Gestalt psychology for example (Wertheimer, 1938) the similarity is seen as the principle of organization of objects in perceptual groups. The concepts **cup** and **tea** are associated but not similar: there is no perceptual principle to group together an object like a cup and a liquid like tea. However, the objects denoted by the concepts **apple** and **pear** are perceptually similar. To remedy this problem SimLex-999 (Hill et al., 2015), a genuine data similarity set containing human judge similarity and concreteness scores for 999 English word pairs, has been built.

An interesting distinction is that between the surface similarity and deep similarity (Vosniadou and Ortony, 1989). The surface similarity is perceptually grounded and it is used in categorization. In contrast, the deep similarity is related to deeper properties not readily accessible to perception. A question we study is: How much of the similarity is grounded in the perceptual properties? In this research the degree of similarity grounded in visual properties is estimated by computer vision models.

If for the English language computational models of similarity have been implemented and evaluated, this is not the case for other languages. In particular, for the Estonian language there is no human annotated set that reflects the true similarity. We translate the SimLex-999 into Estonian and evaluate computational models of similarity based on Estonian language resources: corpora, taxonomies and lexical ontologies.

The rest of the paper is organized as follows. The next section puts our research in context and then the EstSimLex-999 set, the SimLex-999 set translated into Estonian, is presented 3. Section 4 discusses the families of models for computing the similarity between the word pairs in EstSimLex-999. Section 5 presents and discusses the results. In particular, we answer how similarity is influenced by language and quantify the power of the computer vision models to capture the similarity for concrete concepts. The paper ends with the conclusions.

2 Related Work

Felix Hill and coauthors (2015) undertook an extensive discussion of the concept of similarity in Computational Linguistics, introduced the genuine similarity set SimLex-999 and computed the correlations between the similarity measures of corpus based computational models and the human judge scores. Closely following this line of research Ira Leviant and Roi Reichart (2015) translated SimLex-999 in Italian, German and Russian and collected similarity scores from native speakers. They compute correlations between the human judgments and Vector Space Models (VSM) in a multilingual setting.

In the subsequent research the authors improve the similarity computational models and boost the correlation coefficient with the human judgments. For example, Schwartz et al. (2015) learn a word level representation based on symmetric patterns that achieves a Spearman correlation of 0.517 with SimLex-999. An interesting work belongs to Faruqui and Dyer (2015), who used non-distributional word representations derived form Princeton WordNet, FrameNet and Penn Treebank to reach a Spearman correlation of 0.58 with SimLex-999. Hybrid models (Recski et al., 2016),combining features from lexical ontologies and word embeddings, seem to be even better (Spearman Correlation 0.76).

In this work we were not interested in obtaining the best correlation between the computational models and the human judgments. That will be the topic of a future work. Instead, we were concerned with three problems. First, we are interested in how much of similarity is grounded in the visual features, that is, how much of the similarity is surface similarity. By evaluating the similarity using computational vision models we contribute to a better understanding of the notion of similarity itself. Second, we ask how the traditional models derived from Estonian corpora and lexical ontologies correlate with the judgments of native Estonian speakers. In this way we extend the similarity study to other language, a less explored one, yet an interesting one. Third, we study if our computational models trained on Estonian data predict better the EstSimLex-999 scores or the SimLex-999 scores. More precisely we want to know if the language influences the similarity judgments.

3 EstSimLex-999

To translate SimLex-999 the Google Translation API and a bilingual English-Estonian dictionary containing 87665 entries have been used, obtaining rough Estonian equivalents. A native Estonian speaker has chosen the correct translations. If an English word in a similarity pair is ambiguous, the sense that makes the pair more similar is preferred. Finally, after correction and the discussion with an Estonian linguist we have produced the similarity set referred from now on as EstSimLex-999. When translating, we have been careful to preserve the part of speech of the English concepts. This makes the comparison between the computational models of similarity for English and Estonian easier. Nevertheless, due to cultural and linguistic differences some English similarity pairs were hard to translate. For example, the English pair (taxi, cab) was translated as (taksi, takso) even if the second term of the Estonian pair is not widely used. Another example is the pair (supper, dinner). The Estonian culinary tradition does not distinguish between the two concepts, therefore we have translated the pair with the synonymous words (õhtusöök, õhtueine). Please, notice, that for many non-British native English speakers the words *supper* and *dinner* are also synonymous. Some translations would have been more accurate using multiwords, but we abide by the original requirement that the similarity pairs should contain single words only. Overall, we have produce an accurate translation of the English original SimLex-999 set preserving the distribution of the part of speeches and satisfying the demand that the word pairs should not contain multiple words.

Four native Estonian speakers have rated the degree of similarity between each of the 999 pairs.

The rating instructions are the same as in the original study (Hill et al., 2015). These instructions do not attempt to define what similarity is, but rather clarify the concept contrasting it with association, and comparing it with synonymy. The inter-annotator agreement was computed as the average of pairwise Spearman correlations between the scores of all raters. The overall agreement is 0.766. A direct comparison with the correlation coefficient computed in the English study (0.67) is not possible because the number of annotators is different. At this stage we were not interested in recruiting many annotators through platforms like Mechanical Turk, but rather in gaining insights into human similarity judgments by direct discussion with the annotators. In any case, recruiting a comparable number of Estonian speakers is unlikely, as this language is natively spoken by less than 1 million people. The main thing noticed is that there are few pairs of adjectives and verbs highly rated in English but with a low score in Estonian. For example, the English verb pair (appear, attend) has a score of 6.28 in SimLex-999 and its Estonian translation (ilmuma, osalema) has a score equal to 0.5.

4 Models for Similarity Computations

Three families of similarity models are evaluated : distributional models, semantic network models and computer vision models.

The distributional models are an implementation of John Rupert Firth's hypothesis "You shall know a word by the company it keeps" (Firth, 1961) which basically states that words that have similar meanings appear in comparable syntagmatic contexts. Nowadays, the most advanced distributional models are the neural word embeddings.

The second family of models derive the semantic similarity from the taxonomic structure of semantic networks. The IS-A relation induces the inheritance of the properties.The above mentioned concepts, *apple* and *pear*, are similar because they inherit all the properties from their superordinate concept (fruit). Unlike the distributional models, the semantic networks tells us also why the concepts are similar.

The third family of models are the computer vision models. The similarity between two concepts is the distance between their image representations. Because of the visual nature of this similarity the computer vision models work best for concepts representing concrete objects.

In what follows we will briefly describe the models tested.

1. **Word2Vec**. Word2Vec is a distributional model (Mikolov et al., 2013) implemented as a two layer neural network. If two words appear in similar contexts in a corpus the network will output embedding vectors, known as neural vector embeddings, which are close in the embedding space. Word2Vec computes the neural vector embeddings either predicting the target word from the context (this method is known as continuous bag of word (CBOW)) or as the target context from the word (this method is know as Skip Gram).

2. **SenseGram**. SenseGram (Pelevina et al., 2016) is not a distributional model per se, but a method to obtain word senses from word embeddings. This word discrimination method takes as input word embeddings (like those generated by Word2Vec or any other distributional model) and clusters them. The induced word senses correspond to the clusters of word embeddings.

3. **Path Similarity Measures**. The path similarity measures exploit the graph structure of semantic networks to find similarities between concept pairs. We have explored various similarity measures like Leacock-Chodorow similarity (Leacock and Chodorow, 1998).

4. **Autoencoders**. Autoencoders are deep neural networks which learn to reconstruct the input. In the reconstruction process one of the autoencoder layers contains less nodes than the input layer, thus forcing the network to learn a lower level representation of the input. The idea behind using the autoencoders is that the sparse representations learned when encoding similar concepts will be close in the embedding space.

5. **Pretrained Convolutional Neural Networks**. Convolutional Neural Networks (CNN) are deep neural networks architectures suitable for extracting patterns from images. Inspired by experiments in neuroscience (Hubel and Wiesel, 1959), CNN's

first layers train convolution filters to detect low-level features of an image like lines and corners. Higher network levels combine the low level-features to find high-level image features roughly corresponding to the human language semantic descriptions of the objects. For example, they might detect parts, like the wheels or the hood of a car. When CNN are trained on big databases of classified images the semantic representations of the concrete concepts can be "read" from the deeper network levels. These representations are then used to compute concept similarity.

5 Results

First the results for the distributional models are shown, then the results for the semantic network models will be presented. Finally, the results for the neural computer vision models will be shown. The correlation coefficients between the scores assigned by the computational similarity models for interesting subsets (e.g. abstract and concrete concepts) and the two similarity sets are also computed. In the tables in this section the SimLex-999 is abbreviated as SL-999 and the EstSimLex-999 as ESL-999.

5.1 Distributional Models

When evaluating the **Word2Vec** and **SenseGram** models, if the embedding vectors corresponding to the words in the SimLex-999 or EstSimlex-999 are missing, the word-pair is eliminated. The model word similarity score is computed as cosine similarity between the vector embeddings corresponding to the words in the each word pair. Pearson (r), Spearman (ρ), and Kendall (τ) correlations are calculated between EstSimLex-999 and Simlex-999 human judge scores and the model word similarity scores. The word embeddings were trained on Estonian monolingual corpora and the Estonian Wikipedia. The following word embeddings have been used:

- **EA word embeddings**. 9 Skip-Gram and 20 CBOW models, with different parameter settings, were trained on the lemmatized version of etTenTen corpus of Estonian Web [1] by Eleri Aedma. Word senses were induced from the traditional word embeddings using SenseGram. SenseGram finds 1.6 senses/concept, with about 300 word pairs having more than one sense. For the ambiguous word pairs (where at least one of the words in the pair has more than one sense) the word sense that maximizes the cosine similarity score of a word pair is evaluated.

	SL-999			ESL-999		
Model	r	ρ	τ	r	ρ	τ
cbow_1	.42	.42	.29	.46	.47	.33
sg_2	.37	.36	.24	.41	.42	.3
cbow_3	.33	.33	.23	.33	.34	.24

Table 1: The results for the best three distributional models

- **Estnltk pretrained word embeddings**. Estnltk (Orasmaa et al., 2016) contains 8 word pretrained embeddings. 4 of them are trained with the CBOW method and the other 4 were trained with the Skip-Gram method, on the raw and lemmatized versions of the Estonian Reference Corpus (Kaalep et al., 2010). The Estonian Reference Corpus is a 1.3 billion word corpus, crawled from the web, containing mainly newspaper text.

- **Facebook pretrained word embeddings**. The Facebook word embeddings (Bojanowski et al., 2017) have been trained with CBOW method on 294 language versions of Wikipedia.

The distributional models evaluate on average 985 word pairs. Each CBOW and Skip Gram model has 4 meta-parameters : the number of dimensions, the window size, the minimum count threshold and the number of iterations. Due to consideration related to space we only present the best three results in the table 5.1. The whole set of results for the 67 distributional models trained and all the figures and the tables in this paper are available online linked from our github repository. [2]. The best model on the first row in the table 5.1, for example, has been trained with the 300 dimensions, a window size equal to 1, the minimum count threshold being 10, and 20 iterations.

In the first place one can notice that CBOW trained word embedding perform better than Skip-Gram trained word embeddings. Moreover, the correlation coefficients between EstSimLex-999

[1] DOI: 10.15155/1-00-0000-0000-0000-0012EL

[2] https://github.com/estsl/EstSimLex-999

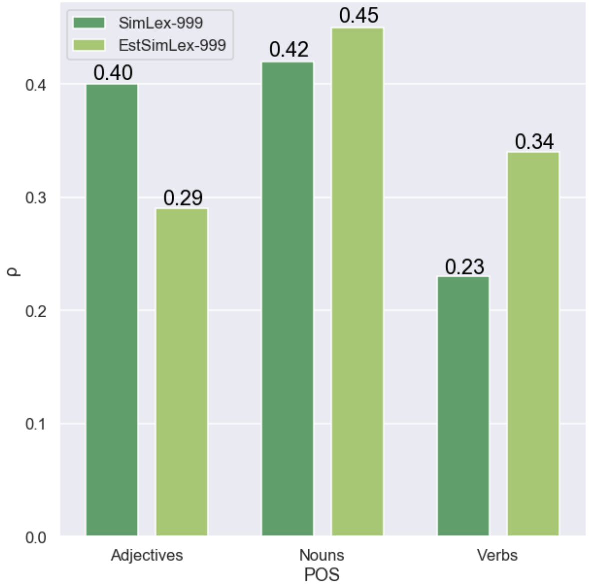

Figure 1: The average performance for POS-based subsets

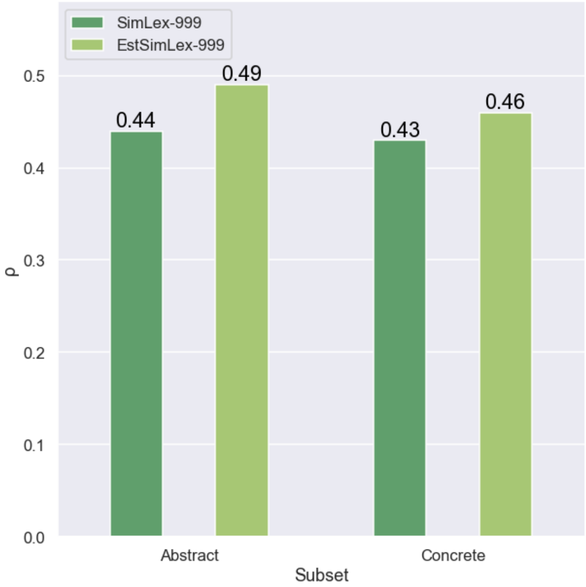

Figure 2: The average performance for the most concrete and abstract subsets

human scores and the model computed word similarity are higher than the correlation coefficients between SimLex-999 human scores and the model computed word similarity. The automatic sense discrimination had a negative influence on the results, as the SenseGram induced vector senses show a slight drop in performance over the traditional word-embeddings. The Estnltk trained word embeddings perform worse than EA word embeddings, but better than Estonian Facebook pretrained word embeddings.

Furthermore, we study if the part of speech category influences the strength of the correlation between human judgments and the distributional models. The model similarity scores between the words in the word pairs is the average similarity scores for all the distributional models.The correlation coefficients between the model scores for 666 noun pairs, 111 adjective pairs and 222 verb pairs and the human judgment scores is calculated.

As it can be seen in figure 1, the best (Spearman) correlation coefficients between the models and the similarity sets are obtained for the nouns. The (Spearman) correlation coefficient between the distributional models and the human judgments is higher for EstSimLex-999 set than for the original SimLex-999 set.

The correlation coefficients between the 250 most concrete word pairs and the 250 most abstract word pair and the distributional models have also been computed. The results presented in figure 5.1 show that, on average, the distributional models correlate better with the abstract human judgments scores and that the correlation coefficient is higher for the EstSimLex-999 set.

5.2 Semantic Network Models

The similarity between the concepts corresponding to the words in EstSimLex-999 word is computed for two semantic networks: the Estonian Wordnet and a taxonomy derived from the Estonian Wikipedia.

As the Estonian Wordnet lists multiple senses for words, a disambiguation procedure to select the most likely sense is implemented. The Cartesian product between the word senses in the semantic network corresponding to the words in the EstSimLex-999 is generated. Thus we obtain a set of word-sense pairs. Subsequently, as explained below, a similarity scores is assigned to each word-sense pair in this set. The word sense pair that maximizes the similarity score is chosen. This procedure of mapping the words onto a semantic network is very effective, obtaining over 90 percent precision for the Estonian Wordnet (Barbu et al., 2018) .

Three similarity measures between the semantic network concepts have been computed: path similarity (PS), Leacock & Chodorow similarity (LC) (Leacock and Chodorow, 1998) and Wu &

	SL-999			ESL-999		
	r	ρ	τ	r	ρ	τ
PS	.47	.47	.35	.54	.52	.39
LC	.36	.36	.26	.41	.43	.31
WuP	.41	.45	.32	.49	.53	.39

Table 2: The results for the Estonian Wordnet

Palmer similarity (WuP) (Wu and Palmer, 1994). Pearson (r), Spearman (ρ), and Kendall (τ) correlations were calculated between EstSimLex-999 and SimLex-999 human judge scores and the network similarity scores for the disambiguated word pairs.

The Estonian Wordnet is an ongoing effort, it pursues roughly the same organization principles as Princeton WordNet (Miller et al., 1990), and it is manually built by a group of linguists. The version used in this study contains approximately 85.000 synsets. The above described disambiguation procedure maps approximately 770 word pairs onto the Estonian Wordnet. The results corresponding to the Estonian Wordnet are in the table 2.

The best results are obtained for Wu & Palmer similarity measure and EstSimLex-999. This similarity measure considers the depth of the concepts in the semantic network hierarchy along with the depth of their Lowest Common Subsumer. Unlike the path similarity measure it favour the concepts that are deeper in the hierarchy. As in the case of the distributional models the EstSimLex-999 correlation scores are better than the SimLex-999 ones. A fact worth noticing is that the difference between the correlation scores for the two similarity sets is greater when we compute the similarity score based on the Estonian Wordnet structure instead of estimating the similarity using distributional models.

The taxonomy was extracted from the (Estonian) Wikipedia page text (Wikipedia Page Taxonomy) by the language technology research group at Università Roma Tre (Flati et al., 2016). The Wikipedia Page Taxonomy contains approximately 87000 concepts. We could map around 200 word pairs onto the Wikipedia Page Taxonomy. The results for this taxonomy are in Table 3.

	SL-999			ESL-999		
	r	ρ	τ	r	ρ	τ
PS	.32	.31	.22	.37	.34	.24
LC	.31	.3	.21	.35	.34	.28
WuP	**.39**	**.37**	.28	.4	**.37**	.27

Table 3: The results for the Wikipedia Page Taxonomy

The correlation coefficients between the similarity measures computed for the Wikipedia Page taxonomy and the human judgments scores are much lower than those computed before (with the Estonian Wordnet). Also, surprisingly and for the first time in this study, there is no statistically significant difference between the correlation coefficients computed with SimLex-999 human judgments scores and the EstSimLex-999 human judgment scores.

5.3 Computer Vision Models

Because the visual similarity is correlated with the level of concreteness of an object, the computer vision models are fed with word pairs where both words have a degree of concreteness higher than the a threshold equal to 4.8 . This criterion gives us 136 word pairs. We have downloaded, using Yandex image search engine 200 images for each word in the selected word pairs.

The first architecture trains a Convolutional Autoencoder (CAE) on the downloaded images. The encoder consists of 3 convolutional layers, each followed by a max-pooling layer. The decoder consists of 3 convolutional followed by upsampling layers. The similarity between two images is calculated as the cosine similarity between the corresponding encoder vectors. The similarity score for a word pair is the average score between all the images corresponding to the words in the pair.

The second architecture is the winner of the ImageNet 2015 competition. It is a CNN network architecture invented by Microsoft Research, called ResNet(He et al., 2016) (abbreviation for Residual Network). DNNs with many layers are difficult to train due to vanishing and exploding gradient problems. ResNet solves these problems with residual learning. The ResNet architecture comes in many variants, depending on the number of layers the network has. The widely employed ResNet-18 variant with 18 layers is used in this study. The network is pretrained on the ImageNet database (Deng et al., 2009) which contains over 1 million images classified under 1000 Princeton WordNet categories. Being trained on such a big

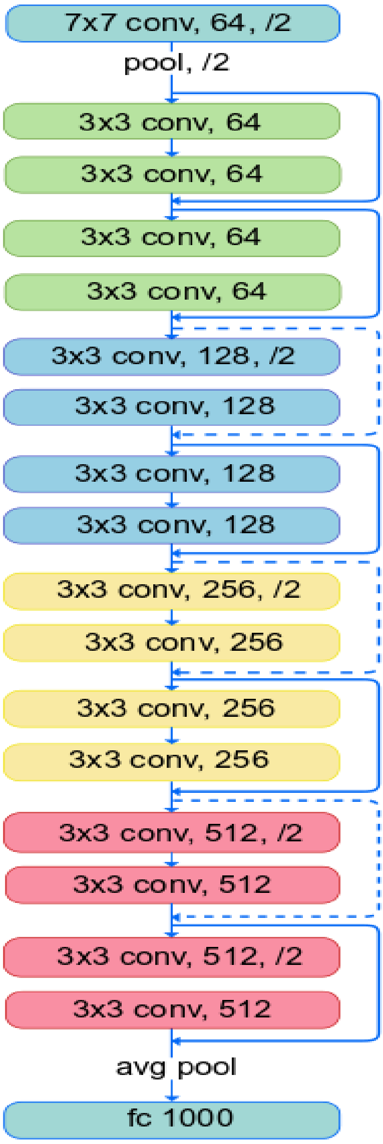

Figure 3: Architecture of ResNet-18

and diverse database of images, ResNet learns rich feature representations that help discriminate between images belonging to different categories.

The architecture of ResNet-18 network is presented in 5.3. As can be noticed the network repeats the same structure, and it ends with the average pool layer that feeds a fully connected layer. The probability that an image belongs to a category is computed by a softmax layer. The network is fed with the downloaded images corresponding to the words in the selected concrete set. The image representation learned by the network is read from the average pool layer. The score this visual model assigns to a word pair is the average cosine similarity score between the pair words image representations. As a way of example let's take the hypothetical word pair (cat, dog). The score assigned by the model to this pair is the average cosine similarity score between the ResNet-18 representations of the images corresponding to the words dog and cat.

Model	SL-999			ESL-999		
	r	ρ	τ	r	ρ	τ
CAE	.25	.28	.19	.17	.22	.15
RN18	.37	**.38**	.26	.34	**.38**	.27

Table 4: The results for the convolutional autoencoder (CAE) and ResNet-18 (RN18) architectures

The results for the two computer vision architecture are presented in Table 4. As expected, the rich visual features learned by the ResNet-18 architecture boost the results (the best results are bold marked in the table) for both similarity sets. The highest correlation coefficients are between the computer vision models and both similarity sets human judge scores.

For the three families of models three correlation coefficients have been computed. These coefficients do not induce a different order on the results, therefore the usage Spearman correlation coefficient in the previous studies is justified.

In general the correlation coefficients between all families of computational models and the human judge scores of EstSimLex-999 are better than the same correlation coefficients and the human judge scores of SimLex-999. This result shows that there is a slight language effect on the perception of similarity.

Regarding the magnitude of the Spearman correlation coefficient for the Estonian side of the equation, the distributional models show a moderate strength [3] of correlation with the human judge scores. This means that the distributional models do capture some of the notion of similarity between the words, but they also capture something else. The best Spearman correlation coefficient is obtained with the Estonian Wordnet (0.53), being better than the best correlation coefficient for distributional models (0.47), but still in the moderate range. It seems that the best predictor of human similarity is derived from a manually built resource containing clearly defined semantic relations.

Less than 40 percents of the similarity of the concrete concepts can be explained by the visual

[3] In the literature the strength is moderate if the coefficient is in the range 0.4-0.59.

semantic features when these features are computed from huge databases of images like ImageNet. Although the empirical evidence heavily depends on the quality of the ImageNet database this finding shows that other factors have significant weight in human similarity judgments. Maybe a case can be that these factors are the deep semantic features we have briefly mentioned in the introduction section. However, a definitive answer to what these factors are and how to account for them goes beyond this research.

6 Conclusions

In this study have addressed some aspects of the computational models of similarity applied to the Estonian language.

In the first place we have found that the neural visual models of similarity can explain a part of the similarity between the words representing concrete concepts. This invites the conclusion that deep similarity models might be involved in accounting for the unexplained part of similarity.

In the second place and differently from the finding in (Leviant and Reichart, 2015) an effect of the language on the similarity has been found. Unlike in that study the Estonian computational models of similarity better correlate with the word pair similarity score assigned by the Estonian subjects that with the scores assigned by English speaking subjects.

In the third place the best computational models are those derived from human built semantic networks. They are better than the neural distributional models but still they correlate moderately with the human judgments. This means that there is more to similarity than taxonomic similarity. On the other hand the Estonian Wordnet is still work in progress, therefore we cannot rule out that a more complete wordnet can boost the similarity scores. Unlike the original study (Hill et al., 2015) we have found that the word embedding computational models better correlate to the scores for nouns and not the adjectives. Intuitively, this result makes sense as nouns have richer mental representations than other morphological categories, therefore one expects that the similarity is better defined for nouns than for other parts of speech.

In the future we will work to better understand the other components of similarity for the concrete concepts, improve and refine the computational models of similarity for the Estonian language and address the same problem for different languages.

Reproducibility

The EstSimLex-999 set annotated with the human judge similarity scores, the code used to compute the results in this paper, the complete set of tables and the figures and most of the resources used in this paper can be referenced from the Github repository https://github.com/estsl/EstSimLex-999.

Acknowledgments

A number of persons have helped us with this study. We like to thank Aliis Aalmann and Kadri Muischnek for the aid in translation of the SimLex-999. We also like to thank Eleri Aedmaa for making available the word and sense embeddings and the anonymous annotators for rating the Estonian word pairs. This study was supported by the Estonian Ministry of Education and Research (IUT20-56).

Language-Agnostic Twitter Bot Detection

Jürgen Knauth
Institute for Computer Science
University of Göttingen
jknauth@uni-goettingen.de

Abstract

In this paper we address the problem of detecting Twitter bots. We analyze a dataset of 8385 Twitter accounts and their tweets consisting of both humans and different kinds of bots. We use this data to train machine learning classifiers that distinguish between real and bot accounts. We identify features that are easy to extract while still providing good results. We analyze different feature groups based on account specific, tweet specific and behavioral specific features and measure their performance compared to other state of the art bot detection methods. For easy future portability of our work we focus on language-agnostic features. With AdaBoost, the best performing classifier, we achieve an accuracy of 0.988 and an AUC of 0.995. As the creation of good training data in machine learning is often difficult - especially in the domain of Twitter bot detection - we additionally analyze to what extent smaller amounts of training data lead to useful results by reviewing cross-validated learning curves. Our results indicate that using few but expressive features already has a good practical benefit for bot detection, especially if only a small amount of training data is available.

1 Introduction

While at the end of the 90s digital communication was still handled exclusively via well-defined Internet protocols, a completely new form of communication has established over the decades using web-based technology: Social media. These are web-based platforms that allow users to publish and exchange messages with each other after registration. These platforms are highly attractive: on the one hand, they establish a form of social community that enables people to enter into new relationships with each other or to maintain existing relationships. On the other hand, these platforms are designed in such a way that their users can easily find new content based on algorithmic recommendations.

Today, these social media platforms cover a wide variety of media. This work focuses on Twitter[1] - a service that enables the publication of short text comments.

As information and opinions are widely disseminated and exchanged via these platforms, the rise of social media as mass communication tools has increasingly attracted the interest of different actors who try to use social media as influencing factors. Businesses recognize the potential to advertise their products in this way at a very early stage, while political actors try to promote their views.

With the rise of such platforms to mass media and the desire to influence public perception and opinion, a comparatively new phenomenon has developed: The use of bots. In addition to normal human users, some social media platforms also feature computer programs that generate and provide content. This phenomenon has been found on Twitter as well as other social media platforms.

Some of these bots are indistinguishable from normal users on a superficial level. This is desired by their creators: Though there are legitimitate applications that justify the use of bots, bots are also used for malicious purposes. E.g. bots can be used for spamming to advertise products or for drawing attention to certain political statements.

As technical methods seem to make it possible to promote certain opinions, there exists at least a

[1] https://twitter.com/

theoretic danger that democratic processes might be in influenced by bots. Badawy et al., 2018 analyzes a set of Russian bots and how their information is picked up by American twitter users related to these bot accounts. Their research shows that information is introduced selectively into social media such as Twitter. Badawy et al., 2018 show that this information gets picked up and is spread - by users and other bots. The extent to which such influence can actually influence public opinion is not yet clear and requires further research. However, the very fact that such information is disseminated makes detecting Twitter bots an important issue to address.

2 Related Work

Detecting Twitter bots has been addressed as a research topic for quite some time. Wang, 2010 reconstructed a graph model based on crawled Twitter accounts and tweets exploiting follower and friend relationships. They use their data to implement a spam detection approach using classic Bayesian classication to distinguish between normal behavior from suspicious behavior on Twitter.

In 2012 a large scale classification study was conducted by Chu et al., 2012 to detect bots, humans and ”cyborgs” in Twitter data. The term ”cyborgs” is used here for accounts that are a symbiosis of humans and bots, making this a multinomial problem. Chu et al., 2012 used a dataset of 2000 manually classified Twitter accounts and achieved an accuracy of about 96% with a random forest approach.

Clark et al., 2015 uses a different approach. They not only crawl Twitter directly to extract tweets but additionally use data from a honeypot. They provided a setup with Twitter accounts being bots themselves. Twitter users following these accounts for no real reason are considered as being bots. Clark et al., 2015 focus on content of the tweets and use three different features to measure tweet similarity and hyperlinks. Based on this they propose a classifier to distingusish between ”organic” and ”robotic” texts achieving an accuracy of 90.32% of the ”organic” and 95.2% of the ”robotic” accounts. They additionally identify different behavior among these accounts indicating that there are several different classes of spammers and spam bots.

Cresci et al., 2015 and Cresci et al., 2017 manually analyzed and annotated over 8000 account data records and conducted an even more in depth analysis of the phenomenon of Twitter bots. Building a classifier they achieved an accuracy of 95% (Cresci et al., 2015). In their 2017 paper they discovered a new generation of social bots being more sophisticated compared to bots already known. They improved their performance by using advanced clustering algorithms and a large set of 126 features and were able to detect up to 97.6% of Twitter bots on one of their data sets.

Newer work uses sophisticated machine learning techniques. Cai et al., 2017 detect bots by modeling users and their behavior using deep learning by focusing on topic, latent sentiment and temporal aspects. Their CNN-LSTM model learns from user content as well as user behavior. With this approach they achieve an F1 score of 88.30% percent for their deep learning model outperforming reference models based on content or behavior alone.

Efthimion et al., 2018 use an approach with support vector machines. They make use of the Levenshtein distance to detect similar posts for their classification approach. This is noteworthy, as we make use of Levenshtein distance as well, but in contrast to Efthimion et al., 2018 use it to detect similarities not among tweet content but on account level. (See below.) Efthimion et al., 2018 use the same data as we use in our work and achieve and accuracy of 95.77% (which we outperform in our work).

Lundberg et al., 2018 provide two classifiers that are used to not only build an offline classifier, but a system that performs online analysis of tweets as they emerge from the Twitter community. They achieve an accuracy of about 98%.

3 Contribution and Outline

3.1 Research Questions

According to the importance of social media and Twitter bots outlined in the introduction, the following scientific questions arise regarding the recognition of Twitter bots:

- Is it possible to detect bots at account level only, without taking into account the content provided by these accounts?
- Does bot detection benefit from content analysis?
- Is it possible to reliably detect bots in a way that avoids language-specific features?

- Creating training data for bot detection is difficult. How large does such a data set have to be in order to achieve useful training results for machine learning? Can a small data set be sufficient?

4 Methodology

4.1 Considerations about Bots and Humans

Our approach to identifying Twitter bots is based on the assumption that bots are fundamentally different from humans in some aspects. Our consideration is that two categories should be distinguished here:

- Technical differences
- Purpose-related differences

4.1.1 Technical Differences

Due to the fact that bots are computer programs, they are not subject to certain human limitations. Computer programs can act instantly in contrast to humans who need time to reflect and are often occupied with other tasks of daily life and work. It can therefore be assumed that human behaviour is different from bot behaviour with regard to timing and the orientation of published content.

Our considerations are also based on the assumption that it is difficult for computer programs to imitate human behaviour. While it is possible to simulate human inadequacies, for example by delaying reactions, it would be difficult for bots to accurately mimic human behavior: This would require extensive statistical analysis of the behaviour of Twitter users. We can therefore assume that bots are created using simpler methods, such as random temporal behaviour, which only resemble human behaviour at first glance.

4.1.2 Purpose-Related Differences

Bots have clear objectives, for example spreading political messages or references to products. Bots bring specific content to attention, hashtags, URLs. So they have some kind of ”agenda” which should be able to be exploited to some extent in general.

It should be noted here that the fact that we and other researchers are able to identify bots quite reliably clearly shows that these assumptions are not unfounded.

4.2 Dataset

Our work is based on the MIB dataset (Cresci et al., 2017), which contains 8375 annotated Twitter accounts.

- 3473 accounts - humans
- 991 accounts - political candidate retweeters
- 3457 accounts - paid apps spammers
- 464 accounts - amazon.com spammers
- Total number of accounts: 8375 accounts

This data set contains data records about the accounts themselves as well as tweets created.

4.3 Baseline

In the next sections we lay out our feature extraction and machine learning process. In order to compare our results with a baseline we reimplement one of the machine learning classification systems described in Kudugunta and Ferrara, 2018. This classifier is quite a high baseline as it performs very well and is - to our knowledge - the current state of the art.

4.4 Feature Extraction

For building a machine learning classifyer we require a matrix of feature values for training and - later on - classifying unseen test data. So in a first first step we extract a variety of features from the Cresci et al., 2017 datasets. These features are discussed in the next subsections.

4.4.1 Account Based Features

The first group of features is derived from account metadata. Our *simple user profile features* directly reflect values the Twitter API provides about users. We additionally derive features with some processing from the screen and user names.

Some of the features are self explanatory or explained by the Twitter API documentation. [2] Nevertheless some of these features require additional discussion.

- **Simple user profile features:** We hypothesize that metadata from the user profile provides valuable information about the user account. Some of this data is generated by

[2] https://developer.twitter.com/en/docs/tweets/data-dictionary/overview/user-object.html

Twitter itself and sometimes difficult to control directly by users. This data contains characteristics about a user's account we can exploit for machine learning. These account features include:

  - *default_profile:* Has the user altered the profile?
  - *geo_enabled:* This feature reflects if users enable adding geographic information if they publish a tweet.
  - *protected:* When true, indicates that this user has chosen to protect their Tweets.
  - *is_verified:* This is some kind of quality marker provided by Twitter: Accounts that are run by people of public interest can be verified as being authentic by Twitter itself.
  - *friends_count:* The number of users this account is following.
  - *followers_count:* The number of followers this account has.
  - *favourites_count:* The number of tweets this user has liked.
  - *listed_count:* The number of public lists this account is a member of.
  - *statuses_count:* The number of tweets issued by this account.
  - *profile_use_background_image:* Has the user provided a background image?

- **User profile name features:** User and screen names are very much subject to a user's choice. Therefore we hypothesize that it provides valuable information that helps to distinguish bots from humans. These features include:

  - *screen_name_length:* The length of the screen name provided by a user.
  - *user_name_length:* The length of the account name provided by a user.
  - *screen_name_digits:* Number of digits in the screen name.
  - *user_name_unicode_group:* See below.
  - *screen_name_unicode_group:* See below.
  - *levenshtein_user_name_screen_name:* See below.

We use some features that are closely related to the screen and user names of accounts. In particular, we determine which of the 105 Unicode code groups an account uses in the screen and user names. This is reflected in the categorical features *user_name_unicode_group* and *screen_name_unicode_group* where we have one feature for every Unicode code group. The rationale behind this feature is that humans tend to be quite creative in their choice of names and sometimes tend to pick characters completely unrelated to the alphabet of their own language. By comparing occurrences of characters in various Unicode code groups we take this behaviour into account.

Furthermore we want to make use of possible differences between an account's screen name and user name. We model this by calculating the respective Levenshtein distance (Levenshtein, 1966). We observed that bot accounts tend to choose user names and screen names that are similar, while humans can be more creative in this respect.

4.4.2 Content Based Features

We derive additional features from the content a user provides.

For that purpose we tokenize the tweets. We tokenize by breaking the tweet text at a variety of spaces and punctuation such as commas, colons, exclamation marks, brackets and similar characters that are commonly used in sentences. This tokenization respects characters occuring in emojis as well. While tokenization in itself is not entirely language agnostic, these heuristics should nevertheless work for a fairly large set of (Latin script) languages.

Then we can extract features based on these tokens. Other features are directly derived from the metadata of tweets.

- **Behavioural features:** We hypothesize that the tweeting behaviour of bots and humans should exhibit differences. We model this behaviour by calculating statistical properties from the data such as minimum, maximum, average, mean, median, standard deviation, skewness, kurtosis, and others.

  - *time_between_retweets (distributional feature):* This set of features models time between retweeting activities of an account.
  - *time_between_tweets (distributional):* This set of features models time between tweeting activities.

  - *tweet_rate (average tweet rate):* The average number of tweets per day

- **Core content features:** We hypothesize that some aspects of intention and emotions can be derived from a tweet's content. The following features honor this in a language independent way.
  - *emojis_classic (distributional feature):* See below.
  - *emojis_kaomji_faces (distributional):* See below.
  - *emojis_line_art (distributional):* See below.
  - *emojis_other (distributional):* See below.
  - *number_of_tokens (distributional):* This feature models the size of a tweet to some extent.
  - *number_of_hashtags (distributional):* The number of hashtag based references contained in tweets.
  - *n_of_tokens_wo_hashtags_urls_symbols (distributional):* A distribution based on the number of plaintext tokens in the tweets excluding hashtags, URLs and non-alphanumeric tokens.
  - *number_of_urls (distributional):* The number of URL based references contained in tweets.
  - *special_char_repeats_rate:* This feature detects sequences of question marks and exclamation marks. These are also often used for affirmation to give special weight to what has been expressed in a tweet. We want to model this aspect.

We assume that a precise sentiment analysis of the twitter text is not available for all languages tweets could be written in. Nevertheless, we want to extract and use emotional aspects from the content. In order to model some basic aspects of emotion we detect various different sets of emoticons here. The extraction is pattern based and derived from public emoticon collections as provided by Wikipedia. The four emoji features above are distributions derived on individual occurrences of emojis in single tweets.

4.5 Feature Groups

Based on these features we build sets of different features for use in different machine learning experiments.

For reasons of getting a more detailed understanding about the performance of various feature sets we group all behavioral features to a feature set named `tweet-behav`, all tweet content related features to a set named `tweet-cont` and all account related features to `account`. We use `account-lev` as a feature set that only includes the Levenshtein distance between user and screen names to test this feature specifically.

As we want to compare our work to Kudugunta and Ferrara, 2018 we reimplented all their account features mentioned in their paper. We later on refer to this feature group with `k_f_reimpl`.

Our own feature group `all` contains almost all features described above leaving out only four minor features as they don't seem to improve the quality of our classifier: Information about the default profile, location, the content of the ”protected” field and information about user background image.

5 Results and Discussion

We generate feature matrices based on different sets of features as described in section *4.5*. This data is normalized by scaling each feature to the unit interval and then used to train and evaluate different machine learning models.

To evaluate the performance of our machine learning classifiers we separate our dataset into a training and validation set by an 80:20 ratio using (deterministic) random selection provided by the scikit-learn framework (Pedregosa et al., 2011).

We have experimented with classical methods such as Logistic Regression[3], Support Vector Machines[4], Random Forests[5] and Multi-layer Perceptrons[6]. The best results were achieved with *AdaBoost*[7] (Freund and Schapire, 1999). Since the training labels are not fully balanced, we follow Kudugunta and Ferrara, 2018 and resampled the training data using SMOTE-ENN (Lemaître et al., 2017).

By using AdaBoost with SMOTE-ENN we achieve the results displayed in table 1. Figure 1 contains some of the corresponding ROC curves.

The feature set **tweet-behav** contains all features related to the tweeting behavior of an account

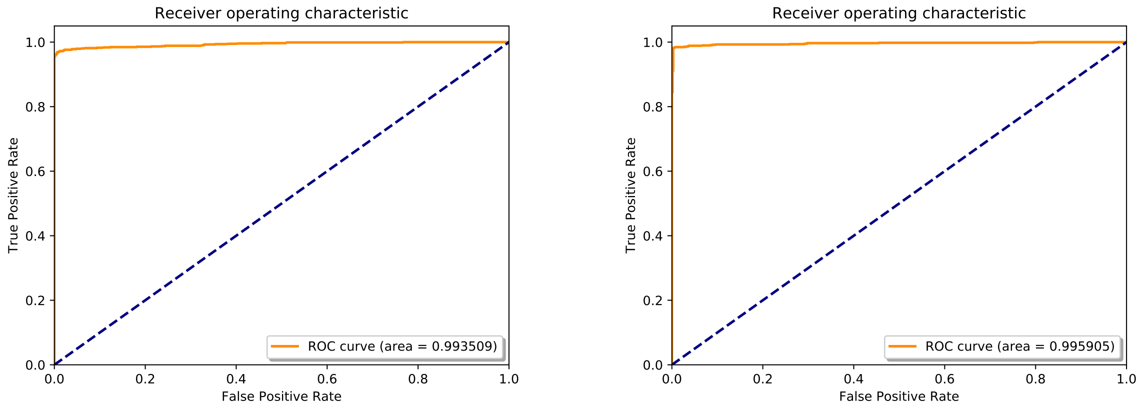
Table 2: The 20 most important features for the system ”all”, sorted by ANOVA F-value.

and **tweet-cont** contains all content features. Our experiments show that neither feature set is able to achieve sufficiently good results, as there is a large number of false positives.

It turned out that using the Levenshtein distance as a feature provides a considerable benefit. It is the most informative feature in the **account** feature set, followed by *geo_enabled*, *statuses_count*, *user_name_length*, *screen_name_length* and features related to account metadata, such as *default_profile*, *favourites_count* and *profile_use_background_image*.

In order to get an idea of how well this feature performs we conducted an experiment using it as the only classifier. We found that by using only this features alone (the **account-lev** feature set) it is possible to achieve an accuracy of 0.8611.

In order to compare our system we reimplemented a classification system as described by Kudugunta and Ferrara, 2018, where AdaBoost with SMOTE-ENN is used to get excellent results. However, although we use the same dataset and the same features, we were not able to achieve the same results. We assume the reason for this is that the exact selection of their training data is unknown to us. For our own analysis we divide the gold standard data using deterministic random selection. Depending on the exact nature of this random selection, it is understandable that each trained system based on this selection will



(a) ROC curve for ”k_f_reimpl”

(b) ROC curve for ”all”

Figure 1: ROC curves

be slightly different and the evaluation results will therefore vary slightly.

With our feature set including features that address the tweet content as well as the the meta data, the unicode groups, the emojis in the content, the user and screen names as well as the the Levenshtein distance between both names we achieved a comparable accuracy of 0.9881 and ROC-AUC value of 0.9959. (For details see table 1.)

6 Further Experiments

In order to estimate the influence of the amount of training data on the quality of such a classifier, we conducted additional experiments and calculated learning curves for several of our systems.

To achieve representative results we use five-fold cross-validation here. Our data set contains the manually tagged data of the 8385 accounts. Therefore 1677 records will be used for validation and 6708 data records remain for training.

Figure 2 displays learning curves for some of our classifiers, all based on AdaBoost. Targeting one of our research questions understanding if smaller amount of training data could be sufficient for building classifiers we extracted upper left areas of some of our learning curves and present them in figure 2. These results indicate that even if data about only a very limited set of Twitter accounts would be available for training bot detection should be possible though - of course - it would not achieve the very best results. As each account in our data set in average provides 607 tweets this seems to be already a sufficient basis to learn from for practical applications.

7 Conclusion

In this paper we addressed the problem of detecting Twitter bots. For easy reuse of our system we extracted various language-agnostic features including account specific features such as comparing screen name and user names as well as behavioural specific features modeling latent temporal aspects of tweeting. We have shown that with AdaBoost and SMOTE-ENN we can achieve a precision of up to 0.9969, an accuracy of 0.9881 and an AUC-ROC value of 0.9959. Additionally we calculated learning curves of several of our approaches in order to understand the impact a smaller amount of data might have on training of classifiers. We concluded that patterns existing in the data emerge quite soon during training. For practical approaches already a set of a view thousand data records will be sufficient for training. Our data set consisted of 8385 manually classified records. This is sufficient data for training classification systems of good quality.

8 Future Work

Naturally bot developers will pick up on results of researchers and improve their implementations of bots in order to perfect their disguise. Classifiers training on existing data might not work as well in future experiments on real data as bots could produce tweet content in such a way that is misleading for existing classifiers. Tweeting behavior could be modeled in such a way that it is less distinguishable from real users. Future research should focus on addressing these aspects closely.

Abstract

In this article, we present a novel multi-domain dataset of Polish text reviews, annotated with sentiment on different levels: sentences and the whole documents. The annotation was made by linguists in a 2+1 scheme (with inter-annotator agreement analysis). We present a preliminary approach to the classification of labelled data using logistic regression, bidirectional long short-term memory recurrent neural networks (BiLSTM) and bidirectional encoder representations from transformers (BERT).

1 Introduction

Linguistic research on sentiment recognition involves two approaches: from the perspective of analysing the occurrence of emotional words and from the perspective of the entire document. The first attempt is usually a consequence of the creation of the sentiment lexicon, e.g. manual annotation of the WordNet (Baccianella et al., 2010). The second results from the analysis of the specific text content in which we see that the sentiment of a word or phrase changes under the influence of the surrounding context (Taboada et al., 2008). This change may vary depending on the domain of the text. As a research material for our research we have chosen online customer reviews from four domains:

- *S – School* – students' reviews on the lecturers[1],
- *M – Medicine* – patients' opinions on doctors[2],
- *H – Hotels* – customer reviews of hotels[3],
- *P – Products* – buyers' opinions on products[4].

In the introduction we focus mainly on the influence of discourse on the classification of the document sentiment. We only briefly present an approach based on the analysis of emotional words. The rest of the article concerns the description of the corpus used in our analysis, guidelines for the description of the text with sentiment for annotators, the results of the pilot stage of annotation, the proper annotation and experiments with automatic recognition of the text polarity.

2 Related work

One approach for recognising polarity of text is to use a dictionary of emotional words – sentiment lexicons, e.g. WordNet annotated with polarity (Kamps et al., 2004; Takamura et al., 2005) and emotions (Janz et al., 2017). Usually the task is to determine the number of occurrence of such words with a specific polarity in the text or use a simple bag of words method (Wang and Manning, 2012). Such a solution has a number of limitations: simple methods cannot cope with irony, sarcasm, negation and more complex text structures that modify the sound of the words that make them up (Wallace et al., 2015).

The second method of analysing text polarity is examination of the sentence level with evaluating each sentence in isolation. This procedure can be supported by the external corpus of labelled sentences (Pang and Lee, 2004; Wilson et al., 2005). Nevertheless, even within one sentence we can sometimes observe several features of the analysed entity and each of them can be assessed dif-

[1] https://polwro.pl/
[2] https://www.znanylekarz.pl/
[3] https://pl.tripadvisor.com/
[4] https://www.ceneo.pl/

ferently. It is advantageous in opinion mining to achieve both an overall opinion and specific information on the reviewed entity and its aspects. It gives us not only a general opinion on the product but allows us to notice a detailed view on the quality of the product.

This year, the first results of the Sentimenti[5] project were published, which aimed to create methods of analysing the content written on the Internet in terms of emotions expressed by the authors of the texts and the emotional impact of the readers. Within the project, a large database has been created, in which 30,000 lexical units from plWordNet database and 7,000 texts were evaluated, most of which are consumer reviews from the domain of hotels and medicine. The elements were evaluated by 20,000 unique Polish respondents in the Computer Assisted Personal Interview survey and more than 50 marks were obtained for each element, which gives more than 1.8 million annotations. Within each mark, polarisation of the element, stimulation and basic emotions aroused by the recipients are determined. The first results concerning the automatic recognition of sound and emotions for this set are presented in (Kocoń et al., 2019). Our article is based on this work in the development of experiments and we are researching texts from similar domains, but using more complex classification methods as described in Section 4. The annotation guidelines for linguists in the task of sentiment analysis on two levels were also developed: text level and sentence level (presented in Section 3).

2.1 From word level to discourse in text polarity analysis

A discourse perspective in sentiment analysis is an attempt to address limitations of previous methods (e.g. problems with negation, focusing on adjectives). It used findings of Rhetorical Structure Theory (Mann and Thompson, 1988). The attempt bears in mind local and global orientation in the text, discourse structure or topicality (Taboada et al., 2008). It allows the researcher to extract the most important sentences from the text in the perspective of the entire discourse context: nucleus satellite method (Wang et al., 2012). The relevance of the sentences is evaluated in relation to the main topic and the analysis omits some less important parts of the text. In Section 3 we present how the genre structure of a customer review affects the text sentiment polarity. It is an enhancement of the discourse perspective in sentiment analysis.

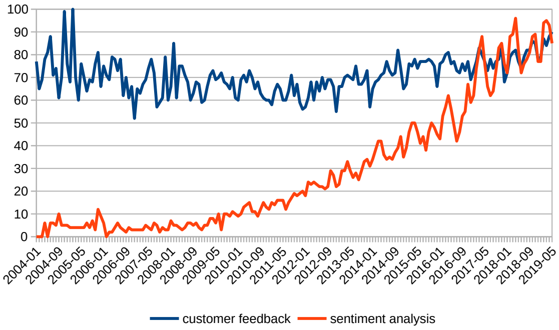

Figure 1: Google Trends (trends.google.com) data showing interest in time for search terms "customer feedback" and "sentiment analysis". On the vertical axis 100 means biggest search term popularity.

2.2 Recognition of sentiment

Sentiment analysis and opinion mining has become an interesting topic for many researches and private companies with constant growth of interest in recent years (see Figure 1), that coincides with the *big data revolution* (Kitchin, 2014). Properly evaluated data can be widely used in fields such as market analysis, public relations and product or customer feedback. Main difficulty in retrieval of those information is non-organised data, unstructured in pre-defined manner. Recently deep neural networks show relatively good performance among all available methods of processing such information (Glorot et al., 2011). Possibility of retrieving data from different sources like social networks (Pak and Paroubek, 2010), publicly available discussion boards or various marketing platforms connected with proper annotations on training data set can provide not only simple positive, negative or neutral classification but lead to accurate fine-grained sentiment prediction (Guzman and Maalej, 2014). In Section 4 we present our approach to solve this task using models based on fastText (Joulin et al., 2017), BiLSTM (Zhou et al., 2016) and BERT (Devlin et al., 2018).

3 Annotation model

Our research on sentiment analysis of customer reviews was conducted in 2018 within CLARIN-PL and it consisted of the pilot stage and the main stage. The preliminary part of analysis involved 3,000 students' opinions about lectures. It is an

[5] https://sentimenti.com/

authentic material provided online by students as a final assessment of the course in each subject. Each text was manually annotated by two annotators: a psychologist and a linguist, who worked accordingly to the general guidelines. In the pilot project we decided to deal with sentiment annotation of the whole text. In the sentiment annotation we used the same set of tags which is applied in *plWordNet 3.0 emo* (Zaśko-Zielińska et al., 2015; Janz et al., 2017) to lexical units: [+m] – strong positive, [+s] – weak positive, [-m] – strong negative, [-s] – weak negative, [amb] – ambiguous, [0] – neutral.

We used *amb* tag but we understood it differently. In annotation of lexical units in WordNet with sentiment *amb* indicated the possibility that units can be positive or negative in various contexts. Hence, in text sentiment analysis we assumed that *amb* denotes *ambiguous* polarity, thus the entire text cannot be clearly described by using neither positive nor negative annotation.

In the annotation we focused primarily on the strategic places in the text. In a customer review these places are the opening and closing sentences, namely the text frame. The beginning consists of the general opinion of the author on the subject of the evaluation and the end includes the author's recommendation to the recipients. The annotators created their first general evaluation based on these two segments. In the body of the review, the authors have only subtly changed these opinions. Regardless of the modification of the main opinion in the text, we did not use the *amb* tag when the text frame was unambiguously positive. The text frame polarity was influenced not only by lexical content but also nonverbal elements, e.g. emoticons or multiplication of punctuation marks.

3.1 An attempt to annotate aspects

The analysis of the content of customer reviews in our pilot project consisted of two stages: the selection of text blocks describing separate aspects and their annotation. Some parts of the text were not of an argumentative nature that could justify the author's decision to polarise the text. They included: advice (e.g. how to sign up for lectures) or general information on lectures, duration of classes, etc.

The main stage of our project was conducted based on text corpus consisting of consumer reviews (80% of texts) and texts from the corresponding domain with high probability of neutral polarity (20% of texts). We observed that the value of inter-annotator agreement in aspect annotation task was very low, below 15% of Positive Specific Agreement, PSA (Hripcsak and Rothschild, 2005).

3.2 New annotation guidelines

In the main stage of the project we decided to annotate the sentiment for the whole text (a *meta* level) and the *sentence* level. We assumed that this strategy allows to establish the acceptable value of PSA. We followed the rule that the *meta* annotation results partially from sentence annotations, however the frame polarity is the main factor for the final meta annotation. We have prepared the following rules of annotation, regardless of whether the entire text or sentence is annotated:

- SP – strong positive – entirely positive;
- WP – weak positive – generally positive, but there are some negative aspects;
- 0 – neutral;
- WN – weak negative – generally negative, but there are some positive aspects;
- SN – strong negative – entirely negative;
- AMB – ambiguous – there are both positive and negative aspects in the text that are balanced in terms of relevance.

Table 1 shows the value of Positive Specific Agreement (Hripcsak and Rothschild, 2005) obtained for a random sample of 111 documents from *Medicine* category.

4 Multi-level sentiment recognition

We selected three different classifiers for the recognition tasks:

- logistic regression (fastText) providing a baseline for text classification (Joulin et al., 2017)
- bidirectional long short-term memory recurrent network in two variants:
  - using word vector representations only
  - using the same vectors extended with general polarity information from sentiment dictionary described in Section 4.1

L	Type	Only A	A & B	Only B	PSA
M	SN	1	33	4	93%
	WN	2	2	2	50%
	0	0	24	0	100%
	AMB	1	2	3	50%
	WP	4	0	0	0%
	SP	0	31	2	97%
	sum	8	92	11	91%
S	SN	10	217	36	90%
	WN	11	1	0	15%
	0	36	273	17	91%
	AMB	2	7	14	47%
	WP	12	0	1	0%
	SP	6	194	8	97%
	sum	77	692	76	90%

Table 1: Annotation agreement between two experts (A and B) at the level (L) of text (meta – M) and sentence (S) for a sample of 111 documents using Positive Specific Agreement metric, PSA (Hripcsak and Rothschild, 2005).

- bidirectional encoder representations from transformers (BERT) with addition of sequence classification layer

We trained logistic regression model using pre-trained vectors for Polish language (Kocoń and Gawor, 2018). This approach is much faster in both training and testing than deep learning classifiers (Joulin et al., 2017), however, it has disadvantage which comes from not sharing parameters by features and classes, therefore overall result can be highly influenced by keywords with bigger class relativity.

BiLSTM on the other side takes into consideration not just words but full text fragment and basing on learnt patterns predicts potential outcome. Texts are divided into tokens and converted to corresponding word embedding vectors generated by fastText (Bojanowski et al., 2017), in this form it is possible to use it as input for neural network. Dimension of used vectors is equal to 300, therefore it must be reflected in the input shape. As a loss function for training a categorical crossentropy was chosen. Model prepared for the task consists of the following layers:

- Gaussian noise layer with standard deviation of 0.01 accepting as input shape up to 128 words with vector matrix for each word of size 300, therefore overall input shape is (128, 300)
- Bidirectional layer with LSTM instances (consisting of 1,024 hidden units using hyperbolic tangent activation method) merged with concatenation
- Dropout layer with dropout ratio equal to 0.2
- Dense layer with number of outputs representing number of all possible labels (6 in our task) using normalised exponential function (softmax) activation

BERT was designed to provide pre-trained deep bidirectional representations conditioning left and right context (Devlin et al., 2018), therefore it achieves best performance on text fragments instead of single sentences. It's architecture allows to fine-tune these representations by adding one additional output layer which suits needs of specified task. For our task as a pre-trained model `BERT-Base, Multilingual Cased`[6] was selected, which consists of 104 languages and 110M parameters, and `BertForSequenceClassification`[7] as a BERT classifier extended for multi-class classification.

4.1 Embedding vector extension

Basing on the data accommodated in plWordNet emo (Zaśko-Zielińska et al., 2015) we prepared the dictionary for all annotated lexical units and all possible levels of sentiment. Due to the lack of word sense disambiguation method, we grouped the sentiment annotations by lemmas. The final dictionary consists of a set of lemmas with assigned numbers representing the proportions of individual sentiment annotations, summing up to 1, e.g. for a lemma *akademicki* (Eng. *academic*) there were 11 annotations: 3 neutral, 4 generally negative, 3 generally positive and 1 entirely positive. Therefore arbitrary values for word "akademicki" are:

- entirely positive = 0.0909
- generally positive = 0.2727
- neutral = 0.2727
- generally negative = 0.3636
- entirely negative = 0.0000

[6] https://github.com/google-research/bert

[7] https://github.com/huggingface/pytorch-pretrained-BERT

- ambivalent = 0.0000

Using the described dictionary we have proposed additional variant of BiLSTM classifier with a word embedding vector extended with the values of sentiment for the lemma of the word from a prepared sentiment dictionary. Lemmas were retrieved during a preparation of the input data using WCRFT part-of-speech tagger (Radziszewski, 2013). Therefore, in this approach the input word vector dimension was extended with 6 values representing sentiment of the word. The final dimension of the word embedding increased from 300 to 306.

5 Evaluation

As in article (Kocoń et al., 2019), three variants of evaluation of the sentiment classification methods were prepared. The basic variant is a single domain in which the classifier is trained, tuned and tested on a set of texts from one domain. The next variant includes an analysis of the ability of the classifier to model the sentiment of the text on a level independent of the domain of the text. For this purpose, we take all available texts except the texts from the selected domain. Then the texts are divided into a training and a validation set. Testing of the model takes place on a test set from a selected domain, not taken into account at the stage of preparing the training and validation set. The third test variant allows to examine the classifiers in order to generalise the task of sentiment analysis in all available domains. For this purpose, texts from all domains are treated as one set, which is randomly divided into train, validation and test sets. Summary of the different types of evaluation:

- *SD – Single Domain* – evaluation sets created using elements from the same domain,

- *DO – Domain Out* – train/dev sets created using elements from 3 domains, test set from the remaining domain,

- *MD – Mixed Domains* – evaluation sets randomly selected from elements belonging to all domains.

Due to the fact that the data are annotated both at the level of the whole text and at the level of each sentence, a *sentence* or *text* may be an *element* in the above list. We use *SDT*, *DOT*, and *MDT* for *text* evaluation types and *SDS*, *DOS*, and *MDS* for *sentence* evaluation types. We use also prefixes of domains (*Hotels, Medicine, School, Products*) as suffixes for *SD** and *DO** variants, e.g. SDS-H is a single domain evaluation type performed on sentences within *hotels* domain, whereas DOT-M is a domain-out evaluation type performed on texts trained on texts outside *medicine* domain and tested on texts from that domain.

Table 2 shows the number of texts and sentences annotated by linguists for all evaluation types, with division into the number of elements within training, validation and test sets. Linguists annotated a total of 8,450 texts from four domains (hotels, medicine, products, school) and 35,789 sentences from two domains (hotels, medicine). The distribution of labels within each domain for texts and sentences is presented in Table 3. Average annotated text length in each domain are as follows: 788 characters in hotels, 802 in medicine, 781 in products and 442 in school.

Type	Domain	Train	Dev	Test	SUM
SDT	Hotels	2534	316	316	3166
	Medicine	2650	330	330	3310
	Products	790	98	98	986
	School	792	98	98	988

Table 3: The percentage of annotated elements in a given domain (SDT – single domain texts, SDS – single domain sentences).

6 Results

Table 4 presents the values of F1-score for each label (columns 3-8), global F1-score (column 9), micro-AUC and macro-AUC (columns 10-11) for all evaluation types related to the texts. In case of evaluation for a single domain for each label, fastText (using Logistic Regression) outperformed other classifiers in 13 out of 21 distinguishable cases. There are 12 cases for which the best score is not higher than F1=0.4. These are highly underrepresented labels, for which the part of the total annotations within the domain is less than 10% (see Table 3). The best results are obtained for *strong positive* and *strong negative* cases. Intermediate labels (*weak* and *ambiguous* variants) are much more difficult to be recognised correctly. In these cases deep neural networks outperform logisitic regression in 6 out of 11 cases. BERT classifier performs much better (13 out of 23 cases) in cross-domain knowledge transfer (DOT and MDT). For these evaluation types only 6 times fastText was better. These observations are consistent with the results of article (Kocoń et al., 2019) for *valence* dimensions.

Table 5 presents results corresponding to those presented in Table 4, but this time for sentence-level annotations. Looking at Table 3, the number of sentences marked as *weakly positive* or *weakly negative* is close to zero. These labels are not being recognised by any classifier. For other labels, regardless of the type of evaluation, the best results are mainly obtained using deep learning methods (label-specific F1-score: all 20 cases; general metrics: 12 out of 15 cases).

7 Conclusions and further steps

The automatic annotation of emotions has both a scientific and an applied value. Modern business is interested in the opinions, emotions and values associated with brands and products. Retailers and merchants collect huge amounts of customer feedback from the store and online. Moreover, the relationship departments monitor the impact of their campaigns and need to know if it was positive and affecting customers. In this context, the results of monitoring feedback, reactions and emotions are of great value as they fuel decisions and behaviors (Tversky and Kahneman, 1989). However, most of the existing solutions are still limited to manual annotations and simplified analysis methods.

Type	Classifier	SP	WP	0	WN	SN	AMB	F1	micro	macro
SDT-H	C1	**80.00**	**30.51**	93.98	00.00	**83.33**	**36.84**	**73.50**	90.87	70.20
	C2	71.11	25.00	00.00	04.76	72.44	00.00	53.00	77.14	66.13

Table 5: F1-scores for sentence-oriented evaluation. Training sets for evaluation types are the same as in Table 2 rows 10-14. Classifiers: C1 - fastText, C2 - BiLSTM, C3 - BiLSTM with word embeddings extended using polarity dictionary, C4 - BERT. Evaluation types are explained in Section 5.

BERT's performance is below the expectations of this advanced method. Looking at both tables (4 and 5), BERT's results are the best in 19 out of 69 label-specific cases, which is exactly as many as fastText was. BiLSTM outperformed other methods in 31 cases. Adding an external sentiment dictionary helped only in 14 label-specific cases. BERT dominance is observed in DOT and MDT cases, especially when analysing general metric values, where the predominance of the method is visible in 11 out of 15 cases. The advantage is repeated for MDS but not for DOS. MDT case is the most promising in terms of the further use of the recognition method in applications such as brand monitoring or early crisis detection. Figure 2 shows the ROC curves (Meistrell, 1990) for this case. The values of the general F1, micro AUC and macro AUC are the highest for the BERT method (see Table 2).

We plan to publish the data created as part of the presented works on an open license soon. We also intend to test the contextualized embedding that we are currently building using the ELMo deep word representations method (Peters et al., 2018), with the use of the large KGR10 corpus presented in work (Kocoń et al., 2019). We also want to train the basic BERT model with the use of KGR10 to investigate whether it will improve the quality of sentiment recognition. It is also very interesting to use the propagation of sentiment annotation in WordNet (Kocoń et al., 2018a,b), to increase the coverage of the sentiment dictionary and to potentially improve the recognition quality as well. This objective can be achieved by other complex methods such as OpenAI GPT-2 (Radford et al., 2019) and domain dictionaries construction methods utilising WordNet (Kocoń and Marcińczuk, 2016).

Abstract

In this paper, we present a new approach for the evaluation, error analysis, and interpretation of supervised and unsupervised Paraphrase Identification (PI) systems. Our evaluation framework makes use of a PI corpus annotated with linguistic phenomena to provide a better understanding and interpretation of the performance of various PI systems. Our approach allows for a qualitative evaluation and comparison of the PI models using human interpretable categories. It does not require modification of the training objective of the systems and does not place additional burden on the developers. We replicate several popular supervised and unsupervised PI systems. Using our evaluation framework we show that: 1) Each system performs differently with respect to a set of linguistic phenomena and makes qualitatively different kinds of errors; 2) Some linguistic phenomena are more challenging than others across all systems.

1 Introduction

In this paper we propose a new approach to evaluation, error analysis and interpretation in the task of Paraphrase Identification (PI). Typically, PI is defined as comparing two texts of arbitrary size in order to determine whether they have approximately the same meaning (Dolan et al., 2004). The two texts in 1a and 1b are considered paraphrases, while the two texts at 2a and 2b are non-paraphrases.[1] In 1a and 1b there is a change in the wording (*"magistrate"* - *"judge"*) and the syntactic structure (*"was ordered"* - *"ordered"*) but the meaning of the sentences is unchanged. In 2a and 2b there are significant differences in the quantities (*"5%"* - *"4.7%"* and *"$27.45"* - *"$27.54"*).

1a A federal magistrate in Fort Lauderdale ordered him held without bail.

1b He was ordered held without bail Wednesday by a federal judge in Fort Lauderdale, Fla.

2a Microsoft fell **5 percent** before the open to **$27.45** from Thursday's close of $28.91.

2b Shares in Microsoft slipped **4.7 percent** in after-hours trade to **$27.54** from a Nasdaq close of $28.91.

The task of PI can be framed as a binary classification problem. The performance of the different PI systems is reported using the Accuracy and F1 score measures. However this form of evaluation does not facilitate the interpretation and error analysis of the participating systems. Given the Deep Learning nature of most of the state-of-the-art systems and the complexity of the PI task, we argue that better means for evaluation, interpretation, and error analysis are needed. We propose a new evaluation methodology to address this gap in the field. We demonstrate our methodology on the ETPC corpus (Kovatchev et al., 2018a) - a recently published corpus, annotated with detailed linguistic phenomena involved in paraphrasing.

We replicate several popular state-of-the-art Supervised and Unsupervised PI Systems and demonstrate the advantages of our evaluation methodology by analyzing and comparing their performance. We show that while the systems obtain similar quantitative results (Accuracy and F1), they perform differently with respect to a set of human interpretable linguistic categories and make qualitatively different kinds of errors. We also show that some of the categories are more challenging than others across all evaluated systems.

2 Related Work

The systems that compete on PI range from using hand-crafted features and Machine Learning algorithms (Fernando and Stevenson, 2008; Madnani

[1] Examples are from the MRPC corpus (Dolan et al., 2004)

et al., 2012; Ji and Eisenstein, 2013) to end-to-end Deep Learning models (He et al., 2015; He and Lin, 2016; Wang et al., 2016; Lan and Xu, 2018a; Kiros et al., 2015; Conneau et al., 2017). The PI systems are typically divided in two groups: Supervised PI systems and Unsupervised PI systems.

"Supervised PI systems" (He et al., 2015; He and Lin, 2016; Wang et al., 2016; Lan and Xu, 2018a) are explicitly trained for the PI task on a PI corpora. "Unsupervised PI systems" in the PI field is a term used for systems that use a general purpose sentence representations such as Mikolov et al. (2013); Pennington et al. (2014); Kiros et al. (2015); Conneau et al. (2017). To predict the paraphrasing relation, they can compare the sentence representations of the candidate paraphrases directly (ex.: cosine of the angle), and use a PI corpus to learn a threshold. Alternatively they can use the representations as features in a classifier.

The complexity of paraphrasing has been emphasized by many researchers (Bhagat and Hovy, 2013; Vila et al., 2014; Benikova and Zesch, 2017). Similar observations have been made for Textual Entailment (Sammons et al., 2010; Cabrio and Magnini, 2014). Gold et al. (2019) study the interactions between paraphrasing and entailment.

Despite the complexity of the phenomena, the popular PI corpora (Dolan et al., 2004; Ganitkevitch et al., 2013; Iyer et al., 2017; Lan et al., 2017) are annotated in a binary manner. In part it is due to lack of annotation tools capable of fine-grained annotation of relations. WARP-Text (Kovatchev et al., 2018b) fills this gap in the NLP toolbox.

The simplified corpus format poses a problem with respect to the quality of the PI task and the ways it can be evaluated. The vast majority of the state-of-the-art systems in PI provide no or very little error analysis. This makes it difficult to interpret the actual capabilities of a system and its applicability to other corpora and tasks.

Some researchers have approached the problem of non-interpretability by evaluating the same architecture on multiple datasets and multiple tasks. Lan and Xu (2018b) apply this approach to Supervised PI systems, while Aldarmaki and Diab (2018) use it for evaluating Unsupervised PI systems and general sentence representation models.

Linzen et al. (2016) demonstrate how by modifying the task definition and the evaluation the capabilities of a Deep Learning system can be determined implicitly. The main advantage of such an approach is that it only requires modification and additional annotation of the corpus. It does not place any additional burden on the developers of the systems and can be applied to multiple systems without additional cost.

We follow a similar line of research and propose a new evaluation that uses ETPC (Kovatchev et al., 2018a): a PI corpus with a multi-layer annotation of various linguistic phenomena. Our methodology uses the corpus annotation to provide much more feedback to the competing systems and to evaluate and compare them qualitatively.

3 Qualitative Evaluation Framework

3.1 The ETPC Corpus

ETPC (Kovatchev et al., 2018a) is a re-annotated version of the MRPC corpus. It contains 5,801 text pairs. Each text pair in ETPC has two separate layers of annotation. The first layer contains the traditional binary label (paraphrase or non-paraphrase) of every text pair. The second layer contains the annotation of 27 *"atomic"* linguistic phenomena involved in paraphrasing, according to the authors of the corpus. All phenomena are linguistically motivated and humanly interpretable.

3a A federal **magistrate** in Fort Lauderdale ordered him held without bail.

3b He was ordered held without bail Wednesday by a federal **judge** in Fort Lauderdale, Fla.

We illustrate the annotation with examples 3a and 3b. At the binary level, this pair is annotated as "paraphrases". At the "atomic" level, ETPC contains the annotation of multiple phenomena, such as the *"same polarity substitution (habitual)"* of "magistrate" and "judge" (marked **bold**) or the *"diathesis alternation"* of *"...ordered him held"* and *"he was ordered by..."* (marked underline).

For the full set of phenomena, the linguistic reasoning behind them, their frequency in the corpus, real examples from the pairs, and the annotation guidelines, please refer to Kovatchev et al. (2018a).

3.2 Evaluation Methodology

We use the corpus to evaluate the capabilities of the different PI systems implicitly. That means, the training objective of the systems remains unchanged: they are required to correctly predict the value of the binary label at the first annotation layer. However, when we analyze and evaluate the performance of the systems, we make use of both the binary and the atomic annotation layers. Our evaluation framework is created to address our main research question (RQ 1):

RQ 1 Does the performance of a PI system on each candidate-paraphrase pair depend on the different phenomena involved in that pair?

We evaluate the performance of the systems in terms of their *"overall performance"* (Accuracy and F1) and *"phenomena performance"*.

"Phenomena performance" is a novelty of our approach and allows for qualitative analysis and comparison. To calculate *"phenomena performance"*, we create 27 subsets of the test set, one for each linguistic phenomenon. Each of the subsets consists of all text pairs that contain the corresponding phenomenon[2]. Then, we use each of the 27 subsets as a test set and we calculate the binary classification Accuracy (paraphrase or non-paraphrase) for each subset. This score indicates how well the system performs in cases that include one specific phenomenon. We compare the performance of the different phenomena and also compare them with the *"overall performance"*.

Prior to running the experiments we verified that: 1) the relative distribution of the phenomena in paraphrases and in non-paraphrases is very similar; and 2) there is no significant correlation (Pearson r <0.1) between the distributions of the individual phenomena. These findings show that the sub-tasks are non-trivial: 1) the binary labels of the pairs cannot be directly inferred by the presence or absence of phenomena; and 2) the different subsets of the test set are relatively independent and the performance on them cannot be trivially reduced to overlap and phenomena co-occurrence.

The *"overall performance"* and *"phenomena performance"* of a system compose its *"performance profile"*. With it we aim to address the rest of our research questions (RQs):

RQ 2 Which are the strong and weak sides of each individual system?

RQ 3 Are there any significant differences between the *"performance profiles"* of the systems?

RQ 4 Are there phenomena on which all systems perform well (or poorly)?

4 PI Systems

To demonstrate the advantages of our evaluation framework, we have replicated several popular Supervised and Unsupervised PI systems. We have selected the systems based on three criteria: popularity, architecture, and performance. The systems that we chose are popular and widely used not only in PI, but also in other tasks. The systems use a wide variety of different ML architectures and/or different features. Finally, the systems obtain comparable quantitative results on the PI task. They have also been reported to obtain good results on the MRPC corpus which is the same size as ETPC. The choice of system allows us to best demonstrate the limitations of the classical quantitative evaluation and the advantages of the proposed qualitative evaluation.

To ensure comparability, all systems have been trained and evaluated on the same computer and the same corpus. We have used the configurations recommended in the original papers where available. During the replication we did not do a full grid-search as we want to replicate and thereby contribute to generalizable research and systems. As such, the quantitative results that we obtain may differ from the performance reported in the original papers, especially for the Supervised systems. However, the results are sufficient for the objective of this paper: to demonstrate the advantages of the proposed evaluation framework.

We compare the performance of five Supervised and five Unsupervised systems on the PI task, including one Supervised and one Unsupervised baseline systems. We also include Google BERT (Devlin et al., 2018) for reference.

The **Supervised PI systems** include:

[S1] Machine translation evaluation metrics as hand-crafted features in a Random Forest classifier. Similar to Madnani et al. (2012) *(baseline)*

[S2] A replication of the convolutional network similarity model of He et al. (2015)

[S3] A replication of the lexical composition and decomposition system of Wang et al. (2016)

[2] i.e. The "diathesis alternation" subset contains all pairs that contain the "diathesis alternation" phenomenon (such as the example pair 3a–3b). Some of the pairs can also contain multiple phenomena: the example pair 3a–3b contains both *"same polarity substitution (habitual)"* and *"diathesis alternation"*. Therefore pair 3a–3b will be added both to the *"same polarity substitution (habitual)"* and to the *"diathesis alternation"* phenomena subsets. Consequentially, the sum of all subsets exceeds the size of the test set.

[S4] A replication of the pairwise word interaction modeling with deep neural network system by He and Lin (2016)

[S5] A character level neural network model by Lan and Xu (2018a)

The **Unsupervised PI systems** include:

[S6] A binary Bag-of-Word sentence representation (baseline)

[S7] Average over sentence of pre-trained Word2Vec word embeddings (Mikolov et al., 2013)

[S8] Average over sentence of pre-trained Glove word embeddings (Pennington et al., 2014)

[S9] InferSent sentence embeddings (Conneau et al., 2017)

[S10] Skip-Thought sentence embeddings (Kiros et al., 2015)

In the unsupervised setup we first represent each of the two sentences under the corresponding model. Then we obtain a feature vector by concatenating the absolute distance and the element-wise multiplication of the two representations. The feature vector is then fed into a logistic regression classifier to predict the textual relation. This setup has been used in multiple PI papers, more recently by Aldarmaki and Diab (2018). While the vector representations of BERT are unsupervised, they are fine-tuned on the dataset. Therefore we put them in a separate category (System #11).

ID	System Description	Acc	F1
	SUPERVISED SYSTEMS		
1	MTE features (baseline)	.74	.819
2	He et al. (2015)	.75	.826
3	Wang et al. (2016)	**.76**	**.833**
4	He and Lin (2016)	.76	.827
5	Lan and Xu (2018a)	.70	.800
	UNSUPERVISED SYSTEMS		
6	Bag-of-Words (baseline)	.68	.790
7	Word2Vec (average)	.70	.805
8	GLOVE (average)	.72	.808
9	InferSent	**.75**	**.826**
10	Skip-Thought	.73	.816
11	Google BERT	.84	.889

Table 1: Overall Performance of the Evaluated Systems

5 Results

5.1 Overall Performance

Table 1 shows the *"overall performance"* of the systems on the 1725 text pairs in the test set. Looking at the table, we can observe several regularities. First, the deep systems outperform the baselines. Second, the baselines that we choose are competitive and obtain high results. Since both baselines make their predictions based on lexical similarity and overlap, we can conclude that the dataset is biased towards those phenomena. Third, the supervised systems generally outperform the unsupervised ones, but without running a full grid-search the difference is relatively small. And finally, we can identify the best performing systems: **S3** (Wang et al., 2016) for the supervised and **S9** (Conneau et al., 2017) for the unsupervised. BERT largely outperforms all other systems.

The *"overall performance"* provides a good overview of the task and allows for a quantitative comparison of the different systems. However, it also has several limitations.

It does not provide much insight into the workings of the systems and does not facilitate error analysis. In order to study and improve the performance of a system, a developer has to look at every correct and incorrect predictions and search for custom defined patterns. The *"overall performance"* is also not very informative for a comparison between the systems. For example **S3** (Wang et al., 2016) and **S4** (He and Lin, 2016) obtain the same Accuracy score and only differ by 0.06 F1 score. With only looking at the quantitative evaluation it is unclear which of these systems would generalize better on a new dataset.

5.2 Full Performance Profile

Table 2 shows the full *"performance profile"* of **S3** (Wang et al., 2016), the supervised system that performed best in terms of *"overall performance"*. Table 2 shows a large variation of the performance of **S3** on the different phenomena. The accuracy ranges from .33 to 1.0. We also report the statistical significance of the difference between the correct and incorrect predictions for each phenomena and the correct and incorrect predictions for the full test set, using the Mann–Whitney U-test[3] (Mann and Whitney, 1947).

Ten of the phenomena show significant difference from the overall performance at p <0.1. Note

[3] The Mann–Whitney U-test is a non-parametric equivalence of T-test. The U-Test does not assume normal distribution of the data and is better suited for small samples.

Table 2: Performance profile of Wang et al. (2016)

that eight of them are also significant at p <0.05. The statistical significance of *"Opposite polarity substitution (habitual)"*, and *"Negation Switching"* cannot be verified due to the relatively low frequency of the phenomena in the test set.

The demonstrated variance in phenomena performance and its statistical significance address **RQ 1**: we show that the performance of a PI system on each candidate-paraphrase pair depends on the different phenomena involved in that pair or at least there is a strong observable relation between the performance and the phenomena.

The individual *"performance profile"* also addresses **RQ 2**. The profile is humanly interpretable, and we can clearly see how the system performs on various sub-tasks at different linguistic levels. The qualitative evaluation shows that **S3** performs better when it has to deal with: 1) surface phenomena such as *"spelling changes"*, *"punctuation changes"*, and *"change of order"*; 2) dictionary related phenomena such as *"opposite polarity substitution (habitual)"*, *"converse substitution"*, and *"modal verb changes"*. **S3** performs worse when facing phenomena such as *"negation switching"*, *"ellipsis"*, *"opposite polarity substitution (contextual)"*, and *"addition/deletion"*.

5.3 Comparing Performance Profiles

Table 3 shows the full performance profiles of all systems. The systems are identified by their IDs, as shown in Table 1. In addition to providing a better error analysis for every individual system, the *"performance profiles"* of the different systems can be used to compare them qualitatively. This comparison is much more informative than the *"overall performance"* comparison shown in Table 1. Using the *"performance profile"*, we can quickly compare the strong and weak sides of the different systems.

When looking at the *"overall performance"*, we already pointed out that **S3** (Wang et al., 2016) and **S4** (He and Lin, 2016) have almost identical quantitative results: 0.76 accuracy, 0.833 F1 for **S3** against 0.76 accuracy, 0.827 F1 for **S4**. However, when we compare their *"phenomena performance"* it is evident that, while these systems make approximately the same number of correct and incorrect predictions, the actual predictions and errors can vary.

Looking at the accuracy, we can see that **S3** performs better on phenomena such as *"Converse substitution"*, *"Diathesis alternation"*, and *"Non-Paraphrase"*, while **S4** performs better on *"Change of format"*, *"Opposite polarity substitution (contextual)"*, and *"Ellipsis"*.

We performed McNemar paired test comparing

Table 5: Difference in phenomena performance: S3 (Wang et al., 2016) and S5 (Lan and Xu, 2018a)

We performed the same test on systems with

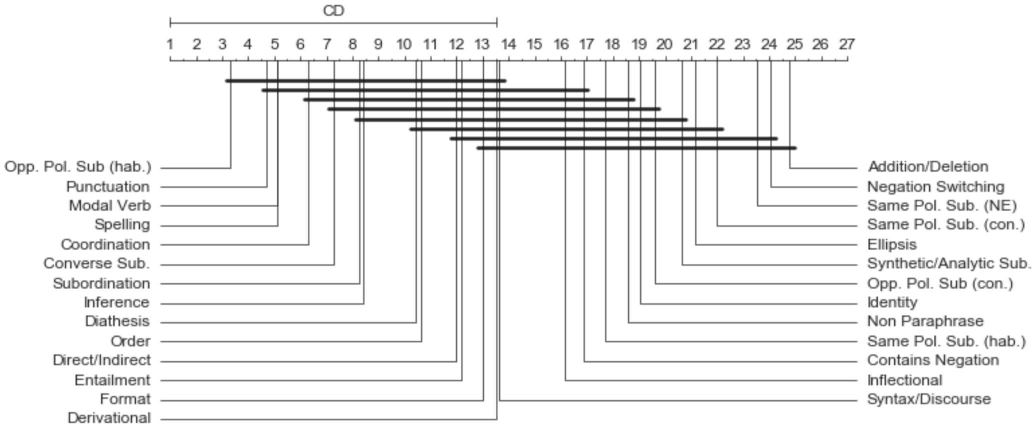

Figure 1: Critical Difference diagram of the average ranks by phenomena

a larger quantitative difference. Table 5 shows the comparison between **S3** and **S5** (Lan and Xu, 2018a). Ten of the phenomena show significant difference with p <0.1 and seven with p <0.05. These results answer our **RQ 3**: we show that there are significant differences between the *"performance profiles"* of the different systems.

5.4 Comparing Performance by Phenomena

The *"phenomena performance"* of the individual systems clearly differ among them, but they also show noticeable tendencies. Looking at the performance by phenomena, it is evident that certain phenomena consistently obtain lower than average accuracy across multiple systems while other phenomena consistently obtain higher than average accuracy.

In order to quantify these observations and to confirm that there is a statistical significance we performed Friedman-Nemenyi test (Demšar, 2006). For each system, we ranked the performance by phenomena from 1 to 27, accounting for ties. We calculated the significance of the difference in ranking between the phenomena using the Friedman test (Friedman, 1940) and obtained a Chi-Square value of 198, which rejects the null hypothesis with p <0.01. Once we had checked for the non-randomness of our results, we computed the Nemenyi test (Nemenyi, 1963) to find out which phenomena were significantly different. In our case, we compute the two-tailed Nemenyi test for k = 27 phenomena and N = 11 systems. The Critical Difference (CD) for these values is 12.5 at p <0.05.

Figure 1 shows the Nemenyi test with the CD value. Each phenomenon is plotted with its average rank across the 11 evaluated systems. The horizontal lines connect phenomena which rank is within CD of each other. Phenomena which are not connected by a horizontal line have significantly different ranking. We can observe that each phenomenon is significantly different from at least half of the other phenomena.

We can observe that some phenomena, such as *"opposite polarity substitution (habitual)"*, *"punctuation changes"*, *"spelling"*, *"modal verb changes"*, and *"coordination changes"* are statistically much easier according to our evaluation, as they are consistently among the best performing phenomena across all systems. Other phenomena, such as *"negation switching"*, *"addition/deletion"*, *"same polarity substitution (named entity)"*, *"opposite polarity substitution (contextual)"*, and *"ellipsis"* are statistically much harder, as they are consistently among the worst performing phenomena across all systems. With the exception of *"negation switching"* and *"opposite polarity substitution (habitual)"*, these phenomena occur in the corpus with sufficient frequency. These results answer our **RQ 4**: we show that there are phenomena which are easier or harder for the majority of the evaluated systems.

6 Discussion

In Section 3.2 we described our evaluation methodology and posed four research questions. The experiments that we performed and the analysis of the results answered all four of them. We briefly discuss the implications of the findings.

By addressing **RQ 1**, we showed that the performance of a system can differ significantly based on the phenomena involved in each candidate-paraphrase pair. By addressing **RQ 4**, we showed that some phenomena are consistently easier or harder across the majority of the systems. These findings empirically prove the complexity of paraphrasing and the task of PI. The results justify the distinction between the qualitatively different linguistic phenomena involved in paraphrasing and demonstrate that framing PI as a binary classification problem is an oversimplification.

By addressing **RQ 2**, we showed that each system has strong and weak sides, which can be identified and interpreted via its *"performance profile"*. This information can be very valuable when analyzing the errors made by the system or when reusing it on another task. Given the Deep architecture of the systems, such a detailed interpretation is hard to obtain via other means and metrics. By addressing **RQ 3**, we showed that two systems can differ significantly in their performance on candidate-paraphrase pairs involving particular phenomenon. These differences can be seen even in systems that have almost identical quantitative (Acc and F1) performance on the full test set. These findings justify the need for a qualitative evaluation framework for PI. The traditional binary evaluation metrics do not account for the difference in phenomena performance. They do not provide enough information for the analysis or for the comparison of different PI systems. Our proposed framework shows promising results.

Our findings demonstrate the limitations of the traditional PI task definition and datasets and the way PI systems are typically interpreted and evaluated. We show the advantages of a qualitative evaluation framework and emphasize the need to further research and improve the PI task. The *"performance profile"* also enables the direct empirical comparison of related phenomena such as *"same polarity substitution (habitual)"* and *"(contextual)"* or *"contains negation"* and *"negation switching"*. These comparisons, however, fall outside of the scope of this paper.

Our evaluation framework is not specific to the ETPC corpus or the typology behind it. The framework can be applied to other corpora and tasks, provided they have a similar format. While ETPC is the largest corpus annotated with paraphrase types to date, it has its limitations as some interesting paraphrase types (ex.: *"negation switching"*) do not appear with a sufficient frequency. We release the code for the creation and analysis of the *"performance profile"* [4].

7 Conclusions and Future Work

We present a new methodology for evaluation, interpretation, and comparison of different Paraphrase Identification systems. The methodology only requires at evaluation time a corpus annotated with detailed semantic relations. The training corpus does not need any additional annotation. The evaluation also does not require any additional effort from the systems' developers. Our methodology has clear advantages over using simple quantitative measures (Accuracy and F1 Score): 1) It allows for a better interpretation and error analysis on the individual systems; 2) It allows for a better qualitative comparison between the different systems; and 3) It identifies phenomena which are easy/hard to solve for multiple systems and may require further research.

We demonstrate the methodology by evaluating and comparing several of the state-of-the-art systems in PI. The results show that there is a statistically significant relationship between the phenomena involved in each candidate-paraphrase pair and the performance of the different systems. We show the strong and weak sides of each system using human-interpretable categories and we also identify phenomena which are statistically easier or harder across all systems.

As a future work, we intend to study phenomena that are hard for the majority of the systems and proposing ways to improve the performance on those phenomena. We also plan to apply the evaluation methodology to more tasks and systems that require a detailed semantic evaluation, and further test it with transfer learning experiments.

Abstract

Machine Translation systems have drastically improved over the years for several language pairs. Monolingual data is often used to generate synthetic sentences to augment the training data which has shown to improve the performance of machine translation models. In our paper, we make use of an Unsupervised Statistical Machine Translation (USMT) to generate synthetic sentences. Our study compares the performance improvements in Neural Machine Translation model when using synthetic sentences from supervised and unsupervised Machine Translation models. Our approach of using USMT for backtranslation shows promise in low resource conditions and achieves an improvement of 3.2 BLEU score over the Neural Machine Translation model.

1 Introduction

Neural Machine Translation systems with encoder-decoder architecture have significantly improved the state-of-the-art for several language pairs (Bahdanau et al., 2015; Vaswani et al., 2017). A majority of the systems in WMT18 used a Transformer approach with varying number of encoder-decoder layers (Bojar et al., 2018).

Supervised Neural Machine Translation systems are data-hungry as they require huge amounts of aligned parallel corpora (Koehn and Knowles, 2017). Additionally, obtaining parallel corpora is expensive and requires expert knowledge in both - source and target languages. To overcome this bottleneck, recent research has focused on unsupervised machine translation where only monolingual corpus is required, eliminating the need for a bilingual parallel corpora. The approaches in unsupervised machine translation have shown promise (Lample et al., 2018; Artetxe et al., 2018, 2019). Nonetheless, the performance of traditional Neural Machine Translation is still better than Unsupervised Machine Translation.

Often monolingual data is used to further improve the performance of a Neural Machine Translation model (Sennrich et al., 2016a; Currey et al., 2017). Backtranslation is one such popular method in which monolingual data is utilized to improve the model performance. In this technique, a model is initially trained in one of the directions (say target to source) and the trained model is used to translate a monolingual corpora to obtain synthetic sentences in the source language. These synthetic sentences are then included in the training set and a new model is trained from source to target. We take advantage of Unsupervised Machine Translation model for backtranslation (i.e. to generate synthetic sentences).

In our paper, we use Unsupervised Machine Translation Model (USMT) to generate the synthetic sentences for Russian-English language pair. Our aim is to improve the performance of the machine translation model using synthetic sentences from USMT model. Additionally, we look provide information on the settings and scenarios which benefit from USMT model and NMT model based backtranslation. To the best of our knowledge, there has been no study on using unsupervised machine translation models for backtranslation.

Our experiments indicated an improvement of 3.2 BLEU points for Russian to English language pair in a low resource setting while using synthetic sentences generated from an USMT model. However, we observed that NMT based backtranslation is superior when sufficient data is available and significantly improves the overall model performance.

Our paper is organized as follows - In the next section, we discuss related works in the field that have motivated us to carry out this study. Next, we

describe the datasets that we used for our experiments. Next, we describe our experimental setup for carrying out the experiments. We then analyze the results for NMT, USMT and other models on Russian - English dataset. We conclude the paper with discussion on future work.

2 Related Works

In this section, we will describe the main ideas and experiments using backtranslation and monolingual data.

Backtranslation was popularized by Sennrich et al. (2016a) where they improved the state-of-the-art in several language pairs. They trained a target to source machine translation model on the aligned parallel corpus. The model was later used to translate target-side monolingual sentences to the source language. These new synthetic sentences were added to the training set and a new model is trained.

On similar lines, Zhang and Zong (2016) use the source-side monolingual data to train the NMT model. They build a baseline NMT model and then use that model to generate the synthetic parallel data. They experiment on self-training as well as multitask learning.

He et al. (2016) introduced a dual learning mechanism for neural machine translation. They train translation models in both directions and use monolingual data to provide feedback on the quality of the translation. Their main contribution was to treat machine translation as a reinforcement learning problem.

Hoang et al. (2018) proposed a simple technique. They do show that iterative backtranslation improves the performance of the system on large datasets. However, they observe that the improvements in low resource datasets were not significant.

As mentioned earlier, obtaining aligned parallel corpora is expensive and cumbersome. Recent efforts in Unsupervised Machine Translation indicate that it is possible to develop a competitive system using only monolingual corpus (Lample et al., 2018; Artetxe et al., 2018).

In our study, we use an unsupervised statistical machine translation system based on Artetxe et al. (2018) [1]. In their paper, they describe a novel method to build a statistical machine translation model using monolingual data without any parallel data. The main idea is to learn word embeddings for each language independently and use linear transformations to bring them to shared space. These embeddings are used to generate the phrase table and then, the SMT is fine-tuned on a synthetic training set. In our work, we make use of this model to generate more synthetic data to be added to the parallel corpora.

3 Data

We perform our experiments on the Russian - English language pair. For training the supervised model (both the back-translated model and re-trained model), we use the Russian - English parallel corpus from WMT 19 [2]. To train our unsupervised model, we used monolingual corpora for Russian [3] and English [4] from Newscrawl 2017 and 2018 datasets. For English, we consider only the Newscrawl 2018 as the monolingual data where as for Russian we combine both Newscrawl 2017 and 2018 for the monolingual data.

We provide more details regarding the data in Table 1.

3.1 Preprocessing

For normalizing punctuation in the parallel corpora, we use the default scripts provided by Moses [5]. We then perform true-casing followed byte-

[1] We use this method as it did not require huge amounts of resource to train compared to other methods such as Artetxe et al. (2019)

[5] https://github.com/moses-smt/mosesdecoder/tree/master/scripts

pair encoding while training the NMT [6] (Sennrich et al., 2016b).

3.2 Postprocessing

We remove byte pair encodings, detrucase and detokenize all the translated sentences before validating the predictions against the test set.

4 Experimental Setup

We describe our experimental setup in this section.

For our unsupervised statistical machine translation model, we use Monoses (Artetxe et al., 2018). We use the defaults for training the unsupervised model from the Monoses code. We train the model on both Russian to English (ru-en) and English to Russian (en-ru) monolingual corpus.

Monoses frameworks trains the model in 8 steps. Steps 1-7 involves training the word embeddings and bringing them to a shared space to build an initial phrase table. In step 8, 2M sentences are generated through backtranslation in both the directions. The phrase table is fine-tuned for 3 iterations using the synthetic sentences to obtain the final model.

We use OpenNMT for training the supervised machine translation models (Klein et al., 2017). We use the default architecture in OpenNMT, which includes an LSTM layer for encoding and another LSTM layer for decoding. Furthermore, we do not use the pretrained word embeddings. For both NMT and retraining the NMT model, we use the same architecture with default values.

To train the USMT model and NMT models, we used a system with 4x vCPUS, NVIDIA Tesla K80 GPU and 61 GB of RAM. The USMT model took about 2 weeks to complete training where as the NMT model usually took about 4-5 hours.

5 Experiments

Our primary aim is to show that we can use an unsupervised machine translation model to improve the performance of NMT systems. At the same time, we want to have a fair validation and investigate numerous scenarios where our approach performs well.

Therefore, in this experiment, we use monolingual data to generate synthetic sentences using both NMT and USMT separately and then, each of them is used to augment the training data for the Neural Machine Translation model. For example, we use back-translated Russian monolingual corpus to generate synthetic English sentences. These English sentences are added to the training corpus (with varying training corpora sizes) with English as the source and Russian as the target. We then train an NMT model from scratch and report our performance on an unseen test set.

In the case USMT, we backtranslate the monolingual corpus using the USMT model and augment the sampled training data. The training data is used to build the NMT model.

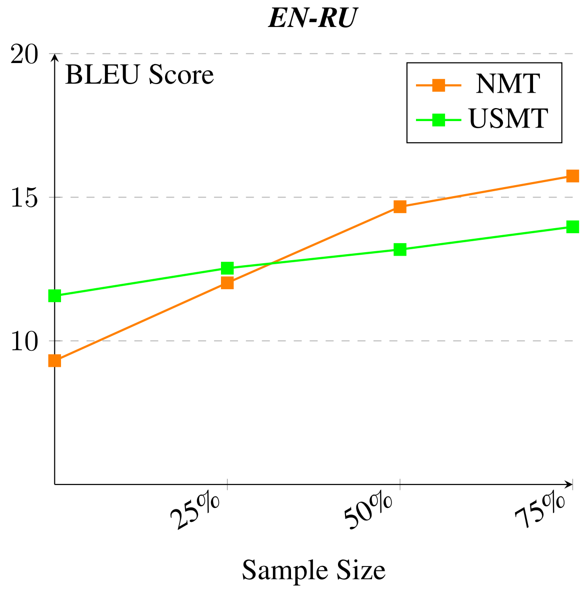

Figure 1: BLEU scores for NMT backtranslation and USMT backtranslation for EN-RU

6 Results

We perform all the experiments mentioned in the Table 2. Each row has a key which corresponds to the type of training corpora. The training corpora includes Only Parallel corpora, Only Monolingual Corpora and a sampled combination of the Parallel Corpora and the backtranslated Monolingual Corpora.

We obtain the baseline NMT model using the parallel corpus without any additional synthetic sentences. As mentioned earlier, we train the parallel corpora using the default encoder-decoder architecture from OpenNMT. Furthermore, we train a baseline USMT model using the monolingual corpora of English and Russian. We report the results in Table 2.

From the baselines of NMT and USMT, it is very clear that NMT outperforms USMT when

75% (∼217K)+ Backtranslated Corpora	**20.17**	19.34	**15.74**	13.97

Table 2: The BLEU scores for the different experiments. The training corpus with x% indicates the percentage of aligned training pairs randomly sampled from the parallel corpora.

there is sufficient data available.

To train the NMT backtranslation models, we sample the parallel corpora in batches of 10%, 25%, 50%, and 75% and train the NMT backtranslation model i.e. NMT model in the reverse direction (target to source). The synthetic data is generated by translating the monolingual corpora in English to Russian and Russian to English respectively. In Table 2, we refer to the synthetic sentences as Backtranslated Corpora. These sentences are combined with the sampled parallel corpora and retrained in the correct direction. In the case of USMT, we directly translate the monolingual corpora and include these synthetic sentences as a part of the training for NMT model in the correct direction.

Our results indicate the following - It can be seen that in critically low resource scenarios, the USMT backtranslated model performs better than the NMT backtranslated model (By 2.4 to 3.2 BLEU points for Russian to English and 0.61 to 2.26 BLEU points for English to Russian). However, the performance of the NMT system dramatically increases with the availability of parallel data. This shows that USMT as a backtranslation model works well mostly in low resource settings.

We can infer that the quality of the backtranslation model has a significant impact on the performance of the model. Additionally, we can see that the NMT model with small amount parallel data combined USMT model improves over the USMT baseline performance.

7 Discussion

In our future experiments, we would like to investigate the effect on lexical properties such as Named Entities and numbers in the predictions. We would also like to experiment our approach with newer techniques from Unsupervised Machine Translation (Artetxe et al., 2019). Additionally, we would like to extend our approach to other languages to comprehensively test our hypothesis.

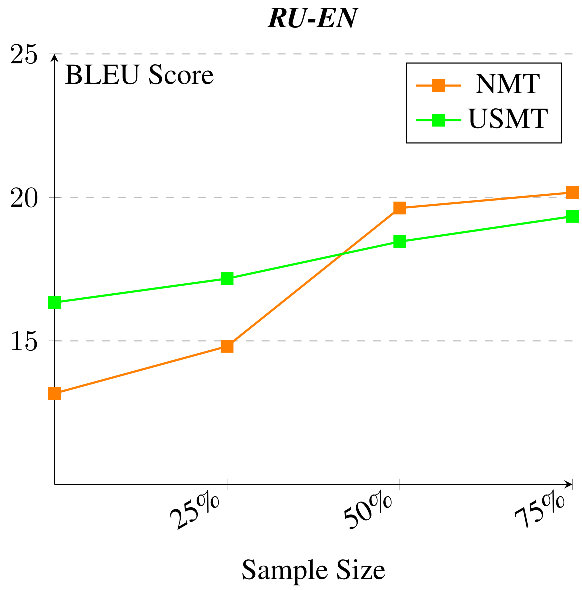

Figure 2: BLEU scores for NMT backtranslation and USMT backtranslation for RU-EN

Our experiments show that Unsupervised Statistical Machine Translation models can be used as a means of obtaining backtranslations to improve the performance of supervised machine translation models. We also note that the improved performances due unsupervised machine translation models are restricted to low resource scenarios. The performance of NMT model with NMT backtranslated sentences is superior when compared to the NMT model with USMT backtranslated sentences. In conclusion, our study helps in identifying the settings which benefit from USMT and NMT backtranslation models.

8 Code

To facilitate reconstruction of our paper, we are releasing the code - https://github.com/anush6/USMT_For_Backtranslation

s.sharoff@leeds.ac.uk

Abstract

The paper describes a computational approach to produce functionally comparable monolingual corpus resources for translation studies and contrastive analysis. We exploit a text-external approach, based on a set of Functional Text Dimensions to model text functions, so that each text can be represented as a vector in a multidimensional space of text functions. These vectors can be used to find reasonably homogeneous subsets of functionally similar texts across different corpora. Our models for predicting text functions are based on recurrent neural networks and traditional feature-based machine learning approaches. In addition to using the categories of the British National Corpus as our test case, we investigated the functional comparability of the English parts from the two parallel corpora: CroCo (English-German) and RusLTC (English-Russian) and applied our models to define functionally similar clusters in them. Our results show that the Functional Text Dimensions provide a useful description for text categories, while allowing a more flexible representation for texts with hybrid functions.

1 Introduction

Comparable corpora are an important prerequisite for translation studies (TS) and contrastive analysis. One wants to make sure that the corpus resources used to explore differences between languages or aspects of translational specificity in several target languages (TL) are comparable in the first place.

One of the common approaches to corpus comparability is to define it as the domain similarity and to rely on the vocabulary overlap as the measure of comparability. A brief summary of possible interpretations of the concept and comparability measures can be found in Li et al. (2018). The authors give a domain-based definition to cross-linguistically comparable corpora: "*document sets in different languages that cover similar topics*". While lexical similarity is an important factor in linguistic variation, we would argue that it does not capture all the translationally relevant features of texts. Neumann (2013), Kruger and Van Rooy (2010) and Delaere (2015) have also highlighted the importance of register and genre in studying translations by showing that different registers produce different types of translationese. Moreover, functional theories within translation studies (TS) insist that what matters in translation is functional adequacy. The target text (TT) is expected to fulfill the same communicative functions as the source text (ST) and meet the TL conventions expected in the situation of TL communication of the message (Nord, 2006). Both Reiss and Vermeer (1984) and Neubert (1985) build their theory of translation around genres or text types, while Shveitzer (1973) underlines the impact of the text functions hierarchy on the translator's linguistic choices.

The above suggests that translational comparability of corpus resources should take into account social and situational constrains of the communication and the the speaker's purpose along with the text topic. The functional and communicative variation of texts is usually interpreted through the concepts of register and genre. For the purposes of this research, we will accept the distinction between the two suggested by Lee (2001). Register, as a text-**internal** view with respect to text categorization, refers to the lexicogrammatic choices made by the author. This notion reflects the differences in the linguistic make-up of texts and it relies on frequencies of lexicogrammatic features such as passive voice, relative clauses or personal pronouns. It is assumed that the observed linguistic variation captures the possible combinations of field, tenor and mode, the most prominent factors of communication (suggested by Halliday (1985)).

On the other hand, genres are understood as conventionally recognizable text categories that can be established on a number of **external** criteria, referring to the function of the text and its situational constrains. According to Lee (2001), most existing corpora rely on the text-external approach to text categorization and the choice of parameters behind it is guided by practical considerations in each case. It has been shown how little comparability there is between the genre classifications used to annotate different corpora (Sharoff, 2018). TS researchers interested in register variation find that existing corpora provide "limited background information on the genres ... and how they were defined" and choose to set up annotation tasks to reorganize the corpora (Delaere, 2015).

One translationally relevant common footing to compare texts from corpora with divergent or absent genre annotation is to rely on their function. On the one hand, text function is an important factor in translation, as texts aimed at informing the reader are translated differently from texts aimed at promoting goods and services (Lapshinova-Koltunski and Vela, 2015). On the other hand, text functions can be used to produce continuous rather than discrete text descriptions and account for hybrid texts. In this research we explore the potential of Functional Text Dimensions (FTD), hand-annotated for English and Russian (Sharoff, 2018) to produce text representations and to build functionally comparable corpora for TS research.

The aim of the present study is solve a practical task of creating research corpora for the study of translational tendencies in English-German and English-Russian translation. To this end, we develop a method to build a reasonably big and functionally homogeneous intersection of the three text collections: CroCo, an English-German parallel corpus (Hansen-Schirra et al., 2006), and the students and professional collections from RusLTC, a English-Russian parallel corpus (Kutuzov and Kunilovskaya, 2014). Our major motivation for this research is to find a way to reconcile the diverging genre annotations that exist in these corpora (see Table 4). We want to reduce the probability that the differences observed in the translations are down to the differences between the sources and are not genuine translational or cultural effects.

The rest of the paper is structured as follows. Section 2 has a brief overview of the topological approach to the text characterization and the research related to corpus similarity and genre classification. In Section 3 we describe our approaches to FTDs modelling and report the results of the intrinsic evaluation of the models. A selection of BNC genres is used to evaluate the models against an independent judgment and to test the clustering approaches to be used in the real-life task (Section 4). Section 5 presents a study that showcases the application of the functional vectors to computing the most similar parts of the two corpora. In Section 6 we aggregate the analytic results and highlight important findings.

2 Related Research

The practical needs to describe and compare corpora have made 'corpusometry' a prominent area of research in corpus linguistics. Below we outline the two major approaches to measuring similarity and describing the corpora contents. The first one is based on lexical features and yields a thematic description of corpus texts. It is one of the most prominent methods of measuring similarity between texts and/or building comparable corpora. For example, Kilgarriff and Salkie (1996) put forward a corpus homogeneity/similarity measure based on calculating χ^2 statistics from frequency lists or N keywords. A lexical approach to estimate the corpus composition is taken by Sharoff (2013). This research compared the results of clustering and topic modelling as ways to represent a corpus content using keywords statistics. In Li et al. (2018), the authors compared the performance of several bilingual vocabulary overlap measures on a specifically designed corpus with known comparability levels and found that frequencies of words with a simple Presence/Absence weighting scheme outperformed other approaches.

Another approach to measuring corpora has to do with calculating frequencies of a range of lexicogrammatic features (tense forms, modals) that allegedly reflect linguistically relevant parameters of the communicative situations. This text-internal approach to the text categorization can be best exemplified by Biber's work (Biber, 1988). He used several dozens of hand-picked text-internal features to place a text along each of the six dimensions (e.g. involved vs informational production or abstract vs non-abstract information). Biber's multidimensional approach to describing text variation has been criticized for lack of interpretability and, more importantly, for being loosely related to any external and situational factors, which cab be a socially more important reality for text categorization than linguistic features. The latter can throw together texts that are perceived as belonging to different genres (Lee, 2001). The attempts to classify genres, particularly, as annotated in the BNC and limited to a selection of major 'tried and tested' three or four top-level categories, have shown that the 67 Biber's features can be an overkill for a task like that. Lijffijt and Nevalainen (2017) report over 90% classification accuracy for the BNC four major genres on just pairs of surface features (such as frequencies of nouns and pronouns, values of type-to-token ratio and sentence length). The results from Kilgarriff and Salkie (1996); Xiao and McEnery (2005) indicate that the most frequent words can cope with the four major BNC categories as well. More specifically, Xiao and McEnery (2005) show that keyword analysis can be used to replicate Biber's results. In effect they analyze differences in the frequencies of mostly functional words that are key to genre identification. In a setting similar to Biber's, Diwersy et al. (2014) use 29 lexicogrammatic features and mildly-supervised machine learning methods to tease apart genres annotated in CroCo. The visualizations they provide indicate that they have managed to clearly separate only fiction and instruction of the eight genres in their experiment.

This demonstrates that describing genres needs a sophisticated approach that takes into account a multitude of criteria such as topic and situated linguistic properties. This research continues the investigation of the functional aspect of genre shaped in Sharoff's Functional Text Dimensions (Sharoff, 2018). Sharoff's work establishes a text-external framework to capture human perception of the texts functionality (as distance to a functional prototype) and to link it to any text-internal representations, with the aim of predicting the functional setup of unknown texts. This work is particularly relevant to our task for three reasons: (1) it provides a solid theoretically grounded approach for comparing texts coming from different or unknown sources and for producing comparative descriptions for the corpora at hand, (2) it is focused on functional and communicative parameters of texts that are particularly important in TS, (3) this framework, like Biber's, provides a flexible way to represent texts functionality along a few dimensions instead of squeezing texts into the atomic genre labels. In effect, FTD framework is a way to produce functional text vectors that position each individual text in a multidimensional functional space and help to account for variation within and across text categories.

3 Modelling: Setup and Results

The annotated data from the FTD project was used to learn models that predicted 10-dimensional vectors for the English texts in our research corpora. Further on, we used these vectors to compare texts and to get functionally similar subcorpora for a subsequent TS research (Section 5).

The annotated data for English consists of 1624 chunks of texts that count about 2 mln tokens from two different sources: 5gthe Pentaglossal corpus (Forsyth and Sharoff, 2014) and ukWac (Baroni et al., 2009). We used the annotations for the 10 most prominent FTD described in Sharoff (2018). Each dimension received a score on a 4-point Likert scale that reflects the proximity of a text to the suggested functional prototype. The inter-annotator agreement is reported at Krippendorff's α >0.76. We refer the reader to Sharoff (2018) for more details on the FTD framework.

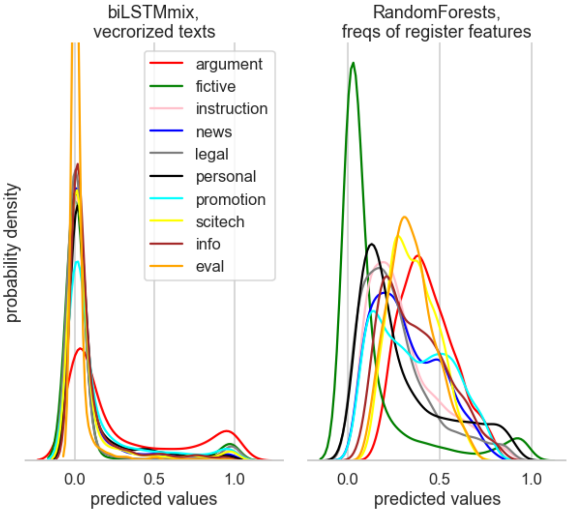
We used two modelling approaches to learn functional vectors from the annotated dataset: a multi-label task in a deep neural network architecture and a set of binary classifiers in a traditional machine learning setting. The respective models produced two types of functional vectors, which demonstrated comparable performance in several evaluation settings. This paper investigates the differences between, and adequacy of, these two types of functional vectors.

In the neural networks scenario, we used a bidirectional LSTM with an attention layer and two types of text input. Firstly, texts received mixed token-PoS representations suggested by Baroni and Bernardini (2006), biLSTMmix throughout this paper and in Table 1). The 1500 most frequent words were kept in their surface form, while the rest of the tokens were converted into their PoS. For example, a sentence “It was published in 1931 by one of New York’s major publishers.” was transformed into “It was VERB in [#] by one of PROPN PROPN major NOUN.” The embeddings for PoS were initialized as random vectors and trained in the Embedding layer. Secondly, we used lemmatised texts, with stop words filtered out (biLSTMlex in Table 1). For both scenarios we used pre-trained word embeddings of size 300, trained on the English Wikipedia and CommonCrawl data, using the skip-gram model, from the WebVectores database (Kutuzov et al., 2017). The preliminary experiments showed that cross entropy as the loss function with the Adam optimizer performed best (Kingma and Ba, 2014). We trained the models for 10 epochs. In the ML case, we reformulated the task as the binary classification task and learnt a classifier for each FTD. To this end, we binarized the existing human annotations by converting ‘0.5’ score to 0 and ‘2’ to 1. To get the real-valued functional vectors we used the probabilities returned for the positive class for each FTD on the assumption that the model would return higher probabilities for texts with a clearer functional makeup. We experimented with features (TF-IDF and Biber’s 67 text-internal register features) and with different algorithms (Support vector machines (SVM), RandomForest (RF), Logistic Regression (LogReg)). SVM and RF results below pertain to the experiments with the grid search optimized for macro F1 score. TF-IDF representation proved to be inferior to the Biber’s features and was excluded from the results below. We added a dummy classifier which randomly predicts a class with respect to the class distribution as a baseline. For register feature extraction (the Biber’s features) we used MAT for English (Nini, 2015).

To use a comparable performance metrics for the two learning approaches, the annotations and the models predictions were transformed into multi-hot vectors.

In Table 1 we report the standard measures averaged over 10 FTDs on the 10-fold cross validation for the six experiments. We accounted for the severe class imbalances in all training settings by using ‘class_weight=balanced’ option, stratified (multi-label) split with cross-validation and, at the evaluation stage, by choosing macro-averaging which penalizes model errors equally regardless of class distributions.

Figure 1. Distribution of predictions for the modeling approaches



From the statistics in Table 1, it follows that the deep learning approach is more accurate in determining the text functionality than the classical algorithms, and the mixed representations work best.

The difference between the models performance, however, is quite slim: it is in the second decimal digit only. A brief glance at the values of the functional vectors components (i.e. values predicted for each FTD) returned by the models reveals the differences in how the models arrive at the same overall result. Figure 1 shows the probability density for the values produced by the best performing models in each learning setup.

Figure 1 demonstrates that biLSTM, unlike the traditional ML algorithms, tends to predict near-zero values, with up to 7-11% of the training texts receiving values smaller than 0.2 on the strongest ‘dominant’ dimension.

In the next section we will show how the predictions of these two models correlate with the experiment-independent judgment we can suggest.

4 Evaluation on BNC Categories

4.1 Genre Classification

To test the functional vectors on the data outside the annotated dataset, we constructed a corpus with the ‘known’ genre composition. To this end, we followed Lee’s scheme for the BNC text

	FTD perspective			FTD minority class	Samples perspective	
	P	R	F1	F1	F1	neg_humming_loss
biLSTMmix	.804	.767	**.776**	.609	.640	.902
biLSTMlex	.787	.747	.757	.576	.596	.895
RF	.732	.756	.723	.532	.517	.846
SVM	.667	.531	.510	.095	.059	.844
LogReg	.664	.734	.659	.480	.527	.753
dummy	.504	.504	.504	.169	.134	.737

Table 1. Results of FTD modelling experiments

categories (Lee, 2001) to select the genres that are, in our opinion, most functionally distinct. The genres that use domain as the major underlying principle were deliberately excluded (religious texts, subcategories of academic texts). Table 2 has the basis parameters of the resulting BNC subcorpus. To find out how well the functional vectors reflect the structure of this functionally-motivated BNC subcorpus, we classified the six genres on the functional vectors produced by our best-performing models and compared their performance to several alternative representations: the raw statistics for Biber's features and log likelihood values for the 446 most common keywords. For brevity, in Table 3 we report the macro-averaged 10-fold cross-validated results only for RandomForest. Several other algorithms (SVM, LR) return approximately the same results.

genre	texts	words
academic(sci)	43	1.3M
editorial	12	115K
fiction(prose)	431	19M
instruct	15	492K
non-acad(sci)	62	2.8M
reportage	87	3.6M
Total	650	30M

Table 2. Basis statistics on the six functionally distinct categories from BNC

From Table 3 it follows that the models learnt on Biber's features coped with the selected BNC genres better than any other representations. However, the best performing pair of surface features from Lijffijt and Nevalainen (2017) — frequencies of nouns and pronouns, which return the reproducible result of over 90% accuracy on the four 'tried and tested' registers of English, — fail in the face of the more fine-grained categories.

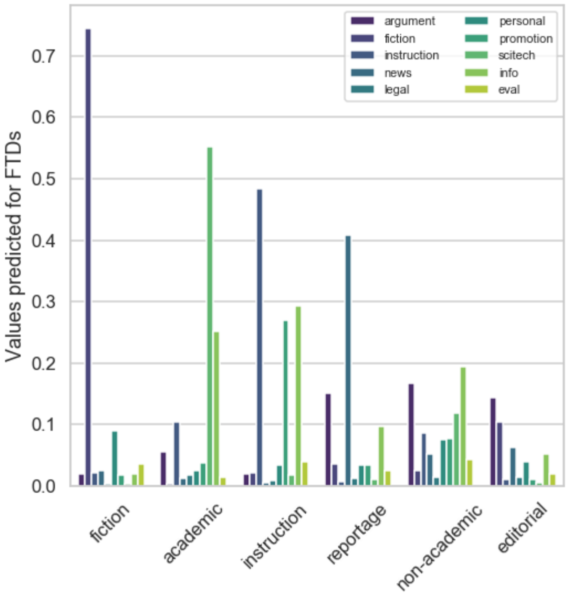
	P	R	F1
biLSTMmix	.84	.75	.79
biLSTMlex	.88	.66	.69
RF	.88	.90	**.89**
Baselines			
67 Biber's features	.93	.88	**.90**
Nouns+Pronouns	.76	.74	.74
keywords	.91	.79	.84

Table 3. BNC classification results

The analysis of the interrelations between the BNC genre labels and the predicted dominant functions suggest that only two categories can be easily mapped to the list of FTDs by all models: fiction and academic texts. The most problematic genres for all models are non-academic writings and editorials. For these texts the models either return no score above the 0.2 threshold on any of the dimensions or similar (relatively low) scores on several dimensions, especially on argumentative, evaluative, informational and personal. Editorials and non-academic texts stand out as functionally hybrid: in Figure 2, which shows the distribution of the FTD values predicted by biLSTM across the six genres, they do not have a functional focus, but integrate several text functions. Their hybrid status is evident from the more uniform distribution of average values for FTDs and from the diversity of text dominants predicted for these genres as well as from the higher percentage of the strong second function in the vectors.

The analysis of the predicted dominant functions against the actual genre labels shows that the best overall fit for BNC is produced by the RandomForest-based model, not the least because it does not produce vectors consisting of very low values only, which results in failure to define texts at all, given the accepted threshold of 0.2 necessary to signal a function. For all genre categories (except editorials) 60-95% of texts can be referred

Figure 2. Average values on the 10 FTDs by BNC genres predicted by biLSTMmix model



to the true genre category following the strongest prediction, if we map genres to FTDs as follows: fiction : fictive, academic : scitech, reportage : news, instruction : instruction, non-academic : argumentative. However, reducing a functional vector to just the strongest component would be unfair to the functionally hybrid texts that fall under the genre labels of non-academic and editorial in our BNC slice.

4.2 Testing the Clustering Method on BNC

The ultimate goal of this work is to produce a functional intersection of two corpora, i.e. to find functionally comparable texts in several sets. In this section we apply two clustering techniques to the BNC selection to determine which text representation and clustering approach is better at matching the annotated genres as class labels.

In the first clustering scenario we ran Affinity Propagation on a square matrix of pair-wise correlations pre-computed as euclidean similarities for the 650 BNC texts. This approach is attractive because it does not require the value of k, which is difficult to deduce in the real application context. We searched through the combinations of parameters to get the highest score for the Adjusted Rand Index (ARI), a clustering metric, which returns the proportion of text pairs that were assigned to the correct cluster, given the gold standard classes. The best clustering solution, with ARI=0.92 and 4 clusters on our BNC selection, was returned for both biLSTMmix and RandomForest vectors at damping=0.9 and preference=-12. The clusters, quite predictably, were built around (1) fiction, (2) reportage (3) non-academic + editorial (4) academic + instructions. Vectors learnt on lemmatized embeddings (biLSTMlex) were not able to converge to this solution.

An alternative clustering technique used in this research was KMeans algorithm with the Elbow Criterion method to determine k. The latter is based on measuring the sum of the squared distances between each member of the cluster and its centroid. k is defined as the number of clusters after which this value drops abruptly. However, this method needs to be applied with regard to the task at hand and some understanding of the data. For BNC k was automatically put at 2, because of the imbalance in our collection towards fiction: more than half of the texts were fiction. The best KMeans result (ARI=0.92) was registered on the RandomForest model vectors for k=5. It was superior to the best biLSTM result in that it separated the instruction cluster. Clustering on Biber's features and keywords did not achieve ARI of more than 0.2 for either Affinity Propagation or KMeans.

5 Case Study: CroCo and RusLTC

In this section we report the results of a case study where we used the functional vectors to get comparable functional clusters from several text collection. Our data comes from the English parts of the three parallel corpora: RusLTC, including student and professional translations subcorpora that have different English sources, and the CroCo corpus. As can be seen from Table 4, the three text collections vary in size, have diverging genre setup, and there is no way to tell whether the same categories include the same texts. In this work CroCo was chosen as the normative corpus, i.e. the starting point for the comparison and clustering operations.

The first step in solving our practical task with KMeans was to determine k. K-value was identified as n+1, where n is the number of the most populous groups formed by the texts with a specific FTD as the dominant function (see Figure 3, which show the ratio of texts with a specific dominant function). For the tree corpora in our experiment it seems possible to set k to 5 or 6. Our ex-

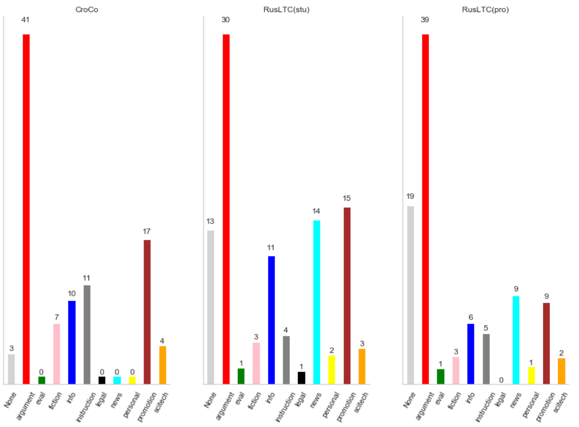
Table 4. Parameters of the parallel corpora

Figure 3. Ratio of texts by the dominant FTD in the research corpora as predicted by biLSTM



periments showed that the difference was not critical for both types of functional vectors: it did not affect the makeup of the most populous cluster in CroCo. The clusters we received for the normative corpus (CroCo) were not at odds with the existing genre annotation (see Appendix). Both models succeed in grouping together instructions and fiction. The difference between the clusterings is in how the models interpret hybrid texts such as popular scientific texts and what aspects of texts they focus as secondary functions. biLSTM, which was learnt on the vectorized patterns of 1500 most frequent words and PoS for other tokens, produces vectors that highlight the fictional, narrative nature of pop-sci, throwing these texts together with fiction (Cluster3), while the classifiers learnt on frequencies of lexicogrammatic features (including inter alia lists of amplifiers and downtoners, private, public and suasive verbs (Quirk et al., 1985)) prioritize the informational and scientific component of pop-sci and group it with tourist informational leaflets (Cluster2).

Taking into account the size and homogeneity of the CroCo clusters, it makes sense to target Cluster 1 in finding functionally similar subsets from RusLTC(stu) and RusLTC(pro). These two collections were clustered with KMeans, the centriods for each cluster were calculated and compared to the CroCo centroids using Euclidean similarity measure. The most similar subsets of the two corpora are the clusters with most similar centroids. In determining k for RusLTC, we looked for a reasonable balance between the similarity and homogeneity scores. For RusLTC(stu) k = 8 and for RusLTC(pro) k = 10 return the best combination of the two.

To triangulate the results from KMeans, we compared them to the results for Affinity Propagation with the parameters tested on the BNC selection. The algorithm returned clusters which shared 85-98% of the files with the most successful KMeans result for all the experiments.

6 Discussion of Results

The primary goal of this project was to test the applicability of the text vectors learnt from the annotated text functions to the task of producing functionally similar subsets of two arbitrary corpora. This involved decisions on the input text representation, learning approach, clustering method and similarity metric. We have found that, first, the functional vectors learned on sequences, patterns and lexicogrammatic properties of texts were more effective in genre/function detection than those learnt on lexical features. Our results from neural networks modelling demonstrated that the functional properties of texts were better captured by the mixed sequences of the most frequent words and PoS than by lemmatized embeddings with stop words filtered out. The purely lexical features (TF-IDF) and keywords statistics proved inferior to lexicogrammar in the alternative ML setting, too.

However, the patterns of the most frequent words and PoS can be more successful with identifying some functions, but not other. In particular, it seems that the functional representations based on the vectorized texts did not quite capture the evaluative, personal and informational FTDs. This can be explained by two factors: first, these functions can rely on lexical features for their expression and, second, they are often annotated as a second strong dimension, unlike the mutually exclusive (genre-pivotal and relatively easy to predict) FTD such as fiction, instruction, news and scitech. To support this argument: in the classification task on the six hand-picked BNC genre categories, the raw Biber's features performed a bit better than the functional vectors learnt on them, while the biLSTMmix vectors demonstrated even less skill in recognizing our select BNC genres, where the majority of texts are of the easy-to-recognize type. On RusLTC(pro) corpus which consists of mass media texts and popular scientific texts, biLSTMmix returns no reliable predictions for the staggering 19% of texts. This analysis shows that FTD detection can benefit from combining vectorized and statistical register features, which we leave for future work.

Second, though our modelling approaches per se are not directly comparable, because they had different objectives and operated on different text representations, we can evaluate their usefulness for the practical task of predicting functional properties of texts. The inspection of the real-valued vectors indicates that the vectors learnt within the classification task setting overestimated the texts functionality (i.e. produced noisy predictions) and were less adequate in determining the functions hierarchy as manifested in the human scores. The two approaches had very similar overall performance in the intrinsic evaluation and in the BNC genre classification task, though in the real application they produce only partially overlapping clusters. This is probably because the models are focusing different properties of texts that are equally relevant for fulfilling text functions, but are more or less pronounced in individual real texts. It seems reasonable to use the union of the two sets for practical purposes. Besides, the models are different in terms of processing effort required, with the model on Biber's features less easily applicable to big corpora.

Third, the effectiveness of the functional representation was ultimately tested in the BNC clustering task. While for Affinity Propagation on pair-wise similarities the type of functional vectors did not matter, the better-performing KMeans proved to be sensitive to the difference in the functional vectors and managed to find a good fit to the BNC genres (5 clusters, ARI=0.92) only for the RandomForest vectors. The functional vectors learnt on embedded mixed representations achieved ARI=0.58 for any k in the range from 4 to 8. Note, however, that any functional vectors were by far better in this task than the baselines: we failed to produce any good clustering results for our BNC selection on the lexical and on the raw register features.

7 Conclusions

This paper presents an approach to deal with a practical issue of constructing functionally comparable corpus resources. We proposed a method to measure functional comparability of the resources at hand and to produce their functionally homogeneous intersection. The method offers a way to verify the researcher's judgments about the corpora comparability which are usually based on pre-existing corpus annotation schemes and researcher's intuition. We show that texts can be described externally via a reference to a number of communicative functions and that the functions are reflected via text-internal linguistic features. We found that functional text representations offer a better clustering result for a corpus with 'known' functions in comparison to keywords and linguistic register features. They can be effectively used to identify functionally homogeneous subsets of texts in a given text collection and to match them to functionally comparable sets from another corpus. The cross-linguistic extension of this research (left for future work) is supposed to equip a researcher with a corpus of non-translations in the TL functionally comparable to the ST. Such a reference corpus would effectively represent the expected TL textual fit (Chesterman, 2004) that is necessary to estimate specificity of translations.

Abstract

Community Question Answering forums are popular among Internet users, and a basic problem they encounter is trying to find out if their question has already been posed before. To address this issue, NLP researchers have developed methods to automatically detect question-similarity, which was one of the shared tasks in SemEval. The best performing systems for this task made use of Syntactic Tree Kernels or the SoftCosine metric. However, it remains unclear why these methods seem to work, whether their performance can be improved by better preprocessing methods and what kinds of errors they (and other methods) make. In this paper, we therefore systematically combine and compare these two approaches with the more traditional BM25 and translation-based models. Moreover, we analyze the impact of preprocessing steps (lowercasing, suppression of punctuation and stop words removal) and word meaning similarity based on different distributions (word translation probability, Word2Vec, fastText and ELMo) on the performance of the task. We conduct an error analysis to gain insight into the differences in performance between the system set-ups. The implementation is made publicly available.[1]

1 Introduction

Community Question Answering (CQA) forums, such as Quora[2] and Yahoo Answers[3], are popular outlets to ask questions and receive answers, as well as to browse through questions and answers. Given the large amount of material on these platforms, a basic problem users encounter is trying to find out if (a variant of) their question has already been posed (and possibly answered) before. Given a target question provided by a user, the automatic task of querying and ranking semantically similar, relevant alternative questions in CQA forums is called *question similarity*.

For efficiency reasons, the question similarity task (also known as question relevance) normally works in two ranking steps. Given a target question, the first step consists of retrieving relevant questions using a general information retrieval technique, such as BM25 (Robertson et al., 2009), or a search engine such as Google (Page et al., 1999). The second step, the focus of this work and of most other studies in this field, consists of reranking the most likely candidate questions with a more fine-grained, domain-specific approach. Optionally, the system could also return whether a candidate question is a duplicate of the query.

The reranking task has been included as a benchmark task (Task 3 - Subtask B) in SemEval-2016/2017 (Nakov et al., 2016, 2017). Using the domain of *Qatar Living*[4], it consisted of re-ranking ten candidate questions retrieved by Google for a target question. Several promising approaches were proposed for this challenge, most notably *SimBOW* (Charlet and Damnati, 2017) based on the SoftCosine metric and winner of SemEval-2017, and KeLP (Filice et al., 2016), which is based on Tree Kernels and provided top results for all the subtasks in the challenge. However, little is known about the effects of particular design choices for these models, especially concerning the preprocessing methods and word-similarity metrics. Moreover, we know little about

how these models perform in comparison to (or combined with) more traditional question similarity techniques.

In this paper we therefore systematically combine and compare the SoftCosine metric and the Syntactic Tree Kernels with the more traditional BM25 and translation-based models. Moreover, we analyze the impact of preprocessing steps (lowercasing, suppression of punctuation and stop words removal) and word-similarity metrics based on different distributions (word translation probability, Word2Vec, fastText and ELMo).

The experiments were mainly conducted on the data of SemEval 2016-2017 - Task 3, based on the Qatar Living corpus. As a secondary goal, we also evaluated our main models in classifying question duplicates on the Quora dataset, so as to assess whether the results that we find apply to different datasets.

Results show that the choice of a preprocessing method and a word-similarity metric have a considerable impact on the final results. We also show that the combination of all the analyzed approaches leads to results competitive with related work in question-similarity.

2 Models

We compare two traditional and two recent approaches in this study: BM25, Translation-Based Language Model (TRLM), SoftCosine and Smoothed Partial Tree Kernels (SPTK - Syntactic Tree Kernels).

BM25 is a fast information retrieval technique (Robertson et al., 2009) used as a search engine in the first step of the shared task by many studies. We used the implementation of BM25 provided by *gensim*[5] as a baseline.

Translation-Based Language Model (TRLM) is a question similarity ranking function, first introduced by Xue et al. (2008). The method combines a language model with a word translation system technique, and is known to obtain better results on the question similarity task than BM25 and only the language model (Jeon et al., 2005). Equation 1 summarizes the TRLM ranking score between questions Q_1 and Q_2:

$$\begin{aligned} TRLM(Q_1, Q_2) = \prod_{w \in Q_1} (1-\sigma)P_{tr}(w|Q_2) + \sigma P_{lm}(w|C) \\ P_{tr}(w|Q_2) = \alpha \sum_{t \in Q_2} Sim(w,t) P_{lm}(t|Q_2) + \\ (1-\alpha)P_{lm}(w|Q_2) \end{aligned} \quad (1)$$

$Sim(w,t)$ denotes a similarity score among words w and t. In the original study, this similarity metric is the word-translation probability $P(w|t)$ obtained by the IBM Translation Model 1 (Brown et al., 1993). Furthermore, C denotes a background corpus to compute unigram probabilities in order to avoid 0 scores.

SoftCosine is the ranking function used by *SimBOW* (Charlet and Damnati, 2017), the winning system of the question similarity re-ranking task of SemEval 2017 (Nakov et al., 2017). The method is similar to a cosine similarity between the tf-idf bag-of-words of the pair of questions, except that it also takes into account word-level similarities as a matrix M. Given X and Y as the respective tf-idf bag-of-words for questions Q_1 and Q_2, Equation 2 summarizes the SoftCosine metric.

$$\begin{aligned} SoftCos(X,Y) = \frac{X^tMY}{\sqrt{X^tMX}\sqrt{Y^tMY}} \\ X^tMX = \sum_{i=1}^{n}\sum_{j=1}^{n} X_i M_{ij} Y_j \\ M_{ij} = max(0, cosine(V_i, V_j))^2 \end{aligned} \quad (2)$$

As $Sim(w,t)$ in Equation 1, M_{ij} represents the similarity between the i-th word of question Q_1 and the j-th one in question Q_2. $cosine$ is the cosine similarity, and V_i and V_j are originally 300-dimension embedding representations of the words, trained on the unannotated part of the Qatar living corpus using Word2Vec (Mikolov et al., 2013) with a context window size of 10.

Smoothed Partial Tree Kernels (SPTK) are the basis of KeLP (Filice et al., 2016), a system introduced by Croce et al. (2011). SPTK applies the kernel trick by computing the similarity of question pairs based on the number of common substructures their parse trees share. The difference with Partial Tree Kernels (PTK) (Moschitti, 2006) is that SPTK also considers word relations.

Besides the different variations of the model, which are well explained in Moschitti (2006) and

[5] https://radimrehurek.com/gensim/summarization/bm25.html

Filice et al. (2016), we designed SPTK in the following form. Equation 3 portrays the notation of the similarity metric among two questions' constituency trees, i.e. T_{Q_1} and T_{Q_2}.

$$TK(T_{Q_1}, T_{Q_2}) = \sum_{n_1 \in N_{T_{Q_1}}} \sum_{n_2 \in N_{T_{Q_2}}} \Delta(n_1, n_2) \quad (3)$$

$N_{T_{Q_1}}$ and $N_{T_{Q_2}}$ are the respective sets of nodes of parse trees T_{Q_1} and T_{Q_2}. $\Delta(n_1, n_2)$ is computed in distinct forms according to three conditions. (1) If the production rules of T_{Q_1} on n_1 and T_{Q_2} on n_2 are different, then $\Delta(n_1, n_2) = 0$. (2) If n_1 and n_2 are similar preterminals, then $\Delta(n_1, n_2) = Sim(w_{n_1}, w_{n_2})$, where Sim is similar to M_{ij} in Equation 2, as well as w_{n_1} and w_{n_2} are the terminal words for n_1 and n_2, respectively. (3) If the production rules of T_{Q_1} on n_1 and T_{Q_2} on n_2 are the same and both are not preterminals, then

$$\Delta(n_1, n_2) = \prod_{j=1}^{child(n_1)} \Delta(child(n_1)_j, child(n_2)_j) \quad (4)$$

So given a pair of constituency tree questions $p = \langle T_{Q_1}, T_{Q_2} \rangle$ to have their relevance scored and a training set of pair trees C, features are extracted in the following way:

$$SPTK(T_{Q_1}, T_{Q_2}) = \{TK(T_{Q_1}, T_{c_1}) + TK(T_{Q_2}, T_{c_2})\} \quad (5)$$

$$\text{where } \langle T_{c1}, T_{c2} \rangle_i \in C$$

The extracted kernel is used in Support Vector Machines Φ, whose output decision function is the relevance score among T_{Q_1} and T_{Q_2}.

Ensemble is the method we propose to combine the relevance scores produced by the previous approaches into a single model. Given questions Q_1 and Q_2 , we trained a Logistic Regression $\phi(Q_1, Q_2)$ with the relevance scores of BM25, TRLM and SoftCosine as features:

$$Ensemble(Q_1, Q_2) = \phi(Q_1, Q_2) \quad (6)$$

After empirically testing different settings, we found that the integration of SPTK in the ensemble method was most effective when interpolating its relevance score separately with the outcome of formula 6. Equation 7 denotes the model:

$$\begin{aligned} EnsSPTK(Q_1, Q_2) = \gamma\phi(Q_1, Q_2) + \\ (1-\gamma)\Phi(SPTK(T_{Q_1}, T_{Q_2})) \end{aligned} \quad (7)$$

We will compare the performance of the ensemble implementation with and without SPTK. For distinction, in the following sections we will refer to the former ensemble method as *Ensemble* and the latter as *EnsSPTK*.

3 Experiments

3.1 Data

Qatar Living We ran our experiments on the data of SemEval 2016-2017 - Task 3 based on the Qatar Living corpus[6]. Its training split consists of 267 target questions, 2,669 related questions (around 10 for each target question), and 26,690 comments (around 10 per related question). The development split and test sets of 2016 and 2017 have 50, 70, and 88 target questions, respectively (with the same proportion of related questions and comments as the training set). Given a target question, each of its related questions, retrieved by Google, was manually annotated as "Perfect Match", "Relevant" or "Irrelevant". The shared-task also provided a large unannotated dataset of Qatar Living, with 189,941 questions and 1,894,456 comments. In the Qatar Living corpus, each question is formed by a subject and a body. For the models BM25, TRLM and SoftCosine, we treat a question combining the subject and body into a single text, whereas we only use the subject for SPTK.

Quora To mitigate duplicate question pages at scale, Quora motivated the development of automated ways of detecting these questions by releasing a dataset with 400,000 pairs of questions together with a label for each entry indicating whether they are semantically identical (i.e., duplicates) or not[7]. We used this dataset to evaluate our most relevant models in the task of detecting question duplicates.

3.2 Settings

For the Translation model (TRLM), C was computed based on the training questions of the dataset used in the evaluation (e.g., Qatar Living or

[6] http://alt.qcri.org/semeval2017/task3/index.php?id=data-and-tools

[7] http://qim.fs.quoracdn.net/quora_duplicate_questions.tsv

Quora). In the Qatar Living corpus, the unannotated part of the data is also used to compute C.

Across the experiments, hyperparameters of the models such as σ and α of TRLM and γ of Ensemble with SPTK were optimized in the development split of the data through Grid Search. Moreover, Support Vector Machines in SPTK and Logistic Regression in Ensemble were implemented based on the Scikit-Learn toolkit (Pedregosa et al., 2011) and had their hyperparameters tuned by cross-validation on the training set.

3.3 Evaluation

In the SemEval shared-task, the question-similarity task was treated as a binary classification task, where the models aim to predict whether a related question is "Perfect Match/Relevant" or "Irrelevant". We evaluate the models using the Mean Average Precision (MAP) as the main metric, and also report F-Score for the classification models. In the Quora dataset, we evaluated the performance of our models in predicting question duplicates also using the F-Score measure.

3.4 Experiment 1: Preprocessing

From the top models for question similarity, little is known about the design process of their preprocessing methods. Filice et al. (2016) do not report on the preprocessing that they applied, and Charlet and Damnati (2017) lowercased the text as well as removed stopwords and punctuation. So in our first experiment, we evaluated BM25, TRLM, SoftCosine, *Ensemble* and *EnsSPTK* with 3 preprocessing methods (and all combinations of them): lowercasing, removal of stopwords[8] and suppression of punctuation. For SPTK we only apply lowercasing, since its constituency trees contain punctuation and stopwords as terminals. The preprocessing methods were applied in the training, development, test and unannotated parts of the data, such that probabilities and word distributions (e.g., word translation probability, Word2Vec, etc.) were affected.

3.5 Experiment 2: Word-Similarity

A central component of all of the evaluated models except BM25 is the use of a word-similarity metric. To evaluate which distribution better captures the similarity between two words for the task, we evaluated all the models using the word-translation probabilities, plus the cosine similarity measure depicted in Equation 2. In the latter, besides Word2Vec representations, we also tested fastText (Bojanowski et al., 2017), a distribution which takes character-level information and tends to overcome spelling variations, and the top layer of ELMo (Peters et al., 2018). To equalize the trials, the data used by the models were lowercased and stripped of stop words and punctuation.

4 Results

The first section of Table 1 lists the MAP of the preprocessing methods in the development part of the corpus for each model. Although the best combination of preprocessing methods differs between models, we see that preprocessing the data is beneficial for the performance of all models, except for SPTK. Between the best results, we see that suppression of punctuation is beneficial for all the models, while the removal of stopwords and lowercasing are detrimental to BM25 and TRLM, respectively.

The lower part of Table 1 lists the performance of each model according to the different word-level similarity metrics. The use of Word translation probabilities appears the under-performing method out of the five, showing the power of the continuous word representations. Surprisingly, we do not observe an improvement of fastText over Word2Vec representations. Even though CQA forums may have very noisy texts, the character-level information that fastText takes into account apparently does not help. Using the top layer of ELMo concatenated with Word2Vec representations leads to the best results in encoding the relation between words, except with TRLM.

Final Results Table 2 lists the results of the models with their best settings in the test sets of SemEval 2016-2017: BM25 with lowercased data without punctuation; TRLM with Word2Vec without stop words and punctuation; SoftCosine with Word2Vec+ELMo, lowercased data without stop words and punctuation; and SPTK with Word2Vec+ELMo and lowercased data. The table also shows the results of the best baseline (e.g., Google) and the winners of the SemEval 2016-2017 challenges. As expected, our best models were the ensemble approaches (e.g., *Ensemble* and *EnsSPTK*), which combine the ranking scores of all the other evaluated approaches and outperform

[8] We used the list of English stopwords provided by the NLTK framework (Bird and Loper, 2004)

Preproc.	**BM25**	**TRLM**	**SoftCosine**	**SPTK**	**Ensemble**	**EnsSPTK**

Table 3: F1 scores of our ensemble method with different preprocessing techniques and word similarity measures on the Quora dev set.

the competitive baselines of SemEval 2016 and 2017.

Regarding the comparison between *Ensemble* and *EnsSPTK* in the test set of Semeval 2016, the approach without SPTK (*Ensemble*) is slightly better on re-ranking similar questions, but is significantly worse on classifying duplicates than *EnsSPTK*. The results are different in the test set of Semeval 2017: the latter approach is slightly better than the former on re-ranking similar questions according to the MAP metric, but shows a non-significant difference in classifying duplicates according to the F-1 score metric.

Although the results between our two best approaches are inconclusive, we argue that the inclusion of SPTK in the ensemble is not beneficial due to the trade-off between efficiency and performance. The SPTK approach, mainly its kernel, is computationally expensive and does not considerably improve the performance of the ensemble. For efficiency reasons we elect *Ensemble* as our best approach.

Checking the coefficients of the trained logistic regression model of *Ensemble*, we saw that the BM25 score (with a coefficient of 4.13) is the most relevant feature of the model, shortly followed by the SoftCosine score (with a coefficient of 3.48) and finally by the TRLM one (with a coefficient of 1.1).

In SemEval-2016, the UH-PRHLT model was the winner of the shared-task (Franco-Salvador et al., 2016). This system is based on a range of lexical (cosine similarity, word, noun and n-gram overlap) and semantic (word representations, alignments, knowledge graphs and common frames) features. In turn, our best model, *Ensemble*, with considerably less features, obtains competitive results in terms of MAP. The same pattern is seen for the SemEval-2017 test set: the Ensemble approach obtained competitive results with the winner *SimBOW*, also based on the SoftCosine metric, in terms of MAP, and outperforms it in F-Score.

Quora results Based on the previous results, we also evaluated the performance of our best question-similarity model, *Ensemble*[9], in classifying question *duplicates* on the Quora dataset. Table 3 depicts the results of our ensemble method with and without preprocessing and using two similarity metrics (Word2Vec and Word2Vec+ELMo). The best F-Score was obtained by the version which preprocesses the questions and represents the words with Word2Vec+ELMo. Results were statistically significant with $p < 0.05$ according to the McNemar's test.

5 Error Analysis

To obtain insight into the improvement by preprocessing setting, in Figure 1 we present the percentage of similar questions that were ranked better (placed on a higher position formerly occupied by a non-similar), equally or worse (switched a lower position with a non-similar) for each model-preprocessing combination in the Qatar Living corpus. The graph shows that each preprocessing manipulation results in both improved rankings and worsened rankings. The model that is least affected by the preprocessing steps is BM25, which shows to be a stable baseline. Most gain is seen for the SoftCosine model with all preprocessing steps, where 38% of the duplicates are ranked better and only 9% is ranked lower than a non-duplicate. Regarding the preprocessing steps applied in isolation, lowercasing leads to most changes for TRLM and BM25, while SoftCosine is most affected after removing stopwords.

The changes in performance by similarity metric are also presented in Figure 1. The highest gains are seen for the TRLM model, which yields an improved ranking for over 20% of the duplicates and a poor re-ranking for 12% to 14% when a similarity metric other than alignment is used. The SPTK model is not helped by a different similarity metric, with the most detrimental effect when combining the model with the translation alignment or fastText. The SoftCosine model with the default Word2Vec is also rather robust, with only a slight improvement when applying one of the ELMo metrics. These metrics do affect the rankings considerably, but lead to fairly equal improvements and declines of the ranking quality.

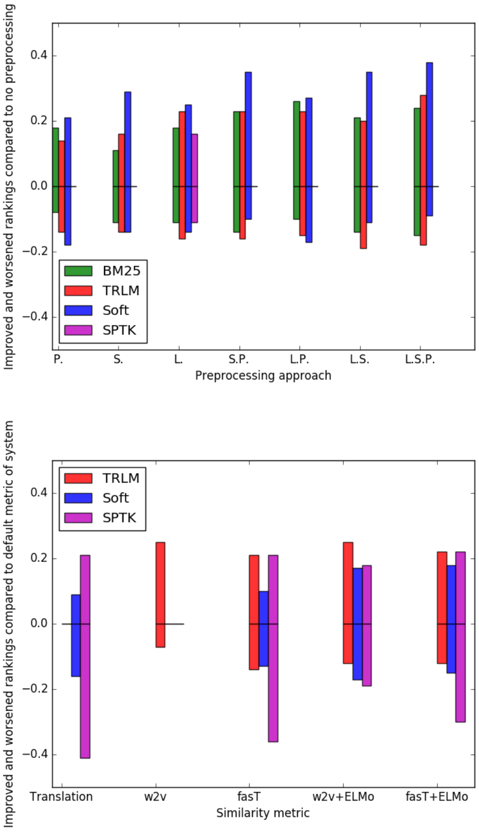

Figure 1: Percentage of similar questions that were ranked better, equally or worse after any of the preprocessing manipulations or similarity metrics combined with each system, in comparison to the standard setting without preprocessing (first graph) or the standard similarity metric for each system (second graph).

The performance patterns presented in Figure 1 show that the SoftCosine metric is affected most by the presence of stopwords. Explicit evidence is presented in Figure 2, which depicts the scores of the SoftCosine settings with and without preprocessing in relation to the number of stopwords in a question-pair. The setting without preprocessing shows a correlation with the number of stopwords: the similarity score goes up as the number of stopwords increases. The setting with preprocessing is, as expected, robust to the number of stopwords. This shows that the SoftCosine metric is considerably affected by the inclusion of stopwords, which hampers performance for the task of question similarity.

In Table 4 we present examples of question pairs in the Qatar Living development set along with their Gold standard label and the preprocessing steps or model that yielded a proper ranking

[9] Given the size of the Quora dataset, computing the kernel trick of SPTK would be intractable.

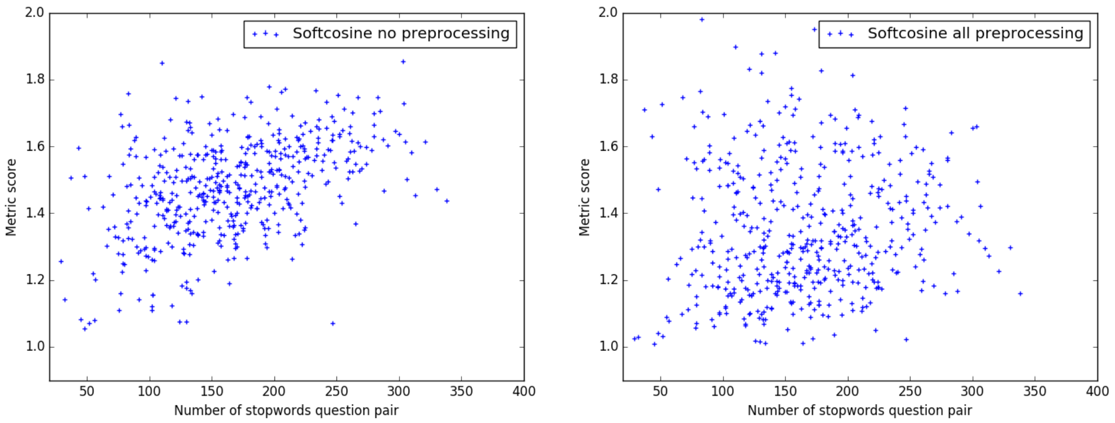

Figure 2: Similarity score in relation to the number of stopwords in a question pair, for the SoftCosine settings with and without preprocessing.

Question ID	Target question (subject - body)	Related question (subject - body)	Gold standard	Best performance
Q314	QLing after working hours - how many of you logon to QL after your working hours?	Surfing QL during office hours - How many hour(s) everyone spend surfing QL during office hours?	Similar	Stopword removal; SoftCosine
Q278	Beach cleaning - I am planning to organize a community service specifically beach cleaning to be carried out by our company staff. Any good suggestion of a beach?	NOT ONE PUBLIC BEACH IN DOHA? - Surrounded by pleasant waters and not ONE public beach! Ridiculous.	Not similar	No lowercasing
Q293	Water theme park in qatar - Hai Friends........ Any one knows the location of watar theme park in qatar; Is it beatiful? childrens have enough ride?? and howmuch fee Thanks	any water theme park in qatar? - Do you know about any water theme park in qatar?	Similar	SPTK

Table 4: Examples of question pairs with particular performance patterns.

for this pair. The first example, with question ID Q314, is of a similar question pair that was most often ranked in a high position by settings that included stopword removal and the SoftCosine model. Stopword removal shows particularly effective for the target question by removing 7 of the 15 words, and SoftCosine best matches 'office hours' to 'working hours'. The second question pair is exemplary of cases where preprocessing is actually detrimental. The related question, not similar to the target question, is partly written in capitals. After lowercasing, the word 'beach' is matched with the target question, which might result in a higher similarity score than questions that are actually similar. The final example, with ID Q293, is particularly well ranked by the SPTK model. On its own, SPTK did not compete with the other models in our study, but the focus on syntactic tree kernels could add a valuable angle to the similarity assessment. In this example, the good assessment by SPTK is likely due to the central phrase 'watar theme park in qatar', which is recurring, albeit with a different spelling, in the related question.

6 Discussion and Conclusion

Until now, careful preprocessing and smart combining of methods have remained understudied in the field of community question answering. Our results highlight that both pay off, yielding state-of-the-art results. Our findings show that lowercasing the input and removing both punctuation and stopwords yields the most robust outcomes, especially for the SoftCosine metric. In addition, representing the meaning of words by means of Word2Vec combined with the top layer of ELMo is the most beneficial word similarity implementation. Combining several metrics implemented with these optimal settings into an ensemble system based on logistic regression yields the best performance in terms of F1-score, being competitive with the winners of the SemEval tasks, and using fewer components.

The error analysis showed that the BM25 model is most stable across different preprocessing metrics, while the SoftCosine model mostly profits from preprocessing. Given the semantic matching that is done as part of SoftCosine and is absent in BM25, we can infer that preprocessing is an important prerequisite for effectively ranking question pairs based on semantic links.

Most of our experimentation was conducted on the Semeval dataset, in which similarity between questions is labeled. We also showed that adjusting preprocessing and word similarity settings leaded to better results in the task of identifying question duplicates, in the Quora dataset. More research is needed to see whether the patterns that we find are dataset-independent.

In future work we aim to compare the optimal models from our current study in a real-world setting, by running A/B testing on a open-domain CQA platform. Through clicks and likes by the users of such a platform, we can obtain insights into the value of these models when applied in the wild with many different question topics.

A Classification-Based Approach to Cognate Detection Combining Orthographic and Semantic Similarity Information

Sofie Labat and Els Lefever

sofie.labat@gmail.com, els.lefever@ugent.be

Abstract

This paper presents proof-of-concept experiments for combining orthographic and semantic information to distinguish cognates from non-cognates. To this end, a context-independent gold standard is developed by manually labelling English-Dutch pairs of cognates and false friends in bilingual term lists. These annotated cognate pairs are then used to train and evaluate a supervised binary classification system for the automatic detection of cognates. Two types of information sources are incorporated in the classifier: fifteen string similarity metrics capture form similarity between source and target words, while word embeddings model semantic similarity between the words. The experimental results show that even though the system already achieves good results by only incorporating orthographic information, the performance further improves by including semantic information in the form of embeddings.

1 Introduction

In general linguistics, the term *cognate* is defined as a “language or a linguistic form which is historically derived from the same source as another language/form” (Crystal, 2008, page 83). The assumption of common etymology is, however, often disregarded in the literature, because certain research areas such as psycho-linguistics or natural language processing (NLP) tend to shift their focus from diachronic to perceptual relatedness (Shlesinger and Malkiel, 2005; Mitkov et al., 2007; Schepens et al., 2013; Hansen-Schirra et al., 2017). We follow this second strand of research in that we define cognates as words with high formal and semantic cross-lingual similarity. Conversely, *false friends* are words which have similar forms, but which differ in their meaning.

The ability to distinguish cognates from non-cognates (and especially) false friends is an important skill for second language learners. Similarly, source language interference is a problem often experienced by translators that is partly caused by the influence of cognates and false friends. Research in natural language processing can address these bottlenecks by, for instance, developing computer tools that aid second language users.

Nevertheless, most studies have mainly focused on the detection of cognates (Bergsma and Kondrak, 2007; Hauer and Kondrak, 2011; Ciobanu and Dinu, 2014; Rama, 2016), while relatively little attention has been devoted to false friends (Frunza and Inkpen, 2007; Mitkov et al., 2007; Ljubešić and Fišer, 2013; Castro et al., 2018). Mitkov (2007) explains that the main goal of investigation is often the cross-lingual identification of equivalent lexical items, as such knowledge can be integrated in other applications. Automatic cognate detection has indeed proven very useful for NLP, e.g. to boost the performance of automatic alignment between related languages or to compile bilingual lexicons (Smith et al., 2017).

The aim of this research is twofold: (1) we introduce a context-independent gold standard which can be used to classify English-Dutch pairs of cognates and non-cognates (among which false friends); (2) we develop a supervised binary classifier able to identify cognates across the English-Dutch language pair on the basis of orthographic and semantic information. Since our focus lies on the detection of cognates for these proof-of-concept experiments, no distinction is made between false friends and non-equivalent words.

The remainder of this paper is organized as follows. In Section 2, we give a brief overview of

Proceedings of Recent Advances in Natural Language Processing, pages 602–610,
Varna, Bulgaria, Sep 2–4 2019.

the existing research and methodologies to cognate detection. Section 3 describes the data and annotation process used to create the context-independent gold standard for English-Dutch cognate pairs, while Section 4 gives an overview of the experimental setup and the two types of information sources, viz. orthographic and semantic similarity features, that were used. In section 5, we report on the results of our classifier (1) incorporating only orthographic features and (2) combining orthographic and semantic similarity features. Section 6 concludes this paper and gives directions for future research.

2 Related Research

Extensive lists of known cognates and false friends are hard to find and expensive to compose, since they require a considerable amount of time and effort from trained lexicographers (Schepens et al., 2012). Especially for low resource languages, this constitutes a serious issue. Therefore, most NLP research on cognates has mainly focused on the automatic detection of such cognate pairs. In the literature, there are three main methods to identify cognates: orthographic, phonetic and semantic approaches. The oldest approaches to tackle this task involve simple string similarity metrics as the longest common subsequence ratio (Melamed, 1999) or the normalized Levenshtein distance (Levenshtein, 1965). More recently, however, the attention has been drawn to machine learning techniques. For instance, Frunza et al. (2007) combine several orthographic similarity measures to train a machine classifier, while Gomes et al. (2011) design a new similarity metric that is able to learn spelling differences across languages.

Different types of approaches can also be combined to distinguish cognates, e.g. Kondrak et al. (2004) join orthographic and phonetic information to distinguish between similar drug names. In order to capture the phonetic similarity between words, Konrak (2000) further developed a software package, called ALINE, which portrays phonemes as vectors of phonetic features, thus creating a phonetic similarity measure. Nevertheless, Heeringa et al. (2010) find that simple phonetic transcriptions still seem to outperform phonetic similarity metrics that are based on phonetic features. Hence, Schepens et al. (2013) propose to calculate a substitution cost for each pair of phonetically transcribed words by taking the edit distance between them. For this research, we opted to only focus on the orthographic proximity, as sound metrics require an additional phonetic transcription, thus making them less-likely to be applied on large data sets. Moreover, Schepens et al. (2013) find that there is a high consistency between orthographic and phonetic similarity measures for Dutch-English cognate pairs.

Whereas orthographic and phonetic features have often been employed to model the similarity between candidate cognate pairs, semantic information has often been ignored. Mitkov (2007) beliefs that this is another result of the main focus of investigation, which is the identification of cognates rather than distinguishing cognates from false friends. Semantic evidence is, however, an important information source, as it can not only be used to represent the semantic (dis)similarity between word pairs, but it can also further increase the accuracy of cognate detection systems. In his own research, Mitkov (2007) distinguishes between two types of semantic approaches: taxonomic and distributional semantic similarity measures. Whereas the first group relies on the taxonomic structure of a resource such as WordNet (Miller, 1995), the second approach relies on large corpora. The latter methods are based on the Distributional Hypothesis (Harris, 1954), which states that words that appear in similar contexts tend to share similar meanings. The different approaches that leverage this principle are typically divided into two categories: count-based methods, such as Latent Semantic Analysis, and predictive methods, such as neural probabilistic language models, which have gained a lot of popularity in today's NLP community. On the one hand, count-based models count how often a given target word co-occurs with its neighbor words in a large text corpus, after which the resulting counts are mapped to a dense vector for each word. On the other hand, predictive models directly try to predict a word from its neighbors in terms of learned dense embedding vectors (Baroni et al., 2014). Word2vec (Mikolov et al., 2013) is a particularly computationally-efficient and popular example of predictive models for learning word embeddings from raw text. In this research, we will incorporate the more recent fastText word embeddings as implemented by Bojanowski et al. (2017).

3 Data Creation

To train and evaluate the cognate detection system, we created a novel context-independent gold standard by manually labelling English-Dutch pairs of cognates and false friends in bilingual term lists. In this section, we describe how the lists of candidate cognate pairs were compiled on the basis of the Dutch Parallel Corpus (Macken et al., 2011) and how a manual annotation was performed to create a gold standard for English-Dutch cognate pairs.

3.1 List of Candidate Cognate Pairs

To select a list of candidate cognate pairs, unsupervised statistical word alignment using GIZA++ (Och and Ney, 2003) was applied on the Dutch Parallel Corpus (DPC). This high-quality parallel corpus for Dutch, French and English consists of more than ten million words and is sentence-aligned. It contains five different text types and is balanced with respect to text type and translation direction. The automatic word alignment on the English-Dutch part of the DPC resulted in a list containing more than 500,000 translation equivalents. A first selection was performed by applying the Normalized Levenshtein Distance (NLD) (as implemented by Gries (2004)) on this list of translation equivalents and only considering equivalents with a distance smaller than or equal to 0.5. This resulted in a list with 28,503 Dutch-English candidate cognate pairs, which was manually labeled.

3.2 Creation of Gold Standard

To create the gold standard for cognate detection, an extensive set of guidelines was established (Labat et al., 2019). The guidelines propose a clearly defined method for the manual labeling of the following six categories:

1. **Cognate**: words which have a similar form and meaning in all contexts. Conform with our working definition for cognates, the source and target words do not need to be etymologically related.

2. **Partial cognate**: words which have a similar form, but only share the same meaning in some contexts.

3. **False friend**: words which have a similar form but a different meaning.

4. **Proper name**: proper nouns (e.g. persons, companies, cities, countries, etc.) and their derivations (e.g. *American*).

5. **Error**: word alignment errors and compound nouns of which one part is a cognate but the other part is missing in one of the languages (e.g. *peripherals - aansturingsperipherals*).

6. **No standard**: words that do not occur in the dictionary (e.g. *num_connectors*) and numbers (e.g. *adm12006e, VI*).

To decide on the correct label, we adopted a context-independent approach applying the following procedure: (1) for every candidate cognate pair, the dictionary Grote Van Dale[1] (henceforth: VD) was consulted; (2) the English word is looked up in the VD, e.g. *salon*, (3) the Dutch translation is inspected in the VD, e.g. *salon: "nice room"* and *salon: "(room for) gathering of people (e.g. from the literary world)"*.

Based on the previously obtained information, a decision is made: in case all meanings of the Dutch word correspond with the English word, we consider them "cognates", in case only part of the Dutch meanings correspond with the English word, we consider them "partial cognates", in case the words have different meanings, we consider them "false friends". An example of partial cognates is the pair *agent-agent*: the Dutch *agent* refers both to (1) a police man and to (2) a representative (e.g. business representative). As only the second meaning of the Dutch word is expressed by the English *agent*, these words are considered partial cognates.

Two important observations should be made. Firstly, we accorded more fine-grained labels in the gold standard that are described in great detail in the annotation guidelines (Labat et al., 2019). For cognates, a distinction was, for instance, made between cognates of which Part-of-Speech (PoS) and meaning are identical in both languages, cognates that differ in PoS (e.g. *organisatie-organizing*) and cognates that differ in agreement (e.g. *organisatie-organisations*). Secondly, it is important to note that a successful dictionary look-up never overruled the "proper name" annotation.

The resulting gold standard is context-independent. Hence, it can be used for both the development and the evaluation of machine

[1] https://www.vandale.be/

learning models that deal with cognate detection. Besides its applications in natural language processing, the gold standard can also form an important new resource for further research on cognates in linguistics, translation studies or psycho-linguistics.

4 Classification

This section describes the experimental setup and the two types of information sources, viz. orthographic similarity and semantic similarity, that were incorporated for the experiments.

4.1 Experimental Setup

In this paper, cognate detection was approached as a supervised classification task. To this end, we applied Support Vector Machines as implemented in sklearn (Pedregosa et al., 2011).

The data set used for the binary classification experiments consisted of the COGNATE pairs (labels "cognate" and "partial cognate") and NON-COGNATE pairs (labels "error" and "false friend"). The categories of "proper name" and "no standard" were removed from the data set as they are always identical translations and would boost the performance of the system in an artificial way. Table 1 gives an overview of the distribution of the two classes in the gold standard data set.

	Cognate	Non-cognate	Total pairs
GS	9,855	4,763	14,618

Table 1: Distribution of the "cognate" and "non-cognate" class labels in the gold standard (GS).

In order to train and test the system, we performed 5-fold cross-validation for which we fixed our 5 subsamples. Hyperparameter optimisation was performed by means of a 5-fold cross-validation grid search on the training folds, resulting in the following values: $kernel$ = RBF, C = 5, $class\ weight$ = None and $gamma$ = 5.

4.2 Orthographic Similarity Features

Fifteen different string similarity metrics were applied on the candidate cognates to measure the formal relatedness between source and target words. Eleven of these fifteen metrics were also used by Frunza et al. (2007). The following list briefly summarizes the orthographic features implemented:

- **Prefix** divides the length of the shared prefix by the length of the longest cognate in the pair.
- **Dice** (Brew and McKelvie, 1996) divides the number of common bigrams times two by the total number of bigrams in the cognate pair, as in $\frac{2 \times |bigrams(x)| \cap |bigrams(y)|}{|bigrams(x)| + |bigrams(y)|}$.
- **Dice (trigrams)** differs from Dice in that it uses trigrams instead of bigrams.
- **XDice** is a variant of Dice as it uses bigrams that are created out of trigrams by deleting the middle letter in them.
- **XXDice** incorporates the string positions of the bigrams into its metric. Therefore, the denominator is no longer multiplied by two, but by $\frac{2}{1 + (pos(x) - pos(y))^2}$.
- **LCSR** stands for the longest common subsequence ratio, which is two times the length of the longest subsequence over the summed length of both sequences.
- **NLS** or the Normalized Levenshtein Similarity equals one minus the minimum number of edits required to change one string sequence to another.
- **LCSR (bigrams), NLS (bigrams), LCSR (trigrams), and NLS (trigrams)** differ from their standard metrics in that they use, respectively, bigrams and trigrams to calculate their results.
- **Jaccard index** models the length of the intersection of both cognate strings over the length of the union of these strings.
- **Jaro-Winkler similarity** is the complement of the Jaro-Winkler distance. Word pairs that from their beginning correspond to a set prefix length will receive higher scores.
- **Spsim option 1 and Spsim option 2** are the only metrics which require supervised training, in order to learn grapheme mappings between language pairs (Gomes and Pereira Lopes, 2011). They are trained by performing 5-fold cross-validation on the positive instances (i.e. cognates) in the data set. Therefore, we created two different train

sets: option 1 includes cognate pairs which differ in agreement or PoS-tags, while option 2 only includes cognates and partial cognates.

4.3 Semantic Information

Besides features that model formal similarity between word pairs, we also included semantic information in our classifier. We opted for word embeddings, as these have shown to be very effective for various NLP tasks. In addition, word embeddings have not yet been used for the task of cognate identification. For the purpose of this research, we worked with fastText word embeddings that were pre-trained on the Wikipedia corpus with the skip-gram model proposed by Bojanowski et al. (2017). The model was trained with the default parameters and the length of the vector was set to 300. A disadvantage of using text-formatted pre-trained embeddings is that we could not generate embeddings for all words in the gold standard list. As a result, we only obtained word embeddings for 12,433 instances, while we have orthographic information for 14,618 instances. Table 2 gives an overview of the distribution of the two classes in the full and reduced gold standard data sets. The experimental results that we obtained for this subset are presented in Section 5.2.

	Cognate	Non-cognate	Total pairs
Ortho	9,855	4,763	14,618
Semantic	8,935	3,498	12,433

Table 2: Distribution of the “cognate” and “non-cognate” class labels in the full (*Ortho*) and reduced (*Semantic*) gold standard data sets.

We chose to work with fastText embeddings instead of regular Word2Vec embeddings because the former model uses n-grams to train its embeddings. In contrast to the Word2Vec models, fastText can create word embeddings for out-of-vocabulary words, which is especially important for low-frequent words. Although the current research only works with pre-trained word entries, in future research we plan to add out-of-vocabulary words by training word embeddings on domain-specific corpora more similar to the DPC corpus that was used to extract the list of candidate cognate pairs. This way, we hope to construct embeddings for all word pairs in the gold standard list.

Once the results for the Dutch and English monolingual embeddings were loaded, the Dutch embeddings were mapped to the English vector space by means of a pre-trained alignment matrix (Smith et al., 2017). Since the embeddings are then situated in the same vector space, one can easily compute the cosine similarity between the two words of a candidate cognate pair. Subsequently, this cosine similarity was used as a semantic feature for our machine learning system.

5 Experimental Results

This section describes the classification results for two sets of experiments, namely (1) a classifier incorporating fifteen orthographic similarity features and (2) a classifier combining the same set of orthographic similarity features with a semantic feature resulting from computing the cosine similarity between the word embeddings of the cognate pair.

5.1 Experiment 1: Orthographic Features

A first set of experiments was conducted to evaluate the performance of the orthographic similarity features for the task of cognate detection. Table 3 lists the averaged precision, recall and F1-score for all individual orthographic similarity features and their combination.

The results show a very good performance of the classifier combining all orthographic similarity information (average F-score of 84%). Especially precision improves considerably when combining the different orthographic similarity metrics. When looking into the results for the individual features, it is clear that some metrics perform very well in isolation, such as LCSR and NLS, which obtain F-scores of around 85% for the positive class (“Cognates”) with good balance of precision and recall.

To get further insight in the informativeness of the various orthographic features, we also trained a conditional inference tree and random forest on the cognate data set. Figure 1 visualizes the model learned by the conditional inference tree at depth 3. The tree indicates which orthographic metric is the most important for that node in the tree. As can be observed in Figure 1, the longest common subsequence ratio is overall the most influential metric, followed by SpSim (option 1) and the Jaro-Winkler similarity.

In addition to the conditional inference tree, a

Table 3: Precision (Prec), Recall (Rec) and F1-score for the individual orthographic similarity features and for the classifier combining all features (%).

random forest was trained in order to further investigate the importance of each metric. Since a random forest uses lots of seeds (in our case: 123) in order to decide on the importance of each variable individually, it provides a somewhat more representative, validated picture of the influence of different metrics. An additional Somers' D value was computed for the random forest in order to check the goodness of fit. With a correlation score of 0.9528739, our random forest forms a good model for unseen data. Figure 2 shows that the model agrees with the conditional inference tree in that it also classifies LCSR, SpSim (option 1) and the Jaro-Winkler similarity as important metrics for the identification of cognates. It does, however, provide some additional information, as it shows that the normalized Levenshtein similarity is also very influential for this binary classification task.

5.2 Experiment 2: Orthographic and Semantic Features

In a second set of experiments, we combined all orthographic similarity features with a semantic feature expressing the cosine similarity between the two word embeddings. Table 4 shows the result of the classifiers incorporating (1) only semantic information and (2) a combination of orthographic and semantic similarity information. As this set of experiments is only conducted on that part of the data set for which word embeddings were retrieved, we also added the updated performance scores for all individual orthographic metrics on this reduced data set.

The classification results listed in Table 4 show some interesting findings. First of all, the embeddings in isolation already obtain good classification results for the "Cognates" class (F-score of 89.14%). Second, the classifier combining orthographic and semantic similarity features clearly outperforms the classifier only incorporating orthographic information.

An analysis of the output reveals that the semantic information indeed helps to detect cognate pairs showing less orthographic resemblance (e.g. *east–oost, older–ouderen, widespread–wijdverbreid, asleep–slaap, sweating–zweten, shame–schaamte, belief–geloof, whole–hele, swarm–zwerm, overheated–oververhitte*). In addition, the word embedding information also generates less false negatives. Examples of pairs that were wrongly labeled as cognates by the classifier relying on orthographic information and that are correctly labeled as non-cognates by the combined classifier are: *affects–effecten, unlocking–blokkering, investments–instrument, slit–gesplit, provide–profielen, brazier–branden, might–high, where–wateren*. On the other hand,

the combined classifier rarely introduces additional false negatives (seven instances in total, e.g. *lead–leiden, include–inhouden, docker–dokwerker*) or additional false positives (three instances in total: *told–toen, escapologist–escapist, because–bepaalde*).

6 Conclusion and Future Work

This paper presents preliminary experiments for combining orthographic and semantic similarity information for cognate detection. The experimental results already show promising scores for

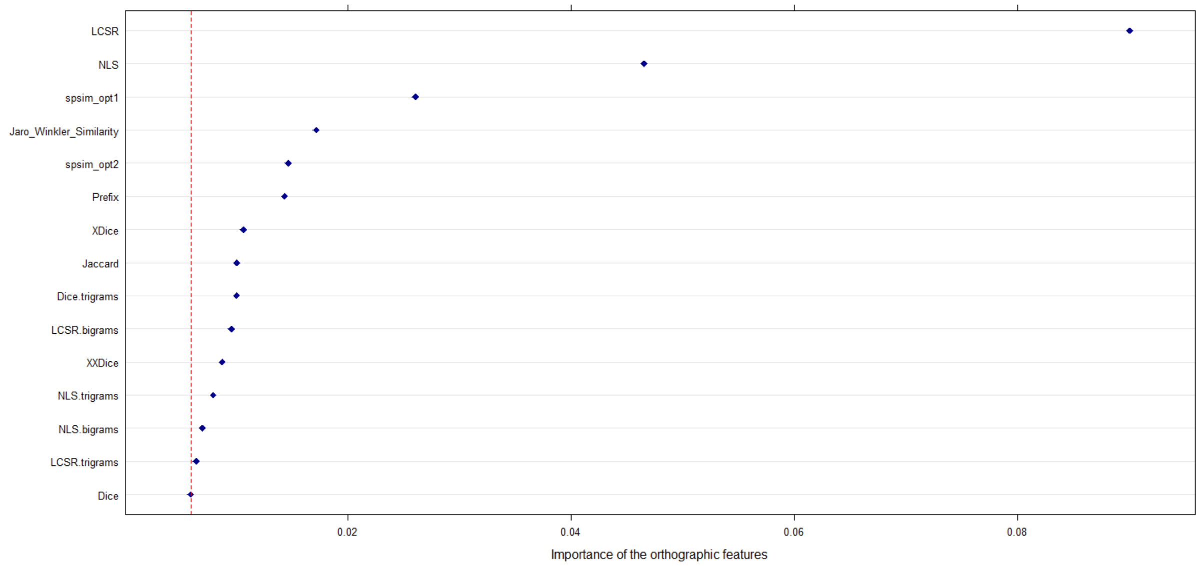

Figure 2: Random Forest indicating the importance the different orthographic similarity features for the current cognate identification task.

a classifier using merely orthographic similarity information. The results, however, revealed that adding semantic information capturing the cosine similarity between the word embeddings of the Dutch and English terms further improves the classification results considerably. As a result, we can conclude that combining orthographic and semantic similarity information is a viable approach to automatic cognate detection.

As we presented proof-of-concept results in this research, there is still a lot of room for future research. Firstly, the implementation of alternative word embeddings is an important direction for future work. We will perform additional experiments with (1) larger and different (e.g. domain-specific) corpora and (2) other embedding approaches to improve the semantic information based on embedding distance. We are confident this will result in high-level quality embeddings for all candidate cognate pairs.

Secondly, it would be interesting to perform multi-class experiments, where a distinction is made between cognates, false friends and non-related word pairs. To this end, a training and evaluation corpus containing cognate candidates in context will be built and manually annotated.

Finally, we plan to compile the corresponding gold standard set for French-Dutch, which is also part of the Dutch Parallel Corpus. This will allow an evaluation of our approach for a different language pair. In addition, this will enable us to perform trilingual machine learning experiments and to gain useful insights into cross-lingual cognate detection.

Resolving Pronouns for a Resource-Poor Language, Malayalam Using Resource-Rich Language, Tamil

Sobha Lalitha Devi
AU-KBC Research Centre, Anna University, Chennai
sobha@au-kbc.org

Abstract

In this paper we give in detail how a resource rich language can be used for resolving pronouns for a less resource language. The source language, which is resource rich language in this study, is Tamil and the resource poor language is Malayalam, both belonging to the same language family, Dravidian. The Pronominal resolution developed for Tamil uses CRFs. Our approach is to leverage the Tamil language model to test Malayalam data and the processing required for Malayalam data is detailed. The similarity at the syntactic level between the languages is exploited in identifying the features for developing the Tamil language model. The word form or the lexical item is not considered as a feature for training the CRFs. Evaluation on Malayalam Wikipedia data shows that our approach is correct and the results, though not as good as Tamil, but comparable.

1 Introduction

Natural language processing techniques of the present day require large amounts of manually-annotated data to work. In reality, the required quantity of data is available only for a few languages of major interest. In this work we show how a resource-rich language, Tamil, can be leveraged to resolve anaphora for a related resource-poor language, Malayalam. Both Tamil and Malayalam belong to the same language family, Dravidian. The methods we focus on exploits the similarity at the syntactic level of the languages and anaphora resolution heavily depends on syntactic features. If the resources available in one language (henceforth referred to as source) can be used to facilitate the resolution, such as anaphora, for all the languages related to the language in question (target), the problem of unavailability of resources would be alleviated.

There exists a recent research paradigm, in which the researchers work on algorithms that can rapidly develop machine translation and other tools for an obscure language. This work falls into this paradigm, under the assumption that the language in question has a less obscure sibling. Moreover, the problem is intellectually interesting. While there has been significant research in using resources from another language to build, for example, parsers, there have been very little work on utilizing the close relationship between the languages to produce high quality tools such as anaphora resolution (Nakov, P and Tou Ng,H 2012). In our work we are interested in the following questions:

If two languages are from the same language family and have similarity in syntactic structures and not in lexical form and script

1. Can the language model developed for one language be used for analyzing the other language?
2. How the lexical form difference can be resolved in using the language model?
3. How to overcome the challenges of script variation?

In this work we develop a language model for resolving pronominals in Tamil using CRFs and using the language model test another language, Malayalam. As said earlier, in this work, we are focusing on Dravidian family of languages. Historically, all Dravidian languages have branched out from a common root Proto-Dravidian. Among the Dravidian languages, Tamil is the oldest language. Though there is similarity at the syntactic level, there is no similarity in lexical form or at the script level among the languages. We are motivated by the observation that related languages tend to have similar word order and syntax, but they do not have similar script or orthography. Hence words are not similar.

Tamil has the most resources at all levels of linguistics, right from morphological analyser to discourse parser and Malayalam has the least. About the similarity of the two languages we give in detail in section 2.

The remainder of this article is organized as follows: Section 2 provides a detailed description of the two languages, their linguistic similarity credits and differences, Section 3 presents the pronominal resolution in Tamil. In Section 4 we introduce our proposed approach on how the language model for Tamil can be used for resolving Malayalam pronouns. Section 5 describes the datasets used for evaluation, experiments and analysis of the results and the paper ends with the conclusion in Section 6.

2 How similar the languages Tamil and Malayalam Are?

As mentioned earlier, both the languages belong to the Dravidian family and are relatively free word order languages, inflectional (rich in morphology), agglutinative and verb final. They have Nominative and Dative subjects. The pronouns have inherent gender marking as in English and have the same lexical form "avan" "he", "aval" "she" and "atu" "it" both in Tamil and Malayalam. Though the pronouns have same lexical form and meaning, it can be said that there is no lexical similarity between the two languages. The similarity between two languages can be at three levels, a) writing script, b) the word forms and c) the syntactic structure.

Script Level: The two languages have different writing form, though the base is from Grandha script. Hence no similarity at the script level.
The Word Level: There is no similarity at the lexical level between the two languages. The Sanskritization of Malayalam contributed to have more Sanskrit verbs in Malayalam whereas Tamil retained the Proto –Dravidian verbs. For example, the word for "talk" in Malayalam is "samsarikkuka" "to talk" which has root in Sanskrit, whereas the Tamil equivalent is "pesuu" "to talk", the root in Pro-Dravidian.
The Syntactic Structure Level: There is lot of similarity at the syntactic structure level between the two languages. Since antecedent to anaphor has dependency on the position of the noun, the structural similarity is a positive feature for our goal. The syntactic similarity at Sentence level, Case maker level, pronominal distribution level are explained with examples.
Case marker level: Both the languages have the same number of cases and their distribution is similar. In both the languages, nouns inflected with nominative or dative case become the subject of the sentence (Dative subject is the peculiarity of Indian languages). Accusative case denotes the object.
Clausal sentences: The clause constructions in both the languages follow the same rule. The clauses are formed by nonfinite verbs. The clauses do not have free word order and they have fixed positions. Order of embedding of the subordinate clause is same in both the languages.
Ex:1

(Ma) [innale vanna(vbp) kutti]/Sub-RP-cl
{sita annu}/Main cl

(Ta) [neRu vanta(vbp) pon]/Sub- RP-cl
{sita aakum}/Maincl

[Yesterday came girl]/subcl
{Sita is}/ Maincl

(The girl who came yesterday is Sita)

As can be seen from the above example, the basic syntactic structure is the same in both the languages. The above example is a two clause sentence with a relative participial clause and a main clause. The relative participial clause is formed by the nonfinite verb (vbp). Using the same example we can find the pronominal distribution.
Ex: 2

(Ma) [innale vanna(vbp) aval$_i$ (PRP)
]/Sub-RP-cl {sita$_i$ annu}/Main cl
(Ta) [neRu vanta(vbp) aval$_i$ (PRP)
]/Sub-RP-cl {sita$_i$ aakum}/Maincl
[Yesterday came she$_i$ (PRP)
]/subcl { Sita$_i$ is} / Maincl
(The she who came yesterday is Sita)

In the above example the pronoun "aval" "she" occurs at the same position in both the languages and the antecedent “sita” also occurs at the same position as shown by co-indexing. Consider another example.

Ex:3

(Ma). sithaa$_i$ kadaikku pooyi. aval$_i$ pazham
Vaangicchu(Vpast)

(Ta). sithaa$_i$ kadaikku cenRaal. aval$_i$ pazham
Vaangkinaal(V,past,+F,+Sg).
Sita shop went. She fruit
bought
(Sita$_i$ went to the shop. She$_i$ bought fruit.)

In the above example there are two sentences and pronoun is in one sentence and antecedent is in another. Here you can see the distribution of the pronoun “aval” and where the antecedent “sita” is occurring. Though Tamil has number, gender and person agreement between subject and verb and Malayalam does not have, this cannot be considered as a grammatical feature which can be used for identifying the antecedent of an anaphor. This grammatical variation does not have an impact on the identification of pronoun and antecedent relations. From the above examples we can see that the two languages have the same syntactic structure at the clause and sentence level. We are exploiting this similarity between the two languages to achieve our goal. We find that using this similarity between the languages, the language model of Tamil can be used to resolve pronouns in Malayalam.

3 Pronoun Resolution in Tamil

3.1 Pronouns in Tamil

In this section, we analyse in detail the pronominal expressions in Tamil. Pronouns are the words used as a substitution to nouns, that are already mentioned or that is already known. There are pronouns which do not refer. Pronouns in Tamil have person (1st, 2nd, 3rd person) and number (singular, plural) distinction. Masculine, feminine and neuter gender distinctions are clearly marked in 3rd person pronouns, whereas in 1st and 2nd person pronouns there is no distinction of masculine, feminine and neuter gender. In this work we consider only third person pronouns. Third person pronouns in Tamil have inherent gender and as in English and they are “avan” he, “aval” she and “atu” it. In this work, we resolve 3rd person pronouns. The distribution of pronouns in various syntactic constructions is explained with examples below.

Ex:4

4a. ***maaNavarkaL****$_i$ paLLikku celkiranar.*
Students(N) school(N)+dat go(V)+present+3pl
(Students are going to the school)

4b. ***avarkaL****$_i$ veekamaaka natakkinranar.*
They(PN) fast(ADV) walk(V)+present+3pl
(They are walking fast.)

Considering Ex 4a and Ex.4b, sentence Ex.4b has 3rd person plural pronoun ‘avarkaL’ as the subject and it refers to plural noun ‘maaNavarkaL’ which is the subject in Ex.4a.

Ex:5

5a. ***raamuvum****$_i$* ***giitavum****$_j$ nanparkaL.*
Raamu(N)+INC Gita(N)+INC friends(N)
(Ramu and Gita are friends.)

5b. ***avan****$_i$ ettaam vakuppil padikkiraan.*
He(PN) eight(N) class(N) study(V)+present+3sm
(He studies in eight standard.)

5c. ***avaLum****$_j$ ettaam vakuppil padikkiaal.*
She(PN) eight(N) class(N) study(V)+present+3sf
(She also studies in eight standard.)

In Ex.5b, 3rd person masculine pronoun ‘avan’ occurs as the subject and it refers to the masculine noun ‘raamu’, subject noun in Ex.5a. Similarly, 3rd person feminine pronoun ‘avaL’ in Ex.5c refers to feminine noun ‘giita’ in Ex.3a. ‘atu’, which is a 3rd person neuter pronoun, will also occurs as genitive/possessive case marker. Consider the following example.

3.1.1 Non-anaphoric Pronouns

The pronouns can also occur as generic mentions without having referent. In English it known as‘pleonastic it’.

Ex:6.

atu *oru malaikalam.*
It(PN) one(Qc) rainy_season (N)
(It was a rainy season.)

In Ex.6, the 3rd person neuter pronoun ‘atu’ (it) do not have a referent. Here ‘atu’ is equivalent to pleonastic ‘it’ in English

3.1.2 Corpus annotation

We collected 600 News articles from various online Tamil News wires. The News articles are from Sports, Disaster and General News domains. The anaphoric expressions are annotated along with its antecedents using graphical tool, PAlinkA, a highly customisable tool for Discourse Annotation (Orasan, 2003) which we customized for Tamil. We have used two tags namely, MARKABLE and COREF. The corpus used for training is 54,563 words which are annotated for anaphora –antecedent pairs and testing corpus is 10,912 words. We have calculated the inter-annotator agreement which is the degree of agreement among annotators. We have used Cohen's kappa as the agreement statistics. The kappa coefficient is generally regarded as the statistics of choice for measuring agreement on ratings made on a nominal scale. We got a Kappa score of 0.87. The difference between the annotators were analysed and found the variation in annotation. It occurred in the marking of antecedents for pronominal. This is common in sentences with clausal inversion, and genitive drop.

3.2 Pronoun Resolution System

Early works in anaphora resolution by Hobbs (1978), Carbonell and Brown (1988), Rich and Luper Foy (1988) etc. were mentioned as knowledge intensive approach, where syntactic, semantic information, world knowledge and case frames were used. Centering theory, a discourse based approach for anaphora resolution was presented by Grosz (1977), Joshi and Kuhn (1979). Salience feature based approaches were presented by Lappin and Leass (1994), Kennedy Boguraev (1996) and Sobha et al., (2000). Indicator based, knowledge poor method for anaphora resolution methods were presented by Mitkov (1997, 1998). One of the early works using machine learning technique was Dagan Itai's (1990) unsupervised approach based on co-occurrence words. With the use of machine learning techniques researchers work on anaphora resolution and noun phrase anaphora resolution simultaneously. The other machine learning approaches for anaphora resolution were the following. Aone and Bennett (1995), McCarty and Lahnert (1995), Soon et al., (2001), Ng and Cardia (2002) had used decision tree based classifier. Anaphora resolution using CRFs was presented by McCallum and Wellner (2003) for English, Li et al., (2008) for Chinese and Sobha et al., (2011, 2013) for English and Tamil.

In Indian languages anaphora resolution engines are demonstrated only in few languages such as Hindi, Bengali, Tamil, and Malayalam. Most of the Indian languages do not have parser and other sophisticated pre-processing tools. The earliest work in Indian language, 'Vasisth' was a rule based multilingual anaphora resolution platform by Sobha and Patnaik (1998, 2000, 2002), where the morphological richness of Malayalam and Hindi were exploited without using full-parser. The case marker information is used for identifying subject, object, direct and in-direct object. Prasad and Strube (2000), Uppalapu et al., (2009) and Dekwale et al., (2013) had presented different approaches using Centering theory for Hindi. Sobha et al., (2007) presented a salience factor based with limited shallow parsing of text. Akilandeswari et al., (2013) used CRFs for resolution of third person pronoun. Ram et al., (2013) used Tree CRFs for anaphora resolution for Tamil with features from dependency parsed text. In most of the published works resolution of third person pronoun was considered and it is a non-trivial task.

Pronoun resolution engine does the task of identifying the antecedents of the pronouns. The Pronoun resolution is built using Conditional Random Fields (CRFs) technique. Though CRFs is notable for sequence labelling task, we used this technique to classify the correct anaphor-antecedent pair from the possible candidate NP pairs by presenting the features of the NP pair and by avoiding the transition probability. While training we form positive pairs by pairing anaphoric pronoun and correct antecedent NP and negative pairs by pairing anaphoric pronouns and other NPs which match in person, number and gender (PNG) information with the anaphoric pronoun. These positive and negative pairs are fed to the CRFs engine and the language model is generated. While testing, when an anaphoric pronoun occurs in the sentence, the noun phrases which match in PNG with the pronoun, that occur in the preceding portion of the sentence and the four preceding sentences are collected and paired with the anaphoric pronoun and presented to CRFs engine to identify the correct anaphor-antecedent pair.

3.2.1 Pre-processing

The input document is processed with a sentence splitter and tokeniser to split the document into sentences and the sentences into individual tokens which include words, punctuation markers and symbols. The sentence split and tokenized documents are processed with Syntactic Processing modules. Syntactic processing modules include Morphological analyser, Part-of-Speech tagger and Chunker. These modules are developed in house.

a) **Morphological Analyser:** Morphological analysis processes the word into component morphemes and assigning the correct morpho-syntactic information. The Tamil morphological Analyser is developed using paradigm based approach and implemented using Finite State Automata (FSA) (Vijay Sundar et.al 2010). The words are classified according to their suffix formation and are marked as paradigms. The number of paradigms used in this system is Noun paradigms: 32; Verb Paradigms: 37; Adjective Paradigms: 4; Adverb Paradigms: 1. A root word dictionary with 1, 52,590 root words is used for developing the morphological anlyser. The morphological analyser is tested with 12,923 words and the system processed 12,596 words out of which it correctly tagged 12,305. The Precision is 97.69% and Recall = 97.46%. MA returns all possible parse for a given word.

b) **Part Of Speech Tagger (**POS tagger): Part of Speech tagger disambiguates the multiple parse given by the morphological analyser, using the context in which a word occurs. The Part of speech tagger is developed using the machine learning technique Conditional Random fields (CRF++) (Sobha L, et.al 2010). The features used for machine learning is a set of linguistic suffix features along with statistical suffixes and uses a window of 3 words. We have used 4, 50,000 words, which are tagged using BIS POS tags. The system performs with recall 100% and Average Precision of 95.16%.

c) **Noun and Verb Phrase Chunker:** Chunking is the task of grouping grammatically related words into chunks such as noun phrase, verb phrase, adjectival phrase etc. The system is developed using the machine learning technique, Conditional Random fields(CRF++) (Sobha L et.al 2010). The features used are the POS tag, Word and window of 5 words. Training Corpus is 74,000 words. The recall is 100%. Average Precision of 92.00%.

3.3 Pronoun Resolution Engine

In both training and testing phase, the noun phrases (NP) which match with the PNG of the pronoun are considered. The features are extracted from these NPs. In the training phase the positive and negative pairs are marked and fed to the ML engine for generating a language model. In the testing phase these NPs with its features are input to the language model to identify the antecedent of a pronoun. Here we have not taken the lexical item or the word as a feature. We have used only the grammatical tags as feature. The features selected represent the syntactic position of the anaphor –antecedent occurrence.

3.3.1 Features Selection

The features required for machine learning are identified from shallow parsed input sentences. The features for all possible candidate antecedent and pronoun pairs are obtained by pre-processing the input sentences with morphological analyser, POS tagger, and chunker. The features identified can be classified as positional and syntactic features

Positional Features: The occurrence of the candidate antecedent is noted in the same sentence where the pronoun occurs or in the prior sentences or in prior four sentences from the current sentence.

Syntactic Features: The syntactic arguments of the candidate noun phrases in the sentence are a key feature. The arguments of the noun phrases such as subject, object, indirect object, are obtained from the case suffix affixed with the noun phrase. As mentioned in section 2 the subject of a sentence can be identified by the case marker it takes. We use morphological marking for the above.

a) PoS tag and chunk tag of Candidate NP, case marker tags of the noun.
b) The suffixes which show the gender which gets attached to the verb.

3.3.2 Development of Tamil Language Model

We used 600 Tamil Newspaper articles for building the language model. The preparation of the training data is described below. The raw corpus is processed with sentence splitter and tokeniser. The tokenized corpus is then preprocessed with shallow processing modules, namely, morphological analyser, part-of-speech tagger and chunker. The training data is prepared from this processed corpus. For each pronoun, the Noun phrase (NP) preceding the pronouns and in the NPs in preceding sentence till correct antecedent NP, which match in Person, number and Gender (PNG) are selected for training. The above features are used for CRF for learning. The system was evaluated with data from the web and the result is given below.

Domain	Testing Corpus (Words)	Precision (%)	Recall (%)
News data	10,912	86.2	66.67

Table 1: Pronominal Resolution (CRFs engine)

4. Resolution of Pronouns in Malayalam Corpus using Tamil Language Model

In this section, we present in detail how Malayalam is tested using Tamil language model. Here Malayalam data is pre-processed as per the requirement of the Tamil language model test data. The test data required four grammatical information, i) POS, ii) the case marker, iii) the number gender and person and iv)chunk information. In the introduction we have asked three questions on how to use a language model in source language be used for testing a target language. The three questions are dealt one by one below.

1. Can the language model developed for one language be used for analyzing the other language?

In this study we have used the language model of the source language Tamil. The features used to develop this language model are POS tag, Chunk tag and the case/ suffix tags. The word form was not considered as a feature. Since these are the features used for learning, the test data also should have these information. As said earlier, Malayalam is not a resource rich language and it does not have pre-processing engines such as POS tagger, Chunker and morphological analysers with high accuracy. Hence we developed a very rudimentary preprocessing systems which can give the POS tag, case/suffix tags and chunk tags.

The POS information: The POS and suffix information are assigned to the corpus using a root word dictionary with part of speech information and a suffix dictionary.

The dictionary has the root words which include all types of pronouns and contains nearly 66,000 root words. The grammatical information (POS) such as noun, verb, adjective, pronoun and number gender person (PNG) information are given for a word in the dictionary.

The suffix dictionary contains all possible suffixes which a root word can take. The suffix includes the changes in sandhi when added to the root word. The suffixes are of two types, i) that which gets attached to nouns called the case suffixes and 2) that which gets attached to verbs called the TAM (Tense, Aspect, and Modal). Using this suffix dictionary we can identify the POS of the word even if the word is not present in the root word dictionary. The suffix dictionary has 1,00,000 unique entries.

The noun chunk information is given by a rule based chunker which works on three linguistic rules. The noun phrases alone are required for anaphora resolution. Chunks are identified using the basic linguistic rule for Noun phrases as given below

1. [determiner] [quantifier][intensifier] [classifier][adjective] {Head Noun}. Here Head noun is obligatory and others are all optional
2. NN+NN combination

3. NN with no suffix+NN with no suffix…… +NN with suffix or without suffix.

Using the above rules we identified the noun chunks in Malayalam. The above discussed preprocessing gives an accuracy of 66% for POS and suffix tagging and 63% for chunking.

2. How the lexical form difference can be resolved in using the language model?

The second question we asked is about the lexical form or words which are not similar in both the languages and how this can be resolved. The analysis of Tamil has shown that the syntactic structure of the language has more prominence over the words in the resolution of anaphors. Hence we have taken the syntactic features and did not take word as a feature. The system learned only the structure patterns.

3. How to overcome the challenges of script variation?

Since word feature is not considered the script do not pose any challenges. Still to have the same script we converted the two languages into one form the WX notation. This helped in having the same representation of the languages.

4. Testing with Malayalam Data

We selected 300 articles from Malayalam Wikipedia, which were on different genre and size. The 300 Malayalam documents from Wikipedia has 7600 sentences with 3660 3rd person pronouns. The distribution of the pronouns is presented in Table 2.

Pronoun	Number of Occurrences with its Inflected forms
avan (3rd person masculine singular)	1120
aval (3rd person feminine singular)	840
avar (3rd person honorific)	420
athu (3rd person nuetor singular)	1280
Total	3660

Table 2. Distribution of 3rd person pronouns in the corpus

As discussed in the earlier section, the preprocessing done for Tamil using syntactic module are morphological information, POS and Chunking information. Hence the same pre-processing information is necessary for Malayalam data as well. The documents are initially preprocessed with a sentence splitter and tokenizer. The tokenized documents are pre-processed using the pos, suffix and chunking systems discussed above to enrich the text with syntactic information.

For each pronoun, we identify the possible candidate antecedents. Those noun phrases that occur preceding the pronoun in the current sentences and preceding four sentences, which match in the person, number gender (PNG) with the select pronoun are identified as possible candidates. For these possible candidates we extract the features required for CRFs techniques as explained in the previous section. After extraction of features for selected candidate antecedents, the antecedent is identified by using language model built using Tamil data. The results are encouraging with 67% accuracy which is a respectable score. The errors and evaluation is given in detail in the next section.

5. Experiment and Discussion

The experiment showed that the resolution of the pronouns “avan” he and “aval” she is similar to that of Tamil documents. The issues related to split antecedent is not addressed and hence pronouns which are referring to coordinated nouns were not resolved. The pronoun which is less resolved is the third person neuter pronouns “atu” compared to other pronouns. The third person neuter pronoun usually has more number of possible candidates, which leads to poor resolution. Consider the following example.

Ex:7

avan	joli	ceytha	jolikkarkku
He(PRP)	work(N)	do(V)+past+RP	worker(N)+pl+dat
vellam	kotuthu.		
water(N)	give(V)+past		

(He gave water to the workers who did the work.)

atu	nallatu	aayirunnu
It(PRP)	good(N)	is (Copula V) +past.

(It was good.)

In this example, the pronoun 'atu' refers to 'vellam” ‘water’; in the previous sentence. In the previous sentence there are two possible candidate antecedents 'vellam' and 'joli 'which are 3rd person nouns. The ML engine chooses 'joli', which is in the initial position of the sentence and in the subject position. When the antecedent is in the object position the engine has not identified it properly. The following table gives the results of pronouns.

Type of pronoun	Precisi on (%)	Recal l (%)
avan (3rd person masculine singular)	70.83	69.52
avaL (3rd person feminine singular)	69.34	68.56
avar/avarkal (3rd person plural/honorofic)	65.45	70.34
atu (3rd person nuetor singular)	56.67	65.67
Total	68.45	67.34

Table 3: Evaluation Results

6. Conclusion

In this paper we explained a method to use high resource language to resolve anaphors in less resource language. In this experiment the high resource language is Tamil and the less resource language is Malayalam. The results are encouraging. The model needs to be tested with more data as future work.

Abstract

We build the first full pipeline for semantic role labelling of Russian texts. The pipeline implements predicate identification, argument extraction, argument classification (labeling), and global scoring via integer linear programming. We train supervised neural network models for argument classification using Russian semantically annotated corpus – FrameBank. However, we note that this resource provides annotations only to a very limited set of predicates. We combat the problem of annotation scarcity by introducing two models that rely on different sets of features: one for "known" predicates that are present in the training set and one for "unknown" predicates that are not. We show that the model for "unknown" predicates can alleviate the lack of annotation by using pretrained embeddings. We perform experiments with various types of embeddings including the ones generated by deep pretrained language models: word2vec, FastText, ELMo, BERT, and show that embeddings generated by deep pretrained language models are superior to classical shallow embeddings for argument classification of both "known" and "unknown" predicates.

1 Introduction

Semantic role labeling (SRL) is one of techniques for shallow semantic parsing of natural language texts that produces predicate-argument structures of sentences. Predicates bear the central meaning of a situation expressed by a text. In most semantic theories, predicates are verbs, verbal nouns, and some other verb forms. Arguments are phrases that fill meaning slots of a situation expressed by a predicate and define its essential details. They answer such questions as "who?", "did what?", "to whom?", "with what?", "where?", "when?", etc. It is said that arguments play semantic roles in a situation as roles define meanings of slots. Role meanings and sizes of role inventories vary in different semantic theories and annotated corpora. Converting a text into such shallow semantic structures helps to abstract from syntactic and morphological representations of sentences and is considered to be an important technique for natural language understanding. In (Jurafsky and Martin, 2009), this is demonstrated with the following example for a predicate *break*.

- John [AGENT] broke the window [THEME].
- John [AGENT] broke the window [THEME] with a rock [INSTRUMENT].
- The rock [INSTRUMENT] broke the window [THEME].
- The window [THEME] broke.
- The window [THEME] was broken by John [AGENT].

Note, that despite the surface syntactic representations of these sentences differ, the core predicate-argument structure retains and only adjusts to available situation details.

Semantic role labeling has been shown to be beneficial in a number of tasks, where it is important to compare or query texts by meaning: machine translation (Shi et al., 2016), question answering (Shen and Lapata, 2007), information search (Osipov et al., 2010), information extraction (Bastianelli et al., 2013), sentiment analysis (Marasović and Frank, 2018), and others.

The whole SRL process can be divided in four steps: predicate identification and identification of its frame (disambiguation), argument extraction (for each predicate), argument classification (or labeling of arguments with semantic roles), and global scoring that deals with linguistic constrains. Predicate-argument structures in some notations can be represented as two-level trees, rooted in predicates, with single tokens (nouns, adjectives, pronouns, proper names) as leaves that denote arguments. We adopt this dependency-based notation and treat the problem of semantic role labeling as constructing such trees.

There are two main types of linguistic corpora that are used for training models for SRL: FrameNet-like (Baker et al., 1998) and PropBank-like (Kingsbury and Palmer, 2002). The Russian-language resource that can be used for supervised training is a FrameBank corpus (Lyashevskaya, 2012; Lyashevskaya and Kashkin, 2015). The underlying semantic model of this resource is close to the one FrameNet is based on. The biggest difference from FrameNet besides semantic role inventory lies in the fact that FrameBank does not group several verbs into frames but introduces “frame” structures for each unique verb. The corpus contains partially annotated text samples with predicates, arguments, and their semantic roles.

A notable limitation of this resource is that there are annotations only for a very limited set of predicates. In this work, we combat the problem of annotation scarcity by introducing two classification models that rely on different sets of features: one for “known” predicates that are present in the training set and one for “unknown” predicates that are not seen in the training data. We show that the model for “unknown” predicates can deal with the lack of annotation by using pretrained embeddings. We perform experiments with various types of embeddings including the ones generated by deep pretrained language models: word2vec (Mikolov et al., 2013), FastText (Bojanowski et al., 2017), ELMo (Peters et al., 2018), BERT (Devlin et al., 2018), and show that embeddings generated by deep pretrained language models are superior to classical shallow embeddings for semantic role labeling in both cases of “known” and “unknown” predicates.

The contribution of this paper is the following:

- We present and evaluate the first full pipeline for semantic role labeling of Russian texts. The developed models and the code are published online[1].
- We show that pretrained embeddings and language models can alleviate the problem of annotation scarcity for predicates.
- We conduct experiments that demonstrate the superiority of using embeddings generated by pretrained language models compared to shallow embeddings like word2vec and FastText.

The rest of the paper is structured as follows. Section 2 discusses the related work on semantic role labeling for Russian and other languages. Section 3 describes the developed pipeline for semantic role labeling of Russian texts. Section 4 presents the results of the experimental evaluation of the developed pipeline. Section 5 concludes and outlines the future work.

2 Related Work

The data-driven methods for semantic role labeling originate from the work (Gildea and Jurafsky, 2002), in which authors propose a statistical model based on various morpho-syntactic features and train it on the FrameNet corpus. The release of the PropBank corpus sparked a notable interest in SRL among researchers. The consecutive works and numerous shared tasks facilitated creation of elaborated machine learning models based on manually engineered lexico-syntactic features (Xue and Palmer, 2004; Punyakanok et al., 2005; Pradhan et al., 2005).

More recent works on semantic role labeling leverage deep neural networks (Collobert et al., 2011) shifting from feature-engineering to architecture-engineering. Several notable approaches suggest doing semantic role labeling in an end-to-end fashion relying only on raw low-level input consisted of characters or tokens and well-known multilayer recurrent networks (He et al., 2017; Sahin and Steedman, 2018; Marcheggiani et al., 2017). State-of-the-art approaches leverage multitask learning (Strubell et al., 2018) and self-attention techniques (Strubell et al., 2018; Tan et al., 2018). Several recent works also report that although the end-to-end approaches have

[1] https://github.com/IINemo/isanlp_srl_framebank/tree/master

managed to show comparable results, syntactic information still significantly helps semantic parsing (He et al., 2018).

It is worth noting a novel approach to creating annotated resources for semantic role labeling. In (He et al., 2015; FitzGerald et al., 2018), instead of annotating a corpora with a scheme grounded in elaborated linguistic theory, which requires highly qualified annotators, researchers suggest question-answer driven approach to construction of annotated resource based on crowd-sourcing. The recently presented QA-SRL Bank 2.0 (FitzGerald et al., 2018) is a large-scale annotated dataset built by non-experts. The construction of such a resource becomes possible due to simplicity of the annotation scheme, which provides an ability to label predicate-argument relationships using question-answer pairs.

There is a number of works devoted to automatic semantic parsing of Russian texts. In (Sokirko, 2001), a rule-based semantic parser is presented that converts a sentence into a semantic graph. The work does not provide numerical evaluation results, and the generated semantic graph is substantially different from predicate-argument structures produced in SRL. In (Shelmanov and Smirnov, 2014), authors present a rule-based semantic parser for Russian that relies on a dictionary of predicates and a set of morpho-syntactic rules created by human experts. They use this parser to automatically annotate representative corpus for supervised training of a transition-based labeler. In (Kuznetsov, 2015; Kuznetsov, 2016), an SVM-based labeling model is trained on FrameBank corpus. Authors rely on feature-engineering approach and suggest to use syntactic features and clusters of lexis. They also implement integer linear programming inference as a post processing step. These works are based on the pre-release version of the FrameBank corpus and do not provide code for data preparation, modeling, and evaluation. They also do not consider argument extraction and the problem with labeling arguments of “unknown” predicates. In (Shelmanov and Devyatkin, 2017), authors experiment with training a neural network models on the FrameBank corpus and suggest using word2vec embeddings for dealing with scarcity of predicate annotations. However, they implement only an argument classification step but not the full SRL pipeline. It is also worth noting that they performed experiments on gold-standard morphological features (POS tags and morphological characteristics), which does not reflect the real-world scenario. In this work, we additionally suggest using embeddings generated by deep pretrained language models, train models on automatically generated linguistic annotations (morphology / syntactic trees), and provide the full pipeline for semantic role labeling including argument extraction. It is also worth noting the Frame-parser project[2], however, it is in an early stage and only implements argument labeling using an SGD classifier.

3 Pipeline for Semantic Role Labeling

The limitations of the FrameBank corpus do not allow to use end-to-end / sequence labeling methods for SRL. Unlike PropBank, its text samples are annotated only partially, so they are not suitable for straightforward training of a supervised argument extractor or a combined pipeline. Therefore, we split our pipeline into multiple stages, some of which leverage rule-based methods.

The pipeline for semantic role labeling assumes that input texts are preprocessed with a tokenizer, a sentence splitter, a POS-tagger, a lemmatizer, and a syntax parser that produces a dependency tree in a Universal Dependencies format (Nivre et al., 2016). The SRL pipeline consists of the following steps: predicate identification, argument extraction, argument classification, and global scoring.

In the predicate identification step, we mark all verbs and some verb forms according to the given POS-tags of sentence tokens. We do not consider verbal nouns as predicates since they are not present in the FrameBank corpus. In the argument extraction step, for each marked predicate, we try to detect its arguments within a sentence by analyzing its syntax dependency tree with a number of manually constructed rules. The arguments in the pipeline are not spans as stated in CoNLL Shared Tasks 2004, 2005, 2012 (Carreras and Màrquez, 2004; Carreras and Màrquez, 2005; Pradhan et al., 2012), but single tokens (nouns, proper names, or pronouns) as stated in CoNLL Shared Tasks 2008, 2009 (Surdeanu et al., 2008; Hajič et al., 2009).

For the argument classification step, we train two neural models that predict roles of arguments

[2] `https://github.com/lizaku/frame-parsing`

of "known" and "unknown" predicates accordingly. We call a predicate "known" if it appears in a training set within a labeled example, and "unknown" if it does not. During the inference we choose a model by simply checking a presence of a given predicate in a list of predicates appeared in the training corpus. The result of model inference is a set of probabilities for each semantic role in the inventory (above a certain threshold).

In the global scoring step, we enforce the final predicate-argument structure to fulfill the important linguistic constraint: in a single predicate-argument structure, each semantic role can be assigned only once, and each argument can have only one role.

The whole pipeline is schematically depicted in Figure 1.

3.1 Argument Extraction

Base arguments are extracted from a syntax tree of a sentence by rules that take into account POS-tags of tokens and direct syntax dependency links rooted in predicates. Arguments are often also connected to predicates not directly but through simple and complex prepositions that consist of several words. Complex prepositions are detected using the predefined list of triplets <PREP, NOUN, syntactic link>. Name of a syntactic link is used to resolve ambiguity between noun phrases and complex prepositions.

We also take into account tokens that are not related to the predicate directly but are homogeneous to base arguments. The tokens that are linked to the base arguments with a conjunct relation ("conj") are considered as extensions of base arguments and are labeled with the same semantic role as the base argument. The list of predicates is also expanded via adding the syntactic subjects and agents connected to the extracted arguments with a nominal subject ("nsubj") relation, as well as with "name" and "appos" in case it is a person name or a title. The nominal modifier ("nmod") relation is used for nominal dependents and often indicates locations. The adverbial clause modifier ("advcl") helps to find the sequences of participle clauses that have a common subject.

3.2 Argument Classification

For argument classification, we train two feed-forward neural-network models: the model for "known" predicates and the model for "unknown" predicates. The feature set of the model for "known" predicates includes embeddings of argument and predicate lemmas, as well as the following sparse lexical and morpho-syntactic features:

- Various types of morphological characteristics of both an argument and a predicate (case, valency, verb form, etc.)
- Relative position of an argument in a sentence with respect to a predicate.
- Preposition of an argument extracted from a syntax tree (including a complex preposition as a single string).
- Name of a syntactic link that connects an argument token to its parent in the syntax tree.
- Argument and predicate lemmas.

We note that the predicate lemma is one of the essential features for high-quality semantic role labeling, since predicates express a situation in a sentence and determine its meaning slots. Similar morpho-syntactic structures with different predicates can express different meanings. Therefore, the lack of annotation for a predicate in a training set hits hard classifier confidence and overall performance on examples with this "unknown" predicate. We combat this problem by introducing a second model that is trained without predicate lemmas as features, so it should rely on predicate lemma word embeddings and other features instead. This model performs worse than the model for "known" predicates on seen predicates but it is also affected less by an absence of a predicate in a training corpus. This happens because predicate lemma embeddings capture predicate semantics, and similarity between these embeddings can help the model to guess meanings of "unknown" predicates.

In this work, we experiment with various types of word embeddings obtained from shallow models word2vec and FastText, as well as from pretrained language models ELMo and BERT. Recently, it has been shown that pretrained language models provide substantially better generalization to downstream models compared to shallow embeddings built by word2vec or FastText algorithms. This happens because language models can take into account contexts of words, for which they generate an embedding, and capture much longer dependencies in texts. ELMo generates contextual word representations by using a

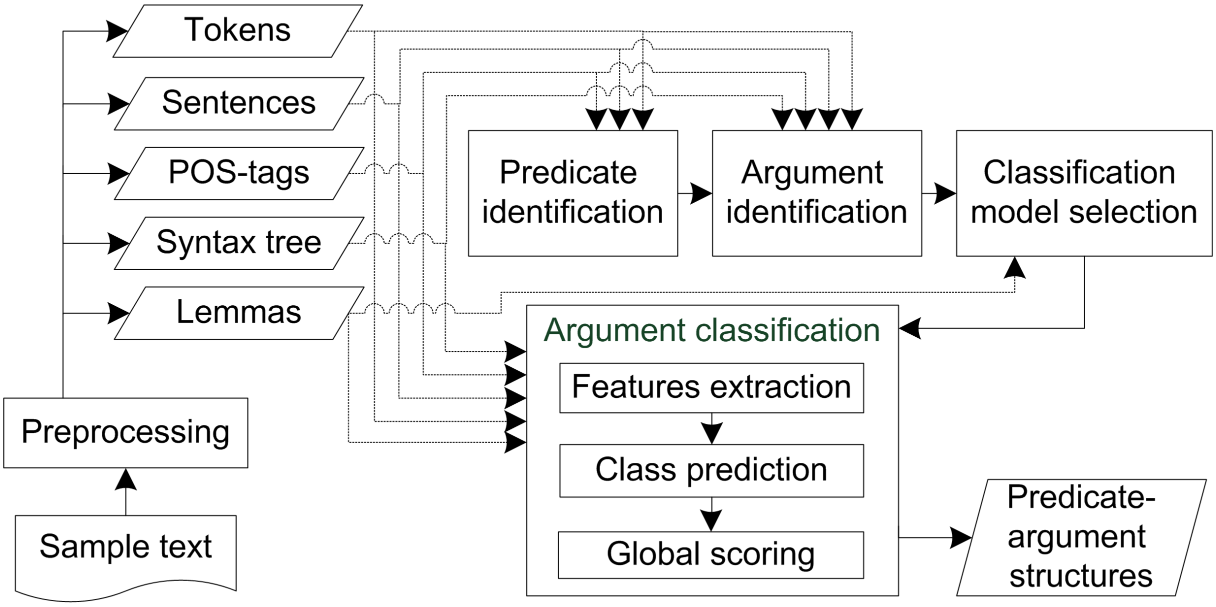

Figure 1: Semantic role labeling pipeline

stack of bidirectional LSTM layers that are trained to predict a following word on the basis of seen context. The output from each layer can be used as a set of features to downstream models. BERT is a masked language model that is trained to predict masked words in a sequence given all other words in the sequence. In addition, it is also trained to simultaneously predict whether two given sentences are consecutive. BERT uses self-attention encoder (Vaswani et al., 2017) that can be much faster than LSTM and can capture longer dependencies across sequences.

The feedforward neural network model for argument classification has three dense layers. Three inputs, namely embedding of a predicate, embedding of an argument, and sparse categorical features are separately passed through the first piecewise layer with ReLU activation. Concatenated outputs of the first layer are then propagated through another ReLU layer and the output layer with softmax activation. Before the activation function, batch normalization is applied on each hidden layer. The network is regularized with dropout. The output of this network is a vector of probabilities for each semantic role in a given inventory.

3.3 Global Scoring

Semantic labels in a single predicate-argument structure are not completely independent from each other. Moreover there is a certain linguistic constraint that requires that there should be no duplicate argument labels, since a meaning slot of a situation can be filled by just a single participant (for the core semantic roles) or a group of homogeneous arguments. In the argument classification step, we use a neural network model to produce a number of probabilities for a list of semantic roles and due to the linguistic constraint, we cannot greedily assign roles with maximum probability. In the global scoring step, we effectively produce the global optimal predicate-argument structure that fulfills the constraint by leveraging an integer linear programming inference (Punyakanok et al., 2004). Formally, it can be described in the following way. Let $x_{ij} \in \{0,1\}$ be a target variable and $x_{ij} = 1$ means an argument j has a semantic role i. Let $p(i,j)$ be a probability of assigning a role i to an argument j estimated by a neural network. Let n and m be the numbers of roles and arguments accordingly. The optimization problem formally:

$$\underset{x_{ij}}{\operatorname{argmax}} \sum_{j}^{m} \sum_{i}^{n} x_{ij} \log p(i,j)$$

$$\sum_{i}^{n} x_{ij} = 1, j = 1..m$$

$$\sum_{j}^{m} x_{ij} = 1, i = 1..n$$

$$x_{ij} \in \{0,1\}, i = 1..n, j = 1..m$$

Table 1: The merging scheme for mixed roles

Original (mixed) role	Destination role
agent – perceiver	perceiver
agent – sbj of mental state	sbj of mental state
result / target	result
location – patient	location
speaker – sbj of psychol. state	sbj of psychol. state

The optimal solution to this problem is used as the final assignment of semantic roles to arguments.

4 Experiments

4.1 Dataset and Preprocessing

FrameBank contains annotated text samples with multiple contextual sentences. Each sentence consists of tokens with their morphological features. We follow preprocessing procedure from (Shelmanov and Devyatkin, 2017) to map annotations to corresponding tokens. We also merged mixed roles annotations from the original dataset into their subsequent roles. See the merging scheme in Table 1.

Unlike (Shelmanov and Devyatkin, 2017), in this work, we do not rely on gold-standard linguistic annotations at all, since the goal of our work is to develop the parser that can process raw texts. To generate linguistic annotations for SRL input, we perform the following linguistic processing steps:

- Tokenization and sentence splitting are performed by NLTK library[3].
- Lemmatization, POS-tagging, and morphological analysis are done by MyStem (Segalovich, 2003).
- Syntax parsing is performed via UDPipe parser (Straka and Straková, 2017) with model trained on SynTagRus (Nivre et al., 2008).

These steps are implemented using the IsaNLP library[4].

The original corpus after preprocessing contains examples for 803 predicates. However, for many predicates there are just few examples, and some semantic roles are also rare. Therefore, we followed (Shelmanov and Devyatkin, 2017) and filtered the dataset keeping only predicates that have at least 10 examples. The filtered dataset retains 643 unique predicates (verbs). We also drop infrequent roles, for which the dataset contains less then 180 examples. The final corpus version contains 52,751 examples for 44 unique semantic roles.

4.2 Embeddings and Pretrained Language Models

In our experiments, we use the following publicly available pretrained word embeddings and language models:

- Word2Vec: RusVectores[5] (Kutuzov and Kuzmenko, 2017). Skip-gram model trained on Russian Wikipedia, dimension: 300.
- FastText: DeepPavlov[6] (Burtsev et al., 2018). Skip-gram model trained on a mixed corpus of Russian Wikipedia and Lenta.ru news texts, dimension: 300.
- ELMo: DeepPavlov. Pretrained on Russian Wikipedia corpus, achieves perplexity of 43.692, 2 layers, dimension: 1024.
- BERT multilingual cased: released by the authors (Devlin et al., 2018). Pretrained on 104 languages, 12 encoder blocks, produces vectors with 768 dimensions.
- RuBERT: DeepPavlov. RuBert is an adaptation of BERT-multilingual with vocabulary enriched with Russian byte-pairs (Arkhipov et al., 2019).

Both ELMo and FastText mitigate out-of-vocabulary problem, so we do not lose any predicates and arguments, while there are some misses for word2vec. BERT models are built upon byte-pair encoding, so we use only the first byte-pair representation for each token as recommended by the authors. It is worth noting that although BERT is a quite large model, it takes only 15 minutes on a single GTX 1080 Ti to encode all examples, compared to 1.5 hours for ELMo.

4.3 Neural Network Hyperparameters

We performed hyperparameter tuning using random search on the task of argument labeling for "known" predicates. The following parameters were selected and used in all further experiments:

[3] https://www.nltk.org/

[4] https://github.com/IINemo/isanlp

[5] http://rusvectores.org/en/

[6] https://deeppavlov.ai/

categorical features layer hidden size – 400, embeddings projection layer hidden size – 100, concatenated vector layer size – 400, dropout – 0.3.

4.4 Experimental Setup

We evaluated the argument extraction step using only the predicate-argument structures labeled in FrameBank and did not take into consideration any other structures in the corpus found by our parser.

For evaluation of argument labeling step, we conducted two experiments using various token representations and dataset splitting schemes.

In the first setup, we evaluate argument classification step on full set of features and test various word representations. Lexical, morphological, and syntax features are encoded in one-hot manner. Macro and micro F1 scores are calculated on a 5-fold cross-validation. Evaluation results are presented in Table 2.

In the second setup, we evaluate the performance of the argument classification models for "unknown" predicates. Thus, we divided the dataset in two parts by leaving 80% of predicates with their examples for training and 20% of predicates for testing. The sets of predicates in training and testing parts do not intersect. The division of predicates was performed at random. For this setup, there was no cross-validation. Instead, we averaged results of 5 models trained with different random seeds. In this experimental setup, we compare models for "unknown" predicates that do not take into account predicate lemma with various types of token embeddings.

To ensure the importance of introducing additional model for "unknown" predicates in our semantic role labeling pipeline and importance of predicate lemma feature, we also evaluate the model for "known" predicates on the test set with "unknown" predicates. The goal of this experiments is to show that the model for "known" predicates overfits on predicate-lemma features and performs worse than models trained specifically for "unknown" predicates, since it is "blind" to its most important feature. We report the results of the model for "known" predicates in this setup only with the embeddings that achieve the best score in the previous experiment. The test results are presented in Table 3.

4.5 Results and Discussion

In the argument extraction step, we achieve 74.48% precision, 85.12% recall, and 79.44% F1-score. We note that many false positives are due to the absence of non-core arguments in our evaluation set. These phrases that bear temporal, locative, and some other types of information are correctly identified by our parser but are considered as mistakes in the evaluation setup resulting in lower precision than it actually is. However, we see that it is the only adequate way to assess extraction quality with partially labeled data.

The results for the argument labeling step presented in Table 2 show that ELMo and BERT outperform all other approaches, including results in (Shelmanov and Devyatkin, 2017), although, unlike them, we do not rely on gold-standard morphological features. In Table 4, we also report the performance per semantic role of the model that uses ELMo word representations.

In many works, BERT outperforms ELMo by a significant margin. However, in our work, there is just an insignificant gap between ELMo and RuBERT. This is probably due to BPE tokenization scheme of BERT, since we take encoded representation only for the first subword unit of each token, with no fine-tuning, leaving a lot of information about words unused.

In the second experimental setup, the gap between RuBERT and ELMo is increased. In this case, the model based on RuBERT shows worse performance than all other approaches. However, there is a certain improvement $\Delta 1.5\%$ of micro F1 score between ELMo and word2Vec-based models. It shows that representations generated by deep pretrained language models can restore semantics of unseen predicates better than shallow models by additionally leveraging the context.

The results of the model for "known" predicates even with the best word representations ELMo are expectedly low. The performance drop compared to the model for "unknown" predicates with the same embeddings is substantial: 10% micro-F1 and more than 8% macro-F1. It is worse than any of other models except RuBERT. This proves that predicate lemma is very important as a feature and SRL pipeline should have two models to process "known" and "unknown" predicates to alleviate the domain shift.

Model	Micro F1	Macro F1
Plain Features Only	76.96 ± 0.67	73.63 ± 0.61
Word2Vec UPOS	79.87 ± 0.34	76.70 ± 0.77
FastText	80.60 ± 0.51	77.39 ± 0.36
ELMo	**83.42** ± 0.60	79.91 ± 0.40
BERT-Multiling	79.04 ± 0.63	75.68 ± 0.72
RuBERT	83.12 ± 0.60	**80.12** ± 0.62

Table 2: Performance of models in the experimental setup with “known” predicates

Model	Micro F1	Macro F1
ELMo (for known pred.)	45.51 ± 0.50	29.31 ± 0.82
Word2Vec UPOS	53.97 ± 0.21	37.29 ± 0.74
ELMo	**55.50** ± 0.51	**37.64** ± 0.41
FastText	49.37 ± 0.43	37.26 ± 0.29
BERT-Multiling	31.81 ± 0.51	21.04 ± 0.13
RuBERT	43.68 ± 0.50	30.84 ± 0.55

Table 3: Performance of models in the experimental setup with “unknown” predicates

5 Conclusion and Future Work

We presented and evaluated the first full pipeline for semantic role labeling of Russian texts. The experiments with various types of embeddings showed that the pretrained language models ELMo and BERT substantially outperform the embeddings obtained with shallow algorithms like word2vec and FastText. We also showed that providing supplementary SRL model for “unknown” predicates can alleviate the problem with annotation scarcity. We note, that in the case of predicting arguments for “uknown” predicates, the deep pretrained language model ELMo also outperformed other types of embeddings. We publish the code of the pipeline that can be used to parse raw Russian texts[7], we also publish the code for model training and experimental evaluation.

In the future work, we are going to apply semi-supervised and unsupervised algorithms to expand the training data and improve the model performance on out-of-domain data.

A Structural Approach to Enhancing WordNet with Conceptual Frame Semantics

Abstract

This paper outlines procedures for enhancing WordNet with conceptual information from FrameNet. The mapping of the two resources is non-trivial. We define a number of techniques for the validation of the consistency of the mapping and the extension of its coverage which make use of the structure of both resources and the systematic relations between synsets in WordNet and between frames in FrameNet, as well as between synsets and frames).

We present a case study on causativity, a relation which provides enhancement complementary to the one using hierarchical relations, by means of linking in a systematic way large parts of the lexicon. We show how consistency checks and denser relations may be implemented on the basis of this relation.

We, then, propose new frames based on causative–inchoative correspondences and in conclusion touch on the possibilities for defining new frames based on the types of specialisation that takes place from parent to child synset.

1 Introduction

The research presented in this paper aims at enhancing WordNet with information about the conceptual structure of verbs based on the mappings between WordNet (WN) and FrameNet (FN). This information includes description of the conceptual elements that receive expression as verbs' arguments and adjuncts as well as the selectional restrictions imposed on these elements.

Our approach relies on the structural features of each of the resources as well as on various kinds of linguistic analysis. The proposed enhancement is directed to: (a) improving the quality of existing mappings; (b) expanding the mappings' coverage; (c) enhancing the description of frames with additional information obtained from WN; (d) proposing structural improvements on the resources based on systemic features (e.g., causativity), including the definition of new conceptual frames; and (e) suggesting further procedures for verification and improvements of precision.

The described methodology is semi-automatic (automatic assignment complemented by manual verification at several stages), but its contribution consists in the devising of a set of procedures to a structured and consistent enrichment of the two resources, which presents an important step towards its automatisation. The enhanced resources will be made available to the research community. As the description of verbs' conceptual structure is largely language independent, the enriched description is applicable cross-linguistically.

2 Prerequisites and Motivation

2.1 Linguistic Resources

WN (Miller, 1995; Fellbaum, 1998) is a large lexical database that represents comprehensively the conceptual and lexical knowledge in the form of a network whose nodes denote cognitive synonyms (synsets) interconnected through a number of conceptual-semantic and lexical relations. The main relation that determines WN's structure (as reflected in the hierarchical treelike organisation of nouns and verbs) is a relation of inheritance of conceptual and lexical features between synsets. The respective pairs of synsets are linked through the relation of hypernymy/hyponymy.

FN (Baker et al., 1998; Baker, 2008) represents lexical and conceptual knowledge couched in the apparatus of frame semantics. Frames are conceptual structures describing particular types of objects, situations, or events along with their components, called frame elements, or FEs (Baker et al., 1998; Baker and Ruppenhofer, 2002; Ruppenhofer et al., 2016). Depending on their status, FEs may be core, peripheral or extra-thematic, cf. Ruppenhofer et al. (2016). For our purposes, we deal particularly with core FEs, which instantiate conceptually necessary components of a frame, and which in their particular configuration make a frame unique and different from other frames. To a lesser degree we touch upon peripheral FEs, which mark notions such as Time, Place, Manner, Means, among others and may be instantiated in any semantically appropriate frame. A Lexical Unit (LU) in FN is a pairing of a word with a meaning; each LU is associated with a frame describing its conceptual semantics.

2.2 Structural Properties of WN and FN

FN frames are related into a netlike structure through a number of frame-to-frame relations part of which also provide a hierarchical organisation. These relations are presented in detail in Leseva and Stoyanova (2019); below, we just sum up those used in the procedures we propose.

Inheritance (Is Inherited by ↔ Inherits from) is the strongest and most prominent relation in FN, which posits a relationship between a more general (parent) frame and a more specific (child) frame so that the child frame elaborates on the parent frame in such a way that each semantic fact about the parent must correspond to an equally or more specific fact about the child (Ruppenhofer et al., 2016, p. 81–82). By definition, *Inheritance* corresponds to the relation of hypernymy/hyponymy in WordNet. In an ideal setting, the hyponyms should be instantiations of the hypernym's frame or of a more specific frame that inherits from the hypernym's frame. For instance, the frame Execution *Inherits from* Killing and is assigned to the WN synset {*execute:1, put to death:1*} – a hyponym of {*kill:1*}, which is assigned the frame Killing.

As the two resources have been developed independently, their relational structure is distinct, one of the major differences being that there are other frame-to-frame relations that to various degrees embody the notion and features of inheritance; we use (some of) them in the definition of the procedures proposed in Section 4.1.

The first one is *Using (Is Used by ↔ Uses)*, a frame-to-frame relation defined as a relationship between two frames where the first one makes reference in a very general kind of way to the structure of a more abstract, schematic frame (Ruppenhofer et al., 2016, p. 83); it may be viewed as a kind of weak inheritance (Petruck, 2015) where only some of the FEs in the parent frame have a corresponding entity in the child frame, and if such exist, they are more specific (Petruck and de Melo, 2012). Thus, the frame Arranging *Uses* the frame Placing and the two frames share the FEs Agent and Theme, while the more specific FE Configuration in the frame Arranging corresponds to the more general FE Goal in the frame Placing; the first frame is exemplified by the synset {*arrange:1, set up:5*} which is a hyponym of {*put:1, set:1, place:1, pose:5*} whose assigned frame is the more general frame Placing.

We consider two more relations although they align with the notion of inheritance only marginally. *Perspective (Is Perspectivized in ↔ Perspective on)* is defined as a relation which indicates that a given situation viewed as neutral may be further specified by means of perspectivised frames representing different possible points-of-view on this neutral situation (Ruppenhofer et al., 2016, p. 82). *Subframe (Has Subframe(s) ↔ Subframe of)* is a relation between a complex frame referring to sequences of states and transitions (each of which can itself be separately described as a frame) and the frames denoting these states or transitions (Ruppenhofer et al., 2016, p. 83–84).

These hierarchical relations are the basis for part of the procedures outlined in Section 4.

2.3 Causativity in WN and FN

Causativity (Is Caused by ↔ Causative of) is a systematic non-inheritance relation where one of the frames represents the causative counterpart of the other, stative or inchoative, frame (Ruppenhofer et al., 2016, p. 85). *Causativity* corresponds straightforwardly to the WN relation *causes*, although this correspondence is exhibited in only a small number of cases (30 pairs) – the relation has not been implemented consistently neither in FN, nor in WN even in clear-cut parts of the lexicon such as those described by the hypernym trees with the roots {*change:1, alter:1, modify:3*} ('cause to change; make different; cause a transformation') and {*change:2*} ('undergo a change;

become different in essence; losing one's or its original nature').

3 Existing Mappings of WN and FN

Previous efforts at linking WN and FN include Shi and Mihalcea (2005), Baker and Fellbaum (2009), WordFrameNet[1] (Laparra and Rigau, 2009, 2010), MapNet[2] (Tonelli and Pighin, 2009), and more enhanced proposals, such as the system Semlink[3] (Palmer, 2009) which brings together WN, FN and VerbNet with PropBank, and its follow-up Semlink+ that brings in mapping to Ontonotes (Palmer et al., 2014). Some procedures for automatically extending the mapping, are presented by Leseva et al. (2018) and a more thorough overview may be found in Leseva and Stoyanova (2019).

Whereas these efforts have resulted in the creation of databases of integrated semantic knowledge, most of them deal with mapping of the units of the original resources to each other – FN LUs and WN synset members (literals), LU definitions and synset glosses, etc. Such a methodology is able to perform mapping in those cases where there is a correspondence between LUs and literals with equivalent or close meaning, but would fail where such correspondence is missing. With 155,287 synonyms in 117,659 synsets and more than 246,577 relations, of which 91,631 are instances of the hypernymy relation[4] as compared with 13,640 LUs and 1,875 frame-to-frame relations[5] in FN, the discrepancy in the size of the data is reflected in the limited coverage of the mappings between synsets and frames. To the best of our knowledge, no further checks and verification have been performed on the mappings, as well.

The approach that we propose in addition to the lexical mapping of units deals with exploring and taking into account the relational structure of the resources (especially the structure of WN), particularly the relation of inheritance which ensures the propagation of conceptual and linguistic features down the trees. We employ features of the relational structure in the definition of procedures for the augmentation of the mapping coverage which are aimed at: (i) discovering existing but unmapped relations between synset members and FN frames; and (ii) transferring frames between synsets through relations of inheritance derived from WN and FN.

4 Enhancing WN Mappings to FN

As noted above, the proposed approach combines the features used in the direct mapping with the structural properties of WN and FN – particularly, the inheritance relations existing between hypernyms and hyponyms in WN and the inheritance (and other similar relations) that determine the hierarchical structure of FN. As shown in Leseva and Stoyanova (2019), although the relations in the two resources have different number and scope, part of them are grounded in similar universal assumptions which leads to partial overlap, depending on their definition and the specificities of the information in the resources.

Apart from the correspondences between FN's *Inheritance* and other relations and the WN hypernymy relation, there are other systematic structural relations which can be applied for the purpose of enhancing the resources. Notable examples are the *Causativity* relation between frames in FN and the *causes* relation defined between causative and stative or inchoative verbs in WN (cf. Section 5).

4.1 Expanding Mappings based on Hierarchical Relations in WordNet

Our work relies on the assumption that in a taxonomic structure such as WN subordinate nodes inherit the properties of their superordinates, i.e. a hyponym elaborates on the meaning of its hypernym and shares its conceptual and linguistic properties. We propose that if a WN synset instantiates a particular FN frame, its hyponyms should (ideally) instantiate the same or a more specific frame which may or may not hold a(n) (inheritance) relation with the more general frame.

This assumption allows us to suggest that in the cases where we are not able to assign a FN frame due to the fact that the coverage of the two resources is non-overlapping and/or other mapping procedures fail, we may resort to assigning the frame of a hypernym to its hyponyms; at worst, the semantic representation will be too general.

There are 14,103 verb synsets in WN, which, unlike nouns that all have a common root, are organised in 566 separate trees. Initially, FN frames

[3] https://verbs.colorado.edu/semlink/

[4] https://wordnet.princeton.edu/documentation/wnstats7wn

[5] https://framenet.icsi.berkeley.edu/fndrupal/current_status

have been assigned to a total of 4,306 synsets out of which 264 are root synsets. In order to improve the quality of the existing mappings and to expand the coverage we performed the following steps: (i) manual verification of the frames assigned to root synsets (resulting in 75 corrected mappings); (ii) semi-automatic assignment of valid frames to selected root synsets with a large number of hyponyms (27 roots); (iii) assignment of a hypernym's frame to its hyponyms in the cases where a hyponym is not directly mapped to FN frames, thus obtaining an extended coverage of 13,226 verb synsets with an assigned FN frame; (iv) definition of further procedures to the end of improving the quality of this assignment (section 4.2).

4.2 Selection of Frames based on the FN and the WN Structure

We devised two types of procedures aimed at obtaining a more specific mapping: (i) procedures that make use of the conceptual and lexical information and the relational structure in FN; (ii) procedures employing the conceptual and lexical information and the relational structure in WN.

As noted above, the first step of assigning a FN frame to a WN synset is transferring the frame assigned to the synset's direct or inherited hypernym. The frame so assigned may either appropriately describe the conceptual structure of the literals in the synset, or it may provide a more general description than an optimally informative one. We therefore view this as a default assignment on the basis of which we try to elaborate to the end of discovering a more suitable or specific frame to which to map the synset. When such a frame is found, we validate it manually and assign it to the hyponyms of the synset under discussion, overriding the more general frame as in Example 1.

Example 1. **Synset**: eng-30-00047945-v {*dress:6; clothe:1; enclothe:1; garment:1*} 'provide with clothes or put clothes on'
Assigned FR from hypernym: Undergo_change
Suggested FR: Dressing (transferred automatically to 13 out of 15 hyponyms such as {*corset:1*} 'dress with a corset', {*vest:1*} 'dress with a vest', {*overdress:2*} 'dress too warmly')

Below, we describe the procedures proposed and how they make use of the relational structure of FN and WN and the following components of the description in the two resources, in particular: (i) WN literals (and synsets) and synset-to-synset relations – especially the hypernymy relation, as well as the relations between synsets with a common hypernym (i.e., sister synsets); and (ii) LUs from a particular FN frame (the verbs listed as instantiations of a given frame), the hierarchical frame-to-frame relations: *Inheritance*, *Uses*, *Subframe*, and *Perspective*, as well as the relation between two frames inheriting from the same frame (i.e., sister frames).

For a synset assigned a frame inherited from its hypernym, we apply the following procedures:

(1) **Literal–LU correspondence using FN relations**: We check whether any of the synset literals appears as a LU in: (a) the assigned frame (to confirm its validity); (b) more specific frames the frame under discussion is linked to by means of any of the considered frame-to-frame relations (to make it more precise); (c) the sister frames of the assigned frame.

Example 2. **Synset**: eng-30-00540946-v {*extend:8; expand:4*} 'expand the influence of'
Assigned FR from hypernym: Cause_change
Suggested FR from (1b): Change_event_duration (LU: extend)
Suggested FR from (1c): Cause_expansion (LU: expand)

(2) **Literal–LU correspondence using WN relations**: We check whether any of the synset literals appears as a LU in: (a) any of the frames assigned to its hyponyms; (b) any of the frames related to the frames in (a) through frame-to-frame relations; and (c) any of the frames assigned to its sister synsets.

Example 3. **Synset**: eng-30-00223374-v {*bolster:1; bolster up:1*} 'support and strengthen'
Assigned FR from hypernym: Cause_change
Suggested FR from (2c): Supporting (LU: bolster)

(3) **General literal–LU correspondence**: We check whether any of the synset literals appears as a LU in any other frame in FN.

Example 4. **Synset**: eng-30-00544936-v {*exalt:1*} 'raise in rank, character, or status'
Assigned FR from hypernym: Cause_change
Suggested FR from (3): Judgment (LU: exalt)

(4) **Keywords**: We use keywords (words contained in the FN frame name, plus their derivatives collected from WN through the *eng_derivative* relation), to identify synset literals and/or definitions containing these keywords as candidates to be as-

signed the frame in question.

Example 5. **Synset**: eng-30-00448864-v {*clean out:1; clear out:1*} 'empty completely'
Assigned FR from hypernym: Cause_change
Suggested FR from (4): Emptying (keyword *empty* found in gloss)

(5) **Direct similarity**: We check the similarity between the gloss of a verb synset and FN LU definitions (even when there is no correspondence between literals and LUs) to identify candidate frames for a given verb synset. We separate: (i) suggested frames related to the one assigned from the hypernym, which are given higher priority; (ii) unrelated suggestions.

Example 6. **Synset**: eng-30-02514187-v {*gloss over:1; skate over:1; smooth over:1; slur over:1; skimp over:1*} 'treat hurriedly or avoid dealing with properly'
Assigned FR from hypernym: Intentionally_act
Suggested FR from (5): Avoiding (which Inherits from Intentionally_act); similarity with the definition of LU *skirt.v* 'avoid dealing with'

(6) **Indirect similarity:** We check the similarity between the glosses of synsets derivationally related to the verb under discussion (as well as the glosses of their hypernyms, which are considered their closest semantic generalisation) and FN LU definitions to identify candidate frames for the verb synset. We separate: (i) suggested frames related to the one assigned from the hypernym, which are given higher priority; (ii) unrelated suggestions.

Example 7. **Synset**: eng-30-00831651-v {*warn:1*} 'notify of danger, potential harm, risk'
Assigned frame from hypernym: Telling
Derivationally related synset: eng-30-07224151-n {*warning:1*} 'a message informing of danger'
Suggested FR from (6): Warning (Inherits from Telling); similarity with the gloss of LU *alert.n* 'a message to inform someone of danger; a warning'

Similarity in procedures (5) and (6) is calculated as a cumulative measure based on coinciding terms in the two definitions. Scores of similarity between two words are highest for full match and lower when stemming is applied. Short words (up to length 3) are disregarded and longer words are given more weight. The final score is normalised by the length (in words) of the definitions.

Through these steps 9,341 new suggestions of more specific or other possible frames have been made for 5,661 synsets with automatically transferred hypernym frames – Table 1 shows the distribution of the new suggestions in terms of the types of procedures that have been applied and the distance of the synset from the hypernym whose frame has been inherited.

Procedure	# 1-step transfers	# 2-step transfers	# 3+ step transfers
(1)	516	231	121
(2)	460	41	17
(3)	1,701	859	145
(4)	1,088	612	27
(5)	1,175	526	202
(6)	1,009	417	194
Unique synsets	3,957	1,388	316

Table 1: Distribution of frames suggested for synsets with automatic frame assignments from the hypernym (rows (1)-(6) include multiple suggestions for the same synset)

4.3 Discussion on Evaluation

These suggestions need to be manually verified as so far no reliable fully automated verification procedure has been established. Since the main objective is to discover, or suggest, a more precise frame than the one assigned from the hypernym, which is not necessarily wrong but rather may be too general, such evaluation needs to measure the degree of relevance as opposed to precision. Furthermore, it will be highly dependent on the granularity of the frames and their hierarchical organisation. Designing such a measure and its automatisation, if at all achievable, is beyond the scope of this work.

Suggestions, although non-definitive, provide useful pointers to candidate frames and thus are valuable in assisting the manual selection of frames. Only in 203 cases are there multiple suggestions as a result of the procedures, out of which in 177 cases 5 or more different frames are suggested. There are 1,056 synsets for which a suggestion is confirmed at least 2 times from the repeated application of the same or different procedures, out of which 265 cases are confirmed 5 or more times.

Given the task, human judgment is indispensable, especially for frames assigned to synsets higher in the tree as errors propagate down and may result in multiple wrong assignments.

5 Causativity and Inchoativity as a Systemic Structural Feature

Another direction of expanding the mappings and verifying the information in both FN and WN is by employing systematic semantic relations such as causativity. It is a non-hierarchical relation that links stative (e.g. {*lie:2*} 'be lying, be prostrate; be in a horizontal position') or inchoative ({*lie down:1, lie:7*} 'assume a reclining position') verbs with their causative ({*lay:2, put down:2, repose:5*} 'put in a horizontal position') counterparts. The relation provides enhancement complementary to the one using hierarchical relations described above and links in a systematic way large parts of the lexicon.

A considerable part of causative and non-causative pairs are formed with the same root and are thus morphologically similar or identical, e.g. EN *change – change*; RO *schimba – schimba*; BG *promenyam – promenyam se*, which makes them easier to identify. Nevertheless, as noted above, causativity is not consistently encoded in WN, and neither is it fully implemented in FN where we have spotted a number of instances of inchoative/stative or causative frames lacking a counterpart in the opposite domain. This means that the verbs instantiating them cannot be appropriately described in FN. Respectively, the mapping of literals instantiating non-defined frames will result in failure of assignment or wrong assignment.

Causativity also has an important application in WN and FN data validation and expansion: exploring the assignment of frames from FN to synsets enables us to check the consistency of assignments, by adopting the following logic: (i) in a tree whose root is a causative synset, all the descendants must be assigned a causative frame; (ii) in a tree with an inchoative/stative root all the descendants must be inchoative/stative; (iii) the pairs of causative–non-causative synsets from corresponding trees should be connected to each other through the WN *causes* relation in a consistent way; (iv) the respective pair of causative–non-causative frames assigned to such a pair of synsets should also be related via the *Is Causative of* relation in FN. The opposite signals either wrong assignment of a frame or inconsistency either in the WN data, that is – the encoding of a stative or inchoative verb in a causative tree or vice versa, or in the FN data – missing or wrong relation between frames, undefined frames, etc.

	Causative change:1;	Non-causative change:2;
From FN	241	251
Direct hypernym	910	624
Indirect hypernym	577	469
Total	1,728	1,344
General frame*	719	561
in %	41.6%	41.7%

Table 2: Analysed data with respect to causativity (* assignments of the most general frame Cause_change for the causative and Undergo_change for the non-causative)

Sections 5.1 and 5.2 describe the procedures for exploring pairs of causative–non-causative trees and extracting information enabling the validation of assigned frames, as well as the increase of the density of causativity relations within FN and WN. Section 5.3 deals with the formulation of new causative or stative and/or inchoative frames.

5.1 Analysis and Consistency Checks

We have extracted two separate WN trees from two root synsets connected by the *causes* relation (see Table 2): (1) eng-30-00126264-v {*change:1; alter:1; modify:3*}, assigned the frame Cause_change; and its corresponding non-causative counterpart (2) eng-30-00109660-v {*change:2*}, assigned the frame Undergo_change.

The checks for consistency with regards to (i)-(iv) above, included the following procedures:

(1) Identifying non-causative synsets in the causative tree and causative synsets in the non-causative tree. These mismatches are identified by pattern matching of the gloss or by analysis aimed at establishing whether the manually assigned frame contradicts the position in the tree. 9 such cases have been found in the causative tree (e.g., eng-30-00416880-v {*even:6; even out:2*} 'become even or more even'). Pattern-matching in the non-causative tree proved to be unreliable. It identified 120 cases of 'make' or 'cause' in the gloss, but only a small number of them were causative synsets (e.g., eng-30-00330565-v {*break up:3; disperse:1; scatter:1*} 'cause to separate'). We propose moving each wrongly placed synset (and the subtree rooting from it) to the rel-

evant tree and attaching it to its real hypernym.

Furthermore, there are synsets which combine the causative and the non-causative meaning and thus, create inconsistency in the WN structure. We identify such synsets by pattern matching of the gloss since they usually have glosses such as 'make or become', 'cause or become', 'cause or undergo'. There are 7 cases in the causative (e.g., eng-30-01253468-v {*coarsen:2*} 'make or become coarse or coarser') and 5 in the non-causative tree (e.g., eng-30-00280532-v {*blacken:1; melanize:1*} 'make or become black'). We propose that such synsets are split into two and placed at the respective positions in the relevant trees. This is an optimal solution as these concepts are not necessarily expressed by the same lexeme cross-linguistically, and such a split improves the consistency of WN.

(2) Identifying non-causative frames assigned to synsets in the causative tree and causative frames assigned to synsets in the non-causative tree. A causative frame is identified based on: keywords such as 'cause' or 'make' in its name or its definition; Agent or Cause/Causer FEs in its conceptual structure; its position as the first member in a *Is Causative of* relation, etc. A non-causative frame is identified based on: keywords such as 'become' or 'undergo'; lack of Agent or Cause/Causer FEs in its structure; its position as the second member of an *Is Causative of* relation.

We found 7 non-causative frames in the causative tree (e.g., eng-30-02190188-v {*quieten:3; hush:5; quiet:9; quiesce:1; quiet down:1; pipe down:1*} 'become quiet or quieter', Frame: Becoming_silent) and 61 causative frames in the non-causative tree (e.g., eng-30-00339085-v {*crush:1*} 'break into small pieces', Frame: Cause_to_fragment). These are clearly either errors in the frame assignment or wrongly encoded synsets as discussed in (1).

(3) Identifying synset pairs connected by the *causes* relation in WN where the causative synset is assigned a non-causative frame or vice versa. Section 5.2 deals with the enrichment of the two resources with instances of the causative relation.

5.2 Densifying Causative Relations in WN and FN

The causative tree stemming from {*change:1*} and the non-causative one stemming from {*change:2*} were aligned using the WN *causes* relation, resulting in 47 pairs of corresponding synsets – one in each tree. A set of consistency checks showed that there are no crossing relations (i.e., no instances where for a causative hypernym C_1 and its hyponym C_2, and a non-causative hypernym N_1 and its hyponym N_2, C_1 causes N_2 and C_2 causes N_1).

Further procedures were proposed to discover pairs of corresponding causative and non-causative synsets unrelated through the causative relation. These are based on pattern matching of the definition and/or on measuring similarity, as well as on an analysis of the synsets position in the WN tree structure, the causative relations in which their sisters, hypernym and hyponyms enter, and the frames assigned to them. On the basis of these linguistic features we have identified 673 possible causative relations between pairs of synsets in the two corresponding trees. After manual validation they may be used to create a more dense structure of causative relations in WN, as well as to extend them to frame-to-frame relations in FN.

5.3 Suggesting New Frames

New frames are suggested where a suitable causative or non-causative frame is not defined in FN to match its existing counterpart. The missing one is defined using the conceptual description of the available frame. Consider the synset {*age:3*} 'make older': we assign it the frame *Cause_change* and then try to acquire additional classificatory information and, possibly, to find a more specific frame by applying the remaining procedures. We confirm that the synset's meaning is causative through the keyword procedure (cf. Section 4.2). Another mapping procedure suggests Aging as the corresponding frame. Aging is a non-causative frame denoting the meaning of an entity undergoing a particular kind of change (see Example 8). Since Aging does not have a causative counterpart in FN, we posit such a frame, Cause_to_age. The conceptual structure of stative/inchoative and causative counterparts is distinguished by the presence of a causative subevent in the latter (Van Valin Jr. and LaPolla, 1997, p. 109) which is associated with a causative (Agent or an Agent-like) participant (FE). Thus, in the discussed example Cause_to_age is derived from Aging by enriching the set of Aging's FEs with the frame elements Cause and Agent. In addition, we posit a *Causative_of* relation between Cause_to_age and Aging. In general, causative frames inherit from the abstract frame Transitive_action so we define an *Inheritance* relation between Transitive_action and Cause_to_age. In such a way the newly-defined relation is integrated into the FN relational structure.

Example 8. Frame: Cause_to_age
Core frame elements: Agent/Cause; Entity
FN definition: An Agent or Cause causes an Entity to undergo a change in age typically associated with some deterioration or change in state.
Example synsets: {*age:3*} 'make older'
FN relation: Inherits_from
Frame: Transitive_action
Core frame elements: Agent/Cause; Patient
Frame definition: An Agent or Cause affects a Patient.

FN relation: Is_Causative_of
Frame: Aging
Core frame elements: Entity
Frame definition: An Entity is undergoing a change in age typically associated with some deterioration or change in state.
Example synset: {*senesce:1, age:2, get on:7, mature:5, maturate:2*} 'grow old or older'

The domain of causativity provides an approach at symmetricising large parts of the lexicon both at a horizontal level (same level lexemes in a taxonomical hierarchy) and in depth as the improvements in the higher levels of the lexicon influence the deeper levels as reflected in the procedure of assigning relations by inheritance described in 4.1.

6 Frame Specialisation and Relations

The observations on hierarchical relations, especially on the more populated ones, such as *Inheritance*, *Using* and *See_also*, shed light on the specialisation that takes place from parent to child in the taxonomic (inheritance) hierarchy. The changes in the causativity domain deal with including/excluding FEs that correspond to causative subevents in the event structure. The modifications that occur in the conceptual and semantic structure include, but are not limited to the following:

– **Reducing the number of core frame elements by incorporating** one of them in the verb's meaning, e.g. {*whip:4*} incorporates the peripheral FE Instrument ('whip') of {*strike:1*} in the frame Cause_harm assigned to both;

– **Reducing the scope of the frame** through imposing more strict selectional restrictions on the FEs, e.g. {*drive:1*} (Operate_vehicle) as a hyponym of {*operate:3*} (Operating_a_system) applies only to land vehicles while other verbs in the frame impose different restrictions on the FE Vehicle;

– **Profiling a different FE** from the one profiled by the hypernym, e.g. {*rob:1*} (Robbery) profiles the Victim, while its hypernym {*steal:1; rip off:2, rip:4*} (Theft) profiles the stolen Goods;

– **Inclusion/exclusion of a causative/agentive FEs** corresponding to a causative subevent in the respective pairs of frames, e.g. {*break:5*} (Cause_to_fragment) and {*break:2, separate:10, fall apart:4, come apart:1*} (Breaking_apart).

Some of the types of specialisation are currently being studied as a point of departure for defining more narrow-scope frames that would allow for more precise predictions about the selectional restrictions and the syntactic realisation of FEs.

7 Future Work

A further goal is to enrich FN by extending its lexical coverage on the basis of the expanded mapping to synsets. Verbs which do not have correspondence among LUs (or no correspondence in a given frame) but belong to synsets that have been successfully mapped to FN frames, will be suggested as possible LUs to be included in the respective frame(s).

A venue of ongoing research is to define precise selectional restrictions on FEs and to implement them as semantic relations between a verb synset and a set of noun synonyms that satisfy these restrictions. In such a way we will enrich WN with relations between verbs and nouns corresponding to participants in their conceptual structure, particularly ones realised as arguments and adjuncts.

The developed resource may have a considerable impact on the development of methods for identification of predicate-argument structure in text, which in turn will facilitate the development of new methods for frame verification and consistency checks on FN and WN.

Acknowledgments

This study has been carried out as part of the project *Towards a Semantic Network Enriched with a Variety of Semantic Relations* funded by the National Science Fund of the Republic of Bulgaria under the Fundamental Scientific Research Programme (Grant Agreement 10/3 of 14.12.2016).

Compositional Hyponymy with Positive Operators

Martha Lewis
ILLC, University of Amsterdam
m.a.f.lewis@uva.nl

Abstract

Language is used to describe concepts, and many of these concepts are hierarchical. Moreover, this hierarchy should be compatible with forming phrases and sentences. We use linear-algebraic methods that allow us to encode words as collections of vectors. The representations we use have an ordering, related to subspace inclusion, which we interpret as modelling hierarchical information. The word representations built can be understood within a compositional distributional semantic framework, providing methods for composing words to form phrase and sentence level representations. The resulting representations give competitive results on simple sentence-level entailment datasets.

1 Introduction

Distributional semantics (Harris, 1954; Firth, 1957) is effective and important within the area of computational modelling of language, particularly as regards to synonymy and paraphrasing. Within the field, at least two additional properties are desirable. Firstly, we would like a method by which we can compose vectors to form representations above the word level. Secondly, we would like a notion of lexical entailment, or hyponymy, with which we can capture a sense of the generality of concepts, and the notion of one concept being an instance of another. Furthermore, we would like these two properties to interact nicely with one another, so that the hyponymy relation is not lost when words are composed. In Bankova et al. (2019) the authors provide theory describing a notion of hyponymy that interacts well with compositionality, but do not provide experimental support. In Balkır et al. (2016) the authors suggest a measure of hyponymy based on entropy which also interacts well with compositionality and provide experimental support. A compositional version of the distributional inclusion hypothesis (DIH) (Geffet and Dagan, 2005) is examined in Kartsaklis and Sadrzadeh (2016). In the current paper, we use the framework of Bankova et al. (2019) to build positive operators that represent words. The operators are built using GloVe vectors (Pennington et al., 2014) and information about hyponym-hypernym relationships, which may be sourced either from human-curated resources like WordNet (Miller, 1995), or unsupervised sources, via the use of pattern-based methods. We give two new measures for graded hyponymy that provide a wider range of comparisons than the entropy-derived measure developed in Balkır et al. (2016) or the eigenvalue-related measure of Bankova et al. (2019).

We test our word representations and measures on a range of datasets. Three of the datasets are single-word entailment and have been designed to test directionality (BLESS) (Baroni and Lenci, 2011), detection (WBLESS) (Weeds et al., 2014), and both directionality and direction together (BIBLESS) (Kiela et al., 2015). We also test our models on the compositional dataset of Kartsaklis and Sadrzadeh (2016). This dataset provides a test for entailment at the phrase and sentence level. We find that our model performs fairly well on BLESS and its variants, and very well on the compositional dataset.

2 Background and Related Work

Vector space models of meaning often rely on some form of the distributional hypothesis: that words that occur in similar contexts have similar meanings. However, as well as deriving word meanings, we also need to give meanings to sentences and phrases. This means that we need some method for composing vector representations of words. Commonly-used methods include neural network methods, as seen in Socher et al. (2013); Bowman et al. (2014), simpler element-wise combination methods (Mitchell and Lapata, 2010), and tensor-based methods (Baroni and Zamparelli, 2010; Coecke et al., 2010; Paperno et al., 2014). Tensor-based methods operate by modelling words of different grammatical types in different vector spaces, and viewing relational words such as verbs and adjectives as linear maps that operate on their arguments. This allows methods from formal semantics to be more easily mapped onto vector space representations, and thereby gives us mechanisms for composing words, in line with their grammatical types, to form phrases and sentences.

We use an extension of the tensor-based approach, based on the methods given in Piedeleu et al. (2015); Bankova et al. (2019); Balkır et al. (2016). We represent nouns as *positive operators*, which can be considered as representing *collections of vectors*. Functional words like adjectives and verbs are now represented as *completely positive maps*, i.e. linear maps which preserve the positivity of their arguments. These can be thought of as linear maps which take valid collections of vectors to valid collections of vectors.

2.1 Related Work

Entailment is an important and thriving area of research within distributional semantics. The PASCAL Recognising Textual Entailment Challenge (Dagan et al., 2006) has attracted a large number of researchers in the area and generated a number of approaches. Previous lines of research on entailment for distributional semantics investigate the development of directed similarity measures which can characterize entailment (Weeds et al., 2004; Kotlerman et al., 2010; Lenci and Benotto, 2012). Geffet and Dagan (2005) introduce a pair of *distributional inclusion hypotheses*, where if a word v entails another word w, then all the typical features of the word v will also occur with the word w. Conversely, if all the typical features of v also occur with w, v is expected to entail w. Clarke (2009) defines a vector lattice for word vectors, and a notion of graded entailment with the properties of a conditional probability. Rimell (2014) explores the limitations of the distributional inclusion hypothesis by examining the properties of those features that are not shared between words. An interesting approach in Kiela et al. (2015) is to incorporate other modes of input into the representation of a word. Measures of entailment are based on the dispersion of a word representation, together with a similarity measure. All of these look at entailment at the word level. Related to the current work are the ideas in Balkır (2014); Balkır et al. (2016). In this work, the authors develop a graded form of entailment based on von Neumann entropy and with links to the distributional inclusion hypotheses developed by Geffet and Dagan (2005). The authors show how entailment at the word level carries through to entailment at the sentence level.

More recent approaches involve specialising word vectors for entailment Vulić and Mrkšić (2018), using non-Euclidean geometries Nickel and Kiela (2017); Nguyen et al. (2017); Le et al. (2019), and using pattern-based hyponymy extraction Roller et al. (2018); Le et al. (2019).

Most approaches, however, provide only word-word hyponymy. To test hyponymy in a compositional setting, we refer to the dataset of Kartsaklis and Sadrzadeh (2016) where a number of sentence and phrase-level hyponymy relationships are built from WordNet (Miller, 1995)

Another approach to detecting lexical entailment is via the identification of certain text patterns which indicate a hyponym-hypernym relationship. Examples are: *y such as x*, *x is a type of y*, which allow us to pick out pairs (x, y) which stand in the relation x is-a y. This approach was first outlined in Hearst (1992) and has been recently used in Roller et al. (2018) to build vectors able to encode the required hierarchical relationships.

In the current paper we provide methods for building word representations as positive operators, using hierarchical information either from human-curated sources such as WordNet, or unsupervised methods such as using Hearst patterns. We will show how these word representations can be composed, and how the hierarchical information percolates to the phrase level. Our contribution is to provide a means of building hierarchically ordered word representations, that can be composed into phrases and sentences. Previous work in this area has either concentrated on word-level hyponymy or phrase-level hyponymy. In this paper we combine the two in one framework.

3 Methods

We model words as collections of vectors, as follows. For a given vector $\vec{v} \in V$,[1] we can 'lift' this vector into the larger space $V \otimes V$, by taking the outer product of the vector with itself. We use the following notation:

$$\bar{v} := \vec{v}\vec{v}^\top \tag{1}$$

When $\vec{v}$ is a unit vector, the resulting matrix $\bar{v}$ is a projection operator. Multiplying another vector $\vec{x}$ by $\bar{v}$ projects $\vec{x}$ onto the one-dimensional subspace spanned by $\vec{v}$. A matrix of the form $\bar{v}$ can be thought of as a collection of just one vector, giving sharp, unambiguous information.

To represent collections of more than one vector, we sum together their matrix representations, resulting in another matrix:

$$\begin{aligned}\{\vec{v}, \vec{w}, \vec{x}\} &\mapsto \bar{v} + \bar{w} + \bar{x} \in V \otimes V \\ &= \vec{v}\vec{v}^\top + \vec{w}\vec{w}^\top + \vec{x}\vec{x}^\top \in V \otimes V\end{aligned}$$

Matrices M built in this way are called *positive operators* and have the following two properties:

- $\forall v \in V. \langle \vec{v}, M\vec{v} \rangle \geq 0$
- M is self-adjoint.

If we additionally impose that M has trace 1, then we can understand M as encoding a probability distribution over $\vec{v} \in V$ (Nielsen and Chuang, 2010). In the present work, we do not impose this condition, instead viewing M as representing a collection of vectors.

The eigenvectors and eigenvalues of M can be thought of as providing a summary of the information contained in M. A matrix of the form $\bar{v} = \vec{v}\vec{v}^\top$ will have one non-zero eigenvalue, corresponding to the normalized eigenvector $\vec{v}/||\vec{v}||$. When multiple vectors have been included in the collection, the matrix M will have more than one non-zero eigenvalue, and these will represent the weights for their corresponding eigenvectors.

We take a kind of extensional stance. We consider words to be modelled as collections of their instances. To model a noun, we can consider the collection of nouns that are hyponyms of that noun, and form the matrix representation corresponding to that collection.

Example 1 (Nouns)**.** Consider the noun *pet*, and suppose we have three types of pet: a pug, a goldfish, and a tabby cat. We give these values in a distributional space spanned by the basis vectors $\{\overrightarrow{\mathit{furry}}, \overrightarrow{\mathit{domestic}}, \overrightarrow{\mathit{working}}, \overrightarrow{\mathit{aquatic}}\}$ as follows:

	pug	*goldfish*	*tabby*
furry	3	0	5
domestic	4	5	5
working	0	0	0
aquatic	0	6	0

We form the representation of the noun *pet* by summing over the matrix representations of each vector:

$$\begin{aligned}[\![\mathit{pet}]\!] &= \overline{\mathit{pug}} + \overline{\mathit{goldfish}} + \overline{\mathit{tabby}} \\ &= \overrightarrow{\mathit{pug}}\,\overrightarrow{\mathit{pug}}^\top + \overrightarrow{\mathit{gfish}}\,\overrightarrow{\mathit{gfish}}^\top + \overrightarrow{\mathit{tabby}}\,\overrightarrow{\mathit{tabby}}^\top \\ &= \begin{pmatrix} 34 & 37 & 0 & 0 \\ 37 & 66 & 0 & 30 \\ 0 & 0 & 0 & 0 \\ 0 & 30 & 0 & 36 \end{pmatrix}\end{aligned}$$

Each of the matrices $\overline{\mathit{pug}}$, $\overline{\mathit{goldfish}}$, and $\overline{\mathit{tabby}}$ has just one non-zero eigenvalue, which is $||\vec{v}||$, and corresponds to the normalised eigenvector $\vec{v}/||\vec{v}||$, for $\vec{v} = \overrightarrow{\mathit{pug}}$, $\overrightarrow{\mathit{goldfish}}$, and $\overrightarrow{\mathit{tabby}}$ respectively.

The matrix $[\![\mathit{pet}]\!]$, however, has three non-zero eigenvalues of 100.52, 35.21, and 0.25, each corresponding to a combination of the basis vectors $\overrightarrow{\mathit{furry}}, \overrightarrow{\mathit{domestic}}, \overrightarrow{\mathit{aquatic}}$. The basis vector $\overrightarrow{\mathit{working}}$ has an eigenvalue of 0, indicating that $[\![\mathit{pet}]\!]$ is orthogonal to the vector $\overrightarrow{\mathit{working}}$.

3.1 Ordering Positive Operators

The set of positive operators on a vector space has an ordering introduced by Löwner (1934). For positive operators A and B, we define:

$$A \sqsubseteq B \iff B - A \text{ is positive}$$

In Bankova et al. (2019) the authors introduce a notion of graded hyponymy. The hyponymy relation may be true up to some error term, as follows. If $A \sqsubseteq B$, then $B - A = D$, where D is some positive operator. If this does not hold, it is possible to add in some error term E so that $A \sqsubseteq B + E$. This is viewed as saying that A entails B to the extent E. We wish to find the smallest such error term.

In Bankova et al. (2019), the error term was of the form $(1 - k)A$ and the scalar $k \in [0, 1]$ gave a graded notion of hyponymy. The effect of this

[1] Throughout the paper, we assume that vector spaces are $\mathbb{R}^n$

scalar is to reduce the size of A until it 'fits inside' B, giving a notion of graded hyponymy that says that A is a k-hyponym of B, $A \sqsubseteq_k B$ if $B - kA$ is positive.

One of the drawbacks of this measure is that if the space spanned by eigenvectors of A, called $Span(A)$, is not a subspace of $Span(B)$, then the value of k must be 0. We therefore consider two new measures, which we now describe. If $B - A$ is not positive, it is possible to make it positive by adding in a positive operator constructed in the following manner.

1. Firstly diagonalize $B - A$, resulting in a real-valued matrix, since $B - A$ is real symmetric.
2. Construct a matrix E by setting all positive entries of $B - A$ to 0 and changing the sign of all negative eigenvalues.

Then $B - A + E$ will give us a positive matrix. This E is our error term. The size of E is bounded above by the size of A, since certainly $B - A + A$ is positive. We propose two different measures related to this error term that give us a grading for hyponymy.

The first measure is

$$k_{BA} = \frac{\sum_i \lambda_i}{\sum_i |\lambda_i|} \tag{2}$$

where λ_i is the ith eigenvalue of $B - A$ and $|\cdot|$ indicates absolute value. This measures the proportions of positive and negative eigenvalues in the expression $B - A$. If all eigenvalues are negative, $k_{BA} = -1$, and if all are positive, $k_{BA} = 1$. This measure is symmetric in the sense that $k_{BA} = -k_{AB}$.

Secondly, we propose

$$k_E = 1 - \frac{||E||}{||A||} \tag{3}$$

where $||\cdot||$ denotes the Frobenius norm. This measures the size of the error term as a proportion of the size of A. Since $A = E$ in the worst case, this measure ranges from 0 when $E = A$ to 1 when $E = 0$.

Example 2 (Full Hyponymy)**.** Recall the example

$$[\![pet]\!] = \overline{pug} + \overline{goldfish} + \overline{tabby}$$

To determine whether a goldfish is a pet, we calculate:

$$[\![pet]\!] - \overline{goldfish} = \overline{pug} + \overline{tabby}$$

Now, since $\overline{pug}$ and $\overline{tabby}$ are both positive, and positivity is preserved under addition, we know that $[\![pet]\!] - \overline{goldfish}$ is also positive. Therefore, under either of our graded measures, the extent to which a goldfish is a pet is 1.

Example 3 (Graded Hyponymy)**.** Now suppose that we define $[\![dog]\!] = \overline{pug} + \overline{collie}$, with $\overrightarrow{pug}$ and $\overrightarrow{collie}$ defined as below:

	pug	*collie*
furry	3	3
domestic	4	2
working	0	2
aquatic	0	0

Then to determine whether a dog is a pet, we calculate:

$$\begin{aligned}
&[\![pet]\!] - [\![dog]\!] \\
&= \begin{pmatrix} 34 & 37 & 0 & 0 \\ 37 & 66 & 0 & 30 \\ 0 & 0 & 0 & 0 \\ 0 & 30 & 0 & 36 \end{pmatrix} - \begin{pmatrix} 18 & 18 & 6 & 0 \\ 18 & 20 & 4 & 0 \\ 6 & 4 & 4 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \\
&= \begin{pmatrix} 16 & 19 & -6 & 0 \\ 19 & 46 & -4 & 30 \\ -6 & -4 & -4 & 0 \\ 0 & 30 & 0 & 36 \end{pmatrix}
\end{aligned}$$

The eigenvalues of $[\![pet]\!] - [\![dog]\!]$ are 75.38, 24.39, -5.77, 0, i.e., they are *not* all positive. This is because the subspace corresponding to $[\![dog]\!]$ is not a subspace of $[\![pet]\!]$, in particular because $[\![dog]\!]$ is not orthogonal to the basis vector $\overrightarrow{working}$.

However, much of $[\![dog]\!]$ is included in $[\![pet]\!]$. Using our graded measures given in equations (2) and (3), we can calculate that under k_{BA}, dog is a hyponym of pet to the extent 0.89 and under k_E, dog is a hyponym of pet to the extent 0.86.

3.2 Composing Positive Matrices

To compose positive matrices, we combine the methods outlined in Bankova et al. (2019) with the type-lifting methods outlined in Kartsaklis et al. (2012) to lift word representations into a higher-dimensional space. The impact of these methods are that we can define nouns and verbs within the same distributional space, and then lift the verb representations to a space that corresponds to a completely positive map.

We have choices about how to implement this type-lifting. One choice is composition, i.e. matrix multiplication, of the two operators. This latter operation results in a matrix that is no longer self-adjoint, and so Piedeleu (2014) suggests using the non-commutative and non-associative operator $M_2^{\frac{1}{2}} M_1 M_2^{\frac{1}{2}}$ in its place. This operator can be thought of as a kind of subspace projection, where M_1 is projected onto M_2. Piedeleu (2014) also notes that the pointwise multiplication of two positive operators is a completely positive map, giving us another choice for composition.

Following Kartsaklis et al. (2012), this gives us a method for building higher-level operators for verbs from lower-level operators. Firstly, we assume the noun space $N \otimes N$ to be equal to the sentence space $S \otimes S$, and refer to these both as $W \otimes W$. Given a representation of an intransitive verb $\llbracket \textit{verb} \rrbracket \in W \otimes W$, the effect of lifting the verb to a higher order space and then composing with a noun $\llbracket \textit{noun} \rrbracket \in W \otimes W$ is to apply the Frobenius multiplication to $\llbracket \textit{noun} \rrbracket \otimes \llbracket \textit{verb} \rrbracket$.

For intransitive verbs we can therefore combine the noun and the verb via three operations which we call **Mult**, **MMult1** (for matrix multiplication), and **MMult2**:

$$\text{Mult: } \llbracket n \textit{ verb} \rrbracket = \llbracket n \rrbracket \odot \llbracket \textit{verb} \rrbracket \tag{4}$$

$$\text{MMult1: } \llbracket n \textit{ verb} \rrbracket = \llbracket n \rrbracket^{\frac{1}{2}} \llbracket \textit{verb} \rrbracket \llbracket n \rrbracket^{\frac{1}{2}} \tag{5}$$

$$\text{MMult2: } \llbracket n \textit{ verb} \rrbracket = \llbracket \textit{verb} \rrbracket^{\frac{1}{2}} \llbracket n \rrbracket \llbracket \textit{verb} \rrbracket^{\frac{1}{2}} \tag{6}$$

For transitive verbs there is one possibility for pointwise multiplication of the operators, since this is both commutative and associative. For the second operation there are a number of composition orders. We will concentrate on two which reflect the difference between composing the verb with the object first and composing with the subject first. We therefore have:

$$\text{Mult: } \llbracket s\ v\ o \rrbracket = \llbracket s \rrbracket \odot \llbracket v \rrbracket \odot \llbracket o \rrbracket \tag{7}$$

$$\text{MMultO: } \llbracket s\ v\ o \rrbracket = \llbracket s \rrbracket^{\frac{1}{2}} \llbracket o \rrbracket^{\frac{1}{2}} \llbracket v \rrbracket \llbracket o \rrbracket^{\frac{1}{2}} \llbracket s \rrbracket^{\frac{1}{2}} \tag{8}$$

$$\text{MMultS: } \llbracket s\ v\ o \rrbracket = \llbracket o \rrbracket^{\frac{1}{2}} \llbracket s \rrbracket^{\frac{1}{2}} \llbracket v \rrbracket \llbracket s \rrbracket^{\frac{1}{2}} \llbracket o \rrbracket^{\frac{1}{2}} \tag{9}$$

4 Experimental Setting

We build representations of words as positive matrices, and selected from a number of alternative embeddings including GloVe vectors (Pennington et al., 2014), FastText (Bojanowski et al., 2017), and distributional vectors built from the concatenation of the UKWaC and Wacky corpora using PPMI and dimensionality reduction, all with 300 dimensions. To select the vector embeddings, we built word matrices as described above and tested them using the word vector evaluation package provided by Faruqui and Dyer (2014). We compared on the Rubinstein and Goodenough (Rubenstein and Goodenough, 1965), WordSim353, (Finkelstein et al., 2002), Miller and Charles (Miller and Charles, 1991), SimLex999 (Hill et al., 2015), SimVerb (Gerz et al., 2016), the Yang and Powers dataset (Yang and Powers, 2006) and the MEN dataset (Bruni et al., 2012). We did not inclue the rare word dataset or the similarity/relatedness splits of WS-353. Word matrices derived from GloVe vectors score best overall when using WordNet-derived hyponyms (table 1). This is also seen in the validation settings of the non-compositional datasets. When using Hearst-derived hyponyms, the generated word matrices perform poorly, although GloVe vectors still score most highly.

Table 1: Performance of word matrices derived from different word embeddings, using WordNet derived hyponyms. Bold highlights the highest value of each row.

	GloVe	Count	FastText
MC	**0.8441**	0.7124	0.8223
MEN	0.4836	0.2861	**0.5090**
RG	**0.8460**	0.6325	0.8387
SIMLEX-999	**0.4426**	0.2638	0.4272
SimVerb	**0.3458**	0.2158	0.3290
WS-353	0.3001	0.1677	**0.3033**
YP-130	**0.5619**	0.3465	0.5166

We compare our WordNet models to a symbolic model called Symb. For this model we mark two words w_1 and w_2 as being in the hyponym-hypernym relationship if w_1 is found in the transitive closure of the hyponyms of w_2.

4.1 Nouns

In order to build positive matrices for nouns, we use information about hypernymy relations. This information can be elicited using human built resources such as WordNet Miller (1995), or using Hearst patterns Hearst (1992). These are patterns like 'y such as x', which give markers for hyponym-hypernym pairs (x, y). To collect the hyponyms of a given word w from WordNet, we traverse the WordNet hierarchy and collect every word w_i in the transitive closure of the hyponymy relation.

For hyponyms generated by Hearst patterns, we use the publicly available dataset described in Roller et al. (2018), and refer the reader to that paper for details of its creation. The dataset consists of a set of word pairs $\mathcal{P} = \{(x_i, y_i)\}_i$ which are in a hyponym-hypernym relationship, together with the count $w(x, y)$ of the number of times that relationship has been seen in the text. As described in Le et al. (2019), the relationships thus extracted are both noisy and sparse, containing cycles and inconsistencies. As one example of this, the dataset contains the pair (*rome*, *european country*). To mitigate these phenomena, we apply a ppmi weighting to the counts. The weighting is as described in Roller et al. (2018), specifically

$$\text{ppmi}(x, y) = \max\left(0, \log\frac{p(x, y)}{p^-(x)p^+(y)}\right),$$

where, letting $W = \sum_{(x,y)\in\mathcal{P}}$, we have:

$$\begin{aligned} p(x, y) &= w(x, y)/W \\ p^-(x) &= \sum_{(x,y)\in\mathcal{P}} w(x, y)/W \\ p^+(x) &= \sum_{(y,x)\in\mathcal{P}} w(y, x)/W \end{aligned}$$

These equations give, respectively, the probability that the pair (x, y) is chosen from $\mathcal{P}$, the probability that x appears as a hyponym, and the probability that x appears as a hypernym. This sets the weighting of various unwanted pairs, such as the aforementioned (*rome*, *european country*), to 0.

To collect the set of hyponyms of a noun, we use only those hyponyms with a non-zero ppmi weighting, and take one transitive step. So the set of hyponyms of a given word x is the union of the sets $\{y_i|\text{ppmi}(x, y_i) > 0\}_i$ and $\{z_{ij}|\text{ppmi}(y_i, z_{ij}) > 0\}_{ij}$. We limit to one transitive step to again mitigate the noisiness of the dataset.

4.2 Verbs

WordNet contains verb hyponymy relationships, and therefore we can use similar methods to extract lists of hyponyms. However, we cannot use Hearst patterns to collate verb hyponymy relationships. As a proxy, we represent verbs as collections of their arguments. The intuition behind this is that of the extensional approach in formal semantics, mapped to distributional semantics in Grefenstette and Sadrzadeh (2011). We can think of both nouns and verbs as predicates, and consider the instances that the predicate applies to.

To collect the arguments of the verbs, we use the concatenation of the dependency parsed ukWaC and WaCky corpora (Ferraresi et al., 2008), and collect those arguments that appear at least 300 times in the corpus.

4.3 Building Matrices

Finally, having collected instances of nouns and verbs, we take the vectors $\overrightarrow{w}_i$ corresponding to each of these instances, take the outer product of each with itself, and add these together, i.e.:

$$[\![w]\!] = \sum_i \overrightarrow{w}_i \overrightarrow{w}_i^\top \in W \otimes W \qquad (10)$$

We have discarded weighting information. Words which have more instances are both more widely dispersed in terms of their eigenvalues, and also larger in terms of their matrix norm.

4.4 Datasets

We evaluate single word representations on the non-compositional BLESS hyponymy subset (Baroni and Lenci, 2011), WBLESS (Weeds et al., 2014), and BIBLESS (Kiela et al., 2015) datasets. We test our models using the hypernymy suite provided by Roller et al. (2018). The BLESS dataset requires the model to infer the direction of a hypernym pair. All pairs in the model are indeed in the hyponym-hypernym relationship, and the model must identify that this is the case. WBLESS consists of a set of pairs which may be in the hyponym-hypernym relationship, or unrelated. Each pair is assigned a value of 1 or 0 based on whether or not there is a hyponymy relationship. The software provided performs 1000 random iterations in which 2% of the data is used as a validation set to learn a classification threshold, and tests on the remainder of the data. Average accuracy across all iterations is reported. The BIBLESS dataset assigns values of 1, 0, and -1 based on whether the first word is a hyponym of the second, whether there is no relationship, or whether the second is a hyponym of the first. The software firstly tunes a threshold using 2% of the data, identifying whether a pair exhibits hypernymy in either direction. Secondly, the relative comparison of scores determines which direction is predicted. Again, the average accuracy over 1000 iterations is reported.

We further test on the compositional datasets from Kartsaklis and Sadrzadeh (2016). This is a series of three datasets, covering simple intransitive sentences, transitive sentences, and verb phrases. The intransitive verb dataset consists of paired sentences consisting of a subject and a verb. In half the cases the first sentence entails the second, and in the other half of cases, the order of the sentences is reversed. For example, we have:

summer finish, season end, T

season end, summer finish, F

The first sentence is marked as entailing, whereas the second is marked as not entailing. The dataset is created by selecting nouns and verbs from WordNet that stand in the correct relationship.

To test our models, we build the basic word representations as in equation (10). We then use the compositional methods outlined in section 3.2 to create the sentence representations. We calculate the graded entailment value between the composed sentence representations, and in results report area under ROC curve for comparison with previous literature. In particular, we compare with the best model from Kartsaklis and Sadrzadeh (2016), which uses a metric based on the distributional inclusion hypothesis, together with a tensor-based compositional model.

4.5 Significance Testing

To test significance of our results, we use bootstrapping Efron (1979) to calculate 100 values of the test statistic (either accuracy or AUC) drawn from the distribution implied by the data. We compare with figures from the literature using a one-sample t-test, and compare between models using a paired t-test. We apply the Bonferroni correction to compensate for multiple model comparisons.

5 Results

5.1 BLESS Variants

We present results on variants of the BLESS dataset in terms of accuracy, for comparison with other models, presented in table 2. Our best perfoming model is the WordNet based model with metric k_E. Althoough this model does not outperform the best supervised model (the differences in score are significant), the differences are fairly minimal (0.01 accuracy). Our methods (and those of others) outperform the symbolic baseline for the BLESS dataset. Our WordNet-based model does outperform the earlier model HyperVec with significance. Hearst-pattern based representations do not perform so strongly.

Table 2: Accuracy on the variants of the BLESS dataset. HyperVec figures are from Nguyen et al. (2017), Hearst from Roller et al. (2018), HypeCones from Le et al. (2019), LEAR from Vulić and Mrkšić (2018). Entries tagged with WN use WordNet.

Model	BLESS	WBLESS	BIBLESS
HyperVec - WN	0.92	0.87	0.81
Hearst	0.96	0.87	0.85
HypeCones	0.94	0.90	0.87
LEAR - WN	0.96	0.92	0.88
Symb - WN	0.91	0.93	0.91
k_{BA} - WN	0.95	0.88	0.84
k_E - WN	0.95	0.91	0.87
k_{BA} - Hearst	0.91	0.84	0.76
k_E - Hearst	0.91	0.86	0.80

Table 3: Area under ROC curve on the KS2016 datasets using k_E and WordNet derived hyponyms. For the SV and VO datasets, MMult1 refers to the model described in equation (5) and MMult2 refers to the model described in equation (6). For SVO, MMult1 refers to the model described in equation (8) and MMult2 refers to the model described in equation (9). $*$ indicates statistically significantly higher than the previous best performance Kartsaklis and Sadrzadeh (2016). $+$ indicates significantly higher than the additive baseline.

5.2 Compositional Datasets

On the KS2016 compositional datasets results are reported in terms of area under ROC curve. Our measures perform particularly well with WordNet derived hypernyms (Tables 3 and 4). This is likely to be due to the fact that both the dataset and our word representations were constructed from WordNet, and hence the high performance is to be expected. More interestingly, the word representations built using unsupervised methods also outperform previous best scores on this dataset, (tables 5 and 6), based on a form of the distributional inclusion hypothesis for tensor-based composition (Kartsaklis and Sadrzadeh, 2016), despite not performing so strongly on the single-word datasets.

6 Discussion and Further Work

We have suggested a mechanism for building the positive operators needed for the theory presented in Bankova et al. (2019), together with two novel measures of graded hyponymy. We tested these representations and measures on a number of well-known datasets, looking at similarity at the word level, hyponymy at the word level and one of which gives hyponymy at the phrase and sentence level. The representations and the measures we have developed perform competitively on these datasets. We have used both human-curated information and unsupervised methods to build the word representations. Unsurprisingly, human-curated information gives better performance.

A nice comparison is with the symbolic model. The fact that our WordNet-based models outperform this baseline shows that the models we propose can provide a ‘smoothed’ representation that allows hyponymy relationships to be inferred. For example, one of the hyponymy relationships not picked up in WordNet is *(oven, device)*. However, there are a number of other instances such as *(electric appliance, device)* that are similar enough to *oven* that *device* can be understood as including *oven*. What cannot be remedied, however, is where a term has no hyponyms in WordNet. For example, *herbivore* has no hyponyms in WordNet. This means that the WordNet-based representations have no way of forming a wide representation of *herbivore* thatincludes any of its instances.

As well as performing well on single-word hyponymy datasets, the representations we build sit within a compositional framework that allows us to form phrases and sentences and to reason about their entailment relationships. The WordNet-based representations behaved particularly well on this dataset, due to the fact that the dataset is built from WordNet. However, it is still an interesting set of results in that our graded measures interact well with the compositional methods we have proposed. Note that the measures we propose result in high baseline values to beat - i.e. for the verb-only and addition models. Again, this is likely due to the construction of the dataset. The dataset is formed from upwardly-monotone contexts, so computing entailment based only on the verb will still perform extremely well. Again, although this is due to the construction of the dataset, is is interesting to note that the measures and word representations we developed can model this structure so well. Furthermore the Hearst-pattern derived representations also outperformed previous work, indicating that these representations interact nicely with compositionality.

Similarities to our approach can be found in the notion of words being represented as Gaussians (Jameel and Schockaert, 2017; Vilnis and McCallum, 2014). The positive operators we build have the same structure as covariance matrices and, if appropriately normalized, are interpreted as representing a probability distribution over vectors. Representing words as Gaussians does not come with a given mechanism for composing words as we do. Exploring these connections is an area of further work.

Finally, a crucial extension to this whole approach is to be able to model hyponymy, composition, and their interaction in more contexts, for example using the natural logic introduced in Barwise and Cooper (1981).

Abstract

Relation Extraction (RE) consists in detecting and classifying semantic relations between entities in a sentence. The vast majority of the state-of-the-art RE systems relies on morphosyntactic features and supervised machine learning algorithms. This paper tries to answer important questions concerning both the impact of semantic-based features, and the integration of external linguistic knowledge resources on RE performance. For that, a RE system based on a logical and relational learning algorithm was used and evaluated on three reference datasets from two distinct domains. The yielded results confirm that the classifiers induced using the proposed richer feature set outperformed the classifiers built with morphosyntactic features in average 4% (F1-measure).

1 Introduction

Relation Extraction (RE) consists in detecting and classifying binary semantic relations between entities in a sentence.

Many RE systems use statistical machine learning techniques, such as feature-based and tree kernels-based methods (Choi et al., 2013) are based on a propositional hypothesis space for representing examples, i.e., they employ an attribute-value representation achieving robust results. However, this representation is not able to effectively capture structural information from parse trees without loss of information (Choi et al., 2013). More recently, other RE systems using deep learning techniques, such as Convolution Neural Networks (Nguyen and Grishman, 2015) and Recurrent Neural Networks (Miwa and Bansal, 2016) have also been proposed. They are based on a dense vector representation of the input words retrieved from word embeddings (Mikolov et al., 2013).

Some other RE systems rely on natural language processing (NLP) techniques for extracting relevant features from the text. They typically integrate shallow NLP tools for coping with lexical and syntactic aspects of the texts such as POS tagging, lemmatization, chunking, and syntactic parsing (Choi et al., 2013). However, according to Zouaq (2011), there are two main reasons to seriously consider deeper linguistic processing for RE: (i) it may provide deeper semantic meaning; (ii) NLP tools are becoming sufficiently robust to be considered as reliable tools for knowledge and model extraction.

Contrarily to related work above, this work subscribes to the idea of performing RE employing the Logical and Relational Learning (LRL) (de Raedt, 2008) approach that can generate classification models from complex data structures such as graphs or multiple tables. More precisely, we rely on Inductive Logic Programming (ILP) (Muggleton, 1991) as one of the most successful relational learning techniques because it employs a symbolic and declarative representation for the examples and the extraction models are both understandable and interpretable by humans. Moreover, ILP allows for many forms of prior knowledge, including semantic resources, to be integrated into the induction of the extraction rules (de Raedt, 2018).

In this paper, we try to answer experimental questions concerning not only the impact of semantic linguistic features but also the integration of external knowledge resources on RE. For that, an ILP-based RE system was employed and evaluated on three datasets from two distinct domains.

The main contribution of this work consists in the experimental validation of our working hypothesis that a feature engineering step comprising a sub-

Proceedings of Recent Advances in Natural Language Processing, pages 648–654,

stantial body of deep linguistic knowledge, in combination with an expressive inductive learning technique, can generate effective RE models.

2 Relational Learning and Inductive Logic Programming

Relational Learning (RL) concerns the learning task from complex, heterogeneous examples represented by multirelational datasets. RL enables the development of applications in many fields including bio-informatics, networks analysis, and drug design (de Raedt, 2008). LRL (DeRead, 2008) combines machine learning and logic-based formalisms to automatically induce first-order rules from multi-relational examples.

ILP (Muggleton, 1991) is one of the most successful LRL-based technique that can not only induce symbolic rules from examples represented as multi-relational data, but also integrate background knowledge (BK) represented as logical clauses in first-order logic (FOL). Unlike traditional machine learning methods, classification models (rules) in ILP are both understandable and interpretable by humans. Most of the current ILP systems induce a set of Horn-clauses and employ Prolog as their core inference engine (Muggleton, 1991).

3 Logical Relational Learning System for Relation Extraction

The main contribution of this paper consists in the experimental validation of our working hypothesis that a feature engineering step composed by a substantial body of deep linguistic knowledge in combination with an expressive inductive learning technique can generate effective RE models. For testing this hypothesis, a LRL RE system (Lima et *al.*, 2017; Lima et *al.*, 2019) was used. The remainder of this section describes the RE system, the rich feature engineering component, and the underlying model for representing semantic features.

3.1 System Architecture

Fig. 1 shows the functional architecture our LRL system for RE. Its major components are highlighted as darker boxes and briefly presented next.

Deep NLP Component. This component performs the automatic annotation of the input documents in English. Its output is formed by XML files containing several layers of linguistics annotations. Its distinguishing characteristic consists in various NLP analysis it performs, starting from tokenization, passing for shallow analysis, and finishing with more advanced semantic analysis.

Figure 1. RE System architecture.

Background Knowledge Generation component. This component automatically generates and represents relevant features from an annotated set of documents. The generated features are converted into a knowledge base implemented as a Prolog factual base.

ILP rule learning component relies on an LRL system rooted on ILP that induces Horn-like extraction rules from training data. The extraction rules follow the same syntax of a Prolog predicate. This learning component is based on GILPS, a general ILP system proposed by Santos (2010).

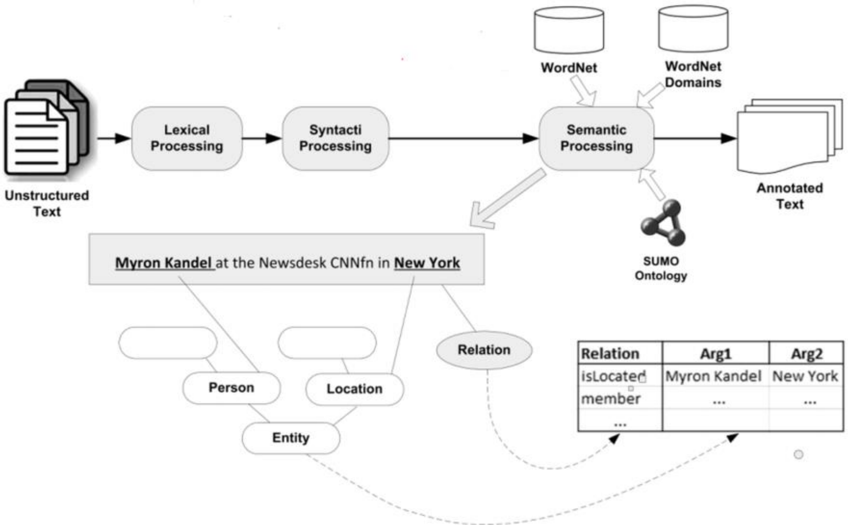
Rule application component. It applies the induced rules on the Prolog factual base generated from new documents not seen in the rule model learning phase. As a result, new instances of relations are identified and extracted.

Due to their importance, the above first two components will be detailed next.

3.2 Feature Engineering via Deep NLP

NLP technologies are of paramount importance in RE, since they can analyze unstructured texts and extracting their meaning. Indeed, the result of NLP analyses (or *annotation process*) is a richer version of the input text with further lexical, syntactical, and semantic metadata seem as a normalized representation of texts.

Due to its inherent complexity, NLP is not carried out in a single large stage. Instead, the annotation process is carried out as a chain of processes in which the output of a previous process becomes the input to the next one. Accordingly, the NLP component in our RE architecture is composed of the three major components as depicted in Fig. 2. The first analysis provides the basic morphological elements and lemmas, i.e., canonical base form of the words. In addition, categorical information is attached to each lexical item as Part-of-Speech (POS) tags (e.g., noun, verb, etc.). This facilitates the posterior task of determining groups of words (chunking analysis) that grammatically belong to the same category. Next, the syntactical analysis (syntactic parsing) identifies the structural relationships holding between words at the sentence level. The final semantic analysis links words to lexical semantic resources, including WordNet (Fellbaum, 1998), SUMO ontology (Niles and Pease, 2003), and WordNet Domain hierarchy (Bentivoli et al., 2004). Such semantic resources offer a variety of semantic relations including synonyms and hyponyms from WordNet, and additional semantic relations between verbs and their arguments considered here as predicates.



Relation	Arg1	Arg2
isLocated	Myron Kandel	New York
member	...	...
...		

Figure 2. Overview of the Deep NLP pipeline.

The Deep NLP component relies on the Stanford CoreNLP[1] for carrying out the following pipeline: tokenization, sentence splitting, POS tagging, lemmatization, NER, and dependency parsing. Chunking analysis is performed by Apache OpenNLP[2], while morphological analysis, gazetteers look-up, and pronoun normalization were implemented as ad hoc programs. That is followed by the Sense Learner (Mihalcea and Faruque, 2004) that disambiguates noun and verbs. Then, using the Java WordNet library[3], the *sense_id* of nouns and verbs are found in WordNet, along with of all synonyms and hyponyms of a given word. In addition, Lin´s similar words dataset (Lin et al., 2003) is used for retrieving a list of N (N = 5) most similar words to a given word. Semantic Role Labeling (SRL) is performed on all verbs by ClearNLP[4]. Still, for verbs, the SuperSense Tagger[5] (Ciaramita and Altun, 2006) finds their selectional preferences. It annotates text with 41 broad semantic categories (WordNet supersenses) for both nouns and verbs. Next, the mapping between all WordNet synsets and the SUMO ontology[6] is exploited for retrieving the related class from the SUMO ontology. Finally, an ad-hoc program maps words to labels from the WordNet Domains **(**Bentivogli *et al.*, 2004). Table 1 summarizes the entire pipeline.

3.3 Relational Representation of Sentences

The goal of the BK Generation Component is to extract and represent features according to a relational model consisting of documents, sentences, phrases, and tokens. They are converted into a Prolog factual base and used as input by the ILP-based learner. There are the four main groups of features:

Lexical features which concern word, lemma, length, and general morphological type information at the token level.

Syntactic features denote word POS tags; head word of nominal, prepositional or verbal chunk; bi-grams and tri-grams of consecutive POS tags of words, chunking features that segment sentences into a noun, prepositional, and verb phrases, chunk head word, and its relative position to the main verb of the sentence.

Semantic features include named entities, entity mentions provided by the corpus as well as all lexical-based semantic features (sense/hypersense,

[6] http://www.adampease.org/OP

synonyms, domain sense), and semantic roles of the verbs with their arguments.

Structural features consist of the structural elements connecting all the above features according to our relational model. They denote (i) the sequencing of tokens preserving the token order in the input sentence; (ii) the part-whole relation between tokens and the chunk containing them; (iii) the sequencing of chunks is represented by edges between their head tokens; and (iv) the grammatical dependency between two tokens in a sentence according to the typed dependencies between words.

The relational representation of all the above types of features is straightforward: a unary predicate in Prolog denotes identifiers, e.g., *token(id),* while binary predicates correspond to attribute–value pairs and relations, e.g., *rel(arg1, arg2).*

4 Experiments

This section reports the results of experiments performed on three benchmark datasets from two distinct domains (newswire and biomedical).

4.1 Experimental Questions

We investigate the effectiveness of the proposed semantic linguistic features used in the induction of the relation extraction rules by the our ILP system. More precisely, we want to answer the following experimental questions (EQ):

EQ1. *Do the features present a complementary contribution to the performance results?*

EQ2. *What is the impact of the semantic linguistic features on the final induced set of extraction rules?*

EQ3. *How well do the rules generalize among different datasets: either in the same domain or in distinct domains?*

4.2 Dataset and Evaluation Measures

Three publicly available RE datasets from the newswire and the biomedical domain containing binary relations were selected for analysis:

reACE 2004/2005. The reACE 2004/2005 datasets introduced by Hachey et al. (2011) are the result of several transformation steps (refactoring, preprocessing, and reannotation) for normalizing the two original ACE datasets so that they adhere to a common notion of relation that is more intuitive and simpler: relation instance denotes a predicate over two arguments, where the arguments represent concepts in the real world.

Table 2 shows the distributions of the relation types in reACE 2005 dataset, whereas Table 3 shows some examples of them.

reACE 2005 - Relation Types	Freq
Employment	228
Membership	36
Located	280
Citizen-Resident-Religion-Ethnic	39
Business	16
Family	42
Geographical	119
Subsidiary	47

Relation type	Example phrases
business (John, superiors)	John´s superiors…
Employ (Investors, “Wall Street”)	Investors on Wall Street…
citizen (voters, Missouri)	Some Missouri voters…

Table 3. Examples of reACE 2005 relations.

IEPA. The Interaction Extraction Performance Assessment (IEPA) corpus (Ding et al.,2002) is a biomedical dataset comprising 303 abstracts retrieved by ten queries suggested by domain experts to the PUBMED repository. An interaction between two terms, i.e., a specific pair of co-occurring chemicals in the IEPA corpus, was defined as a direct or indirect influence of one on the quantity or activity of the other (Ding et al., 2002). Examples of interactions between terms A and B are *"A increased B"*, and "*A activated C, and C activated B*".

Evaluation Measures. The classical IR measures of Precision *P*, Recall *R*, and F1-measure (Baeza-Yates and Ribeiro-Neto, 1999) were used for measuring the effectiveness (impact) of the proposed enhanced features on the RE task.

4.3 Experimental Protocol

We employed five-fold cross-validation which allows both the maximal use of the available training data on all the datasets used in the experiments. Moreover, preliminary experiments were performed for determining the optimal learning parameters according to the criteria of achieving high accuracy and preventing model overfitting. The best parameter setting for the ILP-based learning component found were: *evalfn = coverage*, *i (depth)* = 3, *minpos = 5*, and *noise = 0.2*.

4.4 Results

Table 4 summarizes the results of using several combinations of features on reACE 2004/2005 and IEPA datasets, while Tab. 5 conveniently displays the difference in performance between each pair of corresponding lines indexed by the column id.

Starting from Line 2 in Tab. 4, a given group of features are incrementally added to the baseline (Line 1) which, in turn, includes the following group of features: lexical, syntactic and structural features, i.e., syntactical dependencies (Dep), chunk information (Chunk), POS tagging, and other chunk related features. The baseline setting corresponds to all the features that do not take into account the semantic features (i.e., lexical semantics and mapping to semantic resources). The other lines (Line 2-4) in Tab. 4 integrate other groups of features (NER, Corpus types) to the baseline: NER denotes recognized named entities whereas Corpus types features denote the golden standard annotations already available in the given corpus. For instance, the reACE datasets provide named entities such as *Organizations* and *Person*, while the *IEPA* corpus only assigns the label *protein* to each term denoting a given protein. The last group of features (*semantic*), denotes the semantic features comprising SRL, synonyms/hypernyms, and mapping of words to WordNet, WordNet Domains, SUMO ontology, similar words, and selectional preferences. The missing entries in IEPA column are due to the fact that typical named entities are useless in the IEPA biomedical corpus, and therefore, they were not considered.

5 Discussion on Experimental Questions

This section discusses both the impact of semantic linguistic features on RE, and related aspects on domain adaptability.

On the Impact of Semantic Linguistic Features. EQ1 can be positively answered because by incrementally incorporating new groups of features to the baseline, that contributed to the improvement of the scores for all datasets. Indeed, the performance improves as more features are used, starting with the F-measure of 77.77 and reaching 81.80 for the reACE 2004 dataset. Analogously for the reACE 2005, the best overall F1 performance (71.86%) may indicate that this dataset is more difficult than the reACE 2004. One possible explanation is that, in the reACE 2005 dataset, some relations (particularly *Business*) are very poorly represented with only 16 positive examples, which hampers the overall score. More importantly, the overall F1 scores suggest that the proposed four groups of features have both a positive and complementary impact on the overall F1 scores for all the datasets evaluated.

Concerning EQ2, one can notice that including semantic features into the RE process improves average performance in terms of F1 measure for all datasets. In fact, the boost in F1 measure was 4% in average for the reACE datasets, while for the IEPA dataset, the improvement was more than 3%. However, the impact on both P and R scores were unbalanced for the reACE corpora, since the semantic features contributed relatively more in recall than in precision. This contrast with the results on the IEPA corpus that were very balanced. On the one hand, the highest difference in performance was achieved on the reACE 2005 corpus, as the semantic features improved P in almost 12%. On the other hand, for two other combinations in this dataset (Line 5 and Line 7), adding semantic features to the learner in fact slightly hampered precision. Such impact on both P and R were expected since the effect of adding semantic features to the learner could not only improve R over P, but also provide to it an extended layer of categorization of all terms. Contrastingly, for the IEPA corpus, the use of semantic features slightly increased precision more than recall. After inspecting the final induced extraction rules, we found that this was mainly due to the semantic role labeling features. Actually, many verbs denoting the interaction between two proteins terms in IEPA corpus were correctly annotated along with the roles of its arguments. As a result, the ILP-based learner is more precise when a given verb has semantic role features attached to it.

Table 5. Performance difference between RE models

On Domain Adaptability. Some authors investigated the domain adaptation problem on NER.

Ciaramita et al. (2005) studied the effects of domain adaptation on NER using two distinct datasets for training and testing. They trained several NER classifiers on the CONLL 2003 dataset and evaluated them on a manually annotated section from the Wall Street Journal portion of the Penn Treebank. They found that, even for such similar types of texts, the results of their supervised NER models dropped significantly. However, they had improved scores (almost 5% in F1-measure) just by coupling their original NER system with both a domain-independent dictionary and a simple string similarity function.

In (Pyysalo, 2008), very similar results were reported when a general POS tagger was employed for tagging a dataset from the biomedical domain.

In our work, this same trend was observed since our RE models trained with all the linguistic features yielded, in average, a relative gain up to 4% in F1-measure. In fact, our RE models trained with deep semantic features outperformed the RE models that did not used them according to the statistical significant tests (Wilcoxon signed-rank) for the difference between F1 scores at α = 0.05 (95% confidence interval). These results are very encouraging and seem to validate the proposed features even in a more difficult application scenario handling the changing of domains. To conclude, the overall achieved results suggest that more accurate semantic information about entity instances can contribute a great deal to RE. This is not surprising, given that semantic information, e.g., hypernyms, and classes from an ontology, typically impose strong constraints on the types of the entities participating in a relation, indicating that such kind of feature can have significant discriminative power in RE. Thus, we can also positively answer to EQ3.

6 Conclusion and Future Work

This paper presented a LRL system for RE employed to test of our hypothesis that a set of features based on a deep linguistic analysis can improve RE. This was demonstrated by experimental evaluation showing that automatic acquisition of a substantial body of linguistic knowledge in combination with an expressive inductive learning technique, it is possible to generate effective RE models. Moreover, such features significantly contributed to generalize the proposed RE to other domains of interest.

This research work can be improved in several ways. We intend to test our solution on larger datasets aiming to promote future scalability. In addition, mechanisms for allowing the parallel execution of the IE process will enable the decomposition of the learning problem into smaller more manageable ones. Finally, the system will be adapted Event Extraction, a fundamental IE task in the biomedical domain (Björne and Salakoski, 2015).

Abstract

Mental health is one of the main concerns of today's society. Early detection of symptoms can greatly help people with mental disorders. People are using social networks more and more to express emotions, sentiments and mental states. Thus, the treatment of this information using NLP technologies can be applied to the automatic detection of mental problems such as eating disorders. However, the first step for solving the problem should be to provide a corpus in order to evaluate our systems. In this paper, we specifically focus on detecting anorexia messages on Twitter. Firstly, we have generated a new corpus of tweets extracted from different accounts including anorexia and non-anorexia messages in Spanish. The corpus is called SAD: Spanish Anorexia Detection corpus. In order to validate the effectiveness of the SAD corpus, we also propose several machine learning approaches for automatically detecting anorexia symptoms in the corpus. The good results obtained show that the application of textual classification methods is a promising option for developing this kind of system demonstrating that these tools could be used by professionals to help in the early detection of mental problems.

1 Introduction

Mental health is one of the main concerns of today's society. The World Health Organisation estimates that 1 in 4 individuals experience mental disorders at some stage of their lives. Globally, it is estimated that about 450 million people worldwide are mentally ill, with this kind of illness making up 13% of diseases around the world (Vos et al., 2015).

Traditionally, mental health evaluation is based on face-to-face interviews, self-reported issues or the distribution of questionnaires, which is usually labor-intensive and time consuming. However, in recent years several studies have used different technologies to improve the detection of mental health issues. Specifically, some interesting studies explore the relationship between data from online social networks and users' mental conditions (Rahman et al., 2018). Some of them focus on stress (Thelwall, 2017; Lin et al., 2017), depression (Tsugawa et al., 2015), suicide (O'Dea et al., 2015; Astoveza et al., 2018) or anxiety (Shen and Rudzicz, 2017), and most of them use and extract data from Twitter, probably because the information is open and more accessible than on other platforms, and also because it is one of the most popular social networks among young people. In this paper we focus on mental health problems related to eating disorders because they exhibit the highest mortality rate of any mental illness and 20% of all deaths from anorexia are the result of suicide (Arcelus et al., 2011).

Eating disorders are complex mental disorders considered serious and often fatal illnesses associated with severe disturbances in people's eating behaviors and related thoughts and emotions (Prieto et al., 2014). Common eating disorders include anorexia nervosa, bulimia nervosa, and binge-eating disorder and affect both females and males although they are most usual among young women.

The early detection of eating disorders can increase the chances of recovering, and technology can be applied to developing systems to help professionals. Different approaches to text and data mining methods can be applicable to social media data and may prove invaluable for health monitoring and surveillance. Specifically, Natural Language Processing (NLP), also known as Language Technologies (LT) can be used to generate systems for early anorexia detection. One of the main problems is the lack of resources to train systems and more if we focus on a language other than English.

The main goal of this paper is to develop a system for the automatic detection of anorexia in textual information. For this, we first generated a corpus with tweets written in Spanish including both people talking about anorexia and people talking about healthy food habits. The corpus is called SAD (Spanish Anorexia Detection). Using the SAD corpus, we have developed different models based on Machine Learning approaches that integrate several linguistic features. We have analyzed the results and compared the different approaches.

The rest of the paper is structured as follows: In Section 2 we comment on some related studies. The SAD corpus is described in Section 3, and present some interesting statistics. The different machine learning approaches and the results obtained are shown in Section 4. Finally, the analysis of errors is conducted in Section 5 and conclusions are presented in Section 6.

2 Related Work

The detection of mental health issues using textual information is a recent task mainly inspired by the massive of use and access to social networks. People have become accustomed to using social networks to express all kinds of opinions, feelings and emotions. This valuable information can be captured and treated by an automatic system to learn how people with some health problems use language to express the frustration, depression or bad feelings. In this way, NLP can help to build systems to detect early on health problems such as eating disorders, depression or suicidal tendencies.

Although this task is relatively new, some challenging workshops and shared tasks related to the detection of health conditions have been proposed in recent years. For example, Social Media Mining for Health Applications (SMM4H) is a workshop and share task that has been held since 2016 (Sarker et al., 2016) and continues every year. The main goal is to attract researchers interested in automatic methods for the collection, extraction, representation, analysis, and validation of social media data for health informatics. Furthermore, eRisk (Losada et al., 2017) is a challenging workshop focused on mental health disorders and it has been held from 2017 in the framework of the well-known international conferences CLEF[1]. eRisk explores the evaluation methodology, effectiveness metrics and practical applications (particularly those related to health and safety) of early risk detection on the Internet. The different tasks proposed include depression and anorexia detection.

Concerning to mental health, we can find some interesting papers studying NLP techniques for treating textual information. (Rahman et al., 2018) review several studies focused on detecting mental health using and analyzing the information extracted from social networks. After analyzing several methods, machine learning algorithms, languages and sources of information, the authors conclude that machine learning is the most frequently used method used for mental health detection, with Support Vector Machine (SVM) presenting the best results. In addition, the study shows that Twitter is the major data source from social networks and English is the main language studied in the different papers. In (Prieto et al., 2014) four different health conditions are classified using machine learning methods over a corpus of tweets extracted by applying a set of crafted regular expressions. They integrate some relevant features in order to improve the final system. In addition, this is one of the few papers which center on languages other than English. Specifically, the authors work on Spanish and Portuguese tweets and the results indicate that the approach is a feasible option for tracking health information on social networks.

Regarding eating disorders, we can also find some recent studies. For example, (De Choudhury, 2015) focuses on detecting anorexia on the social network Tumblr using different affective, social, cognitive, and linguistic features. They also analyze the clinical implications of detecting anorexia related content on social media. (Chancellor et al., 2016a) use Instagram in order to study the eating disorders community and propose a statistical model combining topic modeling and clinical annotations. Finally, (Wang et al., 2017) center on Twitter generating a corpus by collecting eating disorders and non-eating disorders data. Then

[1] http://www.clef-initiative.eu/

they train a SVM classifier, obtaining promising results. The high performance achieved suggests that it is feasible to design automatic text analysis tools that give early warnings of signs of eating disorders. However, this study only focuses on English and it is important to prove that the systems can also be applied to other languages. Thus, in this paper we create a Spanish corpus from Twitter with information concerning of anorexia and non-anorexia data. Then we apply several machine learning algorithms in order to demonstrate the feasibility of implementing systems to automatically detect sings of anorexia in Spanish messages written on social networks.

3 SAD Corpus

Anorexia and bulimia are two of the most worrisome eating disorders, affecting adolescents and young people the most. ”Ana y mia” are the names used on the web pages that promote anorexia and bulimia to identify themselves. ”Ana” is anorexia and ”mia” is bulimia. But it is not a recent phenomenon, it began to become popular on the Internet in 2004 (Campos Rodríguez, 2007). Today, they have millions more pages and loyal followers, and the Internet has connected thousands of people with eating disorders. For this reason there are currently several studies of this disease (Moessner et al., 2018; Bermejo et al., 2011; Chancellor et al., 2016b). Specifically, for Spanish there is no set of Twitter messages concerning this problem, and for this reason we have compiled our own corpus, SAD (Spanish Anorexia Dataset) in order to accomplish the experiments.

3.1 Data Collection

We decided to use the social network Twitter because it is currently one of the most common sites for sharing information. This social network allows people to freely post short messages (called tweets) of up to 280 characters. Twitter has rapidly gained popularity worldwide, with more than 326 million active users generating more than 500 million tweets daily.

The task of downloading tweets has been performed through the Application Programming Interface (API) offered by Twitter. The API allows us to download messages using a query in a specific language. Our retrieving system always sets the option to Spanish, thus our classification system only works on tweets in Spanish. However, our method can easily be adapted to other languages since the Twitter API allows specification of the language of the posts retrieved.

In order to obtain enough tweets, we had to download messages from past years, more concretely, in a date range of February 2014 to March 2019.

To make the corpus more interesting, we used as a query different hashtags related to food, nutrition, diet and healthy living in a converse way to anorexia. We collected data referring to anorexia using as query the hashtag *#anaymia* on Twitter. In addition, we collected three sets of reference data as negative samples using the hashtag *#realfood #comidareal* and *#fitness*.

Label 1 (anorexia) has been assigned to tweets that satisfy the query *#anaymia*, label 0 (control) for the other cases. Different messages are shown in Table 1 and in Table 2 we can see the English translation.

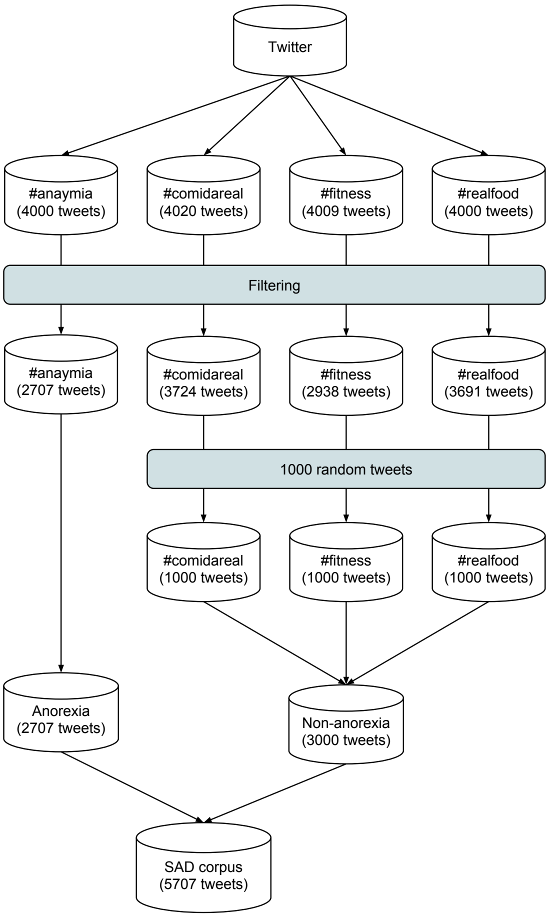

Figure 1: Process of generating the corpus from Twitter.

Tweet	*Label*
Solo quiero llegar a mi casa a comer csm, no puedo más con esta hambre. Pero el hambre es belleza entrando a tu cuerpo.	1
La comida de hoy es ligera, muy ligera. Alcachofas al horno, simplemente llevan ajo, aceite, perejil y sal. Mmmm. #masendocrino #alcachofas #dietasana #dietamediterranea #aove #aceitedeoliva #hungry #cocinaespañola #comidacasera #foodpic #banquetesv	0

Table 1: Examples of Spanish tweets tagged in SAD corpus.

Tweet	*Tag*
I just want to get home to eat, I can no longer cope with this hunger. But hunger is beauty coming into your body.	1
Today's food is light, very light. Baked artichokes, simply with garlic, oil, parsley and salt. Mmmm. #masendocrino #alcachofas #dietasana #dietamediterranea #aove #oaceitedeoliva #hungry #cocinaespañola #comidacasera #foodpic #banquetesv	0

Table 2: Example of translated tweets.

3.2 Data Filtering

Secondly, the extracted data is very noisy, so the set requires thorough cleaning before any analysis can be carried out. The language used by Twitter users contains some attributes that we had to remove to provide useful information for the classification process. This filtering that was performed:

- Repeat - the first filter to be performed was the removal of repeated tweets. Repeated tweets do not bring new information to the collection.
- Hashtag queries - we removed from the tweets the hashtag that we used as a query for downloading messages.
- All hashtag - we also removed tweets that only contained hashtags in the message. This step was followed since the experiments described in Section 4 were carried out without using hashtags.
- Short tweet - finally, tweets containing fewer than four words were removed since we consider that they do not provide enough representative information.

The objective was to obtain as balanced a corpus as possible. For cases of anorexia all tweets were incorporated. For the negative cases, we followed a different strategy, with 1000 random tweets being taken from each hashtag (*#comidareal*, *#fitness* and *#realfood*), in this way, the corpus contains 2707 tweets annotated as positive (anorexia) and 3000 tweets annotated as negative (control). Figure 1 shows the number of tweets downloaded and how the collection decrements at each step.

3.3 Corpus Statistics

In this Section we will focus on obtaining statistics referring to the corpus containing relevant information. These statistics refer to the number of words, stopwords, hashtags, and part-of-speech tagging, among others.

The first study carried out consisted of obtaining the number of tweets, the number of words, the number of users and the number of stopwords in Spanish that exist in the corpus. This is shown in Table 3, where we can find the difference between the messages annotated with anorexia and those annotated as control.

It is interesting to see how the percentage increase in controlled tweets is 44% greater than the anorexia vocabulary, taking into account the number of total words as it can be seen in Table 3. But this information is reasonable because the average of tweet words is higher in controlled cases.

The grammatical labelling can be found in the Table 4. For this study we have used the spaCy[2]

[2] https://spacy.io/

	Total	*Anorexia*	*Control*
Number of tweet	5707	2707	3000
Number of different users	2585	1120	1466
Number of total words	122798	43179	79619
Number of different words	24635	8761	18515
Average of tweet words	21.52%	15.95%	26.54%
Number of total stop words	30619	13118	17501
Number of different stop words	207	183	185
Average of tweet stop words	5.37%	4.85%	5.83%

Table 3: Linguistic statistics on SAD corpus.

library with the module *es_core_news_sm*[3]. spaCy is a free open-source library for NLP in Python.

Table 4 shows the statistics obtained, and in it we can see relevant information on verbs, nouns, adjectives and adverbs. We found special interest in the high number of verbs and nouns used in annotated tweets without anorexia.

We wanted to obtain some statistics about the mood of users and how they express themselves through social networks. To obtain this information we used the resource iSOL (Molina-González et al., 2013). This resource has a list of opinion indicator words in Spanish independent of the domain. The list consists of 2,509 positive words and 5,626 negative. The results are described in Table 5. This table shows that users with anorexia problems use more negative language than users without anorexia. The same happens in the opposite case, whereby the tweets annotated as controlled are written with more positive words.

Finally, Table 6 shows some data about the use of hashtags in the messages collected. We can observe that the number of hashtags used in controlled tweets is much higher than on the contrary, and consequently there is also more variety of hashtags in messages annotated without anorexia.

4 Experiments and Results

In this section, we describe different experiments we carried out to test the validity of the SAD corpus. In particular, we trained several classifiers based on machine learning.

4.1 Pre-Processing

Pre-processing the data is the process of cleaning and preparing the text for classification. It is one of the most important steps because it should help improve the performance of the classifier and speed up the classification process. Online texts usually contain lots a great deal of noise and uninformative parts which increases the dimensionality of the problem and hence makes the classification more difficult. For this reason, we applied pre-processing techniques in order to prepare the data for the text classification. In particular, we preprocessed the tweets of the SAD Dataset following these steps: The tweets were tokenized using NLTK TweetTokenizer[4] and all hashtags were removed.

Features in the context of text classification are the words, terms or phrases that express the opinion of the author. They have a higher impact on the orientation of the text. There are several ways to assess the importance of each feature by attaching a certain weight to it in the text. We use the most popular: The Term Frequency Inverse Document Frequency scheme (TF-IDF). Specifically, using this scheme each tweet is represented as a vector of unigrams.

4.2 Machine Learning Algorithms

Machine learning techniques are popular in the binary classification. For this reason, we decide to employ different machine learning algorithms in order to classify the corpus in anorexic and non anorexic tweets. The algorithms are Support Vector Machine (SVM), Naive Bayes (NB), Random Forest (RF), Multilayer Perceptron (MLP), Logistic Regression (LR) and Decision Tree (DT).

4.3 Results

In this subsection, we report and discuss the performances of our systems on the Spanish anorexic

Table 5: Statistics about positive and negative words in the corpus.

classification task on the SAD corpus. In order to evaluate and compare the results obtained by our experiments, we use the usual metrics in text classification, called precision *(P)*, recall *(R)*, F-score *(F_1)* and Accuracy *(Acc)*.

To determine the optimal classification algorithm, we conducted experiments with the six classification models. We used 10-fold cross validation to evaluate the machine learning classification approaches including: The *SVM* classifier, the *Naive Bayes* classifier, the *Random Forest* classifier, the *Decision Tree* classifier, *Logistic Regression* and the *Multilayer Perceptron* classifier. The test results achieved by these algorithms on the SAD corpus are shown in Table 7.

The classifiers with the best performance were SVM and MLP with the default settings in the Scikit-learn 0.19.1 package (Pedregosa et al., 2011). The other classifiers also showed good results, all achieving an accuracy score superior to 80%. It should be noted that they performed well in both classes (anorexia and control) because the corpus is well balanced.

5 Error Analysis

The main purpose of this section is to carry out an error analysis to identify the weaknesses of our system. For this, we analyze some of the tweets not correctly classified by our system.

Of the total number of tweets (5707), 478 were not correctly classified, only 8.38% of the total tweets. In Figure 2, the confusion matrix of our system can be seen. It shows that there were more false positives (300) than false negatives (178). Therefore, we analyzed some of these tweets manually in order to find the main reasons why our system can be confused.

Table 2 presents some examples of tweets incorrectly classified by our system and Table 1 shows the corresponding translation. Specifically, two of the tweets are false positives and the other two false negatives. On the one hand, if we look at the false positives, we can see that two of the reasons why our system can be wrong is because it detects that there are words related to food and also that the vocabulary of the other tweets labeled as control is very similar to the vocabulary used in anorexia. Therefore, the system is sometimes con-

6 Conclusion

This article presents a new corpus in Spanish for detecting anorexia in social network messages. Several systems are also developed to test the performance of this task with different classifiers. The results obtained show that the performance is very similar in all systems, although SVM and MLP are the only ones that obtain accuracy above 0.9.

Error analysis reveals that there are cases where classification systems do not work properly. Our next goal will be to apply other techniques (such as irony detection or sentiment analysis) in cases where textual information is poor or where rhetorical figures such as irony and sarcasm are used.

A Type-Theoretical Reduction of Morphological, Syntactic and Semantic Compositionality to a Single Level of Description

Erkki Luuk
Institute of Computer Science, University of Tartu, J. Liivi 2, Tartu 50409, Estonia
erkkil@gmail.com

Abstract

The paper presents NLC, a new formalism for modeling natural language (NL) compositionality. NLC is a functional type system (i.e. one based on mathematical functions and their types). Its main features include a close correspondence with NL and an integrated modeling of morphological, syntactic and semantic compositionality. The paper also presents an implementation of NLC in Coq. The implementation formalizes a diverse fragment of NL, with NLC expressions type checking and failing to type check in exactly the same ways that NL expressions pass and fail their acceptability tests. Among other things, this demonstrates the possibility of reducing morphological, syntactic and semantic compositionality to a single level of description. The level is tentatively identified with semantic compositionality — an interpretation which, besides being supported by results from language processing, has interesting implications on NL structure and modeling.

1 Introduction

As shown by Asher (2014), Luo (2010, 2014) and Ranta (1994), in a logical approach (i.e. in one with simpler alternatives such as zeroth, first, second and higher order logic), complex type theories outshine simpler ones in accounting for natural language (NL) phenomena like anaphora, selectional restrictions, etc. The basic judgement in type theory, $a : A$, is read "term a has type A", where

(i) type := a category of semantic value.

Since the notion of type is inherently semantic, it is by definition suited for analyzing universal phenomena in NL, as NL semantics is largely universal (as witnessed by the possibility of translation from any human language to another).

2 Interpreting Natural Language

NL functions and function applications have a distinctive form. Specifically, any *morphosyntactically admissible concatenation* $\mathrm{c}(a, e_1, ..., e_m)$, which is parsed as $a(e_1, ..., e_m)$, is a function or function application term (FFAT) in NL ($e_1, ..., e_m$ may be null). For example, *red*, *red book*, *livre rouge*, etc., are FFATs in idiosyncratic notations (viz. English, French, etc.). As linguistic expressions are FFATs, they are naturally parsed as functions or function applications.

How to decide whether a particular application $a(e_1, ..., e_m)$ holds? Usually, one has a basic intuition about what modifies what (modification is a subcase of function). The main sources for the intuition are morpheme or word classes and semantic contribution tests. For example, *-s* modifies (i.e. is a relation over) *work* in *works* rather than vice versa, as (1) affixes modify stems not vice versa, (2) person/tense and plural markers modify flexibles[1] rather than vice versa, and (3) *-s* contributes to the meaning of *work* in *works* rather than vice versa. By a similar argument, *heavy* modifies *rain* in *heavy rain* rather than vice versa, *sleeps* modifies *john* in *john sleeps* rather than vice versa, etc. In each case, there's a clear asymmetry between functions of the components, as conveyed by (1)–(2) the functions of word and morpheme classes and (3) semantic contribution tests.

While the above methods may seem sufficient by normal standards, for type-driven theories an even more rigorous way of testing NL relations

[1] See Luuk (2010).

is available. We can model a (reasonably large) fragment of NL in a suitable type system to make it *(fail to) type check in exactly the same ways as (hypothetical) NL expressions pass (and fail) acceptability tests*. Call this principle "the correspondence criterion". Arguably, this possibility, the ultimate test for any type-driven linguistic theory, has not been fully explored, while several significant steps in this direction have been taken. Chatzikyriakidis and Luo (2014b, 2016) describe (among other things) a use of proof assistants for testing the logical soundness of linguistic theories, while Grammatical Framework (GF, Ranta (2004)), a statically typed programming language for writing NL grammars, gets closest to a *type-theoretical implementation of NL*. However, GF is a high level tool, mathematically opaque to the end user, and quite specialized. Because it is geared towards writing NL grammars, it does not offer a selection of different mathematical formalisms to work with, being thus unsuitable for a general (low level) modeling of NL and theories thereof. In addition, it does not concern itself with modeling compositional semantics, although a FrameNet API for GF has been proposed and partly implemented (Gruzitis et al., 2012; Gruzitis and Dannélls, 2017).

A powerful feature of typed theories (especially of the richly typed[2] ones — Chatzikyriakidis and Luo (2014b)) is that they allow to capture not only grammatical but also semantic acceptability. The paper shows that a combination of functions and rich typing makes it possible to use *a single type system for modeling the core of NL morphology, syntax and compositional semantics*, thus questioning the soundness of the theoretical distinction between these different NL "layers" (and partly eradicating their even more theoretical "connections" such as the syntax-semantics interface). Because of a wide selection of mathematical formalisms in a richly typed setting, combined with a relatively "instant" compile time type checking, proof assistants (e.g. Coq, Agda, Lean) are suitable tools for such work (cf. Chatzikyriakidis and Luo (2016)). As shown below, implementing polymorphic functions with a subclass of compound types (called lump types) allows to partly collapse different "levels" of NL (morphology, syntax, and compositional semantics).

3 A Note on Selectional Restrictions

More or less overlooked in Montagovian (Montague, 2002) and categorial (Lambek, 1958) traditions, selectional restrictions have recently become a focus of intense research in modern type theories (Asher, 2014; Luo, 2010; Bekki and Asher, 2013). The essence of the semantic (and perhaps even more logical than linguistic) phenomenon of selectional restrictions is prescribing types for a relation's arguments.

There is an important difference between (1) arguments belonging to types and (2) relations imposing types on their arguments. While an argument can clearly belong to different types[3], a relation should not impose different types on its *k*th argument, for a fixed *k*. Modeling selectional restrictions along with grammar is an important motivation for lump types, described below (in section 5.1.1).

4 Introducing NLC

Call the formalism we are considering NLC. It is a type system for modeling NL syntax, morphology and compositional semantics — briefly, compositionality in NL. The basic unit of NLC is a function of a small (usually ≤ 3) arity. The expressions of NLC are functions, function applications, function types (Π-types), lump types, terms of lump types, and universes (types of types). Elementary terms of NLC are functions. This is possible if we interpret "proper arguments" as nullary functions (functions that take no arguments). So functions are divided into proper arguments and proper functions (the latter being functions that take arguments). For a fixed NL k, let T^k be a proper type variable of NLC, where "proper type" refers to a type that is not a universe, and $\mathcal{M}^k$ the set of morphemes[4]. Then we have the rule:

$$\frac{a \in \mathcal{M}^k}{a : T^k} \text{ ATV-Intro},$$

for generating atomic terms of NLC and introducing type variables for them. The rule ATV-Intro says that all morphemes have types in NLC (technically: "if a is a morpheme of language k then a has type T^k").

Some morphemes (e.g. stems) occur only in an argument position (i.e. are proper arguments),

[2] Rich typing coincides mainly (although perhaps not exclusively) with dependent and/or polymorphic types.

[3] E.g. a book is a physical and informational object.

[4] Morphemes are smallest signs (form-meaning correspondences) in language.

while others (e.g. plural markers) are proper functions. More generally, a function or function application is a parsimonious interpretation of morphemes, words, phrases and sentences in NL. *Sentences, multimorphemic words and phrases are function applications*. This amounts to a rigorous interpretation of the more general "principle of compositionality", as it is known at least since Frege[5]. Broadly speaking, there are only two ways to explain the emergence of compositional meaning: by specifying a relation together with its (a) arguments or (b) type. The first corresponds to e.g. function application and the second to function declaration.

In a functional type system, generating complex terms and introducing type variables for them is straightforward (rule CTV-Intro, with T_i^k ranging over proper types):

$$\frac{e_1 : T_1^k, ..., e_m : T_m^k \quad a : T_1^k \to ... \to T_m^k \to T_{m+1}^k}{a(e_1, ..., e_m) : T_{m+1}^k}$$

where $a(e_1, ..., e_m)$ is an application and $T_1^k \to ... \to T_{m+1}^k$ the usual (right-associative) function type. Since CTV-Intro is the standard function type elimination rule, the function type introduction rule is derivable from CTV-Intro.

5 NLC: The Types

Since grammatical (and semantic) categories have a limited, finite number of members, we need some atomic types with limited membership. Let $\mathcal{U}$ denote the top-level universe of NLC. We use axioms of the form $S : \mathcal{U}$ and $T : S$, where S may be a universe, for introducing atomic type constants corresponding to linguistic categories like stem, case, nominative, noun, verb, etc. For proper functions, we need function types (Π-types). Besides this, we need only polymorphism and lump types, both of which can be (in various ways) implemented with function types.

Since a term of type A may contain another term of type A (or in case of a function type, take another term of the type as an argument), we have sufficient complexity without recursion (self-reference, which we do not need). For example, a sentence A containing another sentence B does not imply recursion unless $A = B$ or B references A. Thus, we have same-type-reference without self-reference.

5.1 Polymorphism and Lump Types

The complexity of NLC goes well beyond regular function types. In considering a NL expression type-theoretically, one is frequently inclined to assign it to more than one type. Confining our analysis to only the linguistically relevant features, we may want to type e.g. *stone* as a flexible, physical object, word in nominative case, etc. A way — corresponding to polymorphism — to go about this is to define coercions to (i.e. coercive subtyping for) all the types we need. In fact, we have three possibilities: either we (1) lose some type information, type *stone* (2) polymorphically or (3) with a lump type.

As the nominal and verbal readings of *stone* preclude each other, a polymorphism is required if we want to encode them both (cf. footnote 7). In many other cases, however, a lump type may be preferred. Thus, NLC features types for morphemes, function types, lump types and polymorphism.

5.1.1 Lump Types

While possibility (3) is new, the superclass of lump types, compound types have been used for NL modeling in the form of multi-field record types (Cooper, 2005; Ranta, 2004; Luo, 2011; Chatzikyriakidis and Luo, 2014a). Also, some kind of polymorphism (e.g. by subtyping — Luo (2010)) is frequently thought to be necessary. However, the use of compound types has been so far confined to record types only, i.e. not properly generalized[6]. A compound type is a type which is a syntactic compound of multiple types or their terms. Normally, the compounded types are different; in the degenerate case, they are the same. Examples (or implementations) of compound types include Σ-, Π-, Cartesian product and multi-field record types.

We defined types as "categories of semantic value" but, as the example of *stone* shows, for NL expressions the value covers not only linguistic semantics but also the meanings of syntactic and

[5] The principle is more general because it holds also for interpretations of formal languages.

[6] In many (most?) programming languages that support them, the notion of "compound type" (or "compound data type") is synonymous with a multi-field record type. This is *not* the way it is used here. While a record type can be defined as a (mathematically more fundamental) Σ-, Π- or Cartesian product type (Constable, 2003), I have never seen it defined as a function application.

morphological categories (we will return to this point in section 9). As compared to (1) and (2), packing an expression's meaning into a lump type allows to do away with both the loss of information and typing complexity. Of course, the lump type itself will be complex but this will, hopefully, present less problems than alternatives (1) and (2). As a bonus, the underlying linguistic model will simplify on account of reducing compositional semantics and parts of morphology and syntax to a single level of description. Below is the rule for lump type introduction (LT-Intro):

$$\frac{B : T^k \quad c_0 : C_0^k,\ ...,\ c_{n+1} : C_{n+1}^k \quad B \mapsto c_0, ..., B \mapsto c_{n+1}}{B : C_0^k..C_{n+1}^k}$$

where T^k is a proper type variable, B a term constant and $C_0^k, ..., C_{n+1}^k$ type constants in NLC, $x \mapsto y$ a function interpreting x as y[7], and $C_0^k..C_{n+1}^k$ the notation for a lump type (comprising types C_0^k through C_{n+1}^k, i.e. there must be at least two). LT-Intro is formalism-agnostic — the exact mathematical structure used for lumping is irrelevant. In particular, as shown in Supplement A[8], we can implement lump types for NL as 1) record types, 2) function applications, 3) Cartesian product types, or 4) Π-types. In languages that have them (e.g. TypeScript, Flow...), it is natural to encode lump types as intersection types. Lump types are defined as compound types that satisfy LT-Intro (i.e. we are not interested in empty lump types).

Supplement B[9] proceeds to formalize a diverse fragment of NL with function applications. The fragment comprises stems, nouns, verbs, flexibles, proper names, pronouns, XPs[10], adjectives, sentential, adjectival and generic adverbs, determiners, demonstratives, quantifiers, tense-aspect-mood, gender, number and nonfinite markers, cases, adpositions, sentences (both simple and complex), connectives, connective phrases (for substantives, adjectives, adverbs and sentences), complementizers, copulas, and selectional restrictions (for physical, informational, limbed, biological, animate and sentient entities).

The linguistic categories not formalized in Supplement B are gerunds, participles, auxiliary verbs, interrogatives, numerals, negation, mass/-count distinction and unspecified selectional restrictions (and possibly others). These are omitted not because of a special difficulty formalizing them would pose but because the formalized fragment is sufficiently expressive (and representative of NL) to make the points of utility and feasibility of NL formalization with the combination of compound and polymorphic types. The formalization has been done in the proof assistant Coq (ver. 8.9), making use of its features like Ltac programming, custom notations, etc. Besides showing the use of lump (viz. application) types in NL modeling, Supplement B should fulfill the abovementioned "correspondence criterion".

5.1.2 Polymorphism

Besides lump types, there is some use for polymorphism as well — if not for any other reason, then because NL expressions may be underspecified. E.g. *sleep* and *stone* are flexible stems that can function both as nouns and verbs. As a verb, *sleep* selects for a specific argument, say, a sentient entity (only higher animals can sleep — for trees, stones and bacteria it is not an option). As a noun, it is quite similar to many others: a stem, a flexible in singular, an event, etc. Since verbs are functions, *sleep*'s type must be a function type, but since it also functions as a noun, a polymorphism is desirable. The alternative, defining two distinct *sleeps*, one noun and one verb, would be redundant and inelegant — esp. in a programming language, where (differently from NL) they would have to be formally distinct (e.g. `sleep` and `sleep0`) even in the absence of any discriminating context (markers and/or arguments).

There are several ways to implement polymorphism, but dependent and/or polymorphic types and subtyping are the most common. For example, Coq supports polymorphic types (e.g. `∀x:Type, x`), but an additional formalization layer is sometimes desirable to improve type inference. One of the main obstacles for formalizing NL in Coq (and likely also in other proof assistants) is that NL type inference is much more powerful than that of the (terms of) relatively simple types like sorts, sensu stricto variables (e.g. those defined with `Parameter` and `Variable` in Coq) and function types over them. The reason is that the simple types have an unbounded num-

[7] The interpretations must not preclude each other; if they do (as e.g. the interpretations of *run* as a noun and verb), they are dealt with polymorphism instead.

[8] https://gitlab.com/jaam00/nlc/blob/master/compound.v

[9] https://gitlab.com/jaam00/nlc

[10] Frequently (and theory-dependently) alternatively referred to as NPs or DPs.

ber of terms, while in NL the number is fixed, very limited, and usually known in advance[11]. The only counterexamples to this rule are phrases, clauses and complex words. So the additional layer of formalization is used for downgrading the over-powerful simple types to something on which type inference would work. In Coq, the main devices for such downgrading are inductive types, “canonical structures”, and type classes. Our formalization uses them all, relying most heavily on canonical structures (essentially, canonical records of a record type).

6 Truth-Functionality

So far, the semantics developed here is not truth-functional, i.e. it is type- but not model-theoretic. As type theory is ‘semantic’ by definition, it is clearly sufficient for a semantical cast of semantics without a recourse to model theory. This is evident in programming language semantics, where the role of model theory is marginal as compared to that of type theory. Traditionally, in natural language semantics the opposite is true, as sentential semantics is usually construed as model-theoretic even in a type-theoretical setting (e.g. Chatzikyriakidis and Luo (2015, 2016)). The obvious reason for this is that the (prevailing, i.e. Montagovian) tradition is model-theoretic. For this reason, an optional truth-functionality module has been added to the implementation. Degenerate models (where all NLC sentences (S) are uniformly true, false or undecidable) can be specified trivially by subtyping, e.g.

```
Parameter s_prop:> S -> Prop.
(* all S-s undecidable *)
```

and with only a little effort non-trivial models can be specified, too (with subtyping and a special notation matching NLC constructions with appropriate values). Below is an example from Supplement B:

```
Check $(PRES walk john): Prop. (*False*)
Fail Check $(PAST walk stone). (*type mismatch*)
Check $(PRES sleep john). (*True*)
Check $(PRES sleep (PL boy)). (*False*)
Check $(PAST sleep (-s boy)). (*True*)
Fail Check $sleep. (*type inference fail*)

(*a trivial proof that "boys
don’t sleep" and "john sleeps"*)
Theorem pres: (~ ($ (PRES sleep (-s boy)))) /\
($ (PRES sleep john)). Proof. firstorder. Qed.
```

7 Comparisons

In section 2 we compared NLC with related typed approaches. This section takes a broader (albeit still related) perspective, comparing NLC with Combinatory Categorial Grammar and Head-Driven Phrase Structure Grammar.

7.1 Combinatory Categorial Grammar

A feature of NLC, Combinatory Categorial Grammar (CCG) (Steedman, 2000) and some other categorial formalisms is that they tend to do away with syntax: “...syntactic structure is merely the characterization of the process of constructing a logical form, rather than a representational level...” — Steedman (2000), p. xi[12]. The main differences are as follows. CCG is a categorial formalism, NLC not. CCG has complex (combinatorial) syntactic types of the form $X\backslash Y$ and X/Y instead of lump types with (what is conventionally viewed as) morphological, syntactic and semantic information. Another difference is CCG’s (by default limited) support for word order. (In particular, CCG does not handle concatenations (of terms of types) c$(X/Z, Y, Z)$ and c$(Z, Y, X\backslash Z)$, where Y is nonempty[13].) Also, in CCG, NL constructions of sentence level and below can have multiple structures *independently* of (what is traditionally called) interpretational ambiguity.

7.2 Head-Driven Phrase Structure Grammar

It is also useful to compare NLC with a more dedicated syntactic formalism such as Head-Driven Phrase Structure Grammar (HPSG). As a mature formalism that has been implemented for several languages (Pollard and Sag, 1994; DELPH-IN, 2019), HPSG is currently implementation-wise much superior to NLC (which has been implemented only for a fragment of English[14]), so it is appropriate to compare only formalisms. We start with similarities. Both formalisms model parts of semantics, syntax and morphology, but HPSG’s scope is much wider, as it covers also

[11] The latter will depend on your linguistic theory, as different theories posit different categories and members for them.

[12] However, as described below, CCG still features syntactic types.

[13] I am not sure whether such concatenations exist in NLs with fixed word order, but a decision to rule them out by default is arbitrary. However, perhaps it would be feasible to introduce a special rule for accommodating Y in this case.

[14] Structurally, the fragment is quite universal. In fact, with a slightly more general notation one can approximate a Universal Grammar (a statement that will make more sense after reading section 9 and recalling that NL semantics is universal).

lexicon and word and morpheme orders. Both formalisms are compositional in that the meaning of a sentence is given by its constituent structure (Carnie, 2012), but the ways of achieving this are very different: HPSG uses attributes (features) and attribute value matrices while NLC uses types and functions. With this the similarities seem to end. HPSG and NLC are fundamentally different kinds of formalisms — the former features an extensive set of attributes, rules and attribute complexes, while the latter has only three rules (introducing atomic, function application and lump types), leaving the specification of types to the implementor. In a sense, there is little to compare, as HPSG is a full-blown *NL grammar formalism* (that has been extended to cover also selectional restrictions) while NLC is a *generic type system for modeling NL compositionality*. Thus, NLC is a much simpler and more general system, and its implementor has significantly more freedom in NL modeling than an implementor of HPSG.

8 Implementing NLC

My experience of implementing NLC is quite limited, as I have so far tried to implement it only in one programming language and have implemented at best a half of NL in terms of its general (or typological) category structure. Below is a test of an implementation of NLC. The test is by type-checking possible NL(C) expressions. The code (from Supplement B) is generously commented and should be self-explanatory.

```
Check PAST throw john. (* "John threw"
type checks -- but not as a sentence: *)
Fail Check PAST throw john: S. (* "At the hut"
can be the 3rd argument of "throw": *)
Check PAST throw john (-s stone)
(at (the hut)). (*..but not the 2nd one:*)
Fail Check PAST throw john (at (the hut)).
(* "In a hut" cannot be
an argument of "throw": *)
Fail Check PAST throw john
(-s stone) (in (a hut)).
(* ..but can be a sentence modifier: *)
Check in (a hut) (PAST throw john (-s stone)).
(* ..and so can "at every hut" and
sentential adverbs like "however": *)
Check at (every hut) (PAST throw john
(-s stone)): S.
Check however (PAST throw john (-s stone)): S.
(* Connectives cannot range over a
sentential and nominal argument: *)
Fail Check and (PAST throw john (a stone))
john. (* ..but can range over nominal: *)
Check and (every john) (all (the (-s boy))).
(* ..or sentential arguments: *)
Check and (PAST walk (-s boy)
(to (all (-s hut)))) (PAST sleep john).
(* ..(also w/ optional arguments omitted): *)
Check and (PAST walk john) (PAST sleep john).

(* Examples of lump types *)
(* "John" is an XP, proper name, male, in
nominative, singular, a physical entity: *)
Check john: XP0 Phy NOM SG (Pn Ml).
(* ..and a limbed entity: *)
Check john: XP0 Lim NOM SG (Pn Ml).
(* "The entire hut and all Johns" is an XP
and physical entity in nominative: *)
Check and (the (entire hut))
(all (-s john)): XP2 Phy NOM _ _. (* ..or
pseudo-accusative (by zero-derivation): *)
Check and (the (entire hut))
(all (-s john)): XP2 Phy ACC′ _ _.
(* ..and can be made into a sentient
entity in Lax mode only: *)
Check [and (the (entire hut))
(all (-s john))]: XP2 Sen ACC′ _ _.

(* "John threw madly blue stones at the hut
and red limbed boys." has 2 parses: *)
Check madly (PAST throw) john
(blue (-s stone)) (at (and (the hut)
(red [limbed (-s boy)]))): S.
Check PAST throw john
(madly blue (-s stone)) (at (and (the hut)
(red [limbed (-s boy)]))): S.
(* Here we used "[...]" to make a
limbed entity into a physical one. *)

(* We can stack adverbs and adjectives, and
use adjectival and adverbial connectives: *)
Check all ((and madly madly) red (red
[and blue limbed [-s john]])). (* All madly
and madly red, red, blue and limbed Johns *)
```

In Coq, _ is a placeholder for any admissible term or type. A switch in the file the code is taken from allows to choose between Strict and Lax modes, respecting and ignoring selectional restrictions, respectively. The notation [...] interfaces with the current mode. The example omits all technical details like type definitions, etc. These are not instrumental to NLC, as the type system — i.e. one capturing the morphological, syntantic and semantic compositionality of NL with lump types as faithfully as possible — can be implemented in several ways (cf. Supplement A) and different programming languages. The implementation uses only a tiny subset of Coq's features, and its main functionality, theorem proving, is entirely optional here. As I am not at all convinced that Coq is the best language for implementing NLC, I encourage the interested reader to experiment with a programming language of their choice. That being said, statically typed programming languages with a sufficiently complex type system and advanced type inference have some advantages for this kind of work (e.g. in terms of rigor and the similarity of implemented formulas to NL expressions).

9 Implications

The driving force behind NLC has been to correspond to NL as closely as possible. Since ontology (or world knowledge) interfaces with the compositional semantics of NL, it is desirable to formalize some of it in the form of selectional restrictions. We have collapsed syntactic, morphological and semantic compositionality to a single level — to that of the type system. In effect, some types have become syntactic, but the syntax has only two rules: functionality (CTV-Intro) and lumping (LT-Intro). In sum, the paper (and the underlying formalization) have shown that:

(†) A feature of natural language — viz. morphological, syntactic and semantic compositionality — can be reduced to a single level of description.

It is not clear what (†) means, so let us try to explore it further, by (temporarily) assuming that (†) posits a new level of description — call it compositionality — which, moreover, would have to interface with lexical semantics and (what is left of) morphology and syntax. This would be not only theoretically unheard-of (which would be only a mild objection) but would have the undesirable consequence of complicating the general framework of linguistic theory. However, it would have some positive outcomes as well, namely "eliminating" compositional semantics and simplifying morphology and syntax proper. The general theory of natural language would become more complex while three subtheories (morphology, syntax and semantics) would simplify.

Depending on one's outlook on the general theory of natural language, this might seem like a path worth pursuing. However, below I will argue that it is not the only one. The alternative would be to assume that:

(‡) There's nothing "morphological" or "syntactic" about morphological and syntactic compositionality — it is all just semantic compositionality.

Clearly, (†) and (‡) are not mutually exclusive — in fact, (‡) is just a more radical version of (†) (and incidentally, also subsumes (†)). (‡) just conflates the hypothetical new level of description of (†) with compositional semantics. Word and (subword) morpheme order pertain to syntax and morphology, respectively; the compositionality of words, phrases, morphemes and clauses pertains to semantics. As a desirable consequence, we could continue using the existing general theory of natural language with only a few terminological changes. But (how) would (‡) be viable?

A possible justification would make at least two arguments. First, from the theoretical side, morphological, syntactic and semantic compositionality all refer to certain (parts of) knowledge — namely, about morphology, syntax and world, respectively. The only way to have knowledge is by way of meaning, which, given the above, is clearly linguistic. This consideration roots our enterprise in linguistic semantics. Second, from the formalization side, we are using type theory, which is a theory of semantics (broadly defined[15] — cf. (i)). This argument formally corroborates the claim that NLC models only natural language semantics.

Of course, the fact that NL can be modeled this way does not entail that this is the way it works in the brain[16]. So far, our argument has been solely about modeling: It is more parsimonious to model compositionality in a functional type system than e.g. with syntax trees or phrase structure rewrite rules, since the latter cannot, neither separately nor when combined, account for all compositionality. The only advantage of the rewrite rules and syntax trees over the type-theoretical modeling is that they allow, in principle, to capture word order. However, not all syntactic theories support linear order preserving trees (the Chomskian transformational grammar being a case in point — Chomsky (1965, 1981)). Secondly, a word order rule is, differently from compositionality, not a linguistic universal (there are many languages with flexible word order — Dryer (2013)). Incidentally, this also means that *not all natural languages have syntax*.

One thing that seems to emerge from the literature on language processing is the role of syntax as guiding semantic interpretation, or (more figuratively) serving semantics (Kempson et al., 2001; Morrill, 2010; Christiansen and Chater, 2016). Some authors have explicitly argued against syn-

[15] Historically, the semantics of mathematics, more recently also the semantics of programming languages.

[16] Incidentally, there is little sense in trying to make a case of "how language works in the brain", as there is no consensus on this among psycho- and neurolinguists (Chater and Christiansen, 2016).

tax as a separate representational level of linguistic structure (Pulman, 1985; Steedman, 2000). Topographical patterns of brain activation to nouns and verbs are driven not by lexical (grammatical) class but by semantics and word meaning (Moseley and Pulvermüller, 2014). A cognitive architecture with a multi-level (syntactic, semantic, morphological, etc.) NL processing usually requires positing at least as many memory buffers for it (Levinson, 2016), while our short-term memory (obviously recruited in e.g. dialogues) is very limited (Cowan, 2001). These pieces of evidence from language studies also corroborate (‡).

In sum, we hypothesize that combinatorial (im)possibilities in syntax and morphology are better analyzed as belonging to the domain of compositional semantics. Moreover, the conjecture that the traditional boundaries between the levels of description reflect more of a sociological (a division of labor among linguists) than a linguistic fact is not too bold.

If the hypothesis is correct, nothing remains in syntax except word order[17]. Since word order can label (now already semantic) constituents, as in $John_{\text{SUB}}$ $loves$ $Mary_{\text{OBJ}}$, a limited form of syntax-semantics interface is also expected. This accords with the view of the function of syntax as serving semantics, viz. in interpretation disambiguation, which is the primary function of word order constraints (as witnessed in the example above). Syntax-semantics interface is also an appropriate level for phenomena like anaphora and ellipsis. Likewise, morphology proper retains only (subword) morpheme order and fusion, while morphophonological (i.e. morphology-phonology interface) phenomena like e.g. sandhi must also be accounted for. As a result, syntax and morphology emerge as by-products of a contingent conformation to the serial channel over which language is processed.

10 Conclusion

If we interpret proper arguments as nullary functions, all NL expressions up to the sentence level (i.e. morphemes, words, phrases, clauses and sentences) can be interpreted as functions and function applications. The paper presents NLC, a generic functional type system (i.e. one consisting primarily of functions and their applications). NLC is generic in at least two respects: 1. It is applicable to all NLs, and 2. It allows for generic modeling of morphological, syntactic and semantic compositionality. Besides functions, applications and their types, NLC features polymorphic and lump types. The latter are compound types satisfying LT-Intro. Compound types are types which are syntactic compounds of multiple types or their terms (Σ-, Π- and Cartesian product types are examples of compound types). At its core, NLC is a simple system for an integrated modeling of the morphological, syntactic and semantic compositionality of NL with lump types.

The paper also presents an implementation of NLC in Coq (which, unfortunately, is not quite as simple, which may be Coq's fault). The main goal of the implementation was to formalize a reasonably diverse fragment of NL in NLC, with formalized NLC expressions type checking and failing to type check in exactly the same ways that NL expressions pass and fail their acceptability tests. Aside from this goal's feasibility, the implementation shows several things: (1) the viability and simplicity of NLC for modeling NL compositionality, (2) the utility of lump and polymorphic types in NL modeling, and most importantly, (3) the possibility of reducing morphological, syntactic and semantic compositionality to a single level of description. In discussion we have tried to identify this level as semantic compositionality — an interpretation which, besides being supported by results from language processing (Pulman, 1985; Steedman, 2000; Moseley and Pulvermüller, 2014), has interesting implications on NL structure and modeling. In particular, it may reduce syntax and morphology to word and morpheme orders, respectively (with the syntax-semantics and phonology-morphology interfaces reducing correspondingly), with NL architecture taking on a rather different look. This has also implications on linguistic typology, as syntax would, much like morphology before it (Muansuwan, 2002; Grandi and Montermini, 2005; Klamer, 2005), cease to be a logically necessary component of NL.

Abstract

In this paper, we present our work on developing a vocabulary trainer that uses exercises generated from language resources such as ConceptNet and crowdsources the responses of the learners to enrich the language resource. We performed an empirical evaluation of our approach with 60 non-native speakers over two days, which shows that new entries to expand ConceptNet can efficiently be gathered through vocabulary exercises on word relations.

We also report on the feedback gathered from the users and an expert from language teaching, and discuss the potential of the vocabulary trainer application from the user and language learner perspective. The feedback suggests that v-trel has educational potential, while in its current state some shortcomings could be identified.

1 Introduction

One of the major challenges for the NLP community is the continuing lack of comprehensive and high-quality language resources (LRs) for most languages. While LR creation can partly be approached in an automatic fashion (e.g., by harvesting a vocabulary from existing corpora), it often requires human intervention to reach a high level of quality and coverage. Crowdsourcing (Howe, 2006) is one promising approach that can be leveraged for the task of LR creation. However, any crowdsourcing ambition is faced with the challenge of attracting and retaining crowdworkers and with safeguarding the quality of results produced by the crowd (Daniel et al., 2018). EnetCollect[1] (Lyding et al., 2018; Nicolas et al., 2018) aims at exploring a solution to this challenge by combining the activities performed in language learning with approaches for crowdsourcing language-related datasets. Thus exploring a new path to address the NLP bottleneck of high-quality language resource creation.

In this paper, we present an application for vocabulary training that is specifically designed to crowdsource learners' answers to improve LRs like concept networks. The application builds on top of an architecture for crowdsourcing of language resources (Rodosthenous et al., 2019), which instantiates one of the core ideas of enetCollect: the *implicit crowdsourcing paradigm* (Section 2). Accordingly, the vocabulary trainer aims at a two-fold purpose: serving automatically

Proceedings of Recent Advances in Natural Language Processing, pages 674–683,
Varna, Bulgaria, Sep 2–4 2019.

generated vocabulary exercises and gaining continuous input from the learners to improve LRs.

In the remainder of the paper, we first introduce the vocabulary trainer *v-trel* and describe its different modules and their technical implementation (Section 2). We describe how v-trel instantiates a generic prototype architecture for crowdsourcing language resources (Rodosthenous et al., 2019) and discuss technical decisions taken during the implementation process. Second, we describe the first experiment that has been carried out with a small crowd of advanced language learners[2] (Section 3) and discuss the results and their implications on the potential of the proposed approach. Third, we point out and discuss related work relevant to the presented approach (Section 4). Finally, we sum up preliminary conclusions and indicate directions for future work (Section 5).

2 Vocabulary Trainer

The vocabulary trainer builds on top of a prototype architecture for crowdsourcing language resources (Rodosthenous et al., 2019). It implements an *implicit crowdsourcing paradigm* which follows the idea that if a language resource (e.g., a lexicon) can be used to generate language learning exercises, then the answers of learners to these exercises can be used to improve the resource, which in turn will improve the quality and versatility of the exercises generated (Rodosthenous et al., 2019).[3]

2.1 Motivation and Design

The vocabulary trainer delivers interactive vocabulary exercises for learning word senses. The learner is asked to input words which are related to a given word by the semantic relation `RelatedTo`, and will in the future be extended to other relations such as `PartOf`, `AtLocation` etc. The learner input is collected and evaluated to enhance the LRs that it is generated from.

From the language learning perspective, vocabulary exercises play an important role in language learning (Nation and Hunston, 2013). Hulstijn (2013) notes that every word in a mental lexicon has formal as well as semantic associative features. Depending on the learner's level of language, vocabulary building may encompass single lexical words with a specific meaning or formulaic sequences / lexical chunks where pedagogical relations are structured by a particular object representation or a part of a particular object (Aldabe et al., 2015). As noted by Schmitt (2013), vocabulary learning is a complex phenomenon that may be explored not only from the aspects of form, meaning and usage but also from a representation of different meanings in different contexts.

Vocabulary exercises based on words' semantic relations are considered to be effective activities. Rosenbaum (2001) shows that background knowledge, context and morphology are essential in vocabulary instruction to enable the learner to understand and disambiguate word meanings effectively. The richness of acquired vocabulary depends not only on the number of learned lexical items but also on the ability to connect and share semantic networks of similar concepts. Hadley et al. (2018) argue that *"word learning is not simply the process by which isolated object-label associations are added to the mental lexicon one by one but also involves the learning of interrelated clusters of concepts, in which the knowledge of one concept supports the learning of another"* (p. 42).

From the crowdsourcing perspective, learners are used as crowdworkers to enhance the LR underlying the vocabulary trainer, namely the common sense ontology *ConceptNet*[4] (see Section 2.2). While using the vocabulary trainer for learning word senses the learners are providing their knowledge of related words which is collected and evaluated in order to validate and enhance the LR.

The vocabulary trainer is composed of four modules which are presented in the following subsections: 1) The *exercise generation module* that retrieves words from ConceptNet and generates exercise content (Section 2.2), 2) the *exercise and result storage dispatcher* that ingests the previously created exercise content (Section 2.3), dispatches it to the various learner interfaces and handles the responses from the learners, 3) the *evaluation module* that is responsible for evaluating if learners' contributions are fit for expanding the language resource and assign points to each learner according to the response given (Section 2.4), and 4) the *user interaction module*, where users are presented with the exercises and submit their responses (Section 2.5). In Figure 1, a high-

[2] For the initial experiment we involved proficient non-native speakers of English (see Section 3.2 for details).

[3] The related article discusses the paradigm in more detail and points out strategies to counter the risk of collecting wrong or low-quality data from non-proficient learners.

[4] http://conceptnet.io/

level diagram of the vocabulary trainer's architecture is depicted along with the exchange of data between the core modules of the system.

Interested readers are invited to also browse the project repository [5].

2.2 The Exercise Generation Module

The exercise generation module is responsible for content retrieval from language resources like ConceptNet (Speer et al., 2017) which is a large semantic network that describes general human knowledge and how it is expressed in natural language. ConceptNet provides a large set of background knowledge for different terms that not only describes them but also connects them with other terms using relations such as `RelatedTo`, `AtLocation`, `PartOf`, `IsA`, etc.

In its current version, the exercise generation module is able to search ConceptNet for terms connected with the relation `RelatedTo`, `AtLocation` and `PartOf` and generate exercises using a template such as "Name one thing that is <RELATION> <TERM>". For instance, if a search for knowledge that is `RelatedTo` the term "dog" is initiated, ConceptNet will yield results such as "bark", "pet", "animal", etc. The generation module processes these by removing stopwords, duplicates and terms that have a language other than English. The relevant information is stored in a database to be processed later by other modules along with the exercise data.

Searching ConceptNet is a straightforward process since the knowledge base offers a number of APIs to query it. In our case we use the typical search query[6] to get `relatedTo` terms. The search term is provided in canonical form in ConceptNet, e.g., `/c/en/cat` and offset is the number of records to skip and show the next, as ConceptNet API has a limit of 1000 results per call.

An example of a generated exercise is "Name one thing that is related to dog", where the learner is expected to enter a word that exists in the results retrieved from the knowledge base. In cases where new words are entered by the learner, the evaluation module handles whether they should be added to the knowledge base or not while a specific user feedback strategy is used to account for the unknown correctness of the new answers (see Section 2.4).

2.3 The Exercise and Results Storage Dispatcher Module

Transactions between modules are handled using web services through API calls. Data are presented in a JSON[7] format that can be consumed by any programmatically created interface. Specification of the API is available at the project repository using the Swagger[8] Opensource API management tool. This abstraction layer allows the exploitation of the system from various interfaces without developers having to know its underlying functionality. Currently, the system offers web services for registering users, retrieving exercises from the exercise generation module, checking learners' contributions, assigning points/awards, storing presented hints and showing a leaderboard.

For the latter part, the evaluation module is employed. The outcome of the evaluation module is used to update both the learner's points and awards and the knowledge base list of answers for that specific exercise.

The dispatcher is also directly connected with the database for storing/retrieving data in/from tables and provide another abstraction layer for information handling workflows.

2.4 The Evaluation Module

The evaluation module processes the learner's answers in order to both update the knowledge base with new words and to assign points and award badges to the learners, which are transformed into feedback messages and leaderboards in the user interface.

The evaluation module operates on pairs of exercise and result (see Figure 1) produced each time a user completes one exercise. It checks whether the user's answers are known or new to the knowledge base and evaluates if new answers are valid candidates to enhance it. According to the evaluation points received, badges are assigned to the learners.

More specifically, the evaluation module checks for each user's answer, whether it is part of the results set for that exercise or whether the answer is new. If the answer is part of the knowledge base, the user receives one point. If the answer is new, the user receives *potential* points, and the answer is stored as a candidate answer for that exercise together with the user id. The feedback message

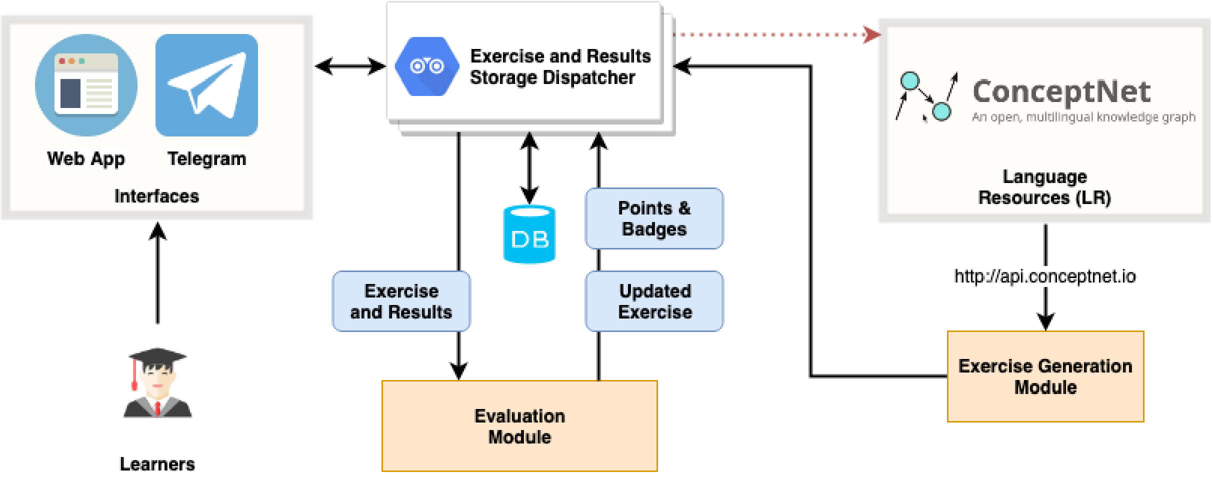

Figure 1: An overview of the vocabulary trainer architecture, depicting the main modules of the architecture, the data interchange between them and user interaction at the interface level.

to the learner informs him that the answer is new and that he is gaining *potential* points, which may transform into actual points if the answer is validated by several users over time.

Every time a predetermined number K of candidate answers has been accumulated, the evaluation process is triggered:

- All new answers are ranked by their occurrence frequency (i.e., how many mentions).
- The top-ranked answer is selected (given that it was mentioned at least N times).
- All learners that gave the selected answer get informed that it was a correct answer and receive two points (transforming *potential* points into actual points).
- In addition, the learner who was the first to give the selected answer receives a badge.
- The knowledge base is updated with the new word for that exercise.
- All occurrences of the selected word are removed from the candidate list.

2.5 User Interaction Module and Prototypical User Interfaces (UI)

In the current version of the vocabulary trainer, two interfaces are implemented: a chatbot on Telegram and a web application. Both interfaces allow the learner to receive and complete exercises on the `RelatedTo` relation. Learners get an immediate response back on the correctness of their answer and when this is not possible (i.e., in cases of unknown answers), they first receive potential points and get notified asynchronously, once the unknown answer was confirmed by other learners.

Currently, the vocabulary trainer forces the user to input a word in order to move to the next exercise. In order to support the learner in case he runs out of ideas for related words on a given exercise, the “I Don’t Know” feature provides functionality for requesting a “hint”. The hint provides the user with a correct related word, which is taken from the knowledge base. After reading the hint, the learner is free to input the hint word or any other word that he/she deems fitting. Whenever a learner uses that feature, there is an underlying mechanism that stores the presented hint in the database.

Within both interfaces, learners can see their points and badges gained and for the Telegram chatbot, they can also access a leaderboard.

Chatbot interface The chatbot interface was implemented on Telegram, a very versatile messaging system. Telegram is available both as a native application for mobile phones and desktop computers for all operating systems and as a web application. It enables the implementation of chatbots via the Telegram Bot APIs[9]. In the implemented chatbot[10], users interact with the system via a standard dialogue chat interface (see Figure 2). Apart from textual input, the interface provides a button area that changes during the dialogue flow to simplify the interaction.

Hi Chrodos, let's play some language game! 10:03 AM

🎯 PLAY VOCABULARY GAME 10:03 AM

Let's play some vocabulary game! 10:03 AM

Name one thing that is related to dog 10:03 AM

Bark 10:03 AM

You have inserted **Bark**.
Good job! 👍 You earned **1 points**! 10:03 AM

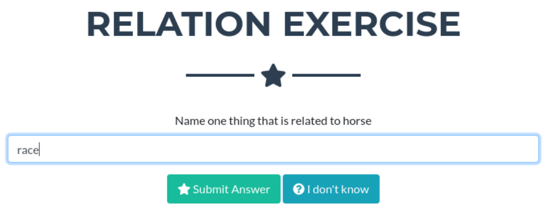
Figure 2: A screenshot from the chatbot interface, where a user is interacting with the system.

Web interface The web interface[11] (see Figure 3) currently offers three exercise types for learners to practice with. It was implemented using a free bootstrap template[12] to ensure a stable interface that works well both on computers and mobile devices.

3 Empirical Evaluation

To evaluate the potential of the v-trel architecture for the purpose of (1) gathering commonsense knowledge and populating the language resource used to generate the exercises, and (2) delivering a meaningful application for vocabulary learning, we designed an experiment as follows.

For the initial experiment, the focus was put on objective (1), evaluating the quality of collected data. However, a feedback questionnaire and the manual analysis of the gathered data by an expert in language teaching served to gain first insights also related to (2), the educational value of such a vocabulary trainer, which need to be expanded on in a follow-up study (see Section 5).



Name one thing that is related to horse

race

Figure 3: A screenshot from the web interface.

Term	`RelatedTo` term	#terms
cat	animal, dog, house. . .	94
dog	friend, puppy, bone. . .	135
bird	chicken, chick, canary. . .	219
cow	sacred, animal, steak. . .	96
fish	water, creature, lure. . .	221

Table 1: An example of the terms retrieved to generate the experiment exercises. The subject is `RelatedTo` the object. In the last column the number of filtered terms is depicted.

3.1 Setup of the Experiment

First we generated 26 exercises using the `RelatedTo` relation from ConceptNet and 26 terms (see Table 1) that fall under the A1 and A2 language learning level. For each of these terms, we acquired more than 20 terms that are related to them. We used the conceptnet.io API to retrieve all terms connected with the `RelatedTo` relation where the language is set to English. We filtered out terms that had less than 20 `RelatedTo` terms in order for the learners to have a plethora of possible answers for the "I Don't Know" feature.

We also implemented a recording mechanism that captures the answers presented to the learner when clicking the "I Don't Know" button for a specific exercise. This served the purpose for us to analyze how the learner used this feature and reacted to the words presented to them while contributing and completing exercises.

For the experiment the evaluation parameters were set to a threshold of K=*5* candidate answers to trigger the evaluation and a minimum limit of N=*2* words for including the candidate into the knowledge base was applied.

3.2 Implementation of the Experiment

The initial experiment was conducted with people from our peer group, about 60 non-native speakers

[11] `http://cognition-srv1.ouc.ac.cy/vtrel/`

[12] `https://startbootstrap.com/themes/freelancer/`

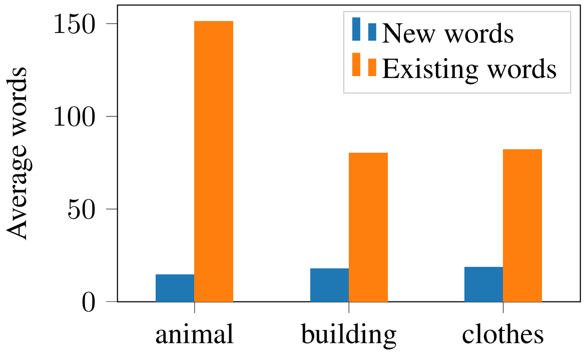


Figure 4: The average number of new and existing words per exercise for each category.

of English, with a high proficiency level.[13] Each of these users received an email with a link to both the Web interface and the Telegram chatbot and was asked to try any of the two for more than ten minutes within a period of two days. At the end of this period, each user received a link to an online questionnaire[14] to provide feedback on both the interfaces and the presented questions.

To summarize, during the 2 days period we managed to gather 4533 contributions to 26 exercises presented to the user in random order. The contributions were collected in 44 distinct user sessions, of which 17 were on the Telegram chatbot and 27 on the Web interface. Presumably, the sessions mostly relate to unique users, although we know of at least one user, who accessed both interfaces (see Section 3.4).[15] We also captured 683 possible answers presented to learners through the "I Don't Know" feature. Out of the 4533 contributions, 449 new words were crowdsourced from the users based on the evaluation mechanism with the parameter settings described above (see Section 2.4 and 3.1). In terms of questionnaire feedback, we gathered 17 fully-completed and 17 partially-completed responses.

3.3 Results Analysis

Characteristics of new words. Overall, the experiment allowed to gather 449 new words, divided by exercise category as follows: 119 words on animals, 168 words on clothing, and 162 words on buildings. The lower number of new words for the category animal relates to the higher number of existing words in the knowledge base for that category (see Figure 4). For example for the term "cow", 15 new words were gathered. Table 2 shows the 8 new words that were named three or more times, while seven words[16] met the minimum threshold of two mentions. This shows that ConceptNet has empty spots even for basic vocabulary like "grass" or "farmer", which could be gathered through the learners. Also, it shows that learners were able to propose advanced vocabulary such as "ruminate" or "pasture".

New word	Frequency	Level
grass	15	basic
calf	6	advanced
meat	5	basic
cowboy	4	basic
farmer	4	basic
herd	4	advanced
horn	3	moderate
pasture	3	advanced

Table 2: Top new words for the term "cow", their frequency of mentions and proficiency levels.

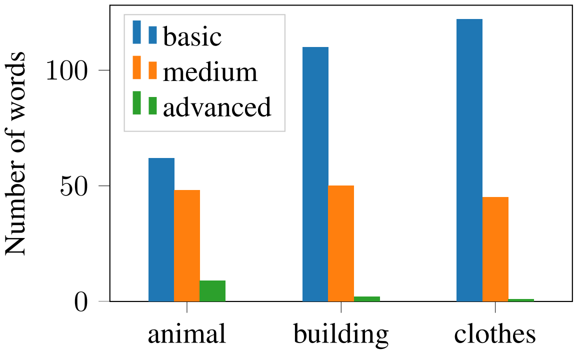

Figure 5: Level of proficiency of new words by exercise category.

A manual analysis of the proficiency level of all new words was carried out by an expert from language teaching. It showed that the vast majority of new words is part of basic vocabulary (65% of all added words), while 32% are of moderate level and only 3% belong to advanced vocabulary.

[13] We are aware that involving speakers with a high English proficiency implicates that the crowd does not represent genuine language learners. By being composed of non-native speakers, we however assume them to resemble advanced learners to a degree that allows to draw meaningful conclusions for the scope of this first evaluation.

[14] LimeSurvey, a Free Opensource online tool was locally deployed: https://www.limesurvey.org

[15] For simplicity, we refer to user sessions as *users*.

[16] New words for term "cow" with two mentions only: *bell, burger, methane, ox, ruminate, sheep* and *veal*

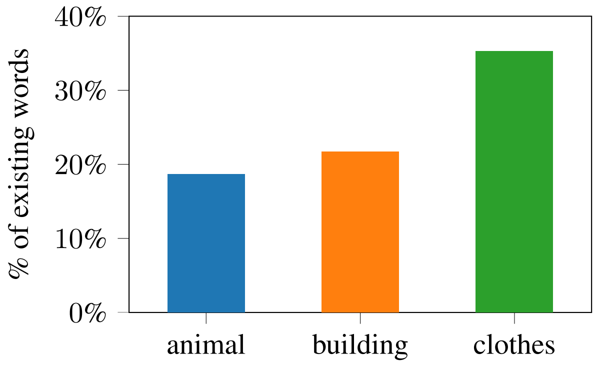

Figure 6: Average percentage of existing words, provided by users, per exercise for each category.

Interestingly, for the animal category the ratio between basic and moderate vocabulary is far more balanced than for the other two categories, also more advanced vocabulary is found (see Figure 5). This could be explained by the higher number of existing words in the knowledge base for the category animal. Most basic words are probably already part of ConceptNet, which implies that new words necessarily need to be more advanced.

Figure 6 shows the average percentage of existing words (per exercise) that were entered by the learners, divided by category. It shows that learners named less than 40% of the words present in ConceptNet[17], while they can still gain knowledge on more than 60% of the words, e.g. by requesting hints through the "I don't know" feature.

Responses to "I Don't Know" hints. Overall, 683 hints were provided to the learners by means of the "I Don't Know" button. In response, 365 words were entered by the learners of which 331 were a direct repetition of the hint word. The lower number of entered words in relation to hints is due to multiple "I Don't Know" clicks before entering a word (up to 17 clicks in a row).

In 34 cases, the word entered in response to the hint(s) was different from the hint(s), which indicates that the hint activated the learner's knowledge on related words. A look at the words shows that:

- 2 times a variation of the lemma was entered
- 11 times an analogy of the hint was entered
- 16 times a different word class was entered

Existing relations in ConceptNet. To get a better idea of the type and quality of words learners contributed regarding our initial LR, i.e., ConceptNet, we queried what other relations might exists in ConceptNet between the search word used for generating the exercise and the contributed words other than the `RelatedTo` relation. From the 26 exercises learners contributed, on average 14.15 words have no other direct relation (not bidirectional) with the original word from ConceptNet, i.e., <SUBJECT> <RELATION> <CONTRIBUTED_WORD>. When searching also for bidirectional relations, 100% of contributed words have such a relation between them in ConceptNet, including `RelatedTo`, which can be taken as indication for the appropriateness of the words added by learners. On average 4.54 new relations (other than direct `RelatedTo`) were identified between the contributed terms and the subject used to generate the exercise.

3.4 Feedback Questionnaire

After the experiment, a feedback questionnaire with six items was sent to all participants:

- Level of English: [A1/A2; B1/B2; C1/C2]
- Interface used: [Chatbot; Web; both]
- What did you notice regarding the UI? [open]
- What did you think of the questions? [open]
- What did you like about this approach to a vocabulary exercise? [open]
- Any other comments? [open]

Out of 34 users, 22 completed the closed questions and 9 to 14 also responded to the open questions; 18 of 22 respondents indicated an advanced level of English; 9 users used the Chatbot, 12 used the Web interface, and one user used both interfaces.

User interface. 9 respondents perceived the interface as clear, easy and pleasant to use, while 9 users criticized unclear navigation and pop-ups interrupting the workflow.

Questions. 9 users remarked that words repeated too often and that the phrasing of the question "name one thing" can be misleading in terms of which word class is requested (3 respondents).

Approach to vocabulary exercise. 12 users evaluated positively the interactivity and simplicity of the exercise, the opportunity to learn new

[17] The lowest coverage were found for category animal, the category with the biggest set of available words.

words by means of the “I don’t know” function, and its effect to reactivate words and to incentivize brainstorming. Still, five users suggested that it is no real vocabulary exercise, that it would be difficult for beginners and that the processing of the answers and assignment of points/feedback was unclear, too open-ended, and lacking negative feedback.

Other comments. The criticism about the way to award points and the overall educative value were stressed further.

3.5 Discussion of the Experiment Results

The analysis of new words shows that our approach is promising for extending ConceptNet with meaningful words, in particular the more advanced level of new words added for the category animal indicates that relevant new terms can be gathered in a progressive fashion (e.g., basic vocabulary is added first). Given that this first experiment was carried out with advanced learners it needs to be evaluated to which extent similar positive results can be achieved with beginner and intermediate learners. Also, the analysis indicates that ConceptNet is ample enough to propose a wide set of new vocabulary to the user (in average more than 60% of the words per exercise). Furthermore, results suggest that this approach can also identify new relations between terms in ConceptNet. Learners managed to reproduce what was already coded in a different manner in the resource and thus improved its completeness.

User feedback verifies that the vocabulary trainer as a User Interface can be improved but the idea behind it is interesting and can be applied in different language learning scenarios.

4 Related Work

Approaches for crowdsourcing language resources can be divided into two broad categories: 1) implicit crowdsourcing, i.e., users carry out any activity of their interest while their data is crowdsourced as a byproduct, and 2) explicit crowdsourcing, i.e., the crowd is actively engaging.

The Duolingo platform (von Ahn, 2013) presents a most similar approach to our work, based on language learning, as it generates language exercises, allowing the crowdsourcing of language-related data (i.e., translations). Other research work based on implicit crowdsourcing has utilized the Games With A Purpose (GWAP) approach (von Ahn and Dabbish, 2008). Among GWAP, in particular the JeuxDeMots game by Lafourcade (2007) shows several similarities to our approach. The game is designed for constructing lexical data in French in a playful way. In order to gain points two players have to agree on words related to given terms. Also, the more recent TileAttack game by Madge et al. (2017) builds on player agreements to gather annotations for text segmentation tasks. In addition, Rodosthenous and Michael (2016) developed a platform that combined automated reasoning with games for acquisition of knowledge rules. Moreover, in work of Guillaume et al. (2016) a game titled ZombiLingo was developed, for annotating dependencies in French data. In work of Chamberlain et al. (2008), the Phrase Detectives game is presented, where players contribute relationships between words and phrases, aiming to create a resource that is rich in linguistic information. Yet another indirect form of crowdsourcing has used large collaborative knowledge bases like Wikipedia to create multilingual resources such as YAGO3 (Mahdisoltani et al., 2015) and DBpedia (Lehmann et al., 2015). Recently, Meurers et al. (2019) have proposed a web-based workbook, which can be integrated into classroom curricula and offers instructive feedback to students while also gathering data on learning processes for Second Language Acquistion (SLA) research.

Research works with explicit crowdsourcing often employ Amazon Mechanical Turk to collect data. For instance, Biemann (2013) created the Turk Bootstrap Word Sense Inventory of frequently used nouns in English and Ganbold et al. (2018) localized the WordNet in the Mongolian language. Related to SLA, MacWhinney (2017) proposes a collaborative platform for collecting and sharing learner data from corpora, online tutors, and Web-based experimentation.

Our research presents an implicit crowdsourcing approach implemented as a vocabulary learning application with open-ended questions for language resource augmentation using multiple user interaction methods (i.e., chatbots and web apps).

5 Conclusion and Future Work

In this paper, we presented the v-trel vocabulary trainer for crowdsourcing language resources and delivering exercises to language learners. V-trel can be accessed through two interfaces, a Telegram chatbot and a Web application.

Moreover, we presented the results of an empirical evaluation and a user satisfaction survey for the vocabulary trainer and provide a relevant discussion of these results. Feedback from users and the analysis of the contributed words are taken into account for updating v-trel with new features such as a more attractive interface, and new exercise types[18]. In addition, we aim at including links to pictures and definitions or examples of use of the "hint" words, to support the learner not only in refreshing their existing vocabulary, but also to acquire new words. These are first steps to strengthen the learning effect of the tool, while in the midterm we foresee to intensify further the collaboration with language teaching experts in order to tailor the offered exercises more closely to specific learning goals.

Also, in future work we aim at implementing more strategies for safeguarding the quality of the acquired data, e.g., control mechanisms for active misuse, further evaluation strategies for new words, which could also involve dynamic retrieval of knowledge from ConceptNet or evaluation cycles re-proposing new words in new exercises, and strengthened gamification elements. In addition, we intend to evaluate the crowdsourced words and their difficulty levels in relation to established reference data such as the *English Vocabulary Profile*[19] or similar resources.

As proposed in the feedback questionnaire, the educational value needs to be validated and improved further. Accordingly, a follow-up user study with focus on the educational aspect is foreseen and will be designed and carried out with authentic learners of different proficiency levels.

Last but not least, the vocabulary trainer will be integrated into the setup of the Revita online system for language learning (Katinskaia et al., 2018) to reach a larger audience. In particular, it can be implemented as a part of a testing mode where crowdsourced questions do not influence the learner's final score. We will also work towards integrating v-trel into Games With A Purpose. Previous work of Rodosthenous and Michael (2016, 2014) suggests that crowdsourcing and GWAPs, in particular, can be used to gather background knowledge

[18] E.g., various new types of vocabulary exercises such as "fill the gap", or "select all verbs among the given words"

Abstract

An author's way of presenting a story through his/her writing style has a great impact on whether the story will be liked by readers or not. In this paper, we learn representations for authors of literary texts together with representations for character n-grams annotated with their functional roles. We train a neural character n-gram based language model using an external corpus of literary texts and transfer learned representations for use in downstream tasks. We show that augmenting the knowledge from external works of authors produces results competitive with other style-based methods for book likability prediction, genre classification, and authorship attribution.

1 Introduction

Literary texts have been computationally modelled by extracting stylistic traits such as readability and writing density, flow of emotions, and even by cover images of books (Maharjan et al., 2018b,a, 2017; Ashok et al., 2013). However, modelling of authors through their work has not been explored until now. An author's style of presenting stories has a great influence on whether a book will be liked by readers or not.

We can find evidence of the effect that an author's style has on readers in book reviews and through readers' comments left on Goodreads[1] shown in Table 1. The readers talk about the impact of the author's writing style on their reading experience. In the first two examples, it left a positive impact on the readers, while in the last it had a negative impact. These examples provide further evidence for the need for modeling authors' writing style for the task of likability prediction of books.

This author's writing style is just perfect in every way, you will feel everything one should experience when you read a genre such as this.
The author's writing style is straightforward which made it easy to understand.
I think that the writing is very uneven. Overwhelmingly episodic, not terribly consistent, and largely as dimensionless as the characters.

Table 1: Readers comments showing the importance of authors' writing style

In this paper we propose a new approach to capture style in text by jointly learning author specific embeddings and character based n-gram embeddings. The idea of using author embeddings is motivated by reader comments as discussed above. The use of character n-gram embeddings comes from previous work on authorship attribution (AA) that has shown character n-grams to have strong prediction value for the task (Kešelj et al., 2003; Peng et al., 2003; Koppel et al., 2009; Stamatatos, 2009; Sapkota et al., 2015). Rather than using plain character-based n-grams, we first annotate them with their functional roles (*prefix*, *suffix*, and *whole-word*). This is necessary since, for example, *off* is semantically distinct from when it is used as a whole word and when it is used as a suffix (e.g. *trade-off*) or when it is used as a prefix (e.g. *offend*).

After obtaining representations for authors and annotated character n-grams using an external corpus of literary texts, we transfer them to tasks where author information is useful, namely book likability prediction and authorship attribution. Moreover, we provide quantitative and qualitative analyses of the author and annotated character n-gram embeddings.

2 Methodology

Figure 1 shows the overall workflow of our proposed method. As shown in the figure, there are two phases. First, we jointly learn embeddings for authors and annotated character n-grams using an external corpus of books written by authors in the Goodreads corpus prepared by Maharjan et al. (2017). We refer to this corpus as Author Corpus. Next, we transfer this knowledge represented as the author and annotated character n-gram embeddings to build book representations. We describe these phases in detail below.

Phase I: Learning from an external corpus

We collected a new external corpus of books from Project Gutenberg to learn author and annotated character n-gram embeddings[2]. It consists of at most five books from each author in the Goodreads corpus (§3.1).

Annotated Character n-grams: We annotate character n-grams according to their position and function in a word as *prefix*, *suffix*, or *whole-word*. We follow the definitions by Sapkota et al. (2015) to decide which n-grams constitute each of these three types. *Prefix* and *suffix* are character n-grams that cover the first and last n-characters, respectively, of a word that is at least $n + 1$ characters. A *whole-word* n-gram is word that is exactly n characters long. This annotation helps to distinguish a single lexical entity as many different semantic entities. For instance, an n-gram like *the* could either be used as a *prefix* (***the**refore*), as a *suffix* (*wrea**the***), a standalone word (***the***), or occur within a word (*wi**the**r*). Note that although we do not explicitly annotate n-grams occurring mid-word, all of the remaining unannotated n-grams will fall under this category. These annotations will ensure that separate embeddings are learned according to the morphological and functional information carried by the n-grams.

Similar to Sapkota et al. (2015), we choose n as 3. While generating character 3-grams, we try various step sizes for sliding our window. With a step size of one, adjacent 3-grams will have two characters in common, one character in common with a step size of two and none with a step size of three. We name them *Overlap*, *Partial*, and *Non-Overlap*, respectively, based on the overlapping of characters in adjacent n-grams. We explore author and annotated character n-gram embeddings under these three settings.

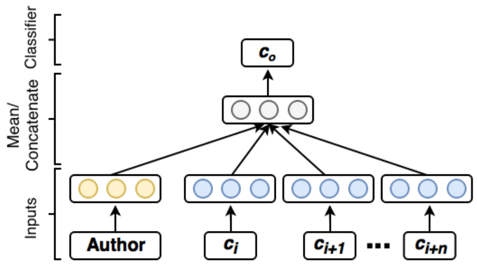

Figure 2: Author2Vec framework to learn author and character n-gram embeddings. $c_i, \ldots, c_{i+n}$ and $c_o = c_{i+n+1}$ are the input and output annotated character n-grams, respectively.

Author2Vec: Given a sequence of annotated character n-grams $c_i, \ldots, c_{i+n}$, and an author a, the objective of our Author2Vec model is to maximize

[2] The source code and data for this paper can be downloaded from https://github.com/sjmaharjan/author2vec.

the following conditional probability for the next-in-sequence output character n-gram c_o:

$$p(c_o|c_i, \ldots, c_{i+n}, a) = \frac{exp(y_{c_o})}{\sum_{c \in V} exp(y_c)} \quad (1)$$

$$y_c = Wh(c_i, \ldots, c_{i+n}; C, a; A) + b \quad (2)$$

where y_c is the unnormalized log probability for annotated character n-gram c in the vocabulary V, W and b are softmax parameters, and h is either the concatenation or mean function applied to character n-gram and author vectors from C and A, respectively. Similar to Le and Mikolov (2014), we call the concatenation method Distributed Memory Concatenation (DMC) and the mean method Distributed Memory Mean (DMM).

Phase II: Building book representations

We use the annotated character n-grams from Phase I to obtain the book's representations. We concatenate this with the book author's embedding and feed them as features to an SVM classifier. Similar to Maharjan et al. (2017), we consider the first 1k sentences from each book in the Goodreads corpus. We define the following three methods to obtain book representations:

Bag of annotated character n-grams (ACn): Similar to bag-of-word (BoW) approach, we generate the annotated character n-grams from books' content. We then represent each book by a sparse vector and weight each annotated character n-grams using their term frequency-inverse document frequency (TF-IDF) scores. The motivation behind using this representation is the success of stylistic analysis in the domain of books success prediction, author attribution, and author profiling.

Mean of Annotated character n-grams embeddings (Mean): Unlike the above method, here we use the annotated character n-gram embeddings to represent each book by a dense vector. We generate the annotated character n-grams from book content and look up their embeddings. A book is then represented by the mean of all annotated character n-gram embeddings generated from its content. Mathematically, the resulting book vector r is represented as $r = \frac{\sum_{i=1}^{N} emb(c_i)}{N}$, where N is the total number of annotated character n-grams for a book, and $emb(.)$ is the function that gets the embeddings for a given annotated character n-gram c.

Inverse Document Frequency (IDF) Weighted Average (Weighted): This method is similar to the above method of averaging the embeddings of annotated character n-grams, but weights each annotated n-grams embedding by their IDF scores before averaging. Mathematically, the resultant book vector r is represented as $r = \frac{\sum_{i=1}^{N} idf(c_i,B)*emb(c_i)}{N}$, where $idf(.)$ is the function that gets the IDF score for given annotated character n-gram c. The $idf(.)$ is learned from the training data and is defined as $idf(c, B) = \log \frac{|B|}{|\{d \in B : c \in d\}|}$, where B is the collection of books, and d is an instance of book.

3 Book Likability Prediction

Here we present results of using the author and character based n-gram embeddings for the task of predicting whether readers will like a book or not. We use likeability as a proxy to measure the success of a book. Narrowing down success as a measure of readers ratings is not ideal. But it gives us a practical starting approach to evaluate our models.

3.1 Dataset

We experiment with the publicly available book likability prediction dataset (Goodreads corpus) from Maharjan et al. (2017). They collected books from Project Gutenberg[3]. They then labeled the books into two categories: *Successful* and *Unsuccessful*, by using the average rating and the total number of reviews received by the books on Goodreads[4]. It consists of 1,003 books (654 *Successful* and 349 *Unsuccessful*) from 8 genres downloaded from Project Gutenberg: *Detective Mystery*, *Drama*, *Fiction*, *Historical Fiction*, *Love Stories*, *Poetry*, *Science Fiction*, and *Short Stories*.

3.2 Experimental Settings

We used the same stratified splits of 70:30 training to test as provided by Maharjan et al. (2017). We used the negative sampling (Mikolov et al., 2013) method to train 300-dimension embeddings for both authors and annotated character 3-grams. We filtered out 3-grams with frequency<2, set the window size to 5, configured the sample threshold to 1e-5 for randomly downsampling higher-frequency 3-grams, and trained for 100 epochs.

We predicted success separately (*Single task (ST)*) as well as simultaneously with genre (*Multi-task (MT)*). We used linear kernel SVM and tuned

the *C* hyper-parameter through a grid search over (1e{-4,...,4}), using three-fold cross validation on the training split.

3.3 Results

Table 2 shows the results for our methods under the *Overlap*, *Partial*, and *Non-Overlap* settings. Our first set of experiments tests book representation methods (*AC3*, *Mean*, and *Weighted*) without author embeddings. The sparse feature representation method *AC3* (71.1%) performs better than embedding aggregation methods, *Mean* (69.9%) and *Weighted* (70.1%), as the mean operation likely removes important information. Here, the *Partial* setting yields the best results.

Our next set of experiments combine book representations with author embeddings and this improves the results in most cases. We obtain the overall highest F1-score of 73.8% with *Weighted* setting under concatenation (DMC) method. This result is statistically significant ($p < 0.02$) over the same setup but without authors' embeddings. This result is also better than the results from the state-of-the-art methods by Maharjan et al. (2017): *Character* 3*-grams* (70.0%) and *All typed* n*-grams* (69.1%). We also see that the DMC method yields consistently better results than the DMM method.

Author embeddings and correctness: We group authors by the genre of their books (in case of multiple genres, we pick the one with the most books). We then obtain representations for successful and unsuccessful authors in that genre by averaging the author vectors for these two classes. Our intuition was that if the distance between these representations is small, there will be fewer correct predictions for that genre. We obtained a large negative Pearson correlation coefficient of -0.753 ($p < 0.03$) between distances and the number of incorrect predictions, supporting our intuition.

Annotated vs Plain Character n-grams: To validate the importance of annotating n-grams, we trained embeddings using unannotated n-grams and performed likability prediction using the best setup from before. This produced an F1-score of 69.9% ($<$ 73.8%) illustrating the usefulness of considering the functional behavior of character n-grams. The performance further decreased to 63.4% with the removal of author embeddings.

Authors as binary vectors: To further confirm the advantage of learning author embeddings from external data, we replace author embeddings with one-hot vectors indicating the book's author. Using the best setup in Table 2, this produced a score of 70.3% ($<$ 73.8%), strengthening our intuition that author embeddings capture style related information, which is relevant for likability prediction.

Author Embeddings and Genre: We experimentally verify that author embeddings capture genre-specific information by using them to perform genre classification. We used the best model, Author (DMC), to automatically infer author vectors for all books in the dataset and fed them to an SVM classifier. We obtained F1-scores of 64.6%, 66.8%, and 64.0% with the *Overlap*, *Partial*, and *Non-Overlap* settings respectively. These scores outperform a random baseline of 15.2%, showing that author embeddings are also capturing more general style traces related to the genre.

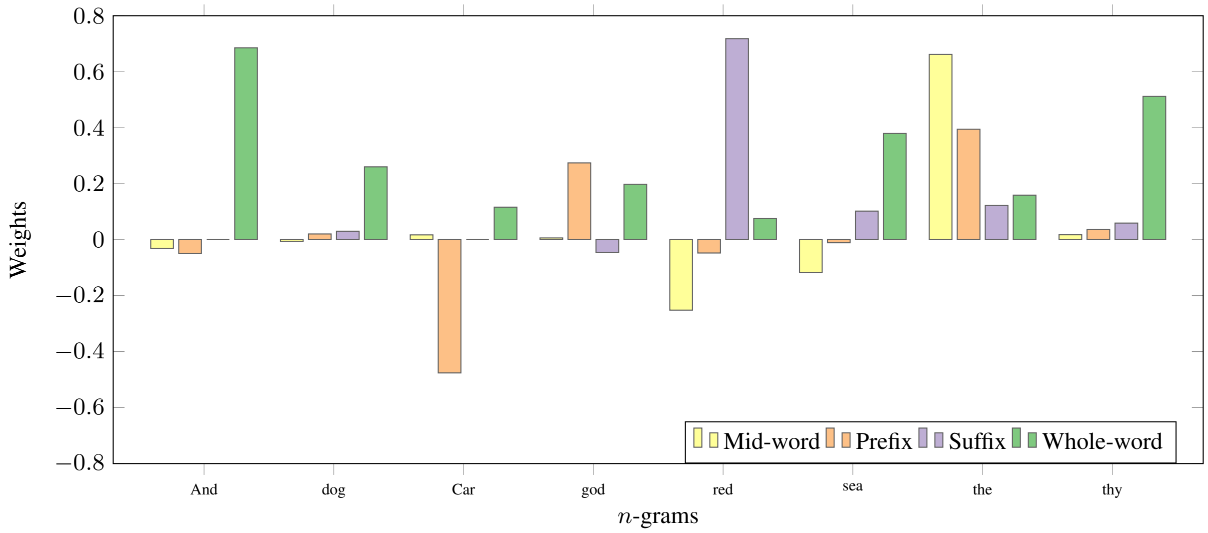

Figure 3: Feature importance assigned by SVM to different character n-grams for the likability prediction task.

4 Discriminative Annotated Character n-grams

Figure 3 shows some of the top positively and negatively weighted annotated n-grams by the classifier. We used the best performing *AC3* model from Table 2, *AC3* under *Partial* setting, to extract the weights for the annotated character n-grams. For each of the annotated n-grams, the figure also plots the weights for all four positional variants. The figure clearly shows that different forms of the same character n-gram have different contributions towards the likability prediction of books. This important piece of information would have been lost if we had treated these different forms of the n-grams as one. For instance, *sea* as a whole-word has a different meaning than when it is used as a prefix or a suffix. Accordingly, the classifier has also weighted them differently. The whole-word form of the n-gram *sea* is weighted higher than its other forms. This also holds for the case of *thy* and *dog*. During this analysis, we also found that quotation marks and male honorific titles were highly weighted by the classifier, similar to what Maharjan et al. (2017) found. This most likely points to the importance of dialogues and the preference of male characters in these books.

5 Analysis of Annotated Char n-grams

In Figure 4, we visualize the annotated character n-gram embeddings by projecting them using PCA. For some n-grams, the embeddings of different annotations are indeed distinct. For instance, the embeddings for *sub* (prefix, mid-word), *est* (whole-word, suffix), *ion* (suffix, whole-word), *mid* (prefix, suffix), and *the* (whole-word, suffix) lie far from each other. On the other hand, *ful* in suffix and mid-word form are close together, since the contexts for *ful* as a suffix (*beautiful*, *careful*) are similar to the contexts where it occurs mid-word (*beautifully*, *carefully*). In addition, we can also see a clear separation between *prefix* and *suffix* n-grams with the *mid-word* and *whole-word* n-grams occupying regions in between. The *suffix* and *prefix* n-grams mostly occupy the regions above and below the zero line respectively. This figure visually demonstrates that learning separate embeddings for n-grams with different functional roles is important to preserve their semantics.

Dataset	**RG (65)**	**WordSim (353)**	**RW (2034)**
Without Annotation	16.21	4.56	16.54
Annotated	30.75	12.27*	20.02**

Table 3: Results for word similarity task showing Spearman's rank correlation ($\rho \times 100$) with similarity scores assigned by human annotators $*p < 0.03$, $**p < 0.0001$

We also empirically show the advantage of these embeddings through the word similarity task using three standard datasets: *RG65* (Rubenstein and Goodenough, 1965), *WordSim353* (Agirre et al., 2009), and *RW* (Luong et al., 2013). Similar to FastText (Bojanowski et al., 2017), we represent a word as an average of the embeddings of its character n-grams. We create two representations

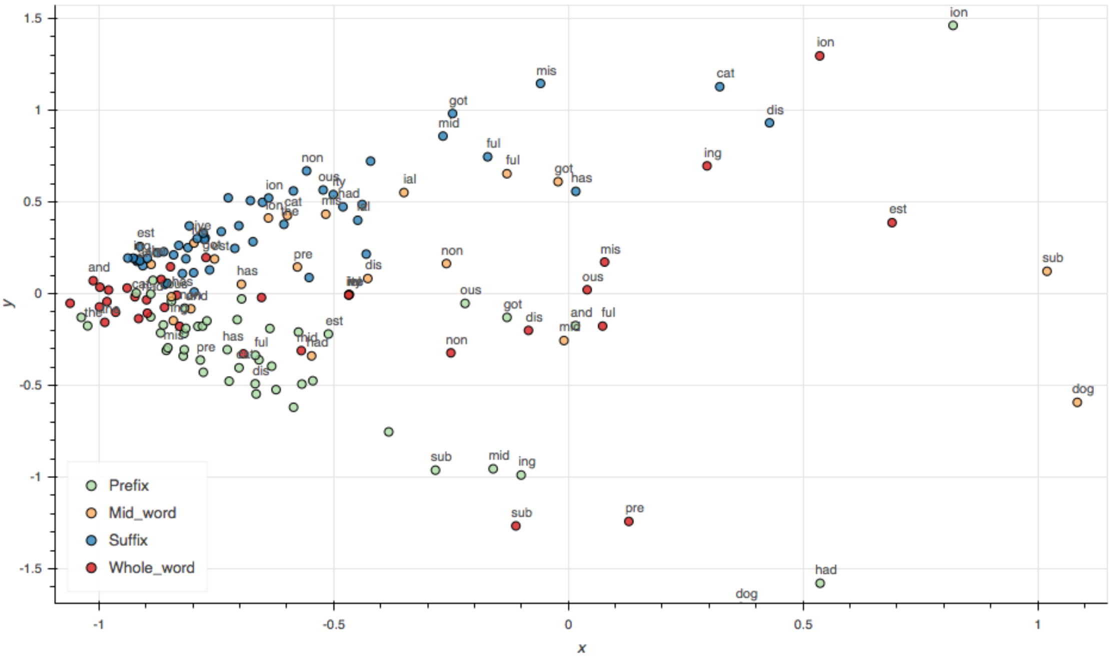

Figure 4: Projection of annotated char n-gram into 2D space using Principal Component Analysis (PCA)

for each word: one using plain character n-grams and another with annotated character n-grams. Table 3 shows the results for the word similarity task with these two different approaches. The Spearman's rank correlation coefficient between human annotations and word vectors composed of our annotated n-gram embeddings are higher than the same obtained from plain n-grams. The difference between the two proposed methods is statistically significant for WordSim353 ($p < 0.03$) and highly statistically significant for RW2034 ($p < 0.0001$). These results demonstrate that annotated character n-gram embeddings are also good at producing high-quality word representations and they might be capturing semantics at some level.

6 Authorship Attribution

Another task to test the effectiveness of our approach is authorship attribution (AA). To ensure that the model learns to discriminate authors and not the genre, we selected books from fiction genres for authors having at least five books that were not used to train our Author2Vec model. We have 12 such authors in our corpus.

We again used the first 1k sentences, used an SVM classifier in a stratified 5-fold cross-validation setup, and tuned the C hyper-parameter using grid search for each fold. Table 4 shows our results along with two baselines: word unigram and character 3-grams with tf-idf. Using only the book representations (Mean or Weighted), we obtained the highest mean accuracy of 86.67%. When we added in the inferred author embeddings (directly getting author embeddings would reveal the author, so we infer author embeddings similar to Le and Mikolov (2014) using only the book content without revealing the actual author of the book), the accuracy improved to 95% ($\sim$ 10% above *Char* 3-*gram*), showing that our approach not only works for likability prediction but also for AA.

7 Related Work

Sapkota et al. (2015) sub-grouped character n-grams according to grammatical classes, like affixes, lexical content, and stylistic classes, like beg-punct and mid-punct. With these sub-groups, they provided empirical evidence to support the importance of character n-grams features in the task of authorship attribution. Iacobacci et al. (2015) showed that learning separate word embeddings for polysemous words yields the state-of-the-art result in word similarity and relational similarity tasks. Separating the same tokens or n-grams helps to preserve their functional and morphological information which is important for all tasks. Learning embeddings for words (Mikolov et al., 2013), n-grams (Zhao et al., 2017), and documents (Le and Mikolov, 2014) and using them as input for various NLP tasks (Samih et al., 2016;

Zhang et al., 2015; Kim, 2014) has shown improvement in performance. Again, Shrestha et al. (2017) showed that applying convolutional neural network (CNN) over character bigrams embeddings improves authorship attribution of short texts like tweets. They visually showed that character bigrams were capturing important stylistic markers to distinguish between bot-like authors and other normal authors. Song and Lee (2017) jointly learned the embedding for users (senders and receivers) and showed that these user embeddings capture the semantic relationship between users through an auto-foldering of emails task. Following these research findings, we also distinguish between the same character n-grams by annotating them with categories defined by Sapkota et al. (2015) and learn separate embeddings for each of them in addition to learning embeddings for authors.

Prior works in likability prediction of books have shown that style is an important aspect (Maharjan et al., 2017; van Cranenburgh and Bod, 2017; Ashok et al., 2013). They captured the style of successful and unsuccessful books using lexical, syntactic, readability, and writing density features, and deep learning methods with only first 1K sentences. Since style is evident even with first few fragments, they obtained competitive results using only first few fragments of books. Maharjan et al. (2017) even showed that around 200 sentences are enough to perform book success prediction with reasonable accuracy. Louis and Nenkova (2013) proposed features to capture different aspects of great writing (surprising, visual and emotional content) and used them in combination with genre-specific features to predict high quality writings in science articles. Iwana et al. (2016) extracted visual features from book covers for genre classification. Also, the potential of using a computer to plot the trajectory of emotion throughout the book and its correlation with success have been discussed (Vonnegut, 1981; Reagan et al., 2016). However, learning and using stylistically aware embeddings for authors in conjunction with other relevant stylistic features extracted from books for the problem has been overlooked. Our work fills this gap by adding author's general writing style learned using an external corpus of books.

8 Conclusions and Future Work

In this paper we explored a new dimension of modeling authors for literary texts by jointly learning annotated character n-gram embeddings and author embeddings using an external corpus. We showed that a book representation using our proposed embeddings significantly improves likability prediction results. Our approach was also able to obtain competitive accuracy for authorship attribution and genre classification, two tasks where style plays a prominent role. Moreover, we also demonstrated that annotated character n-gram embeddings yield higher quality word vectors. These results in likability prediction, authorship attribution, genre classification, and word similarity further demonstrate the usability of annotated character n-grams and author embeddings in varied tasks. In the future, we will extend our method to other domains where authors' information is important, such as author profiling.

Abstract

End-to-end neural approaches are becoming increasingly common in conversational scenarios due to their promising performances when provided with sufficient amount of data. In this paper, we present a novel methodology to address the interpretability of neural approaches in such scenarios by creating challenge datasets using dialogue self-play over multiple tasks/intents. Dialogue self-play allows generating large amount of synthetic data; by taking advantage of the complete control over the generation process, we show how neural approaches can be evaluated in terms of unseen dialogue patterns. We propose several out-of-pattern test cases each of which introduces a natural and unexpected user utterance phenomenon. As a proof of concept, we built a single and a multiple memory network, and show that these two architectures have diverse performances depending on the peculiar dialogue patterns.

1 Introduction

In recent years, there has been an increasing research on neural approaches for conversational systems. Such approaches include the realization of full end-to-end systems (Serban et al., 2016; Bordes et al., 2017), the capacity to incorporate or query structured knowledge sources into neural architectures (Eric and Manning, 2017), the use of zero-shot learning or of synthetic dialogues generation techniques to mitigate effort of domain portability (Zhao and Eskenazi, 2018; Guerini et al., 2018). Although state-of-the-art neural models achieve high performances in many domains, the sheer size of data they require represents a bottleneck, especially for under-resourced dialogue domains. In addition, it is hard to interpret their behaviour since neural models are intrinsically opaque. In this paper we propose a novel methodology to address the aforementioned problems by synthetically creating conversation datasets with peculiar characteristics. In particular, we focus on (i) scalable and portable approaches for generating dialogues from scratch involving complex and structured knowledge, and (ii) strategies for isolating and evaluating specific reasoning capabilities of neural architectures using synthetic *challenge sets*. To this end, we utilize dialogue self-play strategies (Shah et al., 2018) simulating task oriented dialogues between a conversational agent and a user. Dialogue simulation grants complete control over the generated data allowing building special test cases, each of which introduces a natural and unexpected user utterance phenomenon, that has never been seen at training time. It should be noted that the use of natural data would require *manual* annotation/selection of examples for each phenomenon of interest, making this goal intractable.

Another problem with current datasets is the lack of exhaustiveness: they usually focus on one specific domain intent. There are few datasets covering multiple intents in the same scenario, but usually these intents are very different from one another – e.g. weather forecast and play music in a car scenario (Eric and Manning, 2017). For this reason, we choose a compelling low resource dialogue domain, i.e. Banking, that allows us to bring together multiple tasks (e.g. transfer money, check balance, block card).

2 Related Work

Our focus is on synthetic data generation techniques for low-resource domains and for inves-

Proceedings of Recent Advances in Natural Language Processing, pages 693–702,
Varna, Bulgaria, Sep 2–4 2019.

tigating the learning capabilities of neural conversational agents. For this reason, we will discuss some artificial conversational datasets, testing strategies for dialogue models, and the main dialogue systems approaches.

Artificial Datasets. Many conversational datasets rely on crowd sourcing (Jurčíček et al., 2011; Kelley, 1984), cooperating corporations (Raux et al., 2005), already available records (Lowe et al., 2015; Danescu-Niculescu-Mizil and Lee, 2011), or participation with the real world (Yu et al., 2015; Zue et al., 1994). Moreover, available task oriented dialogue datasets are mainly focused on very specific domains, such as restaurant reservation (Jurčíček et al., 2011; Henderson et al., 2014), flight booking (Zue et al., 1994), bus information systems (Raux et al., 2005) and giving directions to rooms in a hotel (Yu et al., 2015). Since the collection of whole dialogues is usually very expensive and time consuming, there have been efforts in building methodologies that allow fast and cheap data collection (Shah et al., 2018; Kelley, 1984). Artificial data generation is an effective methodology for obtaining well defined training datasets. Bordes et al. (2017) uses a simulator for this purpose. Other approaches artificially outline the conversational flow of their examples and then use crowdsourcing to convert dialogue turns into natural language (Shah et al., 2018).

Testing Neural Dialog Models. With the rise of Neural NLP, interpretability has become a major issue. Belinkov and Glass (To appear) survey various methods addressing interpretability. In particular, one line of research deals with challenge sets (Lehmann et al., 1996). While the majority of NLP datasets reflects a natural distribution of language phenomena, challenge sets are meant to restrict their focus on a specific phenomenon (quantifiers, plurals, anaphora, etc.) at a time (Cooper et al., 1996). Analyzing the ability to deal with a specific phenomenon allows evaluating the systems in a more principled way. Challenge datasets have been applied to diverse tasks, such as Natural Language Inference (Wang et al., 2018) and Machine Translation (King and Falkedal, 1990). These datasets offer insight if a model is capable of handling a specific line of reasoning from training data to specific structures at test time.

Methods for conversational scenarios. Many methods have been proposed to deal with conversational scenarios. *Rule Based Systems* are the simplest to implement for the task oriented setting when the flow of the dialogue is already known. They tend to be highly brittle to patterns not seen during their construction or to porting to new domains (Marietto et al., 2013). *Information Retrieval Methods* usually imply the two main approaches, namely TF-IDF and Nearest Neighbor models (Isbell et al., 2000; Jafarpour et al., 2010; Ritter et al., 2011; Sordoni et al., 2015). More recently, *Neural Network Models* have been heavily employed for conversational agents. Sequence-to-sequence models (Vinyals and Le, 2015) perform well for short conversations but fail in longer ones (Hochreiter and Schmidhuber, 1997; Cho et al., 2014). Hierarchical Encoder Decoder Models (Serban et al., 2016) are an extension of the sequence-to-sequence models. They handle the context in a separate RNN and use this context for response generation. Finally, Latent Variable Hierarchical Encoder Decoder models (Serban et al., 2017) represent a further improvement of the Hierarchical Encoder Decoder Model. Other recent approaches have focused on Memory Networks, that use an external memory component build into the system to store long term contexts (Weston et al., 2014). In particular, end-to-end Memory Networks (Sukhbaatar et al., 2015), an extension where every component is trained in an end-to-end fashion, showed promising results in task oriented dialogues (Bordes et al., 2017).

3 Data Generation through Self-Play

Unlike the natural challenge sets discussed in Section 2, our focus is on testing structured reasoning in conversational context, by using synthetic dialogue generation to grant that phenomena under investigation are present only at test time and not at training time. To our knowledge, this is the first attempt to build challenge datasets in an artificial way and to use them for the dialogue domain. Natural data would not be suitable for our purpose since the challenging test phenomena can also be found in the training set. In particular, our dataset is constructed using a dialogue self-play approach (Shah et al., 2018). This approach suggests that we can always simulate a conversation if we treat it like a game. During the simulations, we instantiate two bots; the system and the user. For each conversation, we pick up a user profile, then user and system bots carry on the conversation through pseudo-language ***actions*** regarding

Logical Form	Example Annotation
BOT: How can I help you today ?	*BOT: How can I help you today ?*
inform_intent = transfer	I need to send some money.
inform_intent = transfer {amount}	I want to transfer {amount}
inform_intent = transfer {partner}	Can I send money to {partner}?
inform_intent = transfer {partner} {amount}	I would like to send {amount} to {partner}.
BOT: Who is the recipient?	*BOT: Who is the recipient?*
inform {partner}	It is {partner}.
BOT: What is the transfer amount?	*BOT: What is the transfer amount?*
inform {amount}	Roughly {amount}.

Table 1: Automatically generated logical forms provided to annotators and annotated template samples for a Money Transfer intent with 2 slots. Bot request is provided to annotators to give better context.

the user profile.

Therefore, every conversation is represented as an exchange of actions between the two agents. Each action contains the information on who performed it and what values the agent provided. For each dialog for a chosen intent, the respective system bot asks the relevant slots and the user bot provides the appropriate slot values. The system bot then checks the values provided and issues the next requests accordingly. Both API calls and slot requests are performed through actions. To convert these actions into actual dialogues, we conducted an annotation task with 5 annotators. First, we converted each possible action for all the intents into logical forms (uninstantiated pseudo-code) and asked the annotators to provide natural language templates for each logical form without changing the entity placeholders. We then used the language templates to create natural language utterances by replacing the placeholders with the actual values. In Table 1, we give a few examples of the logical representations provided to annotators and the template they wrote. The conversion to the final plain text has been done by filling annotated templates with a small KB (the user profile). This approach is different from the one proposed by Shah et al. (2018) that uses instantiated pseudo-code since the beginning: it requires much more data annotation and makes it more difficult to detach surface realization from dialogue structure for building challenge sets.

The advantages of our synthetic data generation is twofold. First, it helps us to achieve a better coverage since reducing dialogues to an exchange of actions allows having a formal and simple visualization of all the generated dialogue flows - this is not the case with WoZ data collections (Kelley, 1984). Second, by instantiating each dialogue with different natural language templates, we can create dialogues that have the same structure but different wording.

3.1 The System and User Bot Design

We designed the user and the system bots using a finite state machine approach (Hopcroft et al., 2001), assuming that each dialogue is a flow between states and each utterance is a move from one state to the next. For our experiments, each of these states handles one particular slot. Whenever a user bot provides some information through its action, the system bot changes the state accordingly and performs its own action in response. The user bot then deals with the system action, performs its own and the cycle continues. The dialogue concludes when the system bot reaches an end state and issues an end call action.

3.2 Banking Domain Intents

The user intents/tasks that the dialogues are built upon are in the Banking Domain. We selected several intents to create a dataset that contains: i) conversations that are varied and diverse, and ii) conversations that use similar sentences and slots but to complete different tasks.

Each dialogue is initiated by the system bot asking the first question. To add variability we randomized the number of slots provided by the user in its response, similar to verbosity user trait in (Shah et al., 2018). After these initial turns the system bot ask the respective missing slots. Apart from asking the missing slot, the system bot also validates the value of the slots by calling respective APIs, since by design the User Bot may provide incorrect values and the System Bot is designed to handle all these possible cases. In Table 2, we give an example dialogue to demonstrate how API intensive these dialogues might become. Note that, for each interaction we have a specific user profile, i.e. the possible entities for slots are predetermined. For example, "partner list" for money transfer is fixed, and a user cannot provide a random name. Additionally, dialogues are formed with respect to policy restrictions such that i) the slots for each intent are asked in a strict order, ii) each slot value should be validated through an api call, iii) there are maximum 3 consecutive invalid user utterances after which the dialogue is terminated, iv) the final API call for intent execution randomly returns a success or failure. The valid/invalid user utterances are chosen randomly in each turn. We now list the domain intents and their descriptions as follows:

Making a Transfer. In this intent, USER wants to transfer some money. The system is tasked to fill three slots i.e *user account*, *partner name* and *amount*.

Canceling a Transfer. This intent handles cases where USER wants to cancel a transfer made earlier. The first required slot is the *transaction id* and USER may or may not recall it. If the transaction id cannot be filled, SYSTEM asks for *partner name* and checks for previous transactions.

Blocking a Card. The main slot required for this intent is the *card id*. Similar to the canceling a transfer intent, there are two possible paths for the conversation flow. If USER cannot recall the *card id*, SYSTEM asks another set of slots, which are the *user account* and the *card type*.

Transaction History Query. This intent is for finding a transaction in USER's transaction history by searching the *note* field. Notes are specific texts giving information about the transaction reason, such as "Salary" or "Electricity bill".

Account Balance Query. To search for the account balance, USER is asked to provide the *user account* name.

Account Limit Query. USER searches for the maximum transferable amount from his/her account. This intent, together with account balance, serves to evaluate the disambiguation performance of the conversational models when facing semantically similar intents - in fact their dialogue flow and required slots are identical.

S : How can i help you today?

U : I am really concerned that i lost the bank card, is its deactivation possible?

S : Please enter the card id.

U : I am not sure about the card id

S : Which account does the card belong to?

U : It is associated with my checking account.

A: CALL:CHECK_ACCOUNT, USER_ACCOUNT:CHECKING

A: RESPONSE:ACCOUNT_CHECK, RESULT:FAILED, MESSAGE:'list of available accounts joint , savings'

S : I couldn't find the account you are looking for. Your available accounts are joint , savings. Would you like to change your answer?

U : Yes

S : Which account does the card belong to?

U : It must be savings

A : CALL:CHECK_ACCOUNT, USER_ACCOUNT:SAVING

A : RESPONSE:ACCOUNT_CHECK, RESULT:SUCCESS

S : You have the following cards that belong to your account: prepaid card, credit card. which card would you like to block?

U : Can you block the prepaid card?

A : CALL:CHECK_CARD_NAME, CARD_NAME:PREPAID

A : RESPONSE:CARD_NAME_CHECK, RESULT:SUCCESS

S : Do yo confirm blocking your card?

U : yes

A : CALL:BLOCK_CARD, CARD_ID:SAVINGS-PREPAID

A : RESPONSE:BLOCK_CARD, RESULT:SUCCESS

S : Your card has been successfully blocked.

Table 2: A complete Block card example. U corresponds to User, S to System, and A to API calls.

3.3 Challenge Test Set

We generate a wide variety of test cases using the same dialogue self-play methodology employed for the training data, by modifying the structure of the original dialogues in a principled manner. Each of these test cases represents a particular conversational situation that has never been seen during training but that might happen in real interactions. While we cannot precisely quantify the exhaustiveness of the considered cases in real life scenarios due to the domain restrictions, the synthetic dialogue generation allows us to easily integrate new challenge cases when necessary. Below, we discuss in detail each test case and what function it serves to test. We also present a more conventional test set, i.e. out of templates set, to disclose how much we elevate the difficulty of the task by the challenge test cases. In our experiments, we will disregard Out Of Vocabulary (OOV) cases, i.e. cases where entities of interest at test time are not seen at training time, e.g. the partner name "Michael", (Bordes et al., 2017).

Out of Templates (OOT) Out of templates test case is constructed by sampling annotation templates into training, development and test sets. By doing so, we can test whether the agent can handle user utterances in an unseen linguistic form.

Out of Pattern (OOP) Out of pattern test cases challenge the agents through the conversations with a structure (dialogue flow) that has not been seen during training. We have constructed five out of pattern cases for the challenge test set. Together with each OOP description, we provide an example, where the arrow indicates the answer of the system bot to be predicted, and the part in italic highlights the differences between training and test sets for readability purposes.

1. Turn Compression The training dialogue structure contains a confirmation step after each attempt to fill the current slot with an invalid value. Following a confirming answer from USER for changing the slot value, SYSTEM repeats the slot filling question to USER. In the turn compression challenge test case, we concatenate the confirmation and the new slot answers as the user utterance for the change confirmation question of SYSTEM. The correct system utterance is the validation API call of the new value instead of the slot filling question again. Table 3 shows an example where SYSTEM asks if USER wants to change the *partner name*, and during testing the user gives a confirming answer together with the correct *partner name*.

Sys : Partner name is incorrect, would you like to change it?

User : *Yes*

→**Sys** : *What is the name of the recipient?*

Sys : Partner name is incorrect, would you like to change it?

User : *Yes, change it to Megan*

→**Sys** : *API PARTNER CHECK **Megan***

Table 3: Train/test excerpt of Turn Compression

2. New API The new API challenge is designed to evaluate the performance of an agent in terms of its ability of issuing the required API calls with appropriate slot values. To this end, we create intent utterances in training data either without any extra slot value or odd number of slot values while in the new API challenge set, intent utterances contain only even number of slot values. See Table 4 for an example.

Sys : How can i help you today ?

User : I want to see if my salary was credited

→ **Sys** : API CHECK SALARY

Sys : How can i help you today?

User : I want to see if my salary was credited from Facebook

→ **Sys** : API CHECK SALARY *FACEBOOK*.

Table 4: Train and test excerpt of New API

3. Reordering The training dialogues have a particular slot filling order for each intent. In the reordering challenge set, on the other hand, the order of slots in dialogues is shuffled. The purpose of reordering is to evaluate whether an agent is able to generate the system utterance to fill the correct missing slot after all other slots for the current intent have been filled. In the example given in Table 5, we show the correct system utterance of a new API challenge test case for the missing slot: *user account*.

User : I'd like to transfer some money.

Sys : From which account?

User : from Savings please.

Sys : Who is the recipient ?

User : It is Michael

→ **Sys** : *What is the amount?*

User : I'd like to transfer some money.

Sys : *What is the amount* ?

User : 100 euros.

Sys : Who is the recipient ?

User : It is Michael

→ **Sys** : *From which account?*

Table 5: Train and test excerpt of Slots Reordering

4. Another Slot In a natural conversation, USER can provide an utterance that is irrelevant to the current turn while including a slot value relevant to another one. Example dialogue excerpts for Making a Transfer intent with and without such *another slot* test case are given in Table 6.

5. Audit More In the training dialogues, after SYSTEM requests a new slot value for the value

Sys : What is the partner name ? **User** : *It is Michael.* →**Sys** : *API PARTNER CHECK* ***Michael***
Sys : What is the partner name ? **User** : *Make the amount to be 10k euros .* →**Sys** : *API AMOUNT CHECK* ***10k euros***

Table 6: Train/test excerpt for Another Slot case

changing turn, USER is expected to provide an appropriate value for the slot. In the audit more challenge set, USER provides other slot values along with the requested slot. We test if the system can recognize the changed slot value and issue the appropriate API calls for the slots given by USER. In the example test dialogue given in Table 7, USER changes the amount along with the partner name slot. The correct response of SYSTEM would be the API calls for the given partner name and the amount values.

Sys : What is the partner name ? **User** : *Change it to Michael.* →**Sys** : *API PARTNER CHECK* ***Michael***
Sys : What is the partner name ? **User** : *Change it to Michael and make the amount to be 5k euros.* →**Sys** : *API PARTNER CHECK* ***Michael,*** *AMOUNT CHECK* ***10k euros***

Table 7: Train and test excerpt of Audit more.

We should note that each OOP test can contain only one type of OOP, i.e only turn compression or only new API etc. However, in one dialog there may be more than one instance of the same OOP.

4 Neural Models

For our experiments, we focused on end-to-end Memory Networks (Sukhbaatar et al., 2015), which have been employed in various NLP tasks including non-goal-oriented (Dodge et al., 2016) and goal-oriented (Bordes et al., 2017) dialogue systems. End-to-end memory networks exploit a memory component to store the dialog history, multiple memory look-ups (hops) as an attention mechanism, and short-term context to predict the next response. They yield promising performances in dialogue tasks outperforming some other end-to-end RNN based architectures. In addition, end-to-end memory networks have been shown to be able to perform non-trivial operations such as issuing API calls to KBs (Bordes et al., 2017), which are a key element to our scenario. We implemented 2 variations of memory networks in order to test the feasibility of challenge set by analyzing the performance differences of the networks.

Single End-to-End Memory Network (SMN) replicates the end-to-end memory network presented by Bordes et al. (2017) trained on all dialogues from all intents simultaneously.

Multiple End-to-End Memory Network (MMN) is an ensemble of 6 different Memory Networks, each trained on a single intent and a 7^{th} Memory Network that has the task of selecting the appropriate one for the given dialogue. The training data for the 7^{th} memory network is produced by appending a call-memory-network action after the user utterance that informs the intent in a dialog.

We implemented MMN and tested against SMN to investigate if sharing information from different intents plays a positive role or creates interference, especially for intents that contain the same slot types and have a high semantic similarity.

5 Experiments

We used a learning rate of 0.001, a batch size of 32, and maximum 20 epochs during the training of both networks. We set the embedding size to be 128 as it has been shown to perform good enough for most NLP problems (Bai et al., 2009). For memory networks we empirically used a memory size of 40 and 3 hops.

We have generated 200 dialogues per intent and per test case through the methodology explained in Section 3. We first sampled $1/3$ of the templates to linguistically realize the logical form of training dialogues and $1/3$ for development. For the in-template test cases we then randomly sampled turns from training and development to create test dialogues. Instead, for the OOT test configurations we used the remaining $1/3$ of the templates to generate new linguistically unseen test cases. Similar to Bordes et al. (2017), the networks are evaluated in a ranking, not a generation, task: we test whether for each dialogue turn, the MNs can identify the next (correct) system utterance or API call from a list of candidates. Regarding the evaluation metric, we have used Per-Response Accuracy, which is the number of correct system responses predicted out of all dialogue turns in the whole test set. Each response under test is compared to the predicted response by the model when given a dialogue memory, i.e. context, and a new user utterance.

Considering the banking domain and task scenarios, for which it is almost impossible to record and collect real human interactions, we cannot perform an experiment on real life conversations. Although using WoZ technique and challenge pattern annotation could be applicable, it could not be guaranteed that we can collect reasonable amount of data for the same challenge pattern and we would be obliged to know every pattern in advance. Therefore, we also employ dialogue synthesis for test/challenge set dialogues, which allows for a continuous challenge design by modifying the template combinations and dialogue patterns.

5.1 Test Cases and Results

We compare the memory networks against the per-response accuracy for In Template (IT henceforth) and Out Of Template setting. In Table 8, we show the test results of SMN and MMN models for IT and OOT configurations (including non-OOP and OOP test settings).

	IT		OOT	
Test Case	*SMN*	*MMN*	*SMN*	*MMN*
Non OOP	88.62	**90.17**	87.39	**88.27**
Turn Comp.	27.80	**55.00**	27.90	**54.70**
New API	7.42	**7.83**	**8.17**	6.67
Reordering	**54.50**	45.50	**54.00**	41.50
Another Slot	**38.00**	25.00	**41.50**	27.50
Audit More	15.50	**34.00**	16.00	**35.00**
OOP Avg.	28.64	**33.47**	29.51	**33.07**

Table 8: In template non-challenge/OOP test results, OOT non-challenge/OOP test results in terms of per-response accuracy.

OOP impact. As expected, OOP cases represent a compelling challenge for our MNs, see Table 8. When we compare the results of the non-OOP and the OOP cases, we observe drastic performance differences, both in IT (88.62 vs. 28.64, 90.17 vs 33.47) and OOT (87.39 vs. 29.51, 88.27 vs. 33.07) settings. Still, in some settings both MNs are able to show reasonable performances and different behaviors on different challenge sets (reordering and another slot for SMN, turn compression and audit more for MMN).

Single vs Multiple Memory Network. Concerning the IT cases, MMN slightly outperforms SMN in the non-challenge test setting. In addition, it shows a substantial accuracy increase in turn compression and audit more OOP cases. On the other hand, SMN surpasses MMN in reordering and another slot OOP challenges. A similar outlook of performances is observed for the OOT non-challenge and OOP cases aside from new api challenge, which turns out to be the most difficult OOP challenge and will be discussed later.

We observe that on average MMN outperforms SMN both in IT and OOT cases. One possible explanation is based on how the memory network finds the correct response. The Single Memory Network does so by incorporating all the intents in its selection of the responses. Therefore, it searches for more general responses while the Multiple Memory Network assigns the same task to a specialized Memory network, which is trained on that very specific intent. The specialized memory network is better at finding the correct response since it is trained only on one particular intent data and its search space is implicitly reduced.

As a particular OOP performance comparison, we noticed that SMN is better at selecting the right response during the reordering challenge, which evaluates the ability of the model in learning the necessary slots to accomplish an intent.

In template vs Out of Template. We found out that there is not a major difference between IT and OOT test case performances (slightly better for SMN and slightly worse for MMN). One possible explanation is that the tests have not been conducted in an OOV setting. Therefore, the SMN and MMN may not learn the linguistic patterns to find entities (templates) but they directly learn to recognize the entities and to predict the API calls accordingly.

Multiple Out of pattern. As a final experiment, we wanted to inspect the effect of having the challenge phenomenon of interest appearing more than once in a dialogue, such as the example proposed in Table 10. For this last case we could use only turn compression and audit more, that have a sufficient number of slots to replicate the phenomenon of interest over different slots in the same dialogue. What we observe is that indeed it is difficult

	Per-Response Accuracy	
Test Case	SMN	MMN
Turn Compression	29.61	55.16
Turn Compr. OOT	29.07	55.13
Audit More	10.50	15.02
Audit More OOT	10.90	15.43

Table 9: Multiple Out of Pattern per Dialog

Sys : The partner name you provided is incorrect, would you like to change ?
User : *Yes, change it to Michael (first Occurrence of Turn Compression)*
Sys : Okay, your amount also exceeds the limit, would you like to change ?
***User** : Yes, It is 100 euros (The second occurrence of turn compression)*

Table 10: Example of Multiple OOP dialogue

for both the SMN and the MMN to handle the case of more than one OOP.

It can be seen that there is a drop in the performances of both MNs in Table 9 as compared to previous challenge tests, only for audit more. This drop can be attributed to the differences of the contexts of the conversations that are present in the memory while selecting the response. Since the context is the previous conversation until the chosen turn, for the first case, i.e. the first example in 10, the context is a usual sub-dialogue pattern that is seen during the training. So the responsibility of the agent is to understand the new unseen compressed user utterance and choose the correct response. However, when we test the second turn compression in the same dialogue, i.e. the second turn in 10 where USER changes the amount, the responsibility of the agent is compounded by the fact that in addition to understanding the compressed turn, it has to reason about an unseen context pattern. In other words, the context also contains a form of turn that the agent has never seen during training, which is the first turn compression of the second example in Table 10.

The Easiest and the Hardest Challenge Cases Finally, to investigate the difficulty of challenges that we have introduced with each OOP case, we should focus our attention to the easiest and the hardest cases. We observe that out of all the OOP test cases (both in-template and OOT settings) both memory networks performed quite poorly on handling new APIs. The results suggest that it is harder for the memory networks to interpret a new combination of slots and issue the related API calls. This could be partially explained by the position of the new API cases in the dialogue. By design, new API cases happen at the beginning of the conversation (i.e. giving an intent together with unexpected slots, see example in Table 4). Therefore, the system has no context (no interaction memory) to reason on while selecting the response. On the contrary, for the easier turn compression case, the memory network is already expecting a possible change in the slot value (e.g. "*do you want to change the amount?*") in the following turns, regardless of receiving it in the respective turn or in the next few. In fact, the network is already 'primed' on selecting an amount related API call. Consequently, the memory networks have a better performance on turn compression rather than new API challenge.

6 Conclusions and Future Work

In this paper, we explored some challenges connected to dataset creation for conversational agents and interpretability of neural models. In particular, we propose a methodology to create rich datasets for training end-to-end conversational agents and challenge them on unseen patterns at test time. We then experimented with Memory Networks and investigated their performance on the custom test cases. The apparently low accuracy levels on unseen challenge cases suggest that the synthetic data and challenge generation for low resource dialogue domains can act as a reasonable approximate to real life challenges in such domains. In other words, the more a dialogue model is able to handle these diverse challenges, the more it will be able to handle the unstructured or less structured dialogues in real human-machine interaction. As a future work we would like to test further neural models and create additional OOP challenge sets, even combining additional configurations.

Abstract

Text classification field of natural language processing has been experiencing remarkable growth in recent years. Especially, sentiment analysis has received a considerable attention from both industry and research community. However, only a few research examples exist for Azerbaijani language. The main objective of this research is to apply various machine learning algorithms for determining the sentiment of news articles in Azerbaijani language. Approximately, 30.000 social news articles have been collected from online news sites and labeled manually as negative or positive according to their sentiment categories. Initially, text preprocessing was implemented to data in order to eliminate the noise. Secondly, to convert text to a more machine-readable form, BOW (bag of words) model has been applied. More specifically, two methodologies of BOW model, which are tf-idf and frequency-based model have been used as vectorization methods. Additionally, SVM, Random Forest, and Naive Bayes algorithms have been applied as the classification algorithms, and their combinations with two vectorization approaches have been tested and analyzed. Experimental results indicate that SVM outperforms other classification algorithms.

1 Introduction

Development of technology generates a vast amount of data flow through the internet and encourages the creation of sophisticated methodologies to store and analyze it. Analyzing such huge volumes of data manually could lead to the waste of time and investment. Therefore, currently more automated and efficient ways are implemented to solve the problem.

With the growth of the produced data, a branch of Artificial Intelligence - Natural Language Processing (NLP) had begun to evolve. Text classification is a fundamental part of NLP and has been applied in many areas. The aim of text classification is to group data into predefined categories based on the labeled data using various machine learning techniques. It requires several stages to categorize the data including data collection, preprocessing, and feature extraction. One of the implementation areas of text classification includes sentiment analysis. Sentiment analysis helps to define whether an author's opinion towards a specific topic is negative or positive. Considering the fact that people's opinion directly influences the businesses and organizations it is no surprise that sentiment analysis receives a lot of attention.

Although sentiment analysis has been applied largely worldwide, research on its usage and utility on Azerbaijani language is scarce. English language has the luxury of having numerous annotated datasets as well as having well-tuned text preprocessing techniques. Different from English language, natural language processing algorithms are not improved sufficiently in Azerbaijani which is an agglutinative language and therefore requires special pre-processing approaches. Furthermore, implementation of some well-known feature extraction approaches is not experimented enough and investigating their effectiveness in natural language processing tasks namely, in sentiment analysis for an agglutinative language is one of the main objectives of the research. Additionally, the main purpose of our research is to build supervised machine learning based, automatic sentiment polarity detection system for analyzing Azerbaijani social news articles.

Proceedings of Recent Advances in Natural Language Processing, pages 703–710,
Varna, Bulgaria, Sep 2–4 2019.

2 Literature Review

As sentiment analysis is one of the prominent topics nowadays there exists vast amount of experiments applied with different methods. Sentiment analysis of text for Azerbaijani language had been investigated by Aida-zade et al. (2013). Multi machine learning algorithms had been applied for news classification in Azerbaijani language in (Suleymanov and Rustamov, 2018; Suleymanov et al., 2018; Aida-zade et al., 2018). Cambria (2016) distinguishes three main approaches in the field of sentiment analysis: knowledge-based, statistical and hybrid. The first one is the method of classifying text using rule-based algorithm to extract the sentiment. To help the organizations to improve their decision making and improve customer satisfaction Zaw and Tandayya (2018) applied rule-based algorithm called Contrast Rule-Based sentiment analysis to classify customer reviews automatically. Another rule-based algorithm is proposed by Tan et al. (2015) for classifying financial news articles. According to the research, initial stage was to determine the sentiment of each single sentence in the given financial news. Next stage was calculating positivity/negativity for the whole content of an article.

Sentiment analysis is widely used to measure the public opinion about a given topic. Li et al. (2017) investigated relationship between Dow Jones Industrial Average and public emotions. During experiment approximately 200 million twitter data was collected that mentions 30 companies which are part of the New York Stock Exchange. Researchers applied a different methodology called SMeDA-SA. The method initially extracts all uncertain sentences from the document to create the vocabulary. As a result, the research indicated that stock price of companies can be predicted with the given methodology.

One of sentiment analysis task – subjectivity detection applied before sentiment analysis for increasing accuracy performance. Rustamov et al. applied Adaptive Neuro Fuzzy Inference System (2013a), Hidden Markov Models (2013b) and Hybrid models (2018) for detection of subjectivity analysis. Same techniques had been applied for document level sentiment analysis (Rustamov et al., 2013). The method described by Araque et al. (2017) is an example of deep learning algorithm usage for sentiment analysis. Recently, deep learning is widely used to classify the text as it is capable of extracting public opinion regarding a specific topic and also works excellently with high-level features. During the research, deep learning model was developed using word embedding and linear machine learning model was implemented.

Sentiment analysis can also be used with the combination of different methodologies in the implementation of various applications. One of the researches that benefited from application of sentiment analysis is done by Rosa et al. (2019). In the research, applications collect data about a user and give recommendations based on the data produced by the user. The research proposes an approach for a recommendation system which takes user's current psychological state into account using sentiment analysis. Based on the mood of a user system sends different messages to the user including relaxing, peaceful, calm and etc.

Bansal and Srivastava (2018) applied word2vec model with machine learning algorithms to classify user reviews. The word2vec model was used to represent 400.000 consumer reviews data from Amazon as vectors. Later, the vector representation of data was given to the classifier as an input. In order to classify the data both Continuous Bag of Words (CBOW) and Skip-Gram model were implemented in combination with 4 machine learning algorithms including SVM, Naive Bayes, random forest, and logistic regression.

Severyn and Moschitti (2015) worked on an application that does sentiment analysis of tweets with deep learning models. They have applied unsupervised natural language model to initialize word embeddings which were used as distant supervised corpus in their deep learning model. The model was initialized by using pre-trained parameters of network, then trained on supervised training data from Semeval-2015. According to official test sets' result, their model ranked first in phrase-level and second in message-level tasks.

In some researches it is observed that dictionary-based approaches are also effective to extract the sentiment from text data. Nigam and Yadav (2018) divided collected tweets into lexemes and matched the words with the terms in the dictionary. Matched words were weighted so that negative word gets -1 score and positive word gets +1 score. The overall sentiment of document was calculated by subtracting the weights of positive words from weights of negative words.

3 Methodology

3.1 Data Collection

Data collection and annotation is an essential step for training supervised machine learning algorithms. Not only the collected data should be relevant to the research objective but also the annotation process should be carefully designed in order to have no inconsistencies among labeled data as they could scale up during training phase and lead to unsatisfactory results. For conducting this research using supervised machine learning techniques, approximately 30000 news articles had been collected and monitored from online websites of famous Azerbaijani newspapers. News articles under social category have been observed to contain more sentiment polarity and therefore found to be more suitable for sentiment analysis. The inter-annotator agreement had been established and an additional procedure had been implemented as a control mechanism in order to verify that the agreement had been followed during annotation. One of the main requirements of agreement was to label only the articles in which sentiment has been explicitly expressed. For instance, an article about a social event cannot be annotated for its sentiment unless author explicitly shows its social benefits or downsides. This was done to eliminate any inconsistencies emerging from subjective assessment of annotators. The control mechanism had been implemented as follows. Firstly, each news article was given a unique identifier and after random shuffling, articles were divided into small chunks each containing 500 articles. In the first run each annotator was given a chunk. After all annotators finished the first chunk, the second run began. In the second run, each annotator was given a chunk and additionally 50 more already labeled articles without their labels. By comparing these 50 articles' new labels with old ones, we could determine in which aspects annotators did not agree and made relevant adjustment to the annotation agreement to minimize the amount of disagreement in subsequent runs. In the following runs the steps of the second run were repeated until there was no chunk remaining. 12210 articles were labelled according to above mentioned rules. Among the labeled news articles, 4565 of them were labeled as positive and 7645 were labeled as negative. In the next stages, we had applied k-folds cross validation. In this method k stands for the number of repetitions of splitting data into test and train part. Cross validation is a method in machine learning that is used for assessing the result of the applied algorithm. It helped us to estimate how accurately the model would work in real case situations. By considering that we may not have satisfactory amount of data to train the model, and while splitting data into test and train we eliminate some of the train data and it may cause underfitting problem, we have applied 10-fold cross validation. After each splitting we got the accuracy score and when the splitting ended, we obtained final accuracy by calculating the average.

3.2 Data Preprocessing

Getting clean data was first step of the experiment. In order to get sentiment from data, stop words were cleaned, which have no sentiment but are highly frequent in the dataset and could decrease accuracy. Especially while applying frequency based vectorizer, noisiness of data interrupts quality of classification process.

Dataset contained XML and HTML tags since they were taken from online resources. Especially names of websites, sources of the article, dates, URL links and JS tags were present in the dataset and they affected the prediction accuracy negatively. For example, website names which end with the domain names such as ".az", ".com", ".org", ".net", ".ru", ".edu", ".gov" had been removed. In addition, the ones that started with "http", "https" and "www" and extra time tags were also deleted from data. Furthermore, all unnecessary punctuations were cleaned except semicolon and dash, since they are used in compound words in Azerbaijani language.

Finally, to eliminate difference between same words with different cases (uppercase and lowercase), all tokens had been converted to lowercase. It is needed to mention that after preprocessing, number of words decreased, and consequently, dictionary size was reduced as well which speeded up the processing of data and the classification algorithms.

3.3 Feature Extraction

In terms of natural language processing, there is an essential need to convert text data into a specific format which is appropriate for applying statistical machine learning algorithms. The process is called feature extraction and there exists different methodologies for feature extraction. One of the commonly used methods is called bag of words model (BOW) that treats each single word as a feature. This approach takes collection of documents and converts it into a list of unordered words called vocabulary (Chen et al., 2017). Next step is to create a vector representation of documents according to the size of given vocabulary where existence of each unique word defines the size. In a basic vectorizing models, it counts occurrence of each word in text and converts it to an array of real numbers.

In the domain of machine learning, there exists various vectorization approaches one of which is counting based. Also called frequency based, it provides a sparse representation of corpus of documents as a matrix. However, frequency based vectorizer has several drawbacks. Firstly, not all words have sentiment value despite how frequently it is used in the document, namely, frequency of commonly used words could shadow other more significant and sentiment containing words. Therefore, to solve this problem term-frequency and inverse-document-frequency method (tf-idf) is widely used. In addition to the number of occurrence in the document tf-idf also takes into consideration word's density in the whole corpus of documents. It consists of two parts where term frequency provides count of each word and inverse document frequency reduces value of words that are densely used in the corpus.

Another approach of bag of words model is hashing based vectorizer. It maintains vectors representing each term as an integer value. Different from others, it does not create dictionary, still having larger matrix to encode a document. tf-idf and frequency based vectorizer generates high-dimensional vector representations. Unlike them hashing based vectorizer suggests an efficient way to reduce the dimensionality of the vector. It offers default size for feature vector and provides an option to reduce and increase vector size. However, probability of collision should be considered when choosing the size. If the number of unique words in the vocabulary exceeds the feature size it could lead to collision where several unique words could map to the same integer value.

It is not necessity to present each single unique term as an input to the vectorization method. Different word combinations can be used here including unigram, bigrams, and trigrams. In unigram each word represents one feature. Additionally, we can also take combination of two words called bigrams, and combination of three words at a time called trigrams (Bhavitha et al., 2017).

4 Classifiers

4.1 Random Forest

Random forest is one of the supervised learning algorithms, which is implemented in both regression and classification problems. This classifier is a collection of recursive, tree structured models.

In decision tree, the prediction is done by splitting root training set into subsets as nodes, and each node contains output of the decision, label or condition. After sequentially choosing alternative decisions, each node recursively is split again and at the end classifier defines some rules to predict result. Conversely, in random forest, classifier randomly generate tree without defining rules.

We have implemented random forest algorithm with the different vectorizer methodologies, and n-gram models as shown in Table 1 and got different outcomes as described below.

Feature extraction	**n-grams**	**F1-Score**	**Precision**	**Recall**
Frequency based vectorizer	Unigram	93.21	91.02	95.87
	Bigram	92.15	88.47	95.97
	Trigram	89.79	82.91	97.38
Tf-idf	Unigram	93.33	90.65	95.93
	Bigram	92.27	88.96	96.61
	Trigram	89.95	83.29	97.5

Table 1: Random Forest Classifier Result

While considering the highest F1 score, we got 93.33 percent from the combination of tf-idf vectorizer and unigram model. On the other hand, when taking highest recall and precision score separately, we obtain the highest recall score of 97.38 percent. The highest recall score yields the precision of 82.91 and F1 score of 89.79 percent. Even though the recall is the highest, we got the lowest F1 score from that combination. Additionally, the highest precision score which is 91.02 percent provides 93.21 F1 score and the lowest recall score of 95.87 percent. As visible in the Table 1 the second highest F1 score of 93.21 was obtained from the combination of frequency based vectorizer and unigram model. It is noticeable that the difference between the first highest F1 score of 93.33 percent and the second highest F1 score of 93.21 is too close to each other and therefore was not statistically important. The lowest F1 score of 89.79 percent was obtained from the combination of frequency based vectorizer and trigram model.

4.2 Naïve Bayes

The second machine learning algorithm we have applied to our data set is Naive Bayes classifier. It is a probabilistic model, which is derived from Bayes Theorem that finds the probability of hypothesis activity to the given evidence activity. According to naive Bayes rule each feature is independent from each other and because of the assumption about independence, occurrence of one feature has no impact to others. Depending on the features, Bayes classifier has several forms including Gaussian Naive Bayes classifier, Multinomial Naive Bayes, and Bernoulli Naive Bayes. In this research Multinomial Naive Bayes which is mostly used for document level analysis is implemented. In this classifier, feature representation has been generated by multinomial distribution which reflects frequency of words like vectorization. Probability of an event i happening with multinomial Naive Bayes is formulated as:

$$p(x|C_k) = \frac{(\sum x_i)!}{(\prod x_i)!}\prod_i pki^{x_i}$$

In this paper we have applied Multinomial Naive Bayes classifier using alpha=1 with frequency based vectorizer and tf-idf vectorizer as described in the following table. Alpha parameter prevents model assigning null probabilities in case of 0 term frequency. Below, table 2 clearly indicates the impact of combination of different vectorization methodologies, n-gram models on the F1, recall, and precision score.

Table 2 presents that combination of frequency based vectorizer and bigram model provided the highest F1 score result of 95.47 percent. In contrast, the lowest F1 score result we got among the above combinations was 90.9 percent and was obtained from tf-idf and trigram model. As can be seen from the table the lowest F1 score yields the lowest precision score of 90.0 percent. The highest precision score we got was 97.87 which yields the lowest recall score of 85.4 percent. The highest F1 score of 95.47 percent was obtained from the combination of frequency based vectorizer and bigram model. Additionally, it is noticeable from the table that while considering tf-idf results the highest F1 score we got 94.66 percent which was obtained from bigram model. This combination yields the recall score of 98.24 percent which is the second highest recall score and precision score of 91.34 which is the lowest precision score.

Feature extraction	**n-grams**	**F1-Score**	**Precision**	**Recall**
Frequency based vectorizer	Unigram	94.87	95.87	93.9
	Bigram	95.47	97.24	93.77
	Trigram	91.2	97.87	85.4
Tf-idf	Unigram	94.1	91.54	96.97
	Bigram	94.66	91.34	98.24
	Trigram	90.9	84.2	98.75

Table 2: Multinomial Naive Bayes Classifier Result

4.3 Support Vector Machine

The third classification algorithm that we have applied is SVM. the purpose of SVM classification algorithm is to define optimal hyperplane in N dimensional space to separate the data points from each other. N dimensional space here is number of features:

$$h(x_i) = sign(w * x_i + b)$$

$$min_w \lambda \, ||w||^2 + \sum_{i=1}^{n}(1 - y_i < x_i, w >) \quad (1)$$

Equation (1) describes the calculation of cost function and hypothesis for SVM. One of the important terms used in SVM is kernel parameter. When the data is so huge and hardly computational, kernel is used to speed up and optimize SVM. There are different types of the kernel parameter such as linear kernel, polynomial kernel, rbf kernel, and sigmoid kernel. In this research linear kernel parameter is used. In the research, we analyzed accuracy of SVM classification algorithm with different vectorization and n-gram models which is described in the following table.

Feature extraction	n-grams	F1-Score	Precision	Recall
Frequency based vectorizer	Unigram	95.51	95.4	95.63
	Bigram	95.45	94.17	96.76
	Trigram	92.82	88.73	97.31
Tf-idf	Unigram	96.79	96.48	97.1
	Bigram	95.9	94.45	97.41
	Trigram	93.35	89.19	97.93

Table 3: Linear SVM Result

Table 3 depicts the F1, recall, and precision results for SVM classifier using various feature selection and n-grams models. As can be seen from the table the best F1 score we got 96.79 percent was from the combination of tf-idf vectorizer and unigram model. While considering frequency based vectorizer the highest F1 score which is 95.51 percent was obtained from unigram model. When comparing the F1 score of unigram and bigram models we do not observe huge difference between results. Recall values for the SVM classifier ranged from 95.63 percent to 97.93 percent. The highest recall score was 97.93 which was obtained from the combination of tf-idf and trigram model. As described in table the lowest F1 score 92.82 percent and was gained from trigram model and frequency-based vectorization.

4.4 Data Skewness and Classifier Comparisons

As described in data collection section, the dataset was skewed towards negative samples with 7.6k negative samples and 4.5k positive samples. Having skewness in a dataset can be considered normal as dataset is formed as a result of some natural phenomena which can inherently be biased towards some category or other. In our case, news agencies play the role of data source which seems to be biased towards generating negative news articles. This could be explained by the fact that this type of articles is catchier and preferred more by the readers.

Having data skewness can have a direct impact on the results of a machine learning model and gaining further insights can contribute to obtaining higher results. Therefore, the impact of skewness on our dataset had been researched. Firstly, we examined the precision and recall score per class to see if skewness has a significant impact on the results.

Class	Recall	Precision
Positive	93.58	94.82
Negative	96.89	96.23

Table 4: Per class precision and recall scores of SVM classifier

Table 4 demonstrates that skewness in the dataset affects the performance of the classifier. Therefore, we explored several approaches for optimizing the results while working with skewed dataset. The considerable change came from the application of adjusting sample weights inversely to the frequencies of each class in SVM classifier. By this way, the classifier is penalized more for the mistakes made on samples from underrepresented class, namely positive. This allowed to elevate the recall score to 95.14 percent for the positive class and increase the precision score to 97.07 percent for the negative class, while slightly lowering the recall to 95.95 percent.

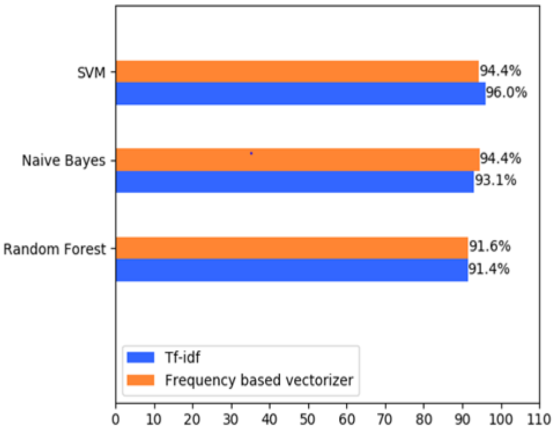

Figure 1: Accuracy of SVM, Naive Bayes, random forest classifiers with vectorization methods

Figure 1 demonstrates the accuracy results obtained from implementation of tf-idf and frequency-based vectorization methods with each classification algorithm. As can be seen from the figure, combination of SVM and tf-idf outperforms other classifiers with the 96 percent accuracy. The minimum accuracy was obtained from the combination of random forest classifier and tf-idf vectorizer with 91.4 percent accuracy. While considering accuracy result it is observable that accuracy range changes between 91 percent and 96 percent. Random forest classifier does not offer huge difference between two vectorization methods as there is only 0.2 percent accuracy difference between tf-idf and frequency-based vectorization methods. When analyzing Naive Bayes classifier, the best accuracy we got was 94.4 percent and was obtained from the frequency based vectorizer.

5 Conclusion

In conclusion, we experimented with three machine learning algorithms on news articles in Azerbaijani language. Comparing one classifier with another, depending on the n-gram model and vectorization method we obtained different results for different combinations. According to the research the highest F1-score we got was 96.79 percent with the implementation of SVM on tf-idf vectorizer and unigram model. Research also revealed that Naive Bayes classifier give its best result 95.47 percent with the combination of frequency based vectorizer and bigram model, while random forest acquires highest F1-score 93.33 percent by using tf-idf based feature extraction and unigram model.

Additionally, for future work we plan to improve our research by enlarging our dataset, adding neutral class, applying rule-based algorithms and observing their performance in our dataset. In addition to them, we are going to apply word embedding with different classification algorithms.

Abstract

In the paper we present the latest changes introduce to Inforex — a web-based system for qualitative and collaborative text corpora annotation and analysis. One of the most important news is the release of source codes. Now the system is available on the GitHub repository (https://github.com/CLARIN-PL/Inforex) as an open source project. The system can be easily setup and run in a Docker container what simplifies the installation process. The major improvements include: semi-automatic text annotation, multilingual text preprocessing using CLARIN-PL web services, morphological tagging of XML documents, improved editor for annotation attribute, batch annotation attribute editor, morphological disambiguation, extended word sense annotation. This paper contains a brief description of the mentioned improvements. We also present two use cases in which various Inforex features were used and tested in real-life projects.

1 Introduction

Development and evaluation of tools for various natural language processing task (named entity recognition, sentiment analysis, cyberbully detection and many other) require dedicated resources in a form of manually or semi-automatically annotated corpora. Corpus-based studies in the domain of Digital Humanities also require a support in the form of specialized tools and system. Both create a demand on development of tools and systems qualitative text corpora management, annotation, analysis and visualization.

Inforex is one of several web-based systems for text corpora annotation which is being developed as an open source project. The other well-known systems include, but are not limited to, WebAnno 3.0 (de Castilho et al., 2016), Brat (Stenetorp et al., 2012) and Anafora (Chen and Styler, 2013). Comparing to the other systems Inforex has some distinct features, including: support for untokenized and tokenized documents, support for both plain text and XML documents (XML tags are used to format the document layout) and integration with CLARIN-PL web services (utilizes on-demand morphological tagging).

In Section 2 we present the basic characteristic of the Inforex system. In Section the 3 we present the recents improvements and new features implemented in the system. In the Section 4 we present two projects in which the latest features were utilized.

2 Inforex Overview

Inforex is a web-based system for text corpora management, annotation and analysis. Since 2018 it is available as an open source project on the GitHub repository and is a part of the Polish CLARIN infrastructure[1] — it is integrated with the official repository for language resources in Polish CLARIN[2]. From the user perspective Inforex requires only a modern web browser to use the system.

Inforex offers several features for collaborative work on a single corpus, including concurrent access to data stored in the central database, role-based access to different modules, flag-based mechanism to track the process of various types of tasks. It support text cleanup, mention annotation, relations between annotations, morpholog-

[1] https://inforex.clarin-pl.eu
[2] https://clarin-pl.eu/dspace/

ical tagging, annotation attributes, metadata and many others. A more comprehensive list of functions can be found in (Marcinczuk et al., 2017).

3 Recent Changes and Improvements

3.1 Open Source Project

After 10 years of development the project has been finally released as an open source project. The source codes are available under the LGPL license and can be obtained from https://github.com/CLARIN-PL/Inforex.

3.2 Easy Installation

The installation process was simplified by converting the system and all required components to run withing a set of Docker containers[3] defined in a Compose file. The Compose[4] file defines four containers: (1) **www** — web server running the Inforex application with background services (see Section 3.3), (2) **db** — MySQL database server, (3) **liquibase** — Liquibase database schema control and (4) **phpmyadmin** — web-based access to the database (for development and maintenance purposes).

A new installation of Inforex boils down to running the following two lines of code:

```
sudo apt-get install composer \
        docker docker-compose
./docker-dev-up.sh
```

3.3 Background Processes

Time consuming tasks, like corpus export or morphological tagging, are handled by processes running in the background. That's how we avoid the web server timeouts and handle task queuing. The background processes have been added to the Docker container with web server and they are automatically run on the container startup.

3.4 Multilingual Morphological Tagging

Inforex uses CLARIN-PL Web Service API[5] (Walkowiak, 2018) to facilitate the on-demand morphological document tagging. CLARIN-PL WS API provides access to morphological taggers for 11 languages. Seven of them are available from Inforex, i.e. Polish, English, German, Russian, Hebrew, Czech and Bulgarian (see Figure 1). Inforex automatically choose the language specific tagger based on the document language set in the metadata.

3.5 Extended Annotation Attribute Editor

We have extended the annotation attribute editor to handle dictionary-based attributes with a large number of possible values (see Figure 2). The improvements include the following:

- Filtering of the list of values,
- Feature to add a new element to the dictionary directly from the value picker level.
- Suggestions based on values assigned to other annotations. We have implemented two heuristic of generating the candidates with different levels of certainty, i.e.:
  - values for other annotations matched by the text form with the Soundex algorithm[6]. The list of candidates is sorted by their frequency,
  - attribute values matched by the annotation text (full or partial matching).

Figure 2: Extended annotation attribute editor

3.6 Batch Annotation Attribute Editor

Up to now the modification of annotation attributes was available only from the *Annotator* perspective using the annotation editor (see Figure 2). When an user had to modify an attribute for each annotation the only way was to go through all the annotations one by one. This process was time

Gmina Bov

Gmina Bov (duń . Bov Kommune) - istniejąca w latach 1970 - 2006 gmina w Danii w okręgu południowej Jutlandii (Sønderjyllands Amt) . Siedzibą władz gminy było miasto Bov , Padborg . Gmina Bov została utworzona 1 kwietnia 1970 na mocy reformy podziału administracyjnego Danii .

Po kolejnej reformie administracyjnej w roku 2007 weszła w skład nowej gminy Aabenraa .

Tokenize

Figure 1: Document tokenization perspective

consuming and error-prone because it was easy to miss some annotations. To overcame these problems we have created a page for batch annotation attribute modification. The page consists of two main components, i.e. a document content with annotation preview and a table with annotations with their attribute (see Figure 3).

3.7 Document Auto Annotation

This feature was designed to reduce user effort in annotating repeatable phrases in and across documents. *Auto annotation* works by annotating in given documents all phrases that were already annotated in other documents. This feature works for both untokenized and tokenized documents, however we advise to use it on tokenized documents as the phrases are aligned with token boundaries and we avoid matching of incomplete words. After running *auto annotation* the new annotations are presented to the user for verification. User can decide whether given annotation is correct, incorrect or the annotation type needs a change (see Figure 4). The discarded annotation are stored in the system for future run of *auto annotation*. During the next use of *auto annotation* the new annotations which were previously discarded are ignored.

3.8 Lemma and Attribute Auto Fill

These features were designed to reduce user effort in setting annotation lemmas and attribute values. They both works in a similar way — for each annotation in the document the lemma or attribute value is set based on other annotations in the corpus. For lemma we collect annotations with the same text form and category. For attribute value we collect annotations with the same text form or lemma and category. In case of ambiguity, i.e. there are more than one possible value of lemma or attribute, the value remain empty and the user has to fill it manually. The lemma auto fill feature is available in the *Annotation lemmas* perspective and the attribute auto fill feature is available in the *Annotation attributes* perspective.

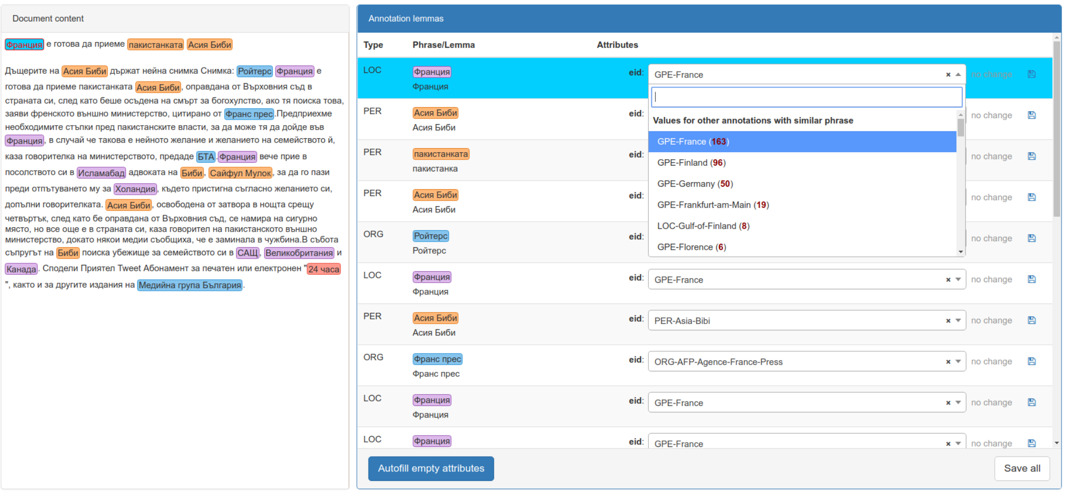
3.9 Tokenization of XML documents

Inforex allows to store documents in one of the two formats: plain text or XML. The XML format is used to encode document structure, like in the KPWr (Broda et al., 2012) and PCSN (Marcińczuk et al., 2011) corpora. During tagging the XML tags should be ignored and only the content should be processed. Thus, we made the tokenization process to be aware of the document format (see Figure 1). For XML format the document content is cleaned from XML tags, than the content is processed by the tagging service and at the end the tokenization is aligned with the original XML document.

3.10 Annotation Attribute Browser

The attribute value browser (see Figure 5) allows to browse corpus annotations by given attribute value. The page consists of three elements:

- View configuration — provides a set of filters, including: shared attribute, document language and subcorpus,
- Attribute values assigned to annotations — list of values their frequency,



Франция е готова да приеме пакистанката Асия Биби

Дъщерите на Асия Биби държат нейна снимка Снимка: Ройтерс Франция е готова да приеме пакистанката Асия Биби, оправдана от Върховния съд в страната си, след като беше осъдена на смърт за богохулство, ако тя поиска това, заяви френското външно министерство, цитирано от Франс прес.Предприехме необходимите стъпки пред пакистанските власти, за да може тя да дойде във Франция, в случай че такова е нейното желание и желанието на семейството й, каза говорителка на министерството, предаде БТА.Франция вече прие в посолството си в Исламабад адвоката на Биби, Сайфул Мулок, за да го пази преди отпътуването му за Холандия, където пристигна съгласно желанието си, допълни говорителката. Асия Биби, освободена от затвора в нощта срещу четвъртък, след като бе оправдана от Върховния съд, се намира на сигурно място, но все още е в страната си, каза говорител на пакистанското външно министерство, докато някои медии съобщиха, че е заминала в чужбина.В събота съпругът на Биби поиска убежище за семейството си в САЩ, Великобритания и Канада. Figure 4: Auto annotation and candidate verification perspective

- Annotations with the selected value.

3.11 Export of Morphological Tagging and Annotations Agreements

For tokenized document Inforex can store up to three layers of morphological tags:

- *Tagger* — tags produced by a tool,
- *Agreement* — tags entered by a user in the agreement mode,
- *Final* — tags approved by the super user.

During export it is possible to define which layer of tags should be exported. It is possible to choose one of the following options (see Figure 6):

- *Final or tagger (if final not present)* — export the *final* tags. For tokens which does not have the *final* tag a *tagger* tag is taken.
- *Final* — export only the *final* tags. If there are tokens without final tags than the missing tags are reported as errors.
- *User (agreement)* — export tags created by selected user. For tokens which does not contain user agreement tags the tagger tags are taken.
- *Tagger* — export tagger tags.

3.12 Improved Support for Word Sense Annotation

The existing mechanism for word sense annotation was limited to a single set of words and their senses (Marcińczuk et al., 2012). We have removed the limitation and allow to define and use any number of sets of word senses in the WSD

perspective. We also added the option to annotate the word senses in an agreement mode for further agreement (see Figure 7). Finally, we have imported all lexical units with their senses from Słowosieć 3.2 (Piasecki et al., 2016) as an annotation set to Inforex.

3.13 Morphological Agreement

The last feature is support for morphological disambiguation agreement. Inforex provides a page with morphological tag agreement across a given set of documents (see Figure 8). The agreement is presented in a numerical form for each documents in the set and after a specific document a list of disagreements is presented. This feature is complemented by a document perspective for comparing and choosing the final morphological tags (see Figure 9).

4 Case Studies

In this section we present two uses cases in which various features of Inforex were used in real-life projects.

4.1 BSNLP 2019 Shared Task

Inforex was used to create the training and testing datasets for the need of 2nd Edition of the Shared Task on Multilingual Named Entity Recognition for Slavic languages[7]. The task aims at recognizing mentions of named entities in news articles in Slavic languages, their lemmatization, and cross-language matching.

More than 10 people were involved in the annotation process for four languages, i.e. Polish, Czech, Russian and Bulgarian. There were 1–3 annotators per language. The annotation process consists of four main steps:

1. Selection of relevant documents — the document were automatically crawled and uploaded to Inforex, therefore some of them were duplicates or text not relevant to the subcorpus topic. The selected documents were marked with a flag *Valid content*.

2. Annotation of named entity mentions — the same set of five annotatation types was used to annotated all the selected documents. For Polish and Czech the annotators utilized the auto annotate feature described in Section 3.7 and we were able to evaluate the usability of

the auto annotation feature. Table 1 contains evaluation of the automatically recognized and added annotations for two languages and two subcorpora (each on a different topic). The auto annotation feature yielded very high precision of 97-99% with relatively high recall of 66-82%. This means that in case of Polish and Czech subcorpora 10k out of 14k annotations were added automatically. It was a significant facilitation of the work.

3. Assignment of annotation lemmas — to assign lemmas the annotators utilized batch lemma editor and lemma auto fill. For the correctly added annotations the lemmas were also automatically assigned.

4. Assignment of cross-lingual identifier — the goal was to assign the same identifier for each mention across all languages referring to the same real-world entity. There were more than 4k identifiers. The annotators utilized the auto fill features described in Section 3.8. The attribute browser was used to validate the entity mentions.

4.2 Polish Translation of the NTU Multilingual Corpus

An ongoing project which goal is to provide Polish translation of the NTU Multilingual Corpus (Tan and Bond, 2011) which consists of two stories from the Sherlock Holmes Canon (The Adventure of the Speckled Band and The Adventure of the Dancing Men. The Adventure of the Speckled Band is the first one translated and prepared for manual annotation. The text was divided into 31 samples (txt files) of a similar size and imported directly into Inforex system. Then automatic morphological tagging was performed using WCRFT morpho-syntactic tagger for Polish (Radziszewski, 2013). The tagger provided morphological disambiguation on the basis of its context but also other possible forms for this particular word were listed. The result of the automatic annotation was then verified by two linguists independently. They were able to see morphological analysis of each token and the decision of the tagger (see Fig. 9). It could be accepted or discarded by the human annotator. It was also possible to add and assign an interpretation which was not identified by the tagger (e.g. in the case of unknown words). Inter-annotator agreement was calculated and its level was high enough (0,97) to perform further. Then, after completion the manual verification of morphological tagging by both linguists team coordinator proceeded with inconsistencies analysis. The decision was made for every token differently

Figure 10: Morphological information provided for human annotators

After the Inforex functionality was developed and primarily used for creation of The Adventure of the Speckled Band corpus, it was successfully applied to prepare Corpus of the colloquial Polish language (Oleksy, 2019) in another project. This corpus has been designed to address the problem of morphological tagging of user-generated content (UGC) as part of the project ”SentiCognitiveServices — next generation service for automating voice of customer and social media support based on artificial intelligence methods”[8]. The whole corpus (approximately 400000 tokens) is manually annotated with morphological information and furthermore the sample of 100 documents was prepared as a result of 2+1 annotation.

5 Summary

The last two years have been productive in the development of the Inforex system. Many new features and extensions were implemented during that time and the most important were presented in this paper. Majority of the features and improvements were dedicated by users. The most important news is the that Inforex has been finally released as an open source project.

Abstract

In this paper, we describe the process of creating a statistical Language Model (LM) for the Tunisian Dialect. Indeed, this work is part of the realization of Automatic Speech Recognition (ASR) system for the Tunisian Railway Transport Network. Since our field of work has been limited, there are several words with similar behaviors (semantic for example) but they do not have the same appearance probability; their class groupings will therefore be possible. For these reasons, we propose to build an n-class LM that is based mainly on the integration of purely semantic data. Indeed, each class represents an abstraction of similar labels. In order to improve the sequence labeling task, we proposed to use a discriminative algorithm based on the Conditional Random Field (CRF) model. To better judge our choice of creating an n-class word model, we compared the created model with the 3-gram type model on the same test corpus of evaluation. Additionally, to assess the impact of using the CRF model to perform the semantic labelling task in order to construct semantic classes, we compared the n-class created model with using the CRF in the semantic labelling task and the n-class model without using the CRF in the semantic labelling task. The drawn comparison of the predictive power of the n-class model obtained by applying the CRF model in the semantic labelling is that it is better than the other two models presenting the highest value of its perplexity.

1 Introduction

Generally, the development of such ASR system for a specific language requires first and foremost the construction of a large speech corpus. This corpus must be based on both an orthographic and a phonetic transcription. In addition, textual data for learning the LM of the system are also required. Nevertheless, these resources are not available directly for Arabic dialects. As a result, the ASR system development for Arabic dialects is fraught with many different kinds of difficulties that it faces. In this perspective, this work is integrated in the field of developing the Tunisian Dialect ASR system for the Tunisian Railway Transport Network. More precisely, we are interested in this paper in presenting our method for constructing a LM; one among the essential components of the ASR system. This model proposes to define the probability distribution on sets of word sequences. Due to the lack of learning data of the Tunisian dialect, it is necessary to find a method that maximizes the amount of information. This corresponds to the appearance of the n-class LM. The main idea of this model is to classify vocabulary words into lexical classes and to calculate the probability of a sequence of words, such as the probability of a sequence of lexical classes (5).

The primary contributions of this paper are as follows:

- Gathering our TARIC (Tunisian Arabic Railway Interaction Corpus) corpus to realize an ASR system for

Proceedings of Recent Advances in Natural Language Processing, pages 720–729,
Varna, Bulgaria, Sep 2–4 2019.

the Tunisian Railway Transport Network. This corpus is based on speech transcriptions. In order to obtain a standardized and normalized corpus, we employed our Tunisian Dialect CODA (Conventional Orthography for Dialectal Arabic) (30).

- We present our proposed method of creating the n-class LM. To achieve this, we show the different stages of our method.
- We evaluate the performance of the discriminative algorithm based on the CRF model in order to perform the semantic labeling task for spontaneous speech in the Tunisian Dialect in the n-class LM construction context.
- Testing the impact of using CRF model in the semantic labelling field. It is also important to assess its effect on creating semantic classes on the one hand, on developing an n-class LM and on its perplexity level on the other hand.
- We eventually disclosed the elaborated experiments we went through and the obtained results.

The remainder of this paper is organized as follows: Section 2 tries to show the main role of ASR system and its components. We also shed light on the main types LM. Section 3 discusses the related work in this field summarizing the main aspects of every work. Section 4 describes the TARIC corpus in Tunisian Dialect used for experiments. In section 5, we present the CRF discriminative model used to perform semantic labeling then, we explain our method to construct n-class LM for Tunisian Dialect. Then Conclusion is drawing in the last section.

2 ASR system and language model

An Automatic Speech Recognition (ASR) system aims to transcribe textual data of a speech signal. Indeed, in the context of statistical modeling of speech, an ASR system is composed of acoustic model, language model (LM) and phonetic dictionary. As our works aim at suggesting a method in order to construct a LM, we provided further explanations of this component by concentrating on its different types that have been proposed in the literature. As we mentioned earlier, the LM seeks to represent the language behavior in order to confirm or refute the propositions made by the acoustic module. In literature, several statistical LM types are recognized as being the most efficient models in ASR. Among these models, we can cite n-gram, sequences of n-words and factorial LM. We will present some examples of the aforementioned approaches in the following sub-sections.

2.1 N-gram model

Thanks to their simplicity and efficiency, n-gram models are the most widely used LM in the speech recognition field. They are based on the assumption that the appearance of a single word depends only on its history. In practice, estimating this probability is very difficult. In fact, no learning corpus can make it possible to observe all the sequences of possible words. As a result, the basic idea of n-gram models consists in considering only the sequences of words of length n, i. e the calculation is approached by a limited history consisting of the n-1 preceding words. The major drawback of this modeling type is that it can lead to assigning a zero probability to any n-gram that has never been encountered in the training corpus. This problem is serious especially when this n-gram could be perfectly valid in linguistics.

2.2 N-class model

Due to the lack of the learning corpus, it is vital to find a method that maximizes the amount of useful information on the one hand and reduces the model parameter space on the other hand. In order to meet this requirement, other methods have emerged recently. They consist in grouping words into classes. This corresponds to the appearance of n-class LM. The chief idea of this model is to group vocabulary words into lexical classes and to estimate the probability of the word sequence, such as the probability of a sequence of lexical classes (5). One of the clearest conception of motivations for n-class models is that a word of a given class, not necessarily found in the learning corpus, inherits the probability of all the other representatives of its class. In addition, it is possible to add words to classes without having to re-estimate the model probabilities. However, the problems faced by n-class models are numerous. The first major difficulty is that this type of model requires the need for a prelabeled learning corpus (24). Nevertheless, manual labeling is particularly heavy despite its exact results.

2.3 Factorial LM

The factored LM is based on the principle that a word is no longer seen as a simple graphic chain but rather as a vector of characteristics (3). These characteristics can include the lemma and the grammatical class of a word, morphs, its kinds, its numbers, or Booleans indicating the word belonging to given semantic classes. On the theoretical side, factorial models have already shown good results for some tasks, such as machine translation (14). At the practical level, few works have relied on this model, especially in the speech recognition task.

To conclude, due to the limitation of our field of work ”Tunisian Railway Transport Network”, several words with similar behaviors exist, (semantic for example) but they do not have the same probability of appearance; their class groupings will therefore be possible. Moreover, the amount of learning data is reduced. In this context, the use of the n-class model is beneficial at several levels. For these reasons, we propose to build an n-class LM that is based mainly on the integration of purely semantic data. Indeed, our method will be used to create a LM based on semantic information for the creation of word classes. The figure 1 shows some words with the same semantic behavior.

3 Related Work

In this Section, we are going to review the existing works related to classify vocabulary words for the construction of an n-type class LM. In the context of training classes of words, (10) proposes a simple word classification algorithm for statistical LM in speech recognition. The classification criterion used in this approach is the similarity of words. Indeed, the principle is based on the criterion of substitution or replacement. According to this algorithm, two words are similar since they can be substituted in the learning corpus (10). According to this automatic word classification approach, the word accuracy rate was increased by 8.6% with a reduction in perplexity of about 6.9% (10). The method proposed by (8) is essentially based on the principle of combining different sources of information at the class formation level. In his work, (8) uses two types of information: contextual information and prior information. The former is the most commonly used, corresponds to n-gram dependencies. This information can be collected not only at the words level, but also at the level of previously constructed classes of words (8). It is fundamental to take into account the contextual information in order to better distribute the words into the classes. Thus, the use of contextual information is of interest in the context of improving the predictability of the model. It makes it possible to offer a better distribution of words into classes and thus, a more balanced distribution of distributions (8). The second type, either semantic or syntactic information, is formalized by categories or grammars. In the approach proposed by (8), the used information a priori is extracted from a learning corpus labeled in grammatical categories. The approach proposed by (29) is based on contextual information (left context and right context), so words that appear frequently in similar contexts should be assigned to the same class. According to (29), different vocabulary words are classified using the k-means algorithm. The particularity of this approach is based on the fact that the number of words in a class is set to k and if there is a class whose number of words is less than k then that class will be merged with another. The main advantage of this algorithm is its simplicity to find centroids and suddenly, the cost of merging words or classes becomes less expensive. The approach developed by (2) proposes to integrate semantic information for the formation of word classes in the statistical LM of ASR system. This approach is based on a pivot language (called IF for Interchange Format), which represents the meaning of the sentence regardless of the language (2). Thus, the criterion of choice of classes is guided by the definition of the pivot language and the most used concepts in the IF.

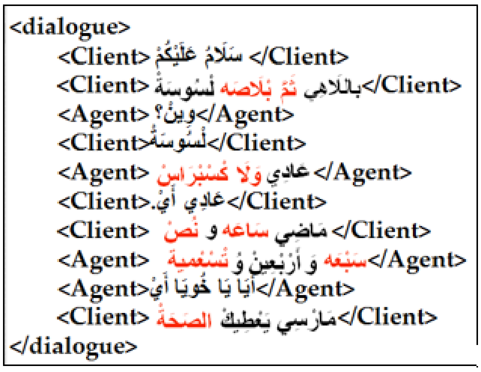
4 Tunisian dialect corpus collection

We create our own corpus of real spoken dialogues corresponding to the information request task in railway stations in collaboration with the Tunisian National Railway Company (SNCFT). This corpus is called TARIC, for Tunisian Arabic Railway Interaction Corpus [16]. The main task of the TARIC corpus is information request in the Tunisian dialect about the railway services in a railway station. These requests are about consultation, train type, train schedule, train destination, train path, ticket price and ticket booking. The creation of the corpus was done based on two steps: the production of audio recordings and the manual transcription of these recordings.This corpus consists of 21,102 statements and 66,082 words.

The Tunisian dialect the Tunisians' mother tongue, which is used in their daily oral communication. It is becoming more and more useful not only in interviews, talk shows and public services but also in blogs, chat rooms, SMS, e-mails, etc. However until now the Tunisian dialect has no standardized spelling. Indeed, this dialect differs from MSA and it does not have a standard spelling because there are no academies of Arabic dialect. Thus, to obtain coherent learning data and to have a robust and powerful language model, it is necessary to utilize a standard spelling. Indeed, there are words with many forms. For example, the word رزرفسيون /reservation/ can be written in four different ways: رَازرفسيون, رَازَارفسيون and ريزرفسيون. As a result, each word has a unique form. Spelling transcription guidelines CODA (Tunisian Dialect writing convention), (30), were adopted.

The normalization step is essential because it presents a key point for the other steps of our method. Among the normalisation Tunisian Dialect words we have: *(i)*Number "sixteen" is written as ستطَاش. *(ii)*To define the future, we must follow the following form: بَاش + verb, for example: بَاش نمشي. *(iii)* To define the negation, we must follow the following form: مَا + verb.

The Tunisian Dialect is characterized by the presence of foreign words, such as for instance: French, English, Spanish, Italian, etc.To transcribe these words, Arabic alphabets have been used. These foreign words have a unique form, for example: رتور [Back], ترَان [train]... At the end of this step, we obtain a standardized corpus, the figure 2 represents a corpus extract before the normalization step.



```

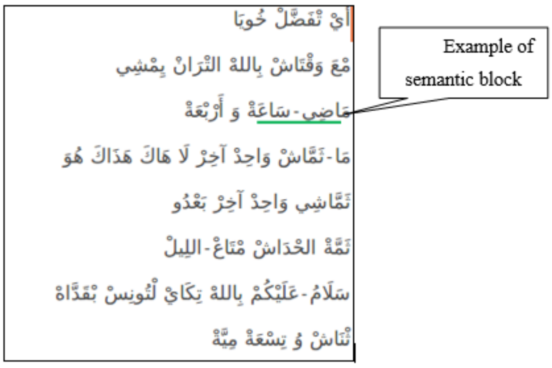
5 N-class LM construction

In this section, we are going to describe our method to create n-class LM based on semantic information for establishing word classes. This method is made up of five distinct stages.

5.1 Pre-processing stage

When we studied our corpus, we noticed that there are words that have no semantic value when they are figured all alone. Only the grouping of these words with other words can give a better semantic value to words that may be insignificant and subsequently useless for our field of work. As a result, we have decided to create semantic blocks that consist of grouping one or more words into a single word. Semantic block is defined as a group of two or more words. Indeed, this pretreatment consists of adding a (-) between two or more words to build a single word. Among the words that can be grouped together to form a semantic block, we find مَاضِي followed by another word to indicate the time for example مَاضِي سَاعَة [1 PM]. Cities whose names are composed such as سيدي بوزيد [name of Tunisian city] مَا [negation] followed by a verb with a negative form to express negation. This

step is necessary because it will be used for semantic labeling and later for the formation of word classes. Indeed, the main objective of this step is to give a better semantic value to words that may be insignificant and subsequently useless for our work. Following this step, we obtain a corpus that contains all the possible semantic blocks. Below (figure 4) is an excerpt from this corpus.



أَيْ تْفَضَّلْ خُويَا
مْعَ وَقْتَاشْ بِاللهْ التْرَانْ يِمْشِي
مَاضِي-سَاعَةْ وَ أَرْبْعَةْ
مَا-تْمَّاشْ وَاحِدْ آخِرْ لَا هَاكَ هَذَاكَ هُوَ
تْمَّاشِي وَاحِدْ آخِرْ بَعْدُو
ثَمَّةْ الحْدَاشْ مْتَاعْ-اللِيلْ
سَلَامْ-عَلَيْكُمْ بِاللهْ تِكَايْ لْتُونِسْ بْقَدَّاهْ
ثْنَاشْ وُ تِسْعَةْ مِيَّةْ

Example of semantic block

Figure 4: Extract of our corpus after semantic blocks formation

5.2 Statistical Semantic labeling

In this sub-section, we present in more details the way we integrate semantic order information for the formation of word classes. According to the previous steps, the semantic labeling step consists in giving a label to each single word or semantic block. We have performed the labeling task of words or semantic blocks extracted from a sentence and their corresponding concepts in the field of railway request information. In this task, each word or semantic block is labeled with a concept indicating its appropriate semantic nature. Thus, semantic labeling is not done word by word because we can find words that can have several meanings depending on the context in which they are used. Subsequently, the labeling of a word or a semantic block is done while taking into account its left and right neighborhood in a sentence. The figure 5 shows examples of semantic labeling.

Figure 5: Extract of semantically labelled corpus

In order to improve the sequence labeling task, we proposed to use a discriminative algorithm based on the Conditional Random Field (CRF) model. Thanks to their ability in learning the sequence tagging tasks efficiently, CRF have been applied to a wide range of NLP applications, such as morpho-syntactic tagging (POS), chunking and language modeling. CRF are probabilistic models for computing the conditional probability of a possible output giving an input sequence also called the observation sequence. To train semantic labeling associations and some predefined feature sets, CRF learns a set of weights w. Learning the parameter set w is usually done by a maximum likelihood learning for $p(\bar{x}|\bar{y};w)$:

$$p(\bar{x}|\bar{y};w) = \frac{1}{z(\bar{x}|w)} exp \sum_{j} w_j F_j(\bar{x},\bar{y}) \tag{1}$$

According to these equations, $\bar{x}$ represents the sequence of words or semantic blocks (observation), $\bar{y}$ represents the sequence of labels, and w stands for the weights. F_j corresponds to a feature function. The latter depends on the sequence of words, the current label, the previous label and the current position in an utterance. We utilized the CRF++ toolkit (16) in our experiments. It is a customizable and open source, which implement the CRF for segmenting and labeling sequential data. It is written in C++, employs fast training based on gradient descent and generates n-best candidates. In order to measure the performance of the labelling task, three evaluation metrics were generally adopted. The latter allow expressing Recall and Precision. These measures could be calculated as follows:

$$Precision = \frac{\#word\ correctly\ Labelling}{\#word\ Labelling} \tag{2}$$

$$Recall = \frac{\#word\ correctly\ Labelling}{\#total\ of\ word} \tag{3}$$

Our purpose is to create training and testing sets decently. We outlined the available datasets for the languages under investigation. We randomly selected 15826 sentences and 49562 words for training, 5276 sentences and 1652 words for testing. The outcomes of the CRF system show a Recall of 88% and a Precision of 87%. Based on the manual examination of the automatic labeling result using CRF, we found that the CRF have the ability to detect composed token specific to the task and label them correctly.

5.3 Construction of semantic classes

The present work, being mainly dedicated to building n-class-based LM, focuses essentially on the formation of semantic classes. Each class represents an abstraction of similar labels. In fact, a semantic class may correspond to a label or a group of labels, whereas a label cannot belong to only one class. Thus, if we consider the two statements: **Sentence 1:** تُونِس دُوزيَام كَلاس [Tunis second class]. **Sentence 2:** سوسَة پروميَار كَلاس [Sousa first class]. They become similar from this point of view because the words تُونِس [name of city] and سوسَة [name of city] belong to the same semantic class grouping ”city” and the words دُوزيَام and پروميَار belong to the same semantic class grouping ”Class”. Indeed, the number of classes must be limited while the number of occurrences of words belonging to same class must be large enough to come up with correct learned probabilities. We therefore choose to limit ourselves to the selection of classes most frequently encountered in our corpus, corresponding to our Field of study ”Tunisian Railway Transport Network”. In this step, we identify the most common label and group them into classes. A class then corresponds to a set of words leading to the same semantic labelling representation.

Table 1: Examples of Semantic Classes

Semantic classes	**Variants semantic tags**
City	Destination-Station..
Schedule	Trip-time, Arrival-hour ..
Response	Confirmation, Negation..

In our case, this classification provides about 20 semantic classes such as [City], [Response], [Request-Concept], [Comparison], [Schedule]. After obtaining the list of semantic classes, as shown in Table 1, we can then directly associate each word of our corpus with the class to which it belongs.

5.4 N-class calculation

We have already done the first experience for n-class LM calculation for Tunisian Dialect. After obtaining the list of semantic classes, we use it in combination with the data of LM to build our new ”semantic” model. In the LM learning corpus all words (or semantic blocks) are replaced by class names. The result is a ”prepared” corpus that contains both words (or semantic blocks) and Semantic classes. Finally, we use the SRILM [1] toolbox to learn LM including semantic classes. SRILM is a toolkit for building and applying statistical LM, primarily for use in speech recognition, statistical tagging and segmentation, and machine translation.

5.5 Evaluation of a LM

Several measures are used to evaluate the quality of LM. We present perplexity as the most used method. Perplexity (PPL) is a quick method to evaluate LM. It is commonly used for several years to judge the quality of LM (15). This evaluation metric is used to measure the prediction ability of LM on a test corpus not seen during learning. The principle of perplexity is to check how much LM can predict the word sequences of the language it is supposed to model. Perplexity is defined by:

$$PPL = 2^{-\frac{1}{n}} \sum_{t=1}^{n} logP(w_t|h) \qquad (4)$$

Where $P(w_t|h)$ represents the probability proposed by the LM for the word knowing the history h. Indeed, the perplexity of LM is between 1 and V, V is the size of vocabulary, that is to say the number of words that compose it. A reduced value of perplexity leads to better LM prediction capability.

As we have already mentioned, a low value of perplexity reflects a strong predictive power of LM. Thus, to better judge our choice of creating an n-class word model, we compared the created model with the 3-gram type model on the same test corpus of evaluation. Additionally, to assess the impact of using the CRF model to perform the semantic labelling task in order to construct semantic classes,

[1] http://www.speech.sri.com/projects/srilm/

we compared the n-class created model with using the CRF in the semantic labelling task and the n-class model without using the CRF in the semantic labelling task. The table below shows a comparison between the n-class model based on the CRF model in the Semantic labeling task and the n-class model without applying the CRF model in the Semantic labeling task together with the n-gram model in terms of perplexity.

Table 2: Value of perplexity calculated on the same test corpus

Type of model	Perplexity
3-gram	74.46
n-class without CRF	4.17
n-class with CRF	3.87

Table 2 shows the very significant relative reduction in perplexity by applying the CRF model in the semantic labelling compared to the other models. These results are consistent with what could be expected: (1) it is the classification based on semantic data that has minimized the perplexity of the obtained LM. The value of the n-class model perplexity remains well below that of the 3-gram model on the test corpus. Interestingly, the same models as for the learning corpus have the lowest perplexity value on the test corpus. (2) the application of CRF model to perform the semantic labelling task affects the improvement in creating semantic classes, by taking into account the n-class LM, and calculating the perplexity rates.

6 Conclusion

In this work, we have interested in constructing a statistical LM as one of the components of ASR system. The main role of this model is to give the probability of distribution on sets of word sequences. In particular, we are interested in n-class LM by using semantic information for the creation of word classes. Our choice is justified by the fact that some words are similar but they do not have the same probability of appearance, so their class groupings will be possible because of the limitation of our field of work ”the Tunisian Railway Transport Network”. The main idea of this model is to group vocabulary words into semantic classes and to consider mainly the calculation of the probability of a sequence of words such as the probability of a sequence of these semantic classes. To do this, we have followed these steps:We firstly construct semantic blocks that consists in grouping one or more words into a single word that we call ”semantic blocks”. Secondly, we do the semantic tagging. So in order to obtain a labeled corpus, the semantic labeling step consists in giving a label for each single word or for each semantic block. To improve the sequence labeling task, we proposed to use a discriminative algorithm based on the Conditional Random Field (CRF) model. Thirdly, we form semantic classes. In fact, a semantic class may correspond to a label or a group of labels, whereas a label cannot belong to only one class.LM calculation based on the SRILM tool. Evaluating the constructed model by calculating its perplexity. In order to test the model generated by our statistical LM system, we compared the created model with the 3-gram type model on the same test corpus. Secondly, to better judge the impact of using the CRF model to perform the semantic labelling task in order to construct semantic classes, we compared the n-class created model based on the CRF in the semantic labelling task and the n-class model without using the CRF in the semantic labelling task. According to this evaluation, we can say that the classification based on semantic data has minimized the perplexity of the LM obtained as compared to the rapport 3-gram LM. Moreover, the use of the CRF model to perform the semantic labelling task has an impact on the improvement in creating semantic classes, by taking into account the n-class LM and calculating the perplexity rates.

Abstract

The absence of diacritical marks in the Arabic texts generally leads to morphological, syntactic and semantic ambiguities. This can be more blatant when one deals with under-resourced languages, such as the Tunisian dialect, which suffers from unavailability of basic tools and linguistic resources, like sufficient amount of corpora, multilingual dictionaries, morphological and syntactic analyzers. Thus, this language processing faces greater challenges due to the lack of these resources. The automatic diacritization of MSA text is one of the various complex problems that can be solved by deep neural networks today. Since the Tunisian dialect is an under-resourced language of MSA and as there are a lot of resemblance between both languages, we suggest to investigate a recurrent neural network (RNN) for this dialect diacritization problem. This model will be compared to our previous models models CRF and SMT (24) based on the same dialect corpus. We can experimentally show that our model can achieve better outcomes (DER of 10.72%), as compared to the two models CRF (DER of 20.25%) and SMT (DER of 33.15%).

1 Introduction

Modern Standard Arabic (MSA) as well as Arabic dialects are usually written without diacritics(24). It is easy for native readers to infer correct pronunciation from undiacritized words not only from the context but also from their grammatical and lexical knowledge. However, this is not the case for children, new learners and non-native speakers as they dont have a good mastery of rich language derivations. Moreover, the absence of diacritical marks leads to ambiguity that affects the performance of NLP tools and tasks. This may generally bring a considerable awkward ambiguity at the data-processing level for NLP applications. Hence, we can notice that automatic diacritization has been shown to be useful for a variety of NLP applications, such as Automatic Speech Recognition (ASR), Text-to-Speech (TTS), and Statistical Machine Translation (SMT)(24).

In this paper, we present our method to automatic dialectical Arabic diacritization. In fact, both previous experiences and works have shown that the use of Recurrent Neural Network (RNN) could give better results for such an MSA diacritization system as compared to the other approaches, like the Lexical Language Model (16), a hybrid approach combining statistical and rule-based techniques (28). For instance, the authors (1) demonstrated in their study that the RNN gave the least DER, compared to the other MSA diacritization works.

Based on the huge similarity between MSA and Tunisian dialect, we decided to benefit from its advantages by testing the RNN performance in the automatic diacritization of Tunisian Arabic dialects. To the best of our knowledge, it is the first work that investigates the RNN for the diacritization of the Tunisian dialect.

In this respect, we performed the task of restorating diacritical marks without taking into account any previous morphological or contextual analysis. Moreover, we diagnosed different aspects of the proposed model with various training options. The latter include the choice of transcription network (long short-term memory (LSTM) networks, bidirectional LSTM (B-LSTM)) and the impact of RNN sizes. The size of the neural network is a function of the number of hidden layers. Our goal is to choose the most pertinent layers

Proceedings of Recent Advances in Natural Language Processing, pages 730–739,
Varna, Bulgaria, Sep 2–4 2019.

in the Tunisian dialect based on the final findings provided by various experiments.

This model will be compared to our previous CRF and SMT models (24) by utilizing the same training and testing corpus.

The remaining of this paper is structured as follows: In Section 2 we describe the linguistic background of the Tunisian dialect, we try to show the complexity of diacritization tasks based on examples and we present the main level of diacritization. Section 3 introduces our proposed model and experiments. Section 4 provides an exhaustive experimental evaluation that illustrates the efficiency and accuracy of our proposed method. Section 5 summarizes the key findings of the present work and highlights the major directions for future research.

2 Linguistic background

2.1 Tunisian dialect

The language situation in Tunisia is "polyglossic", where distinct language varieties, such as the normative language (MSA) and the usual language (the Tunisian dialect) coexist (24).

As an official language, MSA is extensively present in multiple contexts, namely education, business, arts and literature, and social and legal written documents. However, the Tunisian dialect is the current mother tongue and the spoken language of all Tunisians from different origins and distinct social belongings. For this purpose, this dialect occupies a prominent linguistic importance in Tunisia.

Another salient feature of the Tunisian dialect is that it is strongly influenced by other foreign languages. In fact, it is the outcome of the interaction between Berber, Arabic and many other languages such as French, Italian, Turkish and Spanish. The manifestation of this interaction between these languages is obvious in introducing borrowed words. As a result, the lexical register of the Tunisian dialect seems to be more open and contains a very rich vocabulary.

The Tunisian dialect has other specific aspects. Indeed, since this dialects spoken rather than written or taught at school, there is neither grammatical, nor any orthographical or syntactic rules to be followed.

2.2 Challenges in the absence of diacritization in Tunisian dialect

The absence of diacritics signs in the Tunisian dialect texts often increases the morphological, syntactic and semantic ambiguity in the Tunisian dialect. Some of them are presented as follows:

- **Morphological ambiguity:** The absence of the diacritical marks poses an important problem at the association of grammatical information of the undiacritized word (24). For example, the word لعب /lEb/ admits several possible words that correspond to different solutions at the grammatical labeling level. We can find the plural noun "toys" and the verb "play" in 3rd person masculine, singular of passive accomplishment.

- **Syntactic ambiguity:** It should be noted that the ambiguities in the association of grammatical information, related to the undiacritic words, pose difficulties in terms of syntactic analysis (24). For example, the undiacritic expression كتب الولَيِّد عَالبيرو can admit two different diacritization forms that are syntactically accepted.
  - We find the diacritization form كتِب الولَيِّد عَالبيرو [The boy wrote on the desk] whose syntactic structure corresponds to a verbal sentence.
  - In addition, we find the diacritization form whose syntactic structure corresponds to a nominal sentence كتُب الولَيِّد عَالبيرو[The boy's books are on the desk].

- **Semantic ambiguity:**Tthe different diacritization of a word can have different meanings, even if they belong to the same grammatical category. For example, among the possible dicaritization of the word قريت /qryt/ we find the following dicaritization:
  - قرِيت /qryt/ [I read]
  - قَرِيت /qaryt/ [I taught].

  These two diacritic words have the same grammatical category: verb but they have two different meanings.

2.3 Diacritization level

The use of diacritic symbols in several instances is quite crucial in order to disambiguate homographic words. Indeed, the level of diacritization refers to the number of diacritical marks presented on a word to avoid text ambiguity for human readers. There are four levels of possible diacritization.

- **Full Diacritization:** this is the case where each consonant is followed by a diacritic. This type of diacritization is used mainly in classical Arabic, especially in religion-related books and educational writings.

- **Half Diacritization:** the objective of this category is to add diacritics of a word except the letters that depend on the syntactic analysis of the word. Often, it is the before last letter that depends on syntactic analysis of a word but it is not always the case due to the use of suffixes.

- **Partial Diacritization:** is the case of adding only lexical vowels. The latter can be defined as the vowels with which the meaning of words changes. The goal of marking these vowels is to remove ambiguity from the meaning of words.

- **No Diacritization:** This level is completely underspecified. The script is subject to ambiguity, especially with homographs (4).

3 Methodology and experiment step

In recent years, RNN has received a lot of interest in many NLP tasks of sequence transcription problems, such as speech recognition, handwriting recognition and diacritics restoration. So, we select the RNN to evaluate its performance on the diacritization of the Tunisian dialect. In this work, we adopted the full diacritization level, at which all diacritics should be specified in a word.

3.1 Recurrent neural networks

RNN can be mapped from a sequence of input observations to a sequence of output labels. The mapping is defined by activation weights and a non-linear activation function as in a standard MLP. However, recurrent connections allow to access past activations. For an input sequence x_1^T, RNN computes the hidden sequence h_1^T and the output sequence y_1^T by performing the following operations for $t = 1$ to T (13):

$$h_t = H(W_{xh}x_t + W_{hh}h_{t-1} + b_h) \tag{1}$$

$$y_t = W_{hy}h_t + b_y \tag{2}$$

where H is the hidden layer activation function, W_{xh} is the weight matrix between input and the hidden layer, W_{hh} is the recurrent weight matrix between the hidden layer and itself, Why is the weight matrix between the hidden and output layers, b_h and b_y are the bias vectors of the hidden and output layers, respectively. In a standard RNN, H is usually an element-wise application of sigmoid function. Such a network is usually trained using the back-propagation through time (BPTT) training (27).

- **Long short-term memory: LSTM**

An alternative RNN called Long Short-Term Memory (LSTM) is introduced where the conventional neuron is replaced with a so-called memory cell controlled by input, output and forget gates in order to overcome the vanishing gradient problem of traditional RNNs (12). In this case, H can be described by the following composite function (13):

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + W_{ci}c_{t-1} + b_i) \tag{3}$$

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + W_{cf}c_{t-1} + b_f) \tag{4}$$

$$c_t = f_t c_{t-1} + i_t\ tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_c) \tag{5}$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + W_{co}c_t + b_o) \tag{6}$$

$$h_t = o_t\ tanh(c_t) \tag{7}$$

where the σ is the sigmoid function. *i*, *f*, *o* and *c* correspond to, the input, forget, output gates and cell activation vectors respectively.

- **Bidirectional Long short-term memory: B-LSTM**

A BLSTM processes the input sequence in both directions with two sub-layers in order to account for the full input context. These two sub-layers compute forward and backward hidden sequences $\overrightarrow{h}$, $\overleftarrow{h}$ respectively, which are then combined to compute the output sequence y as follows (13):

$$\overrightarrow{h}_t = H(W_{x\overrightarrow{h}} x_t + W_{\overrightarrow{h}\overrightarrow{h}} \overrightarrow{h}_{t-1} + b_{\overrightarrow{h}}) \quad (8)$$

$$\overleftarrow{h}_t = H(W_{x\overleftarrow{h}} x_t + W_{\overleftarrow{h}\overleftarrow{h}} \overleftarrow{h}_{t-1} + b_{\overleftarrow{h}}) \quad (9)$$

$$y_t = W_{\overrightarrow{h}y} \overrightarrow{h}_t + W_{\overleftarrow{h}y} \overleftarrow{h}_t + b_y \quad (10)$$

3.2 Model architecture

In our diacritization task, the basic idea is to attribute a corresponding diacritical label to each character. Hence, we apply RNN to model our sequence data, where a sequence of characters constitutes the input and the probability distribution over diacritics forms the output. Schematically, our RNN structure is employed in this work as the following figure:

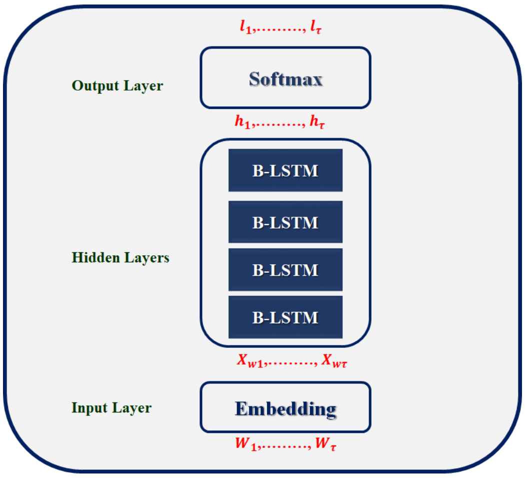

Figure 1: Architecture of our neural network

This can be statistically expressed in this way: Given that $W = (w_1...w_T)$, w indicates a sequence of characters, where each character is related to a label l_t. In this respect, a label may stand for 0, 1 or more diacritics. Furthermore, a real-valued vector x_w is a representation of each character w in the alphabet.

We can state that our neural network consists of 3 layers, namely an input layer, a hidden layer and an output layer. Each layer fulfils a particular purpose. In what follows, we will explain the advantages of each layer.

- **Input layer:** This level consists in mapping the letter sequence w to a vector sequence x. We have checked and prepared data of our corpus. In combining the gemination mark with another diacritic, each character in the corpus has a label corresponding to 0,1 or 2 diacritics. Character embedding input, which is initialized randomly and updated during training, means that each character in the input sentence is represented by a vector of *d* real numbers. It is worth pointing out that adding a linear projection after the input layer affects the learning of a new representation for the latter embedding.

- **Hidden layer:** This layer consists in mapping the vector sequence x to a hidden sequence h. Several types of hidden layers have been used to choose the best performance and the best result in the automatic diacritization of the Tunisian dialect. Hence, these experiments were based on LSTM different layers ranging from one layer to multiple B-LSTM layers.

- **Output layer:** This last layer focuses on mapping each hidden vector h_t to a probability distribution over labels l. In this layer, we use a softmax activation function to produce a probability distribution over output alphabet at each time step.

$$P(l|w_t) = \frac{exp(y_t[l])}{\sum_{l'} exp(y_t[l'])} \quad (11)$$

where $y_t = W_{hy}h_t + b_y$ and $y_t[l]$ is the l^{th} element of y_t.

3.3 Experience

As mentioned above, in order to train the RNN to achieve high accuracy, we apply our experiment based on several training options. These options include the choice of the number of layers in the hidden layer. The aim of this experiment is to determine which options will give optimal accuracy. Indeed, we applied these experiences, in which several types of hidden layers were tested. These layers are ranging from one LSTM layer to multiple B-LSTM layers.

The network is trained using Gradient Descent optimizer with learning rate 0.0003 and a mini-batch size of 200. For dropout, a rate of 0.2 is used both on embedded inputs and after each type of hidden layers; either LSTM or B-LSTM. Weights are randomly-initialized with normal distribution of zero mean and 0.1 standard deviation and weight updates after every batch. The loss function is the cross-entropy loss summed over all outputs. The GPU used is Nvidia GTX 580 that has 16 streaming multiprocessors and 1.5 GB of memory

4 Results and discussion

4.1 Evaluation Metric

In order to measure our model performance, an evaluation metric, known as Diacritic Error Rate (DER) is generally used. DER indicates how many letters have been incorrectly restored with their diacritics. The DER can be calculated as follows (24):

$$DER = \frac{(1 - |TS|)}{|TG|} * 100 \qquad (12)$$

Where $|TS|$ is the number of letters assigned correctly by the system, and $|TG|$ is the number of diacritized letters in gold standard texts.

4.2 Datasets

This section shows a breakdown of different sizes of our data sets, which were gathered from various sources. So far, we have used four existent types of corpora for our teamwork.

- We made use of our TARIC corpus (Tunisian Arabic Railway Interaction Corpus) (24). The latter collected information about the Tunisian dialect used in a railway station. This corpus was recorded in the ticket offices of the Tunis railway station. We recorded conversations in which there was a request for information about the train schedules, fares, bookings, etc. This corpus consists of several dialogues; each dialogue is a complete interaction between a clerk and a client. All the words are written using the Arabic alphabet with diacritics. The diacritics indicate how the word is pronounced. The same word can have more than one pronunciation.

- The second corpus is called STAC (Spoken Tunisian Arabic Corpus)(35). This corpus is a representation of spontaneous discourses in Tunisian dialect. This dialect corpus of transcribed discourses deals with multiple themes, such as social affairs, health, religion, etc.

- We utilized another type of corpus that is the result of a conversion tool from Latin written texts (also called Arabizi) into Arabic scripts following the CODA conversion. The Arabizi corpus is collected from social media like Facebook, Twitter and SMS messaging (22).

- In order to solve the problem of the lack of resources for the Tunisian dialect, we have chosen to gather corpora from blog sites written in this dialect using Arabic alphabets (24). (For more details see (24))

As mentioned above, the Tunisian dialect differs from MSA and it does not have a standard spelling because there are no academies of Arabic dialect. Thus, to obtain coherent learning data, it is necessary to utilize a standard spelling. Indeed, there are words with many forms. For example, the word رزرفسيون /reservation/ can be written in four different ways: رَازرفسيون, رَازَارفسيون and ريزرفسيون.

In this work, spelling transcription guidelines CODA (Tunisian Dialect writing convention), (36), were adopted. CODA is a conventionalized orthography for Dialectal Arabic. In CODA, every word has a single orthographic representation. It uses MSA-consistent and MSA-inspired orthographic decisions (rules, exceptions and ad hoc choices). CODA preserves, also, dialectal morphology and dialectal syntax. CODA is easily learnable and readable. CODA has been designed for the Egyptian Dialect (11) as well as the Tunisian Dialect (36) and the Palestinian Levantine Dialect (20). For a full presentation of CODA and an explanation of its choices, see ((11), (36)).

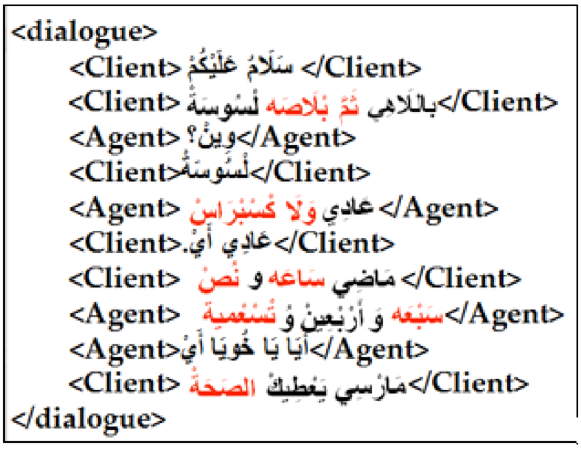
The normalization step is essential because it presents a key point for the other steps of our method. Among the normalisation Tunisian Dialect words we have:

- Number ”sixteen” is written as ستطَاش.

- To define the future, we must follow the following form: بَاش + verb, for example: بَاش نمشي.
- To define the negation, we must follow the following form: مَا + verb.

Let's remember that the Tunisian Dialect is characterized by the presence of foreign words, such as for instance: French, English, Spanish, Italian, etc. To transcribe these words, Arabic alphabets have been used. These foreign words have a unique form, for example: رتور [Back], ترَان [train]...

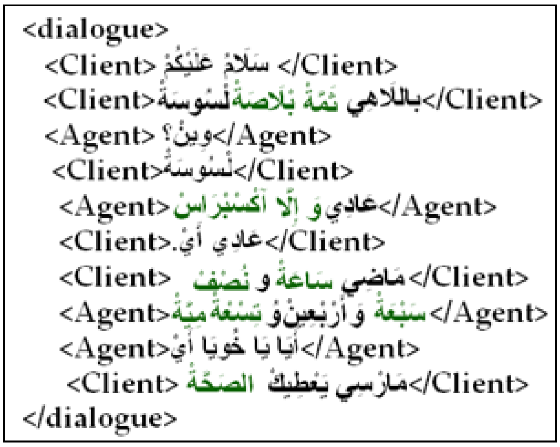
At the end of this step, we obtain a standardized corpus. The figure 2 represents a corpus extract before the normalization step.



```
<dialogue>
    <Client> سَلَامْ عَلَيْكُمْ </Client>
    <Client> بِاللَّاهِي ثَمّ بْلَاصَه لْسُوسَةْ</Client>
    <Agent> وِينْ؟</Agent>
    <Client>لْسُوسَةْ</Client>
    <Agent> عَادِي وَلَا كُسْنْبْرَاسْ </Agent>
    <Client>عَادِي أَيْ.</Client>
    <Client> مَاضِي سَاعَه و نُصّ </Client>
    <Agent> سَبْعَه وَ أَرْبْعِينْ وُ تُسْعْمِية</Agent>
    <Agent>أَيَا يَا خُويَا أَيْ</Agent>
    <Client> مَارْسِي يْعَطِيكْ الصَّحَّة</Client>
</dialogue>
```

Figure 2: Corpus extract before the normalisation step

The figure 3 represents a corpus extract after the normalization step.



```
<dialogue>
  <Client> سَلَامْ عَلَيْكُمْ </Client>
  <Client>بِاللَّاهِي ثَمَّةْ بْلَاصَةْ لْسُوسَةْ</Client>
  <Agent> وِينْ؟</Agent>
   <Client>لْسُوسَةْ</Client>
    <Agent>عَادِي وَ إِلَّا آكْسْنْبْرَاسْ</Agent>
    <Client>عَادِي أَيْ.</Client>
    <Client>  مَاضِي سَاعَةْ و نُصْفْ</Client>
    <Agent>سَبْعَةْ وَ أَرْبْعِينْ وْ تِسْعَةْ مِيَّةْ</Agent>
    <Agent>أَيَا يَا خُويَا أَيْ</Agent>
     <Client> مَارْسِي يْعَطِيكْ الصَّحَّةْ</Client>
</dialogue>
```

Figure 3: Corpus extract after the normalisation step

Since there are no automatic diacritization tools for the Tunisian dialect, and because the MSA tools are unable to treat this dialect due to the differences between the MSA and the Tunisian dialect, we were obliged to diacritize the corpus manually.

Below we provide the most important characteristics in Table 1.

Table 1: Characteristics of our corpus.

	# **statements**	#**words**
TARIC	21,102	71,684
STAC	4,862	42,388
Arabizi	3,461	31,250
Blogs	1582	27,544
Total	31,007	172,866

We aimed to decently create training, development and test sets in order to judge our diacritization models. We outlined the available datasets for the language under investigation. We randomly selected 23,255 sentences for training, 1,550 for development and 6,202 for testing.

Table 2 reports some quantitative information for the datasets.

Table 2: Tunisian dialect diacritization corpus statistics.

	Train	Dev	Test
# Statements	23,255	1,550	6,202
# words	129,649	8,643	34,574
# Letters	64,8247	43,216	172,867

4.3 Result

In this section, we present the evaluation outcome of our established diacritization models. We use DER as an evaluation metric. The adopted RNN has from 1 to 4 hidden layers, each with 250 neurons. This number is chosen after different experiments. We come up with the conclusion that a smaller number of neurons (less than 250) have an impact on accuracy rate and a greater number do not improve it in a significant way. Table 3 gives an overview of the RNN models outcomes in terms of diacritic error rate (DER).

Table 3: Diacritization Error Rate Summary for the Tunisian dialect RNN model

Model	DER
LSTM	13.86%
B-LSTM	12.31%
2-layer B-LSTM	11.53%
3-layer B-LSTM	10.72%
4-layer B-LSTM	10.83%

Table 3 shows the effect of using LSTM and B-LSTM models, and the number of hidden layers on the DER. According to this table, results show a DER of 13.56% for LSTM and 12.31% for B-LSTM. Based on the results of our RNN, we detected an enhancement of 1.55% in DER of the B-LSTM model as compared to LSTM model. This means that B-LSTM is more performant than LSTM.

Moreover, we noticed that increasing the number of B-LSTM layers from one hidden layer to three layers improves accuracy. But, we applied the 3-layer BLSTM because its accuracy is not only closer but also fasther than the 4-layer BLSTM. Indeed, the training time rises from 3:52 to 6:78 hours when the number of layers progresses monotonically from 3 to 4 and the testing time icreases from 3.65 to 5.41 minutes. Hence, the 3-layer B-LSTM configuration was adopted.

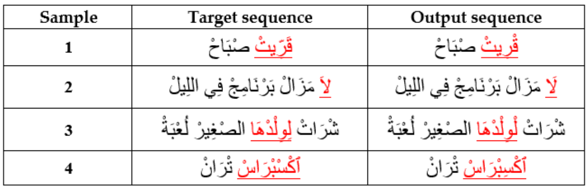
To conclude, a 3-layer BLSTM models achieved the best results.

4.4 Error Analysis

In order to reveal the weaknesses of our automatic diacritic restoration RNN models, we analyzed all errors that are mainly due to the following reasons:

- We noticed that these errors are due to the presence of foreign words in our corpus.
- Some error words with prefixes, or suffixes or both can be significantly perceived. It is hard to diacritize these complex words in a correct way, as the in flection diacritical mark is related to the last letter of the stem rather than to the last letter of the suffix.
- Errors due to form/spelling diacritization errors. Errors caused by ”Shadda” (consonant doubling), or Tanween (nunation). We perceived that restoring ”shadda” is harder than restoring the other diacritics.
- Errors due to missing and incorrect short vowels (i.e. lexical diacritics).

We have manually checked 150 error samples of our input RNN model. The following figure shows an example of 4 sample sequences that have errors. The words that have errors are underlined and in red.



Sample	Target sequence	Output sequence
1	قَرّيتْ صْبَاحْ	قْرِيتْ صْبَاحْ
2	لاْ مْزَالْ بَرْنَامِجْ فِي اللِيلْ	لَا مْزَالْ بَرْنَامِجْ فِي اللِيلْ
3	شْرَاتْ لِولْدْهَا الصْغِيرْ لُعْبَة	شْرَاتْ لْولْدْهَا الصْغِيرْ لُعْبَة
4	آكْسْبْرَاسْ تْرَانْ	آكْسِبْرَاسْ تْرَانْ

Figure 4: Sample sequences with errors

In about 21% of the samples, we have remarked that the absence of ”shadda” in some words can lead to a semantic ambiguity of the verb. For instance, sample 1 shows that target verb قَرِّيت [I taught] is output as قْرِيت [I read]. These two diacritic words have the same grammatical category: verb but they have two different meanings.

Diacritization errors in test samples can cause about 4% of errors. For example, sample 2 displays that the "Fatha" in the word لاَ was mistakenly entered after the last letter rather than the first letter.

Some error words with prefixes, suffixes or both can be significantly perceived, in about 41% of the samples. In another illustration, the error word in sample 3 has both the prefix "la" لِ and the pronoun suffix "haA" هَا.

We also noticed a significant fraction of error words (34%) due to the presence of foreign words in our corpus as in sample 4..

4.5 Comparison with State-of-art Systems

In this section, we compare our proposed RNN model with two other models, namely SMT and a discriminative model as a sequence classification task based on CRFs (24). These two models were realized in our previous works in order to carry on the dialect restoration for the Tunisian dialect. To achieve this comparison, we employed the same dialectical corpus and evaluation metrics.

Concerning the first model, we regarded the diacritization problem as a simplified phrase-based SMT task. The source language is the undiacritic text while the target language is the diacritic text. The basic idea of SMT is to analyze automatically existing human sentences called parallel corpus in order to build translation model. The alignment from words without diacritics to words with diacritics is a monotonic mapping. To do this, we employed moses (21) a SMT tool.Word alignment was done with GIZA++ (25). We implemented a 5-gram language model using the SRILM toolkit (31). We decoded using Moses (21).

In the second model, we decided to get the diacritical marks restoration by focusing on diacritization based on grammatical information. We intended to build dependency relations between words and "POS" tags and to perceive their effects on word diacritizations. In fact, we proposed to scrutinize the integration of grammatical information "POS" for the diacritization with the aid of Conditional Random Fields (CRF)(24).

The following table reviews the accuracy results to restore diacritics automatically from our previous published researches in the Tunisian dialect field.

Table 4: Diacritization results of related work (CRF and SMT models) and our RNN model

Model	**DER**
3-layer B-LSTM	10.72%
CRF	20.25%
SMT	33.15%

As depicted in Table 4, our RNN model (3-layer B-LSTM) provides the best results(DER of 10.72%) compared to both SMT (DER of 33.15%) and CRF (DER of 20.25%) models.

5 Conclusion

The absence of short vowels gives rise to a great ambiguity which influences the results of such NLP applications. An outcome of this study was the development of RNN diacritic restoration model for Tunisian dialect. To the best of our knowledge, this is the first work that deals with the problem of Tunisian dialect diacritizers using RNN.

In order to choose the best configuration of the RNN network, we did several preliminary experiments with different training options. These options concern the hidden layer where we tested the impact of the change of the neural network size and the topology on its performance. Several types of hidden layers are tested, ranging from one layer LSTM to multiple B-LSTM layers. The best accuracy is obtained when using the 3-layer B-LSTM model (DER of 10.72%). We compared our RNN diacritization model with two major models, namely a SMT and CRF models (24). These two models were realized in our previous works in order to carry on the dialect restoration for the Tunisian dialect. During this comparison, we employed the same dialectical corpus and evaluation metrics. About 9.53% DER improvement of RNN model was achieved over the best reported CRF model.

We have two future plans for the diacritization problems of Tunisian dialect. The first plan consists in expanding a rule-based diacritizer system and integrating it into our RNN model in order to ameliorate the outcomes. The second plan focuses on providing morphological analysis of such words to the RNN in order to achieve higher accuracy. The presence of significant fraction of errors in complex words that contain prefixes, suffixes, or both open up new perspectives for future research.

Abstract

One of the main characteristics of social media data is the use of non-standard language. Since NLP tools have been trained on traditional text material, their performance drops when applied to social media data. One way to overcome this is to first perform text normalization. In this work, we apply text normalization to noisy English and Dutch text coming from different genres: text messages, message board posts and tweets. We consider the normalization task as a Machine Translation problem and test the two leading paradigms: statistical and neural machine translation. For SMT we explore the added value of varying background corpora for training the language model. For NMT we have a look at data augmentation since the parallel datasets we are working with are limited in size. Our results reveal that when relying on SMT to perform the normalization, it is beneficial to use a background corpus that is close to the genre to be normalized. Regarding NMT, we find that the translations - or normalizations - coming out of this model are far from perfect and that for a low-resource language like Dutch adding additional training data works better than artificially augmenting the data.

1 Introduction

Probably one of the most persistent characteristics of social media texts is that they are full of non-standard words (Eisenstein, 2013). Several sources of noise can influence the way people write. For example, the different kind of social media platforms available nowadays provide a diverse range of ways to communicate and particular forms of language variations (Ke et al., 2008). Social variables such as gender, age and race can also influence communication style (Schwartz et al., 2013; Blodgett et al., 2016). Location is also an important variable, since it can lead to the use of dialect and non-standard words. (Vandekerckhove and Nobels, 2010; Blodgett et al., 2016).

Very typical for this User-Generated Content (UGC) is the expression of emotions by the use of symbols or lexical variations of the words (Van Hee et al., 2017). This can be done in the form of flooding or the repetition of characters, capitalization, and the productive use of emoticons. In addition, the use of homophonous graphemic variants of a word, abbreviations, spelling mistakes or letter transpositions are very typical, since people tend to write as they speak and/or write as fast as possible.

One can imagine that all those characteristics contribute to an increased difficulty of automatically processing and analyzing UGC. Since Natural Language Processing (NLP) tools have originally been developed for and trained on standard language, these non-standard forms adversely affect language analysis using these tools. One of the computational approaches which has been suggested to tackle this problem is text normalization (Sproat et al., 2001). This approach envisages transforming the lexical variants to their canonical forms. In this way, standard NLP tools can be applied in a next step, after normalization. Kobus et al. (2008) introduced three metaphors to refer to these normalization approaches: the spell checking, automatic speech recognition and machine translation metaphors. In section 2 these approaches are discussed in more depth.

In this work, we follow the third metaphor and tackle text normalization as a Machine Translation (MT) task. We test the two leading paradigms,

Proceedings of Recent Advances in Natural Language Processing, pages 740–749,
Varna, Bulgaria, Sep 2–4 2019.

statistical machine translation (SMT) and neural machine translation (NMT), on English and Dutch parallel corpora with data coming from three genres (text messages, message board posts and tweets). For SMT we explore the added value of varying background corpora for training the language model. For NMT we have a look at data augmentation since the parallel datasets we are working with are limited in size. Our results reveal that when relying on SMT to perform the normalization it is beneficial to use a background corpus that is close to the genre to be normalized. Regarding NMT, we find that the translations - or normalizations - coming out of this model are far from perfect and that for a low-resource language, like Dutch, adding additional training data works better than artificially augmenting the data.

In the following section, we discuss related work on text normalization. In section 3, we give more information about our parallel data and describe the methodology we used to perform the SMT and NMT experiments. Section 4 gives an overview of the results, whereas section 5 concludes this work and offers some prospects for future work.

2 Related Works

Previous research on UGC text normalization has been performed on diverse languages using different techniques ranging from hand-crafted rules (Chua et al., 2018) to deep learning approaches (Ikeda et al., 2016; Sproat and Jaitly, 2016; Lusetti et al., 2018). Kobus et al. (2008) introduced three metaphors to refer to these normalization approaches: the spell checking, automatic speech recognition and translation metaphors.

In the **spell checking metaphor**, corrections from noisy to standard words occur at the word level. As in conventional spelling correction one has to deal with both non-word and real-word errors (Clark and Araki, 2011). The disadvantage of this approach is that all non-standard words (NSWs) have to be represented in the dictionary in order to obtain the corresponding normalization. Therefore, the success of this kind of systems highly depends on the dictionary coverage. However, as UGC is a very generative language and new variants of canonical words and phrases appear constantly, it is very difficult and expensive to maintain a high coverage lexicon. Other works have approached the problem using a noisy channel model. In this model, the goal is to find the intended word w given a word x where the letters have been changed in some way. Correct words in the text remain untouched. This model is probably the most popular and successful approach to spelling correction (Dutta et al., 2015; Goot, 2015). Although spelling correction is mostly performed on languages which are morphologically simple and with a fairly strict word order, like English, there has been some progress for normalization applied to other languages as well, such as Russian (Sorokin, 2017) and French (Beaufort and Roekhaut, 2010).

Text found in social media shares features with spoken language and the **automatic speech recognition metaphor** exploits this similarity. This approach starts by converting the input message into a phone lattice, which is converted to a word lattice using a phoneme-grapheme dictionary. Finally, the word lattice is decoded by applying a language model to it and using a best-path algorithm to recover the most likely original word sequence. This metaphor has mainly been merged with the machine translation (infra) and spell checking (supra) metaphors to improve the quality of the normalization. Kobus et al. (2008), for example, incorporated ideas from speech recognition to text message normalization and combined it with a machine translation system. Beaufort and Roekhaut (2010); Xue et al. (2011) and Han and Baldwin (2011) also combined the automatic speech recognition approach with spell checking and machine translation techniques.

The **machine translation metaphor** treats social media text as the source language and its normalized form as the target language. Several works have tackled the problem of text normalization using this approach. Statistical Machine Translation (SMT) models, especially those trained at the character-level, have proven highly effective for the task because they capture well intra-word transformations. One of the first works following this approach was presented by Aw et al. (2006). They adapted phrase-based SMT to the task of normalizing English SMS producing messages that collated well with manually normalized ones. Besides, they studied the impact of the normalization on the task of SMS translation, showing that SMS normalization, as a preprocessing step of MT, can boost the translation performance. Kaufmann (2010) used a two-step approach for

Source sentence	Target sentence	Translation
iz da muzieksgool vnavnd ? kwt da niemr .	is dat muziekschool vanavond ? ik weet dat niet meer .	is that music school tonight? I don't know that anymore.
wa is je msn k en e nieuwe msn omda k er nie meer op graal . xxx	wat is je msn ik heb een nieuwe msn omdat ik er niet meer op geraak . xx	what is your msn i have a new msn because i can't get it anymore. xx
@renskedemaessc dm me je gsmnummer eens ;-)	<user> doormail me je gsm-nummer eens <emoji>	<user> mail me your cellphone number once <emoji>

Table 1: Source and target pairs as parallel data for a machine translation approach.

the normalization of English tweets: he first preprocessed the tweets to remove as much noise as possible and then used a machine translation approach to convert them into standard English. MT approaches when used at the character level, also have the advantage of being effective when small training data is provided, thanks to their small vocabulary size. De Clercq et al. (2013) proposed a phrase-based method to normalize Dutch UGC comprising various genres. They performed experiments at several levels of granularity: character and word level. In a preprocessing step they handled emoticons, hyperlinks, hashtags and so forth. Then they worked in two steps: first at the word level and then at the character level. This approach revealed good results across various genres of UGC; however a high number of phonetic alternations still remained unresolved. Schulz et al. (2016) made a modification to the previous work by combining the three metaphors (machine translation, spell checking and speech recognition) in a multi-modular system and by using a novel approach for decoding. This led to an improvement in the selection of the best normalization option. Furthermore, they showed a performance improvement of state-of-the-art NLP tools on UGC data when normalization is used as a previous step.

Recently, neural networks have proven to outperform many state-of-the-art systems in several NLP tasks (Young et al., 2018). The encoder-decoder model for recurrent neural networks (RNN) was developed in order to address the sequence-to-sequence nature of machine translation and it obtains good results for this task (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014; Luong et al., 2015). The model consists of two neural networks: an encoder and a decoder. The encoder extracts a fixed-length representation from a variable-length input sentence, and the decoder generates a correct translation from this representation. Some works on text normalization have followed the same approach. Ikeda et al. (2016) performed text normalization at the character level for Japanese text and proposed a method for data augmentation using hand-crafted rules. They proved that the use of the synthesised corpus improved the performance of Japanese text normalization. Mandal and Nanmaran (2018) presented an architecture for automatic normalization of phonetically transliterated words to their standard forms in a code-mixed scenario improving the accuracy of a pre-existing sentiment analysis system by 1.5%. Lusetti et al. (2018) performed text normalization over Swiss German WhatsApp messages and compared it to a state-of-the-art SMT system. They showed that integrating language models into an encoder-decoder framework can reach and even improve the performance of character-level SMT methods for that language.

In this work, we also consider the normalization task as a MT problem and test both statistical and neural machine translation. For SMT, we explore the added value of varying background corpora for training the language model. For NMT, we investigate whether we can overcome the limited data set size by using data augmentation.

3 Methodology

Our objective is to go from noisy to standard text and we tackle this normalization problem using a Machine Translation (MT) approach. As in general MT, a translation model is trained on parallel data consisting of pairs (x, y) of source sentences/words (= noisy text) and their corresponding target equivalents (= standard). Table 1 lists some examples of the noisy data we are dealing with.

3.1 Parallel Corpora

We relied on existing Dutch (Schulz et al., 2016) and English (De Clercq et al., 2014) corpora that were manually normalized[1] (Table 2). Three genres were included for both languages:

Tweets (TWE) which were randomly selected for both languages from the social network.

Message board posts (SNS) which were in both languages sampled from the social network Netlog, which was a Belgian social networking website targeted at youngsters.

Text messages (SMS) which were sampled from the Flemish part of the SoNaR corpus (Treurniet et al., 2012) for the Dutch language and from the NUS SMS corpus (Chen and Kan, 2013) for English.

Genre	# Sent.	# Words		%
English		Ori	Tgt	
TWE	810	13477	13545	0.50
SNS	2592	26881	27713	3.00
SMS	1435	20663	22946	**3.94**
Dutch				
TWE	842	13013	13024	0.08
SNS	770	11670	11913	2.04
SMS	801	13063	13610	**4.19**

Table 2: Parallel corpora data statistics in both languages.

Table 2 shows the number of parallel sentences in each corpus and the number of words before and after normalization. Regarding the level of noise, we observe that the text messages required most normalization operations in both languages (an increase of 3.94% for English and one of 4.19% for Dutch). We also notice that the Dutch tweets required hardly any normalization (0.08%). This can be explained by the fact that this platform has been mainly adopted by professionals in Belgium who write in a more formal style (Schulz et al., 2016).

3.2 SMT Approach

The core idea behind SMT relies on the noisy channel model. In this task, two basic components are integrated:

$$\underset{y \in W}{\operatorname{argmax}}\ P(y|x) = \underset{y \in W}{\operatorname{argmax}}\ P(x|y)P(y)$$

The translation model $P(y|x)$ is responsible for the correctness of the translation from the source $x = x_1, x_2, ..., x_m$ to the target sentence $y = y_1, y_2, ..., y_n$. The language model $P(y)$ is responsible for the fluency of the sentence in the target language. W is the set of all target sentences.

To achieve better context-sensitive source-target mappings, traditional SMT systems rely on phrase-level translation models. These models allow to build a phrase table to store aligned phrase pairs in the source and target language. This is a difficult task since one word in one language may correspond to several words in the other language. However when translating from noisy to standard text we can assume that most of the words have a one-to-one mapping. Figure 1 illustrates the architecture of an SMT system.

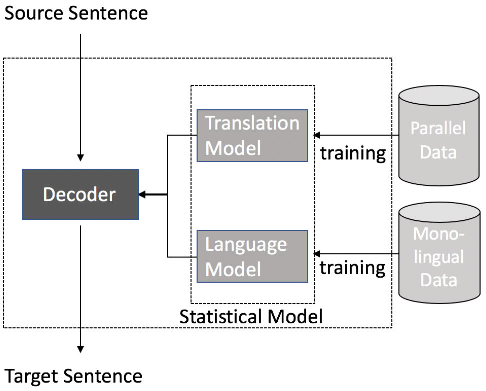

Figure 1: SMT architecture.

For social media translation we suspect that depending on the level of noise of the parallel data, the use of different monolingual corpora for training the language model should lead to better results. Due to the unavailability of a monolingual social media text corpus, we needed to find a resource that somewhat resembles this specific domain. We chose to work with existing corpora comprising two flavors of transcribed speech, namely subtitles and transcriptions of parliamentary debates, because we believe that these can better represent, to some extent, the user-generated content that we can find in social media texts. Table 3 represents the different corpora we used for our experiments. For the English experiments we relied on three different background corpora for constructing our language models: the OpenSubtitles corpus (OPUS) (Tiedemann, 2012b) which is a collection of documents from http://www.opensubtitles.org/; the Europarl corpus (Koehn et al., 2006), extracted from the proceedings of the European Parliament; and the combination of both. A similar approach was

[1] All data was normalized following the procedure described in Schulz et al. (2016)

taken for Dutch, for which we used an in-house subtitles dataset, Europarl, and the combination of both.

Corpus	Sentences
English	
OPUS	22,512,649
Europarl	2,005,395
Combined	OPUS+Europarl
Dutch	
Subtitles	8,056,693
Europarl	2,000,113
Combined	OPUS+Europarl

Table 3: Size (expressed in sentences) of the monolingual corpora used for training our LMs.

3.3 NMT Approach

Neural Machine Translation incorporates the advantages of newly developed deep learning approaches into the task. Sequence-to-Sequence (seq2seq) models have been used for a variety of NLP tasks including machine translation obtaining state-of-the-art results (Luong et al., 2015; Young et al., 2018). In this approach both input and output sentences are going in and out of the model. As described in the literature overview, the model consists of two neural networks: an encoder and decoder (See Figure 2). The encoder extracts a fixed-length representation from a variable-length input sentence (*A B C D*), and the decoder generates a correct translation from this representation (*X Y Z*). In the figure <eos> marks the end of a sentence. The encoder-decoder model is trained on a parallel corpus consisting of aligned source sentences and their normalized forms (see Table 1).

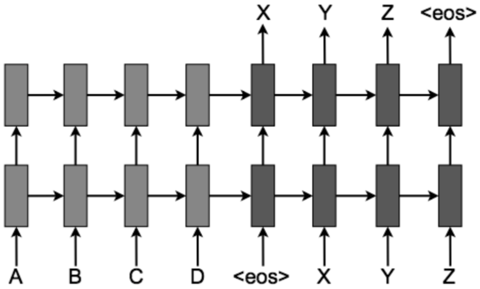

Figure 2: Encoder-decoder architecture. The light-color nodes represent the encoder and the dark-color ones the decoder. Image taken from Luong et al. (2015).

Neural systems, however, require huge amounts of data in order to perform properly. The training data we have available for text normalization amounts to only a few hundred sentences, as can be derived from Table 2. Moreover, manually annotating more training is highly time-consuming. Under these conditions, we decided to experimentally verify whether it is more beneficial to use a data augmentation technique (step A) which possibly resolves the data scarcity problem (Saito et al., 2017) or to annotate more data (step B). We tested this on the Dutch corpus and one particular genre, namely text messages (SMS). For step A, we augmented the parallel data by duplicating monolingual subtitles data on both the source and target side. For step B, we sampled and manually annotated ten thousand extra tokens from the Flemish part of the SoNaR corpus (Treurniet et al., 2012)[2].

We relied on OpenNMT[3] to train our encoder-decoder model. OpenNMT is an open source (MIT) initiative for neural machine translation and neural sequence modeling (Klein et al., 2017). The main system is implemented in the Lua/Torch mathematical framework, and can easily be extended using Torch's internal standard neural network components. We used the version of the system with the basic architecture which consists of an encoder using a simple LSTM recurrent neural network. The decoder applies attention over the source sequence and implements input feeding (Luong et al., 2015).

3.4 Evaluation

For evaluating the results of the normalization we calculated Word Error Rate (WER), a commonly used machine translation evaluation metric. WER is derived from the Levenshtein distance (Levenshtein, 1966), working at the word level instead of the character level. It takes into account the number of insertions (INS), deletions (DEL) and substitutions (SUBS) that are needed to transform the suggested string into the manually normalized string. The metric is computed as follows:

$$WER = \frac{INS + DEL + SUBS}{N}$$

where N in the number of words in the reference.

Table 4 reports WER computed between the original and target parallel sentence pairs that were

[2] Following the same annotation guidelines as Schulz et al. (2016)

[3] http://opennmt.net

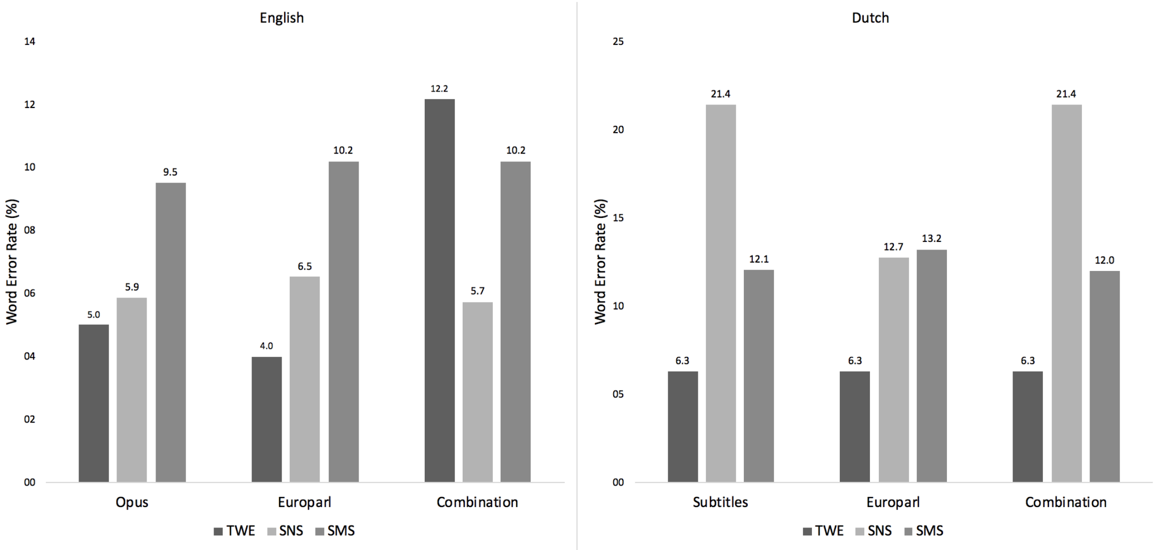

Figure 3: Normalization results at the token level. The left chart presents the results on the English datasets and the right one the results on the Dutch dataset.

used for training our models.

Word Error Rate (%)		
Genre	English	Dutch
TWE	12.160	10.592
SNS	15.400	21.390
SMS	17.190	25.130

Table 4: WER values (in percentage) at the sentence level

WER values were calculated per sentence and averaged within the document. The higher the value, the more operations are needed to obtain the target sentence. Looking at the values, we again notice that genres requiring the most and least normalization are the text messages (SMS) and tweets (TWE), respectively.

4 Experiments

4.1 Varying Background Corpora for SMT

With the first round of experiments we want to research the influence of varying the monolingual data that are used to construct the language models. We trained LMs at the character level using unigrams and bigrams and at the token level. All LMs were built using the SRILM toolkit (Stolcke, 2002) with Witten-Bell discounting which has proven to work well on small data sets (Tiedemann, 2012a; Mahmudul Hasan et al., 2012; De Clercq et al., 2013). To evaluate the performance of each LM, Word Error Rate (WER) was calculated.

The parallel data (Table 2) used for training the translation model were divided using 80% for training the model and 10% for development and testing, respectively. The target sentences from the training set were also added to the monolingual corpus for training the language model.

Despite several works reporting better results when using a character-level approach (De Clercq et al., 2014; Lusetti et al., 2018) our experiments revealed the best performance with SMT at the token level. The bar charts in Figure 3 present the results of SMT at the token level with the different LMs.

Regarding the monolingual background corpora, we notice that Europarl leads to the best results for the tweets (TWE) genre which was actually the genre with the least noise (see Section 3.1). Our experiment shows WERs of 4% and 6.3% for English and Dutch, respectively. This result was to be expected as the word usage in Europarl is mostly standard and therefore close to the word usage in the tweets. The same is true for the genre comprising the most noise, i.e text messages. The word usage in the Subtitles/OPUS dataset is less standard and closer to spoken language and, indeed, also in this case we obtained a WER of 9.5% for English using OPUS, and a WER of 12% for Dutch using a combination of the Subtitles dataset and Europarl.

In addition, we also computed the number of insertions (INS), deletions (DEL) and substitutions

(SUBS) in the original sentence pairs (Ori) and after normalization (Norm) (Table 5).

English						
	INS		DEL		SUBS	
Genre	Ori	Norm	Ori	Norm	Ori	Norm
TWE	91	36	15	**30**	34	22
SNS	354	64	66	43	109	62
SMS	377	63	44	**57**	135	54
Dutch						
TWE	22	19	0	**5**	39	**45**
SNS	386	159	18	**36**	76	47
SMS	0	0	2	**3**	94	85

Table 5: Number of operations required before (Ori) and after (Norm) normalization.

Ideally, the number of operations after normalization should be reduced to zero. As can be derived from the table many operations were strongly reduced; however, many cases still need to be solved. We will have a closer look at some of these cases in the next section.

4.2 Error Analysis of the SMT Results

The number of remaining insertions is mostly linked to the problem of abbreviation expansions. Very common abbreviations like *lol* or *omg* are always corrected, whereas others like *r.e.* and *p.e.* for *religious* and *physical education* or *cum on den* for *come on then* are not corrected since they never appear in the training data.

When we consider the deletions, we can observe that flooding or repetition of characters is often not solved with SMT. For example, tokens like *okkk*, *awwwww* or sentences like *immaaa dooiin fiine !* remained unchanged. A straightforward way to overcome this problem could be to reduce the number of repetitions to two or three in some cases as a pre-normalization step. The second factor that affects the number of deletions is the hypernormalization of some words. This leads to an increase in the number of operations since sometimes we will have to perform more deletion operations on the predicted sentences than on the original ones (these instances are indicated in bold in Table 5). This is for example the case with the name *al* which was incorrectly normalized to *all* or the normalization of *i can 't really think...* into *i can not really not think*. These problems also affect the number of substitutions. In general, we also notice that the normalization of Dutch presents a higher number of errors.

4.3 NMT Approach to UGC Normalization

As we explained before, neural approaches have obtained state-of-the-art results for the task of Machine Translation. Neural approaches however, are well-known to require big amounts of parallel data in order to perform properly. Especially for Dutch, which can be considered a low-resource language, it is difficult to find freely available parallel data and annotating new data is both money and time-consuming.

Under these conditions we decided to experimentally verify whether it is more beneficial to use a data augmentation technique (step A) which possibly resolves the data scarcity problem (Saito et al., 2017) or annotate more data (step B). We tested this on the Dutch corpus and one particular genre, the most noisy one, namely text messages (SMS).

For Step A, our idea was to make use of the monolingual subtitles corpus in both sides of the parallel data in order to augment the number of sentences available for training our model. Doing this, we obtain a bigger dataset consisting of the Dutch SMS parallel corpus and the Dutch Subtitles dataset which is duplicated in the source and target data. That is a total of 8,057,334 parallel sentences for training.

src sent.	wa gaat je doen ? xxx
norm sent.	wat gaat je doen ? xxx
src sent.	oeiiii misterieus <emoji> xxx
norm sent.	oeiiii misterieus <emoji> xxx
src sent.	dne dvd vn is ni goe ze . ge kunt nx zien . mt betale . x
norm sent.	het dvd hem is niet niet het maar wat wat in ik . niet betale . x x x x x

Table 6: Original (src) and predicted (norm) sentences using the NMT approach.

Unfortunately, as can be derived from the table above, results following this approach are very poor. It is common in the output to find repetition of words like in the third sentence (*niet, wat* and *x*). Besides, some sentences that needed normalization like the second sentence in the table, were not normalized at all. For example, the words *wat* and *niet* in the first and last sentence respectively, were correctly normalized. These results may have been determined to a great extent by the unbalance in the parallel sentences. However, we could see a slight improvement compared to the results using only the small parallel data in this architecture. For that case, the system output consisted of sentences of the type <*emoji*> *, de , , , . . .* <*emoji*>. These are random repetitions of the most represented tokens like *ik* (*I* in English), punctuation marks or <*emoji*> labels.

In order to corroborate our other hypothesis, we collected and manually normalized more data for step B. In order to check how this system works at different levels of granularity, we also performed experiments using bigram and unigrams of characters. Regarding the results, also for NMT the results are better at the word level than at the character level, with WERs of 15% instead of 29% and 26% for bigram and unigram, respectively.

4.4 Error Analysis of the NMT Results

Using the new data configuration the system is capable to correctly translate sentences like the first one in Table 7.

src sent.	aahn , ok ma cva dan kzal dan wel wa zoeken xp merci eh x
norm sent.	ah , oké maar ça va dan ik zal dan wel wat zoeken <emoji> merci h x
tgt sent.	ah , oké maar ça va dan ik zal dan wel wat zoeken <emoji> merci h x
src sent.	zal dan eentje **v** mezelf sturen . zorgen we morgenavond dan voor verrassing **v** kareltje ?
norm sent.	zal dan eentje van mag sturen . zorgen we morgenavond dan voor cocktail van droomt ?
tgt sent.	zal dan eentje van mezelf sturen . zorgen we morgenavond dan voor verrassing voor kareltje ?

Table 7: Original (src), predicted (norm) and target (tgt) sentences using the NMT approach trained on the extended dataset.

However, the system still produces a large number of odd normalizations. In the second sentence in Table 7, for example, only the bold words should have been normalized. However, only one of those two words was correctly normalized, the other one was normalized but not into its correct form. On the other hand, the system also produces odd translations of words that already were in their standard form. For example the word *mezelf* is changed to *mag* and we got *cocktail van droomt* instead of the desired normalization, ie. *verrassing voor kareltje*.

In general, while the results using this approach are very poor, the experiments revealed that having a bigger parallel training corpus could improve the performance of this system.

5 Conclusions and Future Work

In this article, we have presented two different approaches to text normalization of social media text: statistical and neural machine translation. We applied text normalization to English and Dutch text from different genres: text messages, message board posts and tweets. Best results were achieved at the token level for all genres and for both SMT and NMT.

For the SMT experiments, regarding the different corpora that were used to construct the LM, we found that Europarl gave the best results for the least noisy genre (tweets). The same is true for the noisiest genre (text messages). Considering our results, it seems to be important to make variations in the background data for building the LM, depending on the amount of noise and vocabulary that is present in the genre. With respect to the remaining errors we believe that following a modular approach instead of only using SMT could lead to a much better performance.

Our NMT approach performs poorly due to the scarcity of the data, although we did find that for a low-resource language like Dutch adding additional training data works better than artificially augmenting the data. The data augmentation technique used, however, was very basic and we believe that other techniques could lead to better results, such as hand-crafted rules for the production of abbreviations or the use of previously trained embedding in order to build similar sentences helping to generalize better.

Exploring those other data augmentation techniques is a first avenue for future work. Besides we also want to test the benefits of the integration of a neural LM in the encoder-decoder model to help with the translation of out-of-vocabulary words.

Abstract

Fake reviews are increasingly prevalent across the Internet. They can be unethical and harmful. They can affect businesses and mislead customers. As opinions on the Web are increasingly relied on, the detection of fake reviews has become more critical. In this study we explore the effectiveness of sentiment and emotions based representations for the task of building machine learning models for fake reviews detection. The experiment performed with three real-world datasets demonstrate that improved data representation can be achieved by combining sentiment and emotion extraction methods, as well as by performing sentiment and emotion analysis on a part-by-part basis by segmenting the reviews.

1 Introduction

The Internet has evolved into a content creation platform where people express their opinions and experiences. Online reviews written by users have significant impact on customers and companies. Potential customers often consult reviews before making a purchase. Reviews help potential customers to gain insights from other people's experiences, particularly in making choices on purchasing products or services. At the same time, companies need reviews on their products or services in order to get feedback and maintain good reputation. However, not all reviews available in the Internet are genuine. Profusion of reviews of questionable quality increase concerns about their trustworthiness. Moreover, users with malintent often post fake reviews (FR) to mislead customers by promoting or demoting products or target stores. Authors of FR can sway customer choices towards companies with which they are associated, or against competitors making fake reviews a lucrative business. There has been an increase in FR profusion lately. According to the report of the Harvard Business School (Luca and Zervas, 2016) the percentage of fake reviews on YELP[1] increased from 5 % in 2006 to 20% in 2013. This makes FR detection an important challenge to be addressed.

FR were firstly categorized by Jindal et al. (2008) into three groups: (1) Untruthful opinions: mislead readers by giving positive reviews to promote or demote target object, (2) Reviews on brands only: the reviewer focus on the brands, producers or sellers of a product or service without commenting on the product or service, (3) Non-reviews: the reviews are irrelevant to the product and do not contain opinions but advertisements or questions. The first category is the most challenging type to detect, and that is the focus of our paper. Given the large numbers of reviews posted daily, automatic methods would be preferred over manual ones as illustrated in (Ott et al., 2011). Recent years have witnessed an increased impetus on machine learning methods for data-driven FR detection (Mukherjee et al., 2013; Ott et al., 2011; Rout et al., 2017)

The performance of machine learning models for detecting FR is heavily influenced by the data representation (or features) in their application (Bengio et al., 2013). Text analytics has conventionally focused on domains such as labelling news stories or grouping disease reports based on severity where the human authors of text documents are largely passive to the usage of downstream analytics. FR mitigation methods, on the other hand, are in direct conflict with the intents of FR peddlers, generating interest-

[1] https://www.yelp.co.uk/

ing gamification dynamics. This makes it important for data-driven FR solutions to rely on more generic or higher-level data representations rather than simple lexical ones based on words, phrases and sentences. This is because FR filters using higher-level generic features may naturally be expected to be more robust and resistant to simple workarounds by FR authors such as word and phrase replacements. Further, higher-level features may have limited volatility across domains; thus, FR detection methods based on them may be more transferable across domains.

In this paper, we evaluate the effectiveness of emotion and sentiment based representations for the task of building machine learning models for FR detection. In particular, we illustrate that improved data representations can be achieved by leveraging a plurality of emotion and sentiment extraction methods, as well as by estimating emotions and sentiments on a part-by-part basis by segmenting the reviews. We illustrate the improved effectiveness of multiple emotion and sentiment features as well as review-segmented features by evaluating over real-world datasets.

2 Related Work

Representation learning focuses on developing a more instructive feature set for training a classification model that helps to boost the FR detection process (Li et al., 2017; Yilmaz and Durahim, 2018). Within past research, diverse features selection methods have been employed to detect FR. These may be divided into two classes: review-centric and reviewer-centric features. Reviewer-centric features are related to the reviewer's behaviour (Fontanarava et al., 2017) rather than the review itself. Those features include textual features, rating features, and temporal features. Review-centric features are derived from the content of a review. Commonly used review-centric features include Bag-of-words, TF-IDF (Term-frequency inverse-document- frequency), POS (part of speech) tags, word n-grams (Ahmed et al., 2018), and word embedding vectors (e.g. Word2vec, Doc2vec) (Krishnamurthy et al., 2018; Yilmaz and Durahim, 2018). A recent study by Jia et al. (2018) explored the application of linguistic features to distinguish between fake and non-fake reviews. They used Yelp filter dataset in their study and applied Term Frequency, Word2vec, and Latent Topic Distribution for data representation. They trained three machine learning models i.e. SVM, Logistic Regression, and Multi-layer Perceptron and found that LDA+Logistic Regression and LDA+Multi-layer Perceptron performed better with 81.3% of accuracy.

With representations being only a means to enable better FR identification, it is useful to briefly outline the classification techniques that have been employed for FR detection. Ott et al., (2011) used word n-gram features in combination with a SVM classifier. Banerjee and Chua (2014) employed a Logistic Regression classifier over POS tags and writing style features (e.g., tense of words) for FR detection. Algur et al., (2010) explored a similarity-oriented method for FR detection over domain-specific product features.

As mentioned earlier, our representations are centred on emotion and sentiment based features. There has been very little prior work on using such features for FR detection. An early work in sentiment analysis for FR detection was conducted by Peng and Zhong (2014), whereas (K et al., 2019) explore utility of emotions in health fake news detection. Peng and Zhong (2014) chose SentiWordNet and MPQA lexicons and analysed sentiment on review and product features. In our experiment, we used IBM, Afinn, SenticNet, and Biu Liu lexicons. To our knowledge, this is the first study detecting FR by means of combination emotion and sentiment analysis. Taking cue from the previous work of FR detection, we use Random Forest classifier, in our experiments.

3 Methodology

In this section we describe our proposed approach to online FR detection using emotion and sentiment based text representation.

3.1 Emotion and Sentiment Analysis

For the purpose of sentiment and emotion analysis, we apply three different sentiment lexicons and one emotion analysis API.

- **IBM Watson Natural Language Understanding.** Natural Language Understanding (NLU)[2] is a collection of APIs that offer text analysis through natural language processing. One of the feature of IBM Watson NLU is emotion analysis. The API takes a text as an input and returns the category which the

[2] https://www.ibm.com/services/natural-language-understanding/

text belongs to, stored in a list variable: $< KeyValuePair < String, Double >>$ e.g. ”emotion” : {”sadness”:0.336228}. Each item in the list contains the category (emotion) name and the categorization score. IBM Watson NLU can detect five emotions: anger, disgust, fear, joy, and sadness. For example, for an an input ’I love apples! I don’t like oranges’, the NLU API returns (sadness: 0.32665, joy: 0.563273, fear: 0.033387, disgust: 0.022637, anger: 0.041796).

- **SenticNet lexicon.** SenticNet[3] performs tasks such as polarity detection and emotion recognition. Instead of merely relying on word co-occurrence frequencies, it leverages semantics and linguistics. This lexicon contains a list of words with their polarity and intensity values. The intensity is a float number between -1 and +1. For example, according to the SenticNet lexicon ’abandoned’ is a negative word with intensity of -0.85. Each word in the lexicon is assigned with only one polarity and intensity value.
- **AFINN lexicon.** AFINN[4] lexicon is a list of English terms rated with valence on a scale -5 (negative) and +5 (positive). This lexicon has been manually labelled by Finn Årup Nielsen (2011). AFINN provides two versions of lexicon: the newest version AFINN-111 with 2477 words and phrases and AFINN-96 with 1468 unique words and phrases on 1480 lines. Our experiment use AFINN-111 as it is the most up-to-date version.
- **Biu Liu lexicon.** Biu Liu[5] lexicon consists of 6789 words including 2006 positive and 4783 negative words (Hu and Liu, 2004). This lexicon does not provide any sentiment scores and only provides positive/negative labels.

3.2 Representation Learning

In this work we explore whether sentiment and emotions extracted from a review can be used to train machine learning models for distinguishing between fake and non-fake reviews. We perform the sentiment/emotion analysis with different levels of granularity on a part-by-part basis by segmenting the reviews.

3.2.1 Sentiment Based Representation

The process of constructing sentiment based representation of a review is presented in Algorithm 1. We first split a review into P segments, each one containing the same number of sentences. For example, if P=4, then we split a review into 4 segments. For each segment we identify all positive and all negative words using the lexicons. In the next step, all positive sentiment values and all negative sentiment values within the segment are accumulated together. In the case of AFINN and SenticNet, all positive and negative values are summed in each segment. For Biu Liu lexicon, all positive and all negative words are counted. Following this, the segment is represented by a two dimensional vector $[pos(s_i), neg(s_i)]$, where $pos(s_i)$ and $neg(s_i)$ represent the accumulated/counted positive and negative sentiment values. Finally, all P vectors (one generated for each segment) are concatenated. The concatenated vector is returned as the sentiment representation of the entire review. The process looks the same for all sentiment lexicons.

Algorithm 1 Sentiment Based Representation

```
Input: Review $R$, number of segments $P$, sentiment lexicon $L$
Output: Sentiment representation of $R$
Split $R$ into $P$ equal segments $s_1, \ldots, s_P$
for all $s_1, \ldots, s_P$ do
    Tokenise $s_i$ into set of words $W$
    Retrieve sentiment values for all words in $W$ using $L$
    Accumulate all positive sentiment values in $W$ as $pos(s_i)$
    Accumulate all negative sentiment values in $W$ as $neg(s_i)$
    $v_i = [pos(s_i), neg(s_i)]$
end for
$v(R) := [v_1, \ldots, v_P]$
return $v(R)$
```

3.2.2 Emotion Based Representation

The process of generating emotion based representation is presented in Algorithm 2. As in the case of the sentiment based representation, a review is first divided in P segments. All sentences in each segment is then passed to the IBM Watson API. As the output we obtain vector with the five emotions’ scores. Finally, the emotion vectors obtained for all the segments are concatenated. The

[3] https://sentic.net/

[4] https://pypi.org/project/afinn/

[5] http://www.cs.uic.edu/l̃iub/FBS/opinion-lexicon-English.rar

output vector is returned as the emotion representation of the entire review.

Algorithm 2 Emotion based Representation

```
Input: Review $R$, number of segments $P$, emotion lexicon $L$
Output: Emotion representation of $R$
Split $R$ into $P$ equal segments $s_1, \ldots, s_P$
for all $s_1, \ldots, s_P$ do
    Get vector $v_i$ with emotions scores from $L$
end for
$v(R) := [v_1, \ldots, v_P]$
return $v(R)$
```

3.2.3 Multi-Segment Based Representation

The process of multi-segment representation learning is presented in Algorithm 3. With this technique, the sentiment/emotion based representation is first generated for different numbers of segments $1 \ldots P$. Following this, all vectors obtained for $p = 1 \ldots P$ are concatenated to form the final representation. In this way, the output vector contains more granular information on the distribution of sentiment or emotions within a review.

Algorithm 3 Multi-Segment Representation

```
Input: Review $R$, maximum number of segments $P$, lexicon $L$
Output: Vector representation of $R$
for all $p \in 1 \ldots P$ do
    Obtain $v_p(R)$ calling Algorithm 1 or 2 and passing $R$, $p$ and $L$ as parameters
end for
$v(R) := [v_1(R), \ldots, v_P(R)]$
return $v(R)$
```

3.2.4 Combined Sentiment and Emotion Based Representation

The last representation type that we explore is the combined sentiment and emotion based representation. The process is presented in Algorithm 4. First, a review is divided into P segments. The representation of each segment is generated by concatenation of sentiment and emotion representations obtained with Algorithms 1 and 2 respectively. Finally, representations of all segments are merged together.

Algorithm 4 Combined sentiment and Emotion Based Representation

```
Input: Review $R$, number of segments $P$, sentiment lexicon $L_s$, emotion lexicon $L_e$
Output: Vector representation of $R$
Split $R$ into $P$ equal segments $s_1, \ldots, s_P$
for all $s_1, \ldots, s_P$ do
    Get sentiment representation $V_s(R)$ applying Algorithm 1 with $R$, $P$ and $L_s$
    Get emotion representation $V_e(R)$ applying Algorithm 2 with $R$, $P$ and $L_e$
    $v_i = [V_s(R), V_e(R)]$
end for
$v(R) := [v_1, \ldots, v_P]$
return $v(R)$
```

4 Experimental Results and Discussion

In this section we present the experimental evaluation of the proposed four different sentiment/emotion based representations. Each of the representations are separetely used to build a machine learning model for FR detection. We conducted an extensive set of experiments in order to answer the following key questions:

- Do sentiment/emotion based representations help in FR detection?
- Which of the proposed representations is the most effective for FR detection?
- Can higher sentiment/emotion granularity level improve the data representation?

4.1 Experimental Setup

Datasets. We collected our datasets from two different sources. We used gold standard spam review dataset from Ott et al., (2011), and Yelp dataset from Rayana and Akoglu (2015). The Ott dataset contains reviews about hotels. Yelp Zip and Yelp NYC are extracted from Yelp filtered dataset. Yelp NYC is a collection of reviews from restaurants located in New York City (NYC) while Yelp Zip is a collection of restaurant's reviews in zip code area in NY State. Each of the datasets contains true labels of the reviews, i.e. fake or non-fake label assigned to each review. Table 1 shows the size and class distribution for each of the datasets. In our experiment, we only consider reviews that contain more than 10 sentences. We presume that proposed representation learning techniques would not be effective for short reviews since sparse text does not allow to identify emotions and sentiments well. Table 2 demonstrates the statistics of the datasets after filtering.

Dataset	Non-fake	Fake
YELP ZIP	528019	80439
YELP NYC	322097	36860
Ott	800	800

Table 1: Statistics of the datasets

Dataset	Non-fake	Fake
YELP ZIP	170261	15108
YELP NYC	105080	6185
Ott	340	270

Table 2: Statistics of the datasets after filtering

Learning. As the machine learning algorithm we used Random Forest (RF) given that it was reported as one of the most effective in FR detection (Chowdhary and Pandit, 2018; Saumya and Singh, 2018; Viviani and Pasi, 2017). However, any other learning algorithm can be applied instead. We set n_estimator=100 and random state=42 for the RF parameter. All the experiments are performed with 5-fold cross-validation and the prediction performance is evaluated with application of F-measure. Given the very high class imbalance in the Yelp NYC and Yelp Zip, we randomly select number of non-fake reviews equal to the number of FR in order to balance the training data.

4.2 Sentiment and Emotion Granularity

In this section we investigate what level of granularity in terms of sentiment and emotion is the most representative for FR detection. Tables 3-5 demonstrate the F-measure obtained by RF with each of the datasets and sentiment and emotion based representations for reviews. For the parameter P we used values from 1 to 4. For each table, the first row represents results obtained by RF applied with the emotion based representation obtained with the IBM Watson API. The three bottom columns contain results obtained for the sentiment based representation generated with each of the three sentiment lexicons. Each column refers to a different value of parameter $P = 1 \times 4$. The last column presents results obtained for multi-segment based representation.

We can observe from the tables that in the majority of cases, the higher the granularity (P) the better the prediction performance. It can also be noted that the multi-segment based representation tends to perform better than when a single segmentation is applied. The only exception is the Biu Liu lexicon, which for Yelp, Zip, and Ott obtained the best results for $P = 1$.

Lexicon	P=1	P=2	P=3	P=4	P1-4
IBM	0.570	**0.584**	**0.589**	**0.584**	**0.597**
SenticNet	0.506	0.510	0.522	0.523	0.524
Biu Liu	**0.574**	0.540	0.547	0.558	0.557
AFINN	0.550	0.542	0.549	0.555	0.563

Table 3: RF's F-measure over Yelp ZIP dataset.

Lexicon	P=1	P=2	P=3	P=4	P1-4
IBM	**0.554**	**0.569**	**0.578**	**0.569**	**0.584**
SenticNet	0.511	0.520	0.523	0.525	0.526
Biu Liu	0.546	0.523	0.543	0.543	0.555
AFINN	0.524	0.529	0.541	0.544	0.557

Table 4: RF's F-measure over Yelp NYC dataset.

Lexicon	P=1	P=2	P=3	P=4	P1-4
IBM	**0.620**	**0.605**	0.543	0.533	0.590
SenticNet	0.533	0.529	0.483	0.525	0.570
Biu Liu	0.618	0.561	**0.592**	**0.576**	**0.600**
AFINN	0.523	0.560	0.580	0.545	**0.600**

Table 5: RF's F-measure over Ott dataset.

4.3 Sentiment vs. Emotion

In this section we compare the results obtained by RF applied with the sentiment and the emotion based representations of data. We can see from Tables 3-5 that IBM emotion lexicon obtained the best performance in comparison to the three sentiment lexicons in the Yelp Zip and NYC datasets. This may be considered unsurprising since emotions provide more fine grained information for the classifiers to work with. For the Ott dataset, Biu Liu and AFINN lexicon obtained better results for some of the greater values of P.

In order to perform better comparison between the sentiment and emotion based representations we calculated average of the results obtained for each of the granularity levels: $P1, P2, P3, P4, P1 - 4$. The results are demonstrated in Figure 1. We can observe from the graphs that the IBM emotion lexicon performs significantly better than any of the other sentiment lexicons apart from the Ott dataset where it is outperformed by the Biu Liu lexicon.

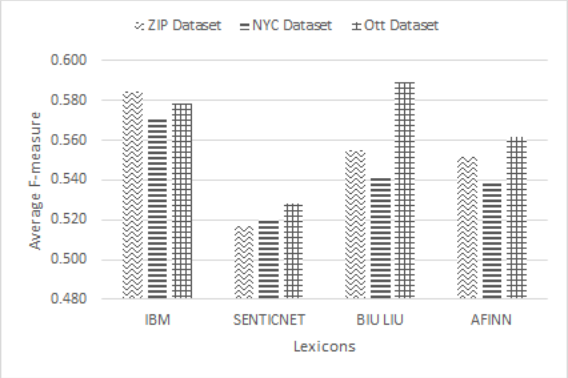

Figure 1: Average F-measure obtained for all values of P

4.4 Combined Sentiment and Emotion Based Representation

Table 6 demonstrates results obtained for the combined sentiment and emotion based representation generated according to the Algorithm 4. We can observe that for Zip and NYC datasets the best results were obtained when multi-segment based representation was applied. With Ott the best performance was obtained for $P1$.

Dataset	P1	P2	P3	P4	P1-4
ZIP	0.589	0.596	0.599	0.599	**0.602**
NYC	0.580	0.580	0.589	0.584	**0.588**
Ott	**0.653**	0.624	0.606	0.604	0.640

Table 6: F-measure obtained with combined sentiment and emotion representation learning.

In Figures 2-4 we compare the performance of the combined sentiment and emotion based representation with the emotion based representation, which so far obtained the most promising results. We can observe that the combined approach obtained better results in each case, with the difference in F-measure being quite significant for Zip and NYC datasets. This demonstrate that improved data representation can be achieved by applying combination of different emotion and sentiment extraction methods.

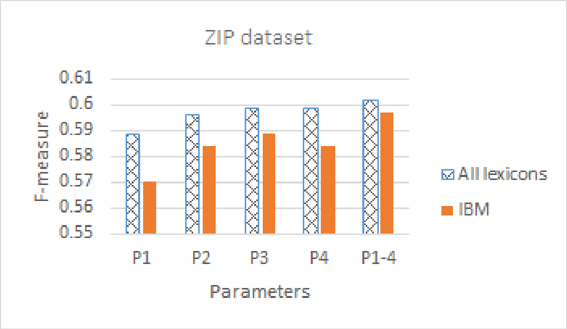

Figure 2: Combined sentiment-emotion vs. emotion representation learning for Zip

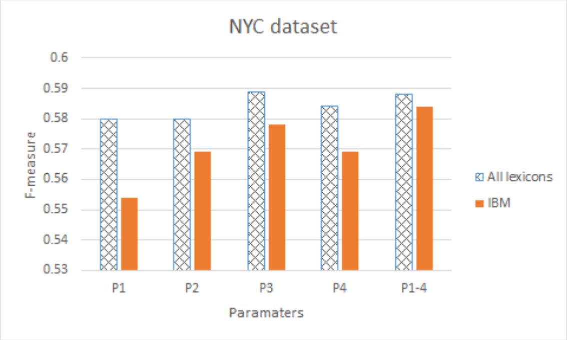

Figure 3: Combined sentiment-emotion vs. emotion representation learning for NYC

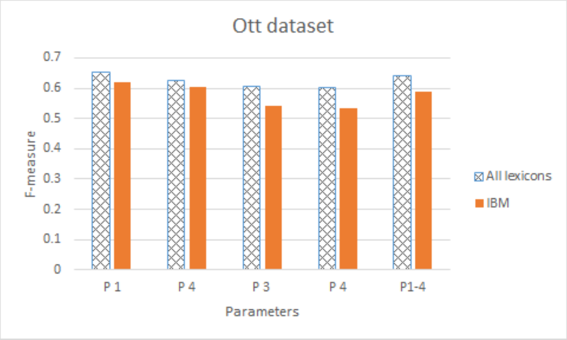

Figure 4: Combined sentiment-emotion vs. emotion representation learning for Ott

5 Conclusions and Future Work

In this paper, we analyzed the effectiveness of emotion and sentiment based representations estimated over varying text grabularities, for the task of fake review classification. Through an empirical study across three real-world datasets, we find consistent evidence that combinations of emotions and sentiments work better than either of them separately. Further, we observe that combining emotion and sentiment representations obtained across different text granularities yields better accuracies over the restaurant review datasets. As future work, we plan to carry on research on cross domain between different datasets. We also want to observe how sentiment and emotion work on neural network model such as CNN and LSTM using generic as well as custom-built lexicons (Bandhakavi et al., 2017).

Turning Silver into Gold: Error-Focused Corpus Reannotation with Active Learning

Pierre André Ménard, Antoine Mougeot
Centre de recherche informatique de Montréal
pierre-andre.menard@crim.ca, antoine.mougeot@crim.ca

Abstract

While high quality gold standard annotated corpora are crucial for most tasks in natural language processing, many annotated corpora published in recent years, created by annotators or tools, contains noisy annotations. These corpora can be viewed as more *silver* than *gold* standards, even if they are used in evaluation campaigns or to compare systems' performances. As upgrading a silver corpus to gold level is still a challenge, we explore the application of active learning techniques to detect errors using four datasets designed for document classification and part-of-speech tagging.

Our results show that the proposed method for the seeding step improves the chance of finding incorrect annotations by a factor of 2.73 when compared to random selection, a 14.71% increase from the baseline methods. Our query method provides an increase in the error detection precision on average by a factor of 1.78 against random selection, an increase of 61.82% compared to other query approaches.

1 Introduction

As machine learning is increasingly predominant in natural language processing tasks, the need for annotated data, and more specifically linguistic annotations, intensify greatly. Tasks like bias detection, named entity detection (NER) and recognition, part-of-speech (POS) tagging, semantic role labeling, assessment evaluation in discourse, dependency parsing and sentiment analysis can all be modeled as machine learning problems. They require a large amount of human annotated information to enrich raw textual resources. Creating large annotated resources for these tasks requires a lot of time and effort to insure a carefully planned and well-defined annotation protocol, obtain and encode expert knowledge, do curation steps and so on. Even when using highly qualified human annotators, errors can always make their way into the final annotated corpus. Another way to obtain annotations is to apply existing state-of-the-art algorithms (also trained on previously annotated data) on a raw corpus.

While some researchers publish new versions of their hard earned annotated resources based on the feedback obtained from users, others often have to set them aside to work on other projects and resources, leaving the corpora with their original errors. One way to improve these resources without the same level of effort would be to reannotate them using an active learning process to quickly find errors and discrepancies and resubmit them to expert annotators.

This article relates an experiment which explores the potential application of active learning for corpus reannotation, which context is detailed in Section 2 with related works listed in Section 3. Two new approaches and multiple baselines are then explained in Section 4, followed by the list of datasets used (Section 5) and the experiments combining all these elements (Section 6). We then comment on the experiment (Section 7) and close with a review of the work done and some future works in the final section.

2 Context

This section gives an overview of the two main aspects of this research, namely corpus reannotation and active learning, with their challenges and possibilities. The current work is at the crossroad of these two topics.

Proceedings of Recent Advances in Natural Language Processing, pages 758–767,
Varna, Bulgaria, Sep 2–4 2019.

2.1 Corpus Reannotation

The errors present in annotated corpora can have many sources. They can be simple typographical errors created during transcription or from the begining on uncurated information. On a higher cognitive level, another frequent cause of error is annotators' discrepancies over expert knowledge, in which disagreement over labels are not solved in a consistent way. Protocol inconsistencies are yet another source of noise in annotated corpora, often encountered when unforeseen cases fail to be brought to light, managed, or added to the protocol. Moreover, there is also all the possible causes from the annotator side, like misunderstanding the protocol, errors caused by fatigue, solving ambiguities with the most favorable case instead of reporting it, and many others. All these issues can diminish the quality of the annotations.

The nature of an annotation task can also influence the risk of generating errors. Intuitively, fine-grained classifications are often considered more error-prone than those with a small number of class values. This can be attributed to fuzzy frontiers between close-by values, overlapping values (i.e. choosing between ”entertainer” and ”comedian”) or failing to recall a specific classification option in a very large set of values.

Errors might also occur based on the interpretation of different annotators on the same case. This can be the case in named entity classification tasks, when an occurrence can be considered both an organization and a location (i.e. “I went to register at the office of University X”). These are edge cases that are often overlooked in annotation protocols and might result in inconsistencies in the final annotated corpus.

A silver standard corpus (Rebholz-Schuhmann et al., 2010) is usually defined as a noisy set of ground truth annotations provided automatically by state-of-the-art algorithms, while *gold* labels are the higher quality annotations created by expert annotators. The silver labels are normally produced manually by human agents, but can also be obtained automatically by tools or trained prediction models. Of course, the gold labels might still contain some degree of noise, but they are considered of better overall quality than the silver version.

Corpus reannotation can be a tedious undertaking, as it not only requires the same expert domain knowledge to correct the annotations, but also a deep understanding of the original protocol, often created by another team. It may also require to modify the protocol or classification values, and also require an additional effort of the annotators to assess if they are not creating more errors when modifying an original answer. For all these reasons, it is important to explore ways by which some of the effort might be lowered, such as the application of active learning on noisy corpora.

2.2 Active Learning

Active learning (Cohn et al., 1996) has been used to lower the annotation effort needed to train a prediction model in natural language processing tasks. It traditionally involves a dialogue between one (or more) human annotator(s) and a machine learning algorithm, the former being proficient at annotating instances that the latter is providing based on relevance measures. The process can be split into three distinct steps.

The first one, called *seeding*, is where the algorithm must choose instances without being able to rely on any annotation from the expert. The chosen instances are submitted to be annotated by the expert. This starts the second and longest step, the *querying* phase. The active learning engine iterates between training a prediction model with the gold values (training set) from the expert, choosing new instances relevant to training a better model, submitting them to the expert and adding the expert's answers back into the training set. The third step, *stopping*, is applied after each training of the querying phase. It checks if there is enough information in the model to annotate the rest of the corpus automatically so that the annotation can stop. A bad stopping criterion might overfit the model, lowering its predictive power.

One challenge of active learning is to balance between specializing the classification on known cases (for example, annotation errors), thus improving the performance for current classes, or exploring the problem space to find unknown but relevant instances that could improve the overall performance of the model.

The goal of the current experiment is not to produce the best prediction model, but to explore if the reannotation effort on a corpus can be reduced by using the active learning process with different algorithms. These algorithms should not target the most informative instances for a prediction model, but instead choose those that are more likely to be errors. If successful, the model should then be able to extract more errors as it progresses.

3 Related Works

While different flavors of reannotation have been used for natural language processing tasks on text corpora, the work of (Rehbein and Ruppenhofer, 2017) is the most similar to our contribution from an error finding perspective with active learning. They evaluate the query-by-committee (QBC) and variational inference (VI) active learning methods to perform error detection on part-of-speech tagging and named entity recognition (NER) tasks. These approaches were tested in four contexts: in-domain (same type of training and testing data) on English POS, out-domain (different training and testing) on English POS, new task and language on German NER, and real-world context with human annotators on POS task. After 1,000 iterations, the VI approach generally gives a better noise reduction than QBC. While the POS task is similar to the one used in our experiment (although on a different language), the NER task uses only 4 class values (location, organization, person and miscellaneous) while documents in our classification task can be categorized into a high number of types. They do not specify the experimental seeding methods used to choose the first examples.

Another similar research is Skeppstedt (2013) which uses active learning with two sources of tools generated annotation in order to tag and classify named entities in Swedish clinical text documents. The challenge of combining multiple pre-annotated sources and active learning is to provide the right quality of information. If the sources are too noisy, the task will be more difficult and unreliable. On the other hand, providing high-quality sources might lower the attention and interest of the annotators. The proposed method tries to overcome these two points by showing the sources without specifying which one is most likely to be correct. No performance evaluation was done for the proposed approach.

Other experiments make usage of preannotated information without applying active learning methods, like (Chou et al., 2006) who use a semantic role labeling tool trained on PropBank to pretag a biomedical corpus called BioProp. After the automatic annotation step, a human annotator manually checks the silver values and corrects them as needed. Other reannotation efforts may be conducted by adding human resources to the task to distribute the effort among multiple users. This is the proposition made in (Hovy et al., 2014) by applying crowd sourced reannotation. In the same multiuser settings, (Lin et al., 2016) propose an approach to reannotate labels by integrating another human oracle in order to improve the quality of the annotations.

4 Methods

In order to improve noise detection, we focus on the seeding and querying steps of the active learning process. As the goal is to facilitate annotation of incorrect annotation, and not to create a prediction model per se, we did not explore the stopping phase. The following sections detail the baselines as well as the new methods used for the experiments in Section 6.

4.1 Seeding Methods

The seeding method's main goal from a reannotation perspective is to provide the highest error ratio for the budgeted seed size. This contrasts with a usual active learning task which is to find the most informational instances to annotate in order to improve the model's performances.

To capitalize on the silver classification information, we used outlier detection methods separately on each unique silver value. Our hypothesis for this is that most of the annotations should be of good quality, although noisy, meaning that clustering the instances for a single silver value should produce one or many clusters of correctly classified instances. A large enough dataset should then provide a cluster for each valid manifestation (depending on the features used) of a silver value. As the clusters represent valid cases, the outliers should represent either rare cases or, ideally, noisy labels which should be reannotated by the expert.

For each silver value of a corpus, a random instance was chosen in the detected outliers, to test the hypothesis that they should mostly be incorrectly annotated cases.

Four other outlier detection methods were tested as baselines to assess their performances and compare them to the above method. These are not normally used in the seeding phase and they do not consider the presence of a silver value in the feature set. The first is the one-class SVM (Schölkopf et al., 2001) which trains a support vector machine with a radial basis kernel function and returns the lowest supported instances in a distribution.

The local outlier factor (Breunig et al., 2000) computes the local deviation of density for an instance with its closest neighbors using a k-nearest approach. If the local density of the close-by instances is significantly higher, the instance is considered an outlier and is selected for human annotation.

The isolation forest algorithm (Liu et al., 2008) detects outliers by selecting the most isolated instance of a randomly selected feature set and split point in the value range. These splits are then projected into a tree structure and the average path length to an instance gives its degree of isolation, choosing the highest degree of isolation as the best potential instance to annotate.

Finally, the covariance detector (Rousseeuw and Driessen, 1999) uses a Gaussian distribution around the density cluster to assess the degree to which an instance might be part of that cluster.

4.2 Querying Methods

The proposed *double centroid* approach is based on the hypothesis that an annotator, either human or tool, tend to produce similar types of errors through the annotation process. The source of these types could be the inability to differentiate between two classes, unknown terminology, etc.

The method first use density-based clustering to group together newly annotated instances from the seeding or previous querying steps. It is applied once on erroneous instances, where the silver and new gold values did not match, and once on non-erroneous instances, where the silver and new gold values matched. This gives multiple clusters containing either noisy (C_n) or matching (C_m) annotations.

$$rank(l) = \left| \sum_{i=1}^{C_n} \frac{|C_i|}{dist(l, C_i)^2} - \sum_{j=1}^{C_m} \frac{|C_j|}{dist(l, C_j)^2} \right| \quad (1)$$

As shown in equation 1, for each silver instance l that was not yet picked for relabeling, a weighted squared distance $dist(l, C)^2$ is calculated separately against each cluster centroid. The weight used is the cluster cardinality $|C|$, so that nearer and larger clusters have more influence on an instance. These weighted distances are then summed up with opposing values, in this case C_n clusters having a positive influence and C_m having a negative one. The algorithm then selects those that have the highest value, following the hypothesis that they would be similar to known errors.

Other methods often applied in a standard active learning process have also been used as a basis of comparison with the proposed method, namely *distance to centroid*, *cosine similarity*, *hierarchical clustering* and *margin query*.

Distance to centroid calculates a density center point (centroid) from each instance of a specific gold value asked from the expert annotator. Each instance is then checked against each centroid and the ones which are furthest from all points are selected.

The cosine similarity works in a similar way as the previous method but uses the cosine between the instance and the centroids to assess the proximity.

Hierarchical clustering also uses the distance to clusters as a degree of uncertainty to choose ambiguous instances, but goes one step further by splitting these instances to choose only those which are the most different from one another. This usually helps to provide a better sample to annotate and avoid ambiguous but very similar instances.

Margin query chooses the instances with the smallest difference between the most probable predicted class and the second most probable.

5 Datasets

For this experiment, we used a total of four datasets, two targeting a document classification task and two for a text sequence classification task on part-of-speech tags.

As there were no publicly available manually corrected datasets, and correcting an existing one would have been too time consuming for the scope of this project, we simulated the noise level by applying a classification tool to each manually annotated corpus. They are each presented in the following sections and Table 1 shows the size and error rate for each of them. The error rate is calculated by dividing the number of errors in the silver standard (compared to the gold standard) by the total number of elements. Sections 5.5 and 5.6 describe how the noise was generated for each corpus to calculate the error rate.

Corpus	Size	Error rate
Reuters	9,149 docs	0.0941
WoS	46,985 docs	0.3916
GSD-French	402,120 words	0.1015
Sequoia	70,572 words	0.1080

Table 1: Corpus size (documents or words) and error rate.

5.1 WOS-46895

The WOS corpus (Kowsari, Kamran et al., 2018) contains 46,985 documents in English taken from the Web of Science website. Each document contains the abstract from a published scientific paper. These documents were picked from the fields of psychology, medical sciences, biochemistry, computer science and three specialization of engineering. While each document is only classified in a single topic, terminology coverage of some topics overlaps with others, such as between biochemistry and medical sciences.

Each topic is further broken down into 134 specialized areas, varying from 9 to 53 areas for each topic. While this dataset was primarily created for hierarchical classification, we only used the 134 areas (the second layer of classification) for the purpose of this research.

5.2 Reuters

The Reuters-21578 corpus (Lewis, 2004) is composed of 10,788 English documents consolidated for the text classification challenge of document understanding conference (DUC). There are 90 categories in the corpus. However, that dataset was originally used for multi-class classification. To use it for our research, we extracted only the articles having a single class and kept only the classes that appeared more than once in the dataset. The final dataset is made of 9,149 instances across 56 categories like *acq* and *earn*. The labels' distribution is heavily skewed as two of these classes make up 75% of the dataset instances.

5.3 French-GSD

We used the French portion of the GSD corpus (McDonald et al., 2013), version 2.2 at the time of writing. We merged the three parts (dev, train, test) into a single corpus consisting of 402,426 words (16,448 sentences). While it is fully tagged with dependence trees, we only retained the 17 universal dependency-based part-of-speech tags from the open class (*ADJ*, *ADV*, *INTJ*, etc.), the closed class (*ADP*, *AUX*, *CCONJ*, *DET*, etc.) and the other class (*PUNCT*, *SYM*, *X*). The feature set for each instance included the token's position in the sentence, surface form, lemma, length, presence of space after the token and case type (capitalized, all capital letters or mixed case).

5.4 Sequoia

The Sequoia corpus (Candito and Seddah, 2012) contains 3,099 French sentences (70,572 tokens) taken from different corpora such as Europarl, *L'Est Republicain* newspaper, French Wikipedia and European Medicine Agency. It has initially been annotated with constituency trees and then converted to surface syntactic dependency trees. In our experiment, we only classified the part-of-speech (POS) information. The feature set was the same as the French-GSD corpus.

5.5 POS Processing and Vectorisation

The GSD and Sequoia corpora were initially tagged manually with universal part-of-speech tags[1] which we used as the gold standard. While dependency information was widely available in the original corpus, we removed them as they would not be available in a raw text corpus without applying a high quality dependency analyzer. We kept morphological features as listed in Section 5.3.

In order to create a silver version of the dataset, each token was automatically reannotated with TreeTagger (Schmid, 1997) to provide a new set of tags. These tags were then converted to the universal part-of-speech tagset to make them comparable with the original corpus tags.

These corpora were then vectorized to be processable by the classification algorithms, projecting the information of each instance in a feature space. The feature set was also enriched for each instance with the information from the last five tokens and the next five tokens. The sentence boundaries were respected, so that the first token in a sentence would only get the next five tokens, the second token would get the previous token and the next five, and so on. As the algorithms used cannot deal with nominal data, each feature was one-hot encoded. Once encoded, each dataset contained 1,156 features including the silver annotation.

[1] https://universaldependencies.org/u/pos/

5.6 Classification Preprocessing and Vectorisation

The text documents in the WOS and Reuters corpora were stemmed using Porter stemmer (Porter, 1997) and had their stop words removed. In order to simulate silver level annotations, the corpora were vectorized and annotated using a five-parts iteration. In other words, the corpus was split into five batches containing 20% of the corpus, a model was trained on the gold values of 80% of the corpus, recreating a new model to annotate the remaining 20%, and a different batch was swapped to be annotated each time.

The two corpora were then vectorized with two word embeddings methods, fastText (Bojanowski et al., 2016), Word2vec (Mikolov et al., 2013), and the tf-idf (Salton and McGill, 1986) statistical method. The feature set size of the output vector from each method, either produced with neural networks or statistical measure, was set to 1,000 features.

Corpus	Method	F1
Reuters	fastText	0.87
	Word2vec	0.88
	tf-idf$_3$	0.91
WOS-46895	fasttext	0.59
	Word2vec	0.57
	tf-idf$_3$	0.61

Table 2: Performances of vectorization methods.

To see which one provided the best expressivity with its features, the vectors for each corpus were evaluated with ten-fold validation using logistic regression as the passive learning algorithm. The results in Table 2 show the performances for each vectorization method on each corpus. While the results are quite close to one another, the statistical tf-idf method using unigrams to trigrams (Tf-idf$_3$) provides higher results on all datasets. For this reason, we use the feature set provided by this method for the experiments.

6 Experiment

6.1 Seeding Experiment

We use the error rate of the corpus (as previously reported in Table 1) as a random baseline for seeding, which is the equivalent of making a random selection. As studied in (Hu et al., 2010), most of the papers either use this type of seeding method for active learning, choose a fixed number of instances from each target class value (knowledge that would not be accessible in a real world setting) or simply fail to mention the method.

The methods described in the previous section were run 100 times to smooth out the randomness effect of some outlier selection methods. It also helped to show if most of the outliers were in fact valid errors to be detected. Each chosen outlier was then compared to the gold value to verify if it was an error or a valid annotation. The number of unique silver values were not scaled down to a specific seed size so as to provide an overall measure of performance.

As some clustering methods do not scale well with large datasets, we applied a feature reduction algorithm on each dataset. We used a random forest (Breiman, 2001) estimator using 100 trees, building each one with a random subset of features from the dataset, evaluating the relevance of each feature and discarding the less meaningful ones. The Sequoia and French-GSD corpora were respectively reduced to 261 and 223 features, while 250 and 334 features were retained from the Reuters and WOS-46895 corpora. The silver annotation was used as the relevance indicator for this process instead of the gold which would not be available in a real setting.

The results presented in Table 3 show an improvement across all methods compared to baseline performances. The error rate column is averaged from all the results in the experimental runs. The gain is the ratio between the average error rate and the baseline performance from Table 1 (error rate column) using a random selection or a standard seeding method.

While all seeding methods provide an improvement compared to the baseline, the local outlier factor method seems the most promising when assessed from the average gain global score over all corpora. Performances on the WOS corpus were not favored by any of the four methods and were just marginally better with the local outlier factor.

6.2 Querying Experiment

The four baseline methods detailed in Section 4 were applied to each vectorized corpus for the document classification and POS tagging tasks. To avoid boosting the performance of the error seeking query method, we did not use the previous approaches for seeding. Instead we randomly se-

Method	Measure	Reuters	WoS	Sequoia	French-GSD	Average gain
SVM	EDP	0.3576	0.4346	0.1429	0.2938	
	Gain	3.80	1.11	1.32	2.89	2.28
Covariance	EDP	0.3606	0.4331	0.1786	0.2971	
	Gain	3.83	1.11	1.65	2.93	2.38
Isolation	EDP	0.3424	0.4336	0.1929	0.2267	
forest	Gain	3.64	1.11	1.79	2.23	2.19
Local	EDP	0.4030	0.4369	0.2000	0.3729	
outlier	Gain	4.28	1.12	1.85	3.67	**2.73**

Table 3: Seeding phase error detection precision and gain.

lected a subset of 20 instances for the seeding step. This ensured that the initial training set would have about the same standard level of errors as in the rest of the corpus. The query phase selected 20 instances per iteration before retraining the random forest model. These queries were answered by an artificial annotator who had access to the corresponding gold values. Each method was run on the corpora 20 times to smooth out the variability of the random aspects of some methods.

Table 4 shows the average error detection precision (EDP) for the complete set of experiments. It is the ratio between the number of errors detected (where silver and gold labels does not match) and the total number of queried instances at a specific point. A score of 1 would mean that the algorithm only submitted errors to be reannotated by the oracle. As the active learning process can be stopped at any point, the recall score is not used as it would imply that all errors should be submitted before the end of the process.

The gain ratio is the error detection precision divided by the corresponding corpus error rate. Gain values lower than one mean a lower performance than random selection. The EDP shown was calculated after 200 annotations, meaning one seed and 19 query iterations. This number was choosen from real-world experiences, where annotators usually consider that some errors should be encountered at that point, if any are to be found.

We can see that the proposed double centroid method outperformed all the other approaches on every corpus. Most methods did not perform well on the WoS corpus, which incidentally had four times the error rate of other corpus. The best gain ratio of our method was when detecting POS tagging errors on the FR-GSD and classification errors on the Reuters corpora. Aside from double centroid, most other methods performed at the same level as the others, except for distance to centroid on the Reuters corpus.

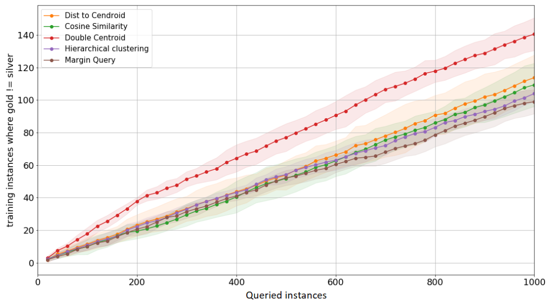

Figure 1: Performances of querying methods on the Reuters corpus.

As seen on Figure 1, which shows all methods applied to the classification task on the Reuters corpus for a total of 1,000 instances annotated, all methods seem to have a relatively stable slope. The double centroid method loses some velocity after hitting 220 instances. The other methods diverge near the end, but not very distinctively.

7 Analysis and Discussion

Looking at the slopes in Figure 1 at the start of the process, we can see that they start at about the same level of performance before settling into their tendencies. This is mainly due to the fact that the seed does not contain many instances about different gold values to provide significant clusters.

Why the performance drops on the WoS corpus compared to Reuters or other corpora can be attributed in part to the low expression power of the vectorized feature set shown in Table 2. They pro-

Method	Measure	Reuters	WoS	Sequoia	French-GSD	Average gain
Distance to	EDP	0.1194	0.3954	0.1049	0.1196	
centroid	Gain	1.27	1.01	1.03	1.11	1.10
Cosine	EDP	0.0974	0.3796	0.1198	0.1003	
similarity	Gain	1.04	0.97	1.18	0.93	1.03
Hierarchical	EDP	0.1110	0.3943	0.1196	0.1079	
clustering	Gain	1.18	1.01	1.18	1.00	1.09
Margin	EDP	0.1032	0.3937	0.1074	0.1057	
query	Gain	1.10	1.01	1.06	0.98	1.03
Double	EDP	0.1982	0.4283	0.2499	0.1565	
centroid	Gain	2.11	1.09	2.46	1.45	**1.78**

Table 4: Query phase error detection precision and gain after 200 instances.

vided only two thirds of the performance on the passive learning task compared to those produced from the Reuters corpus. While pretrained word embeddings could have been used, we wanted to avoid the issue of unknown tokens when dealing with specialized corpora.

In order to lower even more the effort of annotators, the next logical step would be to validate if the final prediction model was either as good or better at predicting any type of instances on the remaining corpus when compared to a standard, non-error detecting active learning process. This would entail that an error detection model could simply be used to annotate the remaining instances, correcting more errors and minimizing the creation of additional noise.

8 Conclusion and Future Work

We experimented with active learning methods on noisy corpora to lower the noise level, thus improving the overall quality of the datasets. Our proposed seeding method targeting error detection provided a gain factor of 2.73 when compared to the most used random seeding in active learning, while our double centroid method provided a 61.82% increase for finding noisy annotations when compared to baseline approaches used for active learning.

While there is room for improvement, these results show the potential application of active learning for corpus annotation. The applicability on two NLP tasks on different units (words or documents) shows a good adaptability of the tested methods, as the use of two languages in the corpora to avoid relying on language-specific techniques.

One untested hypothesis is if these methods provide the same level of performance when applied to corpora with human-generated noise instead of tool-generated noise. We expect that noise level might be lower in published and broadly used datasets if reannotated with the original protocol. This might influence the effectiveness of the tested methods.

These approaches should be tested on a broader set of natural language processing tasks, such as sentiment analysis, information quality, relevance identification, named entity classification, etc. This would either help to further advance the demonstration about the effectiveness of these methods, or to develop new approaches to facilitate the task of reannotation.

Some influential aspects of active learning have been left aside in this experiment as they did not directly implicate human annotators, like the cognitive charge of annotation correction for a human agent. This requires not only to assess the context of the existing annotation to deduce the correct annotation, but also to ponder, when the existing annotations differ, if they are not adding more noise.

Abstract

With recent efforts in drawing attention to the task of replicating and/or reproducing[1] results, for example in the context of COLING 2018 and various LREC workshops, the question arises how the NLP community views the topic of replicability in general. Using a survey, in which we involve members of the NLP community, we investigate how our community perceives this topic, its relevance and options for improvement. Based on over two hundred participants, the survey results confirm earlier observations, that successful reproducibility requires more than having access to code and data. Additionally, the results show that the topic has to be tackled from the authors', reviewers' and community's side.

1 Introduction

"As a community, we need to know where our approaches fail, as much – if not more so – as where they succeed." Despite this statement by Fokkens et al. (2013), we are still aiming at higher, faster, better results with little outside verification. And although it has become good practise to share code, data and parameters, previous work and experience indicate that sharing is still not as common as one would hope for. Call for Papers in major conferences encourage to submit or reference data and to submit code, i.e., in supplemental material[2]. But recent work indicates that this is not done thoroughly enough (Mieskes, 2017; Cohen et al., 2017; Wieling et al., 2018). Other factors mentioned by Fokkens et al. (2013), such as preprocessing methods, experimental setup, system variation, etc., are rarely reported. Pedersen (2008) urges to not fear any dispossession of a tool, and highlights that sharing code will result in its use in new systems and citations of the work describing this code. Moreover, we should consider sharing software as a way to improve it more efficiently. In recent years, we have seen a rise in attention targeted towards the task of replication for example in the COLING 2018 selection criteria[3], the LREC 4REAL Workshops (Branco et al., 2016, 2018) and the recent LREC initiative for replication.[4] But so far the task of replicating previous results has little merit in itself, but is rather only a (baseline) part in a paper. Additionally, normally it only gets reported in successful or mainly successful cases. Following the argument by Fokkens et al. (2013), the cases where it fails, hardly ever get reported, despite Calls for Papers encouraging negative results[5] and although they might be equally or even more important than the successful replication.

Our contribution therefore is to identify how the community views the topic of replication and what role each individual plays as an author, as a reviewer and as part of the NLP community. In conducting a survey, which drew answers from over two hundred respondents, we get a better picture of the factors that support or hinder making repli-

[1] We use *replication* to describe related efforts, regardless of the exact aim (see (Cohen et al., 2018))

[2] see for example http://www.acl2019.org/EN/call-for-papers.xhtml "ACL (...) encourages the submission of supplementary material to report (...) details necessary for the replication of the experiments."

[4] This call occurred 5 weeks after we posted our call and are unrelated, but the latter might be inspired by our survey, see http://wordpress.let.vupr.nl/lrec-reproduction/.

[5] "A negative result" http://www.acl2019.org/EN/call-for-papers.xhtm (Short Papers)

cation more visible and how the three factors described above influence this. Our results indicate that the participants in general regard replication as an important issue and that the NLP community could do more to support replication, which would strengthen the field as a whole.[6]

2 Related Work

One of the earliest reports of a replication effort addresses manual word-sense disambiguation based on four words, representing different degrees of difficulty (Kilgarriff, 1999). The author reports that humans agree in this task on average in 95% of the cases. Following Fokkens et al. (2013), others look into parameters that influence the replicability of results. Dakota and Kübler (2017); Marrese-Taylor and Matsuo (2017) and Horsmann and Zesch (2017) report various parameters and problems with replication experiments for morphology and syntax.

In the field of biomedical NLP, Olorisade et al. (2017) assess the reproducibility of findings published in 33 papers. They notice that data sets were missing, making it impossible to reproduce results for 80% of the papers. These figures are in line with results reported by Mieskes (2017). They consider that a permanent link to the resources (data set, software, etc.) must exist along with published papers. As part of a NLP challenge, Névéol et al. (2016) report results on replicating experiments from three systems submitted to the CLEF eHealth track. They show that replication is feasible although "ease of replicating results varied". They suggest the allowance of extra pages for papers, where information required to replicate an experiment could be reported.

Moore and Rayson (2018) illustrate how to publish relevant details to reduce efforts in repeatability and generalisability. Suggestions include using only open data, open source code and providing extensive documentation in the code.

Wieling et al. (2018) describe one example where exact replication was possible and the authors list the parameters that allowed them to do so: a virtual image, containing all code and all data or providing CodaLab worksheets. Their study, which compared the situation in sharing research artefacts between 2011 and 2016 indicates that, while the situation has improved and the availability of data is high, access to code is less so and requesting code is unsuccessful in most of the cases. Based on results of their actual replication experiments, *at most 60%* of the studies are replicable, but only if the need for exact replication was relaxed.

Fares et al. (2017) present a repository and infrastructure containing texts, tools and embeddings for English and Norwegian. Their aim is to facilitate replicability and testing of previous results. Dror et al. (2017) propose a "replicability analysis framework" and demonstrate its use on various tasks such as part-of-speech tagging or cross-domain sentiment classification. They specifically target cases where algorithms are compared across multiple data sets. The results indicate that testing on a range of data sets is only beneficial if the data sets are heterogeneous.

3 Survey Design

Our survey has 18 questions, of which many were conditional and show only if they apply to the respondent. Thus, not all questions have been answered by all participants, while most multiple-choice questions allow for several answers, resulting in more answers than participants for these questions. Questions are grouped into three categories: (i) replication work in general, (ii) replicating one's own work and (iii) replicating others' work.

General questions quiz participants on their perception of replication work. We also inquire about their current position to investigate potential correlation with other aspects of the survey. Questions addressing participants' replication experience specifically enquired about research artefacts availability (data, code, parameters, etc.) and about the timeline of the replication experience in order to assess attrition.

The survey was advertised on professional mailing lists (BioNLP, Corpora, LN and GLCL[7]) and social network (LinkedIn). The appendix gives details on the progression of responses. With respect to sensitive data, only e-mail addresses were provided, on a voluntary basis, and we follow the ACM Code of Ethics and Professional Conduct[8],

[6] The complete results of the survey are available at https://github.com/replicateNLP/Survey-RANLP2019. Please note, that due to privacy regulations, we had to remove some free text answers that contain personal information, such as E-Mail addresses, which were given on a voluntary basis.

specifically sections 1.6 and 1.7.

Figure 1 illustrates the flow of the questionnaire. If a person did neither replicate their own or someone elses work, they only had to answer the blue marked questions. If a participant tried to replicate his/her own work, but not someone elses work, they only had to answer the blue and the orange questions. Only persons who have experience in replicating their own and someone elses work had to go through the whole questionnaire, including the green questions.[9] This flow in addition to the possibility to give more than one answer in some questions results in different numbers of answers for each question.

4 Results

We received 225 responses and the two biggest groups of participants in our study identify themselves as graduate students and postdocs.

With respect to when work on replication has been done, 36 participants (16%) gave more than one anwer, indicating that they did work on replication at various stages of their career. Most answers (50.3%) state that replication was done on MSc or PhD level, less on PostDoc level (20.7%) and slightly more as Faculty members (24.3%). However, we did not find strong correlations between the respondents' position and opinion on the importance (or lack thereof) of reproducibility. Figure 2 shows the absolute numbers for this question, while Figure 3 shows the numbers for the participants current position.

4.1 General Stance towards Replicability

The answers show that in 56.4% of the cases, work on replication is considered "Important" and another 7.5% state that it is "Somewhat Important". Only 2 answers indicate that this work is "Unimportant". 20% of the answers regard work on replication as publishable, while 11.8% deem it unpublishable. 87 participants gave more than one answer. The majority (49) consider work on replication as important *and* publishable, while 26 of them consider it important *but not* publishable (see Figure 4 for the absolute numbers).

4.2 Replicating one's Own Work

Roughly 70% (156) of the participants declare they have tried to replicate their own work while about 30% have not tried (total 225).

With respect to how often replication of the same experiment was tried, 15 participants gave more than one answer, giving us 172 answers (see Figure 5 for the detailed figures). Of these, 28.5% indicate that replication was tried only once, while 38.4% tried 3 times or more.

When looking at the last attempt (total answers 234), nearly half (47.0%) report that they reached the same general conclusions, while 23.1% state that they reached the same figures. A little less than 10% report that they managed to reimplement the system, but got significantly different results. Another 14.9% could not find either the code or the data or the parameters used for the experiment (see Figure fig:resultsOwn for the absolute numbers). 52 participants gave more than one answer of which 25 report that they reached the same general conclusions *and* the same figures. Overall, the results indicate that even in the case when researchers try to replicate their own work, they fully succeed in only 23.1% of the cases.

4.3 Replicating Others' Work

About 60% (total 130) of the participants report that they tried to replicate someone else's work (see Figure 7 for detailed, absolute numbers). 51 respondents gave more than one answer with respect to the results achieved when replicating somebody else's work, resulting in 211 answers. Approximately 40% of the answers state that they reached the same general conclusions or figures, while another 33.6% of the answers state that they managed to re-implement or re-run the system, but with significantly different results. Nearly 23.1% of the responses state that re-implementation or re-runnning of experiments was not achieved (see Figure 8 for the absolute responses for this question). This means that over half of the replication experiments failed, either early on or at the level of results achieved.

4.4 Accessibililty of Research Artefacts

For finding research artefacts such as code, data and parameters, respondents gave several answers, resulting in 250 answers for where the code can be found, 260 answers for finding data and resources and 233 answers for finding the experimental parameters. GitHub is by far the most popular (36.4% of the answers) for accessing *code*, but more than 23.6% of the answers state that code is found on the authors' personal webpage,

which does not guarantee availability beyond that person maintaining his/her webpage. More than 14% of the answers report that the code could not be found. *Data* is also primarily published via a GitHub or personal webpages (25% and 25.7% of the answers respectively). 11.1% report that the material used for the experiments could not be found. *Parameters* for experiments are primarily found in the respective publications (40.3% of the answers), while 21.9% of the answers state they could be found on GitHub as well. 13.7% report that they could not find parameters at all. Figure 9 illustrates the absolute numbers concerning the availability of code, while Figure 10 and Figure 11 illustrate them for other resources and parameters respectively.

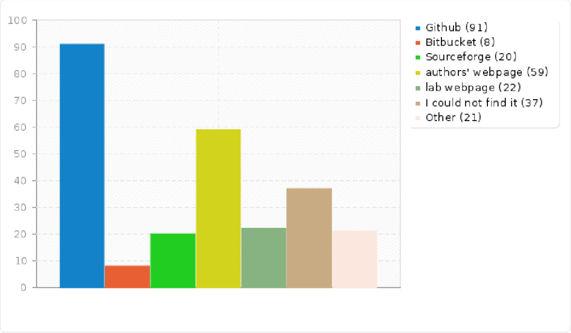

Figure 9: Sources for Accessing the Code for replication.

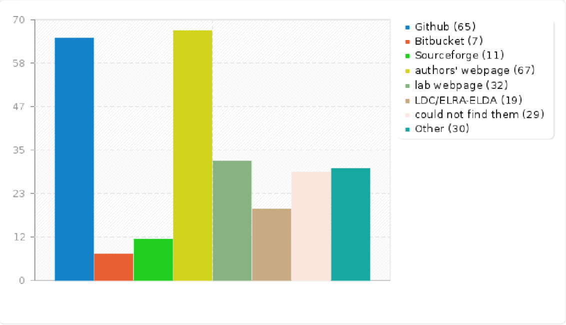

Figure 10: Sources for Accessing Data and other Resources.

Concerning these three elements, the text box associated with “Other” very frequently mentions “personal communication” or “e-mail” as a way of obtaining necessary information. This gives rise to a range of further issues, legal, ethical and in terms of transparency. Besides, it is only possible if authors actually answer such e-mails.

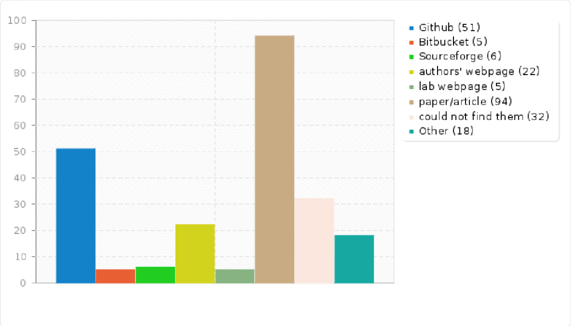

Figure 11: Sources for Accessing Parameters for Replication.

In our survey, 40% of the participants report that they tried to get in touch with the authors (see Figure 12), but only in about 30% of the reported cases received a helpful answer (164 answers received, as 41 participants gave more than one answer). Approximately 20.1% mention that unhelpful answers were received and almost 23.8% never received any answer. Due to evolution of careers, 13.4% found out that the person had left the lab or the e-mail bounced, resulting in almost 40% of examples where authors were unreachable (see Figure 13).

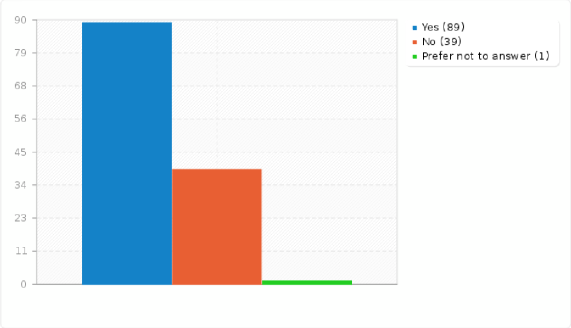

Figure 12: Participants who state that they reached out to original authors.

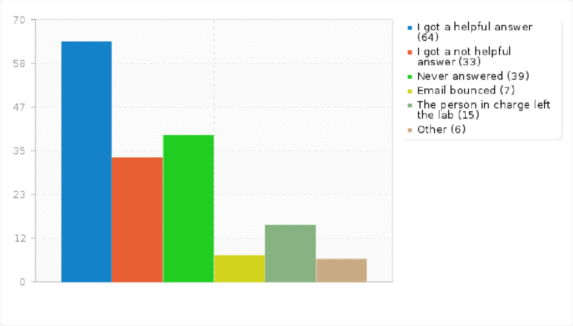

Figure 13: Quality of Answers by original authors.

5 Discussion

The survey results suggest that **replicability is perceived as an important issue** by a majority of responses ($\geq 60\%$). It is difficult to compute an accurate response rate for the survey, because we do not know the extent of the population comprised by subscribers to the mailing lists and professional networks that we reached out to. However, if we approximate the target population using the average participation in a *ACL conference (N=1,000), we can estimate the response rate at about 20%. This has previously been described as an "acceptable" response rate for online surveys.[10] While the responding population includes researchers with a wide range of seniority as well as members of academia and industry, it could be biased by their interest in replication. The results, and especially the comments, indicate that this is most likely not the case as some participants do not see the value in replicating previous results. They state that replicating previous work is only an "exercise" and actually an "overload" on the already busy researchers' schedule. One comment states that *"10 year old systems are irrelevant"* and *"ML is moving so fast"*, which renders replicability studies essentially worthless. This could explain why the two largest groups performing replicability studies are on PhD or PostDoc level.

What does this mean for replicability? Responses indicate a variety of views on how replicability should be facilitated. One comment states that there is already a culture of sharing and publishing data and code and this should be enough. Another participant states that in industrial research publishing data or code is difficult, but suggests that the validity of an approach can be proven by applying the method to other data and in reaching the same general conclusions. Some participants support the idea of giving more visibility to replicability by making it a prominent topic at major conferences and by enforcing reporting guidelines towards reproducibility.

Some participants mention that replicability is crucial to be taken seriously as a scientific field, even stating that the field is "suspect" if replication fails. One participant suggests that *"every paper*

[10] http://socialnorms.org/what-is-an-acceptable-survey-response-rate/

cited enough times should be replicated".

6 Conclusions and Future Work

Based on a survey we gave insight into the NLP community's view on replicability. We targeted three different facets of this topic: Authors publishing their work, Researchers building on top of other researchers' work and the Community, supporting such efforts. Our results show that on the authors' side more information has to be shared openly, rather than via personal communication. The use of reporting guidelines formalized into a protocol has been suggested recently for clinical NLP (Velupillai et al., 2018). Earlier studies from the clinical domain suggest that adherence to such guidelines is suboptimal (Samaan et al., 2013) and methods to improve adherence are being investigated (Blanco et al., 2017). The task of creating guidelines falls to the community and the adherence of such guidelines could become part of the reviewing process.

Experiments in replication fail more often than not. If we document and store all relevant information so that results could be reproduced by ourselves (e.g., before the final paper submission), the package could be published completely. Results by Wieling et al. (2018) indicate that images containing all the material or technical lab books published on CodaLab might be a way to proceed. Additionally, failure to replicate previous work (i.e. not achieving the same results and/or not being able to draw the same conclusions as previously reported), should be publishable in a way that gives us scientific merit and could be encouraged more.

Based on the comments, each of us, in all of our individual roles can improve the situation: As authors, we can be more diligent when reporting our experiments and experimental setup—even testing the replicability of our experiments ourselves. As reviewers, we can be more careful to check the supplementary material for relevant information, pointing out missing elements. As a community, we can appreciate replication more and develop guidelines both for authors and for reviewers.

Future Work The next steps include, but are not limited to, analyzing whether the supplementary material and appendices actually do improve replicability, as stated by Névéol et al. (2016). Furthermore, evaluating the repository offered by Fares et al. (2017), whether other researchers actually build on top of it and with what results. NAACL recently initiated a "test of time" award. This could be extended to consider experimental work that has been cited often and gained influence on a shorter time-scale. This work could be verified for a follow-up conference. Replicability could also become a factor in the best paper awards.

Unsupervised Data Augmentation for Less-Resourced Languages with no Standardized Spelling

Alice Millour and **Karën Fort**

karen.fort@sorbonne-universite.fr

Abstract

Non-standardized languages are a challenge to the construction of representative linguistic resources and to the development of efficient natural language processing tools: when spelling is not determined by a consensual norm, a multiplicity of alternative written forms can be encountered for a given word, inducing a large proportion of out-of-vocabulary words.

To embrace this diversity, we propose a methodology based on crowdsourcing alternative spellings from which variation rules are automatically extracted. The rules are further used to match out-of-vocabulary words with one of their spelling variants. This virtuous process enables the unsupervised augmentation of multi-variant lexicons without requiring manual rule definition by experts. We apply this multilingual methodology on Alsatian, a French regional language and provide (i) an intrinsic evaluation of the correctness of the obtained variants pairs, (ii) an extrinsic evaluation on a downstream task: part-of-speech tagging.

We show that in a low-resource scenario, collecting spelling variants for only 145 words can lead to (i) the generation of 876 additional variant pairs, (ii) a diminution of out-of-vocabulary words improving the tagging performance by 1 to 4%.

1 Natural Language Processing and Non-Standardized Languages

Non-standardized languages present a great productivity of spelling variants for a given word. The absence of standardized spelling points up the geographical and demographic variations that might exist and are otherwise smoothed down. This variability results in the coexistence of alternative written forms, hence in a large proportion of out-of-vocabulary words in the context of supervised machine learning.

In what follows, we first present our approach to generate spelling variant pairs based on an initial set of crowdsourced spelling variant pairs. This method is language independent and relies on resources that do not require expert knowledge, hence can easily be crowdsourced.

Second, we exemplify the use of such a method to reduce the proportion of unknown words that undermines supervised algorithms in the context of non-standardized languages.

1.1 Working with Multi-Variant Linguistic Resources

The question of variation in non-standardized languages naturally arises starting when one begins the process of corpus building (or collection). When dialectal and spelling variants overlap, inter- and intra-dialectal variations can be hard, not to say impossible, to untangle. In the following, we will design as "spelling variant" any variant due to either dialectal variation, spelling convention variation, or an accumulation of both.

Although one might chose to work on corpora produced in a controlled environment, in which the spelling conventions and writers are carefully chosen, this setup is unlikely to produce satisfying results on real-life data.

Producing linguistic resources, be it lexica, raw or annotated corpora, represents a cost that cannot be afforded for languages missing resources in the broad sense, including funding and experts. Crowdsourcing has proven to be a viable option to produce quality resources at a reduced cost (Chamberlain et al., 2013). Applying crowdsourcing to less-resourced non-standardized lan-

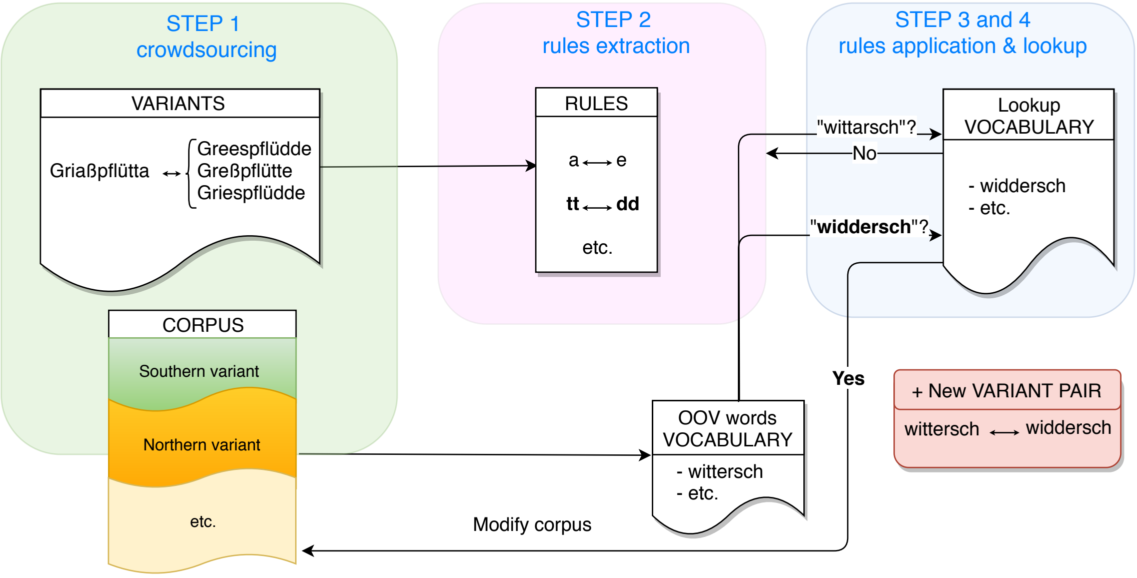

Figure 1: Data augmentation process.

guages presents additional difficulties such as accessibility to the speakers, or representativity of contents (Millour and Fort, 2018b).

Yet, when a community of speakers can be found on-line, it seems necessary to empower them to produce raw corpora and to document variability. In fact, the speakers appear to be, collectively, the only experts of the mechanisms at stake.

To meet this goal, we developed a crowdsourcing platform that collects two types of resources: (1) raw texts and (2) spelling variants on these texts. These resources are used to seed the unsupervised augmentation of the multi-variant lexicon following a process that we detail in Figure 1.

1.2 Process Overview

Given an existing linguistic resource (corpus, lexicon, or both) R_{Lookup} and a set of out-of-vocabulary words Voc_{OOV}, the process consists of four steps:

1. crowdsourcing spelling variant pairs,
2. automatic rules extraction,
3. application of the rules on elements of Voc_{OOV},
4. lookup of the resulting transformed spelling in R_{Lookup}.

These steps are detailed in sections 2 and 3 and illustrated with their application on Alsatian.

In the context of OOV words reduction in a given corpus, step 4 is followed by a transposition of those for which a variant has been identified in R_{Lookup}. Especially, in the context of supervised machine learning, one cannot expect to find all existing variants in a training corpus. By replacing an OOV word by one of its already known spelling variants, we make the most of the annotations we have at our disposal (see Section 4).

1.3 The Case of Alsatian

Alsatian is a French regional language counting 550,000 speakers in 2004 (Barre and Vanderschelden, 2004). This continuum of Alemannic dialects is an example of language in which the dialectal variants are not erased in the written form by any spelling system.

Initiatives such as the Orthal guidelines (Crévenat-Werner and Zeidler, 2008) have been developed to unify the Alsatian spelling while being respectful of its variations. Yet, these keep the variability (*Kìrisch* and *Kìch* are the Orthal version of *Kerisch* and *Kîch*, Northern and Southern possible versions for the word "church"), and are still unknown by a majority of Alsatian Internet users as shown by a recent survey (Millour, 2019).

For this reason, the dialectal variations (6 to 8 variants emerge from the continuum) combine with the variety of spelling habits, which might depend, for instance, on the linguistic backgrounds of the speakers.

Also, since there exist an active community of on-line speakers, Alsatian is a good candidate for crowdsourcing experiments.

2 Crowdsourcing Spelling Variants

We developed a slightly gamified crowdsourcing platform, Recettes de Grammaire[1] which allows us to collect (i) raw corpora in the shape of cooking recipes, (ii) part-of-speech annotations on the recipes, and (iii) alternative spellings. The platform is language independent and its source code is freely available on GitHub[2] under the CeCILL v2.1 license.[3]

We do not differentiate variants due to a variation in dialects, in spelling or in an accumulation of these two factors during collection.

The addition of a new spelling variant can be performed: (i) by adding a variant to any word that is present on the platform by clicking on a word cloud on the main page (see Figure 2), (ii) by dynamically editing the written contents on the website thanks to a feature called "Personally, I would have said it like that!", illustrated on Figure 3.

These features enable the participants to modify the content they read and further annotate in a manner that suits their writing habits. In fact, feedback we received on previous experiments led on crowdsourcing part-of-speech annotations for Alsatian (Millour and Fort, 2018a) highlighted the fact that some participants felt unrepresented by the texts on the platform, and that annotating dialectal or spelling variants they are not familiar with was an obstacle hard to overcome.

The interface allows the participants to provide an alternative spelling for either a single word or a sequence of words. Although the latter facilitates the task for the participants, it sometimes leads to alternative spellings which number of words did not match the original version, hence could not be immediately aligned. In such cases and when possible, the alternative spellings were manually aligned with the original version.

So far, the collected resource contains 367 variants provided by 10 participants for 145 words (with two to six variants per word), e.g. {*bìtsi*, *bessel*, *béssel*}, "a bit of".

The only information we possess about these participants is the languages they speak and their place of origin, when they fill it in in their profile. Based on the information provided by 8 of them, we can assume that 3 to 4 dialectal areas are covered by the towns of origin of the participants. No assumption can be made regarding their proficiency in Alsatian.

The size of this resource does not allow us to perform direct lookup for any out-of-vocabulary word me might encounter. However, we can use the aligned variants to identify substitution patterns, and extract sets of rules we apply to any OOV word as described in the following section.

3 Unsupervised Data Augmentation

3.1 Rules Extraction

In the manner of (Prokić et al., 2009), we used ALPHAMALIG[4], a multi sequence alignment tool, to perform the alignment of our variants necessary to the extraction of substitution patterns. The tool requires to be provided with an alphabet of symbols, weighted with the match, mismatch, insertion and deletion scores of given characters. Since we have no *a priori* knowledge of these scores, the only assumption we made is that vowels are more likely to match vowels than consonants and vice versa. Insertion and deletion are given the same scores for all characters. An example of the alignment obtained for four crowdsourced variants is given in table 1.

ˆ	G	A	L	-	R	**Ì**	**E**	**W**	L	**E**	K	**Ü**	**E**	C	H	**E**	$	(1)
ˆ	G	A	L	**E**	R	**I**	**E**	**B**	L	**E**	K	**Ü**	**E**	C	H	**A**	$	(2)
ˆ	G	A	L	**E**	R	-	**E**	**W**	L	**E**	K	**Ù**	-	C	H	**E**	$	(3)
ˆ	G	A	L	-	R	**Ì**	**A**	**W**	L	**A**	K	**Ü**	**A**	C	H	**A**	$	(4)

Table 1: Alignment of four variants of the Alsatian (compound) word for "carrot cake".

From the produced alignments we can identify substitution patterns of different degrees of rigidity, depending on the size of the context. We extract three sets of rules which either force the matching of the left (L), right (R) or both contexts (L+R).

The ˆ and $ characters, respectively representing the beginning and the end of a word, are in-

Figure 3: Spelling addition (1) and visualization (2) (highlighted words present at least one additional variant).

terpreted as elements of context. The rules are extracted from each pair of the combination of the aligned variants. From the aligned variants (1) and (2) showcased in Figure 1, four L+R rules are extracted: LR ↔ LER ; RÌE ↔ RIE ; EWL ↔ EBL ; HE$ ↔ HA$. The eight left-and-right-context-only corresponding rules are deduced from the L+R rules.

Since the result we seek is not to normalize the spelling, each rule can be used in both directions which are considered equally frequent.

From the 367 variant pairs collected for Alsatian, we extracted 213 unique rules using the left and right contexts, 227 rules using the left context only, 186 rules using the right context only.

3.2 Variant Identification and Filtering

Given a vocabulary of known words V_{lookup}, the identification of potential variants of an OOV word includes (i) optional preliminary filtering, (ii) application of rules, and (iii) lookup:

1. preliminary filtering (optional): if the unknown word is identified as a known proper noun in the lexicon, it is ignored.

2. application of the rules: for each set of rules, L+R, L, R, used in this order, the subset of rules applying to the original OOV word $R_{original\_word}$ is identified, and ordered by rule frequency. From this subset, we apply on the OOV word each possible *combination* of rules, meaning that if three rules A, B, C apply, the sequences of rules {A},{B},{C},{A;B},{A;C},{B;C} and {A;B;C} are applied.

3. lookup: the sequence of rules apply until the produced form is matched with a word present in V_{lookup}.

Although this “brute-force” method generates a great quantity of noise, the filtering operated by V_{lookup} leads to the matching of OOV word with existing variant candidates.

Since part of the dialectal and spelling variation mechanisms may be similar to some of the language morphological rules (such as gender, number, conjugation or declension), the generated variant pairs should be manually checked in context.

This phenomenon is illustrated by the analysis of the pairs generated for Alsatian in Section 5.

4 Evaluation on a Downstream Task

To illustrate the benefits of the identification of variant pairs, we evaluate its impact on a downstream task: part-of-speech (POS) tagging.

Previous experiments on Alsatian from (Millour and Fort, 2018b) have shown that using multiple variants for training can lead to a drop of accuracy on the sections of the evaluation corpus which do not match the variants represented in the training corpus (-1.4% accuracy when a corpus of Strasbourg specific variant is added in the training of a Southern variant only).

In this context, we use our methodology to match OOV words from the evaluation corpus with their potential spelling variant appearing in the training corpus.

It is important to understand that this process is independent from the tagger, and occurs after it has been trained. The extraction of pairs is performed at the time of annotation on a previously **unseen** corpus.

4.1 Language Resources and Tools Used for Evaluation

Experiments in POS tagging Alsatian include our previous work (Millour and Fort, 2018b), which uses `MElt` (Denis and Sagot, 2012), a freely available sequence labeller achieving at best 84% accuracy when the variants in the training and the evaluation corpus are carefully controlled. Experiments using word embeddings have been also been carried on Alsatian by (Magistry et al., 2018), using a raw corpus of 200 000 tokens and reaching 91% accuracy.

In the following experiments, we chose to train `MElt`, which enables us to take advantage of available lexicons existing for Alsatian. The differential in performance is more interesting to us than the performance *per se*, which is why we chose not to focus on testing our methodology on other taggers.

Two POS-tagged corpora are available for Alsatian. Both are made of texts produced in an uncontrolled environment (such as `Wikipedia`[5]) and contain multiple variants of the language:

- The `Crowdsourced Corpus` (Millour and Fort, 2018b), $C_{rowd}C$, annotated by benevolent participants on a dedicated crowdsourcing platform `Bisame`[6] with the universal POS tagset (Petrov et al., 2012) extended with two categories: APPART (preposition-determiner contraction), and FM (foreign words). The corpus contains 9,282 tokens (439 sentences), and is available under CC BY-NC-SA license. The accuracy of the annotations provided by the benevolent participants has been evaluated to 93% (Millour and Fort, 2018b).

- The `Annotated Corpus for the Alsatian Dialects` (Bernhard et al., 2018a), $T_{rad}C$, annotated with the tagset described above, extended with the categories EPE (epenthesis) and MOD (modal verb) (Bernhard et al., 2018b). The corpus contains 12,570 tokens (533 sentences) and is available under CC BY-SA license. It was annotated manually by expert linguists.

We manually corrected $T_{rad}C$ to match the tagset used in $C_{rowd}C$.

The corpus resulting from the concatenation of the two corpora, $C_{oncat}C$, was used for the following experiments. We performed a cross validation on 4 subdivisions (80% used for training, $C_{oncat}C80$, 20% for the evaluation, $C_{oncat}C20$).

We also have at our disposal two lexica:

- a multi-variant lexicon $M_{ultiVar}L$ of 54,355 entries annotated with their POS, containing grammatical words (Bernhard and Ligozat, 2013), verbs from (Steiblé and Bernhard, 2016), and various entries from (i) the Office for Alsatian Language and Culture (OLCA)

[5] See `https://als.wikipedia.org`

[6] See `https://bisame.paris-sorbonne.fr`.

bilingual lexicons, (ii) the dictionary compiled by the Culture and Heritage of Alsace Association (ACPA), and (iii) a multilingual French-German-Alsatian dictionary (Adolf, 2006).

- the `Lexicon of Place Names in the Alsatian Dialects` which contains 1,346 entries (Bernhard, 2018), used during training only.

4.2 Application of the Methodology

Since the identification of potential variant pairs depends on the initial conditions of the experiment, *i.e.* the corpus, and optionally, the lexica used to train the model beforehand, we present two experiments in which these parameters vary.

For each experiment, we extract from the training corpus the vocabulary VT_lookup and from the external lexicon, the vocabulary VL_lookup. We use the set of rules presented in Section 3.1.

We prioritize the lookup in VT_lookup to further ease the evaluation of the generated pairs relying on the context.

If the length of the OOV word is less or equal to four characters (^ and $ excluded), only the L+R rules are applied: it has been observed in preliminary tests that shorter words were more likely to lead to erroneous matching such as *das* (determiner) /*dass* (subordinating conjunction) or *dien* (auxiliary) /*dene* (determiner). Additionally, we force the variant candidates to have the same letter case as the OOV word.

After variant pairs have been generated, the OOV words are replaced by their variant candidate, and the pre-trained model is applied on the transposed evaluation corpus. After the corpus has been tagged, the transposed words are replaced by they original form.

4.3 Experiment 1: Uncontrolled Setup

By "uncontrolled", we mean that training and evaluation corpora are both extracted from a shuffled corpus that contains multiple variants.

Our first model is trained with $C_{oncat}C80$ (17,136 words) and evaluated on $C_{oncat}C20$ (4,374 words) before and after its transposition. After the application of the three sets of rules, using both the vocabularies extracted from $C_{oncat}C80$ and $M_{ultiVar}L$ for the lookup, 56 variant pairs were discovered and the same number of words were transposed.

	Before transp.	After transp.
Overall	0.859	0.864
OOV words	24%	22%

Table 2: Accuracy of the model trained on multi-variant corpora, before and after the corpus transposition.

The proportion of OOV words was diminished by around 2% resulting in an improvement of the tagging performance of 0.5 points (see table 2). This minimal impact is expected since the performance on "known words" is around 10 points higher than on OOV words in this setup. In fact, considering the sizes of our corpora, lowering the number of OOV words of 100 is expected to improve the overall results of 0.2 points.

4.4 Experiment 2: Controlled Setup

By "controlled", we mean that training and evaluation each contain a specific variant of Alsatian selected in a multi-variant corpus. In the following, we compare homogeneous and heterogeneous setups, in which the training and evaluation corpora either contain the same or distinct variants of Alsatian.

To highlight the effect of our methodology in an heterogeneous context, met when no corpus of each possible variant is available, we manually split $C_{oncat}C$ in two sub-corpora $N_{orth}C$ (4,880 words) and $S_{outh}C$ (7,690 words) based on the frequencies of the -e and -a noun endings, which are specific of the Northern and Southern variants respectively.

The results of these experiments are presented in table 3.

Unsurprisingly, the best results are obtained when training and evaluation corpora are of the same variant. Yet, we can observe that in this setup, the effect of transposition to identified variants has a higher impact on the proportion of OOV words and the tagging performances.

The efficiency of the methodology largely depends on: (i) the respective and relative sizes of the training and evaluation corpora, (ii) the variation in variants existing between them.

This experiment shows that the performance of a tool trained on a given corpus can be improved by modifying the corpus it is applied on to match the vocabulary it was trained with.

	$N_{orth}C20$		$S_{outh}C20$	
$N_{orth}C80$			Before transp.	After transp.
Overall	0.853		0.714	**0.752**
OOV words	40%		54%	52%
$S_{outh}C80$	Before transp.	After transp.		
Overall	0.788	**0.809**	0.864	
OOV words	51%	48%	29%	

Table 3: Accuracy of the model trained on mono-variant corpora, before and after the corpus transposition.

5 Obtained Results

The newly created resource contains 876 pairs of variants, from which 400 were identified in the training corpus, and 476 in the lookup lexicon. The size of the created resource depends on the size of the lookup corpora and lexicon, and on the number of rules. The application of the method to any unpreviously seen text may increase the number of variant pairs.

A subset of 60 pairs of these automatically generated variant pairs were submitted to an Alsatian teacher, familiar with both the dialectal and spelling variants. The pairs were presented in the context of their sentence. The expertise of the teacher was used to measure the precision of the pairs, not the recall.

Among the 60 pairs:

- 30 were actual dialectal or spelling variants.
- 13 were pairs of different forms of identical words, *e.g.*: *ìhm* (dative pronoun) / *ìrhem* (genitive pronoun), *kált* (feminine adjective) / *kálte* (masculine adjective), *wùrd* (future auxiliary) / *wärd* (conditionnal auxiliary) etc.
- 10 were caused by erroneous matching we managed to correct by making the adjustments described in section 4.2, i.e. (i) forcing the case of potential variants to match the case of the original OOV word, (ii) limiting the application of rules considering only left or right context to words which size is over four characters.
- 7 were caused by erroneous matching we were not yet able to correct *e.g.* *kräfti* ("strongly", adverb) / *kräftiger* ("stronger", adjective), *mine* ("mine", determiner) / *meine* ("believe", verb) etc.

These results show that the generated variant pairs should be hand-checked, a task that can itself be crowdsourced, provided that we have access to the context of appearance of both elements.

By construction, the newly generated pairs will not provide additional substitution rules. Yet, they provide information on the frequency of the substitution patterns.

Additionally, the erroneous variant pairs manually filtered out can be used as counter examples of variants, and further used to train variant classifiers (see, for instance, (Barteld, 2017)).

6 Related Work

Dealing with non-standardized, less-resourced languages, takes us to the limits of NLP: first, we have no standard to rely on and not enough expert linguists to help us, and second, very few language resources are available for us to work with, even raw corpora. These two constraints are rarely met in the literature and, to our knowledge, the solution we propose has never been used before.

However, it closely relates to other experiments that involve at least a standard spelling and sometimes an expert linguist supervision. One such example is VARD 2, a tool that allows to manually and automatically standardize Early Modern English (Baron and Rayson, 2008, 2009). Another one concerns the Basque language (Etxeberria Uztarroz et al., 2014) and proposes a solution to map the variations of the language to the standard form using an existing morphological analyzer and a parallel corpus. Obviously, a lot of more or less recent publications concern the design and use of morphophonological rules, in particular in various flavors of FSTs, but most of them require the intervention of a highly-skilled linguist.

Among such publications, the work by Kimmo Koskenniemi on modeling regular correspondences between Finnish and Estonian is particularly inspiring (Koskenniemi, 2013), but inapplicable in our case. The same goes for the type for work described in (Theron and Cloete, 1997), in which the rules are automatically extracted but with a known (morphological) goal.

The closest work to ours is that described in (Barteld, 2017), as it focuses on detecting spelling variants in Middle Low German unrelated to a standard. Yet, the described method requires the training of a classifier to filter the generated pairs. This classifier is based on a resource that contains 1,834 pairs of spelling variants, a resource that is unavailable for most non-standardized languages.

Regarding Alsatian more specifically, Bernhard (2014) aligns spelling variants relying on a multi-variant bilingual French-Alsatian lexicon annotated with part-of-speech and a phonetization of Alsatian. This high dependency on existing resources make this method challenging to adapt to other languages for which the only available experts are the very speakers of the language.

7 Conclusion

We have presented a method to automatically generate pairs of spelling variants based on a small subset of crowdsourced pairs.

The method does not require manual rules definition by experts and is language independent. The resources needed to perform variant pair detection can be easily produced by the speakers, who hold the knowledge of the of the variation mechanisms. The crowdsourcing of variants, unlike that of POS tags, requires no prior training.

In fact, even the expertise necessary for the validation of the variant pairs is about to be transferred to the participants of the crowdsourcing platform.

The originality of this methodology is that once the rules have been extracted, the process feeds from previously unseen texts. This is particularly useful in a less-resourced scenario where a raw corpus is being collected from various sources.

The code of both the gamified crowdsourcing platform and the variants generation is freely available on GitHub[7]. The created multi-variant lexicon is also available under a CC license.

We plan to extend this work to other non-standardized languages. We have started working on adapting the platform to Mauritian, a French-based Creole, the morphology of which is very different from that of Alsatian.

Abstract

This paper describes a new approach for the task of contextual emotion detection. The approach is based on a neural feature extractor, composed of a recurrent neural network with an attention mechanism, followed by a classifier, that can be neural or SVM-based. We evaluated the model with the dataset of the task 3 of SemEval 2019 (EmoContext), which includes short 3-turn conversations, tagged with 4 emotion classes. The best performing setup was achieved using ELMo word embeddings and POS tags as input, bidirectional GRU as hidden units, and an SVM as the final classifier. This configuration reached 69.93% in terms of micro-average F1 score on the main 3 emotion classes, a score that outperformed the baseline system by 11.25%.

1 Introduction

Emotions are an intricate part of human communication. Being able to interpret and react to the emotions of others allows one to better communicate. Emotion information can be extracted from a variety of physiological sources, such as electroencephalography (EEG) signals (Zhang et al., 2016), skin temperature (Li and Chen, 2006), speech signals (Trigeorgis et al., 2016) and facial expressions (Mao et al., 2015), as well as text (Yassine and Hajj, 2010).

The rise of social media and the availability of human-written online diaries, blog posts, and comments has lead to an increase in research on the automatic detection of sentiment and emotion from textual data.

Sentiment analysis and opinion mining can range from coarse-grained binary classification of texts into positive or negative classes to finer-grained classification into a variety of emotion categories, such as happy, sad, angry, and scared. Such a classification is useful in business and marketing (Medhat et al., 2014), and a variety of downstream NLP applications, such as text-to-speech, to maintain the emotion present in text, and human-computer interaction in order to take into account the emotional state of users and make responses more human-like (Hirat and Mittal, 2015).

Fine-grained emotion detection based solely on text is a challenging task. As only linguistic cues are available, facial expressions and voice features, which are known to be discriminating (Poria et al., 2016), cannot be used. In addition, several emotions can be expressed textually by the same linguistic cues, such as emotion keywords, interjections, and emojis (Liew and Turtle, 2016). Finally, many pieces of text, especially online comments, posts, and tweets are too short to allow for correct classification. These challenges highlight the importance of using contextual information in order to detect the emotion conveyed in a piece of text.

The goal of this work is to investigate the effectiveness of different models using neural networks and Support Vector Machines (SVM) for contextual emotion detection in textual conversations.

2 Related Work

Textual emotion detection has typically been addressed as a multi-class classification task, where a text is classified into different emotional categories, ranging from basic emotions to finer-grained emotional classes. Studies focusing on emotion detection have made use of different corpora and different evaluation metrics.

Dini and Bittar (2016) broke down the task of emotion detection from tweets into a cascade of decisions: classifying tweets into emotional and non-emotional categories, and then tagging the emotional tweets with the appropriate emotion label. For the latter, they compared a symbolic system using gazetteers, regular expressions, and graph transformation, with a machine learning system using a linear classifier with words, lemmas, noun phrases, and dependencies as features. Using their collected corpus of emotional tweets, the rule-based approach achieved an F1 score of 0.41, while the machine learning approach yielded an F1 score of 0.58 on 6 emotion classes.

Mohammad and Bravo-Marquez (2017) made use of an SVM regression model to determine the intensity of 4 emotions: anger, fear, joy, and sadness in a dataset of tweets that they have previously collected and annotated. As features, they used word and character n-grams, word embeddings trained using the word2vec skip-gram model (Mikolov et al., 2013), and affect-related lexical features. Using the Pearson correlation coefficient as evaluation metric, they demonstrated that word embeddings yield better results than n-gram features. They achieved their best average result of 0.66, using a combination of word embeddings and lexical features.

Abdul-Mageed and Ungar (2017) also collected their own dataset of emotional tweets using emotion hashtags. They trained word embeddings on the training data, employed a gated recurrent neural network (Cho et al., 2014) as a classifier and achieved an average F1 score of 0.87 over 3 emotion datasets, labelled with 8 emotions.

Abdullah and Shaikh (2018) proposed an approach to detect the intensity of affect in tweets. Their features include feature vectors extracted using the *AffectiveTweets* package of *Weka* (Holmes et al., 1994), as well as word2vec and doc2vec (Le and Mikolov, 2014) embeddings. They developed three models using different subsets of the feature set as input to either a dense feed-forward network or a Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) network. Using the dataset of SemEval 2018 task 1 (Affect in Tweets) (Mohammad et al., 2018), they achieved their best Spearman correlation score of 0.69 over 4 emotions by averaging over the outputs of the three models.

More recently, Khanpour and Caragea (2018) focused on domain-specific emotion detection. They created a dataset of 2107 sentences taken from online forums on the Cancer Survivors Network website[1]. In order to combine the strengths of lexicon-based and machine learning approaches, they proposed a model that uses word2vec embeddings as input to a Convolutional Neural Network (CNN) (LeCun et al., 1999). The CNN generates feature vectors which are then augmented with domain-specific lexical features. The combined features are then used as input to an LSTM network which classifies the texts into 6 different emotion categories.

While most of the literature has focused on the detection and assessment of emotions in online textual data, few researchers have investigated emotion detection in textual conversations. We argue that the detection of emotions from dialogues poses new challenges compared to emotion detection from monologues, as the utterances made by different interlocutors can influence differently the emotional state of a speaker.

In this work, we investigate the effectiveness of neural feature extraction for the task of emotion detection in short dialogues.

3 Dataset and Task

The dataset used in this work is taken from Chatterjee et al. (2019b). It consists of short 3-turn dialogues between two speakers (turn 1 uttered by speaker 1, turn 2 uttered by speaker 2, and turn 3 uttered by speaker 1 again). Table 1 shows two samples of the dataset[2].

The goal is to detect the emotion of speaker 1 in turn 3, taking into account the previous turns. The data is annotated with 4 emotions: *happy*, *angry*, *sad*, and *others*. In order to simulate a real-life task, the distribution of the labels in the dataset is highly imbalanced: 50% of the training data belongs to the *others* class, while 14%, 18%, and 18% of the training data is dedicated to classes *happy*, *angry*, and *sad*, respectively. The test and development sets are even more imbalanced, with 85% of the samples labelled as *others*. Table 2 summarizes some statistics of the dataset.

4 The Model

Figure 1 shows the overall architecture of our model for the task of contextual emotion detection. The model is composed of two main components: 1) the neural feature extractor and 2) the classifier.

4.1 The Neural Feature Extractor

As shown in Figure 1, the neural feature extractor is a recurrent neural network with an attention mechanism. The feature extractor is responsible for creating dense vector representations for each dialogue turn. As a result, the model uses 3 feature extractors, one for each dialogue turn.

Each neural feature extractor is composed of an input layer, a recurrent layer, and an attention layer, explained below.

The Input Layer takes as input the vector representations of each word in the corresponding dialogue turn. Each dialogue turn is a sequence of tokens, represented as a vector $[x_{i,1}, x_{i,2}, \ldots, x_{i,t}, \ldots, x_{i,n}]$, where $x_{i,t}$ is the corresponding vector for the t-th word in the i-th dialogue turn, and n is the length of the i-th turn. The vector representation for each token ($x_{i,t}$) is composed of the word embedding corresponding to the token, concatenated with a one-hot representation of the token's part-of-speech (POS) tag.

The Recurrent Layer takes as input the token vectors ($[x_{i,1}, x_{i,2}, \ldots, x_{i,t}, \ldots, x_{i,n}]$), and processes them in a forward and a backward passes. In the forward pass, the content value of the hidden layer at a specific time-step is calculated using the value of the input at the current time-step, and the content value of the hidden layer in the previous time-step.

Equation 1 shows how the content value of the hidden layer is calculated at a specific time-step t, where x_t represents the input value in the current time-step, and h_t and $h_{t\pm1}$ represent the content value of the hidden node in the current and previous/next time-steps (in the forward or backward pass), respectively, and f_h is the function that calculates the value of h_t using x_t and $h_{t\pm1}$. Subsequently, the output of the hidden layer is calculated using Equation 2, where y_t is the output of the hidden layer at time-step t, and f_y is the function that calculates the output value based on h_t.

$$h_t = f_h(x_t, h_{t\pm1}) \tag{1}$$

$$y_t = f_y(h_t) \tag{2}$$

The Attention Layer is a function that automatically assigns weights to the output of the recurrent layer at each time-step, and calculates the weighted sum of the outputs using their corresponding weights (Vaswani et al., 2017). Following several works that have shown significant improvement in text classification with the use of attention (e.g. Yang et al., 2016; Zhou et al., 2016; Wang et al., 2016; Cianflone et al., 2018), we incorporated an attention mechanism in our contextual emotion detection framework. Equation 3 shows the overall mechanism of our attention layer, where $\omega_{t'}$ represents the corresponding weight for the output of the recurrent layer at time-step t' in, and n is the number of time-steps (i.e. the length of the dialogue turn).

$$Attention = \sum_{t'=1}^{n} y_{t'}\omega_{t'} \tag{3}$$

In our model, the weights are calculated by applying a single N-to-1 feed-forward layer on

the output of the recurrent layer at each time-step (where N is the size of the output of the recurrent layer), concatenating the results, and applying a softmax over them. Equations 4 and 5 show the mechanisms used to calculate the weights, where w corresponds to the weights in the single-layer neural network, and ν_t is the single value, which is the result of feeding y_t to the fully-connected layer.

$$\nu_t = y_t \times w \tag{4}$$

$$\omega = Softmax([\nu_1, \nu_2, \nu_3, \ldots, \nu_n]) \tag{5}$$

4.2 The Classifier

As shown in Figure 1, we experimented with two types of classifiers at the output layer: A fully-connected neural network, followed by a softmax activation function, and an SVM, which takes as input the neural representations generated by the 3 latent feature extractors for each dialogue turn.

The neural classifier is trained jointly with the neural feature extractors, while the SVM classifier is completely trained after each training epoch of the neural network, using the features extracted by the 3 neural feature extractors.

5 Experimental Setup

The neural network components of our model were developed using PyTorch (Paszke et al., 2017) and the SVM was developed using the Scikit-learn library (Pedregosa et al., 2011). In this section, we will explain the different setups that we experimented for the task of contextual emotion detection.

5.1 Word Embeddings

In order to test our model, we experimented with two different pretrained word embeddings. As the first word embedder, we chose GloVe (Pennington et al., 2014), which is pretrained on 840B tokens of web data from Common Crawl, and provides 300d vectors as word embeddings. As our second word embedder, we experimented with ELMo (Peters et al., 2018), which produces word embeddings of size 1024, and is pretrained on the 1 Billion Word Language Model Benchmark[3] (Chelba et al., 2014).

The main reason for choosing these two word embedders was to evaluate the effect of their embedding mechanisms for our task. As opposed to GloVe which assigns a word embedding to each token, the ELMo word embedder calculates the embedding for each token from its constituent characters by also taking into account its textual context. We suspected that this approach would lead to better results in our task (see Section 6).

5.2 POS Tags

The spaCy library[4] was used for tokenization and POS tagging, and the Penn Treebank tagset standard (Marcus et al., 1993) was followed for assigning POS tags to tokens. This lead to one-hot vectors for POS information of size 51.

5.3 Recurrent Units

Long Short-term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Units (GRU) (Cho et al., 2014) were both experimented with as the building blocks of the recurrent layer. For both LSTM and GRU, 2 layers of 25 bidirectional recurrent units were stacked.

5.4 Neural Network Optimization

The Adam optimizer (Kingma and Ba, 2014) with a learning rate of 10^{-4} was used to train the neu-

[3] The selected versions of GloVe and ELMo lead to the best results in our task. We also experimented with other versions of the two, but their performances were inferior.

[4] `https://spacy.io/`

ral network. Cross-entropy with class weights was used as the loss function. In order to handle the imbalanced class distribution in the dataset (see Table 2), the corresponding weight for each class was calculated proportional to the inverse of the number of samples for that class in the training data. This way, more penalty was applied to the network when an error was made on a sample from a minority class rather than a more frequent one.

Minibatches of size 32 were used during training and testing, and zero-padding was applied in order to handle different input sequence lengths. In order to minimize padding, samples with similar average lengths of tokens over the three turns were put in the same batch.

Finally, in order to avoid the exploding gradient problem (Pascanu et al., 2012), gradient clipping with a norm of 0.5 was applied.

5.5 SVM Hyperparameters

The SVM utilizes a polynomial kernel with degree of 4. To set the parameter γ, the `svm.SVC` model in Scikit-learn was initiated with its parameter `gamma` set to `auto`, which automatically sets γ to the inverse of the number of features extracted by the neural feature extractor. In our model, this value was set to 1/150, since each of the three neural feature extractors extracts 50 features from the dialogue turn that it handles.

5.6 Overall Training Process

As indicated in Section 4.2, the neural classifier was trained jointly with the neural feature extractors, while the SVM was trained separately after each epoch, using the extracted features on the training data.

The models with either neural or SVM classifier were trained for 50 epochs, and the model's parameters were saved after each training epoch. The optimal parameters were then picked as the ones that led to the highest micro-average F1 score on the three main emotion classes (all except class *other*) on the development dataset. This final model with the optimal trained parameters was then evaluated on the test set.

6 Results

The official evaluation metric used at the EmoContext shared task is the micro-average F1 score over the three main emotion classes, i.e. *happy*, *angry*, and *sad* (ignoring the 4th class, *others*).

Figure 2 shows the performance of each model on the development dataset, throughout the training process. As Figure 2 shows, using both the neural classifier and the SVM classifier, the models with GRU as the recurrent units and ELMo embeddings as input features were generally superior to the others.

The notation *<type-of-recurrent-unit>+<type-of-classifier> with <type-of-input-features>* is used in the rest of the paper, to refer to each model; for example, *LSTM+NN with GloVe* refers to the model that uses LSTM units in the recurrent layer, fully-connected neural layer as classifier, and GloVe embeddings as input; whereas *GRU+SVM with ELMo+POS* denotes the version of our model with GRU units in the recurrent layer, SVM as the classifier, and ELMo embeddings and one-hot encoded POS tags as input.

As indicated in Section 5.6, the final versions of the models were chosen based on their performance on the development dataset, i.e. for each model, the final set of trained parameters were the one that yielded the maximum micro-average F1 score on the three emotion classes on the development dataset.

The results achieved from our models are also compared with the baseline system, provided by the EmoContext 2019 shared task (Chatterjee et al., 2019a). The baseline system is composed of a neural network with 128 LSTM units in the hidden layer, and as input features, uses the GloVe word embeddings, pretrained on 6 billion tokens from Wikipedia 2014 and the Gigaword 5 corpus[5].

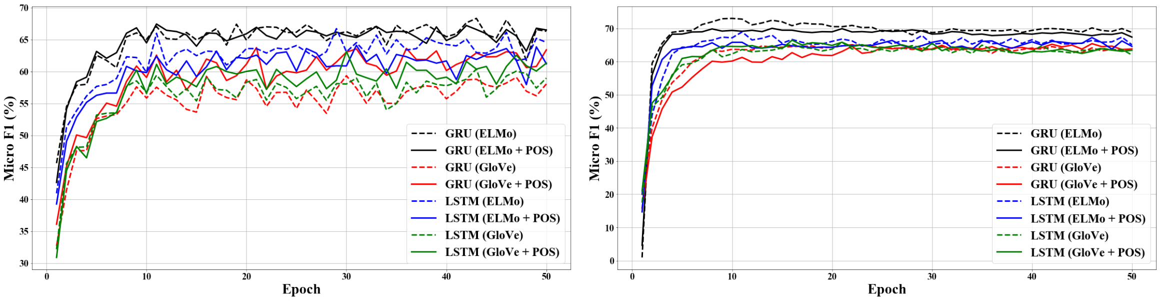
Table 3 shows the performance of each model[6], where the best micro-average F1 scores are highlighted in bold. The results show that the model *GRU+SVM with ELMo* yields the best performance of 73.03% on the development data, while the model *GRU+SVM with ELMo+POS* outperforms all the other models on the test dataset with a micro-average F1 score of 69.93%, by being marginally better than *GRU+SVM with ELMo*[7].

The results also show that, with the exception of the two models *LSTM+NN with GloVe* and *GRU+NN with GloVe* which have inferior perfor-

[5] `https://catalog.ldc.upenn.edu/LDC2011T07`

[6] At the time of writing this paper, the F1 score of the baseline model had not been released for each emotion class.

[7] The result that we submitted to the EmoContext shared task was slightly higher than the current result (70.72%), which was achieved by also using the features from the development dataset to train the SVM classifier.



(a) With the neural classifier.

(b) With the SVM classifier.

Figure 2: Performance of the model (in micro-average F1 score over the three main emotion classes) on the development dataset, as a function of the number of training epochs

mance than the baseline system on the test dataset, all the other models significantly outperform the baseline model on both development and test data.

7 Discussion

To better understand the results, we analyzed the effect of different components of the model.

7.1 Effect of Input Features

The results in Table 3 demonstrate that the models that use ELMo as word embeddings have a significantly higher performance than the ones with GloVe. We believe that this is due to two main reasons: 1) The ELMo word embedder is character-based, which allows it to better handle out-of-vocabulary words, and 2) ELMo takes into account the textual context of the token when extracting the word embedding.

Table 3 also shows that the use of POS tags leads to a significant improvement with the models that utilize GloVe word embeddings. On the other hand, for the models that use ELMo embeddings as input, this is not the case. As Table 3 shows, in several occasions, the use of POS tags has even reduced the performance of ELMo-based models. We believe that, in the case of GloVe, where the word embeddings are context-independent, POS tags can improve token representations to also take into account the textual context in which the tokens have occurred. However, since ELMo already takes into account the textual context when extracting the token representations, POS tags do not help much and can even be redundant in some cases.

7.2 Effect of the Recurrent Units

The results in Table 3 show that for the models that incorporate ELMo embeddings, the ones that use GRU in their recurrent layer significantly outperform the ones with LSTM; however, this behavior cannot be observed in GloVe-based models, as we can see several cases, where the LSTM-based models are slightly better.

It could be concluded that, for the current task, since GloVe word embeddings are context-independent, a stronger recurrent unit is required to capture the context, while in the case of ELMo, where context is already taken into account, a simpler recurrent unit such as GRU is enough while being less prone to overfitting.

7.3 Effect of the Classifiers

Table 3 shows that, in almost all cases, the models with the SVM classifier significantly outperform the ones with the neural classifier. We believe that, although the neural network may have been able to reach similar results as the SVM, the latter reached this performance using less fine-tuning due to its explicit design to optimize the margin size between classes.

On another note, Figure 2 shows that the models with the SVM classifier were significantly more robust and demonstrated much less performance fluctuation during training than the ones with the neural classifier. We believe that this is due to the more deterministic nature of SVM in comparison to the neural networks.

However, the most important drawback of the SVM was the training time: since the SVM classifier was trained separately from feature extractors, training it entailed additional training time to the model. All being said, we believe that, if training

Model	Input Feature	F1 Score on Development Data				F1 Score on Test Data

Table 3: The performance of each model on the development and test datasets, in terms of F1 score on each emotion class, and micro-average F1 over the three main emotion classes. The AVERAGE is computed over the proposed models and does not include the baseline.

time is not a concern, the SVM classifier is a better option than the neural one.

An interesting finding regarding the SVM classifier is that, in contrast to the neural network where applying class-weights to the loss function helped improve the performance of the models, applying class-weights to the SVM decreased its performance.

7.4 A Closer Look at Emotion Classes

The row labelled *AVERAGE* in Table 3 provide information regarding the difficulty of detecting each class. Table 3 shows that, among the three main classes, *happy*, *angry*, and *sad*, the class *happy* was the most difficult to detect.

Table 2 shows that the low average F1 score for class *happy* is probably due to the significantly smaller number of samples with this class in the training data (14%) in comparison to the samples from the other two emotion classes (18% and 18%). Although the weighted loss functions (see Section 5.4) somehow managed to handle the imbalanced class distribution in the data, the optimal weights are not necessarily proportional to the inverse of the frequency of classes.

7.5 Quality of the Extracted Neural Features

To better understand the contribution of the extracted neural features from the feature extractors, we calculated the mutual information between the values of each neural feature and the classes.

Figure 3 shows the average and the standard deviation of the mutual information between the features extracted from each neural feature extractor in each model and the classes in the training data. Since both the neural and the SVM classifiers use the same set of neural features, we did not differentiate between models with similar neural feature extractors and different classifiers.

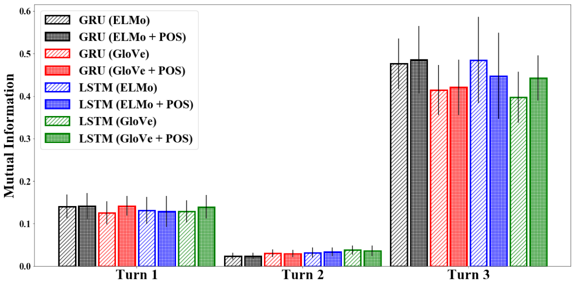

Figure 3: The average mutual information between the features of each dialogue turn, extracted by each neural feature extractor, and the classes.

As Figure 3 shows, in all cases, the features extracted from the third turn of the conversation have the highest mutual information with the classes, and the ones from the second turn have the lowest. This agrees with the nature of the dataset, where the label is assigned to the emotion of speaker 1 (who uttered dialogue turns 1 and 3) after the third turn is uttered. This also indicates that the nature of emotion detection in the context of dialogues is different from that in monologues in two ways: not only do the utterances by different speakers contribute differently to the emotional state of a speaker, but also the timing of the utterances by the same speaker has an impact on the contribution of that utterance to the emotion classification.

Figure 3 shows that the difference in average mutual information between the extracted features and the emotional classes are higher for features from the third (i.e. the most recent) dialogue turn. As expected, the features from the ELMo-based models have significantly higher mutual information with the classes than the ones from the GloVe-based models. The features from the third dialogue turn in models with GRU have slightly higher mutual information than the ones from the models with LSTM. However, the standard deviation between the features extracted by the GRU-based models are significantly smaller than the ones with LSTM, showing that between the models with LSTM and the ones with GRU, the features extracted from the models with GRU had more similar amount of contribution to the classification task than the ones from the LSTM. This has led to the GRU-and-ELMo-based models outperforming the others.

A surprising finding is that the neural features extracted by the GRU-based models from the second dialogue turn have the least mutual information with the classes in comparison to the ones from the other models. Observing this, we experimented with our classifiers by disregarding the neural features from the second turn; however, this lead to a slight performance drop. We hypothesize that, although the neural features from the second dialogue turns bring only a small contribution to the classification, the GRU-based models tend to focus more on the features from the other two turns. This leads to the second feature extractor being less focused upon, and as a result, being less trained than the ones from other models.

8 Conclusion and Future Work

In this paper, we proposed a model for the task of contextual emotion detection. We evaluated our model with the EmoContext 2019 shared task dataset (Chatterjee et al., 2019b), which consists of 3 turn conversations tagged with one of the labels: *happy*, *sad*, *angry*, and *others*, based on the emotion present in the last dialogue turn.

The proposed model utilizes an attention-based recurrent neural network. We experimented with GloVe and ELMo embeddings, alongside POS tags as input, LSTM and GRU as recurrent units, and a neural or an SVM classifier. The best result on the test dataset was achieved with ELMo and POS tags as input, GRU as recurrent units, and SVM as the final classifier. Using this setup, we reached a performance of 69.93% in terms of micro-average F1 score which is a significant improvement over the baseline of 58.68%.

Three future directions can be proposed. The first is to investigate a more effective way of handling the imbalanced distribution of labels in the dataset. As a example, methods for finding the optimal class-weights for training the models can be investigated.

Secondly, the use of different number of features for each dialogue turn can be studied. As shown in Figure 3, features extracted from different dialogue turns had different levels of contribution to the final classification. In that case, more features could be extracted from turns 3 and 1 (uttered by the same speaker) in comparison to turn 2, which has the least contribution to the classification.

Lastly, knowing that the SVM classifier is capable of outperforming the neural one, studies can be performed in order to make the extracted features more suitable for the SVM classifier.

Abstract

Word meaning change can be inferred from drifts of time-varying word embeddings. However, temporal data may be too sparse to build robust word embeddings and to discriminate significant drifts from noise. In this paper, we compare three models to learn diachronic word embeddings on scarce data: incremental updating of a Skip-Gram from Kim et al. (2014), dynamic filtering from Bamler and Mandt (2017), and dynamic Bernoulli embeddings from Rudolph and Blei (2018). In particular, we study the performance of different initialisation schemes and emphasise what characteristics of each model are more suitable to data scarcity, relying on the distribution of detected drifts. Finally, we regularise the loss of these models to better adapt to scarce data.

1 Introduction

In all languages, word usage can evolve over time, mirroring cultural or technological evolution of society (Aitchison, 2001).

For example, the word "Katrina" used to be exclusively a first name until year 2005 when hurricane Katrina devastated the United States coasts. After that tragedy, this word started to be associated with the vocabulary of natural disasters.

In linguistics, *diachrony* refers to the study of temporal variations in the use and meaning of a word. Detecting and understanding these changes can be useful for linguistic research, but also for many tasks of Natural Language Processing (NLP). Nowadays, a growing number of historical textual data is digitised and made publicly available. It can be analysed in parallel with contemporary documents, for tasks ranging from text classification to information retrieval. However, the use of conventional word embeddings methods have the drawback to average in one vector the different word's usages observed across the whole corpus. This *static* representation hypothesis turns out to be limited in the case of temporal datasets.

Assuming that a change in the context of a word mirrors a change in its meaning or usage, a solution is to explore diachronic word embeddings: word vectors varying through time, following the changes in the global context of the word. While many authors proposed diachronic embedding models these last years, these methods usually need large amounts of data to ensure robustness.

However, temporal datasets often face the problem of scarcity; beyond the usual scarcity problem of domain-specific corpora or low-resource languages, a temporal dataset can have too short compared to the volume of the full dataset.[1] Moreover the amount of digital historical texts is limited for many languages, particularly for oldest time periods.

This paper addresses the following question: In case of scarce data, how to efficiently learn time-varying word embeddings? For this purpose, we compare three diachronic methods on several sizes of datasets. The first method is incremental updating (Kim et al., 2014), where word vectors of one time step are initialised using the vectors of the previous time step. The second one is the dynamic filtering algorithm (Bamler and Mandt, 2017) where the evolution of the embeddings from one time step to another is controlled using a Gaussian diffusion process. Finally, we experiment dynamic Bernoulli embeddings (Rudolph and Blei, 2018) where the vectors are jointly trained on all time slices.

These three models are briefly described in section 3. The hyper-parameters are specifically tuned towards efficiency on small datasets. Then, we explore the impact of different initialisation

[1] A short period can be one month or less, depending on the domain.

scheme and compare the behaviour of word drifts exhibited by the models. Finally, we experiment regularising the models in order to tackle the faults detected in the previous analysis. The experiments in section 4 are made on the *New York Times Annotated Corpus* (NYT) [2] (Sandhaus, 2008) covering two decades.

2 Related Work

The first methods to measure semantic evolution rely on detecting changes in word co-occurrences, and approaches bases on distributional similarity (Gulordava and Baroni, 2011) . The use of automated learning methods, based on word embeddings (Mikolov et al., 2013), is recent and has undergone a increase in interest these last two years with the successive publication of three articles dedicated to a literature review of the domain (Kutuzov et al., 2018; Tahmasebi et al., 2018; Tang, 2018). In this section, we mainly consider this second line of work, along with the peculiarities of scarce data.

Kim et al. (2014) developed one of the first method to learn time-varying word sparse representations. It consists in learning an embedding matrix for the first time slice t_0, then updating it at each time step t using the matrix at $t-1$ as initialisation. This method is called incremental updating . Another broadly used method it to learn an embedding matrix for each time slice independently; due to the stochastic aspect of word embeddings, the vectorial space for each time slice is different, making them not directly comparable. Thus, authors perform an alignment of the embeddings spaces by optimising a geometric transformation (Hamilton et al., 2016; Dubossarsky et al., 2017; Szymanski, 2017; Kulkarni et al., 2015)).

In the case of sparse data, in addition to the approximative aspect of the alignment that harms the robustness of the embeddings, these methods are sensitive to random noise, which is difficult to disambiguate from semantic drifts. Moreover, the second one require large amounts of data for each time step to prevent overfitting. Tahmasebi (2018) shows that low-frequency words have a much lower temporal stability than high-frequency ones. In (Tahmasebi et al., 2018), the authors explain that usual methods for diachronic embeddings training such as the two previously presented are inefficient in the case of low-frequency words and hypothesise that a new set of methods, pooled under the name of *dynamic* models, may be more adapted. These models use probabilistic models to learn time-varying word embeddings while controlling the drift of the word vectors using a Gaussian diffusion process. Bamler and Mandt (2017) uses Bayesian word embeddings, which makes the algorithm more robust to noise in the case of sparse data; while Rudolph and Blei (2018) relies on a Bernoulli distribution to learn the dynamic embeddings jointly across all time slices, making the most of the full dataset.

Outside of the framework of diachrony, several attempts aim at improving or adapting word embeddings to low-volume corpora in the literature. It can involve morphological information (Luong et al., 2013) derived from the character level (Santos and Zadrozny, 2014; Labeau et al., 2015), and often make use of external resources: semantic lexicon (Faruqui et al., 2015), and pre-trained embeddings from larger corpora (Komiya and Shinnou, 2018). However, to our knowledge, no work has attempted to apply similar solutions to the problem of sparse data in temporal corpora, even thought this situation has been faced by many authors, often in the case of short time steps for social media data (Stewart et al., 2017; Bamler and Mandt, 2017; Kulkarni et al., 2015).

3 Diachronic Models

This section briefly describes the three models under study: the Skip-Gram incremental updating algorithm from Kim et al. (2014), the dynamic filtering algorithm of Bamler and Mandt (2017), and the dynamic Bernoulli embeddings model from Rudolph and Blei (2018). We consider a corpus divided into T time slices indiced by t. For each time step t, every word i is associated with two vectors u_{it} (word vector) and v_{it} (context vector).

3.1 Incremental Skip-Gram (ISG)

This algorithm relies on the skip-gram model estimated with negative sampling (SGNS) method described in (Mikolov et al., 2013) and it can be summarised as follows. The probability of a word i to appear in the context of a word j is defined by $\sigma(u_{i,t}^T v_{j,t})$, with σ being the sigmoid function. Words i and j are represented by their embedding

[2] https://catalog.ldc.upenn.edu/LDC2008T19

vectors $u_{i,t}$ and $v_{j,t}$) at time t. The matrices U_t and V_t gathers all of them for the whole vocabulary. The context is made of a fixed number of surrounding words and each word in the context are considered as independent of each other.

The negative sampling strategy associates to each observed word-context pair (the positive examples) n^+_{ijt}, a set of negative examples n^-_{ijt}. The negative examples are sampled for a noise distribution following Mikolov et al. (2013).

Let n^{+-}_t denote for the time step t, the union of positive and negative examples. The objective function can be defined as the following log-likelihood:

$$\begin{aligned} log\, p(n^{+-}_t|U_t, V_t) &= \mathcal{L}_{pos}(U_t, V_t) + \mathcal{L}_{neg}(U_t, V_t) \\ &= \sum_{i,j=1}^{L} (n^+_{ijt} log\, \sigma(u^T_{i,t} v_{j,t}) + n^-_{ijt} log\, \sigma(-u^T_{i,t} v_{j,t})) \end{aligned} \tag{1}$$

For the first time slice, the matrices U_1 and V_1 are initialised using a Gaussian random noise $\mathcal{N}(0, 1)$ before being trained according to equation (1). Then, for each successive time slice, the embeddings are initialised with values of the previous time slice following the methodology of (Kim et al., 2014). This way, the word vectors of each time step are all in the same vectorial space and directly comparable.

3.2 Dynamic Filtering of Skip-Gram (DSG)

This second method relies on the Bayesian extension of the SGNS model described by Barkan (2015). The main idea is to share information from one time step to another, allowing the embeddings to drift under the control of a diffusion process. A full description of this approach, denoted as the filtering model, can be found in (Bamler and Mandt, 2017).

In this model, the vectors $u_{i,t}$ and $v_{i,t}$ are considered as latent vectors. Under a Gaussian assumption, they are represented by their means $(\mu_{u_{i,t}}, \mu_{v_{i,t}})$ and variances $(\Sigma_{u_{i,t}}, \Sigma_{v_{i,t}})$. They are initialised for the first time slice with respectively a zero mean vector and a identity variance matrix.

The temporal drift from one time step to another follows a Gaussian diffusion process with zero mean and variance D. This variance is called the *diffusion* constant and has to be tuned along with the other hyperparameters. Moreover, at each time step a second Gaussian prior with zero mean and variance D_0 is added, resulting in the following distributions over the embeddings matrices U_t:

$$\begin{aligned} p(U_1|U_0) &\sim \mathcal{N}(0, D_0) \\ p(U_t|U_{t-1}) &\sim \mathcal{N}(U_{t-1}, D)\, \mathcal{N}(0, D_0). \end{aligned} \tag{2}$$

The same equation stands for V_t. Training this model requires to estimate the posterior distributions over U_t and V_t given n^{+-}_t. This (Bayesian) inference step is unfortunately untractable. In (Bamler and Mandt, 2017), the authors propose to use variational inference (Jordan et al., 1999) in its online extension (Blei et al., 2017). The principle of variational inference is to approximate the posterior distribution with a simpler variational distribution $q_\lambda(U, V)$ (λ gathers all the parameters of q). This variational posterior will be iteratively updated at each time step. The final objective function can be written as follows:

$$\begin{aligned} \mathcal{L}_t(\lambda) = E_{q_\lambda}&[log\, p(n^{+-}_t|U_t, V_t)] \\ &+ E_{q_\lambda}[log\, p(U_t, V_t)|n^{+-}_{1:t-1}] \\ &- E_{q_\lambda}[log\, q_\lambda(U_t, V_t)]. \end{aligned} \tag{3}$$

This loss function is the sum of three terms: the log-likelihood (computed following equation (1)), the log-prior (which enforces the smooth drift of embedding vectors, sharing information with the previous time step), and the entropy term (approximated as the sum of the variances of the embedding vectors).

3.3 Dynamic Bernoulli Embeddings (DBE)

The DBE models extends the *Exponential Family Embeddings* (EFE)(Rudolph et al., 2016), a probabilistic generalisation of the *Continuous Bag-of-Words* (CBOW) model of Mikolov et al. (2013). The main idea is that the model predicts the central word vector conditionally to its context vector following a Bernoulli distribution. A detailed description of the model can be found in (Rudolph and Blei, 2018).

Each word i has T different embeddings vectors u_{it}, but this time, the context vectors v_i are assumed to be fixed across the whole corpus. The embedding vector u_{it} drifts throughout time following a Gaussian random walk, very similarly to equation (2):

$$\begin{aligned} U_0,\ V &\sim \mathcal{N}(0, \lambda_0^{-1} I), \\ U_t &\sim \mathcal{N}(U_{t-1}, \lambda^{-1} I). \end{aligned} \tag{4}$$

The *drift* hyper-parameter λ controls the temporal evolution of U_t, and is shared across all time steps. The training process, described more precisely by Rudolph and Blei (2018), relies on a variant of the negative sampling strategy described by Mikolov et al. (2013). The goal is to optimise the model across all time steps jointly, by summing over t the following loss function:

$$\mathcal{L}_t = \mathcal{L}_{pos}(U_t, V) + \mathcal{L}_{neg}(U_t, V) + \mathcal{L}_{prior}(U_t, V). \quad (5)$$

The two first terms are computed as in equation (1). The third term is defined as :

$$\mathcal{L}_{prior}(U_t, V) = -\frac{\lambda_0}{2}\sum_{i=1}^{L}\|v_i\|^2 - \frac{\lambda_0}{2}\sum_{i=1}^{L}\|u_{i,0}\|^2 - \frac{\lambda}{2}\sum_{i,t}\|u_{i,t} - u_{i,t-1}\|^2. \quad (6)$$

The role of $\mathcal{L}_{prior}$ is twofold: it acts as a regularisation term on V and U_t, and as a constraint on the drift of U_t, preventing it from going to far apart from U_{t-1}

4 Experimental Results

The goal of this study is to compare the behaviour of the three algorithms described in section 3 in case of low-volume corpora. We evaluate their predictive power on different volumes of data to compare the impact of two initialisation methods, and analyse the behaviour of the drift of the embeddings.

4.1 Experimental Setup

We use the *New York Times Annotated Corpus* (NYT) (Sandhaus, 2008) [3] containing around 1 855 000 articles ranging from January 1^{st} 1987 to June 19th 2007. We divide the corpus into $T = 20$ yearly time steps (the incomplete last year is not used in the analysis) and held out 10 % of each time step for validation and testing. Then, we sample several subsets of the corpus : 50 %, 10%, 5% and 1% of the training set. This way, we can compare the models on each subset to evaluate their ability to train a model in the case of low-volume corpora.

We remove stopwords and choose a vocabulary of $V = 10k$ most frequent words. Indeed, a small vocabulary is more adequate for sparse data in a temporal analysis in order to avoid having time steps were some word does not appear at all. The total number of words in the corpus after preprocessing is around 38.5 million. It amounts to around 200k words per time step in the 10 % subset of the corpus, thus only 20k in the 1 % subset.

To tune the hyperparameters, we use the log-likelihood of positive examples $\mathcal{L}_{pos}$ measured on the validation set. We train each model for 100 epochs, with a learning rate of 0.1, using the Adam optimiser. For the DSG model, we use a diffusion constant $D = 1$ and a prior variance $D_0 = 0.1$ for both corpora. For the DBE model, we use $\lambda = 1$ and $\lambda_0 = 0.01$.

We choose an embedding dimension $d = 100$, as the experiments show that a small embedding dimension, as in (Stewart et al., 2017), leads to smoother word drifts and makes the model less sensitive to noise when the data is scarce.

We use a context window of 4 words and a negative ratio of 1; we observed that having a higher number of negative samples artificially increased the held-out likelihood, but equalised the drifts of all the words in the corpus. Thus, in an extreme scarcity situation, each negative sample has a high weight during training: the number of negative samples has to be very carefully selected depending on the amount of data.

4.2 Impact of Initialisation on Sparse Data

The embedding vectors of the ISG and DBE models are initialised using a Gaussian white noise, while the means and variances of DSG are initialised with null vectors and identity matrices respectively. However, a good initialisation can greatly improve the quality of embeddings, particularly in the case of scarce data.

We experiment the impact of two types of initialisation on the log-likelihood of positive examples on the test set.

Internal initialisation:

We train each model in a static way on the full dataset. Then, we use the resulting vectors as initialisation for the first time step of the diachronic models. This methods is especially suitable for domain-specific corpora where no external comparable data is available.

[3] released by the Linguistic Data Consortium

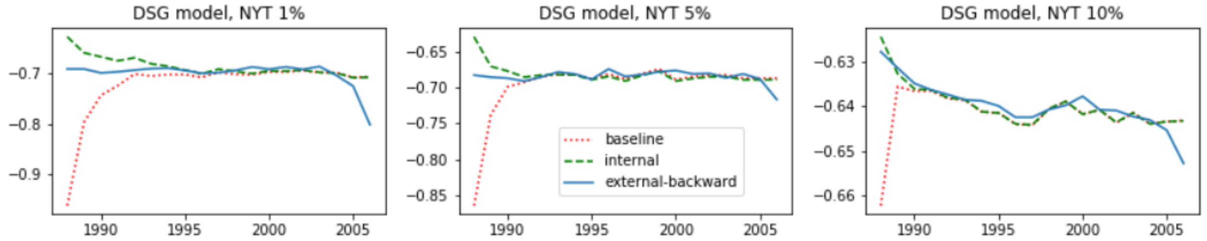

Figure 1: Log-likelihoods for the DSG model on three subsets of the corpus, comparing the baseline (random initialisation) with the two initialisation methods: *internal* is the initialisation from the full dataset while *external-backward* is the initialisation with the Wikipedia vectors, with training from most recent to oldest time step.

Backward external initialisation:
We use a set of embeddings pre-trained on a much larger corpus for initialisation : The Wikipedia corpus (dump of August 2013) (Li et al., 2017) with vectors of size 100. These embeddings are representative of the use of words in 2013; and in general, large corpora exist almost exclusively for recent periods. Thus, we choose to use the pre-trained embeddings as initialisation for the *last* time step (the most recent). Then, we update the embeddings incrementally from new to old (*reverse incremental updating*).
This method would be particularly suitable for corpora with low volume in older time slices, as it is the case for most of the historical dataset in languages other than English.
For the DSG model, the pre-trained vectors are used as the mean parameter for each word. The variance parameter is fixed at 0.1. Experiments with a prior variance of 0.01 and 1 had a lowest log-likelihood on the validation set.

The log-likelihood curves in figure 1 show that the internal initialisation has a better impact on the likelihood at the beginning of the period, as it is closer to the data than the external initialisation. The positive impact of the backward external initialisation increases with the volume of data.

Overall, the mean log-likelihoods across all time steps (Table 1) are higher using the internal initialisation. We conjecture that internal initialisation is more profitable to the model when the period is short (here, two decades) with low variance. The backward external initialisation has very close scores to the internal one, and is more suitable for higher volume datasets with a longer period, as it gives higher benefit to the likelihood for bigger subsets.

Initialisation / Model	**Random**	**Internal**	**Backward external**
ISG	-3.17	-2.589	-2.686
DSG	-0.749	-0.686	-0.695
DBE	-2.935	-2.236	-2.459

Table 1: Log-likelihood on the 5% subset of the NYT corpus for each model, with the three initialisation schemes.

4.3 Visualising Word Drifts

A high log-likelihood performance does not necessarily imply that the drifts detected by the models are meaningful. In this section, we examine the distribution of word drifts outputted by each model with the internal initialisation. The computed drift is the L2-norm of the difference between the embeddings at t_0 and the embeddings at each t:

$$drift(U_t) = \left[\sum_{i=1}^{L} (u_{i,t} - u_{i,t_0})^2 \right]^{1/2} \quad (7)$$

In the case of the DSG model were the words are represented as distributions, we compute the difference of the mean vectors.

We plot the superimposed histograms of *successive* drifts (Figure 2) from $t_0 = 1987$ to each successive time step, for all studied models. For example, on the histograms, the lightest colour curve represents the drift between $t_0 = 1987$ and $t = 2006$ and the darkest one is the drift between $t_0 = 1987$ and $t = 1988$.

A first crucial property is the *directed* aspect of the drifts: when the words progressively drift away from their initial representation in a directed fashion. On 10 % of the dataset, the DBE model shows well this behaviour, with a very clear colour gradient. It is also the case for the other models on this subset. With 1 % of the dataset on the contrary, the ISG model is unable to display a directed be-

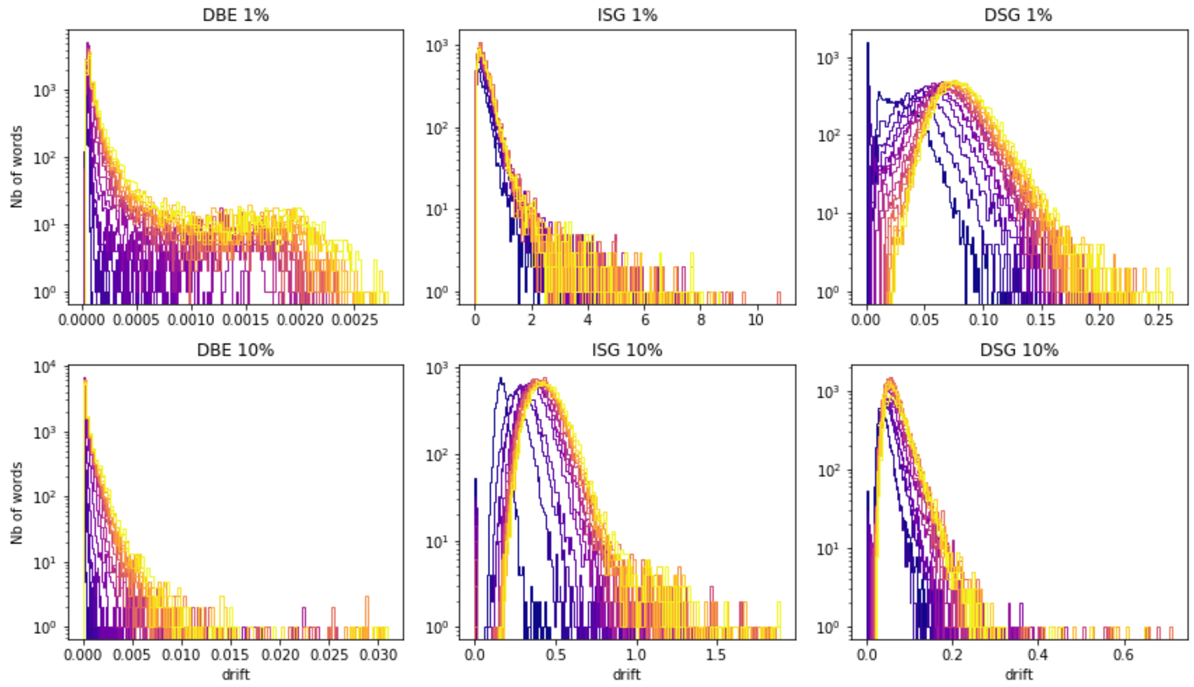

Figure 2: Histogram of word drift for each model on two subsets of the NYT corpus. The drifts are computed from $t_0 = 1987$ to each successive time step, and superposed on the histogram. The lightest colours indicate drifts calculated until the most recent time steps. The number of words are on logarithmic scale.

haviour (no colour gradient), while the two other models do. This is justified by the use of the diffusion process to link the time steps in equations 2 and 5: it allows the DSG and DBE models to emphasise the directed fashion of drifts even in the situation of scarce data.

The second property to highlight is the capacity of the models to discriminate words that drift from words that stay stable. From the human point of view, a majority of words has a stable meaning (Gulordava and Baroni, 2011); especially on a dataset covering only two decades like the NYT. The DBE model has a regularisation term (equation 6) to enforce this property, and a majority of words have a very low drift on the histogram. However, on 1 % of the dataset, this model can not discriminate very high drifts from the rest. The ISG and DSG models have a different distribution shape, with the peak having a drift superior to zero. The only words that do not drift on their histograms are the one that are absent from a time step.

To conclude, both the DBE and DSG model are able to detect directed drifts even in the 1 % subset of the NYT corpus, while the ISG can not. However, the drift distributions of the DBE and DSG models have a much shorter shorter tail on the 1 % subset than on the 10 % subset: they are not able to discriminate very high drifts from the rest of the words in extreme scarcity situation.

4.4 Regularisation Attempt

To tackle the weakness of the DBE and DSG models on the smallest subset, we attempt to regularise their loss in order to control the weight of the highest and lowest drifts. Our goal is to allow the model to:

- better discriminate very high drifts;
- be less sensitive to noise, giving lower weight to very low embedding drifts.

We test several possible regularisation terms to be added to the loss. The best result is obtained with the *Hardshrink* activation function, which is defined this way :

$$\begin{aligned} HardShrink(x) &= x, \text{ if } x > \beta \\ &= -x, \text{ if } x < -\beta \\ &= 0, \text{ otherwise} \end{aligned} \tag{8}$$

For the DSG and DBE models, we add to the loss the following regularisation term, amounting to a thresholding function applied to the drift:

$$\text{reg}_\beta = \alpha * HardShrink(\text{drift}(U_t), \beta) \tag{9}$$

Where α is the regularisation constant to be tuned, β is the threshold of the hardshrink function, and the drift is computed according to equation 7. The regularisation term is minimised. The activation function acts as a threshold to limit the amount of words having an important drift. We choose β as the mean drift for both models.

For both DSG and DBE, the right tail of the distribution of the drifts with regularisation (Figure 3) is much longer than in the original model (Figure 2). Moreover, in the case of the DSG model, more words have a drift very close to zero.

To conclude, the regularised DSG model considers more words as temporally stable. Furthermore, regularising the loss of the dynamic models allows to better discriminate extreme word embedding drifts for very small corpora.

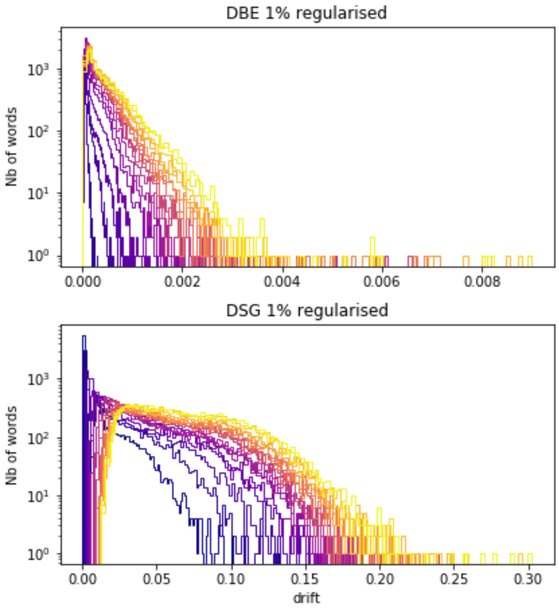

Figure 3: Histogram of word drift for the DBE and DSG regularised models on the 1 % subset.

5 Summary & Future Work

To summarise, we reviewed three algorithms for time-varying word embeddings: the incremental updating of a skip-gram with negative sampling (SGNS) from Kim et al. (2014) (ISG), the dynamic filtering applied to a Bayesian SGNS from Bamler and Mandt (2017) (DSG), and the dynamic Bernoulli embeddings model from Rudolph and Blei (2018) (DSG), a probabilistic version of the CBOW.

We proposed two initialisation schemes: the internal initialisation, more suited for low volume of data, and the backward external initialisation, more suited for higher volumes and long periods of temporal study. Then, we compared the distributions of the drifts of the models. We conclude that even in extreme scarcity situations, the DBE and DSG models can highlight directed drifts while the ISG model is too sensitive to noise. Moreover, the DBE model is the best at keeping a majority of the words stable. This property, as long as the ability to detect directed drift, are two important properties of a diachronic model. However, both have low ability to discriminate the highest drifts on a very small dataset. Thus, we added a regularisation term to their loss using the *Hardshrink* activation function, successfully getting longer distribution tails for the drifts.

An important future work is the multi-sense aspect of words. Polysemy is a crucial topic when dealing with diachronic word embeddings, as the change in usage of a word can reflect various changes in its meaning. However, the more different senses are taken into account, the more data is needed to tackle it. An evolution of the DSG model presented in this paper to adapt to this problem would be to represent words while taking into account the context of each occurrence of a word to disambiguate its meaning. Brazinskas et al. (2018) propose such model in a static fashion, where word vectors depends on the context and are drawn at token level from a word-specific prior distribution. The framework is similar to the Bayesian skip-gram model from Barkan (2015) used in the DSG model; but the goal is to predict a distribution of meanings given a context for each word occurrence. We are working on adapting this model to a dynamic framework.

A Fast and Accurate Partially Deterministic Morphological Analysis

Hajime Morita **Tomoya Iwakura**
Fujitsu Laboratories Ltd., Kanagawa, Japan
{hmorita, iwakura.tomoya}@fujitsu.com

Abstract

This paper proposes a partially deterministic morphological analysis method for improved processing speed. Maximum matching is a fast deterministic method for morphological analysis. However, the method tends to decrease performance due to lack of consideration of contextual information. In order to use maximum matching safely, we propose the use of Context Independent Strings (CISs), which are strings that do not have ambiguity in terms of morphological analysis. Our method first identifies CISs in a sentence using maximum matching without contextual information, then analyzes the unprocessed part of the sentence using a bi-gram-based morphological analysis model. We evaluate the method on a Japanese morphological analysis task. The experimental results show a 30% reduction of running time while maintaining improved accuracy.

1 Introduction

Morphological analysis segments a text into a sequence of morphemes. The analysis is the first step of analyzing languages such as Chinese, Thai and Japanese. In Japanese, the analysis is a compound task of word segmentation, POS tagging, recognition of conjugation and lemmatization.

Japanese morphological analysis derives a word dictionary. The dictionary is a set of tuples of word surface (conjugated form), base form (lemma of words) and POS tags. Given an input string of a sentence, the morphological analyzer enumerates all substrings of the sentence that are listed in the dictionary. Then the analyzer builds a large lattice (DAG) of the words as a set of candidate word sequences. Because the lattice often becomes large, the lattice building tends to be a bottle neck of the morphological analysis. Finally, the analyzer selects a path on the lattice and gets the analysis result.

Morphological analysis is often used as a preprocessing step for shallow analyses on a large amount of texts collected from Web. These analyses include word counting, keyword extraction and named entity recognition. Morphological analysis tends to occupy a larger part of the processing time in the tasks. Therefore, we investigated a new morphological analysis method that improves efficiency and performance.

There are three kinds of Japanese morphological analysis methods in terms of the range of using contexts. The first group is maximum matching-based methods that do not use context (Sproat et al., 1996; Nagata, 1997; Sassano, 2014). Maximum matching is a significantly fast deterministic method for morphological analysis. However, this method tends to have a low performance, because it often fails an segmentation of phrases which have ambiguity depending on their context. The second group is neural network based methods that do not have explicit limit to the range of context (Morita et al., 2015; Chen et al., 2015; Wang et al., 2016; Kurita et al., 2017; Tolmachev et al., 2018). However, neural network based methods generally require heavy computational cost. The third group is commonly used local context based methods (Kudo et al., 2004; Neubig et al., 2011; Zheng et al., 2013; Kaji and Kitsuregawa, 2013; Kurohashi and Kawahara, 2014). The methods typically use bi-grams as their context. Among these methods, the bi-gram based methods are faster than neural network based methods and their performance is not far from that of neural network based methods.

This paper proposes a partially deterministic morphological analysis method for improved processing speed. We improve processing speed by incorporating maximum matching (the first group) to a bi-gram-based morphological engine (the third group).

In order to alleviate the performance loss of maximum matching, we propose a concept of Context Independent Strings (CISs), which are strings having no ambiguity in terms of morphological analysis. We also propose an algorithm for the building of the CISs dictionary from the large amount of automatically analysed texts. The dictionary maps CISs to the results of morphological analysis (sequence of words and POS tags).

Our method first applies maximum matching to a sentence using the CIS dictionary. CISs in a sentence are deterministically analyzed by the dictionary. Then the method analyze the rest part of the sentence using a bi-gram-based morphological analysis. We can use high-performance and computationally heavy methods such as neural network based methods for the building of the dictionary. That is, we can partially use their analysis results without recomputing through the CIS dictionary.

We obtain CISs from automatically parsed large texts with a state-of-the-art morphological analyzer JUMAN++ (Morita et al., 2015; Tolmachev et al., 2018). We evaluate this method on a Japanese morphological analysis task. The experimental results show a 30% reduction of running time while maintaining improved accuracy.

2 Context Independent Strings

The key idea of using maximum matching without performance loss is to separate character strings into two classes: context independent string (CIS) and context dependent string (CDS).

A CIS is a string that has a one-to-one correspondence with its grammatical analysis result, while a CDS has two or more grammatical analysis results that depend on its contexts. A CIS has to satisfy two conditions:

- The string does not have two or more grammatical analysis results.
- The analysis result is not affected by any strings adjacent to the beginning and end of the strings.

We describe CISs with the following three examples.

```
(A)  床の間
   (alcove, or gap of floor )
(B)  南京
   (Nanjing)
(C)  南       京都      病院
   (South) (Kyoto) (hopital)
```

(A) is a string that does not satisfy the first condition of CIS. “床の間” has two grammatical analysis result: “床の間 (alcove)” with one word or “床 (floor) + の (to) + 間 (gap)” with three words. The analysis depends on the context where the string occurred.

In (B), the string “南京” has only one grammatical analysis result “南京” (Nanjin). However, the string is a part of (C) “南京都病院”, and the string corresponts “南” (South) + the first character of “京都” (Kyoto). That violates the second condition of CIS.

When we segment the example (C) “南京都病院” (South Kyoto Hospital) using word-level maximum matching, the example is segmented into “南京+都+病院” (Nanjin metropolitan hospital) instead of correct segmentation “南+京都+病院” (South Kyoto hospital). This is because the longest word matched from the beginning of the example (C) is CDS (“南京”).

In fact, whole (C) is an example of a CIS. There is no “南京+都+病院” (Nanjin metropolitan hospital)“, and then the string has only one grammatical analysis result.

3 Proposed Method

This section describes the building method of a CIS dictionary, and deterministic morphological analysis using the CIS dictionary.

3.1 Building a CISs Dictionary

A CIS dictionary is a data structure where each CIS is associated to its morphological analysis result.

We built the CIS dictionary using the algorithm showed in **Algorithm 1**. In this method, the dictionary is built from a large automatically analyzed corpus C. We collected word N-grams n_j, their surfaces surface(n_j) and pointers j of the sentences in which the N-grams occurred, as a set of candidates (H, N, S).

In STEP (1) at the line 14 of Algorithm 1, when an identical surface was associated with two or

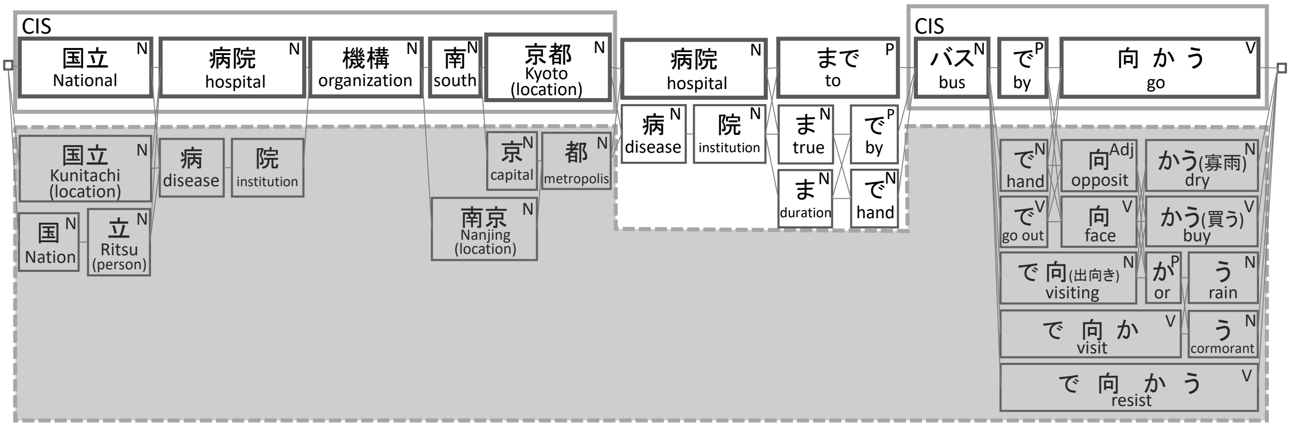

Figure 1: Example of a lattice that is built by our baseline method and our proposed model using a CIS dictionary. The CIS dictionary contains "国立病院機構南京都" and "バスで向かう", so the corresponding results are loaded from the dictionary. The word candidates surrounded by dotted line are not generated in our proposed model. Our implementation builds a CIS dictionary from word sequences of length 5 or less. Thus, even though "国立病院機構南京都病院" (6 words) is clearly a CIS, it is not in the dictionary.

more N-grams, or the N-grams occurred less frequently than a predetermined threshold T, the surfaces are discarded from the candidates. We aim to discard ambiguous strings similar to example (A).

In STEP (2) at the line 15, we remove CDSs that violate the second condition of CIS. As we can see from Example (B), the surface of CDS appears in a part of other word N-gram. The $\mathrm{findString}$ gives a set of sentences where the string p occurs in corpus C. The step checks there is no occurrence of the string p that appears in a part of another N-gram. We discarded any surface that occurred in a sentence in which the corresponding N-gram did not occur. This is because the occurrence indicates that the surface was a part of another different N-gram.

In STEP (3) at the line 15, the step is filtering using a heuristic. If the corpus is sufficiently large, the process considers any string before and after the N-gram. However, it is infeasible to cover all contexts of all expressions in a corpus of limited size. For the purpose of augmenting the corpus, we discarded the N-grams where words at the beginning or ending of N-gram are sensitive to preceding and succeeding strings. Specifically, if the beginning or end of the N-gram is a one-character word and is not in a predefined white list (punctuations, and a part of particles), the N-gram is discarded by this step. We assume that one-character words are often a suffix or prefix of other words and these words are sensitive to the surrounding contexts. We show the process as $\mathrm{isSensitive}$ function in Algorithm 1.

Finally, we build a CIS dictionary D using the collected CISs and their analysis result.

3.2 Analysis using a CIS Dictionary

There are three steps to analyse a sentence using a CIS dictionary: (1) Deterministic analysis by maximum matching with a CIS dictionary, (2) Building lattice by lookup dictionary and (3) Search for the least cost path on the lattice. We show our algorithm in Algorithm 2.

First, **LookUpLongestCIS** in Algorithm 2 finds CISs with the maximum match of a CIS dictionary from each character of the input sentence. If a CIS is found, the algorithm skips the range of matched string, and calls **LookUpLongestCIS** again. If it is not found, the step is restarted from the next character. The algorithm calls *LookUpDictionary* and builds a word lattice for each span where any analysis result is not obtained with the maximum matching.

Finally, whole sentence is connected as one lattice, and a word sequence with the lowest cost is obtained by Viterbi algorithm. On this lattice, the spans deterministically analyzed are expressed as nodes corresponding to the analysis result obtained from the dictionary, and their costs are 0. Other costs are calculated by a bi-gram model.

Figure 1 shows an example of a lattice that is built by our proposed method.

Algorithm 1 An algorithm for building a CIS dictionary

```

```
S $\leftarrow \{c_0, \ldots, c_n\}$, $i \leftarrow 0$, $j \leftarrow 0$, $k \leftarrow 0$
$L$ = A lattice structure
while $i \leq N$ do
    result, length $\leftarrow$ LookUpLongestCIS(S, $i$)

    if result != $\phi$ then
        L[$i$] $\leftarrow$ result
        $i \leftarrow i$ + length
    else
        $i \leftarrow i$ + 1
    end if
end while
for $j = 0$ to $N$ –(2) do
    if $j$ is processed by LookUpLongestCIS then
        continue
    end if
    L[$j$] $\leftarrow$ LookUpDictionary(S,$j$)
end for
return Viterbi(L) –(3)
```

4 Experiments

4.1 Data and Models

We build a CIS dictionary using Mainichi News articles published from 1991 to 2010. The corpus contains approximately 2 million articles. We analyzed the corpus using JUMAN++ v1.02 (Morita et al., 2015). We set threshold T to 4, and limited the maximum N-gram length to 5.

A morphological dictionary used in our models is stemmed from JUMAN++ v1.02. We trained our feature parameters of CRF using L-BFGS (Kudo et al., 2004; Liu and Nocedal, 1989). We trained our models using Kyoto University Web Document Leads Corpus (Hangyo et al., 2012; Kawahara et al., 2014) that contains approximately 15,000 manually annotated sentences. The corpus contains manually annotated word segmentations, POS tags, dependencies, predicate-argument structures including zero anaphora, and so on. We used sentences with id (w201106-00000–w201106-00023) for training and sentences with id (w201106-00024) for development.

We evaluated the performance of our methods by KNB corpus (Hashimoto et al., 2011) that consists of 249 articles (4,186 sentences). The corpus contains manually annotatted word segmentation, POS tags and dependencies. Then, we evaluated the efficiency of our models by measuring running times of analysis on news articles of Yomiuri Shimbun in 2013. The text consists of approximately 300 thousand articles (approximately 4 million sentences).

We measured the performance of the methods by two performance measures Word and Word+POS. Word is the F-value of word segmentation, and Word+POS is the F-value of joint evaluation of word segmentation and POS tagging.

4.2 Performance Evaluation

We compared our proposed model with the baseline and JUMAN++. Partially deterministic analysis using a CIS dictionary did not lose to their performance but slightly improved in both Word and Word+POS. Our baseline is almost a reimplementation of MeCab (Kudo et al., 2004) and performs almost equally. JUMAN++ is an upper bound of our proposed model because a deterministically analyzed part of the analysis result is almost equivalent with the result of JUMAN++.

Table 1: Performance comparison of various systems.

Method	Word (F-val)	Word+POS (F-val)
Baseline	95.94	95.07
Partially deterministic (Proposed)	**95.99**	**95.17**
JUMAN++	96.84	96.15

Table 2: Comparing running times of various systems.

Method	Time (seconds)
Baseline	315.3
Partially deterministic (Proposed)	**223.4**
MeCab	124.5
JUMAN++	341705.7

4.3 Running Time Comparison

We compared our systems with publicly available implementations. MeCab is the fastest, but our implementation (Baseline) marks similar running time. Since our baseline model is not largely different from MeCab, the difference of running time is due to the implementation. Partially deterministic analysis reduces running time by 30%. If we implement our proposed method on MeCab or JUMAN++, we suspect it will improve their efficiency.

5 Conclusion

We presented a new fast partially deterministic morphological analysis method. We introduced the concept of Context Independent Strings and presented an algorithm for building a dictionary of CISs from a large corpus. We checked that the proposed method improved both efficiency and performance of morphological analysis. The method reduced the running time by 30% and improved the performance 0.1 pt in Word+POS.

Abstract

Languages may be differently distant from each other and their mutual intelligibility may be asymmetric. In this paper we introduce `incom.py`, a toolbox for calculating linguistic distances and asymmetries between related languages. `incom.py` allows linguist experts to quickly and easily perform statistical analyses and compare those with experimental results. We demonstrate the efficacy of `incom.py` in an incomprehension experiment on two Slavic languages: Bulgarian and Russian. Using `incom.py` we were able to validate three methods to measure linguistic distances and asymmetries: Levenshtein distance, word adaptation surprisal, and conditional entropy as predictors of success in a reading intercomprehension experiment.

1 Introduction

1.1 Related Work

Linguistic phenomena may be language specific or shared between two or more languages. With regard to cross-lingual intelligibility, various constellations are possible. For example, speakers of language A may understand language B better than language C, i.e. $[A(B) > A(C)]$ while speakers of language B may understand language C better than language A, i.e. $[B(C) > B(A)]$. For instance, Ringbom (2007) distinguishes between *objective* (established as symmetrical) and *perceived* (not necessarily symmetrical) cross-linguistic similarities. Asymmetric intelligibility can be of linguistic nature. This may happen if language A has more complicated rules and/or irregular developments than language B, which results in structural asymmetry (Berruto, 2004).

Recently, in the INCOMSLAV framework (Fischer et al., 2015; Jágrová et al., 2016; Stenger et al., 2017a,b), measuring methods were developed that are of direct relevance for modelling cross-lingual asymmetric intelligibility. While it has been common to use (modifications of) the Levenshtein distance (Levenshtein, 1966) to predict phonetic and orthographic similarity (Beijering et al., 2008; Gooskens, 2007; Vanhove, 2016), this string-edit distance is completely symmetric. To account for asymmetric cross-lingual intelligibility Stenger et al. (2017b) employ additional measures of conditional entropy and surprisal (Shannon, 1948). Conditional character adaptation entropy and word adaptation surprisal, as proposed by Stenger et al. (2017b), quantify the difficulties humans encounter when mapping one orthographic system to another and reveal asymmetries depending on stimulus-decoder configurations in language pairs.

Similarly, the research of Jágrová et al. (2016) shows that Czech and Polish, both West Slavic, using the Latin script, are orthographically more distant from each other than Bulgarian and Russian, South and East Slavic respectively using the Cyrillic script. Both language pairs have similar lexical distances, however, the asymmetric conditional entropy based measures suggest that Czech readers should have more difficulties reading Polish text than vice versa. The asymmetry between Bulgarian and Russian is very small with a predicted minimal advantage for Russian readers (Stenger et al., 2017b). Additionally Stenger et al. (2017a) found that word-length normalized adaptation surprisal appears to be a better predictor than aggregated Levenshtein distance when the same stimuli sets in different language pairs are compared.

1.2 This paper

To calculate linguistic distances and asymmetries, perform statistical analyses and visualize the obtained results we developed the linguistic toolbox `incom.py`. The toolbox is validated on the Russian-Bulgarian language pair. We focus on word-based methods in which segments are compared at the orthographic level, since orthography is a linguistic determinant of mutual intelligibility which may facilitate or impede reading intercomprehension. We make the following contributions.

1. We provide implementations of various metrics for computing linguistic distances and asymmetries between languages.

2. We demonstrate the use of `incom.py` in an intercomprehension experiment for the Russian-Bulgarian language pair.

3. We show how `incom.py` can be used to validate word adaptation surprisal and conditional entropy as predictors for intercomprehension and discuss benefits over Levenshtein distance.

The remainder of this paper is structured as follows. The considered distance metrics implemented in the `incom.py` toolbox are introduced in Section 2. Section 3 describes the linguistic data used in the experiments. Section 4 presents the evaluation results of the statistical measures and compares them with the intelligibility scores obtained in a web-based cognates guessing. Finally, in Section 5, conclusions are drawn and future developments outlined.

2 Linguistic Distances and Asymmetries

2.1 Distance measures

We start with the introduction of basic notations and present the implemented distance measures.

2.1.1 Notation

Let L denote a language such as Russian or Bulgarian. Each language L has an associated alphabet – a set of characters – $\mathcal{A}(L)$ which includes the special symbol $\varnothing$[1]. We use $w \in L$ to denote a word in language L and $c_i \in w$ to denote the i-th character in word w. Note that while L is a set, w is not and may contain duplicates. Further, we assume the characters $c_i \in w$ are ordered with c_0 being the first and $c_{|w-1|}$ being the last character of word w, where the length $|w|$ of a word w is given by the number of characters it contains, including duplicates. Given two words w_i, w_j, the *alignment* of w_i and w_j results in two new words $\widetilde{w}_i, \widetilde{w}_j$ where $|\widetilde{w}_i| = |\widetilde{w}_j|$. We say character $s_k \in \widetilde{w}_i$ is aligned to character $t_l \in \widetilde{w}_j$ if $k = l$. That is, they occur at the same position.

2.1.2 Levenshtein distance

Levenshtein distance (LD) (Levenshtein, 1966) is, it its basic implementation, a symmetric similarity measure between two strings – in our case words – $w_i \in L_1$ and $w_j \in L_2$. Levenshtein distance quantifies the number of operations one has to perform in order to transform w_i into w_j. Levenshtein distance allows to measure the orthographic distance between two words and has been successfully used in previous works for measuring the linguistic distance between dialects (Heeringa et al., 2006) as well as the phonetic distance between Scandinavian language varieties (Gooskens, 2007). When computing Levenshtein distance between two words $\mathrm{LD}(w_i, w_j)$, three different character transformations are considered: character deletion, character insertion, and character substitution. In the following we use $\mathcal{T} = \{\text{insert}, \text{delete}, \text{substitute}\}$ to denote the set of possible transformations. A cost $c(t)$ is assigned to each transformation $t \in \mathcal{T}$ and setting $c(t) = 1\ \forall t \in \mathcal{T}$ results in the most simple implementation.

`incom.py` allows computing $\mathrm{LD}(w_i, w_j)$ based on a user-defined cost matrix $\mathbf{M}$, which contains the complete alphabets $\mathcal{A}(L_1), \mathcal{A}(L_2)$ of two languages L_1, L_2 as rows and columns, respectively, as well as the costs for every possible character substitution. That is, for two characters $s \in \mathcal{A}(L_1)$ and $t \in \mathcal{A}(L_2)$, $\mathbf{M}(s, t)$ is the cost of substituting s by t. This user defined cost matrix allows computing linguistically motivated alignments by incorporating a linguistic prior into the computation of the Levenshtein distance. For example, we assign a cost costs of 0 when mapping a character to itself. In case of $\mathbf{M}$ being symmetric, the Levenshtein distance remains symmetric. Along with the edit distance between the two words w_i and w_j our implementation of the Levenshtein distance returns the alignments $\widetilde{w}_i, \widetilde{w}_j$ of w_i and w_j, respectively. Given the length $K = |\widetilde{w}_i|$ of the alignment, we are fur-

[1] $\varnothing$ plays an important role when computing alignments. We will also refer to it as *nothing*

ther able to compute the normalized Levenshtein distance $\mathrm{nLD}(w_i, w_j) = \frac{\mathrm{LD}(w_i,w_j)}{K}$. For computing both the alignment and the resulting edit distance `incom.py` uses the Needleman-Wunsch algorithm (Needleman and Wunsch, 1970) following a dynamic-programming approach.

2.1.3 Word adaptation surprisal

Given two aligned words $\widetilde{w}_i$ and $\widetilde{w}_j$, we can compute the *Word Adaptation Surprisal* (WAS) between $\widetilde{w}_i$ and $\widetilde{w}_j$. Intuitively, word adaptation surprisal measures how confused a reader is when trying to translate w_i to w_j character by character. In order to define WAS formally, we introduce the notation of *Character Adaptation Surprisal* (CAS). Given a character $s \in \mathcal{A}(L_1)$ and another character $t \in \mathcal{A}(L_2)$, the character adaptation surprisal between s and t is defined as follows:

$$\mathrm{CAS}(s,t) = -\log_2(P(t \mid s)) \tag{1}$$

Now, the word adaptation surprisal between $\widetilde{w}_i \in L_1$ and $\widetilde{w}_j \in L_2$ can be computed straightforwardly by summing over all characters of the aligned word pair, i.e.

$$\mathrm{WAS}(\widetilde{w}_i, \widetilde{w}_j) = \sum_{k=0}^{K-1} \mathrm{CAS}(s_k, t_k) \tag{2}$$

where $K = |\widetilde{w}_i| = |\widetilde{w}_j|$. Similarly, the normalized word adaptation surprisal is computed as

$$\begin{aligned}\mathrm{nWAS}(\widetilde{w}_i, \widetilde{w}_j) &= \frac{1}{K}\sum_{k=0}^{K-1} \mathrm{CAS}(s_k, t_k) && (3)\\ &= \frac{1}{K}\mathrm{WAS}(\widetilde{w}_i, \widetilde{w}_j) && (4)\end{aligned}$$

Note that in contrast to Levenshtein distance, word adaptation surprisal is not symmetric.

Computing CAS (and hence also WAS) depends on the conditional probability $P(t|s)$, which is usually unknown. `incom.py` estimates $P(t|s)$ by $\hat{P}(t|s)$ which is based on corpus statistics. Given the alignments of a corpus $\mathcal{C}$ of word pairs produced by the Levenshtein algorithm, we compute $P(t|s)$ by counting the number of times t is aligned with s and divide over the total number of occurrences of character s, i.e.

$$\begin{aligned}\hat{P}(L_2 = t | L_1 = s) &= \frac{count(L_1 = s \wedge L_2 = t)}{count(L_1 = s)} && (5)\\ &\approx P(L_2 = t | L_1 = s) && (6)\end{aligned}$$

Certainly the quality of the estimate $\hat{P}(L_2 = t|L_1 = s)$ depends on the size of the corpus $\mathcal{C}$. In addition to the corpus based estimated character surprisals, `incom.py` provides functionality to modify the computed CAS values in a manual post-processing step. Based on this, the modified word adaptation surprisal can be computed as:

$$\mathrm{mWAS}(\widetilde{w}_i, \widetilde{w}_j) = \sum_{k=0}^{K-1} \mathrm{mCAS}(s_k, t_k) \tag{7}$$

where mCAS denotes the modified character adaptation surprisal. Similar to using a user defined cost matrix $\mathbf{M}$ when computing the Levenshtein distance, using modified character surprisal allows to incorporate linguistic priors into the computation of word adaptation surprisal.

2.1.4 Conditional entropy

Another asymmetric measure that is supported by our `incom.py` toolbox is *Conditional Entropy* (CE) (Shannon, 1948). Formally, the entropy of a discrete random variable X is defined as the weighted average of the surprisal values of this distribution. As discussed above, we can obtain the character surprisals based on the alignments obtained when computing the Levenshtein distance. Using these surprisal values we can compute the entropy of a language L as

$$H(L) = -\sum_{c \in L} P(L = c)\log_2 P(L = c) \tag{8}$$

In this work we are interested the entropy of a language L_1, e.g. Russian, that we compare to the entropy of another language L_2, e.g. Bulgarian. Thus we compute the conditional entropy between two languages L_1 and L_2.

$$\mathrm{CE}(L_1|L_2) = -\sum_{c_2 \in L_2} P(c_2)H(L_1|L_2 = c_2) \tag{9}$$

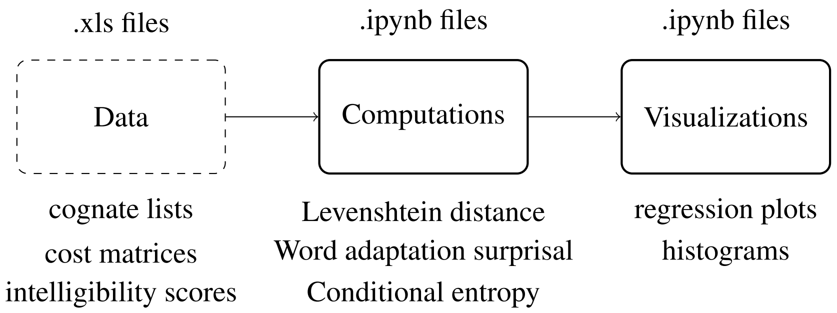

Figure 1: High-level overview of the `incom.py` toolbox.

Intuitively, CE$(L_1|L_2)$ measures the difficulty for a L_1 reader reading language L_2. Note that similar to the word adaptation surprisal, both entropy and conditional entropy highly depend on the number of available word pairs and only serve as an approximation to the true (unknown) entropy and conditional entropy, respectively.

2.2 `incom.py` toolbox

A high-level overview of the `imcom.py` toolbox is shown in Figure 1. The toolbox is a collection of jupyter notebooks based on the pandas and NumPy libraries[2]. To foster reproducibility and provide a resource for other researchers to easily compute linguistic distances and asymmetries we make `imcom.py` available online `https://github.com/uds-lsv/incompy`. In addition to computing distances and asymmetries based on a corpus of word pairs, `incom.py` readily supports visualizing the obtained results.

3 Data Sources

3.1 Language material

The Bulgarian (BG) and Russian (RU) data used in this work comes from a collection of parallel word lists consisting of internationalisms, Pan-Slavic vocabulary, and cognates from Swadesh lists. The words belong to different parts of speech, mainly nouns, adjectives, and verbs. We chose to use vocabulary lists instead of parallel sentences or texts in order to exclude the influence of other linguistic factors. The lists, each containing 120 words, were manually adjusted by removing non-cognates by possibly substituting them with etymologically related items, if such could be found, and adding further cognates[3]. Thus, for example, BG–RU ние–мы (nie–my) ‘we’ was removed and the BG звяр (zvjar) ‘beast’ instead of животно (životno) ‘animal’ was added to its RU cognate зверь (zver’) ‘animal, beast’. In a second step, a cross-linguistic rule set was designed taking into account diachronically motivated orthographic correspondences, e.g. BG–RU: б:бл, ж:жд, я:е, ла:оло etc. Following (Fischer et al., 2015) we apply the rule set to the parallel word lists in a computational transformation experiment and categorized all cognates in the respective pairs as either (i) identical, or (ii) successfully transformed, or (iii) non-transformable by this rule set. The stimuli selection for the online experiments (Section 3.2) is based on the successfully transformed ones: 128 items of a total of 935 (from all lists, excluding doublets). In this way we could exclude possible different derivational morphemes between related languages (e.g. BG–RU хладен–холодный (chladen–cholodnyj) ‘cold’) in order to focus on the impact of mismatched orthographic correspondences for cognate intelligibility. Even though it may seem artificial to test isolated words, the underlying assumption here is that correct cognate recognition is a precondition of success in reading intercomprehension. If the reader correctly recognizes a minimal proportion of words, he or she will be able to piece the written message together.

3.2 Web-based experiments

The orthographic intelligibility between BG and RU was tested in web-based experiments (`http://intercomprehension.coli.uni-saarland.de/en`) in which 71 native speakers of BG and 94 native speakers of RU took

[2] `https://jupyter.org`, `https://pandas.pydata.org`, `https://www.numpy.org`

[3] Shared inherited words from Proto-Slavic, shared loans, for example, internationalisms. Cognates are included in the definition; partial cognates are pairs of words which have the same meaning in both languages only in some contexts, for example, BG мъж (măž) ‘man, husband’ and RU муж (muž) ‘husband’.

		Stimuli	
		Bulgarian	Russian
Native	Bulgarian	–	74.67%
	Russian	71.33%	–

Table 1: Intercomprehension scores from free translation tasks performed by humans.

part. The participants started with registration and then completed a questionnaire in their native language. The challenges were presented: 2 with each 60 different BG stimuli in each group for RU speakers and 2 with 60 different RU stimuli in each group for BG speakers. The order of the stimuli were randomized. The participants saw the stimuli on their screen, one by one, and were given 10 seconds[4] to translate each word into RU or into BG. It was also possible to finish before the 10 seconds were over by either clicking on the 'next' button or pressing 'enter' on the keyboard. After 10 seconds the participants saw the next stimulus on their screen. During the experiment the participants received feedback in form of emoticons for their answers. The results were automatically categorized as 'correct' or 'wrong' via pattern matching with pre-defined answers: some stimuli had more than one possible translation and we also provided a list of so-called alternative correct answers. For example, the BG word път (păt) 'way' can be translated in RU as путь (put') or дорога (doroga), so both translations were counted as correct.

The analysis of the collected material[5] is based on the answers of 37 native speakers of Bulgarian (31 women and 6 men between 18 and 41 years of age, average 27 years) and 40 native speakers of Russian (32 women and 8 men between 18 and 71 years of age, average 33 years). The mean percentage of correctly translated items constitutes the intelligibility score of a given language (Table 1).

The results show that there is virtually no asymmetry in written intelligibility between BG and RU: the BG participants understand a slightly larger number of the RU words (74.67%) than the RU participants understand the BG words they are presented with (71.33%). This can be explained by the fact that there are only slight differences between the two languages on the graphic-orthographical level (for more details see (Stenger et al., 2017b)).

4 Results

4.1 Levenshtein distance and intelligibility score

Using `incom.py` we compute the orthographic LD in both directions and further consider the normalized Levenshtein distance nLD between the 120 BG and RU cognates motivated by the assumption that a segmental difference in a word of two segments has a stronger impact on intelligibility than a segmental difference in a word of ten segments (Beijering et al., 2008; Stenger et al., 2017a). There is a general assumption that the higher the normalized LD, the more difficult it is to translate a given word (Gooskens, 2007; Vanhove and Berthele, 2015; Vanhove, 2016). Thus, we correlate the normalized LD and the intelligibility scores from our experiments for both language pairs. The correlation results are presented in Figure 2. We find a correlation between orthographic distance (normalized LD) and the intelligibility of BG words for RU readers of $r = –0.57$ ($p = 1.4e − 11$) and $r = –0.36$ ($p = 6.3e − 05$) for BG readers. Both correlations are significant and confirm the above hypothesis. However, the LD accounts for only 32% ($R^2 = 0.32$) of the variance in the intelligibility scores for RU readers and for only 13% ($R^2 = 0.13$) of the variance in the intelligibility scores for BG readers, leaving the majority of variance unexplained. Recall from Section 2 that LD is a symmetric measure, and therefore it does not capture any asymmetries between correspondences. If, for instance, the RU vowel character а always corresponds to а for a BG reader, but in the other direction, BG а can correspond to а, о or я for a RU reader, then a measure of linguistic distance is required to reflect both this difference in adaptation possibilities and the uncertainty involved in transforming а. Such asymmetries are effectively captured by the next two intelligibility measurements of word adaptation surprisal and conditional entropy, both of which are implemented in the `incom.py` tool-

[4] The time limit is chosen based on the experience from other reading intercomprehension experiments. The allocated time is supposed to be sufficient for typing even the longest words, but not long enough for using a dictionary or an online translation tool.

[5] For the present study we exclude those participants who have indicated knowledge of the stimuli language(s) in the questionnaire and analyze the results only of the initial challenge for each participant in order to avoid any learning effects.

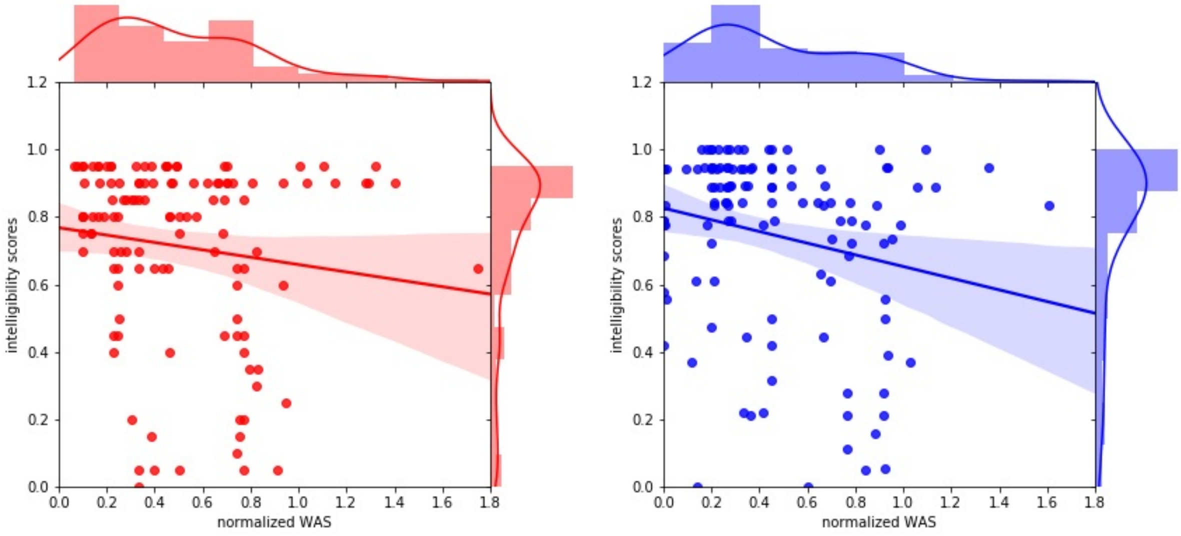
box.

4.2 Word adaptation surprisal and intelligibility score

Word adaptation surprisal (WAS), in particular the normalized word adaptation surprisal (nWAS), helps us to predict and explain the effect of mismatched orthographic correspondences in cognate recognition. We assume that the smaller the normalized WAS, the easier it is to guess the cognate in an unknown, but (closely) related language. The correlation between the normalized WAS and the intelligibility scores is displayed in Figure 3. We find a low but significant negative correlation ($r = –0.22, p < 0.05$) between nWAS and written word intelligibility for BG readers. However, the negative correlation ($r = –0.13$) between nWAS and written word intelligibility for RU readers is not significant ($p = 0.14$). This can be explained by the fact that WAS values are given in bits and depend heavily on the probability distribution used.

Recall that with `incom.py`, we get the character adaptation surprisal (CAS) from our character adaptation probabilities (see Section 2 above). CAS and WAS values allow quantifying the unexpectedness both of individual character correspondences and of the whole cognate pair. This gives a quantification of the overall unexpectedness of the correct cognate. However, identical orthographic correspondences may still have a small surprisal value, for example, from a RU perspective the correspondence а:а has a surprisal value of 0.5986 bits resulting in an increase of the WAS value. Thus, we decided to manually modify our WAS calculation in such a way that all identical orthographic correspondences are measured with 0 bits. The calculated CAS values for mismatched orthographic correspondences remain unchanged in the modified calculation. Using the modified word adaption surprisal, we find a negative significant correlation between the modified nWAS and written word intelligibility also for RU readers ($r = –0.21$, $p < 0.05$). However, the modified nWAS accounts only for 12% ($R^2 = 0.123$) of the variance in the intelligibility scores for BG readers and the modified nWAS accounts for less than 5% ($R^2 = 0.044$) of the variance in the intelligibility scores for RU readers. This leaves the question why the correlation at the cognate level is so low. A possible explanation is that a cognate in an unknown closely related language will be easier to understand as it is more similar to the cognate in one's own language, because each cognate pair may have its own constellation of factors, affecting intelligibility, where one factor may overrule another factor, e.g., the number of orthographic neighbors in one's own language that



(a) BG-RU

(b) RU-BG

Figure 3: Normalized word adaptation surprisal as a predictor for intelligibility. 3a Shows Russian native speakers reading Bulgarian. 3b Shows Bulgarian native speakers reading Russian.

are very similar to the stimulus, the number of mismatched orthographic correspondences in the stimulus and their position, the word frequency in one's own language, the word length of stimulus etc. The estimated character values seem not to exactly reflect this constellation.

4.3 Conditional entropy and intelligibility score

For the BG–RU language pair the difference in the full conditional entropies (CE) is very small: 0.4853 bits for the BG to RU transformation and 0.4689 bits for the RU to BG transformation, with a very small amount of asymmetry of 0.0164 bits. These results predict that speakers of RU reading BG words are more uncertain than speakers of BG reading RU words. This is in accordance with the experimental results where the language combination with the slightly higher CE (RU speakers reading BG) had a slightly lower intelligibility score (see Table 1). Thus, CE can be a reliable measure when explaining even the small asymmetry in the mutual intelligibility.

Using `incom.py` we calculated entropy values of BG and RU characters in order to analyse asymmetries on the written (orthographic) level in more details. Figure 4 shows the entropy values of 6 BG characters е, ъ, а, щ, и, я, and the special symbol ∅ for RU readers and the entropy values of 5 RU characters о, е, я, у, л for BG readers (on the right). Note that the alignment of ∅ to any other character c corresponds to the case where Russian readers have to fill in a character. The entropy calculations reveal that, for example, BG readers should have more uncertainty with the RU vowel character о, while RU readers should have more difficulties with the adaptation of the BG vowel character е. This means that the mapping of the RU о to possible BG characters is more complex than the opposite direction. More precisely, the RU о can map into 4 BG vowel characters (о, а, ъ, е) or to *nothing* (∅), the BG е can map into 3 RU vowel characters (е, ё, or я). Certainly, in an intercomprehension scenario a BG or a RU reader does not know these mappings and the respective probabilities. However, the assumption is that the measure of complexity of the mapping can be used as an indicator for the degree of intelligibility (Moberg et al., 2007), because it reflects the difficulties with which a reader is confronted in 'guessing' the correct correspondence. Our experimental results indeed show that BG readers have greater problems with the RU о than RU readers with the BG character а or *nothing* (∅) in cognate pairs like RU–BG холод – хлад (cholod – chlad) 'cold', борода – брада (boroda – brada) 'beard', ворона – врана (vorona – vrana) 'crow'.

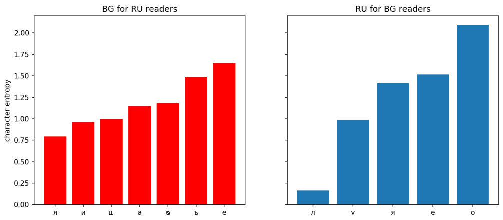


Figure 4: Character entropy values when translating from Russian to Bulgarian and vice versa.

5 Discussion and Outlook

Previous research in reading intercomprehension has shown that (closely) related languages may be differently distant from each other and their mutual intelligibility may be asymmetric. In this paper we present `incom.py` – a toolbox for computing linguistic distances and asymmetries. With `incom.py` we perform experiments on measuring and predicting the mutual intelligibility of Slavic languages, as exemplified by the language pair Bulgarian-Russian by means of the Levenshtein distance, word adaptation surprisal, and conditional entropy. Using a small corpus of parallel cognate lists we validated linguistic distances and asymmetries as predictors of mutual intelligibility based on stimuli obtained from written intelligibility tests. The results of our statistical analyses clearly support normalized Levenshtein distance as a reliable predictor of orthographic intelligibility at the word level for both language pairs tested. However, we find that only 32% (for RU readers) and 13% (for BG readers) of the variance in the intelligibility data is explained by the orthographic similarity quantified by means of the normalized Levenshtein distance. We find that the predictive power of the Levenshtein distance is different within the two language pairs. It must be mentioned here that the RU stimuli are in general longer (5.09 characters) than the BG stimuli (4.61 characters). Thus, the BG readers should intuitively delete more characters while the RU readers should add more characters in order to guess the correct cognate.

Previous research has shown that deletions and additions, the basic operations performed when computing Levenshtein distance, are not of equal value in the mutual intelligibility: it appears that deletions are more transparent for the participants in terms of subjective similarity than additions (Kaivapalu and Martin, 2017). This means that there is room for improvement in our orthographic distance algorithm. Word adaptation surprisal measures the complexity of a mapping, in particular, how predictable the particular correspondence in a language pair is. The surprisal values of correspondences are indeed different. However, they depend on their frequency and distribution in the particular cognate set. Most important and in contrast to Levenshtein distance, surprisal can be asymmetric. The character adaptation surprisal values between language A and language B are not necessarily the same as between language B and language A. This indicates an advantage of the surprisal-based method compared to Levenshtein distance. Our results show that the predictable potential of word adaptation surprisal was rather weak despite its modification. We assume that word adaptation surprisal should to a larger extent take into account relevant factors in reading intercomprehension, for example, orthographic neighbors (words that are very similar to the stimulus word and differ only in one character). Something we keep as future work.

Conditional entropy can reflect the difficulties humans encounter when mapping one orthographic system on another. The underlying hypothesis is that high predictability improves intelligibility, and therefore a low entropy value should correspond to a high intelligibility score. This result is as we expected. We have calculated conditional entropy for Bulgarian and Russian using a cognate word list from intelligibility tests. In our experiments, conditional entropy – like the intelligibility task – reveals asymmetry between Bulgarian and Russian on the orthographic level: the conditional entropy in Bulgarian for Russian readers is slightly higher than the conditional entropy in Russian for Bulgarian readers. This means that the slightly higher entropy is found in the language pair where there is slightly lower intelligibility. Thus, we were able to show that conditional entropy can be a reliable measure when explaining small asymmetries in intelligibility. In future work we plan to extend `incom.py` with additional functionality to compute distances and asymmetries on the phonological level. Additionally, it might be interesting to consider the morphological level which has been shown to be helpful when processing words for humans with limited reading abilities (Burani et al., 2008).

Acknowledgments

We would like to thank Klára Jágrová and Volha Petukhova for their helpful feedback on this paper. Furthermore, we thank the reviewers for their valuable comments. This work has been funded by Deutsche Forschungsgemeinschaft (DFG) under grant SFB 1102: Information Density and Linguistic Encoding.

A Holistic Natural Language Generation Framework for the Semantic Web

Axel-Cyrille Ngonga Ngomo[1] **Diego Moussallem**[1] **Lorenz Bühmann**[2]

Abstract

With the ever-growing generation of data for the Semantic Web comes an increasing demand for this data to be made available to non-semantic Web experts. One way of achieving this goal is to translate the languages of the Semantic Web into natural language. We present LD2NL, a framework for verbalizing the three key languages of the Semantic Web, i.e., RDF, OWL, and SPARQL. Our framework is based on a bottom-up approach to verbalization. We evaluated LD2NL in an open survey with 86 persons. Our results suggest that our framework can generate verbalizations that are close to natural languages and that can be easily understood by non-experts. Therewith, it enables non-domain experts to interpret Semantic Web data with more than 91% of the accuracy of domain experts.

1 Introduction

Natural Language Generation (NLG) is the process of automatically generating coherent Natural Language (NL) text from non-linguistic data (Reiter and Dale, 2000a). Recently, the field has seen an increased interest in the development of NLG systems focusing on verbalizing resources from Semantic Web (SW) data (Gardent et al., 2017). The SW aims to make information available on the Web easier to process for machines and humans. However, the languages underlying this vision, i.e., Resource Description Framework (RDF), SPARQL Query Language (SPARQL) and Web Ontology Language (OWL), are rather difficult to understand for non-expert users. For example, while the meaning of the OWL class expression `Class: Professor SubClassOf: worksAt SOME University` is obvious to every SW expert, this expression ("Every professor works at a university") is rather difficult to fathom for lay persons.

Previous works such as SPARQL2NL (Ngonga Ngomo et al., 2013) and SPARTIQULATION (Ell et al., 2012) have already shown the usefulness of the verbalization of SPARQL [1] and RDF in areas such as question answering (Lehmann et al., 2012) and the explanation of the output of systems based onSW technologies (Ngonga Ngomo et al., 2013). However, other SW languages are rarely investigated, such as OWL.

In this paper, we present an open-source holistic NLG framework for the SW, named LD2NL, which facilitates the verbalization of the three key languages of the SW, i.e., RDF, OWL, and SPARQL into NL. Our framework is based on a bottom-up paradigm for verbalizing SW data. Additionally, LD2NL builds upon *SPARQL2NL* as it is open-source and the paradigm it follows can be reused and ported to RDF and OWL. Thus, LD2NL is capable of generating either a single sentence or a summary of a given resource, rule, or query. To validate our framework, we evaluated LD2NL using experts 66 in Natural Language Processing (NLP) and SW as well as 20 non-experts who were lay users or non-users of SW. The results suggest that LD2NL generates texts which can be easily understood by humans. The version of LD2NL used in this paper, all experimental results will be publicly available.

2 Related Work

According to Gatt and Krahmer (2017), there has been a plenty of works which investigated the generation of NL texts from Semantic Web Technologies (SWT) as an input data (Cimiano et al., 2013;

[1] SPARQL is the query language for RDF data.

Duma and Klein, 2013; Ell and Harth, 2014; Biran and McKeown, 2015). However, the subject of research has only recently gained significant momentum due to the great number of published works in the WebNLG (Colin et al., 2016) challenge along with deep learning techniques (Sleimi and Gardent, 2016; Mrabet et al., 2016). RDF has also been showing promising benefits to the generation of benchmarks for evaluating NLG systems (Gardent et al., 2017; Perez-Beltrachini et al., 2016).

Despite the plethora of recent works written on handling RDF data, only a few have exploited the generation of NL from OWL and SPARQL. For instance, Androutsopoulos et al. (2013) generates sentences in English and Greek from OWL ontologies. Also, SPARQL2NL (Ngonga Ngomo et al., 2013) uses rules to verbalize atomic constructs and combine their verbalization into sentences. Therefore, our goal with LD2NL is to provide a complete framework to verbalize SW concepts rather than become the state of the art on the respective tasks.

3 Background

3.1 OWL

OWL[2] (OWL Working Group, 2009) is the de-facto standard for machine processable and interoperable ontologies on the SW. In its second version, OWL is equivalent to the description logic $\mathcal{SROIQ}(D)$. Such expressiveness has a higher computational cost but allows the development of interesting applications such as automated reasoning (Bühmann et al., 2016). OWL 2 ontologies consist of the following three different syntactic categories:

Entities, such as *classes*, *properties*, and *individuals*, are identified by IRIs. They form the primitive terms and constitute the basic elements of an ontology. Classes denote sets of individuals and properties link two individuals or an individual and a data value along a property. For example, a class `:Animal` can be used to represent the set of all animals. Similarly, the object property `:childOf` can be used to represent the parent-child relationship and the data property `:birthDate` assigns a particular birth date to an individual. Finally, the individual `:Alice` can be used to represent a particular person called ”Alice”.

Expressions represent complex notions in the domain being described. For example, a *class expression* describes a set of individuals in terms of the restrictions on the individuals' characteristics. OWL offers existential (**SOME**) or universal (**ONLY**) qualifiers and a variety of typical logical constructs, such as negation (**NOT**), other Boolean operators (**OR**, **AND**), and more constructs such as cardinality restriction (**MIN**, **MAX**, **EXACTLY**) and value restriction (**VALUE**), to create class expressions. Such constructs can be combined in arbitrarily complex class expressions `CE` according to the following grammar

```
CE = A | C AND D | C OR D | NOT C | R
    SOME C | R ONLY C | R MIN n | R MAX
     n | R EXACTLY n | R VALUE a | {a1
    ,...,am}
```

where `A` is an atomic class, `C` and `D` are class expressions, `R` is an object property, `a` as well as $\mathtt{a}_1$ to $\mathtt{a}_m$ with $\mathtt{m} \geq 1$ are individuals, and $\mathtt{n} \geq 0$ is an integer.

Axioms are statements that are asserted to be true in the domain being described. Usually, one distinguish between (1) *terminological* and (2) *assertional* axioms. (1) terminological axioms are used to describe the structure of the domain, i.e., the relationships between classes resp. class expressions. For example, using a subclass axiom (**SubClassOf:**), one can state that the class `:Koala` is a subclass of the class `:Animal`. Classes can be subclasses of other classes, thus creating a taxonomy. In addition, axioms can arrange properties in hierarchies (**SubPropertyOf:**) and can assign various characteristics (**Characteristics:**) such as transitivity or reflexivity to them. (2) Assertional axioms formulate facts about individuals, especially the classes they belong to and their mutual relationships. OWL can be expressed in various syntaxes with the most common computer readable syntax being RDF/XMLA more human-readable format is the Manchester OWL Syntax (MOS) (Horridge et al., 2006). For example, the class expression that models people who work at a university that is located in Spain could be as follows in MOS:

```
Person AND worksAt SOME (University AND
    locatedIn VALUE Spain)
```

Likewise, expressing that every professor works at a university would read as

```
Class: Professor
  SubClassOf: worksAt SOME University
```

[2] www.w3.org/TR/owl2-overview/

3.2 RDF

RDF (RDF Working Group, 2014) uses a graph-based data model for representing knowledge. Statements in RDF are expressed as so-called triples of the form `(subject, predicate, object)`. RDF subjects and predicates are Internationalized Resource Identifierss (IRIs) and objects are either IRIs or literals.[3] RDF literals always have a datatype that defines its possible values. A predicate denotes a *property* and can also be seen as a binary relation taking subject and object as arguments. For example, the following triple expresses that Albert Einstein was born in Ulm:

```
:Albert_Einstein :birthPlace :Ulm .
```

3.3 SPARQL

Commonly, the selection of subsets of RDF is performed using the SPARQL query language.[4] SPARQL can be used to express queries across diverse data sources. *Query forms* contain variables that appear in a solution result. They can be used to select all or a subset of the variables bound in a pattern match. They exist in four different instantiations, i.e., *SELECT*, *CONSTRUCT*, *ASK* and *DESCRIBE*. The *SELECT* query form is the most commonly used and is used to return rows of variable bindings. Therefore, we use this type of query in our explanation. *CONSTRUCT* allows to create a new RDF graph or modify the existing one through substituting variables in a graph templates for each solution. *ASK* returns a Boolean value indicating whether the graph contains a match or not. Finally, *DESCRIBE* is used to return all triples about the resources matching the query. For example, 1 represents the following query "Return all scientists who were born in Ulm".

```
SELECT ?person
WHERE {
    ?person a dbo:Scientist;
        dbo:birthPlace dbr:Ulm.
}
```

Listing 1: All scientists who were born in Ulm

4 LD2NL Framework

The goal of LD2NL is to provide an integrated system which generates a complete and correct NL representation for the most common used SW modeling languages RDF and OWL, and SPARQL. In terms of the standard model of NL generation proposed by Reiter & Dale (Reiter and Dale, 2000b), our steps mainly play the role of the micro-planner, with focus on aggregation, lexicalization, referring expressions and linguistic realization. In the following, we present our approach to formalizing NL sentences for each of the supported languages.

4.1 From RDF to NL

4.1.1 Lexicalization

The lexicalization of RDF triples must be able to deal with resources, classes, properties and literals.

Classes and resources The lexicalization of classes and resources is carried out as follows: Given a URI u we ask for the English label of u using a SPARQL query.[5] If such a label does not exist, we use either the fragment of u (the string after `#`) if it exists, else the string after the last occurrence of `/`. Finally this NL representation is realized as a noun phrase, and in the case of classes is also pluralized. As an example, `:Person` is realized as `people` (its label).

Properties The lexicalization of properties relies on the insight that most property labels are either nouns or verbs. While the mapping of a particular property `p` can be unambiguous, some property labels are not as easy to categorize. For examples, the label `crosses` can either be the plural form of the noun `cross` or the third person singular present form of the verb `to cross`. To automatically determine which realization to use, we relied on the insight that the first and last word of a property label are often the key to determining the type of the property: properties whose label begins with a verb (resp. noun or gerund) are most to be realized as verbs (resp. nouns). We devised a set of rules to capture this behavior, which we omit due to space restrictions. In some cases (such as `crosses`) none of the rules applied. In these cases, we compare the probability of $P(p|\texttt{noun})$ and $P(p|\texttt{verb})$ by measuring

$$P(p|X) = \frac{\sum\limits_{t \in synset(p|X)} \log_2(f(t))}{\sum\limits_{t' \in synset(p)} \log_2(f(t'))}, \qquad (1)$$

where $synset(p)$ is the set of all synsets of p, $synset(p|X)$ is the set of all synsets of p that are of

[3] For simplicity, we omit RDF blank nodes in subject or object position.

[4] http://www.w3.org/TR/sparql11-query

[5] Note that it could be any property which returns a NL representation of the given URI, see (Ell et al., 2011).

the syntactic class $X \in \{\texttt{noun}, \texttt{verb}\}$ and $f(t)$ is the frequency of use of p in the sense of the synset t according to WordNet. For

$$\frac{P(p|\texttt{verb})}{P(p|\texttt{noun})} \geq \theta, \tag{2}$$

we choose to realize `p` as a noun; else we realized it as a verb. For $\theta = 1$, for example, `dbo:crosses` is realized as a verb.

Literals Literals in an RDF graph usually consist of a *lexical form* `LF` and a *datatype IRI* `DT`, represented as `"LF"^^<DT>`. Optionally, if the datatype is `rdf:langString`, a non-empty *language tag* is specified and the literal is denoted as *language-tagged string*[6]. The realization of language-tagged strings is done by using simply the lexical form, while omitting the language tag. For example, `"Albert Einstein"@en` is realized as `Albert Einstein`. For other types of literals, we further differentiate between built-in and user-defined datatypes. For the former, we also use the lexical form, e.g. `"123"^^xsd:int` ⇒ `123`, while the latter are processed by using the literal value with its representation of the datatype IRI, e.g., `"123"^^dt:squareKilometre` as `123 square kilometres`.

4.1.2 Realizing single triples

The realization ρ of a triple `(s p o)` depends mostly on the verbalization of the predicate `p`. If `p` can be realized as a noun phrase, then a possessive clause can be used to express the semantics of `(s p o)`, more formally

1. $\rho(\texttt{s p o}) \Rightarrow$
   $\texttt{poss}(\rho(\texttt{p}),\rho(\texttt{s})) \wedge \texttt{subj}(\texttt{BE},\rho(\texttt{p}))$
   $\wedge\, \texttt{dobj}(\texttt{BE},\rho(\texttt{o}))$

For example, if $\rho(\texttt{p})$ is a relational noun like `birth place` e.g. in the triple `(:Albert_Einstein :birthPlace :Ulm)`, then the verbalization is `Albert Einstein's birth place is Ulm`. Note that `BE` stands for the verb “to be”. In case `p`'s realization is a verb, then the triple can be verbalized as follows:

2. $\rho(\texttt{s p o}) \Rightarrow$
   $\texttt{subj}(\rho(\texttt{p}),\rho(\texttt{s})) \wedge \texttt{dobj}(\rho(\texttt{p}),\rho(\texttt{o}))$

For example, in `(:Albert_Einstein :influenced :Nathan_Rosen)` $\rho(\texttt{p})$ is the verb `influenced`, thus, the verbalization is Albert Einstein influenced Nathan Rosen.

4.2 Realization - RDF Triples to NL

The same procedure of generating a single triple can be applied for the generation of each triple in a set of triples. However, the NL output would contain redundant information and consequently sound very artificial. Thus, the goal is to transform the generated description to sound more natural. To this end, we focus on two types of transformation rules (cf. (Dalianis and Hovy, 1996)): *ordering and clustering* and *grouping*. In the following, we describe the transformation rules we employ in more detail. Note that clustering and ordering (4.2.1) is applied before grouping (4.2.2).

4.2.1 Clustering and ordering rules

We process the input trees in descending order with respect to the frequency of the variables they contain, starting with the projection variables and only after that turning to other variables. As an example, consider the following triples about two of the most known people in the world:

```
:William_Shakespeare rdf:type :Writer .
:Albert_Einstein :birthPlace :Ulm .
:Albert_Einstein :deathPlace :Princeton
:Albert_Einstein rdf:type :Scientist .
:William_Shakespeare :deathDate
"1616-04-23"^^xsd:date .
```

The five triples are verbalized as given in 3a–3e. Clustering and ordering first take all sentences containing the subject `:Albert_Einstein`, i.e. 3b –3d, which are ordered such that copulative sentences (such as Albert Einstein is a scientist) come before other sentences, and then takes all sentences containing the remaining subject `:William_Shakespeare` in 3a and 3e resulting in a sequence of sentences as in 4.

3. (a) William Shakespeare is a writer.
   (b) Albert Einstein's birth place is Ulm.
   (c) Albert Einstein's death place is Princeton.
   (d) Albert Einstein is a scientist.
   (e) William Shakespeare's death date is 23 April 1616.

4. Albert Einstein is a scientist. Albert Einstein's birth place is Ulm. Albert Einstein's death place is Princeton. William Shakespeare's is a writer. William Shakespeare's death date is 23 April 1616.

4.2.2 Grouping

Dalianis and Hovy (1996) describe grouping as a process “collecting clauses with common elements and then collapsing the common elements”. The common elements are usually subject noun

[6] In RDF 1.0 literals have been divided into 'plain' literals with no type and optional language tags, and typed literals.

phrases and verb phrases (verbs together with object noun phrases), leading to *subject grouping* and *object grouping*. To maximize the grouping effects, we collapse common prefixes and suffixes of sentences, irrespective of whether they are full subject noun phrases or complete verb phrases. In the following we use $X_1, X_2, \ldots X_N$ as variables for the root nodes of the input sentences and Y as variable for the root node of the output sentence. Furthermore, we abbreviate a subject $\mathtt{subj}(X_i, s_i)$ as $\mathtt{s}_i$, an object $\mathtt{dobj}(X_i, o_i)$ as $\mathtt{o}_i$, and a verb $\mathtt{root}(\mathit{ROOT}_i, v_i)$ as $\mathtt{v}_i$.

Subject grouping collapses the predicates (i.e. verb and object) of two sentences if their subjects are the same, as specified in 5 (abbreviations as above).

5. $\rho(\mathtt{s}_1) = \rho(\mathtt{s}_2) \wedge \mathtt{cc}(\mathtt{v}_1, \mathit{coord})$ $\Rightarrow$ $\mathtt{root}(Y, \mathtt{coord}(\mathtt{v}_1, \mathtt{v}_2)) \wedge \mathtt{subj}(\mathtt{v}_1, \mathtt{s}_1) \wedge \mathtt{dobj}(\mathtt{v}_1, \mathtt{o}_1) \wedge \mathtt{subj}(\mathtt{v}_2, \mathtt{s}_1) \wedge \mathtt{dobj}(\mathtt{v}_1, \mathtt{o}_2)$

An example are the sentences given in 6, which share the subject Albert Einstein and thus can be collaped into a single sentence.

6. Albert Einstein is a scientist and Albert Einstein is known for general relativity.
⇒ Albert Einstein is a scientist and known for general relativity.

Object grouping collapses the subjects of two sentences if the realizations of the verbs and objects of the sentences are the same, where the *coord* $\in$ {and, or} is the coordination combining the input sentences X_1 and X_2, and $\mathtt{coord} \in \{\mathtt{conj}, \mathtt{disj}\}$ is the corresponding coordination combining the subjects.

7. $\rho(\mathtt{o}_1) = \rho(\mathtt{o}_2) \wedge \rho(\mathtt{v}_1) = \rho(\mathtt{v}_2) \wedge \mathtt{cc}(\mathtt{v}_1, \mathit{coord})$ $\Rightarrow$ $\mathtt{root}(Y, \mathrm{PLURAL}(\mathtt{v}_1)) \wedge \mathtt{subj}(\mathtt{v}_1, \mathtt{coord}(\mathtt{s}_1, \mathtt{s}_2)) \wedge \mathtt{dobj}(\mathtt{v}_1, \mathtt{o}_1)$

For example, the sentences in 8 share their verb and object, thus they can be collapsed into a single sentence. Note that to this end the singular auxiliary was needs to be transformed into its plural form were.

8. Benjamin Franklin was born in Boston. Leonard Nimoy was born in Boston. ⇒ Benjamin Franklin and Leonard Nimoy were born in Boston.

4.3 From OWL to NL

OWL 2 ontologies consist of Entities, Expressions and Axioms as introduced in subsection 3.1. While both expressions and axioms can be mapped to RDF[7], i.e. into a set of RDF triples, using this mapping and applying the triple-based verbalization on it would lead to a non-human understandable text in many cases. For example, the intersection of two classes `:A` and `:B` can be represented in RDF by the six triples

```
_:x rdf:type owl:Class .
_:x owl:intersectionOf _:y1 .
_:y1 rdf:first :A .
_:y1 rdf:rest _:y2 .
_:y2 rdf:first :B .
_:y2 rdf:rest rdf:nil .
```

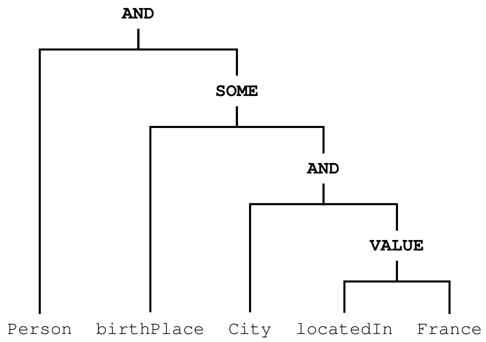
The verbalization of these triples would result in `Something that is a class and the intersection of something whose first is A and whose rest is something whose first is B and whose rest ist nil.`, which is obviously far away from how a human would express it in NL. Therefore, generating NL from OWL requires a different procedure based on its syntactic categories, OWL expressions and OWL axioms. We show the general rules for each of them in the following.

4.3.1 OWL Class Expressions

In theory, class expressions can be arbitrarily complex, but as it turned out in some previous analysis (Power and Third, 2010), in practice they seldom arise and can be seen as some corner cases. For example, an ontology could contain the following class expression about people and their birth place:

```
Person AND birthPlace SOME (City AND
    locatedIn VALUE France)
```

Class expressions do have a tree-like structure and can simply be parsed into a tree by means of the binary OWL class expressions constructors contained in it. For our example, this would result in the following tree:



Such a tree can be traversed in post-order, i.e. sub-trees are processed before their parent nodes recursively. For the sake of simplicity, we only process sub-trees that represent proper

[7] http://bit.ly/2Mc0vIw

class expression in our example, i.e. we omit `birthPlace`, `locatedIn`, and `France`. Moreover and again for simplicity, we'll explain the transformation process by starting from the right-hand side of the tree. Thus, in our example we begin with the class expression `City` which is transformed to `everything that is a city` and `locatedIn VALUE France` resulting in `everything that is located in France` by application of a rule. Both class expressions are used in the conjunction `City AND locatedIn VALUE France`. Thus, the next step would be to merge both phrases. An easy way is to use the coordinating conjunction `and`, i.e. `everything that is a city and everything that is located in France`. Although the output of this transformation is correct, it still contains unnecessarily redundant information. Therefore, we apply the aggregation procedure described in Section 4.2.2, i.e. we get `everything that is a city and located in France`. Yet, the aggregation can still be improved: if there is any atomic class in the conjunction, we know that this is more specific than the placeholder `everything`. Thus, we can replace it by the plural form of the class, finally resulting in `cities that are located in France`. The same procedure is applied for its parent class expression being the existential restriction

```
birthPlace SOME (City AND locatedIn
    VALUE France)
```

This will be transformed to `everything whose birth place is a city that is located in France`. Note, that we used the singular form here, assuming that the property `birthPlace` is supposed to be functional in the ontology. In the last step, we process the class expression `Person`, which gives us `everything that is a person`. Again, due to the conjunction we merge this result with with the previous one, such that in the end we get `people whose birth place is a city that is located in France`.

4.3.2 OWL Axioms

As we described in Section 4.3, OWL axioms can roughly be categorized into terminological and assertional axioms. Therefore, we have different procedures for processing each category:

Assertional Axioms (ABox Axioms) - Most assertional axioms assert individuals to atomic classes or relate individuals to another individual resp. literal value. For example, axioms about the type as well as birth place and birth date of Albert Einstein can be expressed by

```
Individual: Albert_Einstein
  Types: Person
  Facts: birthPlace Ulm, birthDate "
      1879-03-14"^^xsd:date
```

Those axioms can simply be rewritten as triples, thus, we can use the same procedure as we do for triples (Section 4.1.2). Converting them into NL gives us `Albert Einstein is a person whose birth place is Ulm and whose birth date is 14 March 1879`. OWL also allows for assigning an individual to a complex class expression. In that case we'll use our conversion of OWL class expressions as described in Section 4.3.1.

Terminological Axioms (TBox Axioms) - According to Power and Third (2010), most of the terminological axioms used in ontologies are subclass axioms. By definition, subclass and superclass can be arbitrarily complex class expressions $\mathtt{CE}_1$ and $\mathtt{CE}_2$, i.e. $\mathtt{CE}_1$ **`SubClassOf`** $\mathtt{CE}_2$, but in praxis it is quite often only used with atomic classes as subclass or even more simple with the superclass also beeing an atomic class. Nevertheless, we support any kind of subclass axiom and all other logical OWL axioms in LD2NL. For simplicity, we outline here how we verbalize subclass axioms in LD2NL. The semantics of a subclass axiom denotes that every individual of the subclass also belongs to the superclass. Thus, the verbalization seems to be relatively straightforward, i.e. we verbalize both class expressions and follow the template : every $\rho(\mathtt{CE}_1)$ is a $\rho(\mathtt{CE}_2)$. Obviously, this works pretty well for subclass axioms with atomic classes only. For example, the axiom

```
Class: Scientist
  SubClassOf: Person
```

is verbalized as `every scientist is a person`.

4.4 From SPARQL to NL

A SPARQL `SELECT` query can be regarded as consisting of three parts: (1) a *body section* `B`, which describes all data that has to be retrieved, (2) an *optional section* `O`, which describes the data items that can be retrieved by the query if they exist, and (3) a *modifier section* `M`, which describes all solution sequences, modifiers and aggregates that are to be applied to the result of the previous two sections of the query. Let *Var* be the set of all variables that can be used in a SPARQL query. In addition, let R be the set of all resources, P the set of all properties and L the set of all literals contained in the target knowledge base of the SPARQL queries at hand. We call $x \in Var \cup R \cup P \cup L$ an *atom*. The basic components of the body of a SPARQL query are triple patterns $(\texttt{s}, \texttt{p}, \texttt{o}) \in (Var \cup R) \times (Var \cup P) \times (Var \cup R \cup L)$. Let W be the set of all words in the dictionary of our target language. We define the realization function $\rho : Var \cup R \cup P \cup L \rightarrow W^*$ as the function which maps each atom to a word or sequence of words from the dictionary. The extension of ρ to all SPARQL constructs maps all atoms x to their realization $\rho(x)$ and defines how these atomic realizations are to be combined. We denote the extension of ρ by the same label ρ for the sake of simplicity. We adopt a rule-based approach to achieve this goal, where the rules extending ρ to all valid SPARQL constructs are expressed in a conjunctive manner. This means that for premises $P_1, \ldots, P_n$ and consequences $K_1, \ldots, K_m$ we write $P_1 \wedge \ldots \wedge P_n \Rightarrow K_1 \wedge \ldots \wedge K_m$. The premises and consequences are explicated by using an extension of the Stanford dependencies[8].

For example, a possessive dependency between two phrase elements e_1 and e_2 is represented as $\texttt{poss}(e_1, e_2)$. For the sake of simplicity, we slightly deviate from the Stanford vocabulary by not treating the copula to be as an auxiliary, but denoting it as BE. Moreover, we extend the vocabulary by the constructs conj and disj which denote the conjunction resp. disjunction of two phrase elements. In addition, we sometimes reduce the construct $\texttt{subj(y,x)} \wedge \texttt{dobj(y,z)}$ to the triple $\texttt{(x,y,z)} \in W^3$.

5 Experiments

We evaluated our approach in three different experiments based on human ratings. We divided the volunteers into two groups—domain experts and non-experts. The group of domain experts comprised 66 persons while there were 20 non-experts forming the second group. In the first experiment, an OWL axiom and its verbalization were shown to the experts who were asked to rate the verbalization regarding the two following measures according to Gardent et al. (2017): (1) Adequacy: Does the text contain only and all the information from the data? (2) Fluency: Does the text sound fluent and natural?. For both measures the volunteers were asked to rate on a scale from 1 (Very Bad) to 5 (Very Good). The experiment was carried out using 41 axioms of the Koala ontology.[9] Because of the complexity of OWL axioms, only domain experts were asked to perform this experiment.

In the second experiment, a set of triples describing a single resource and their verbalization were shown to the volunteers. The experts were asked to rate the verbalization regarding adequacy, fluency and *completeness*, i.e., whether all triples have been covered. The non-experts were only asked to rate the fluency. The experiment was carried out using 6 DBpedia resources.In the third experiment, the verbalization of an OWL class and 5 resources were shown to the human raters. For non-experts, the resources have been verbalized as well, while for domain experts the resources were presented as triples. The task of the raters was to identify the resource that fits the class description and, thus, is an instance of the class. We used 4 different OWL axioms and measured the amount of correct identified class instances.

Results In our first series of experiments, the verbalization of OWL axioms, we achieved an average adequacy of 4.4 while the fluency reached 4.38. In addition, more than 77% of the verbalizations were assigned the maximal adequacy (i.e., were assigned a score of 5, see Fig. 1). The maximal score for fluency was achieved in more than 69% of the cases (see Fig. 1). This clearly indicates that the verbalization of axioms generated by LD2NL can be easily understood by domain experts and contains all the information necessary to access the input OWL class expression.

Experiments on the verbalization of summaries for RDF resources revealed that verbalizing resource summaries is a more difficult task. While the adequacy of the verbalization was assigned an average score of 3.92 by experts (see Fig. 2), the fluency was assigned a average score of 3.47 by experts and 3.0 by non-experts (see Fig. 2). What these results suggest is that (1) our framework generates sentences that are close to that which a domain expert would also generate (adequacy). However (2) while the sentence is grammatically

[8] For a complete description of the vocabulary, see https://stanford.io/2EzMjmo.

[9] https://bit.ly/2K8BWts

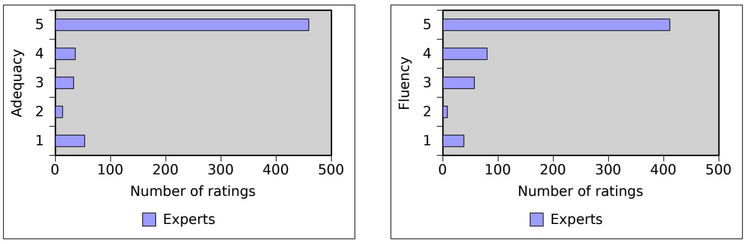


Figure 1: Experiment I: adequacy (left) and fluency (right) ratings

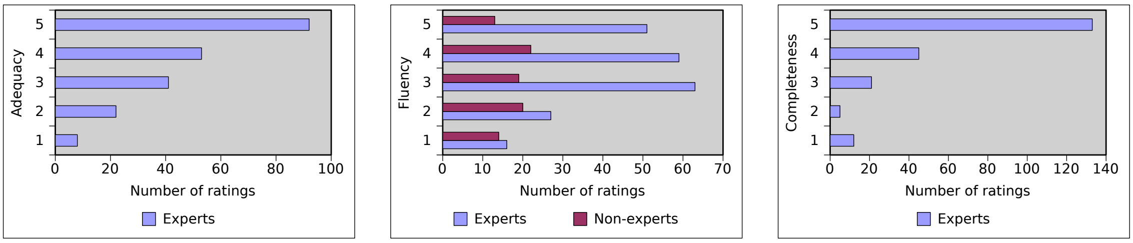

Figure 2: Experiment II: adequacy (left), fluency (middle) and completeness (left) results

sufficient for the experts, it is regarded by non-domain experts (which were mostly linguists, i.e., the worst-case scenario for such an evaluation) as being grammatically passably good but still worthy of improvement. The completeness rating achieves a score of 4.31 on average (see Fig. 2). This was to be expected as we introduced a rule to shorten the description of resources that contain more than 5 triples which share a common subject and predicate. Finally, we measured how well the users and experts were able to understand the meaning of the text generated by our approach. As expected, the domain experts outperform the non-expert users by being able to find the answers to 87.2% of the questions. The score achieved by non-domain experts, i.e., 80%, still suggest that our framework is able to bridge the gap pertaining to understand RDF and OWL for non-experts from 0% to 80%, which is more than 91.8% of the performance of experts.

Discussion Our evaluation results suggest that the verbalization of these languages is a non-trivial task that can be approached by using a bottom-up approach. As expected, the verbalization of short expressions leads to sentences which read as if they have been generated by a human. However, due to the complexity of the semantics that can be expressed by the languages at hand, long expressions can sound mildly artificial. Our results however also suggest that although the text generated can sound artificial, it is still clear enough to enable non-expert users to achieve results that are comparable to those achieved by experts. Hence, our first conclusion is that our framework clearly serves its purpose. Still, potential improvements can be derived from the results achieved during the experiments. In particular, we will consider the used of attention-based encoder-decoder networks to improve the fluency of complex sentences.

6 Conclusion and Future Work

In this paper, we presented LD2NL, a framework for verbalizing SW languages, especially on RDF and OWL while including the SPARQL verbalization provided by SPARQL2NL. Our evaluation with 86 persons revealed that our framework generates NL that can be understood by lay users. While the OWL verbalization was close to NL, the RDF was less natural but still sufficient to convey the meaning expressed by the corresponding set of triples. In future work, we aim to extend LD2NL to verbalize the languages SWRL (Horrocks et al., 2004) and SHACL (Knublauch and Kontokostas, 2017).

Building a Comprehensive Romanian Knowledge Base for Drug Administration

Bogdan Nicula[1], Mihai Dascalu[1], Maria-Dorinela Sirbu[1], Stefan Trăușan-Matu[1] and Alexandru Nuta[2]

[1]University Politehnica of Bucharest, 313 Splaiul Independentei, 060042, Bucharest, Romania
[2]All Business Management, Str. Vasile Conta 19, sc. A, et. 1, ap. 8, Bucharest, Romania

Abstract

Information on drug administration is obtained traditionally from doctors and pharmacists, as well as leaflets which provide in most cases cumbersome and hard-to-follow details. Thus, the need for medical knowledge bases emerges to provide access to concrete and well-structured information which can play an important role in informing patients. This paper introduces a Romanian medical knowledge base focused on drug-drug interactions, on representing relevant drug information, and on symptom-disease relations. The knowledge base was created by extracting and transforming information using Natural Language Processing techniques from both structured and unstructured sources, together with manual annotations. The resulting Romanian ontologies are aligned with larger, well-established, English medical ontologies. Our knowledge base supports queries regarding drugs (e.g., active ingredients, concentration, expiration date), drug-drug interaction, symptom-disease relations, as well as drug-symptom relations (e.g., searching for the drug that might be most useful for treating a given set of symptoms).

1 Introduction

The conventional way of accessing information regarding drug administration and storage strategies, recommendations and precautions, effects and side-effects is via medical leaflets. However, most of the times the text is too complex, too cluttered with information, that the leaflet ends up being ignored by the consumer. At the same time, when consumers must take multiple drugs as result of overlapping treatment schemes, it becomes increasingly difficult for them to keep in mind all mentioned precautions and counter-indications. This paper presents a knowledge base built upon medical leaflets and existing medical ontologies aimed at aiding Romanian consumers when adding new drugs to their treatment schemes.

The knowledge base consists of a set of two ontologies built from information extracted from websites of pharmaceutical producers and national agencies, which were combined with English medical ontologies. The first ontology is used to better structure the leaflet content and provide easy access to information concerning administration and storage strategies, together with possible side-effects. This ontology is aligned with a larger English-based ontology - DINTO (Herrero-Zazo et al., 2015) - in order to discover incompatibilities between drugs and to warn the user whether two administered drugs might interact one with another. The second ontology is focused on diseases. Translations for both diseases and symptoms were added for Romanian language, allowing customers to lookup possible explanations for their symptoms. Moreover, the gap between the two ontologies is filled in by indexing the description and recommendation texts for the drug leaflets, therefore enabling users to directly search what drugs might help them deal with certain symptoms.

These tools are not supposed to replace in any manner actual pharmacists, and an extra opinion from a pharmacist or a physician is always recommended when asking for a drug, given a set of symptoms. The aim of our system is to provide support and easy access to essential information, when no similar solutions are available for Romanian language.

Proceedings of Recent Advances in Natural Language Processing, pages 829–836,
Varna, Bulgaria, Sep 2–4 2019.

The second section of this paper covers similar knowledge bases, as well as systems providing similar information for English language. The third section describes the data extraction and the architecture of our knowledge base. The last two sections focus on the current results, shortcomings and ways of further improving our knowledge base.

2 Related Work

2.1 Medical Ontologies

Multiple knowledge bases for English language exist, covering different medical areas of interest. Part of them were developed by authors of the Open Biological and Biomedical Ontology (OBO) Foundry (Smith et al., 2007) which focuses on collaborations and on defining a common set of principles for developing medical ontologies. The foundry's mission is to develop a set of interoperable ontologies that are well formed and scientifically accurate. These ontologies are built using semantic web technologies (Berners-Lee et al., 2001) and they are usually made available in OWL (McGuinness et al., 2004) format. Over 150 ontologies are currently listed on the OBO webpage (http://www.obofoundry.org/).

Out of all the ontologies developed by OBO members, the following knowledge bases are relevant for the functionalities presented in this paper:

- CHEBI (Chemical Entities of Biological Interest), containing information regarding a diverse set of chemical compounds relevant for biological interests (Hastings et al., 2015).
- DINTO (The Drug-Drug Interactions Ontology), covering information on how 2 active ingredients interact one with another; DINTO is integrated with CHEBI.
- DOID (Human Disease Ontology), a taxonomy of human diseases (Kibbe et al., 2014).
- SYMP (Symptom Ontology), including symptoms which may be indicative of a disease. SYMP was developed as part of the Gemina project (Schriml et al., 2009) and is integrated with DOID.

Besides OBO, other detailed medical ontologies have been created, such as FMA (The Foundational Model of Anatomy Ontology) (Rosse and Mejino Jr, 2003) developed by the University of Washington, which focuses on the structure of the human body. Generic ontologies are also available, such as DBpedia (Bizer et al., 2009) built by using data from Wikipedia, but they do not offer information relevant for the task at hand.

2.2 Medical Applications

Several applications offering drug-related information exist for English Language. They allow users to search a drug by name, illness or medical procedure, and offer the possibility of testing whether two drugs are incompatible due to harmful interactions between their active substances.

One of the most known portals making medical information available and easy to interpret for non-professional users is WebMD. WebMD offers two applications, Medscape and the WebMD app. Medscape is focused on the more practical aspects of healthcare, offering features such as identifying pills based on a set of physical features, computing the body mass index (BMI) or other relevant metrics based on user's input, and searching for nearby medical professionals and hospitals. The WebMD app is focused more on offering theoretical insights regarding drugs and diseases. It offers the possibility of searching a disease based on a list of symptoms, searching for remedies based on age, gender and severity of the symptoms, and it can notify the user when the US Food and Drug Administration (FDA) has published new information regarding a drug from the user's treatment profile.

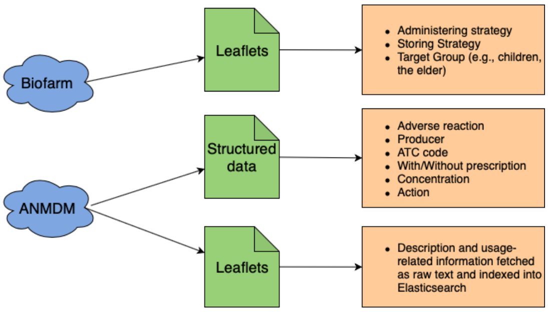
Other applications, such as Drugs.com, offer similar features, but also take into account community feedback as a mechanism for informing users. The application facilitates communication within its user-base, allowing customers to find relevant and useful information from peers who underwent similar experiences. This application also differentiates itself from the rest by offering two different views based on the user's medical proficiency. Users with little medical knowledge are directed towards pages with simple and easy-to-grasp information, while experts are provided access to more complex content, which includes more scientific terms.

A specific sub-category of applications is focused on providing drug-administration assistants. One such example is CareZone. These systems allow users to register all drugs on their current treatment scheme, and offer the possibility of entering and keeping track of different medical parameters, such as blood sugar levels. Apart from that, the application can also be used to set up reminders for administering drugs.

3 Method

3.1 Corpus

There is no established medical or biological ontology for Romanian language. However, public information is readily available in both structured and unstructured format. Medical leaflets are available either as .pdf files or integrated in web pages made available by both private drug producers (e.g., Biofarm) and by state authorities (e.g., The National Agency for Drugs and Medical Devices - ANMDM). The web page of ANMDM also contains structured information (e.g., active substances, concentrations, therapeutical role) for all approved drugs. Figure 1 contains an overview of extracted information from the considered data sources; specific details are provided in the follow-up subsections.



Biofarm
ANMDM
Leaflets
Structured data
Leaflets

• Adverse reaction
• Producer
• ATC code
• With/Without prescription
• Concentration
• Action
• Description and usage-related information fetched as raw text and indexed into Elasticsearch

Figure 1: Considered data sources.

The functionalities supported by our knowledge base can be split into three different categories:

- Accessing drug-related information, including inferences of drug-drug interactions, given two or more drugs.
- Finding the most probable disease given a set of symptoms, or listing the set of symptoms that correspond to a certain disease.
- Finding the drug that is most likely to address a given symptom (e.g., flu medication in case of fever and coughing).

3.1.1 Information Regarding Drugs

Both ANMDM structured web information regarding drugs, as well as medical leaflets obtained from ANMDM and private drug producers were used to create a drugs ontology. A total of 220 leaflets from Biofarm (Figure 2) and 1138 leaflets from ANMDM were parsed (Figures 3-4), containing information on 15,093 drugs having 1330 different active substances.

1. CE ESTE ANTISPASMIN ŞI PENTRU CE SE UTILIZEAZĂ

Antispasmin este indicat utilizării la adulţi, adolescenţi şi copii cu vârsta peste 6 ani.
Antispasmin este un medicament antispastic.
Antispasmin este utilizat pentru reducerea durerilor provocate de diverse colici (biliare, renale, vezicale, dureri din timpul ciclului menstrual, spasme uterine), ca antispastic în diverse afecţiuni digestive (ulcer la nivelul stomacului, gastrită, enterită, spasme ale cardiei şi pilorului, sindromul colonului iritabil, colită spastică însoţită de constipaţie, balonare), dureri de cap cu senzaţie de tensiune intracraniană.

2. ÎNAINTE SĂ UTILIZAŢI ANTISPASMIN

Nu utilizaţi Antispasmin
- dacă sunteţi alergic (hipersensibil) la clorhidrat de drotaverină sau la oricare dintre celelalte componente ale Antispasmin;
- dacă aveţi afecţiuni grave ale ficatului, rinichiului sau la nivelul inimii.

Aveţi grijă deosebită când utilizaţi Antispasmin
- dacă medicul dumneavoastră v-a spus că aveţi porfirie;
- dacă aveţi tensiune arterială mică;
- dacă utilizaţi Antispasmin timp îndelungat (medicul dumneavoastră vă poate indica evaluarea funcţiei hepatice).
Antispasmin nu este recomandat copiilor cu vârsta sub 6 ani, deoarece nu sunt disponibile date privind siguranţa şi eficacitatea la această grupă de vârstă.

Utilizarea altor medicamente
Vă rugăm să spuneţi medicului dumneavoastră sau farmacistului dacă luaţi sau aţi luat recent orice alte medicamente, inclusiv dintre cele eliberate fără prescripţie medicală.
Dacă utilizaţi Antispasmin împreună cu alte medicamente, îşi pot modifica reciproc modul lor de acţiune.
Informaţi-l pe medicul dumneavoastră dacă utilizaţi levodopa, înainte de a începe tratamentul cu Antispasmin.

Sarcina şi alăptarea
Adresaţi-vă medicului dumneavoastră sau farmacistului pentru recomandări înainte de a lua orice medicament.
Utilizarea Antispasmin în timpul sarcinii necesită prudenţă.
Nu se recomandă administrarea Antispasmin în timpul alăptării.

Conducerea vehiculelor şi folosirea utilajelor
Dacă în timpul tratamentului cu Antispasmin prezentaţi senzaţia de lipsă de echilibru în spaţiu a corpului sau de învârtire a obiectelor din jur, este necesar să evitaţi activităţile potenţial periculoase, conducerea vehiculelor şi folosirea utilajelor.

Informaţii importante privind unele componente ale Antispasmin
Antispasmin conţine lactoză monohidrat. Dacă medicul dumneavoastră v-a atenţionat că aveţi intoleranţă la unele categorii de glucide, vă rugăm să-l întrebaţi înainte de a lua acest medicament.

3. CUM SĂ UTILIZAŢI ANTISPASMIN

Acest medicament se eliberează fără prescripţie medicală. Trebuie să discutaţi cu medicul dumneavoastră sau cu farmacistul dacă nu sunteţi sigur.

Adulţi, adolescenţi
Doza recomandată este de 120-240 mg clorhidrat de drotaverină pe zi (3-6 comprimate Antispasmin pe zi), fracţionat în 2-3 prize.

Copii cu vârsta peste 6 ani
Doza recomandată este de 80-200 mg clorhidrat de drotaverină pe zi (2-5 comprimate Antispasmin pe zi), fracţionat în 2-5 prize.
Trebuie să vă adresaţi medicului dumneavoastră dacă după 3 zile de tratament simptomele dumneavoastră nu se ameliorează.

Copii cu vârsta sub 6 ani
Deoarece nu sunt disponibile date privind siguranţa şi eficacitatea administrării, Antispasmin nu este indicat la acest grup de vârstă.

Dacă aţi utilizat din Antispasmin mai mult decât trebuie
Adresaţi-vă imediat medicului dumneavoastră sau mergeţi la departamentul de urgenţe al celui mai apropiat spital dacă aţi utilizat mai multe comprimate de Antispasmin decât trebuie.

Dacă aţi uitat să utilizaţi Antispasmin
Daca aţi uitat să utilizaţi o doză, luaţi medicamentul imediat ce vă amintiţi. Totuşi, dacă este timpul pentru următoarea doză, luaţi-o doar pe aceasta. Este important să nu luaţi o doză dublă pentru a compensa doza uitată.

Dacă aveţi orice întrebări suplimentare cu privire la acest medicament, adresaţi-vă medicului dumneavoastră sau farmacistului.

4. REACŢII ADVERSE POSIBILE

Ca toate medicamentele, Antispasmin poate provoca reacţii adverse, cu toate că nu apar la toate persoanele.
Reacţiile adverse sunt clasificate în funcţie de frecvenţă, după cum urmează: foarte frecvente (afectează mai mult de 1 din 10 pacienţi); frecvente (afectează mai puţin de 1 din 10 pacienţi); mai puţin frecvente (afectează mai puţin de 1 din 100 pacienţi); rare (afectează mai puţin de 1 din 1 000 pacienţi); foarte rare (afectează mai puţin de 1 din 10 000 pacienţi); frecvenţă necunoscută (nu poate fi estimată din datele disponibile).
Rare: durere de cap, ameţeli, insomnie, palpitaţii, tensiune arterială mică, greaţă, constipaţie.

Antispasmin a fost asociat cu apariţia porfiriei acute.

Dacă vreuna dintre reacţiile adverse devine gravă sau dacă observaţi orice reacţie adversă nemenţionată în acest prospect, vă rugăm să spuneţi medicului dumneavoastră sau farmacistului.

5. CUM SE PĂSTREAZĂ ANTISPASMIN

Nu utilizaţi Antispasmin după data de expirare înscrisă pe ambalaj după "Data expirării". Data de expirare se referă la ultima zi a lunii respective.
A se păstra la temperaturi sub 25°C, în ambalajul original.
A nu se lăsa la îndemâna şi vederea copiilor.
Medicamentele nu trebuie aruncate pe calea apei menajere sau a reziduurilor menajere. Întrebaţi farmacistul cum să eliminaţi medicamentele care nu vă mai sunt necesare. Aceste măsuri vor ajuta la protejarea mediului.

6. INFORMAŢII SUPLIMENTARE

Ce conţine Antispasmin
- Substanţa activă este clorhidratul de drotaverină. Fiecare comprimat conţine clorhidrat de drotaverină 40 mg.
- Celelalte componente sunt: lactoză monohidrat, amidon de porumb, povidonă K 25, talc, stearat de magneziu.

Cum arată Antispasmin şi conţinutul ambalajului
Antispasmin se prezintă sub formă de comprimate lenticulare de culoare galbenă.
Ambalaj
Cutie cu un blister din PVC/Al a câte 20 comprimate.
Cutie cu un blister din PVC-A clar/Al a câte 20 comprimate.

Figure 3: Structured information scrapped from ANMDM.

The ontology was built from scratch and the attributes for each drug instance were either copied from the structured ANMDM web entry, or were extracted from the corresponding medical leaflets (such as the administering strategy). The extraction was done partially via a rule-based approach, but manual extraction was necessary for some of the more complex entries, when no reliable pattern could be identified.

As it can be seen in Figure 5, the ontology is centered on the Drug class, which represents a certain type of drug, but not an actual product that can be bought in stores. All instances of the Drug

PROSPECT: INFORMAŢII PENTRU UTILIZATOR

Antispasmin 40 mg comprimate
Clorhidrat de drotaverină

Citiţi cu atenţie şi în întregime acest prospect, deoarece el conţine informaţii importante pentru dumneavoastră.
Acest medicament este disponibil fără prescripţie medicală. Cu toate acestea, este necesar să utilizaţi Antispasmin cu atenţie, pentru a obţine cele mai bune rezultate.

- Păstraţi acest prospect. S-ar putea să fie necesar să-l recitiţi.
- Întrebaţi farmacistul dacă aveţi nevoie de mai multe informaţii sau sfaturi.
- Trebuie să vă prezentaţi la medic dacă simptomele dumneavoastră se înrăutăţesc sau nu se îmbunătăţesc după 3 zile.
- Dacă vreuna dintre reacţiile adverse devine gravă sau dacă observaţi orice reacţie adversă nemenţionată în acest prospect, vă rugăm să-i spuneţi medicului dumneavoastră sau farmacistului.

<u>În acest prospect găsiţi:</u>

1. CE ESTE ANTISPASMIN ȘI PENTRU CE SE UTILIZEAZĂ

Antispasmin este indicat utilizării la adulţi, adolescenţi şi copii cu vârsta peste 6 ani.
Antispasmin este un medicament antispastic.

Antispasmin este utilizat pentru reducerea durerilor provocate de diverse colici (biliare, renale, vezicale, dureri din timpul ciclului menstrual, spasme uterine), ca antispastic în diverse afecţiuni digestive (ulcer la nivelul stomacului, gastrită, enterită, spasme ale cardiei şi pilorului, sindromul colonului iritabil, colită spastică însoţită de constipaţie, balonare), dureri de cap cu senzaţie de tensiune intracraniană.

2. ÎNAINTE SĂ UTILIZAŢI ANTISPASMIN

Nu utilizaţi Antispasmin
- dacă sunteţi alergic (hipersensibil) la clorhidrat de drotaverină sau la oricare dintre celelalte componente ale Antispasmin;
- dacă aveţi afecţiuni grave ale ficatului, rinichiului sau la nivelul inimii.

Aveţi grijă deosebită când utilizaţi Antispasmin
- dacă medicul dumneavoastră v-a spus că aveţi porfirie;
- dacă aveţi tensiune arterială mică;
- dacă utilizaţi Antispasmin timp îndelungat (medicul dumneavoastră vă poate indica evaluarea funcţiei hepatice).

Figure 4: Content extracted from ANMDM leaflets.

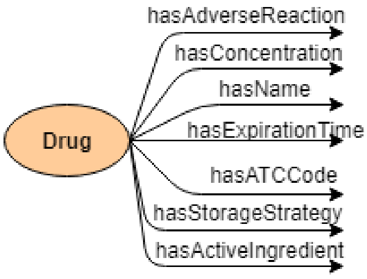

Figure 5: Romanian drug ontology - drug class simplified view.

class contain the same combination of active ingredients, but they may have different concentrations, different names, different expiration times, etc.

This ontology was aligned to its larger English counterpart, DINTO. The data from the two ontologies was merged at active substance level. Difficulties were encountered as, even though most active substances use conventional names for chemical entities derived from Latin, their names differ from Romanian to English (for instance, ”acidum ascorbicum” in the Romanian ontology is equivalent with ”ascorbic acid” in DINTO). This alignment was done in 2 phases. First, 500 active substances were merged because they either represented perfect matches, or they matched after applying a small set of conventional changes (e.g., removing the ”-um” prefix from the Romanian version). Second, the remaining 800 active substances were matched by analyzing the closest correspondent in the other ontology in terms of Levenshtein distance (Levenshtein, 1966), followed by a manual validation of the match.

3.1.2 Information Regarding Symptoms and Diseases

The English DOID and SYMP ontologies were used as a starting point (see Figure 6). Both the names of the symptoms and of the diseases were translated into Romanian via Google Translate, and then they were manually corrected in order to eliminate mistakes. Names containing polysemic words proved to be most difficult for the automated translation – for instance, a symptom describing a change in the pupil, was mistakenly interpreted as something related to a school student, not to the human eye.

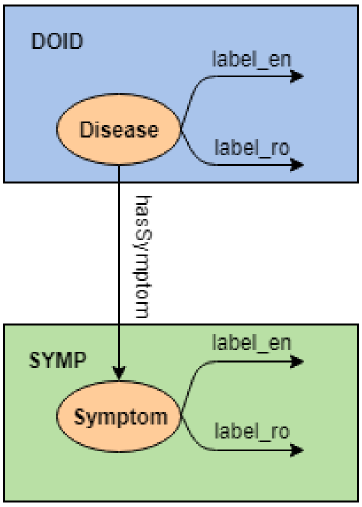

Figure 6: Romanian disease ontology - simplified view.

In total, names for over 900 symptoms and 10000 diseases were translated, allowing Romanian users to use the full benefits offered by the DOID ontology, without the need of English proficiency.

3.1.3 Connecting Symptoms to Drugs

There are no datasets containing information on what drugs should be administered for certain symptom in Romanian language. However, a usage section exists in each medical leaflet describing cases in which the drug should be taken (e.g., to numb pain, to reduce coughing, to lower body temperature and eliminate fever, etc.). Thus, the usage section for each of the 1138 leaflets was extracted from the ANMDM website and was indexed into Elasticsearch (Divya and Goyal, 2013), allowing users to find drugs with the usage description that most closely fits the set of provided symptoms.

3.2 Architecture and Processing Pipeline

The knowledge base can be hosted on a single server consisting of two different applications (see Figure 7). First, an instance of a Fuseki semantic repository server (Jena, 2019) was used to host the aforementioned ontologies: the Romanian drug ontology, DINTO, and a merge between DOID and SYMP called DOID-merged, to which we have added extra labels for Romanian. This repository allows users to query the ontologies via the SPARQL query language (Prud'hommeaux and Seaborne, 2008). Second, an Elasticsearch instance stores unstructured leaflets and can be queried in order to find drugs that are most likely helpful in relieving one or more symptoms.

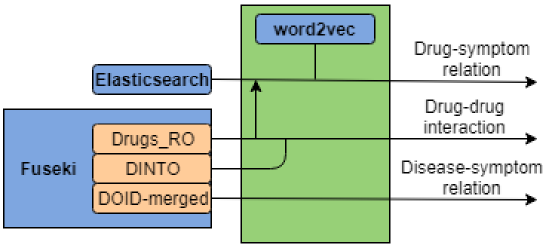

Figure 7: Knowledge base architecture.

On top of the two applications that act as information sources, a user interface allows users lacking experience on semantic web technologies to easily access the information. The user requests made at these endpoints are transformed into valid SPARQL and Elasticsearch queries. Furthermore, this interface can act as an autocorrect, by suggesting symptoms and drugs present in our dataset.

In the case of querying for the most helpful drugs given a set of symptoms, the relevance of the Elasticsearch information retrieval is improved by adding semantic information. For a given set of candidate texts from leaflets, each corresponding to a different drug, a word2vec (Mikolov et al., 2013) model trained on a 1-billion word Romanian corpus is used to compute the semantic similarity between it and the given set of symptoms. This is done by computing aggregate embeddings for the two text representations, and then computing cosine similarity. The Elasticsearch query score and the cosine similarity are both min-max normalized with regard to the set of candidate symptom-drug pairs extracted with Elasticsearch, their average is computed, and the candidate having the best average score is selected in the end.

Extra functionalities are added on top of the Fuseki repository and Elasticsearch server, such as suggesting possible matches when the string representing a searched drug/disease/symptom was not found. These suggestions are made by using a Levenshtein edit distance. In the case of symptoms, however, the same sensation can be expressed in multiple ways; thus, we rely on a very strict Levenshtein distance search to account for small typing errors. If this fails, a semantic search is used, looking for the symptom in the knowledge base for which the word2vec embedding is closest to the embedding of the input text.

4 Results

4.1 Drug Information and Drug-Drug Interactions

Our knowledge base offers access to structured information regarding the 15,093 drugs and 1,330 active substances. The information regarding drugs includes both numeric attributes (e.g., time until expiration), as well as text attributes (e.g., usage recommendations which were not standardized as format).

Users can search for the list of drugs with which any given one may interact because the Romanian drug ontology was aligned with DINTO. This search is done at active substance level. In case of drugs containing a combination of active substances, we consider that drugs A and B may interact if, for at least one active substance from A, there is at least one active substance from B with which it interacts. For example, if the user wants to check the interaction between *"OTOTIS"* which is based on a combination of two active ingredients (namely *"ciprofloxacinum"* and *"fluocinolonum"*) and *"ENAFILZIL"* which is based on *"sildenafilum"*, the knowledge base will search if either *"ciprofloxacinum"* or *"fluocinolonum"* interact with *"sildenafilum"*. As *"ciprofloxacinum"* interacts with *"sildenafilum"*, the system will conclude that the 2 drugs interact. If the same user wants to find the list of all the drugs which interact with *"OTOTIS"*, a list of all the drugs containing at least one active substance that interacts with either of *"ciprofloxacinum"* or *"fluocinolonum"* is generated and it will contain 35 entries.

4.2 Symptom-Disease Information

Our consolidated knowledge base contains 900 symptoms and 10,000 diseases from DOID and SYMP with names translated into Romanian language. The user can enter a list of symptoms to search for the disease that matches most symptoms. As mentioned before, if a symptom does not exist, two sequential attempts are performed to find its closest correspondent in our knowledge base. First, symptoms with a Levenshtein distance of 2 or less are searched. Second, if no result is found in the previous step, a word2vec embedding of the input string is computed, and the symptom from the knowledge base having the closest embedding to it is considered its equivalent.

For example, if a user searches for diseases that have *"mic de statură"* (eng, *"short stature"*) as a symptom, the results would be *"trichorhinophalangeal syndrome type II"*, *"Albright's hereditary osteodystrophy"*, *"spondyloepimetaphyseal dysplasia, strudwick type"* or *"Renpenning syndrome"*, as these are the only diseases linked to that symptom according to DOID and SYMP. If users make 1-2 typos when writing the symptom, the most relevant symptoms is suggested, and they can redo the search with the correct version. If they enter *"corp mic"* (eng, *"small body"*) or *"scund"* (eng, *"short"*), the first recommendation would fail, but the second one would suggest "short stature" as the most similar symptom based on a semantic similarity search.

4.3 Connecting Symptoms to Relevant Drugs

Considering a search for a combination of *"tuse, febră, durere de cap"* (eng, *"coughing, fever, headache"*), several types of analgesics, aspirin, paracetamol, and 2 types of cough syrup are recommended. The bottom results focus on yellow fever or other diseases that contain only a part of the symptoms specified as input.

In most simple use cases, the first entries are relevant. However, the symptom of a disease can be, in some cases, the effect of a drug that is targeted against a totally different disease. For instance, if the user searches symptoms related to diarrhea, such as *"scaun moale"* (eng, *"loose stool"*), some of the first drugs to be recommended are laxatives, but this would not be the wisest choice of medication. This happens because the effect of the medicine is, in some cases, mentioned alongside with the symptoms it should alleviate.

5 Conclusions

This paper presents a medical knowledge base for Romanian language focused on drugs. It is built using medical leaflets in Romanian and structured information regarding the drugs that was extracted from the ANMDM website. The knowledge base is also integrated with English ontologies in order to make more powerful inferences, such as searching for drug-drug interactions. The provided information can be structured into three main categories: drug related information, disease-symptom information, and drug-symptom information. To our knowing, this is the most comprehensive effort of building a knowledge base for Romanian drugs, their counter-indications, as well as potential relations to exhibited conditions.

The drug related information was extracted directly from official Romanian sources, thus it can be considered reliable. In order to keep the knowledge base up to date, the sources need to be crawled periodically in order to ensure that new information is always added, and that deprecated records are eliminated promptly. Information concerning drug-drug interactions is based on the DINTO ontology, which was last updated in 2016 and is still relevant. Nevertheless, we warn users that the information presented by our services is not a valid substitute for the opinion of a medical professional or a pharmacist. In the future, apart from drug-drug interactions, the knowledge base could also take into account pre-existing conditions or dietary choices which may interact with a certain treatment scheme. Part of this information is already available in DINTO, but it would need to be translated and integrated in our knowledge base.

The disease-symptom information is based on the DOID and SYMP ontologies. The name of the diseases and symptoms were automatically translated using Google Translate, and then manually corrected, if necessary. The two ontologies are still actively maintained; thus, the knowledge base needs to refresh this information from time to time in order to get the latest version. As is the case with the previous category, this information is not exhaustive and cannot substitute the knowledge of a professional.

The drug-symptom information is based only on medical leaflets crawled from the ANMDM website, which needs to be updated every several weeks. In some cases, the drug-symptom queries are very effective, for instance when searching for drugs targeting flu-like symptoms, such as fever and coughing. In other cases, the queries mistake the symptoms that the drug should address, with the drug's effect. These types of mistakes cannot be avoided for the time being due to manner in which the information was indexed. If more structured information regarding the drug-symptom relation could be extracted from the leaflets, either manually or by using different NLP techniques, these outlier cases would be addressed.

Our knowledge base provides real aid for Romanian users requiring drug-related information, and no similar initiatives exist at national level. The system cannot substitute the knowledge of a professional, and there are still problems to be addressed, but it is still an easy-to-use and useful tool for informing a user on medical treatments. Further improvements will be explored, including the orientation towards a personal health assistant for drug administration, similar in some degree to Babylon Health AI (https://www.babylonhealth.com/ai).

6 Future Work

In the future, we aim to expand even further our knowledge base. This can be done by indexing medical leaflets from other drug producers, as well as extracting more complex information from leaflets - for instance, contraindications expressed as rules (e.g. do not take certain antibiotics, such as tetracycline, with milk, other dairy products, calcium supplements, or antacids). Furthermore, we aim to integrate our knowledge base with other information sources, such as the Unified Medical Language System (Bodenreider, 2004).

Summary Refinement through Denoising

Nikola I. Nikolov, Alessandro Calmanovici, Richard H.R. Hahnloser
Institute of Neuroinformatics, University of Zürich and ETH Zürich, Switzerland
{niniko, dcalma, rich}@ini.ethz.ch

Abstract

We propose a simple method for post-processing the outputs of a text summarization system in order to refine its overall quality. Our approach is to train text-to-text rewriting models to correct information redundancy errors that may arise during summarization. We train on synthetically generated noisy summaries, testing three different types of noise that introduce out-of-context information within each summary. When applied on top of extractive and abstractive summarization baselines, our summary denoising models yield metric improvements while reducing redundancy.[1]

1 Introduction

Text summarization aims to produce a shorter, informative version of an input text. While extractive summarization only selects important sentences from the input, abstractive summarization generates content without explicitly re-using whole sentences (Nenkova et al., 2011). In recent years, a number of successful approaches have been proposed for both extractive (Nallapati et al., 2017; Narayan et al., 2018) and abstractive (Chen and Bansal, 2018; Gehrmann et al., 2018) summarization paradigms. Despite these successes, many state-of-the-art systems remain plagued by overly high output redundancy (See et al. (2017); see Figure 3), which we set out to reduce.

In this paper, we propose a simple method (Figure 1, Section 3) for post-processing the outputs of a text summarization system in order to improve their overall quality. Our approach is to train dedicated text-to-text rewriting models to correct errors that may arise during summarization, focusing specifically on reducing information redundancy within each individual summary. To achieve this, we synthesize from clean summaries noisy summaries that contain diverse information redundancy errors, such as sentence repetition and out-of-context information (Section 3.2).

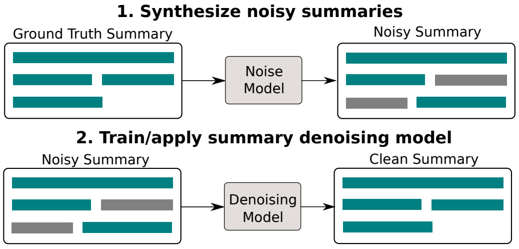

Figure 1: Overview of our approach to summary denoising. We alter ground truth summaries to generate a noisy dataset, on which we train denoising models to restore the original summaries.

In our experiments (Section 5), we show that denoising yields metric improvements and reduces redundancy when applied on top of several extractive and abstractive baselines. The generality of our method makes it a useful post-processing step applicable to any summarization system, that standardizes the summaries and improves their overall quality, ensuring fewer redundancies across the text.

2 Background

Post-processing of noisy human or machine-generated text is a topic that has recently been gathering interest. Automatic error correction (Rozovskaya and Roth, 2016; Xie et al., 2018) aims to improve the grammar or spelling of a text. In machine translation, automatic post editing of translated outputs (Chatterjee et al., 2018) is commonly used to further improve the translation quality, standardise the translations, or adapt them

[1] Code available at https://github.com/ninikolov/summary-denoising.

to a different domain (Isabelle, 2007).

In (Xie et al., 2018), authors synthesize grammatically incorrect sentences from correct ones using backtranslation (Sennrich et al., 2016a), which they use for grammar error correction. They enforce hypothesis variety during decoding by adding noise to beam search. Another work that is close to ours is (Fevry and Phang, 2018), where authors introduce redundancy on the word level in order to build an unsupervised sentence compression system. In this work, we take a similar approach, but instead focus on generating information redundancy errors on the sentence rather than the word level.

3 Approach

Our approach to summary refinement consists of two steps. First, we use a dataset of clean ground truth summaries to **generate** noisy summaries using several different types of synthetic noise. Second, we train text rewriting models to correct and **denoise** the noisy summaries, restoring them to their original form. The learned denoising models are then used to post-process and refine the outputs of a summarization system.

3.1 Generating Noisy Summaries

To generate noisy datasets, we rely on an existing parallel dataset of articles and clean ground truth summaries $S = \{s_0, , ..., s_j\}$. We iterate over each of the summaries and perturb them with noise, according to a *sentence noise distribution* $p_{noise} = [p_0, p_1, ..., p_N]$. p_{noise} defines the probability of adding noise to a specific number of sentences within each summary (from 0 up to a maximum of N noisy sentences), with $\sum p_{noise} = 1$.

For all experiments in this work, we use $p_{noise} = [0.15, 0.85]$ in order to ensure consistency, meaning that ˜15% of our noisy summaries contain no noisy sentences, while ˜85% contain one noisy sentence. Initial experiments showed that distributions which enforce larger or smaller amounts of noise lead to stronger or weaker denoising effects. Our choice of noise distribution showed good results on the majority of systems that we tested; we leave a more rigorous investigation of the choice of distribution to future work.

In addition to adding noise, we generate 3 noisy summaries for each clean summary by picking multiple random sentences to noise. This step increases the dataset size while introducing variety.

3.2 Types of Noise

We experiment with three simple types of noise, all of which introduce *information redundancy* into a summary. Our aim is to train denoising models that minimize repetitive or peripheral information within summaries.

Repeat picks random sentences from the summary and repeats them at the end. Repetition of phrases or even whole sentences is a problem commonly observed in text generation with RNNs (See et al., 2017), which motivates efforts to detect and minimize repetitions.

Replace picks random sentences from the summary, and replaces them with the closest sentence from the article. This type of noise helps the model to learn to *refine* sentences from the generated summaries, paraphrasing sentences when they are too long or contain redundant information.

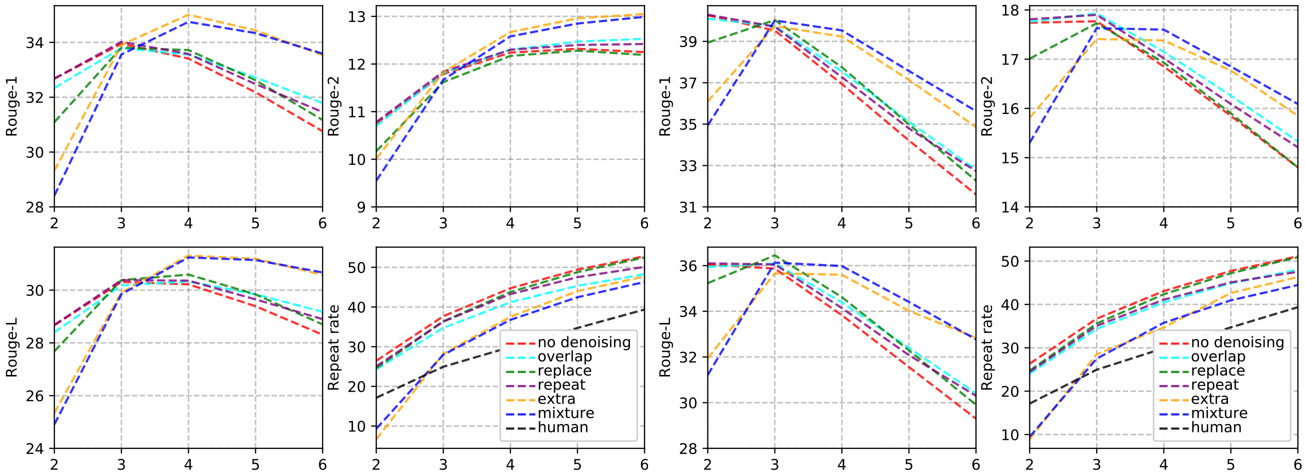
Extra picks random sentences from the article, paraphrases them, and inserts them into the summary, preserving the order of the sentences as they appear in the article. With this type of noise, a model learns to delete sentences which are out of context or contain redundant information. To paraphrase the sentences, we use the sentence paraphrasing model from (Chen and Bansal, 2018), trained on matching sentence pairs from the CNN/Daily Mail dataset.

Mixture mixes all the above noise types uniformly into a single dataset, keeping the same dataset size as for the individual noise types. With mixture, we explore whether the benefits of each noise type can be combined into a single model.

4 Experimental Setup

Dataset We use the CNN/Daily Mail dataset[2] (Hermann et al., 2015) of news articles and summaries in the form of bullet points, and follow the preprocessing pipeline from (Chen and Bansal, 2018). We use the standard split of the dataset, consisting of 287k news-summary pairs for training and 13k pairs for validation. We follow Section 3.1 to generate noisy versions of the datasets to be used during training. During testing, instead of clean summaries that contain noisy sentences, we input summaries produced by existing extractive or abstractive summarization systems.

[2] https://github.com/abisee/cnn-dailymail



(a) Denoising the LexRank system.

(b) Denoising the RNN-Ext system.

Figure 2: Metric results (Rouge-1/2/L and Repeat rate) on denoising extractive summarization systems. The x-axis in all plots is the number of extracted sentences. `human` is the result of the ground truth summaries (only for the Repeat rate).

Denoising models For all of our denoising experiments, we use a standard bidirectional LSTM encoder-decoder model (Sutskever et al., 2014) with 1000 hidden units and an attention mechanism (Bahdanau et al., 2014), and train on the subword-level (Sennrich et al., 2016b), capping the vocabulary size to 50k tokens for all experiments[3]. We train all models until convergence using the Adam optimizer (Kingma and Ba, 2015).

In addition to our neural denoising models, we implement a simple denoising baseline, `overlap`, based on unigram overlap between sentences in a summary. `overlap` deletes sentences which overlap more than 80%[4] with any other sentence in the summary and can therefore be considered as redundant.

Evaluation We report the ROUGE-1/2/L metrics (Lin, 2004). We also report the *Repeat* rate (Nikolov et al., 2018) $rep(\mathbf{s}) = \frac{\sum_i o(\overline{s_i}, s_i)}{|\mathbf{s}|}$ which is the average unigram overlap o of each sentence s_i in a text with the remainder of the text (where $\overline{s_i}$ denotes the complement of sentence s_i). Since the repeat rate measures the overlapping information across all sentences in a summary, lower values signify that a summary contains many unique sentences, while higher values indicate potential information repetition or redundancy within a summary.

5 Results

5.1 Extractive Summarization

We experiment with denoising two extractive systems: LexRank (Erkan and Radev, 2004) is an unsupervised graph-based approach which measures the centrality of each sentence with respect to the other sentences in the document. RNN-Ext is a more recent supervised LSTM sentence extractor module from (Chen and Bansal, 2018), trained on the CNN/Daily Mail dataset. It extracts sentences from the article sequentially. Both extractive systems require the number of sentences to be extracted to be given as a hyperparameter, in our experiments we test with summary lengths ranging from 2 to 6 sentences[5].

The results on extractive summarization are in Figure 2a for *LexRank* and Figure 2b for *RNN-Ext*, where we plot the metric scores for varying numbers of extracted sentences for each of the two systems. For both LexRank and RNN-Ext, we observe ROUGE improvements after denoising over the baseline systems without denoising. The `repeat` and `replace` methods yielded more modest improvements of 0.5-1 ROUGE-L points, performing comparably to the simple `overlap` baseline. The most effective noise types are `extra` and `mixture`, yielding improvements of up to 2 ROUGE-L points for LexRank and up to 3.5 ROUGE-L points for RNN-Ext. The superior performance to `overlap` indicates that the addi-

[3] We use the `fairseq` library `https://github.com/pytorch/fairseq`

[4] We empirically found that this threshold is sufficiently high to prevent unnecessary deletion and sufficiently low to detect near-identical sentences.

[5] The average sentence count of a summary in the CNN/Daily Mail dataset is 3.88.

System	Denoising approach	ROUGE-1	ROUGE-2	ROUGE-L	Repeat	#Sent	#Tok

Table 1: Results on denoising abstractive summarization. **Repeat** is the Repeat rate, while **#Sent** and **#Tok** are the average numbers of sentences or tokens in the summaries. Best **ROUGE** results for each model are in bold. *Human* is the result of the ground truth summaries, while *Article* uses the original article as the summary.

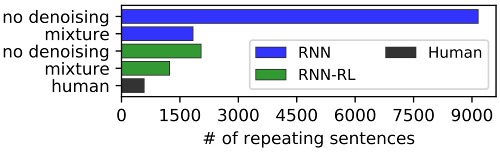

Figure 3: Number of sentence repetitions before and after denoising.

tional denoising operations learned by our models (see Figure 4a) are beneficial and can lead to more polished summaries that also may contain abstractive elements.

The gains from denoising are greater for longer summaries of more than two sentences. Long summaries are more likely to be affected by redundancy. For shorter summaries, denoising might lead to deletion of important information, thus denoising needs to be applied more carefully in such cases. Furthermore, for all sentence lengths and noise types, we observe a reduction in the Repeat rate after denoising, demonstrating that our approach is effective at reducing redundancy.

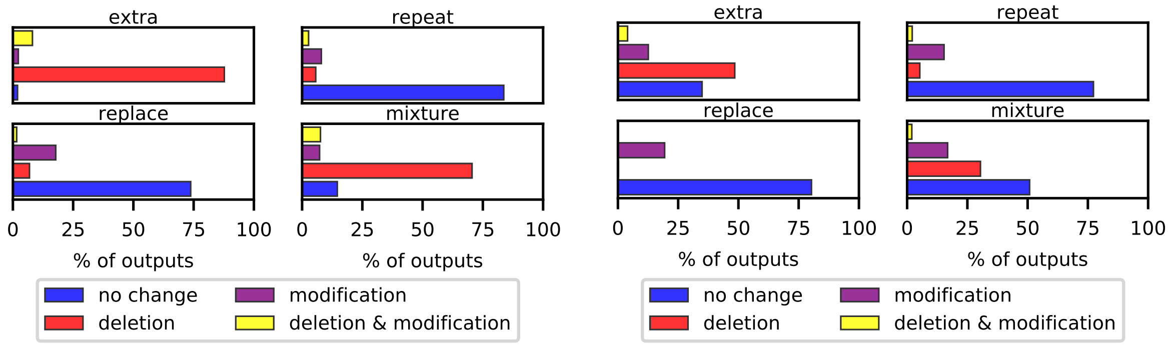
In Table 1, we additionally include the result from using the whole articles (*Article*) as input to our `mixture` model. Denoising is effective in this case, indicating that our approach may be promising for developing abstractive summarization systems that are fully unsupervised, similar to recent work in unsupervised sentence compression (Fevry and Phang, 2018).

5.2 Abstractive Summarization

For abstractive summarization, we test two systems. The first is a standard LSTM encoder-decoder model with an attention mechanism (*RNN*), identical to our denoising network from Section 4. The second, *RNN-RL*, is a state-of-the-art abstractive system proposed in (Chen and Bansal, 2018) that combines extractive and abstractive summarization using reinforcement learning. We train *RNN* ourselves, while for *RNN-RL*, we use the outputs provided by the authors.

Our metric results from denoising abstractive summarization are in Table 1. In Figure 3, we also compute the approximate number of sentence repetitions on the test set, by calculating the number of sentences that overlap significantly ($> 80\%$) with at least one other sentence in the summary.

For the *RNN* model, the `repeat` noise helps to remove repetition, halving our repetition metric, while boosting the ROUGE scores. This result is similar to our much simpler `overlap` baseline based on sentence deletion. The other noise types help to reduce redundancy, bringing the *Repeat* rate closer to that of *Human* summaries. This, however, comes at the cost of a decrease in ROUGE. For *RNN-RL*, while denoising helps to reduce repetition, none of our noise types managed to yield ROUGE improvements. One reason for this may be that this model already comes with a built-in mechanism for reducing redundancy which relies on sentence reranking (Chen and Bansal, 2018). However, as shown in Figure 3 (and in our example in Table 2), this model still generates many more sentence repetitions than found in human summaries. In overall, our approach is effective at reducing redundant information in abstractive summaries, how-



(a) RNN-Ext extractive system, extracting 5 sentences.

(b) RNN abstractive system.

Figure 4: Types of denoising operations applied to an extractive (left) and an abstractive (right) system (averaged over our test set).

ever this comes with a potential loss of information, which can lead to a reduction in ROUGE. Thus, our denoising methods are currently better suited for extractive than for absctractive summarization. Our work therefore calls for the development of novel types of synthetic noise that target abstractive summarization.

5.3 Analysis of Model Outputs

In Figure 4, we quantify the types of operations (deletion or modification of one or more sentences, or no change) our denosing models performed on the summaries produced by the extractive *RNN-Ext* (Figure 4a) and abstractive *RNN* system (Figure 4b). The `replace` and `repeat` noises are the most conservative, leaving over 75% of the summaries unchanged. `extra` is the most prone to delete sentences, while `repeat` and `replace` are most prone to modify sentences. We see a similar pattern for both extractive and abstractive summarization, with an increase of deletion for longer summaries produced by the extractive system. This indicates that our approach flexibly learns to switch between operations depending on the properties of the noisy input summary.

In Table 2 we show example outputs from denoising extractive and abstractive summaries produced for a sports article from our test set. All baseline summarization systems produced outputs that contain redundancy: for example, the first three sentences generated by the *RNN* system, and the 3rd and 4th sentences produced by the *RNN-RL* system are almost identical. To denoise the summaries, our models used diverse operations such as deletion of one or two sentences (e.g. *RNN* system, *Repeat* noise), rewriting (e.g. *RNN-RL* system, *Replace* noise, where *”dinorah santana , the player s agent , said her client had rejected the offer of a three-year contract extension”* is paraphrased to *”the player s agent said she had rejected the offer of a three-year contract”*), or even a combination of deletion and rewriting (e.g. *RNN-RL* system, *Repeat* noise).

6 Conclusion

We proposed a general framework for improving the outputs of a text summarization system based on denoising. Our approach is independent of the type of the system, and is applicable to both abstractive and extractive summarization paradigms. It could be useful as a post-processing step in a text summarization pipeline, ensuring that the summaries meet specific standards related to length or quality.

Our approach is effective at reducing information repetition present in existing summarization systems, and can even lead to ROUGE improvements, especially for extractive summarization. Denoising abstractive summarization proved to be more challenging, and our simple noise types did not yield significant ROUGE improvements for a state-of-the-art system. Our focus in future work, will, therefore, be to estimate better models of the noise present in abstractive summarization, to reduce information redundancy without a loss in quality, as well as to target other aspects such as the grammaticality or cohesion of the summary.

Large-Scale Hierarchical Alignment for Data-driven Text Rewriting

Nikola I. Nikolov and **Richard H.R. Hahnloser**
Institute of Neuroinformatics, University of Zürich and ETH Zürich, Switzerland
{niniko, rich}@ini.ethz.ch

Abstract

We propose a simple unsupervised method for extracting pseudo-parallel monolingual sentence pairs from comparable corpora representative of two different text styles, such as news articles and scientific papers. Our approach does not require a seed parallel corpus, but instead relies solely on hierarchical search over pre-trained embeddings of documents and sentences. We demonstrate the effectiveness of our method through automatic and extrinsic evaluation on text simplification from the normal to the Simple Wikipedia. We show that pseudo-parallel sentences extracted with our method not only supplement existing parallel data, but can even lead to competitive performance on their own.[1]

1 Introduction

Parallel corpora are indispensable resources for advancing monolingual and multilingual text rewriting tasks. Due to the scarce availability of parallel corpora, and the cost of manual creation, a number of methods have been proposed that can perform large-scale sentence alignment: automatic extraction of *pseudo-parallel* sentence pairs from raw, comparable[2] corpora. While pseudo-parallel data is beneficial for machine translation (Munteanu and Marcu, 2005), there has been little work on large-scale sentence alignment for monolingual text-to-text rewriting tasks, such as simplification (Nisioi et al., 2017) or style transfer (Liu et al., 2016). Furthermore, the majority of existing methods (e.g. Marie and Fujita (2017); Grégoire and Langlais (2018)) assume access to some parallel training data. This impedes their application to cases where there is *no parallel data available whatsoever*, which is the case for the majority of text rewriting tasks, such as style transfer.

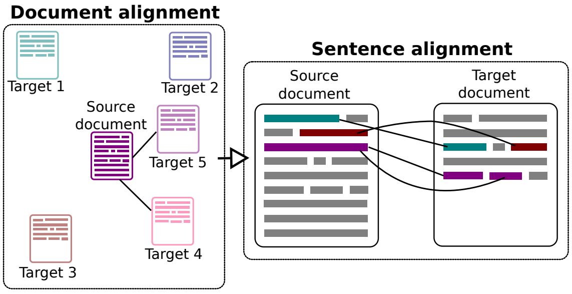

Figure 1: Illustration of large-scale hierarchical alignment (**LHA**). For each document in a *source* dataset, **document alignment** retrieves matching documents from a *target* dataset. In turn, **sentence alignment** retrieves matching sentence pairs from within each document pair.

In this paper, we propose a simple unsupervised method, Large-scale Hierarchical Alignment (**LHA**) (Figure 1; Section 3), for extracting pseudo-parallel sentence pairs from two raw monolingual corpora which contain documents in two different author styles, such as scientific papers and press releases. LHA hierarchically searches for document and sentence nearest neighbors within the two corpora, extracting sentence pairs that have high semantic similarity, yet preserve the stylistic characteristics representative of their original datasets. LHA is robust to noise, fast and memory efficient, enabling its application to datasets on the order of hundreds of millions of sentences. Its generality makes it relevant to a wide range of monolingual text rewriting tasks.

We demonstrate the effectiveness of LHA on automatic benchmarks for alignment (Section 4), as well as extrinsically, by training neural machine translation (NMT) systems on the task of text simplification from the normal Wikipedia to the Simple Wikipedia (Section 5). We show that

[1] Code available at https://github.com/ninikolov/lha.

[2] Corpora that contain documents on similar topics.

Proceedings of Recent Advances in Natural Language Processing, pages 844–853,
Varna, Bulgaria, Sep 2–4 2019.

pseudo-parallel datasets obtained by LHA are not only useful for augmenting existing parallel data, boosting the performance on automatic measures, but can even be competitive on their own.

2 Background

2.1 Data-Driven Text Rewriting

The goal of text rewriting is to transform an input text to satisfy specific constraints, such as simplicity (Nisioi et al., 2017) or a more general author style, such as political (e.g. democratic to republican) or gender (e.g. male to female) (Prabhumoye et al., 2018; Shen et al., 2017). Rewriting systems can be valuable when preparing a text for multiple audiences, such as simplification for language learners (Siddharthan, 2002) or people with reading disabilities (Inui et al., 2003). They can also be used to improve the accessibility of technical documents, e.g. to simplify terms in clinical records for laymen (Abrahamsson et al., 2014).

Text rewriting can be cast as a data-driven task in which transformations are learned from large collections of parallel sentences. Limited availability of high-quality parallel data is a major bottleneck for this approach. Recent work on Wikipedia and the Simple Wikipedia (Coster and Kauchak, 2011; Kajiwara and Komachi, 2016) and on the Newsela dataset of simplified news articles for children (Xu et al., 2015) explore supervised, data-driven approaches to text simplification. Such approaches typically rely on statistical (Xu et al., 2016) or neural (Štajner and Nisioi, 2018) machine translation.

Recent work on unsupervised approaches to text rewriting without parallel corpora is based on variational (Fu et al., 2017) or cross-aligned (Shen et al., 2017) autoencoders that learn latent representations of content separate from style. In (Prabhumoye et al., 2018), authors model style transfer as a back-translation task by translating input sentences into an intermediate language. They use the translations to train separate English decoders for each target style by combining the decoder loss with the loss of a style classifier, separately trained to distinguish between the target styles.

2.2 Large-Scale Sentence Alignment

The goal of **sentence alignment** is to extract from raw corpora sentence pairs suitable as training examples for text-to-text rewriting tasks such as machine translation or text simplification. When the documents in the corpora are *parallel* (labelled document pairs, such as identical articles in two languages), the task is to identify suitable sentence pairs from each document. This problem has been extensively studied both in the multilingual (Brown et al., 1991; Moore, 2002) and monolingual (Hwang et al., 2015; Kajiwara and Komachi, 2016; Štajner et al., 2018) case. The limited availability of parallel corpora led to the development of **large-scale sentence alignment** methods, which is also the focus of this work. The aim of these methods is to extract pseudo-parallel sentence pairs from raw, non-aligned corpora. For many tasks, millions of examples occur naturally within existing textual resources, amply available on the internet.

The majority of previous work on large-scale sentence alignment is in machine translation, where adding pseudo-parallel pairs to an existing parallel dataset has been shown to boost the translation performance (Munteanu and Marcu, 2005; Uszkoreit et al., 2010). The work that is most closely related to ours is (Marie and Fujita, 2017), where authors use pre-trained word and sentence embeddings to extract rough translation pairs in two languages. Subsequently, they filter out low-quality translations using a classifier trained on parallel translation data. More recently, (Grégoire and Langlais, 2018) extract pseudo-parallel translation pairs using a Recurrent Neural Network (RNN) classifier. Importantly, these methods assume that *some parallel training data is already available*, which impedes their application in settings where there is no parallel data whatsoever, which is the case for many text rewriting tasks such as style transfer.

There is little work on large-scale sentence alignment focusing specifically on monolingual tasks. In (Barzilay and Elhadad, 2003), authors develop a hierarchical alignment approach of first clustering paragraphs on similar topics before performing alignment on the sentence level. They argue that, for monolingual data, pre-clustering of larger textual units is more robust to noise compared to fine-grained sentence matching applied directly on the dataset level.

3 Large-Scale Hierarchical Alignment (LHA)

Given two datasets that contain comparable documents written in two different author styles: a

source dataset $\mathbf{S^d}$ consisting of N_S documents $\mathbf{S^d} = \{s^d_1, ..., s^d_{N_S}\}$ (e.g. all Wikipedia articles) and a **target** dataset $\mathbf{T^d}$ consisting of N_T documents $\mathbf{T^d} = \{t^d_1, ..., t^d_{N_T}\}$ (e.g. all articles from the Simple Wikipedia), our approach to large-scale alignment is hierarchical, consisting of two consecutive steps: **document** alignment followed by **sentence** alignment (see Figure 1).

3.1 Document Alignment

For each source document s^d_i, document alignment retrieves K nearest neighbours $\{t^d_{i_1}, ..., t^d_{i_K}\}$ from the target dataset. In combination, these form K pseudo-parallel document pairs $\{(s^d_i, t^d_{i_1}), ..., (s^d_i, t^d_{i_K})\}$. Our aim is to select document pairs with high semantic similarity, potentially containing good pseudo-parallel sentence pairs representative of the document styles of each dataset.

To find nearest neighbours, we rely on two components: document embedding and approximate nearest neighbour search. For each dataset, we pre-compute document embeddings $e_d()$ as $I_s = [e_d(s^d_1), ..., e_d(s^d_{N_S})]$ and $I_t = [e_d(t^d_1), ..., e_d(t^d_{N_T})]$. We employ nearest neighbour search methods[3] to partition the embedding space, enabling fast and efficient nearest neighbour retrieval of similar documents across I_s and I_t. This enables us to find K nearest *target* document embeddings in I_t for each *source* embedding in I_s. We additionally filter document pairs whose similarity is below a manually selected threshold θ_d. In Section 4, we evaluate a range of different document embedding approaches, as well as alternative similarity metrics.

3.2 Sentence Alignment

Given a pseudo-parallel document pair (s^d, t^d) that contains a **source** document $s^d = \{s^s_1, ..., s^s_{N_J}\}$ consisting of N_J sentences and a **target** document $t^d = \{t^s_1, ..., t^s_{N_M}\}$ consisting of N_M sentences, sentence alignment extracts pseudo-parallel sentence pairs (s^s_i, t^s_j) that are highly similar.

To implement sentence alignment, we first embed each sentence in s^d and t^d and compute an inter-sentence similarity matrix P among all sentence pairs in s^d and t^d. From P we extract K nearest neighbours for each source and each target sentence. We denote the nearest neighbours of s^s_i as $NN(s^s_i) = \{t^s_{i_1}, \ldots, t^s_{i_K}\}$ and the nearest neighbours of t^s_j as $NN(t^s_j) = \{s^s_{j_1}, \ldots, s^s_{j_K}\}$. We remove all sentence pairs with similarity below a manually set threshold θ_s. We then merge *all* overlapping sets of nearest sentences in the documents to produce pseudo-parallel sentence sets (e.g. $(\{s^s_e, s^s_i\}, \{t^s_j, t^s_k, t^s_l\})$ when source sentence i is closes to target sentences j, k, and l and target sentence j is closest to source sentences e and i). This approach, inspired from (Štajner et al., 2018), provides the flexibility to model multi-sentence interactions, such as sentence splitting or compression, as well as individual sentence-to-sentence reformulations. Note that when $K = 1$, we only retrieve individual sentence pairs.

The final output of sentence alignment is a list of pseudo-parallel sentence pairs with high semantic similarity and preserved stylistic characteristics of each dataset. The pseudo-parallel pairs can be used to either augment an existing parallel dataset (as in Section 5), or independently, to solve a new author style transfer task for which there is no parallel data available (see the supplementary material for an example).

3.3 System Variants

The aforementioned framework provides the flexibility of exploring diverse variants, by exchanging document/sentence embeddings or text similarity metrics. We compare all variants in an automatic evaluation in Section 4.

Text embeddings We experiment with four text embedding methods:

1. *Avg*, is the average of the constituent word embeddings of a text[4], a simple approach that has proved to be a strong baseline for many text similarity tasks.

2. In *Sent2Vec*[5] (Pagliardini et al., 2018), the word embeddings are specifically optimized towards additive combinations over the sentence using an unsupervised objective function. This approach performs well on many unsupervised and supervised text similarity tasks, often outperforming more sophisticated supervised recurrent or convolutional architectures, while remaining very fast to compute.

[3] We use the Annoy library `https://github.com/spotify/annoy`.

[4] We use the Google News 300-dim Word2Vec models.

[5] We use the public unigram Wikipedia model.

3. *InferSent*[6] (Conneau et al., 2017) is a supervised sentence embedding approach based on bidirectional LSTMs, trained on natural language inference data.

4. *BERT*[7] (Devlin et al., 2019) is a state-of-the-art supervised sentence embedding approach based on the Transformer architecture.

Word Similarity We additionally test four word-based approaches for computing text similarity. Those can be used either on their own, or to refine the nearest neighbour search across documents or sentences.

1. We compute the unigram string overlap $o(\mathbf{x}, \mathbf{y}) = \frac{|\{\mathbf{y}\} \cap \{\mathbf{x}\}|}{|\{\mathbf{y}\}|}$ between source tokens $\mathbf{x}$ and target tokens $\mathbf{y}$ (excluding punctuation, numbers and stopwords).

2. We use the *BM25* ranking function (Robertson et al., 2009), an extension of TF-IDF.

3. We use the Word Mover's Distance (*WMD*) (Kusner et al., 2015), which measures the distance the embedded words of one document need to travel to reach the embedded words of another document. WMD has recently achieved good results on text retrieval (Kusner et al., 2015) and sentence alignment (Kajiwara and Komachi, 2016).

4. We use the Relaxed Word Mover's Distance (*RWMD*) (Kusner et al., 2015), which is a fast approximation of the WMD.

4 Automatic Evaluation

We perform an automatic evaluation of LHA using an annotated sentence alignment dataset (Hwang et al., 2015). The dataset contains 46 article pairs from Wikipedia and the Simple Wikipedia. The 67k potential sentence pairs were manually labelled as either *good* simplifications (277 pairs), *good* with a *partial* overlap (281 pairs), *partial* (117 pairs) or *non-valid*. We perform three comparisons using this dataset: evaluating document and sentence alignment separately, as well as jointly.

For sentence alignment, the task is to retrieve the 277 good sentence pairs out of the $67k$ possible sentence pairs in total, while minimizing the number of false positives. To evaluate document alignment, we add 1000 randomly sampled articles from Wikipedia and the Simple Wikipedia as noise, resulting in 1046 article pairs in total. The goal of document alignment is to identify the original 46 document pairs out of 1046×1046 possible document combinations.

This set-up additionally enables us to **jointly** evaluate document and sentence alignment, which best resembles the target effort of retrieving good sentence pairs from noisy documents. The two aims of the joint alignment task are to identify the *good* sentence pairs from within either $1M$ document or $125M$ sentence pairs, in the latter case without relying on any document-level information whatsoever.

4.1 Results

Our results are summarized in Tables 1 and 2. For all experiments, we set $K = 1$ and report the maximum F1 score ($\mathbf{F1}_{max}$) obtained from varying the document threshold θ_d and the sentence threshold θ_s. We also report the percentage of true positive (**TP**) document or sentence pairs that were retrieved when the F1 score was at its maximum, as well as the average speed of each approach (**doc/s** and **sent/s**). The speed becomes of a particular concern when working with large datasets consisting of millions of documents and hundreds of millions of sentences.

On document alignment, (Table 1, left) the *Sent2Vec* approach achieved the best score, outperforming the other embedding methods including the word-based similarity measures. On sentence alignment (Table 1, right), the WMD achieves the best performance, matching the result from (Kajiwara and Komachi, 2016). When evaluating document and sentence alignment jointly (Table 2), we compare our hierarchical approach (*LHA*) to global alignment applied directly on the sentence level (*Global*). *Global* computes the similarities between all $125M$ sentence pairs in the entire evaluation dataset. LHA significantly outperforms Global, successfully retrieving three times more valid sentence pairs, while remaining fast to compute. This result demonstrates that document alignment is beneficial, successfully filtering some of the noise, while also reducing the overall number of sentence similarities to be computed.

The *Sent2Vec* approach to LHA achieves good performance on document and sentence align-

[6] We use the GloVe-based model provided by the authors.

[7] We use the base 12-layer model provided by the authors.

Table 1: Automatic evaluation of Document (left) and Sentence alignment (right). **EDim** is the embedding dimensionality. **TP** is the percentage of true positives obtained at $\mathbf{F1}_{max}$. Speed is calculated on a single CPU thread.

			Document alignment				**Sentence alignment**			
	Approach	**EDim**	$\mathbf{F1}_{max}$	**TP**	θ_d	**doc/s**	$\mathbf{F1}_{max}$	**TP**	θ_s	**sent/s**
Embedding	Average word embeddings (Avg)	300	0.66	43%	0.69	260	0.675	46%	0.82	1458
	Sent2Vec (Pagliardini et al., 2018)	600	**0.78**	**61%**	0.62	343	0.692	48%	0.69	1710

	(Hwang et al., 2015)	-	-	-	-	-	0.712	-	-	-
	(Kajiwara and Komachi, 2016)	-	-	-	-	-	0.724	-	-	-

†: These models are specifically designed for sentence embedding, hence we do not test them on document alignment.

Table 2: Evaluation on large-scale sentence alignment: identifying the *good* sentence pairs without any document-level information. We pre-compute the embeddings and use the Annoy ANN library. For the WMD-based approaches, we re-compute the top 50 sentence nearest neighbours of Sent2Vec.

Approach	$\mathbf{F1}_{max}$	**TP**	**time**
LHA (Sent2Vec)	0.54	31%	33s
LHA (Sent2Vec + WMD)	**0.57**	**33%**	1m45s
Global (Sent2Vec)	0.339	12%	15s
Global (WMD)	0.291	12%	30m45s

ment, while also being the fastest to compute. We therefore use it as the default approach for the following experiments on text simplification.

5 Empirical Evaluation

To test the suitability of pseudo-parallel data extracted with LHA, we perform empirical experiments on text simplification from the normal Wikipedia to the Simple Wikipedia. We chose simplification because some parallel data are already available for this task, allowing us to experiment with mixing parallel and pseudo-parallel datasets. In the supplementary material[8] we experiment with an additional task for which there is no parallel data: style transfer from scientific journal articles to press releases.

We compare the performance of neural machine translation (NMT) systems trained under three different scenarios: 1) using **existing** parallel data for training; 2) using a **mixture** of parallel and pseudo-parallel data extracted with LHA; and 3) using pseudo-parallel data **on its own**.

5.1 Experimental Setup

NMT model For all experiments, we use a single-layer LSTM encoder-decoder model (Cho et al., 2015) with an attention mechanism (Bahdanau et al., 2015). We train our models on the subword level (Sennrich et al., 2015), capping the vocabulary size to 50k. We re-learn the subword rules separately for each dataset, and train until convergence using the Adam optimizer (Kingma and Ba, 2015). We use beam search with a beam of 5 to generate all final outputs.

Evaluation metrics We report a diverse range of automatic metrics and statistics. *SARI* (Xu et al., 2016) is a recently proposed metric for text simplification which correlates well with simplicity in the output. SARI takes into account the total number of changes (additions, deletions) of the input when scoring model outputs. *BLEU* (Papineni et al., 2002) is a precision-based metric for machine translation commonly used for evaluation of text simplification (Xu et al., 2016; Štajner and Nisioi, 2018) and of style transfer (Shen et al., 2017). Recent work has indicated that BLEU is not suitable for assessment of simplicity (Sulem et al., 2018), it correlates better with meaning preservation and grammaticality, in particular when using multiple references. We also report the average Levenshtein distance (LD) from the model outputs to the input (LD_{src}) or the target reference (LD_{tgt}). On simplification tasks, LD correlates well with meaning preservation and grammaticality (Sulem et al., 2018), complementing BLEU.

Extracting pseudo-parallel data We use LHA with *Sent2Vec* (see Section 3) to extract pseudo-parallel sentence pairs for text simplification. To ensure some degree of lexical similarity, we exclude pairs whose string overlap (defined in Section 3.3) is below 0.4, and pairs in which the target sentence is more than 1.5 times longer than the source sentence. We use $K = 5$ in all of our align-

wiki-news-74	133K	25.66	17.25	19%	2%
wiki-news-70	216K	26.62	16.29	19%	2%

ment experiments, which enables extraction of up to 5 sentence nearest neighbours.

Parallel data As a parallel baseline dataset, we use an existing dataset from (Hwang et al., 2015). The dataset consists of 282K sentence pairs obtained after aligning the parallel articles from Wikipedia and the Simple Wikipedia. This dataset allows us to compare our results to previous work on data-driven text simplification. We use two versions of the dataset in our experiments: `full` contains all 282K pairs, while `partial` contains 71K pairs, or 25% of the full dataset.

Evaluation data We evaluate our simplification models on the testing dataset from (Xu et al., 2016), which consists of 358 sentence pairs from the normal Wikipedia and the Simple Wikipedia. In addition to the ground truth simplifications, each input sentence comes with 8 additional references, manually simplified by Amazon Meachanical Turkers. We compute *BLEU* and *SARI* on the 8 manual references.

Pseudo-parallel data We align two dataset pairs, obtaining pseudo-parallel sentence pairs for text simplification (statistics of the datasets we use for alignment are in Table 3). First, we align the normal `Wikipedia` to the `Simple Wikipedia` using document and sentence similarity thresholds $\theta_d = 0.5$ and $\theta_s = \{0.72, 0.65\}$, producing two datasets: `wiki-simp-72` and `wiki-simp-65`. Because LHA uses no document-level information in this dataset, alignment leads to new sentence pairs, some of which may be distinct from the pairs present in the existing parallel dataset. We monitor for and exclude pairs that overlap with the testing dataset. Second, we align `Wikipedia` to the `Gigaword` news article corpus (Napoles et al., 2012), using $\theta_d = 0.5$ and $\theta_s = \{0.74, 0.7\}$, resulting in two additional pseudo-parallel datasets: `wiki-news-74` and `wiki-news-70`. With these datasets, we investigate whether pseudo-parallel data extracted from a *different domain* can be beneficial for text simplification. We use slightly higher sentence alignment thresholds for the news articles because of the domain difference.

We find that the majority of the pairs extracted contain a single sentence, and 15-20% of the source examples and 5-10% of the target examples contain multiple sentences (see Table 5 for additional statistics). Most multi-sentence examples contain two sentences, while 0.5-1% contain 3 to 5 sentences. Two example aligned outputs are in Table 4 (additional examples are available in the supplementary material). They suggest that our method is capable of extracting high-quality pairs that are similar in meaning, even spanning across multiple sentences.

Randomly sampled pairs We also experiment with adding random sentence pairs to the parallel dataset (`rand-100K`, `rand-200K` and `rand-300K` datasets, containing 100K, 200K and 300K random pairs, respectively). The

random pairs are uniformly sampled from the Wikipedia and the Simple Wikipedia, respectively. With the random pairs, we aim to investigate how model performance changes as we add an increasing number of sentence pairs that are non-parallel but are still representative of the two dataset styles.

5.2 Automatic Evaluation

The simplification results in Table 6 are organized in several sections according to the type of dataset used for training. We report the results of the top two beam search hypotheses produced by our models, considering that the second hypothesis often generates simpler outputs (Štajner and Nisioi, 2018).

In Table 6, `input` is copying the normal Wikipedia input sentences, without making any changes. `reference` reports the score of the original Simple Wikipedia references with respect to the other 8 references available for this dataset. `NTS` is the previously best reported result on text simplification using neural sequence models (Štajner and Nisioi, 2018). `baseline-`{`282K, 71K`} are our parallel LSTM baselines, trained on 282K and 71K parallel pairs, respectively.

The models trained on a *mixture* of *parallel* and *pseudo-parallel* data generate longer outputs on average, and their output is more similar to the `input`, as well as to the original Simple Wikipedia `reference`, in terms of the LD. Adding pseudo-parallel data frequently yields BLEU improvements on both Beam hypotheses: over the *NTS* system, as well as over our baselines trained solely on parallel data. The BLEU gains are larger when using the smaller parallel dataset, consisting of 71K sentence pairs. In terms of SARI, the scores remain either similar or slightly better than the baselines, indicating that simplicity in the output is preserved. The second Beam hypothesis yields higher SARI scores than the first one, in agreement with (Štajner and Nisioi, 2018). Interestingly, adding out-of-domain pseudo-parallel news data (`wiki-news-`$\star$ datasets) results in an increase in BLEU despite the potential change in style of the target sequence.

Larger pseudo-parallel datasets can lead to bigger improvements, however noisy data can result in a decrease in performance, motivating careful data selection. In our *parallel and random* setup, we find that an increasing number of random pairs added to the parallel data progressively degrades model performance. However, those models still manage to perform surprisingly well, even when over half of the pairs in the dataset are random. Thus, neural machine translation can successfully learn target transformations despite substantial data corruption, demonstrating robustness to noisy or non-parallel data for certain tasks.

When training solely on *pseudo-parallel* data, we observe lower performance on average in comparison to parallel models. However, the results are encouraging, demonstrating the potential of our approach in tasks for which there is no parallel data available. As expected, the out-of-domain news data (`wiki-news-all`) is less suitable for simplification than the in-domain data (wiki-simp-all), because of the change in output style of the former. Results are best when mixing all pseudo-parallel pairs into a single dataset (pseudo-all). Having access to a small amount of *in-domain* pseudo-parallel data, in addition to *out-of-domain* pairs, seems to be beneficial to the success of our approach.

5.3 Human Evaluation

Due to the challenges of automatic evaluation of text simplification systems (Sulem et al., 2018), we also perform a human evaluation. We asked 8 fluent English speakers to rate the grammaticality, meaning preservation, and simplicity of model outputs produced for 100 randomly selected sentences from our test set. We exclude any model outputs which leave the input unchanged. Grammaticality and meaning preservation are rated on a Likert scale from 1 (Very bad) to 5 (Very good). Simplicity of the output sentences, in comparison to the input, is rated following (Štajner et al., 2018), between: -2 (much more difficult), -1 (somewhat more difficult), 0 (equally difficult), 1 (somewhat simpler) and 2 (much simpler).

The results are reported in Table 7, where we compare our parallel baseline (baseline-272K in Table 6) to our best model trained on a mixture of parallel and pseudo-parallel data (wiki-simp-65) and our best model trained on pseudo-parallel data only (pseudo-all). We also evaluate the original Simple Wikipedia references (reference) for comparison. In terms of simplicity, our pseudo-parallel systems are closer to the result of reference than is baseline-272K, indicating that they better match the target sentence style. baseline-272K and wiki-simp-65 perform similarly to the references in terms of grammaticality, with baseline-272K having a small edge. In terms of meaning preservation, both do worse than the references, with wiki-simp-65 having a small edge. pseudo-all performs worse on both grammaticality and meaning preservation, but is on par with the simplicity result of wiki-simp-65.

In Table 8, we also show example outputs of our best models (additional examples are available in the supplementary material). The models trained on parallel plus additional pseudo-parallel data produced outputs that preserve the meaning of 'Jeddah' as a city better than our parallel baseline, while correctly simplifying *principal* to *main*. The model trained solely on pseudo-parallel data produces a similar output, apart from wrongly replacing *jeddah* with *islam*.

Table 7: Human evaluation of the Grammaticality (**G**), Meaning preservation (**M**) and Simplicity (**S**) of model outputs (on the first Beam hypothesis).

Method	G	M	S
reference	4.53	4.34	0.69
baseline-272K	4.51	3.68	0.9
+ wiki-simp-65	4.39	3.76	0.74
pseudo-all	4.02	2.96	0.77

Table 8: Example model outputs (first Beam hypothesis).

Method	Example
input	jeddah is the **principal** gateway to mecca , islam ' s holiest city , which able-bodied muslims are required to visit at least once in their lifetime .
reference	jeddah is the **main** gateway to mecca , the holiest city of islam , where able-bodied muslims must go to at least once in a lifetime .
baseline-282K	it is the highest gateway to mecca , islam .
+ wiki-sim-65	jeddah is the **main** gateway to mecca , islam 's holiest city .
+ wiki-news-74	it is the **main** gateway to mecca , islam ' s holiest city .
pseudo-all	islam is the **main** gateway to mecca , islam 's holiest city .

6 Conclusion

We developed a hierarchical method for extracting pseudo-parallel sentence pairs from two monolingual comparable corpora composed of different text styles. We evaluated the performance of our method on automatic alignment benchmarks and extrinsically on automatic text simplification. We find improvements arising from adding pseudo-parallel sentence pairs to existing parallel datasets, as well as promising results when using the pseudo-parallel data on its own.

Our results demonstrate that careful engineering of pseudo-parallel datasets can be a successful approach for improving existing monolingual text-to-text rewriting tasks, as well as for tackling novel tasks. The pseudo-parallel data could also be a useful resource for dataset inspection and analysis. Future work could focus on improvements of our system, such as refined approaches to sentence pairing.

{omote@ai.cs, tamura@cs, ninomiya@cs}.ehime-u.ac.jp

Abstract

In this paper, we propose a novel model for Transformer neural machine translation that incorporates syntactic distances between two source words into the relative position representations of a self-attention mechanism. In particular, the proposed model encodes pair-wise relative depths on a source dependency tree, which are the differences between the depths of two source words, in the encoder's self-attention. Experiments show that our proposed model achieved a 0.5 point gain in BLEU on the Asian Scientific Paper Excerpt Corpus Japanese-to-English translation task.

1 Introduction

Machine translation (MT) has been actively studied for many decades. In recent years, neural machine translation (NMT) has become dominant. In particular, the Transformer model (Vaswani et al., 2017), which is based solely on attention mechanisms, has advanced the state-of-the-art performance on various translation tasks and has become the focus of many MT researchers nowadays. Unlike recurrent neural network (RNN) based models (Sutskever et al., 2014; Luong et al., 2015) or convolutional neural network (CNN) based models (Gehring et al., 2017), the Transformer model attends to words in the same sentence, i.e., a source sentence or a target sentence, through the self-attention mechanisms in each encoder and decoder. In addition, it encodes the positional information of each word, such as the word order, as positional encoding (PE) so that recurrent and convolutional structures are excluded and training can be parallelized. Since NMT appeared, translation performance has been improved by using the syntactic information, such as phrase structures or dependency structures, of the source-side, target-side, or both (Ding and Palmer, 2005; Chen et al., 2017; Eriguchi et al., 2017; Wu et al., 2018). In semantic role labeling (SRL), though the task is not MT, Strubell et al. (2018) improved a Transformer-based model through the learning of self-attention weighting on the basis of syntactic information, i.e., dependency structures. Hence, it is expected that the performance of Transformer NMT will be improved by incorporating syntax information.

In this paper, we aim to improve Transformer NMT by using dependency structures. Some researchers have improved Transformer NMT by modifying self-attention. Shaw et al. (2018) used relative position information between two words encoded in self-attention in addition to the absolute position information of words.

Inspired by Shaw et al. (2018), we propose a novel Transformer NMT model that incorporates the relationships between two words on source dependency structures into relative position representations in self-attention. In particular, the proposed model adds a vector that encodes relative positional relationships between words on source dependency structures to a word embedding vector. It adds only dependency information to the word embedding vector; hence, there is no need to change the whole Transformer's mechanism or objective function, and it is easy to adapt the mechanism to other extended Transformer models because it is highly extensible. Strubell et al. (2018)'s method is different from our work in that their task is SRL, and to learn the attention between words directly from dependency structures, they largely changed the Transformer's model and objective function.

We evaluate the effectiveness of the proposed model on the WAT'18 Asian Scientific Paper Excerpt Corpus (ASPEC) Japanese-to-English translation task. The experimental results demonstrate that our approach achieves a 0.5 point gain in BLEU over baseline Transformers (Vaswani et al., 2017; Shaw et al., 2018).

2 Related Work

NMT performance has been improved by using the syntactic information of source language sentences, target language sentences, or both.

Some researchers have focused on phrase structures as syntactic information. Aharoni and Goldberg (2017) incorporated target-side phrase structures into NMT, and Eriguchi et al. (2016) and Ma et al. (2018) incorporated source-side phrase structures. Our work is different from their research in that we focus on dependency structures rather than phrase structures. In addition, while their models are based on RNN-based NMT models, we aim to improve a Transformer NMT model.

Other researchers have focused on dependency structures as syntactic information. Chen et al. (2017) proposed a hybrid NMT model of RNNs and CNNs to incorporate syntactic information into an encoder. Their model first learns source dependency representations to compute dependency context vectors by using CNNs. The RNN-based encoder-decoder model learns a translation model, which is provided with the CNNs' syntactic information. Sennrich and Haddow (2016) proposed an RNN-based NMT model that combines embedding vectors of linguistic features such as part-of-speech tags and dependency relation labels on a source sentence with the embedded representations of the source words. Eriguchi et al. (2017) proposed a hybrid model, called NMT+RNNG, that learns parsing and translation by combining recurrent neural network grammar into an RNN-based NMT.

Most existing dependency-based NMT models, including the above-mentioned models, are improvements over RNN-based NMT models, which, in terms of structure, differ greatly from the Transformer model. Because we make the proposed model consider dependency information in self-attention, which is the Transformer's characteristic structure, the usage of dependency information is different from their models.

Recently, Wu et al. (2018) and Ma et al. (2019) incorporated syntactic information into Transformer NMT. Wu et al. (2018) proposed a dependency-based NMT model that uses dependency trees for both source and target languages. Their model encodes source sentences with two extra sequences linearized from source dependency trees and jointly generates both target sentences and their dependency trees. They applied their model not only to bi-directional RNNs but also to the Transformer, but did not improve the Transformer's architecture. In contrast, we improve the Transformer model so that it incorporates source dependency information by encoding pair-wise relative depths on a source dependency tree, which are the differences between the depths of two source words, in the encoder's self-attention.

Ma et al. (2019) proposed several strategies for improving NMT with neural syntax distance (NSD), which has been used for constituent parsing (Shen et al., 2018), and dependency-based NSD, which is an extension of the original NSD for dependency trees. In their work, they proposed a syntactic PE for Transformer NMT in order to incorporate positions on a dependency tree for each word via an absolute PE mechanism. In contrast, our model uses relative dependency-based distances between two words via a relative PE mechanism in the encoder's self-attention.

3 Background

In this section, we first describe the baseline of our proposed model, the Transformer model. Then, we describe a Transformer model that employs relative PE.

3.1 Transformer

Transformer (Vaswani et al., 2017) is an encoder-decoder model that has a distinct architecture based on self-attention. Figure 1 shows the architecture of the model. Unlike RNN-based NMT and CNN-based NMT, Transformer does not have a recurrent or convolutional configuration of networks. Instead, it encodes source sentences as intermediate representations by using self-attention and decodes them by using self-attention and encoder-decoder attention.

The encoder maps an input sequence $(\boldsymbol{x_1}, \ldots, \boldsymbol{x_n})$ to a sequence of vector representations $Z = (\boldsymbol{z_1}, \ldots, \boldsymbol{z_n})$. Given Z, the decoder generates an output sequence $(\boldsymbol{y_1}, \ldots, \boldsymbol{y_{n'}})$. In both the encoder and decoder, the embedding layer converts input tokens (source tokens in the

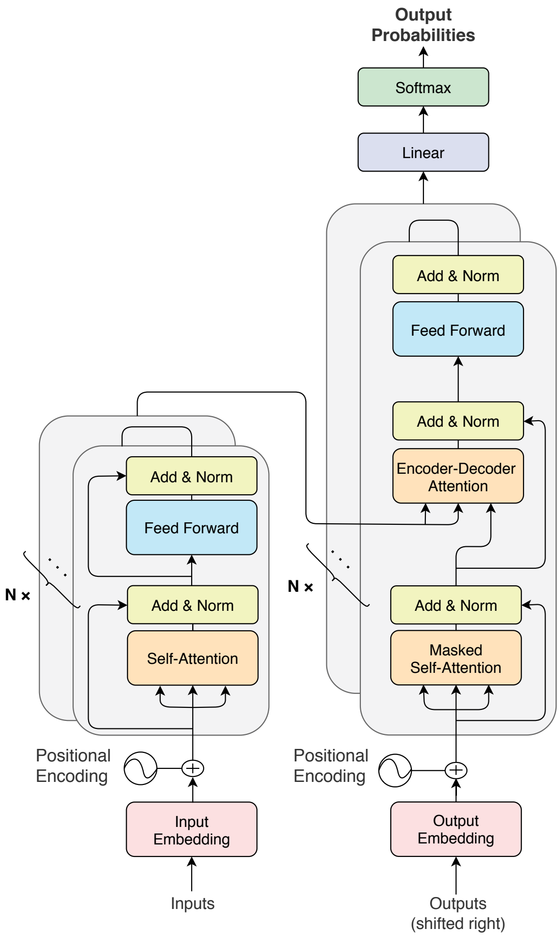

Figure 1: Architecture of Transformer

encoder and target tokens in the decoder) to vectors of dimension d_{model}. Because the information on proximity between tokens is not considered in self-attention itself, the information on a token's position is embedded by using positional encoding (PE). Specifically, PE provides a matrix that represents the absolute position information of tokens in a sentence, and Transformer adds PE to the embedding matrix of the input tokens. Each element of PE is computed by the following equations, which are sine and cosine functions of different frequencies.

$$PE(pos, 2i) = \sin(pos/10000^{2i/d_{model}}),$$
$$PE(pos, 2i+1) = \cos(pos/10000^{2i/d_{model}}),$$

where pos is the position of each input token, i is the dimension of each element, and d_{model} is the embedding dimension of an input token. The input of the encoder's or decoder's first layer is the embedding matrix added with the positional encoding.

The encoder's layer has two sub-layers. The first sub-layer is a multi-head self-attention mechanism, and the second layer is a simple, position-wise fully connected feed-forward network (FFN). The decoder's layer has three sub-layers. The first sub-layer is a masked multi-head self-attention mechanism, the second sub-layer is a multi-head encoder-decoder attention mechanism, and the third sub-layer is the FFN.

Residual connection (He et al., 2016) is applied to the sub-layers, followed by layer normalization (Ba et al., 2016), i.e., the output of each sub-layer is $LayerNorm(x + Sublayer(x))$, where $Sublayer(x)$ is the output of the original sub-layer.

The self-attention and the encoder-decoder attention employ a multi-head attention mechanism. The multi-head attention first computes h dot-product attentions after linearly mapping three input vectors, $\boldsymbol{q}, \boldsymbol{k}, \boldsymbol{v}$[*1] $\in \mathbb{R}^{1\times d_{model}}$, from d_{model} dimension to d_k dimension with parameter matrices, $W_i^Q, W_i^K, W_i^V \in \mathbb{R}^{d_{model}\times d_k}(i = 1, \ldots, h)$, where d_{model} is the dimension of input vectors, and $d_k = d_{model}/h$. In what follows, each dot-product attention is referred to as a head (H_i $(i = 1, \ldots, h)$).

$$H_i = Attention(\boldsymbol{q'}, \boldsymbol{k'}, \boldsymbol{v'}), \quad (1)$$

$$Attention(\boldsymbol{q'}, \boldsymbol{k'}, \boldsymbol{v'}) = softmax(\frac{\boldsymbol{q'}\boldsymbol{k'}^T}{\sqrt{d_k}})\boldsymbol{v'}, \quad (2)$$

$$\boldsymbol{q'} = \boldsymbol{q}W_i^Q, \boldsymbol{k'} = \boldsymbol{k}W_i^K, \boldsymbol{v'} = \boldsymbol{v}W_i^V. \quad (3)$$

Then, multi-head attention linearly maps concatenated heads with a parameter matrix, $W^o \in \mathbb{R}^{d_{model}\times d_{model}}$.

$$MultiHead(\boldsymbol{q}, \boldsymbol{k}, \boldsymbol{v}) = Concat(H_1, \ldots, H_h)W^O. \quad (4)$$

The encoder's self-attention computes Equation 4 by substituting the intermediate states of the encoder, $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n$, for $\boldsymbol{q}, \boldsymbol{k}, \boldsymbol{v}$. Specifically, each head computes the following weighted sum.

$$\boldsymbol{z}_i = \sum_{j=1}^{n} \alpha_{ij}\boldsymbol{x}_j W^V, \quad (5)$$

where $\boldsymbol{z}_1, \ldots, \boldsymbol{z}_n$ are the outputs of the self-attention. Each coefficient, α_{ij}, is computed by using a softmax function:

$$\alpha_{ij} = \frac{\exp(e_{ij})}{\sum_{k=1}^{n}\exp(e_{ik})}, \quad (6)$$

[*1] In this paper, we treat a vector as a row vector according to the original paper (Vaswani et al., 2017) unless otherwise noted.

where e_{ij} is computed:

$$e_{ij} = \frac{(\boldsymbol{x}_i W^Q)(\boldsymbol{x}_j W^K)^T}{\sqrt{d_z}}, \tag{7}$$

where d_z is the dimension of $\boldsymbol{z}_i$.

The decoder's self-attention computes Equation 4 by substituting the intermediate states of the decoder for $\boldsymbol{q}, \boldsymbol{k}, \boldsymbol{v}$. During inference, however, it is not possible for the decoder to get the information on the words that will be generated later when predicting a word, i.e., only the intermediate states of the sub-sequence that has been generated can be used for self-attention. Hence, masked self-attention is introduced to the decoder's self-attention so as not to calculate the self-attention between a predicted word and succeeding words. Masked self-attention is calculated by changing Equation 7:

$$e_{ij} = \begin{cases} \frac{(\boldsymbol{x}_i W^Q)(\boldsymbol{x}_j W^K)^T}{\sqrt{d_z}} & (i \geq j), \\ -\infty & (otherwise). \end{cases} \tag{8}$$

The coefficient representing the strength of the relationship between a certain word and the word located behind it ($i < j$) becomes zero, and it can be controlled so as not to consider the relationship. Hence, Equation 6 is changed:

$$\alpha_{ij} = \begin{cases} \frac{\exp{(e_{ij})}}{\sum_{k=1}^{n} \exp{(e_{ik})}} & (i \geq j), \\ 0 & (otherwise). \end{cases} \tag{9}$$

In the encoder-decoder attention, the intermediate states of the decoder are used for $\boldsymbol{q}$, and the outputs of the encoder are used for $\boldsymbol{k}, \boldsymbol{v}$.

The FFN for input $\boldsymbol{x}$ compute as follows:

$$FFN(\boldsymbol{x}) = max(0, \boldsymbol{x}W_1 + \boldsymbol{b}_1)W_2 + \boldsymbol{b}_2, \tag{10}$$

where $W_1 \in \mathbb{R}^{d_{model} \times d_{ff}}$, $W_2 \in \mathbb{R}^{d_{ff} \times d_{model}}$ are parameter matrices, and $\boldsymbol{b}_1$, $\boldsymbol{b}_2$ are biases.

3.2 Transformer with Relative Positional Encoding

Shaw et al. (2018) proposed an extended transformer model that captures the pairwise relationships between input elements in terms of relative positions in both the encoder and decoder. In their method, the relationships between the intermediate representations $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$, i.e., relative position information between the i-th and j-th words in an input sentence, are represented by vectors $\boldsymbol{a}_{ij}^V, \boldsymbol{a}_{ij}^K \in \mathbb{R}^{d_k}$. The relative position representations are added to the output of the sub-layer to be the input to the next layer. Specifically, the following equation is used instead of Equation 5.

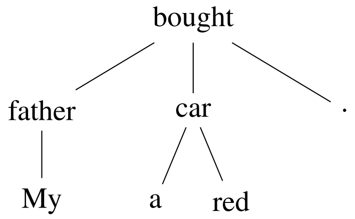

Figure 2: Example of Dependency Tree

$$\boldsymbol{z}_i = \sum_{j=1}^{n} \alpha_{ij}(\boldsymbol{x}_j W^V + \boldsymbol{a}_{ij}^V). \tag{11}$$

The following equation is also used for the substitution of Equation 7 in order to consider relative position relationships between words in calculating e_{ij}:

$$e_{ij} = \frac{\boldsymbol{x}_i W^Q (\boldsymbol{x}_j W^K + \boldsymbol{a}_{ij}^K)^T}{\sqrt{d_z}}. \tag{12}$$

Shaw et al. (2018) assume that relative position information is not useful when the distance is long. They define the maximum relative position as a constant k. In addition, the relative position relationships between two words are captured by $2k + 1$ unique labels as follows, considering that succeeding words are in a positive direction and preceding words are in a negative direction.

$$\boldsymbol{a}_{ij}^K = \boldsymbol{w}_{clip(j-i,k)}^K, \tag{13}$$

$$\boldsymbol{a}_{ij}^V = \boldsymbol{w}_{clip(j-i,k)}^V, \tag{14}$$

$$clip(x, k) = max(-k, min(k, x)), \tag{15}$$

where $\boldsymbol{w}^K = (\boldsymbol{w}_{-k}^K, \ldots, \boldsymbol{w}_k^K)$ and $\boldsymbol{w}^V = (\boldsymbol{w}_{-k}^V, \ldots, \boldsymbol{w}_k^V)$ ($\boldsymbol{w}_k^K, \boldsymbol{w}_k^V \in \mathbb{R}^{d_k}$) are relative position representations to be learned.

4 Dependency-Based Relative Positional Encoding for Transformer

In this section, we explain our proposed method, which encodes relative positions on source dependency trees in Transformer. We first introduce the inter-word distance on source dependency trees and then explain dependency-based relative positional encoding, which provides relative position representations on the trees. The dependency-based encoding is incorporated into

	My	father	bought	a	red	car	.
My	0	-1	-2	0	0	-1	-1
father	1	0	-1	1	1	0	0
bought	2	1	0	2	2	1	1
a	0	-1	-2	0	0	-1	-1
red	0	-1	-2	0	0	-1	-1
car	1	0	-1	1	1	0	0
.	1	0	-1	1	1	0	0

Table 1: Examples of Dependency-based Inter-Word Distances

the self-attention mechanism, following the idea of relative positional encoding (Shaw et al., 2018).

The inter-word distance on dependency trees is defined as the relative depth between two words in dependency trees. The relative depth $dist_{ij}$ between node n_i and node n_j corresponding to word w_i and word w_j is defined as follows:

$$dist_{ij} = depth(n_j) - depth(n_i), \tag{16}$$

where $depth(n)$ is the depth of node n in a dependency tree. For example, in Figure 2, the depth of "bought" (w_3) relative to "My" (w_1) is calculated by $dist_{1,3} = 0 - 2 = -2$. Table 1 shows a list of the inter-word distances on the dependency tree shown in Figure 2.

The relative position between node n_i and node n_j in a source dependency tree is represented by vectors, $\boldsymbol{b}^V_{ij}, \boldsymbol{b}^K_{ij} \in \mathbb{R}^{d_k}$, and the following equations are used instead of Equations 11 and 12.

$$\boldsymbol{z}_i = \sum_{j=1}^{n} \alpha_{ij}(\boldsymbol{x}_j W^V + \boldsymbol{b}^V_{ij}), \tag{17}$$

$$e_{ij} = \frac{\boldsymbol{x}_i W^Q (\boldsymbol{x}_j W^K + \boldsymbol{b}^K_{ij})^T}{\sqrt{d_z}}. \tag{18}$$

We assume that the influence of a distance decreases if the distance is longer than some certain threshold. We limit the maximum distance to a constant l. The relative position representations $\boldsymbol{b}^V_{ij}$ and $\boldsymbol{b}^K_{ij}$ between node n_i and node n_j in a dependency tree are defined with inter-word distance labels:

$$\boldsymbol{b}^K_{ij} = \boldsymbol{w}^K_{clip(dist_{ij},l)}, \tag{19}$$

$$\boldsymbol{b}^V_{ij} = \boldsymbol{w}^V_{clip(dist_{ij},l)}. \tag{20}$$

Using these expressions, the encoder's self-attention networks learn the relative position representations on a source dependency structure. We call this model $Transformer_{dep}$.

We also describe a hybrid model that learns both relative position representations on dependency structures and relative position representations for linear relations in sentences, i.e., the relative positional encoding explained in Section 3.2. This hybrid method is called $Transformer_{dep+rel}$. The $Transformer_{dep+rel}$ model uses the sum of $\boldsymbol{a}^V_{ij}$ and $\boldsymbol{b}^V_{ij}$ and the sum of $\boldsymbol{a}^K_{ij}$ and $\boldsymbol{b}^K_{ij}$ as relative position information between two words. $\boldsymbol{z}_i$ and e_{ij} are defined in $Transformer_{dep+rel}$ as follows:

$$\boldsymbol{z}_i = \sum_{j=1}^{n} \alpha_{ij}(\boldsymbol{x}_j W^V + \boldsymbol{a}^V_{ij} + \boldsymbol{b}^V_{ij}), \tag{21}$$

$$e_{ij} = \frac{\boldsymbol{x}_i W^Q (\boldsymbol{x}_j W^K + \boldsymbol{a}^K_{ij} + \boldsymbol{b}^K_{ij})^T}{\sqrt{d_z}}. \tag{22}$$

5 Experiments

5.1 Experimental Setup

We experimented on the WAT'18 Asian Scientific Paper Excerpt Corpus (ASPEC) (Nakazawa et al., 2016) by using the Japanese-to-English language pair. We tokenized English sentences by using Moses (Koehn et al., 2007) and Japanese sentences by using KyTea (Neubig et al., 2011). We also parsed the dependency of the Japanese sentences by using EDA[*2].

For model learning, we used 1,341,417 sentence pairs of 50 words or less for both the English and Japanese sentences from the first 1.5 million sentence pairs of the training data (train-1.txt, train-2.txt). The Japanese dictionary was comprised of words that appeared 7 times or more in the training data, and the English dictionary was comprised of words that appeared 10 times or more in the training data. The other words were replaced with $\langle UNK \rangle$ tags representing unknown words. We used 1,790 sentences (dev.txt) as validation data and 1,812 sentences (test.txt) as test data.

We compared our models, $Transformer_{dep}$ and $Transformer_{dep+rel}$, with two baseline Transformer NMT models, $Transformer_{abs}$ (Vaswani et al., 2017), which learns absolute position representations, and $Transformer_{rel}$ (Shaw et al., 2018), which learns relative position representations in a sentence.

Hyper-parameters of all Transformer models were determined, following the settings of Vaswani et al. (2017). We set the number of stacks

[*2] http://www.ar.media.kyoto-u.ac.jp/tool/EDA/

Model	BLEU
$Transformer_{abs}$	25.91
$Transformer_{rel}$	26.72
$Transformer_{dep}$	26.10
$Transformer_{dep+rel}$	27.22

Table 2: Experimental Results

$\boldsymbol{b}_{ij}^V$	$\boldsymbol{b}_{ij}^K$	BLEU
✓	✓	16.71
×	✓	16.60
✓	×	15.62
×	×	8.69

Table 3: Experimental Results for Ablating Relative Position Representations $\boldsymbol{b}_{ij}^V, \boldsymbol{b}_{ij}^K$

of the encoder and decoder layers to 6, the number of heads to 8, and the embedding dimension to 512. We used the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 10^{-9}$. We used the same warm-up and decay strategy for the learning rate as Vaswani et al. (2017), with $4,000$ warm-up steps.

The maximum distances of the relative position for linear relations in the sentences and dependency-based relations were set as $k = 2$, $l = 2$ for $Transformer_{rel}$, $Transformer_{dep}$, and $Transformer_{dep+rel}$[*3]. The batch size was 256, the number of epochs was 30, and the model with the best accuracy for the validation data was applied to the test data. In our experiments, target sentences were generated by a greedy algorithm.

5.2 Results

The evaluation results are shown in Table 2. We used BLEU to evaluate the translation performance. As shown in the table, $Transformer_{dep}$ improved by 0.19 BLEU points against $Transformer_{abs}$. This means that the dependency-based positional encoding was effective for the Transformer model. Although the effectiveness of our dependency-based positional encoding ($Transformer_{dep}$) was not as great as the relative positional encoding ($Transformer_{rel}$), the hybrid model ($Transformer_{dep+rel}$) achieved the best result among these models. $Transformer_{dep+rel}$ improved by 1.31 BLEU points against $Transformer_{abs}$ and by 0.50 BLEU points against $Transformer_{rel}$. From these results, on the Japanese-to-English translation task, the performance of Transformer NMT can be improved by incorporating source dependency structures into relative position representations.

5.3 Discussion

Shaw et al. (2018) verified the effectiveness of both $\boldsymbol{a}_{ij}^V$ and $\boldsymbol{a}_{ij}^K$, representing relative positional relationships. They showed that the translation accuracy was comparative when $\boldsymbol{a}_{ij}^V$ was removed from their model, but the translation accuracy decreased when $\boldsymbol{a}_{ij}^K$ was removed. This means that $\boldsymbol{a}_{ij}^K$ was an effective representation, but $\boldsymbol{a}_{ij}^V$ was less effective. In this section, to confirm the effectiveness of the dependency-based representations, we conducted ablation experiments on $\boldsymbol{b}_{ij}^V$ and $\boldsymbol{b}_{ij}^K$. We evaluated the Japanese-English translation performance for $Transformer_{dep}$. The absolute positional encoding was removed from all models, following the settings of Shaw et al. (2018)'s verification. Specifically, we evaluated (i) the $Transformer_{dep}$ model that used only $\boldsymbol{b}_{ij}^V$, where Equation 18 was changed to Equation 7, (ii) the $Transformer_{dep}$ model that used only $\boldsymbol{b}_{ij}^K$, where Equation 17 was changed to Equation 5, and (iii) the $Transformer_{dep}$ model that used neither $\boldsymbol{b}_{ij}^V$ and $\boldsymbol{b}_{ij}^K$, i.e., $Transformer_{abs}$ without the absolute positional encoding.

The settings for the ablation experiment were as follows. In model training, we used the first 100,000 sentence pairs of 50 words or less for both English and Japanese sentences, which were extracted from the training data (train-1.txt). Both the Japanese dictionary and the English dictionary were comprised of words that appeared 2 times or more in the training data, and the other words were treated as unknown words with UNK tags. The batch size was 100, and the number of epochs was 50. Other settings were the same as the main experiments in Section 5.1.

The results are shown in Table 3. Table 3 shows that $Transformer_{dep}$ using only $\boldsymbol{b}_{ij}^V$ was 1.09 points lower than the baseline $Transformer_{dep}$, which used both $\boldsymbol{b}_{ij}^V$ and

[*3] We chose $k = 2$ because Shaw et al. (2018) showed that BLEU scores for $k \geq 2$ are nearly unchanged. l was tuned on development data.

$\boldsymbol{b}_{ij}^K$, while $Transformer_{dep}$ using only $\boldsymbol{b}_{ij}^K$ was 0.11 points slightly lower than the baseline $Transformer_{dep}$. Table 3 also shows that the $Transformer_{dep}$ that used neither $\boldsymbol{b}_{ij}^V$ and $\boldsymbol{b}_{ij}^K$ was 8.02 points lower than the baseline $Transformer_{dep}$, which was significantly worse.

These results were consistent with the experimental results in Shaw et al. (2018). The dependency-based relative position representations, $\boldsymbol{b}_{ij}^K$ and $\boldsymbol{b}_{ij}^V$, were shown to be effective, but $\boldsymbol{b}_{ij}^K$ was more effective than $\boldsymbol{b}_{ij}^V$.

6 Conclusion

In this paper, we proposed a novel Transformer NMT model that incorporates syntactic distances between two source words into the relative positional encoding of an encoder's self-attention mechanism. We demonstrated that our proposed model improved the translation accuracy, in terms of BLUE score, on the ASPEC Japanese-to-English translation task.

For future work, we would like to improve our model by introducing relative positional encoding to target dependency structures, i.e., dependency-based relative positional encoding for decoders. For example, we would like to integrate our encoding into the dependency-based decoder in (Wu et al., 2018).

Abstract

Images and text represent types of content which are used together for conveying user emotions in online social networks. These contents are usually associated with a sentiment category. In this paper, we investigate an approach for mapping images to text for three types of sentiment categories: positive, neutral and negative. The mapping from images to text is performed using a Kernel Ridge Regression model. We considered two types of image features: *i)* RGB pixel-values features, and *ii)* features extracted with a deep learning approach. The experimental evaluation was performed on a Twitter data set containing both text and images and the sentiment associated with these. The experimental results show a difference in performance for different sentiment categories, in particular the mapping that we propose performs better for the positive sentiment category in comparison with the neutral and negative ones. Furthermore, the experimental results show that the more complex deep learning features perform better than the RGB pixel-value features for all sentiment categories and for larger training sets.

1 Introduction

A quick look at an image is sufficient for a human to say a few words related to that image. However, this very easy task for humans is a very difficult task for the existing computer vision systems. The majority of previous work in computer vision has focused on labeling images with a fixed set of visual categories. However, even though closed vocabularies of visual concepts are a convenient modeling assumption, they are quite restrictive when compared to the vast amount of rich descriptions and impressions that a human can compose.

Some approaches that address the challenge of generating image descriptions have been proposed (Kulkarni et al., 2013; Karpathy and Fei-Fei, 2015). However, these models only rely on objective image descriptors, and do not take into account the subjectivity which appears when describing an image on social networks.

In this work, we want to take a step forward towards the goal of generating subjective descriptions of images that are close to the natural language that is used in social networks. Figure 1 gives a hint to the motivation of our work by showing several samples which were used in the experimental evaluation. Each sample consists of an image and the subjective text associated to it, and has has a sentiment associated to it: negative, neutral or positive.

The goal of our work is to generate subjective descriptions of images. The main challenge towards this goal is in the design of a model that is rich enough to simultaneously reason about contents of images and their representations in natural language domain. Additionally, the model should be free of assumptions about specific templates or categories and instead rely on learning from the training data. The model will go beyond the simple description of an image and give also a subjective impression that the image could make upon a certain person. An example of this is shown in the image from bottom-right of Figure 1, in which we do not have a captioning or description of the animal in the image but the subjective impression that the image makes upon the looker.

Our core insight is that we can map images to subjective natural text by leveraging the image-sentence data set in a supervised learning approach in which the image represents the input and the

Figure 1: Motivation Figure: Our model treats language as a rich label space and generates subjective descriptions of images. Examples of samples used in the experimental evaluation. Each sample consists of a pair made of an image and the subjective text associated to it. Each sample has a sentiment associated to it: a., b. samples convey a negative sentiment; c. sample conveys a neutral sentiment; d. sample conveys a positive sentiment.

sentence represents the output. We employ a Kernel Ridge Regression for the task of mapping images to text. We considered two types of image features: *i)* RGB pixel-values features, and *ii)* features extracted with a deep learning approach. We used a bag-of-words model to construct the text features. In addition, we consider several sentiment categories associated to each image-text sample, and analyze this mapping in the context of these sentiment categories.

We investigate data from Twitter. These data contain images and text associated to each image. The text is a subjective description or impression of the image, written by a user. Data from social networks, and especially Twitter, is usually associated to a sentiment, which could be a positive, neutral or negative sentiment. We designed a system that automatically associates an image to a set of words from a dictionary, these words being not only descriptors of the content of the image, but also subjective impressions and opinions of the image.

One of the interesting findings of our work is that there is a difference in performance for different sentiment categories, in particular the mapping performs better for the positive sentiment category in comparison with the neutral and negative categories. Furthermore, the experimental results show that the more complex deep learning features perform better than the RGB pixel-value features for all sentiment categories and for larger training sets.

The paper is organized as follows. Section 2 discusses related works. Section 3 describes a Kernel Ridge Regression model for image to text mapping. Section 4 shows the experimental evaluation performed on a real-world data set. Section 5 finishes with conclusions and directions for future research.

2 Related Work

Image captioning. The research presented in this paper is in the direction of image captioning, but goes further to map images to text. The texts that we consider are not only descriptions of the images, which is the task of image captioning, but they contain subjective statements related to the images. Mapping images to text is an extension of the image captioning task, and this mapping allows us to build some dictionaries of words and select from these dictionaries the words which are the most relevant to an image. The learning setting that we investigate in this paper is different to the image captioning setting, because our system automatically associates an image to a set of words from a dictionary, these words being not only descriptors of the content of the image, but also subjective opinions of the image. Image captioning has been actively studied in last years, a recent survey on image captioning is given in (Bai and An, 2018). Several approaches for image captioning are making use of the deep learning techniques (Bai and An, 2018; P. Singam, 2018).

Image description. Several approaches that address the challenge of generating image descriptions have been proposed (Kulkarni et al., 2013; Karpathy and Fei-Fei, 2015; Park et al., 2017; Ling and Fidler, 2017). However, these models only rely on objective image descriptors, and do not take into account the subjectivity which appears when describing an image on social networks.

Sentiment analysis. We investigate mapping images to text in the context of sentiment analysis. Most of the previous research in sentiment analysis is performed on text data. Recent works focus on sentiment analysis in images and videos (Yu et al., 2016; You et al., 2015; Wang et al., 2016). The research on visual sentiment analysis proceeds along two dimensions: *i)* based on hand-crafted features and *ii)* based on features generated automatically. Deep Learning techniques are capable of automatically learning robust features from a large number of images (Jindal and Singh, 2015). An interesting direction for sentiment analysis is related to word representations and capsule networks for NLP applications (Xing et al., 2019; Zhao et al., 2019).

3 Kernel Ridge Regression for Mapping Images to Text

Let $X = \{x_1, x_2, \ldots, x_n\}$ and $Y = \{y_1, y_2, \ldots, y_n\}$ be the set of inputs and outputs, respectively, and n represents the number of observations. And let $F_X \in \mathbb{R}^{d_X \times n}$ and $F_Y \in \mathbb{R}^{d_Y \times n}$ denote the input and output feature matrices, where d_X, d_Y represent the dimensions of the input and output features respectively. The inputs represent the images, and the input features can be either simple RGB pixel-values or something more complex, such as features extracted automatically using convolutional neural networks (O'Shea and Nash, 2015). The outputs represent the texts associated to the images and the output features can be extracted using Word2Vec (Ma and Zhang, 2015).

A mapping between the inputs and the outputs can be formulated as a multi-linear regression problem (Cortes et al., 2005, 2007). Combined with Tikhonov regularization, this is also known as Kernel Ridge Regression (KRR). The KRR method is a regularized least squares method that is used for classification and regression tasks. It has the following objective function:

$$\arg_W \min\left(\frac{1}{2}||WF_X - F_Y^T||_{\mathcal{F}}^2 + \alpha\frac{1}{2}||W||_{\mathcal{F}}^2\right) \quad (1)$$

where $||\cdot||_{\mathcal{F}}$ is the Frobenius norm, α is a regularization term and the superscript ^{T} signifies the transpose of the matrix.

The solution of the optimization problem from Equation 1 involves the Moore-Penrose pseudo-inverse and has the following closed-form expression:

$$W = F_Y F_X^T (F_X F_X^T + \alpha I_{d_X})^{-1} \in \mathbb{R}^{d_Y \times d_X} \quad (2)$$

which for low-dimensional feature spaces $(d_X, d_Y \leq n)$ can be calculated explicitly (the I_{d_X} in Equation 2 represents the identity matrix of dimension d_X).

For high-dimensional data, an explicit computation of W as presented in Equation 2 without prior dimensionality reduction is computationally expensive. Fortunately, Equation 2 can be rewritten as:

$$\begin{aligned} W = & \; F_Y F_X^{\mathrm{T}} (F_X F_X^{\mathrm{T}} + \alpha \mathrm{I}_{d_x})^{-1} \\ = & \; F_Y (F_X^{\mathrm{T}} F_X + \alpha \mathrm{I}_n)^{-1} F_X^{\mathrm{T}} \end{aligned} \quad (3)$$

Making use of the kernel trick, the inputs x_i are implicitly mapped to a high-dimensional Reproducing Kernel Hilbert space (Berlinet and Thomas-Agnan, 2011):

$$\Phi = [\phi(x_1), \; \ldots, \; \phi(x_n)]. \quad (4)$$

When predicting a target y_{new} from a new observation x_{new}, explicit access to Φ is never actually needed:

$$\begin{aligned} y_{\text{new}} = & \; F_Y (\Phi^{\mathrm{T}}\Phi + \alpha \mathrm{I}_n)^{-1} \Phi^{\mathrm{T}} \phi(x_{\text{new}}) \\ = & \; F_Y (K + \alpha \mathrm{I}_n)^{-1} \kappa(x_{\text{new}}) \end{aligned} \quad (5)$$

With $K_{ij} = \phi(x_i)^{\mathrm{T}} \phi(x_j)$ and $\kappa(x_{\text{new}})_i = \phi(x_i)^{\mathrm{T}} \phi(x_{\text{new}})$, the prediction can be described entirely in terms of inner products in the higher-dimensional space. Not only does this approach work on the original data sets without the need of dimensionality reduction, but it also opens up ways to introduce non-linear mappings into the regression by considering different types of kernels, such as a Gaussian or a polynomial kernel.

4 Experimental Evaluation

4.1 Dataset

We used a data set with images and text that was introduced in (Vadicamo et al., 2017). The data have been collected from Twitter posts over a period of 6 months, and using an LSTM-SVM architecture, the tweets have been divided into three sentiment categories: positive, neutral, and negative. For image labelling the authors have selected data with the most confident textual sentiment predictions and they used these predictions to automatically assign sentiment labels to the corresponding images. In our experimental evaluation we selected 10000 images and the corresponding 10000 tweets from each of the three sentiment categories. Figure 1 shows examples of image and text data used in the experimental evaluation.

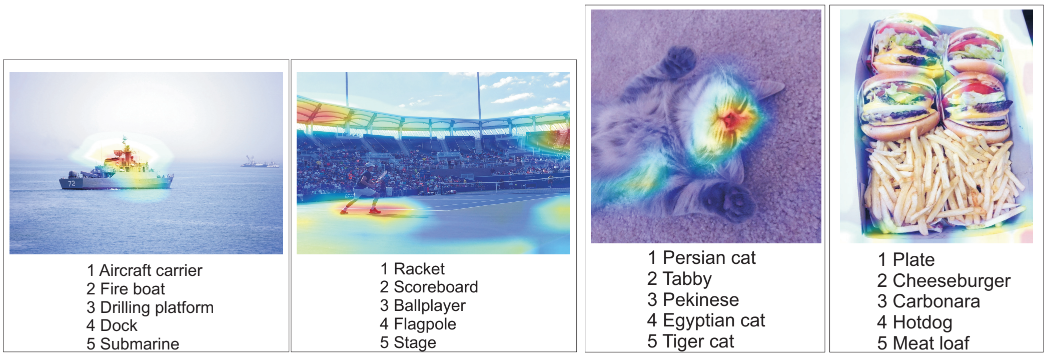

Figure 2: Visualizing heatmaps of class activation in an image.

4.2 Image and Text Features

4.2.1 Image Features

The research on feature extraction from images proceeds along two directions: i) traditional, handcrafted features, and ii) automatically generated features. With the increasing number of images and videos on the web, traditional methods have a hard time handling the scalability and generalization problem. In contrast, automated generated feature-based techniques are capable to automatically learn robust features from a large number of images (Jindal and Singh, 2015). We discuss below how these two directions for extracting features from images apply in our case, in particular, we use RGB pixel-values features for the first direction and Deep Learning based features for the second direction.

RGB pixel-values. In this approach for extracting features from images, we simply convert the images into arrays. Each image was sliced to get the RGB data. The 3-channels RGB image format was preferred instead of using 1-channel image format since we wanted to use all the available information related to an image. Using this approach, each image was described by a 2352 (28 x 28 x 3)-dimensional feature vector.

Deep Learning based features. Deep Learning models use a cascade of layers to discover feature representations from data. Each layer of a convolutional network produces an activation for the given input. Earlier layers capture low-level features of the image like blobs, edges, and colors. This primitive features are abstracted by the high-level layers. Studies from the literature suggest that while using pre-trained networks for feature extraction, the features should be extracted from the layer right before the classification layer (Rajaraman et al., 2018). For this reason, we extracted the features from the last layer before the final classification, so the entire convolutional base was used for this. The features were extracted using the pre-trained convolutional base VGG16 network (Simonyan and Zisserman, 2014). For computational reasons, the images were resampled to a 3232 pixel resolution. The model was initialized by the ImageNet weights. For understanding what part of an image was used to extract the features, visualizing heatmaps of class activation technique was employed. This is a technique which illustrates how intensely the input image activates different channels, how important each channel is with regard to the class and how intensely the input image activates the class. Figure 2 illustrates the heatmaps of class activation for some random images using VGG16 as a pre-trained convolutional base. The VGG16 model makes the final classification decision based on the highlighted parts from each image, and furthermore each image is associated with the five most representative captions.

4.2.2 Text Features

We used a Bag-of-Words (BoW) model (Harris, 1954) for extracting the features from the text samples. The first step in building the BoW model consists of pre-processing the text: removing nonletter characters, removing the html tag from the Twitter posts, converting words to lower cases, removing stop-words and making the split. A vocabulary is built from the words that appear in the text samples. The input of the BoW model is a list of strings and the output is a sparse matrix with the dimension: number of samples x number of words in the vocabulary, having 1 if a given word from the vocabulary is contained in that particular text sample. We initialized the BoW model with a maximum of 5000 features. We extracted a vocabulary for each sentiment category, and the corresponding 0-1 feature vector for each text sample.

4.3 Experimental Results

Evaluation Measure

Each output of our model represents a very large vector of probabilities, with the dimension equal to the number of words in the dictionary (approximately 5000 components). Each component of the output vector represents the probability of the corresponding word from the vocabulary as being a descriptor of that image. Given this particular form of the output, the evaluation measure was computed using the following algorithm:

1. we sorted in descending order the absolute values of the predicted output vector;
2. we created a new vector containing the first 50 words from the predicted output vector;
3. we computed the Euclidean distance between the predicted output vector values and the actual output vector.

The actual output vector is a sparse vector, a component in this vector is 1 if the corresponding word from the vocabulary is contained in that particular description of the image.

The values computed in step 3) described above were averaged over the entire test data set and the average value obtained was considered as the error.

Experimental Protocol

We designed an experimental protocol, that would help us answer the following questions:

1. Could our proposed Kernel Ridge Regression model map images to natural language descriptors?
2. What is the difference between the two types of image features that we considered? In particular, we are interested whether the more complex deep learning features give a better performance in comparison to the simple RGB pixel-values features.
3. Is there a difference in performance based on the sentiment associated to each image-text sample?

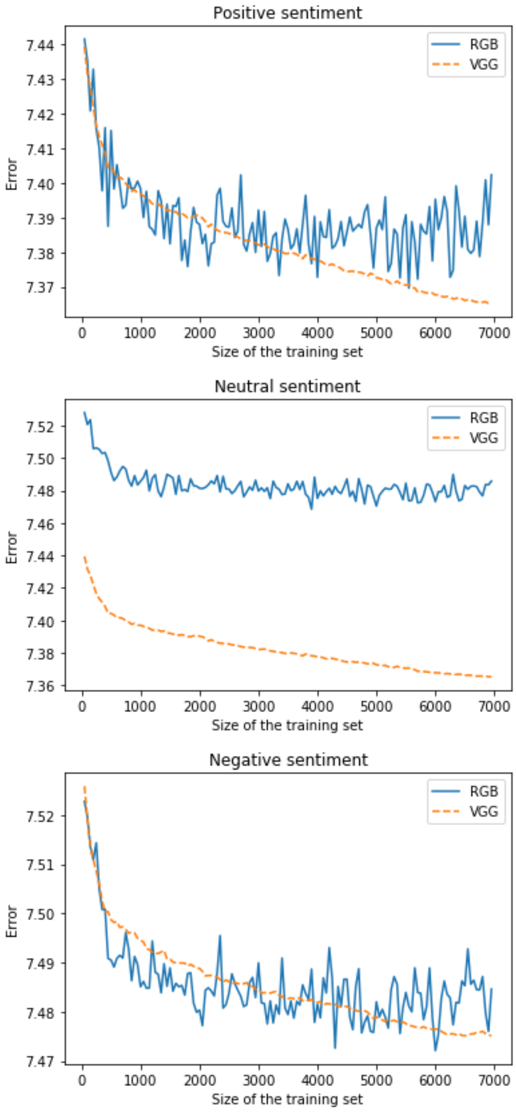

Figure 3: The plots show mean errors and standard deviation for different sizes of the training set. Comparison between RGB pixel-values features and the more complex VGG16 features. The different rows correspond to different sentiment categories: top row - positive sentiment category, middle row - neutral sentiment category, bottom row - negative sentiment category.

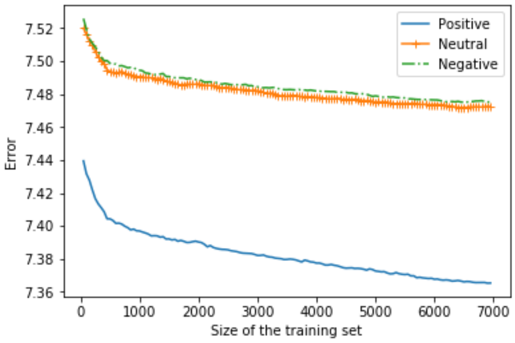

Figure 4: Comparison of the learning performance based on the type of sentiment using the VGG16 image features.

We designed the following experimental protocol. For each of the three sentiment categories, we randomly split the data 5 times into training and testing, taking 70% for training and the rest for testing. For training the model, we considered different sizes of the training set: from 50 to 7000 observations with a step size of 50. For a correct evaluation, the models built on these different training sets, were evaluated on the same test set. The error was averaged over the 5 random splits of the data into training and testing.

Results

The first two questions raised above can be answered by analyzing the experimental results shown in Figure 3. The plots show the learning curve (mean errors and standard deviations) for different sizes of the training set and for different sentiment categories. Since the error decreases as the training size increases, we can say that there is a learning involved, thus our proposed model can map images to natural language descriptors.

The plots from Figure 3 also show the comparison between the RGB pixel-values and VGG16 features for the three categories of sentiments considered. Overall, the more complex deep learning features give a better performance in comparison to the simple RGB pixel-values features.

To answer the third question, we analyzed the experimental results shown in Figure 4. There is a significant difference in learning performance for the positive sentiment category in comparison with the other two categories, both using RGB pixel-values features and VGG16 features. The positive category is simpler to be learned because of the subjective part from images: a positive feeling can be interpreted as positive for the majority of the people, but a neutral or a negative sentiment can be interpreted as having a different meaning depending on the people.

Furthermore, analyzing again Figure 3, we see that the neutral sentiment category has a different behaviour in comparison with the positive and negative sentiment categories, with respect to the image features used. In the case of neutral sentiment, the more complex VGG16 features appear to have a better performance than the simpler RGB pixel-values features as the size of the data increases. For positive and negative sentiment categories the simpler RGB pixel-values features lead to an error which varies a lot, while using the VGG16 features, the error is more stable.

5 Conclusions and Future Work

In this work, we investigated a method for image to text mapping in the context of sentiment analysis. The mapping from images to text was performed using a Kernel Ridge Regression model. We considered two types of image features: *i)* the simple RGB pixel-values features, and *ii)* a more complex set of image features extracted with a deep learning approach. Furthermore, in this paper we took a step forward form the image captioning task, which allows us to build some dictionaries of words and select from these dictionaries the words which are the most relevant to an image. We performed the experimental evaluation on a Twitter data set containing both text and images and the sentiment associated with these. We found that there is a difference in performance for different sentiment categories, in particular the mapping performs better for the positive sentiment category in comparison with the neutral and negative ones for both features extraction techniques.

We plan to further extend our approach by investigating the input-output kernel regression type of learning (Brouard et al., 2016). The output kernel would allow us to take into account the structure in the output space and benefit from the use of kernels. We also plan to integrate in our model textual captions of images obtained using a pre-trained network (Simonyan and Zisserman, 2014). The textual captions could be used as a new type of features and can be compared and integrated with the other two types of image features considered.

Abstract

This study is an attempt to contribute to documentation and revitalization efforts of endangered Laz language, a member of South Caucasian language family mainly spoken on northeastern coastline of Turkey. It constitutes the first steps to create a general computational model for word form recognition and production for Laz by building a rule-based morphological analyser using Helsinki Finite-State Toolkit (HFST). The evaluation results show that the analyser has a 64.9% coverage over a corpus collected for this study with 111,365 tokens. We have also performed an error analysis on randomly selected 100 tokens from the corpus which are not covered by the analyser, and these results show that the errors mostly result from Turkish words in the corpus and missing stems in our lexicon.

1 Introduction

The Laz language, which is mainly spoken on the northeastern coastline of Turkey and also in some parts of Georgia has been recorded as a 'definitely endangered[1]' language in UNESCO Atlas of the World's Languages in Danger. It belongs to South Caucasian language family[2] with the number of speakers estimated to be between 130,000 and 150,000 according to UNESCO 2001 records and between 250,000 and 500,000 according to more recent studies (Haznedar, 2018). Until the 1920s it was a spoken language with only some written collection of Laz grammar and folklore studies. Later, İskender Tzitaşi became the pioneer in developing a writing system for Laz based on Latin alphabet and later 'Lazuri Alboni' (Laz Alphabet) and only after 1990s, the written texts started to come out as several associations were founded for the preservation of Laz language and culture. Now with all these efforts, Laz has been thought in public schools in Turkey as an elective language course since 2013 (Kavaklı, 2015; Haznedar, 2018).

There is not much research on lexicon and syntax of Laz and the first academic level research studies began by the end of 20th century. In 1999, the first dictionary for Laz (Turkish—Laz) was prepared and published by İsmail Bucaklişi and Hasan Uzunhasanoğlu. The following years, Bucaklişi also published the first Laz grammar book (Kavaklı, 2015) and has begun teaching Laz at Boğaziçi University in İstanbul as an elective course since 2011. The foundation of the *Lazika Publishing Collective* in 2011 has given rise to the publication of more than 70 books on Laz language and literature (Kavaklı, 2015).

Laz language is only one of many that faces the danger of extinction. By the end of this century, many will not survive with the decreasing number of the native speakers of such languages (Riza, 2008). This has alarmed not only native speakers of these languages but also research community to direct their attention for language documentation as well as preservation and revitalization studies for these languages (Ćavar et al., 2016; Gerstenberger et al., 2017). Bird (2009) calls out for a 'new kind of computational linguistics' in his paper that would protect this endangered invaluable cultural heritage by helping to accelerate these studies, and he ends his paper with these words 'Who knows, we may even postpone the day when these languages utter their last words.' which emphasizes the importance of each and every attempt to keep these languages alive.

Riza (2008) gives accounts on language diversity on the Internet by pointing to the fact that many en-

[1] UNESCO defines the degree of definitely endangered as the situation in which "children no longer learn the language as mother tongue in the home".

[2] The Southwest Caucasian language family consists of four languages: Svans, Mingrelians, Georgian and Laz.

dangered languages lacks access to Information and Communication Technology and the representation of these languages on digital environment is rather low. Considering Laz resources online, there are some online dictionaries and only a couple of web sites that give information about the Laz language and culture, and many of them are mostly in Turkish or English. He suggests that regarding 'digital language divide' such small regional languages must be represented more by creating and using resources in digital format.

One of the drawbacks while working with these languages is clearly the small amount of data to begin with (written or spoken, annotated or non-annotated) (Riza, 2008). Current dominant computational methods and tools are mostly used on languages with large corpora, following a statistical approach to train their systems according to a relevant task. However, with little data at hand these methods may not present a good solution. Therefore, Gerstenberger et al. (2017) suggests a rule-based morpho-syntactic modelling for annotating small language data. On their study of Komi language, his results show by-far significant advantages of rule-based approaches for endangered languages by providing much more precise results in tagging as well as 'full- fledged grammatical description based on broad empirical evidence' and a future development for computer-assisted language learning systems.

In this study, the aim is to create a morphological analyzer using the Helsinki Finite State Toolkit (HFST) that will help to overcome manual annotation of a potential Laz corpus. Additionally, as Gerstenberger et al. (2017) suggest, these may later help developing programs to be able to facilitate learning of Laz, considering the increase of interest in Laz courses not only in secondary schools but also in universities such as Boğaziçi University and İstanbul Bilgi University (Haznedar, 2018). From spelling and grammar-checkers to machine translation systems and language learning materials, this small study will hopefully lead to further developments on Laz language in the field of Computational Linguistics.

The remainder of the paper is laid out as follows: in Section 2, the grammatical structure of Laz is discussed and later, in Section 3.1 and 3.2 the process of preparing a lexicon and corpus for Laz is described. The Section 4 gives and explains the details of the morphological analyzer and the usefulness of Flag diacritics for representing Laz verbal complex and for generating complex verbal word forms.

2 Laz

There are eight dialects of the Laz language, none of which is considered to be normative or 'standard'. Even though underlyingly the structure of these dialects is the same, they show lexical and morphological, as well as phonological differences. There are two main groups. The Western dialects (Gyulva), such as Pazar (Atina), Çamlıhemşin (Furthunaşi gamayona), Ardeşen (Arthaşeni) and the Eastern dialects (Yulva) as Fındıklı (Viʒe), Arhavi (Arkabi), Hopa (Xopa), Borçka-İçkale (Çxala).[3]

For the purposes of this initial study we have chosen to base the analyser on the Pazar dialect. The reasons for this are twofold: Firstly the Pazar dialect is less irregular in terms of verbal inflection and secondly a separate and well-documented grammar of Laz written in English is based only on this dialect.[4] Unfortunately, there is no study yet that would provide an analysis of Laz grammar to be treated as 'standard' (Haznedar, 2018).

2.1 Verbs

In terms of morphosyntactic alignment, Laz is an ergative–absolutive language. It marks the subject of unergative predicates and transitives with agentive/causer subjects with ergative case while the subject of unaccusative predicates and the direct object of transitive and ditransitive verbs are inflected with nominative case. These patterns are marked differently on the verbal complex, depending on their case markings which also indicate their argument types. The verb encodes person information both preverbally and postverbally as seen in Table 1 and Table 2 and 3.[5] While we can observe verbs agreeing with agent-like arguments and sole argu-

[3] We exclude the Sapanca dialect as the region in which it is spoken is further away from the other dialects. Speakers of the Sapanca dialect are considered to be migrated from Batum, Georgia to Sapanca, Turkey (Bucaklişi and Kojima, 2003)

[4] The main grammar book used for this study is Pazar Laz written by Öztürk and Pöchtrager (2011) which is based on courses given by İsmail Bucaklişi in Boğaziçi University and it is the most recent and only complete study on a dialect of Laz written in English which would enable us to define grammatical rules for the morphological analyser. The grammar book by René Lacroix (2009) was also referred to several times but since it is mostly based on Arhavi (Arkabi) dialect and written in French, we used it when we needed to look for more examples for certain structures and specific details, especially valency-related vowels on the verbal complex and verb classes.

[5] It should be noted that post-verbal person markers encode tense information as well.

ments in both positions at the same time, we can only observe theme-patient (of mono-transitive and ditransitive verbs) and dative marked recipient-goal or applied non-core argument agreement in preverbal position. Additionally, Laz applies a hierarchical selection rule among arguments while marking person in -2 pre-verbal position seen in Table 1. This can be represented as in (1), where D represents the dative-marked arguments in the structure and P represents theme/ patient argument type while A means agent-like argument type.[6]

(1) D1/2 > P1/2 > A1 > D3=P3=A2/3

The reason why D1/2 arguments comes first but not D3 is that D3 is unmarked; therefore, overt A/S1 markings fills the position if they are available in the structure. Only when we have A2/3 type argument, the position remains empty. We will also discuss this topic later in Section 4.1.

(2) *Bere-k Lazuri d-i-gur-am-s.*
child-ERG Laz.NOM PV-VAL-learn-TS-PRS.3.*a*.SG
'The child is learning Laz.'

(3) *Bere-s Lazuri dv-a-gur-e-n.*
child-DAT Laz.NOM PV-APPL-learn-TS-PRS.3.S.SG
'The child is able to learn Laz.'

The case markings of arguments are apt to change despite their argument type when the general construction of the predicate changes, which in turn changes the verbal complex as in present perfect constructions and in expressing ability and involuntary actions.[7] They lead to the backgrounding of agent-like arguments; therefore, we can only observe 3.SG in post-verbal person marking position unless NOM marking objects are emphasized. Emphasizing such arguments allow the verbal complex to bear their marking in post-verbal position, as in (2) and (3) from Öztürk and Pöchtrager (2011).

As seen in the example, the verb not only takes *a-* valency vowel and ability related *-e(r)* TS suffix but also changes the person marking as well. There are also valency-changing operations such as applicativization, causativization and reflexivization which introduces non-core dative marked arguments, nominative and dative-marked arguments, and verbal reflexivization through a theme argument or a non-core argument[8] respectively. All these operations commonly mark the verb with different valency-related vowel in the same preverbal position. Therefore, under conditions where the verb is needed to be inflected both applicativization and causativization at the same time, APPL vowel `i/u-` suppresses CAUS vowel `o-`. This is important for us since when we mark the verb with APPL, the structure should allow CAUS construction as well. We will discuss such intersecting constructions and how we deal with them in our lexicon file in Section 4.1 in detail. An example of this from Öztürk and Pöchtrager (2011) is given in (4).

(4) *Him Ayşe-s bere*
S/he Ayşe.DAT child-NOM
u-bgar-ap-ap-u-n
APPL-cry-CAUS-CAUS.PERF-TS-PRS.3.A.SG
'S/he has made Ayşe make the baby cry.'

Table 1 shows the pre-verbal complex of Pazar Laz and Table 2 and 3 show post-verbal complex which we have based our main FST continuation classes on.

2.2 Substantives

Adjectives, adverbs and nouns together constitute substantive category in the language since they behave similarly within a sentence depending on the suffixes they carry as well as their position. An adverb can take dative suffix *-s* and an adjective can be used as a noun by taking case or plural marker. The differentiation between these categories are not very clear.

As mentioned partially above, Laz marks nouns with case markings such as ergative *-k*, nominative (unmarked), dative *-s*, allative *-şe* (showing the direction of an event), ablative *-şe(n)*[9] (indicating the source of an event), genitive *-şi* and instrumental -te. Other than these case markings, nouns are marked plural marking *-pe* and only some nouns ending with *a* take *-lepe* as plural marker. Since there is no phonological rule for this alternation, we need to categorise each noun in our lexicon manually for our morphological analyser.

2.3 Orthography

Orthographically, we have adopted the Laz alphabet given below which is an extended version of Turk-

[6] Intransitive verbs only has S 'sole' argument which has the same marking pattern with A arguments.

[7] These three constructions are called *inversion* constructions which require certain type of predicates, specifically those including agent-like arguments, and ergative case is never available for these constructions.

[8] This additionally assumes the function of applicativization.

[9] Final *n* only occurs with post-position *doni*; therefore, we will mark every noun with both forms.

-4	-3	-2	-1	0
Affirmative preverb	Spatial preverb	Person marker	Valency-related vowel	**Root**
o-, ko-, do-, menda-	ama-, ce-, cela-, çeǩo-, çeşǩa-, do-, dolo-, e-, eǩo-, ela-, eşǩa-, eǯo-, eyo-, gama-, go-, gola-, goyo-, ǩoǩo-, ǩoşǩa-, me-, mela-, menda-, meşǩa-, meyo-, mo-, mola-, moǩo-, moşǩa-, moǯo-, moyo-, oǩo-, exo-, ǩoǯo-, oxo-, gela-, ǩoǯa-	*S-A.1: v-,p-, p̌-, b, (f-) **P-D.1: m- P-D.2: g-, k-, ǩ *'S-A' = Sole or agent-like arg **'P-D' = Patient/theme arg or Dative marked arg	i/u-, i-, a-, o-	-t̆ax- 'break'

Table 1: Pre-verbal complex the numbers in the header refers to the pre-verbal position relative to the verbal root. The spatial preverb is a prefix that indicates the direction or manner of an event. The different forms of person markers are realised based on the laryngeal properties of the following consonant. This will be later discussed in Section 4.2.

0	1	2	3	4	5	6

ish alphabet based on Latin letters. Across texts, they have been encoded with different characters but these forms will be the standard for our study.

3 Resources

3.1 Lexicon

The lexicon composed for this study comes from the *Büyük Lazca Sözlük* (Didi Lazuri Nenapuna). It is the most extensive dictionary available for Laz prepared by Hasan Uzunhasanoğlu , İsmail Bucaklişi and İrfan Çağatay Aleksiva in 2007 in Laz and Turkish.

The verbs were extracted from the dictionary automatically whereas other word classes were extracted semi-automatically. The words are taken as entries with their dialect labels[10] and if available, dialect-specific forms as seen in (5).[11]

(5) doinu [Atn., Viw, dorinu Gyl., Ark., Xop., doǩunapa Sap.]

We have prepared verb word lists for each dialect separately as well as a complete word list for all. Considering the possibility that dialects may borrow words from one another, we decided to build a lexicon based on not only the Pazar dialect but all dialects of Laz. This is an important strategy to form a 'common source lexicon' (Beesley and Karttunen, 2003). However, for the sake of simplicity, we have excluded nominal and verbal compounds from our lexicon.

The challenging part in preparing the lexicon has been the stemming process for verbs since the verbs in the dictionary are in their infinitival form and some of them also include preverbs. Even though the preverbs have been easily separated, the infinitive suffixes were harder to process. For example, there are verbs ending with *-alu* and while some of these verbs include *-al* suffix in their bare form, some do not. It means that they are lexically determined.

Even though noun declension was easy to define, extracting substantives from the dictionary and carefully separating them into nouns, adverbs, and adjectives as well as categorizing other syntactic elements like interjections, conjunctions and pronominals were among the hardest tasks for this study. We needed to separate these word classes semi-automatically because there were words that should be put in more than one category such as in both noun and adjective or adjective and adverb (determined only by sentential position) or noun and adverb. Therefore, it could not be possible for us to include words (except verbs) that belong to other dialects other than Pazar for this study.

3.2 Corpus

We have collected different type of written texts for our Laz corpus. However, differences in terms of dialects have forced us to divide texts into their corresponding dialects for this study since we have decided on working Pazar Laz first the reasons of which are discussed in Section 2. Unfortunately, Pazar Laz has almost no written text known in the literature. The only resource we have is an 800 page document consisting of 111,365 tokens collected by İsmail Bucaklişi, a native speaker of Pazar Laz, by himself which contains daily conversations and stories shared in his immediate circle. It should be noted that it also contains Turkish words and sentences given as translations throughout the document the effects of which on the results can be seen in Section 5.2.

4 Methodology

The purpose of this project is to develop a computational model for morphological analysis for Laz by using the Helsinki Finite-State Toolkit (HFST; (Linden et al., 2011)) which is popular in this field of research. A finite-state transducer associates a morphological analysis with the corresponding phonological representation. Xerox `lexc` and `twolc` formalism supported by HFST are used to create lexicon files and a two-level grammar file respectively (Beesley and Karttunen, 2003).

4.1 Lexicon Files

The `lexc` (**Lex**icon **C**ompiler) formalism is used to define lexicons which contain grammatical labels and morphotactic rules for the morphemes in the language (Beesley and Karttunen, 2003).

4.1.1 `lexc` File for Substantives

The substantive `lexc` file has 27 tags for morphemes indicating person, number and case information and 18 continuation classes for morphotactics or word-formation rules together with the

[10] The following dialect codes were found in the dictionary: *'Yul' (Eastern dialects), 'Gyl' (Western dialects), 'Viw' (Viʒe), 'Xop' (Xopa), 'Ark' (Arkabi), 'Çxl' (Çxala), 'Atn' (Atina/Pazar), 'Fur' (Furthunaşi gamayona), 'Arş' (Arthaşeni), 'Sap' (Sapanci).*

[11] (5) shows that *doinu* 'to give birth' belongs to *Atn.* and *Viw.* dialects, and it takes the form of *dorinu* in *Gyl., Ark.* and *Xop.* dialects, and *doǩunapa* in *Sap.* dialect.

a	*b*	*c*	*ç*	*ç̆*	*d*	*e*	*f*	*g*	*ğ*	*h*	*x*	*i*	*j*	*k*	*ǩ*	*l*
[a]	[b]	[dʒ]	[t͡ʃ^{h}]	[tʃ’]	[d]	[e]	[f]	[g]	[ɣ]	[h]	[x]	[i]	[ʒ]	[k^{h}]	[k’]	[l]
m	*n*	*o*	*p*	*p̌*	*r*	*s*	*ş*	*t*	*ť*	*u*	*v*	*y*	*z*	*ž*	*ʒ*	*ʒ̆*
[m]	[n]/[ŋ]	[p]	[p^{h}]	[p’]	[r]	[s]	[ʃ]	[t^{h}]	[t’]	[u]	[v]/[w]	[j]	[z]	[dz]	[ts^{h}]	[t͡s’]

Table 4: The 34 letters of the Laz alphabet. The letters ǩ p̌ ť ç̆ ʒ̆ ʒ and ž represent ejective consonants.

lexemes. We specified pronouns as personal pronouns, possessive pronouns, demonstratives, reflexives, interrogative pronouns, indefinite pronouns, quantifiers as well as numerals in different continuation classes. We have continuation classes for case and plural markers to show nominal inflection. There are two forms of plural markings and ablative markings each, whose differentiation is lexical, not phonological. Therefore, we have encoded this information in our lexicon by using flag diacratics that will be explained in Section 4.1.3.

4.1.2 `lexc` File for Verbs

The `lexc` file for Laz verbal complex has 53 tags for the morphemes encoding preverb, valency-related, mood, tense, person and number information and 19 continuation classes which correspond to the affixes in the verbal complex as defined in Öztürk and Pöchtrager (2011) also seen in Table 1, 2 and 3 with three additions — additive position for suffix *-ti*, — question for *-i*, — participle for *-eri*.

We have mostly followed the description in Öztürk and Pöchtrager (2011) when naming the tags and classes.

The final combined `lexc` file also includes interjection, conjunction, negation, post-position and pre-position lexicons with 5 more tags.

4.1.3 Flag Diacritics

Laz verb complex has required substantial use of *flag diacritics*[12] to solve problems like dependent person marking, and causativisation or applicativisation processes, which require preverbal valency-related vowel marking as well as postverbal causative markers at the same time. The hierarchical selection rule for person marking position preverbally among the arguments of the verb is easily applied using flag diacritics. We have allowed structures with 3rd person prefixes to only occur in structures with 3rd person suffixes by disallowing paths including 1st and 2nd person prefixes. This is done by setting a flag, @P.D-P.3@ which means **P**ositive setting of the D-P (dative–patient) type argument bearing 3rd person information and later in person suffix continuation class we reject/**D**isallow those paths with positively setting of 3rd person information by setting @D.D-P.3@ for the 1st and 2nd person suffixation. Additionally, we can also reject paths that include combinations of 1st and 2nd person D-P with 1st and 2nd person A (agent) respectively since the language does not allow such constructions. We use the same patterns as above for these rules.

We have also found flag diacritics useful for overwriting of valency-related vowels. In such constructions, we engage in two separate operations/constructions at the same time such as causativisation and present perfect construction both of which mark the verb with their specific valency-related vowel in the -1 position. However, Laz allows overwriting causative *o-* to be overwritten by applicative *i-* while keeping post verbal causative markers *-in* or *-ap*. We have managed to form these constructions by also allowing applicative *i-* (as well as causative *o-*) to have flag @P.CAUS.PRS@ which will let them through paths defined with @R.CAUS.PRS@ (**R**equire the causative feature to be present). These paths are naturally those causative suffixes which do not allow structures with related valency vowel otherwise.[13]

Other flag diacritics include N which sets the related feature as **N**egative. In our study, we use them for subjunctive suffix and its special construction with thematic suffixes. They do not normally occur together but we can see that they do in constructions with the imperfective suffix in between in (6) from Öztürk and Pöchtrager (2011).

[12] Flag diacritics are used for feature-setting and feature-unification operations. They represent long-distance constraints for dependencies within a word (Beesley and Karttunen, 2003). As a member of the same language family, Georgian also shows these kinds of long-distance dependencies in verbal complex which are effectively treated again with this device in order to build a computational grammar for Georgian (Meurer, 2009).

[13] Additionally, Laz allows only intransitive bases to take the *-in* causative suffix, so we have also tried to use flag diacritics to differentiate between transitive and intransitive bases by encoding the information onto verb itself. However, since we have automatically extracted verbs from the dictionary, we could not label all of them (2240 verb roots) as transitive or intansitive for this study, we ignore this differentiation and allow all verb roots to be able to bear both *-in* and *-ap* suffixes.

(6) *m-i-t́ax-ap-ur-t́-a-s*
D1-APPL-break-CAUS.PERF-TS-IMPRF-SUBJ-PRS.3.S.SG
'Let say that I have broken it.'

If the subjunctive follows imperfective (sets thematic suffix information as @N.THM.PRS@), the path allows subjunctive (normally disallows thematic suffixes as @D.THM.PRS@) to follow thematic suffix after imperfective; therefore, we need to get rid of @P.THM.PRS@ setting by re-setting the same feature to N as @N.THM.PRS@ which will allow the structure to go through the path by taking non-past person markers that are set as @D.TNS.PST@ disallowing past tense constructions.

The substantive `lexc` file includes only one flag diacratic case which is to label nouns that take *-lepe* plural marker instead of *-pe*. We label the noun root with @P.LEPE.PRS@ in order for it to be able to take the path with @R.LEPE.PRS@ label.

4.2 `twol` File

The `twolc` (**Two-l**evel **C**ompiler) formalism is used to define phonological and morphophonological alternations. The `twol` file mostly includes person marking elements differing based on the following consonant's laryngeal property for verbal inflection. We define rules/environments to account for morphophonological changes in the structure with archiphonemes[14] as given in Figure 1.

Laz also exhibits a phonological change in noun stems starting with *n* sound when preceded by ejective *p̌*-, the person prefix for 1.SG. The two consonants are combined and becomes *m*. We represent this as ejective *p̌* turning to *m* and dropping the initial *n* of the stem. Additionally, the final *i* sound of noun stems becomes *e* when the stem is inflected with plural marker.

```
"Assimilation of person prefix to p-"
{V}:p <=> _ >: Voiceless: ;

"Assimilation of person prefix to b-"
{V}:ṕ <=> _ >: Ejectives: ;
```

Figure 1: Two two-level phonological rules for assimilation. The underspecified prefix archiphoneme {V} is restricted to surface either as *p* before voiceless consonants or *ṕ* before ejective consonants.

We also observe a morphologically-conditioned phonological alternation for valency-related vowels. The alternation for valency-related vowels *i/u-* depends on the preverbal person information, *i-* for 1st and 2nd person, and *-u* for 3rd person.

The preverbs show a great amount of morphophonological alternations in their final vowels, such as *a, e* and *o*. When they combine with overt person prefixes (consonants) together with valency related vowels, final *o* and *a* become *e* or *o* and the change is not always predictable. They can also turn into *v* or can be dropped. Even though they may end with the same vowel, the alternations can be different when followed by the same sound; therefore; we need to define different archiphonemes for the same vowel. For example, the final *o* sound in *exo-* drops when it attaches to a verbal complex starting with *a* sound but not the one in *moyo-*.

5 Results

We have evaluated the morphological analyser by calculating the naïve coverage and doing error analysis on randomly selected 100 tokens from the corpus.

5.1 Coverage

The coverage is measured by calculating the number of the tokens that receive at least one morphological analysis by the analyser. It should also be noted that the tokens may have other analysis that is correct but not provided by the analyser even though they get at least one analysis.[15] We have collected a corpus for Pazar Laz which consists of 111,365 tokens mentioned before in Section 3.2. The final morphological analyser has 64.9% coverage over this corpus.

Corpus	Tokens	Coverage
Pazar Laz	111,365	64.9%

Table 5: Naïve coverage of the analyser

5.2 Error Analysis

We have looked at the tokens that are not covered by the morphological analyser. Randomly selected 100 tokens has been examined and separated according to their error type seen in Table 7. It should also be

[14] An archiphoneme is used as a placeholder to be later replaced with the appropriate sound determined by morphophonological rules written in `twol` file. They are given inside curly brackets.

[15] Unfortunately since there is no annotated corpus which can be used as the 'gold standard', we were unable to calculate *precision* and *recall* that could show the average accuracy of the analysis provided by the transducer.

Category	Number of Stems

Missing or erroneous morphotactic rule	13	12.0%
Typing errors	7	6.4%
Loanwords	7	6.4%
Missing or erroneous Phonological rule	5	4.6%
Total	108	

Table 7: Error analysis for randomly selected 100 tokens

noted that some of them may go into more than one category.

The highest percentage of unrecognized tokens belongs to the category of ‘Missing lexeme’. This is partly because of the fact that our lexicon for substantives was not large enough to account for the phonological and lexical differences for stems in different dialects. For example, *açkvaneri* ‘next time’ appearing in our corpus belongs to Xopa dialect but not to Pazar dialect according the the dictionary. It also includes lexemes which do not appear in the dictionary and consequently not in our lexicon as well as those which are simply missed out during the automatic extraction of words from the dictionary.

We still have certain morphotactic rules to work on to be able to cover inflectional morphology of Laz such as verb inflection for adverbial clauses such as the *-şa* suffix meaning ‘while’ (related to the allative suffix normally attached to nouns).

6 Future Work

Since we still have problems with verb stemming and separating substantives into nouns, adjectives and adverbs as well as determining other word classes and their inflectional morphology, our current lexicon can be manually checked and extended accordingly. We definitely need to improve the coverage of the morphological analyser not only for Pazar Laz but also for other dialects of Laz for the future studies. This requires both defining morphotactics for other dialects and carefully separating and including lexemes from the dictionary. It is also equally important to prepare a gold standard corpus for Laz to be able to evaluate the accuracy of the analyser. Additionally, investigating borrowed words from specifically Turkish and how they are adapted and used in Laz will also improve the results. Derivational morphology is also nontrivial to look into to expand the lexicon.

7 Concluding Remarks

We have presented the first ever morphological analyser for Laz, a language in the Caucasian language family spoken in Turkey. The analyser currently covers the Pazar dialect.

This study will hopefully lead to further studies for language documentation and revitalization efforts for Laz in a larger context.

Abstract

Very short texts, such as tweets and invoices, present challenges in classification. Although term occurrences are strong indicators of content, in very short texts, the sparsity of these texts makes it difficult to capture important semantic relationships. A solution calls for a method that not only considers term occurrence, but also handles sparseness well. In this work, we introduce such an approach, the **T**erm **B**ased **Se**mantic **C**lusters (TBSeC) that employs terms to create distinctive semantic concept clusters. These clusters are ranked using a semantic similarity function which in turn defines a semantic feature space that can be used for text classification. Our method is evaluated in an invoice classification task. Compared to well-known content representation methods the proposed method performs competitively.

1 Introduction

Bag-of-words approaches (Harris, 1954) to text classification rely on measures of term occurrence, or co-occurrence, such as $tf \cdot idf$ (Salton and Buckley, 1988), log-likelihood (Dunning, 1993), and mutual information (Church and Hanks, 1990). Such methods, despite their enduring popularity, are well known for their shortcomings in dealing with numerous natural language issues, such as morphological, semantic, and other types of variation and ambiguity (Augenstein et al., 2017). These issues become more critical in very short texts, such as microblogs, chat logs, reviews and invoices, because of the lack of data and context that could provide more reliable measures and a source for semantic disambiguation.

Distributional semantic models (Baroni and Lenci, 2010) such as pre-trained word embeddings (Pennington et al., 2014; Grave et al., 2018) encode words as fixed sized real-valued vectors. Embeddings may address the issues of data sparseness and lack of extensive context, by providing a semantic representation model that is not as sensitive to literal word occurrence in the data, thus providing semantic information coverage of out-of-vocabulary words (Bojanowski et al., 2017). This is because embeddings may allow for any given word to be mapped to a real-valued vector (e.g. by using character n-grams), even if it hasn't been observed during training. Additionally, embeddings implicitly capture semantic, syntactic and lexical properties, thereby representing implicit relationships. In this way, embeddings provide a rich representation that is otherwise difficult to attain. In a short text scenario, despite early findings that a small corpus size may not be sufficient for representing the relationships between words and documents (Song et al., 2014), availability of pre-trained embeddings makes this issue less of a concern. Despite these advantages and growing popularity, embeddings trained on general language data usually do not perform well in (i) specialised domains (Liu et al., 2018; Kameswara Sarma, 2018) and in (ii) languages with richer morphological variation than English (Zervanou et al., 2014). In this work, we attempt to address these issues while exploiting the advantages of pre-trained word embeddings in a text classification task for very short, domain specific texts in a morphologically rich language, i.e., invoices in Dutch.

Our aim is to classify short invoice descriptions, in such a way that each class reflects a different group of products or services, as illustrated in the examples in Table 1. When considering such texts, the augmented information offered by embeddings is crucial, because such texts abound in ellipsis, grammatical errors, misspellings, and

Table 1: Example documents and classes

semantic variation. The inherent advantage of embeddings in dealing with out-of-vocabulary words presents, at the same time, the disadvantage of providing a text representation that does not focus on the importance of individual terms for the classification. Conversely, measures of term occurrence focus heavily on individual term importance but are very sensitive to variation. In very short text and domain-specific applications, where occurring terms are both strong indicators of the respective text class, as well as abound in variation, the preferred solution would combine embeddings to extracted terms. For example, for invoices, each occurring term in an invoice description is highly informative of the respective invoice text class. Hence a method is required that not only focuses on such terms, but also leverages the flexibility of embeddings. Our proposed method **T**erm **B**ased **Se**mantic **C**lusters (TBSeC) attempts to provide such a solution. The contribution of this paper lies in (i) combining the advantages of word embeddings with conventional term extraction techniques (ii) apply our method in an application domain not previously investigated, namely invoice text, which is characterised by specialised terminology and very short, elliptical and/or ungrammatical text, in a language that is morphologically richer than English and therefore posing an additional challenge in statistical approaches.

TBSeC proposes a two-stage methodology. In the first stage we use class-specific textual information to build semantic concept clusters. Concept clusters are vector representations of strongly related terms that are distinctive for a certain class. In the second stage, we compute cluster similarity scores on generated concept clusters for a given description. This serves as a ranking function that can be used in both unsupervised and supervised learning tasks.

The remainder of this paper is organized as follows: section 2 discusses related work; section 3 elaborates on the TBSeC method; section 4 outlines the experimental setup and section 5 discusses the results. We conclude with our main observations and suggestions for further work.

2 Related work

Text or document classification is defined as the assignment of text sections or entire documents to a predefined set of categories (Feldman and Sanger, 2007). For this purpose, algorithms process various types of text representations which are used as features for describing content. To our knowledge, invoice text classification has not been investigated previously[1]. Work related to text classification of short texts has been applied for microblogs (Singh et al., 2016; Ren et al., 2016; Missier et al., 2016), email subject classification (Alsmadi and Alhami, 2015) and spam detection (Bahgat et al., 2016).

Initial approaches to document content representation used counts of term frequency and inverse document frequency, $tf \cdot idf$ (Salton and Buckley, 1988), whereby frequently occurring terms are assumed to represent document content and inverse document term frequency scores select the most distinctive terms for a given document within a collection. Various subsequent approaches use variants of term occurrence measures with probabilities, such as $\chi 2$-test, log likelihood (Dunning, 1993) and mutual information (Church and Hanks, 1990), or attempt to combine statistical measures with various types of linguistic and stop-word filters, so as to refine the keyword results. Considerations regarding term ambiguity and variation also led to rule-based approaches (Jacquemin, 2001) and resource-based approaches exploiting existing thesauri and lexica, such as UMLS (Hliaoutakis et al., 2009), or WordNet (Aggarwal et al., 2018). Knowledge poor statistical approaches, such as Latent Semantic Analysis (Deerwester et al., 1990) and Latent Dirichlet Allocation (Blei et al., 2003) attempt to detect document content in an unsupervised manner while reducing the dimensionality of the feature space of other bag-of-word approaches, but are also sensitive to sparse data and variation in short texts.

The advent of large semantic resources in the form of pre-trained word embeddings (Pennington et al., 2014; Grave et al., 2018) gave rise to a new line of approaches employing word embeddings for document content representation, such as Word2Vec (Mikolov et al., 2013), FastText (Bojanowski et al., 2017), GloVe (Pennington et al.,

[1] An approach reported by Bartoli et al. (2010) focuses on image features of scanned invoices rather than the invoice text.

2014), and ELMo (Peters et al., 2018). Within this line of approaches, methods have also been developed using word embeddings specifically for document classification, such as task-oriented word embeddings (Liu et al., 2018) and word-sense based embeddings (Jin et al., 2016). Embedding models encoding words in documents or document sections have also been developed, such as Doc2vec (Le and Mikolov, 2014), Infersent (Conneau et al., 2017), Skip-thought (Kiros et al., 2015) and FastSent (Hill et al., 2016). Such type of embeddings can be employed to calculate the semantic similarity between texts, but the risk is that intricate word-specific semantic relationships are lost. Methods originating from text similarity research using word rather than document embeddings, such as Kusner et al. (2015); Kenter and De Rijke (2015); De Boom et al. (2016) attempt to address this issue. Embeddings have been also used for keyphrase extraction via supervised (Mahata et al., 2018) and unsupervised (Bennani-Smires et al., 2018) approaches.

Finally, the problem of variation and data sparsity with very short texts has been addressed in the past with query expansion approaches (Vechtomova, 2009). For text similarity purposes query expansion techniques have been used for document term augmentation, exploiting relevant search results and a matrix representation (Sahami and Heilman, 2006; Abhishek and Hosanagar, 2007) or a combination of search results page count difference and lexico-syntactic patterns derived from text snippets (Bollegala et al., 2007).

3 The TBSeC methodology

Our proposed method, TBSeC, consists of two stages: In the first stage we use class-specific textual information to build semantic concept clusters. Concept clusters are vector representations of strongly related terms that are distinctive for a certain class. In the second stage, we compute cluster similarity scores on generated concept clusters for a given description, thereby forming a semantic feature space. This serves as a ranking function that can be used in both unsupervised and supervised learning tasks.

3.1 Concept clustering

Concept clustering starts by extracting distinctive terms, particular to a class[2]. Distinctive terms are extracted based on normalized term frequency. For a given class, word embeddings belonging to found terms are used to form numerous clusters. Hence, for each class multiple clusters are created and each cluster can be seen as a group of terms that are closely related. Each cluster is transformed into a concept cluster vector by taking the respective word embeddings of terms and computing the mean over each dimension. This process is illustrated in Figure 1, with actual examples included and word embeddings indicated as vectors with dots.

Specifically, the method works as shown in Algorithm 1 for n distinct classes, k most frequent terms to be incorporated as cluster and normalized term frequency (i.e., Bag-of-words, B_{ij}) threshold t. A more detailed description is given underneath the algorithm. Algorithm line numbers refer to steps as denoted in Figure 1.

Terms that provide a clear distinctive value to a class are retrieved using term frequency and L1 normalization over rows and columns. Terms not appearing in the vocabulary of the embedding model, or having a score below the normalized threshold t are filtered out. Word embeddings for these selected terms are employed to create concept clusters for each class using the DBSCAN clustering model (Ester et al., 1996). Terms can either be included in a multi-term cluster through DBSCAN clustering or can be added as a single-term cluster when occurring frequently enough based on k. Ultimately, for each class i, concept clusters are created as a single vector equal to the averaged embedding of included terms.

3.2 Semantic cluster similarity

We adapt the similarity measure by Kenter and De Rijke (2015), which is based on the BM25 framework (Robertson et al., 2009), to propose our semantic cluster similarity measure. We combine idf scoring with word by word cosine similarity to calculate a weighted similarity score.

The Kenter and De Rijke (2015) function for calculating semantic text similarity between two sentences s_l and s_s is as defined as follows:

[2] In the case of invoice classification, each class refers to a specific expense type.

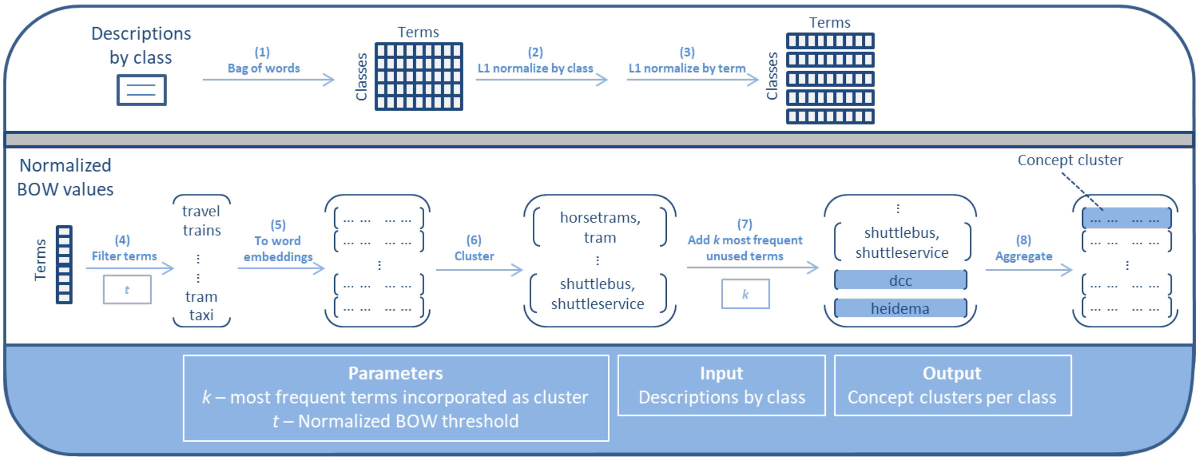

Figure 1: Concept clustering process diagram. *Upper panel*: Preparing normalized bag of words using descriptions by class. *Lower panel*: Employing found values to create concept clusters for a given class

$$f_{sts}(s_l, s_s) = \sum_{w \in s_l} IDF(w) \cdot \frac{sem(w, s_s) \cdot (k_1 + 1)}{sem(w, s_s) + k_1 \cdot (1 - b + b \cdot \frac{|s_s|}{avgsl})} \tag{1}$$

Parameters k_1 and b are inherited from the BM25 framework and serve as smoothing parameters. Parameter k_1 influences what semantic text similarity value is approached asymptotically, thereby limiting the influence that semantic term similarity can have. Parameter b provides a degree of importance to sentence length ratio $\frac{|s_s|}{avgsl}$, comparing sentence length to the average sentence length $avgsl$ of sentences being ranked. The function sem returns the semantic term similarity of term w with respect to text s, as follows:

$$sem(w, s) = \max_{w' \in s} f_{sem}(w, w') \tag{2}$$

where f_{sem} is a vector similarity function that is typically computed as cosine similarity.

In TBSeC, the Kenter and De Rijke (2015) function is adapted to compare each sentence to all composed concept clusters. In our implementation, parameter b is redundant, because each concept cluster is represented as a single embedding and the measure is computed by a single cosine similarity score. Moreover, we normalize our similarity score with the number of terms appearing in the sentence to allow for use in a supervised learning task. Finally, we remove term-specific weighting, for four reasons: First, idf scoring imposes a hefty constraint on the terms that can be used because of the predefined vocabulary. Second, we argue that the limited amount of terms appearing in a description justifies the exclusion of term-specific weighting. Each term in the description holds an important piece of information and differentiating is not essential. Third, terms that don't hold considerable semantic importance are not likely to steer the score towards an incorrect class. Each concept cluster is created to serve as a distinctive concept, thus making it unrealistic that unimportant terms will relate to it well. Fourth, terms in descriptions are subject to frequent misspellings and personal abbreviations, making idf scores inherently unreliable in this setting.

Based on the changes to Equation 1 discussed above, our function for calculating semantic cluster similarity f_{scs} between text s and concept cluster c is defined as follows:

$$f_{scs}(s, c) = \frac{1}{|s|} \cdot \sum_{w \in s} \frac{(sem(w, c) \cdot t(w)) \cdot (k_1 + 1)}{(sem(w, c) \cdot t(w)) + k_1} \tag{3}$$

where $t(w)$ is the term frequency of term w in the text. The score is normalized by the number of terms $|s|$ in text s. In addition to smoothing parameter k_1, two other hyper parameters sem_{th} and sem_{sq} are added to influence scoring. These hyper parameters affect the result of sem as follows.

$$sem(w, c) = \begin{cases} f_{sem}(w, c) & \text{if } f_{sem}(w, c) \geq sem_{th} \\ & \text{and } sem_{sq} = \text{false} \\ f_{sem}(w, c)^2 & \text{if } f_{sem}(w, c) \geq sem_{th} \\ & \text{and } sem_{sq} = \text{true} \\ 0 & \text{if } f_{sem}(w, c) < sem_{th} \end{cases} \tag{4}$$

Algorithm 1 Concept Clustering

Parameters:
k - No. of most frequent terms to be incorporated as cluster
t - Normalized bag of words threshold
Input:
D_i , $i \in \{1, \dots , n\}$ - Merged descriptions for each class
Output:
C_i , $i \in \{1, \dots , n\}$ - Concept clusters for each class

```
① $B_{ij} \leftarrow$ Calculate bag of words using $D_i$,
  with found vocabulary set $V$,
  $i \in \{1, \dots , n\}, j \in \{1, \dots |V|\}$
  $C_i \leftarrow$ Instantiate empty concept cluster array,
  with $i \in \{1, \dots , n\}$

  for $i \in \{1, \dots , n\}$ do
②     $B_{i*} \leftarrow$ L1 normalize $B_{i*}$          ▷ Normalize by class
  end for
  for $j \in \{1, \dots |V|\}$ do
③     $B_{*j} \leftarrow$ L1 normalize $B_{*j}$          ▷ Normalize by term
  end for
  for $i \in \{1, \dots , n\}$ do                    ▷ For each class
④     Retrieve terms in vocabulary with a score $> t$
      and occur more than once
      $terms \leftarrow$ Array of found terms that appear in
      word embedding vocabulary
⑤     $emb \leftarrow$ Respective word embeddings of $terms$
      $C_i \leftarrow$ CREATE CLUSTERS($emb, k, terms$)
  end for
  return $C$

  function CREATE CLUSTERS($emb, k, terms$)
      Instantiate $DBSCAN$ clustering model with
      $eps$, $min\_samples$ and
      $metric = cosine\ similarity$
      Fit $emb$ on $DBSCAN$ model
⑥     $clusters \leftarrow$ formed clusters as collections of
      word embeddings
      for $term$ in $k$ most frequent $terms$ do
          if $term$ not used in $clusters$ then
              $e \leftarrow$ word embedding of $term$
⑦             $cluster$.append([$e$])
          end if
      end for
      $concepts_c \leftarrow$ empty concept cluster array
      with $c \in \{1, \dots , |clusters|\}$
      for $c \in \{1, \dots , |clusters|\}$ do
⑧         $concepts_c \leftarrow$ coordinate mean over each
          dimension
      end for
      return $concepts$
  end function
```

The semantic threshold sem_{th} serves as a way to add a semantic similarity bound above which it will be presumed to hold importance. Parameter sem_{th} achieves that when $f_{sem}(w, c)$ is under the set threshold value, that $sem(w, c)$ equals 0. Squaring $f_{sem}(w, c)$ through sem_{sq} increases term importance of terms that are a near match and lowers importance of terms that match to a lesser extend. Squaring $f_{sem}(w, c)$ therefore promotes the divergence of semantic similarity scores.

Semantic cluster similarity f_{scs} produces features for use in supervised learning applications, but the initial performance of TBSeC is measured without a predictive model. For this reason, a similarity score for each class is required in order to rank the classes. This is calculated as scs for each class i, by extracting the maximum score over all concept clusters $c \in C_i$ (see C_i in Algorithm 1):

$$scs(s, C_i) = \max_{c \in C_i} f_{scs}(s, c) \tag{5}$$

4 Experimental setup

This section covers data description, data processing and the experimental set-up for our method.

4.1 Data

Our invoice data originate from an auditing company. In the data, as illustrated in the examples in Table 1, each class refers to a particular type of expenses. Available data is accessed from a data directory, where each file is specific to a client. For our purposes, only the *invoice description* and *class assignment* are relevant. The volume of the entire data directory amounts to approximately 1.5 million instances. There is a total of 111 unique classes to which assignments are made. The five classes that are least represented have 24, 106, 178, 418 and 452 entries respectively. Invoice descriptions on average contain 2.80 terms, with a standard deviation of 1.55.

4.2 Word embeddings

Pre-trained Dutch FastText word embeddings[3] are used for sentence embedding construction and for use in semantic similarity computations (Bojanowski et al., 2017). The FastText embedding model was trained on Dutch Wikipedia.

[3] https://github.com/facebookresearch/fastText/blob/master/docs/pretrained-vectors.md

4.3 Data processing

Descriptions are processed using a procedure similar to the one used in training the FastText model. Special characters are replaced with a whitespace, stopwords in both the English and Dutch language are dropped, digits are removed and finally terms are retrieved by splitting on any sequence of unicode whitespace characters. When creating validation sets special care is taken to remove duplicates and to include data from all individual clients and all classes in a randomized manner. As a result, largely balanced validation sets are formed with data from various sources.

4.4 Learning algorithm

During supervised learning a Support Vector Machine[4] is used with regularization parameter $C = 0.1$ and a linear kernel. This classifier performed best when compared to other feasible classifiers (e.g. random forest), given a local working memory bounded set-up, and allows for the use of sparse matrices. Regularization parameter C regulates the importance of focusing on correctly classifying training samples in favor of realizing a hyperplane with a large minimum margin. A high C can lead to overfitting, a low C can lead to the inability to learn meaningful decision boundaries. We set C to 0.1 since it appears to offer a good balance on the basis of the main validation set in terms of limited running time and general performance.

4.5 Parameter tuning

Prior to including our framework in a supervised learning task, we optimize the parameters (see section 5.1 for results). We construct an initial set of concept clusters using preset values $k = 5$ and $t = 0.8$. Parameters are set such that the model offers a well-performing baseline with low chances of overfitting. Initial concept clusters are used to tune semantic cluster similarity parameters. This order of parameter tuning is chosen, because it is relatively straightforward to pick sensible values for k and t, as opposed to f_{scs} hyperparameters. Table 2 lists the attempted combinations of parameter settings for f_{scs}.

Parameter	Distinct values
k_1	[1.2, 1.6, 2.0]
sem_{sq}	[true, false]
sem_{th}	[0, 0.1, 0.2, 0.3, 0.4]

Table 2: f_{scs} parameter settings

After parameter tuning for semantic cluster similarity, employed concept clusters are reconsidered. Values in the range from 5 to 50 with a step size of 5 are attempted for the k most frequent terms incorporated as cluster.

Validation is performed on a dataset with approximately 5,000 entries. Performance differences for f_{scs} are evaluated using three performance measures: (1) accuracy, (2) ranking loss and (3) standardized score. Accuracy is calculated by picking the class with the highest semantic similarity score as predicted class and finding the percentage of correctly classified instances. Ranking loss is calculated by obtaining the rank of the true class. The standardized score is calculated by standardizing all scores for a given instance and retrieving the score of the true class. By standardizing it can be observed how the score for the true class is positioned against all other scores. Ultimately, the objective is to maximize the accuracy and standardized score and to minimize ranking loss. Afterwards, we investigate the influence of parameter k for concept cluster construction on the basis of accuracy and dimension size. Accuracy is calculated as an unsupervised score as well as a 5-fold cross validated supervised score. Both scoring methods use best values for k_1, sem_{th} and sem_{sq} which are found in the previous step. Results are compared to determine an appropriate value for parameter k for use of features in a predictive model.

4.6 Invoice classification

We use the proposed semantic cluster similarity matching method, to measure performance in a classification task. We compare the performance to existing methods and we test whether combining methods leads to an increase in performance.

The parameters for generation of semantic cluster similarity scores are set in accordance with values obtained during parameter tuning.

For validation, a dataset containing approximately 20,000 entries is used. The data is used to perform 5-fold cross validation to determine overall performance. For all tests, we chose to use accuracy as performance quality measurement. Only one out of 111 classes shows significant imbalance, which for testing overall method performance is deemed negligible. Consequently, no balancing is performed and no alternative quality measure, such

1.6	true	0.2	21.26	28.40	1.4739

Table 4: Best f_{scs} configurations

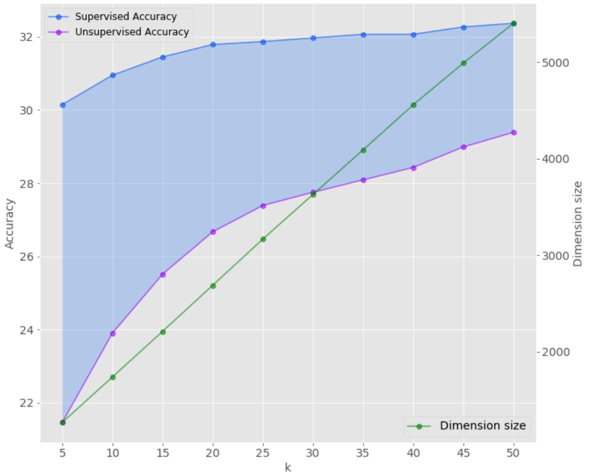

Figure 2: Concept clustering parameter tuning

as macro-averaged recall or F1-score is used.

Our benchmarks consist of other state-of-the-art content feature generation methods: term frequency (tf), *tf* · *idf*, Latent Semantic Analysis (*LSA*, Deerwester et al. (1990)), Latent Dirichtlet Allocation (*LDA*, Blei et al. (2003)), concatenated power mean word embeddings (*P-mean*, Rücklé et al. (2018)), and FastText sentence embeddings (Bojanowski et al., 2017). All benchmark methods, parameter settings and dimension sizes are shown in Table 3.

Feature transformation models (*tf*, *tf*·*idf*, LSA, LDA) are trained on the entire training directory. Additionally, when using such transformation models, words are stemmed to reduce inflectional word forms to their word stem.

5 Results

This section discusses our results from parameter tuning and the subsequent supervised classification task.

5.1 Parameter tuning

5.1.1 Semantic cluster similarity

Parameter combinations have been attempted and results have been retrieved for the used dataset. For each quality measure, the 3 best scores have been retrieved, returning all instances that conform to that score. The results are shown in Table 4.

Table 4 tells us that squaring the semantic similarity score works well. High accuracy scores are retrieved, accounting for the fact that evaluations are made based on maximum similarity scoring instead of a predictive model. As we are able to retrieve six configurations, we note that quality measures tend to score parameter settings similarly. The configuration with $k_1 = 2.0$, $sem_{sq} = true$ and $sem_{th} = 0.0$ across quality measures is the best performing.

5.1.2 Concept clustering

Next, we study the influence of parameter k on concept cluster construction. For each setting, we present the accuracy scores and dimension sizes in Figure 2.

With increasing k, more concept clusters of unused single terms are added. As a result, the dimension size steadily increases. We can see that accuracy also shows an increasing trend with the value of k. When more unused single terms are added, we run the risk of overfitting. The ratio of single terms to broader concept clusters increases with k, thereby relatively shifting the focus from broader concepts to frequently occurring distinctive individual terms. This behaviour is also reflected in the graph, in the relative performance difference between unsupervised and supervised scoring. Although supervised accuracy is undoubtedly higher with lower number of concept clusters, both accuracy scores converge with increasing k. By adding unused single terms, the unsupervised ranking method is able to capture an increasing number of edge cases, leading to a convergence in performance. This behaviour is an indication of overfitting.

After carefully considering the points above, we proceed with value $k = 20$. This choice appears to offer a good compromise between generalizing ability and direct performance gains. The primary

tf & TBSeC & FastText	**47.86**	0.42	86.38	0.10

Table 5: Invoice classification results

goal of TBSeC is relating input to broader concepts, which is why a relatively moderate value for k is preferred.

5.2 Invoice classification

In this section, we discuss the results of our method against state-of-the art benchmark methods in a supervised invoice classification task. The results, consisting of cross validated accuracy scores with standard deviation (sd), are shown in Table 5 under header 'Benchmark'. The fact that term frequency has comparable performance to $tf \cdot idf$ reinforces the notion that all terms within an invoice description are important to take into account and that term-specific weighting has limited value. Moreover, techniques that are concerned with dimensionality reduction (LSA, LDA) perform worse, arguably because they truncate a large amount of information, most of which should have been retained. Sentence embeddings and our method TBSeC perform relatively well, with accuracy scores nearing performance levels of $tf \cdot idf$ and term frequency. Furthermore, a large feature space (1500D) that is achieved with P-mean embeddings appears to have a positive influence on the amount of information that is contained. It is also found that methods $tf \cdot idf$, term frequency and P-mean have a tendency to overfit on the data, having cross-validation training accuracy scores of over 80%. In comparison, TBSeC and FastText have training accuracy scores closer to test accuracy scores.

Combinations of techniques are attempted next to improve performance. The feature combinations are formed by concatenating the feature spaces of each method. The most successful combinations are highlighted in Table 5 under header 'Feature combinations'. Combining feature generation techniques leads to surprising results. P-mean performs well as sole feature, but doesn't yield better results when combined with other techniques. In contrast, FastText does pair well with other techniques and improves performance levels. Moreover, when TBSeC is used performance is even better. Term frequency in combination with both TBSeC and FastText does also improve performance, although slightly. TBSeC and FastText are more likely to be complementary as soon as TBSeC encompasses lower number of concept clusters, but this doesn't guarantee better overall performance. In the current configuration it manages to perform better, but the difference is not major. The tendency to overfit for $tf \cdot idf$, term frequency and P-mean is a likely cause for some of the other unsuccessful feature combinations.

6 Conclusion

A new feature generation framework TBSeC was presented that is suited to the prediction of well defined classes on the basis of very short texts (2.8 words on average). Generated features were proven to be able to function well independently and jointly with traditional feature generation techniques. Performance and reliability was improved by pairing multiple disjoint feature generation techniques, including TBSeC. A combination of highly specific features with more flexible ones was found to lead to the best results. Combinations of features were found to reach a bound in effectiveness, highlighting that methods ultimately start impeding each other. Businesses can use our method to derive actionable insights from online user generated content such as firm-specific tweets, online reviews and customer chats logs. Future work could test TBSeC on larger texts, since it offers more room to differentiate from sentence embeddings.

Quotation Detection and Classification with a Corpus-Agnostic Model

Sean Papay & Sebastian Padó

Institute for Natural Language Processing
University of Stuttgart, Germany
{sean.papay,pado}@ims.uni-stuttgart.de

Abstract

The detection of quotations (i.e., reported speech, thought, and writing) has established itself as an NLP analysis task. However, state-of-the-art models have been developed on the basis of specific corpora and incorporate a high degree of corpus-specific assumptions and knowledge, which leads to fragmentation. In the spirit of task-agnostic modeling, we present a corpus-agnostic neural model for quotation detection and evaluate it on three corpora that vary in language, text genre, and structural assumptions. The model (a) approaches the state-of-the-art on the corpora when using established feature sets and (b) shows reasonable performance even when using solely word forms, which makes it applicable for non-standard (i.e., historical) corpora.

1 Introduction

Quotation is a general notion that covers different kinds of direct and indirect speech, thought, and writing in text (Semino and Short, 2004). Quotations are a prominent linguistic device used to express claims, assessments, or attitudes attributed to speakers. Consequently, the analysis of quotations is gaining traction in computational linguistics and digital humanities, providing evidence for speaker relationships (Elson et al., 2010; Agarwal et al., 2012), inter-speaker sentiment (Nalisnick and Baird, 2013), politeness (Faruqui and Pado, 2012), and narrative structure (Jannidis et al., 2018).

As is often the case with semantic phenomena, manual annotation of quotations has shown to be slow and resource-intensive, in particular when undertaken in conjunction with the annotation of speakers and information quality (Brunner, 2013; Pareti, 2015). This provides the rationale for automatic *quotation recognition* methods. After a first round of rule-based methods (Pouliquen et al., 2007; Brunner, 2013), recent supervised models use mostly sequence classifiers (Pareti et al., 2013; Almeida et al., 2014; Scheible et al., 2016).

Not surprisingly, these corpora differ substantially across a number of relevant dimensions. including text genre, annotation scheme, and theoretical assumptions. For example, Pareti et al. (2013) focus exclusively on newspaper text and focus on developing a *uniform* annotation schema that captures the shared properties of all kinds of annotations. Thus, even though this corpus contains direct, indirect, and mixed quotations, these not marked as instances of their specific subtypes. In addition, each quote is assumed to be introduced by a *cue* (markables are shown surrounded by red square brackets):

(1) Hillary Clinton on Saturday [acknowledged]$_{\text{CUE}}$ [the state of the economy is good]$_{\text{QUOTE}}$.

This assumption is generally true for newspaper text, and simplifies the task of quotation detection.

The situation is rather different in the literary texts considered by Semino and Short (2004). Cues are much more varied, and are sometimes omitted entirely, such as in this exchange from Dickens' *Christmas Carol*:

(2) ["Much!"]$_{\text{QUOTE}}$ – Marley's voice, no doubt about it.
["Who are you?"]$_{\text{QUOTE}}$
["Ask me who I was."]$_{\text{QUOTE}}$

The study follows a generally more *differentiating* approach. It develop and annotate a rich typology of different subtypes of quotations to distinguish, e.g., direct from indirect quotations, and speech from thoughts from writing.

Not surprisingly, therefore, all models for quotation detection were developed for one specific corpus. This leads to two problems:

1. The models inherit the corpora's *structural and theoretical assumptions*, such as the presence of a cue assumed by models for the Pareti et al. (2013) corpus.

2. The models typically include *domain-specific* features and knowledge sources that happened to be available from the corpus, such as lists of likely cue verbs or syntactic realizations of quotations.

This corpus dependence amounts to conceptual overfitting: while it leads to better fit for the original corpus, models are not transferable to new domains and analysis schemes. In other words, it leads to serious *fragmentation*.

In this paper, we develop and evaluate a *corpus-agnostic* neural model architecture for automatic quotation recognition that makes as few assumptions as possible about the corpus to be modelled but is still expressive enough to deal with the challenge of recognizing quotation spans of essentially arbitrary length (Scheible et al., 2016). In this respect, we see our study as a step towards transfer learning (Pan and Yang, 2009) and task-agnostic learning (Hashimoto et al., 2017). We find that our model can perform reasonably well across corpora differing in genre, language, and structure.

2 Related Work: Datasets and Models

We now review the state of the art in automatic quotation annotation, describing the three major quotation corpora for English and German and the corresponding models. We exclude corpora that focus on one specific quotation subtype such as the Columbia Speech Attribution corpus (Elson and McKeown, 2010) which only covers direct speech.

2.1 PARC Dataset

Dataset. The Penn Attribution Relation Corpus (Pareti, 2015), version 3 (PARC3) is a subset of the Penn Treebank, annotated with quotations and attribution relations. It consists of English newswire text from the Wall Street Journal. Each attribution relation consists of a cue, optionally a source (speaker), and content (quotation span), all marked as text spans. As part of the Penn Treebank, PARC3 provides manually annotated tokenization, POS tags, lemmas, and constituency parses.

Quotation spans are not labeled with more specific types, but PARC3 distinguishes informally (based on the surface form) between direct quotations (starting and ending with quotation marks), indirect quotations (without any quotation marks), and mixed quotations (everything else).

Pareti model. Pareti (2015), an extension of Pareti et al. (2013), presents a pipeline architecture for quotation annotation. It first applies a k-NN classifier to identify quotation cues within the corpus. Then, a linear-chain conditional random field (CRF) is used to identify quotation spans in the vicinity of each cue. The Pareti model builds on corpus-specific knowledge, including lists of cue verbs, and handcrafted features sensitive to punctuation conventions in English newswire text.

Scheible model. Scheible et al. (2016) retain the pipeline architecture of Pareti (2015) and its feature set, but replace the components. Cue annotation is performed with an averaged perceptron. More importantly, they replace quotation annotation proper with a sampling-based procedure: a perceptron samples tokens as likely span boundaries, which are then combined into complete quotation spans, using a semi-Markov model.

2.2 STOP Dataset

Semino and Short (2004) presents a corpus-based ontology of quotations in English text. It introduces two dimensions: (a), speech vs. thought vs. writing; and (b), direct vs. indirect vs. free indirect vs. reported, yielding a Cartesian product of twelve quotation subclasses. These are used to annotate the Speech, Thought, and Writing Presentation corpus (STOP). It comprises 120 sections, split evenly across three genres (fiction, newspaper, and biographies), of about 2,000 words each (Total size: 250,000 tokens; 8,000 quotations). The corpus has no linguistic annotation: the only features available are words' surface forms. To our knowledge, there are no models for this dataset.

2.3 *Redewiedergabe* Dataset

Dataset The Redewiedergabe ('reported speech') corpus (RWG) (Brunner, 2013) is a corpus of German narrative text, comprising thirteen public-domain German narratives (1787–1913). The quotation annotations in RWG adopt the scheme by Semino and Short (2004) and distinguish direct, indirect, free indirect, and reported variants of speech, thought, and writing. The total size of the corpus is 57.000 tokens, and 17.000 quotation spans.

Unlike STOP, RWG contains some linguistic information, namely POS tags, lemmas, and mor-

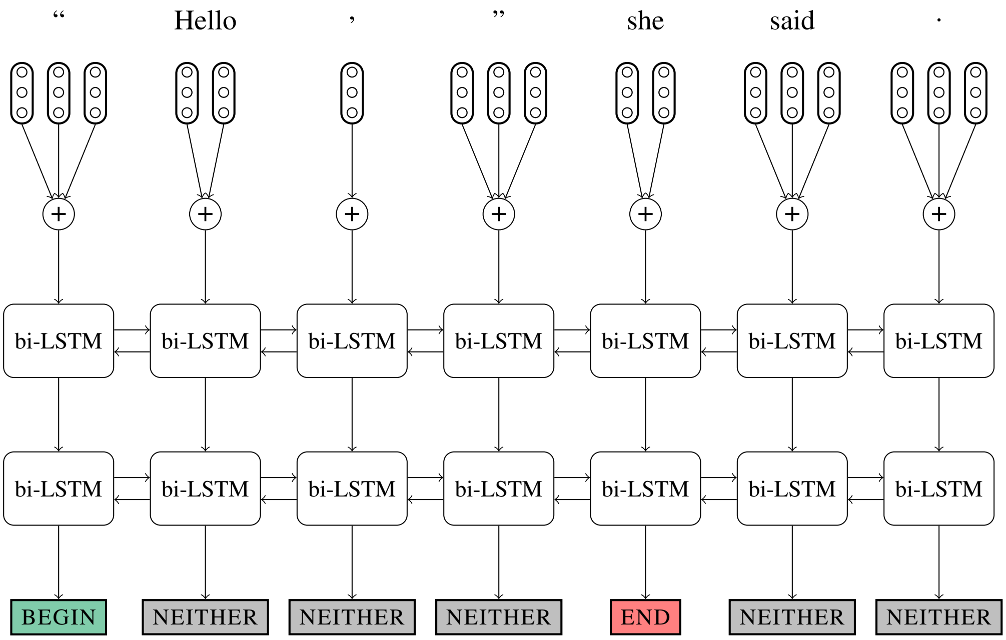

Figure 1: The NQD architecture. Tokens are represented as a bag of feature embeddings, and each token sequence is processed by a 2-layer bi-LSTM network, before a max-entropy classifier labels each token.

phological features (case, number, gender). This information is obtained automatically, though.

Models. Brunner (2013) proposes two models for quotation annotation on RWG. Both models work at the sentence level and predict only the presence of absence of quotations, not their spans (even though this information is annotated). The first model is rule-based (**Brunner RB**). It uses a set of handcrafted rules to identify direct, indirect, reported, and free indirect quotations. The second model (**Brunner ML**) is a simple classification model based on random forests.

3 Neural Quotation Detection (NQD)

We now define a neural architecture, NQD, with the goal of modeling the quotations in all three corpora described in Section 2. We design our model to leverage the commonalities across datasets, while not depending on the features of any dataset in particular. As all datasets involve long quotation spans with long-distance dependencies, an LSTM-based approach was natural, given such models' ability to capture very long-distance dependencies of up to 200 tokens (Khandelwal et al., 2018). Conversely, given the structural differences between corpora, we decided against a pipeline model like those employed by Pareti (2015) and Scheible et al. (2016) which predict cues first and then quotation spans. NQD predicts quotations directly without explicitly identifying cues.

NQD frames quotation prediction as token classification, classifying each token as either beginning a quotation (BEGIN), ending a quotation (END), or neither (NEITHER). Quotation spans then consist of all tokens starting with a BEGIN tag, up to (but not including) the next END or BEGIN tag, or the end of sequence. This model is not limited to the sentence level: it is able to make predictions for a whole document and in this manner can capture very long quotation spans (Scheible et al., 2016). Concretely, the sequence-to-sequence architecture comprises a 2-layer bi-LSTM network, with the outputs of the second bi-LSTM feeding into a 3-class softmax classifier. Thus, the model takes token sequences as input and produces a sequence of token labels. Figure 1 shows a schematic diagram of the NQD architecture. For datasets with multiple quotation types, NQD uses a separate sequence-to-sequence model for each span type, connecting them by weight sharing. All NQD code is available from https://www.ims.uni-stuttgart.de/forschung/ressourcen/werkzeuge/index.en.html.

In the input token sequences, each token is a bag of features. Each feature value is represented as an n-dimensional continuous vector, and each token is represented as the sum of these vectors.

This approach to feature representation allows our model to work with corpora with arbitrary types of token-level features. In the simplest case, when only raw text is present in the corpus, each token is given a single feature for that token's word. If other token-level features are present, such as POS-tags, lemmas, or even parse tree information, these can be incorporated as additional feature vectors, without requiring any changes to the model architecture. Feature vectors can also be initialized to pre-trained representations (e.g. word embeddings) when these are available, or initialized randomly and learned when they are not. Section 2 describes in detail which features are used for the corpora we experiment with.

4 Experimental Evaluation

We now train and test NQD on the three corpora and compare against the state-of-the-art.

4.1 Experimental Setup

PARC3. For PARC3, we train a single classifier on the quote content spans and ignore the cue and source spans. As features, we use token surface forms, lemmas, POS tags, as well as, for each token, the bags of constituents that start with, end with, and contain it. These features are a subset of the features used by Scheible et al. (2016) and Pareti (2015), and like these studies, we use gold standard annotation. We initialize the features for word surface forms with the default GloVe Wikipedia word embeddings (Pennington et al., 2014). Our model makes predictions on entire documents at a time. We use performance on the corpus's development set to guide early stopping during training, and we evaluate on the corpus's test set.

STOP. For STOP, we train four classifiers for the four quote types (direct, indirect, free indirect, reported). We train and evaluate our model on a per-document basis as for PARC3. We use word surface forms (and their GloVe embeddings) as features, we used no other features in this model. As the corpus contains no held-out development or test sets, we used 10-fold cross validation to evaluate our model, using 8 folds for training, 1 for development, as 1 as for testing in each iteration.

RWG. For RWG, we adopt the same four-classifier setting as for STOP, using the word, lemma, POS, and morphological features available. For the sake of comparability with (Brunner, 2013), we train and evaluate on individual sentences, as opposed to entire documents. We use 10-fold cross validation again, randomly partitioning all corpus sentences into 10 subsets. We use GloVe embeddings pre-trained on the German Wikipedia.[1]

Evaluation. Previous studies on PARC3 adopted an exact span match setting, i.e., only those predicted spans that exactly match a gold standard span count as true positives. We report precision, recall, and F_1 in this setting for PARC3 and STOP. For RWG, we report the sentence-level accuracy used by Brunner (2013). In this mode, we train and predict with our model as before, but for evaluation we just record whether the model predicts the presence of a quotation type in a sentence.

4.2 Results

PARC3. The results in Table 1 show that NQD cannot beat the performance of Scheible et al. (2016), but does almost as well as Pareti et al. (2013). Given that our model is substantially simpler than either of these two (both include a special cue classifier, dictionaries, etc.), we see this as a success. Our model is competitive with the Scheible et al. model with regard to recall, but shows subpar precision for all quotation types, indicating a remaining weakness in the input encoding: for direct quotations, quote characters should provide strong indicators for quotation boundaries.

Note that these results, as well as the earlier studies (Pareti et al., 2013; Scheible et al., 2016), use unrealistic gold standard features. Therefore, we ran a second version of NQD using only word features, but no tags or structural information. The model is clearly worse, but still surprisingly good at 61% F_1. Not surprisingly, we see the highest drop for indirect quotations, which are most sensitive to syntactic structure. This indicates that NQD does a reasonable job in a setting that is realistic in general, and particularly so for non-standard corpus varieties (e.g., historical and literary corpora) that are often used in Digital Humanities.

STOP. To our knowledge, the results in Table 2 are the first modeling results on STOP. In comparison to PARC3, the results are noticeably lower. It is still the case that direct quotations are easiest to find, but their F_1 is somewhat lower than in PARC3. Indirect quotations are much more difficult, and free indirect quotations essentially impossible. This involves multiple factors: (a) STOP is

significantly smaller, but more varied, than PARC3, providing sparser training data; (b) STOP covers a wider variety of quotation types, some of these are intrinsically difficult to model – in particular free indirect quotations (McHale, 2009).

RWG. The results in Table 3 show a picture that is overall similar to PARC3:[2] NQD does not outperform the state-of-the-art, but approximates it closely despite the lack of corpus-specific tuning. As in STOP, we see the lowest results for free indirect quotations, showing that this class is generally hard to classify. In general, even though this resource's size and annotation are similar to STOP, we see significantly higher numbers. This is mostly due to the different evaluation we use for RWG to compare to previous work: detecting the presence of quotes is easier than identifying their spans.

On RWG, we also run a basic NQD with only word form information. With this corpus and evaluation, this results in a drop of merely 3 points F_1 – due to losses on the indirect and free indirect categories – which bolsters the potential of this configuration.

5 Error Analysis

To gain some insights into the failure modes of NQD, we perform a brief qualitative analysis of the cases where our model gave false predictions.

These errors can broadly be divided into three categories: cases where the model predicts the presence of extraneous quotations (false positives), cases where the model fails to identify existing quotations (false negatives), and cases where the model correctly identified the presence of a quote, but did not correctly determine its boundaries (boundary mismatch, leading both false positives and false negatives in our exact span evaluation). We focus our error analysis on PARC, the previously best explored of our three corpora. In the examples, gold-standard quotations are marked with red square brackets, as above, and model-predicted quotations are marked with blue parentheses.

5.1 False Positives

Among the false positives produced by our model was a surprising number of quotations that are correct according to PARC's guidelines, but which are not annotated in the corpus. As an example, our model correctly identifies the presence of an

[2] Brunner (2013) does not report overall results. We compute them as micro-averages over reported per-type results.

unannotated quotation in the following sentence:

(3) (Britain's retail price index rose 0.7% in September from August and was up 7.6% for the year), the Central Statistical Office said.

Outside of these cases, proper false positives seem to be rare. Many of the false positives we found were boundary mismatches, discussed separately below.

5.2 False Negatives

Among the false negatives we analyzed, we found that the model is most likely to miss "tricky" quotations that are unusual in their grammatical structure. In particular, it tends to miss a class of quotations that are expressed as short noun phrases or adjectival phrases embedded within a non-quotation sentence such as

(4) Mandela, considered [the most prominent leader of the ANC] remains in prison. But [his release within the next few months] is widely expected.

According to the PARC guidelines, these are cases of quotations since they are attributable statements, but they are difficult for the model to retrieve since they are hard to distinguish from "non-quotation" nominal phrases – in particular in cases like this one, where there are not even overly realized speakers. In STOP and RWG, these cases might arguably not even be annotated as quotations.

5.3 Boundary Mismatches

A large proportion of the errors of NQD are boundary errors, where the model identifies the presence of a quotation, but fails to identify its exact boundaries. This can happen when our model correctly predicts one quotation boundary, but not the other.

For example, in the following sentence, our classifier identified the first quotation's beginning, but not its end (it also failed to identify the second quotation entirely – a false negative):

(5) He reiterated ([his opposition to such funding], but expressed [hope of a compromise].

This type of error occurs both for noun phrases and verb phrases and embedded sentences, but for different reasons: noun phrases are difficult to recognize since they are not marked by punctuation as are almost all other cases of quotation spans; verb phrases, on the other hand, can become arbitrarily complex. In the case above, the segmentation problems are exacerbated by the fact that the noun phrase quotation span occurs in a complex syntactic environment involving coordination.

6 Conclusion

In this paper, we have argued that existing models of automatic quotation annotation suffer from the tight relation between corpus annotation and model properties in particular in terms of model reusability. As an alternative, we have presented a general neural architecture, NQD, that can be trained "as is" on various corpora that differ in terms of genre, structure, and language. While the model does not reach the state of the art on any particular corpus, it performs close to it on all of them. Notably, the model is also able to deal relatively graciously with the absence of linguistic information. We will release an implementation with pre-trained models.

As NQD makes independent predictions for each token, it cannot model correlations and mutual exclusions between labels, and there is no guarantee for well-formed output class sequences. We investigated a number of extensions, including linear-chain CRF layers that are effective for Named Entity Recognition (Lample et al., 2016), but did not obtain improvements. We believe this is due to the unbounded length of quotation spans which is challenging for CRFs (Scheible et al., 2016).

The overall greatest challenge that NQD faces is data scarcity — all existing corpora with manual annotation are small, and our results show consistently bad performance for infrequent quotation types. In this situation, transfer learning seems like a natural proposition, and our model makes it possible for the first time to apply straightforward transfer learning to quotation annotation. In future work, we will explore this direction.

Abstract

In today's world, the spreading of fake news has become facile through social media which diffuses rapidly and can be believed easily. Fact Checkers or Fact Verifiers are the need of the hour. In this paper, we propose a system which would verify a claim(fact) against a textual source provided and classify the claim to be true, false, out-of-context or inappropriate with respect to that source. This would help us to verify a fact as well as know about the source of our knowledge base against which the fact is being verified. We used a two-step approach to achieve our goal. First step is about retrieving the evidence related to the claims from the textual source. Next step is the classification of the claim as true, false, inappropriate and out of context with respect to the evidence using a modified version of textual entailment module. The accuracy of the best performing system is 64.95%.

1 Introduction

Fact Checking is one of the biggest buzzwords of this era. Many a time, the news transmitted through social media can be moulded and altered when so many people share information and it is hard to discern between fact and fiction. So there is a need to verify every piece of information we observe in our day-to-day life to be true or false. A solution to this problem is, we check each claim or fact manually against a reliable source and then label the claim or fact to be either true or false which is time consuming for large data. Vlachos and Riedel (2014) discussed the fact verification process as an ordinal text classification task, where they created a data-set using the manually annotated data present on sites like PolitiFact, FactCheck, FullFact. The FakeNews Challenge[1] by Riedel et al. (2017) addresses fact-checking as a simple instance detection problem, which mainly checks whether the given instance is in accordance with the article or not. Recently Thorne et al. (2018a) published a huge data set to deeply understand the process of large scale fact-checking. All of the above approaches rely completely upon the source against which data is to be verified, but in some cases, the source text might contain limited or no amount of information about the claim and a claim might be *Out-of-Context* of this source text. This leads to a problem of classifying a claim to be within the scope/context of the source text or not. Concretely, we do need a system which would not only classify a claim to be true or false but also check whether the source text is sufficient enough to classify the claim. To address this issue, in this paper, we come with an approach to verify facts or claims against a reliable source and classify them into 4 different classes.

In our approach, a claim or fact is classified as *True* (if a proper supporting evidence is available from the source text), *False* (if a contradicting evidence is available from the source text), *Inappropriate* (nothing can be concluded about the claim based upon evidence retrieved) or *Out-of-Context* (out of the scope of the source text). Prior to the classification, the evidence is retrieved from the

[1] www.fakenewschallenge.org/

textual source related to a given claim. If the textual source has no knowledge about the claim, it would be labelled as '*Out-of-Context*' for example if we have a source text about sports and we need to verify a claim related to politics then the claim is *Out-of-Context*. Although if it has some information about the claim it would further be classified as *True*, *False* or *Inappropriate*. The result would be '*True*' if the source supports the claim, it would be '*False*' if the source opposes the claim and it would be labelled as '*Inappropriate*' if the evidence is not sufficient to conclude the classification of the claim, e.g., knowing that Michael Jackson was a singer, we cannot infer whether his children will be singers. This is something inappropriate to the information provided. Hence the claim 'Michael Jackson's children would be singers' is an inappropriate claim for the evidence 'Michael Jackson was a Singer'. This labelling would not only help in knowing about the claim but also helps us to know about our textual source as well. The labels *Inappropriate* and *Out-of-Context* claim tell us whether the textual source has enough information to conclude about the claim or not, if a claim is *Out-of-Context* then the domain of our source text can be expanded to answer the claim. *Inappropriate* means that we do have required knowledge about the claim and also cannot conclude anything based upon this available knowledge. The best performing version of our system is seen to be giving 63.06% accuracy.

In Section 2 we have mentioned various works done by different authors related to fact extraction and verification. Section 3 explains the data-set collection and the system architecture to classify claims against a textual source. Section 4 describes the stages of this experiment which are evidence retrieval, similarity measures used to obtain the relation between claim and evidence, the first level of classification of the claim into in-context and out-context, then the further classification of in-context claims to *True*, *False* and *Inappropriate* claim. In Section 5 we discussed error analysis of our system along with the results obtained on using different classification algorithms on our data for classification purpose and comparative measure between different models. In Section 6 we conclude about our model with its practical usage in the real world.

2 Related Work

There has been a substantial amount of work done in the field of fact verification. Vlachos and Riedel (2014) provided the first dataset related to fact verification containing 211 labelled claims in the political domain with evidence hyperlinks. An alternative is Wang (2017) which released a dataset called LIAR dataset for detecting fake news, which contains 12.8K claims labelled manually using POLTIFACT.COM[2] on different context. Alhindi et al. (2018) extended the LIAR dataset and labelled a claim using the speaker related metadata without using the evidence. Basically, they used the justification given by the humans at the end of the article in the summary. Modelling the extracted justification along with the claim yielded better results rather than using a machine learning model for binary classification and a six way classification. Ferreira and Vlachos (2016) later presented a new modified dataset known as Emergent, where they had 300 claims and 2,595 related articles and they came to the conclusion that fact verification can also be treated as Natural Language Inference Task, as they used textual entailment to predict whether the article supports the claim or not. The latest large scale dataset is prepared Thorne et al. (2018a) which was annotated manually and used for verification against textual sources. It contains 185,441 claims generated from Wikipedia. These claims were classified Supported, Refuted and Not Enough Info by annotators. In this, Recognizing Textual Entailment (RTE) component was proceeded by an evidence retrieval module. The accuracy measured found to be 31.87% if evidence was taken into consideration and 50.91% if evidence is ignored. The only drawback of this system is its restriction to the Wikipedia domain. Thorne and Vlachos (2018) conducted a survey on automated fact checking research stemming using natural language processing and other related fields. According to this survey, the inputs for verification system play a vital role. Evidence retrieval plays a vital role in solving the fact verification problem. Fact checking requires the apt evidence against which sentences can be predicted to be true or false. Chen et al. (2017a) provides a framework for open domain question answering upon Wikipedia and SQuAD data set. This involved machine reading along with the document

[2] www.politifact.com

retrieval and then identifying the answers. We deal with a similar retrieval problem like open domain Question Answering, which would be succeeded by verification using textual entailment. Natural Language Inference is basically a task to find out whether a hypothesis entails, contradicts or is neutral about the claim. There have been recent developments in these fields like the SNLI dataset for learning natural language inference built by Bowman et al. (2015). Different neural NLI models (Nie and Bansal (2017); Parikh et al. (2016); Chen et al. (2017b); Gong et al. (2018)) that achieve promising performance. Parikh et al. (2016) has the highest accuracy on the Stanford Natural Language Inference task. We used the similar approach as the FEVER (Thorne et al., 2018c) but, instead of a three class classification we have extended it to a four class classification namely *True*, *False*, *Inappropriate* and *Out-of-Context*. These two modules combined together help us in validation of a fact. In 2018, a shared task known as the FEVER Shared Task (Thorne et al., 2018b) was held which dealt with the fact verification problem. The FEVER shared task is closely related to our work as it uses the same two modules. The following are some of the systems that participated in the FEVER shared task: Nie et al. (2018) have scored the maximum of 64% accuracy in the FEVER shared task, in which they used the neural semantic matching networks. For both the evidence retrieval and RTE model they enhanced the working using the neural networks. Hidey and Diab (2018) known as the Team Sweepers, made the evidence retrieval system better using lexical tagging and syntactic similarity. They used multitask learning and trained both the components together and set the parameters in a way using reinforcement learning so that it can first find sentences related to the claim and then find their relation with the claim. DeFactoNLP (Reddy et al., 2018) aimed at retrieving the evidence for the valuation of the claim from Wikipedia. The retrieval of documents which is considered as evidence is done by TF-IDF vectors of the claim and the sentences in the documents followed by inputting them to a textual entailment recognition module. Then the Random forest classifier is used for the classification of the claim. Lee et al. (2018) have introduced a method by developing a neural ranker using decomposable attention model and lexical tagging instead of TF-IDF for evidence retrieval part. Lexical tagging is done by using two lexical tags name such as Parts-of-Speech and Named Entity Recognition to enhance the performance.

3 System Architecture

In this section, we discuss the overview of our system and our approach for classifying a claim based upon a particular source text. Our approach is divided into two stages: Evidence Retrieval and Classification of claim as *True*, *False*, *Inappropriate* or *Out-of-Context* using a textual entailment module. The reason for using textual entailment is because it precisely gives us a relationship between an evidence and a claim. In the first stage i.e., evidence retrieval, given a claim, we find its TF-IDF vectors corresponding to the source text against which it is being verified.

Later we find out the cosine similarity between the TF-IDF vector of a claim to each of the sentences present in the source text. Then, we filter out the top four sentences which have the highest cosine similarity values and consider this as the evidence for that particular claim as discussed in section 3.2. The reason for considering top 4 sentences is that they closely correspond to the nearest sentences to the claim. In the next stage, the extracted evidence and the present claim are passed into a Textual Entailment module which returns the probabilities of two texts entailing, contradicting or neutral towards each other. These probabilities along with other variables discussed later are used as a feature vector for our classification model. The entire claim classification process is explained in 3.3. Section 3.1 describes the process of preparation of the dataset.

3.1 Dataset

Due to the uniqueness of our classification, we were supposed to either prepare our own dataset or modify an existing standard dataset for serving our purpose. Here, we have done both, we modified a dataset known as the SICK dataset and prepared a new dataset called the NITA dataset.

3.1.1 SICK Dataset

The main target of our experiment was to classify a claim based upon its evidence, so we required a dataset consisting of sentence pairs and a correlation between these two sentences. Hence we used a publicly available dataset known as the SICK dataset. The SICK-2014 dataset (Marelli et al., 2014) was introduced as Task 1 of the SemEval

ID	Sentence1	Sentence2	Entailment	Score
23	A group of kids is playing in a yard and an old man is standing in the background	A group of boys in a yard is playing and a man is standing in the background	yes	4.5
14	A brown dog is attacking another animal in front of the man in pants.	Two dogs are fighting.	unknown	3.5
13	Two dogs are wrestling and hugging.	There is no dog wrestling and hugging.	no	3.3

Table 1: Sample SICK dataset with entailment labels and relatedness scores.

Source Text	Claim/Fact	Label
The Lion King	Mufasa is Father of Simba	True
The Lion King	Ram killed Ravan	Out of Context
The Lion King	Cats hate Lions	Inappropriate Claim.

Table 2: Sample NITA dataset.

2014 conference and in contrast to SNLI (Bowman et al., 2015), it is geared at specifical benchmarking semantic compositional methods, aiming to capture only similarities on purely language and common knowledge level, without relying on domain knowledge, and there are no named entities or multi-word idioms. It consists of total 10,000 pairs of sentences.

We modified the SICK dataset as per our classification by adding two more columns to it. We manually labelled a claim and an evidence pair to be in-context or out-context based upon their relatedness score as given in the dataset, which indicates the semantic similarity of these pair of sentenced. Firstly, we labelled all the pairs with relatedness score less than 3 as *Out-of-Context* and other claims as *True*, *False* or *Inappropriate* based upon their textual entailment labels provided by the SICK dataset.

3.1.2 NITA Dataset

After considering SICK dataset we even wanted to develop our own dataset consisting of source texts and claims along with their labels as follows:

- **Source Text Collection**: We collected some short stories and articles related to *sports, movies, mythology, moral stories, Wikipedia articles* in English language and considered them as source texts. The total number of source texts collected in this way turned out to be 53 .

- **Claim Generation**: Corresponding to these 53 stories/articles/textual content, we prepared a total of 928 claims. The purpose was to generate claims about a single fact which could be arbitrarily complex and allowed for a variety of expressions for the entities. The claims were generated based upon every source text. For example, consider "The rabbit tortoise race" as the source text, one of the claims related to this source text can be "Rabbit won the race".

- **Claim Labelling**: Classifying whether a claim is *True*, *False*, *Inappropriate* or *Out-of-Context* based on the evidence from source text was done at this stage. We checked every claim manually with respect to its source text and labelled the claim accordingly. The labelling is done as per the meaning of each label which was discussed in the introduction section.

- **Dataset Validation**: Considering the complexity of labelling of claims, we considered validation of the data set generated by us. For this purpose we tried to analyse the labels we gave to each claim, where labels generated by one person were analysed by other to establish an inter annotator agreement. We considered around 30% that is 240 claims for this validation process and calculated the Fleiss k score (Fleiss, 1971) to be 0.876.

LABEL	No. of Claims
TRUE	170
FALSE	170
OUT-OF-CONTEXT	420
INAPPROPRIATE	168
Total No. of Claims	**928**

Table 3: NITA Dataset Splitting based upon Labels

3.2 Evidence Retrieval

We used the concept of Document Retrieval from the DrQA system (Chen et al., 2017a). Firstly, we find out the Term Frequency-Inverse Document Frequency (TFIDF) vectors (Hiemstra, 2000) for a claim and the sentences of the source text. We then calculate the cosine similarity between the claim and each sentence. Thereafter, we pick the top four similar sentences based on the cosine similarity between the bigram TF-IDF vectors of the sentences and the claim. These sentences are finally chosen as possible sources of *evidence*. Now, we are left with claim and evidence pairs.

3.3 Classification

In this final stage, we classify all the claims to be *True*, *False*, *Inappropriate* or *Out-of-Context* using machine learning classification models. The features for this classification are obtained by passing a claim and an evidence to a textual entailment module in order to obtain probabilities of entailment, contradiction and neutrality between claim and evidence. The RTE is the process of determining whether a text fragment (Hypothesis H) can be inferred from another fragment (Text T) (Sammons et al., 2012). The RTE module receives the claim and the set of possible evidences from the previous stages. Let there be 'n' possible sources of evidence for verifying a claim. For the ith possible evidence, let $\mathrm{s_i}$ denote the probability of it entailing the claim, let $\mathrm{r_i}$ denote the probability of it contradicting the claim, and let $\mathrm{u_i}$ be the probability of it being uninformative. The RTE module calculates each of these probabilities. The SNLI corpus (Bowman et al., 2015) is used for training the RTE model. This corpus is composed of sentence pairs T, H where T corresponds to the literal description of an image and H is a manually created sentence. If H can be inferred from T, the "Entailment" label is assigned to the pair. If H contradicts the information in T, the pair is labelled as "Contradiction". Otherwise, the label 'Neutral' is assigned. We chose to employ the state-of-the-art RTE by (Parikh et al., 2016). We selected this because at the time of development of this work, it was one of the best performing systems on the task with publicly available code.

For a particular claim *c* and an evidence *e* let s_i denote the probability of it entailing the claim, let r_i denote the probability of it contradicting the claim, and let u_i be the probability of it being uninformative returned by textual entailment. Below are some variables we considered for our convenience:

$$cs_i = \begin{cases} 1 & \text{if } s_i \geq r_i \text{ and } s_i \geq u_i \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

$$cr_i = \begin{cases} 1 & \text{if } r_i \geq s_i \text{ and } r_i \geq u_i \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

$$cu_i = \begin{cases} 1 & \text{if } u_i \geq s_i \text{ and } u_i \geq r_i \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

$$CosineSimilarity = \Big\{ cos(\theta) = \frac{C.E}{||C||||E||} \tag{4}$$

The similarity variable used here is cosine similarity between claim and evidence. The value C and E denote the vector notation of claim *c* and evidence *e* based upon their word frequency. Consider the cosine similarity between claim and evidence *i* to be S_i. Using above variables we form a feature vector for each claim and evidence pair for the classification model *i* as:

$$\textit{feature vector} =< s_i, r_i, u_i, cs_i, cr_i, cu_i, S_i >$$

The above *feature vector* give us an understanding of how closely two statements are related i.e., a relationship between claim and evidence. Some statements which are a negation to each other may have high cosine similarity but then their contradiction probability would be high which would help the learning algorithm to classify claims accurately. We used both the datasets i.e., the SICK dataset and the NITA dataset, along with the above mentioned feature vector for training and testing purpose of various machine learning classification models like Naïve Bayes, Logistic Regression, Support Vector Machine, Random Forest and Multi-Level Perceptron. These models were used as they are widely used in the industry for practical applications.

4 Experiments

As mentioned in section 3, our model of fact verification consists of two stages:

1. *Retrieving evidence related to the claim from the source text.*

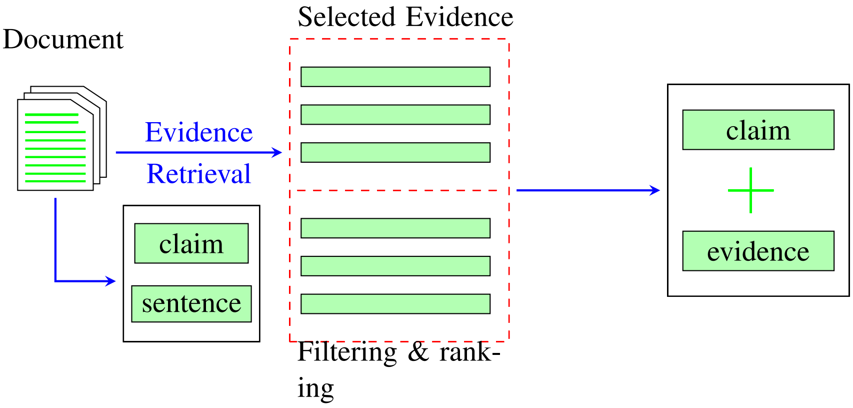

Figure 1: System Overview: Document Retrieval, Sentence Selection, and Claim Verification.

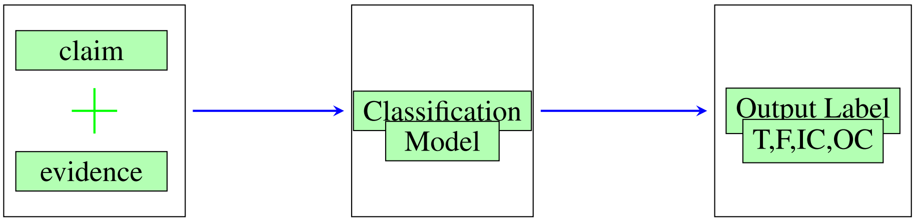

Figure 2: System Overview: Claim Classification Process.

Relatedness		**Entailment**	
[1-2) range	923 (10%)	NEUTRAL	5595 (57%)
[2-3) range	1373 (14%)	CONTRADICTION	1424 (14%)
[3-4) range	3872 (39%)	ENTAILMENT	2821 (29%)
[4-5) range	3672 (37%)		

Table 4: Distribution of SICK sentence pairs for each gold relatedness level and entailment label.

2. *Classifying a claim to be True, False, Inappropriate and Out-of-Context with respect to the source text.*

4.1 Evidence Retrieval

We used the uni-gram TF-IDF vector of sentences of the source text and the claim and computed the cosine similarity between various sentences from source text and claim. Based upon their cosine similarities, we selected a concatenation of top four sentences as evidence for the claim from the source text. After the evidence is retrieved, we are now left with a claim and an evidence upon which classification of claim is to be carried out in the next stage. In NITA dataset, we have a column describing the name of source text from which we wish to derive evidence from the claim.

4.2 Classification of Claims

In this stage we classify the claims using textual entailment module. For accomplishing the textual entailment task, we used the decomposable attention model developed by Parikh et al. (2016). This model was trained and tested upon the Stanford Natural Language Inference (SNLI) Corpus and has a test accuracy of 86.8% . We used this model to obtain probabilities of entailment, contradiction, and neutrality between a claim and evidence and further developed more variables as discussed in Section 3. The feature vector along with modified SICK data was passed into various classification models. We used the same approach for the NITA dataset. The test and train dataset split for both the above experiments was 60% training, 20% cross validation and 20% testing. The results of experiments on both the datasets are as in Table 5 which consists of the weighted average of all

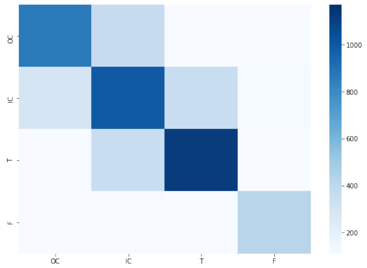

Figure 3: Random Forest Confusion Matrix for SICK Dataset

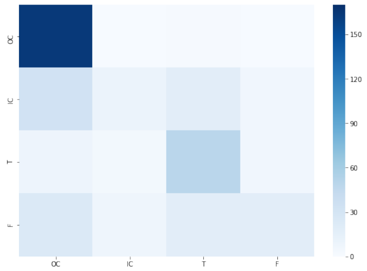

Figure 4: Random Forest Confusion Matrix for NITA Dataset

the results.

SICK dataset consists of pair of sentences and their relationship, hence evidence retrieval part for this dataset is skipped. The highest accuracy model observed with both the datasets is the "Random Forests" model with 100 trees and a maximum depth of 5.

5 Error Analysis

On observing the results it was found that the false claims were the most error-prone and have the least correct results. The SICK dataset gave better results in comparison to the NITA dataset prepared by us which is depicted by the random forest confusion matrix in Figure 3 and 4. The reason behind this could be that the evidence retrieved in the evidence retrieval part was not appropriate consisting of punctuation symbols and the other unwanted context in its text. On observing the results it was found that the false claims were the most error-prone and have the least correct results. The possible reasons for this could be the low probability rate of contradiction returned by the textual entailment module and also high cosine similarity, because in some instances the claim and evidence pair can be a negation of each other and hence have high word similarity. Next, upon observing results produced by the classification model, we saw that most inappropriate claims were classified as true and some true claims were classified as inappropriate. This ambiguity is mainly due to evidence supporting a claim partially, the probability of entailment for this would be high but due to variance in cosine similarity between claim and evidence there can arise an ambiguity. The overall system performance is at par with other existing fact verification systems as mentioned in section in terms of accuracy. Further modifications to improve the performance of the system are discussed in the next section .

6 Conclusion and Future Scope

The uniqueness in our approach is classifying a fact into four classes, this not only gives information about the fact whether it is true or false but also gives us an insight whether the source text we are using is limited. The *Out-of-Context* label particularly tries to validate the scope of our source text whether the source is enough to classify a particular fact/claim.

Here we discussed about the modification of the SICK dataset as per our requirement along with our approach of carrying out the process of classifying our claims. Compared to the existing fact verification systems such as FEVER systems which classifies a claim only into 3 classes, our model classifies a claim into 4 classes giving additional information. Our system can have many practical applications like subjective paper correction, fake news identifier, social media fact checking, etc. We believe that our system will provide a stimulating challenge for claim/fact extraction and verification systems and be effective for knowing about the scope of the source.

In future, we wish to tackle the problem of restricting our system for a particular source text, by enabling the system to extract evidence from a larger source like the internet itself by using various APIs provided by prominent search engines such as Google API to get appropriate evidence. Next thing we wish to implement further as a modification in our system is come up with a larger dataset comprising of our 4 class classification labels to train our system for better accuracy.

Data-set	Model	Precision	Recall	F1-score	Accuracy
SICK	Naive Bayes	0.53	0.53	0.50	0.535
	SVM	0.58	0.58	0.57	0.582
	Random Forest	0.63	0.63	0.63	0.630
	Logistic Regression	0.57	0.58	0.57	0.577
	MLP	0.63	0.62	0.63	0.624
NITA	Naive Bayes	0.61	0.63	0.59	0.631
	SVM	0.62	0.65	0.61	0.649
	Random Forest	0.61	0.65	0.61	0.649
	Logistic Regression	0.61	0.65	0.60	0.649
	MLP	0.61	0.64	0.61	0.644

Abstract

This paper presents Semantic Neural Networks (SNNs), a knowledge-aware component based on deep learning. SNNs can be trained to encode explicit semantic knowledge from an arbitrary knowledge base, and can subsequently be combined with other deep learning architectures. At prediction time, SNNs provide a semantic encoding extracted from the input data, which can be exploited by other neural network components to build extended representation models that can face alternative problems. The SNN architecture is defined in terms of the concepts and relations present in a knowledge base. Based on this architecture, a training procedure is developed. Finally, an experimental setup is presented to illustrate the behaviour and performance of a SNN for a specific NLP problem, in this case, opinion mining for the classification of movie reviews.

1 Introduction

In recent years, the increase in the volume of available data has provided both new techniques and new challenges for discovering relevant knowledge. The huge amount of information produced daily makes it impossible for humans to manually build organized representations of all this information. On the other hand, the surplus of information enables the design of statistical learning techniques which scale better with large data. Deep learning approaches have successfully obtained state-of-the-art results for many learning problems, from image recognition to natural language parsing. Instead of handcrafted representations designed by experts, deep learning automatically builds representations from raw data that are suitable for a given machine learning problem.

When deep learning is used, we can often identify structures inside a neural network, which can be explained as high-level concepts that are automatically discovered during the learning process (Bengio, 2012). For instance, in the image recognition domain, often internal neurons or groups of neurons can be identified to recognize common visual features such as textures or patterns or even specific objects (Le, 2013). Hence, the neural network is able to build high-level concepts from low-level input (i.e., pixels). This ability to discover higher-level features is one of the main strengths of deep learning and representational learning in general (Bengio, 2012). However, one of the main challenges of deep learning is interpreting the internal representations of a neural network in terms that can be understood by humans and mapped to clearly defined domain concepts (Montavon et al., 2017).

To address this challenge, our proposal is to“persuade” a neural network to build representations that can be interpreted in terms of a formal conceptualization (such as a knowledge base). This intuitive approach, as opposed to hand-crafting features, would still allow the neural network to learn the best representation of the input, while enabling a better interpretation and explanation of the whole learning process.

Our approach involves designing specific neural network components —Semantic Neural Networks (SNNs)— that are trained to learn how to map raw input to specific domain concepts that are extracted from a convenient knowledge base. These components could then be included in larger deep learning architectures, providing a semantic representation of the input that the rest of the network could learn to use for solving a specific problem.

In this work, SNNs have been designed to represent the relevant concepts of a knowledge base as part of the artificial network architecture. Hence, during the whole process, the structures that map to specific concepts and relations are clearly identifiable inside the network. This process attaches a semantic meaning to the network architecture, which is useful for debugging and understanding the learning dynamics. Furthermore, the SNN is trained to learn the specific instances in the knowledge base and their relations. This way, the SNN not only encodes abstract concepts, but also true facts about instances of those concepts. Preliminary source code is available online for the research community.[1]

When used as a component of a larger deep learning architecture, a SNN that is trained for a specific knowledge domain can be seen as a semantic representational component. Its input consists of a low-level representation of data, (for example, words or entities), and its output consists of an implicit representation of this data expressed in terms of the learned domain. This representation can be seen as a type of embedding that maps raw input to a semantic space defined by the concepts and relations of the learned knowledge base. The SNN is used as a representational layer in a larger neural network, for a natural language processing problem in which the semantic representation induced by the learned knowledge base is expected to be a good representation.

The paper is organized as follows. Section 2 presents a review of related works and relevant concepts in the domain of representational learning, with an emphasis on different semantic representations of natural language. In section 3 the architecture and training procedure for the SNN is formalized and explained. Section 4 presents a brief experimental setup designed to illustrate the behavior and performance of a SNN in a specific natural language problem. Finally, section 5 discusses the main contributions of this proposal, whereas section 6 presents the final conclusions of the research and highlights possible future lines of development.

2 Related Works

Building semantic representations of raw input data, specifically for natural language text, is a common task for many machine learning problems. In this section we present different approaches to the design of semantic representations for natural text.

Network-Based Approaches for semantic representations usually consist of defining some similarity metric based on the relations of terms in some knowledge base, interpreted as a graph. It is based in the assumption that words which are connected by short paths in a knowledge base should have similar semantics. WordNet is commonly used as a knowledge base where different semantic relations among words can be exploited for defining similarity metrics. Using WordNet (Miller, 1995), several semantic similarity metrics are defined by exploring the graph structure of the knowledge base, mostly depending on the graph structure of words, such as *Hirst-St-Onge* (Hirst and St-Onge, 1998) and *Leacock-Chodorow* (Leacock and Chodorow, 1998). In this direction, other researchers include information content formulae to measure appearances of terms in a corpus, such as the *Resnik* metric (Resnik, 1999).

Corpus-Based Similarity Metrics are defined by some measure of the co-occurrence of terms in a corpus of natural text. The intuitive idea is that words which co-occur within the same context must have similar semantics. One such metric is PMI-IR (*point mutual information - information retrieval*) (Turney, 2001), which considers the information content of each pair of words (w_i, w_j), measured as the relative number of co-occurrences of w_i and w_j in a document, with respect to the individual count of occurrences of each word. Another corpus-based similarity metric based is ESA (*explicit semantic analysis*) (Gabrilovich and Markovitch, 2007), which considers Wikipedia as a corpus for building a co-occurrence matrix of words. A similar approach is HAL (*hyperspace analogue to language*) (Lund and Burgess, 1996), which also builds a co-occurrence matrix, but only considering words within a small window.

Dimensionality Reduction Techniques such as PCA (*principal component analysis*) (Martinsson et al., 2011) can be interpreted as a projection from the BOW (bag of words) or TF-IDF (term frequency - inverse document frequency) space to a semantic space. An interesting recent approach, that mixes ideas from the previous tech-

[1] `https://github.com/knowledge-learning/snn`

niques, is the family of word embedding algorithms (Mikolov et al., 2013). In word embeddings, similar to PCA, each word is mapped to a vector which encodes the semantics of the word. The embedding is chosen such that a word's vector contains an implicit representation of the probabilistic distribution of the word's context in a given corpus. To achieve this, a neural network is trained to predict, given a word w_i's embedding, the probability that some other word w_j appears in a small window centered around w_i. In this sense, word embeddings can be seen as a generalization of corpus-based metrics, whereby the best representation is learned from the data, rather than handcrafted. Even though word embeddings don't explicitly model specific semantic relations (such as hypernymy, or synonymy), it has been shown that several interesting semantic relations get encoded in specific directions in the embedding space, enabling the solution of analogue inference queries (Schnabel et al., 2015).

Entity Embeddings are a specific type of embedding technique that encodes the context of entities in a knowledge base. Several metrics can be used to define the notion of "context similarity" when using a knowledge base for entity embedding. For example, embeddings can be designed such that a particular direction d_r is associated with each particular relation of the knowledge base, such that $e_i + d_r \approx e_j$ whenever e_i and e_j are related by r. These formulations allow a semantic meaning to be attached to a particular algebraic operation and properties, and enable a whole new field of study that finds the "meaning" of, say, other directions d which are orthogonal to or linearly dependent on a specific relation. Entity embeddings have been extended to encode also the hierarchical structure of knowledge bases (Hu et al., 2015) and mixed with word embeddings for tasks such as entity disambiguation (Yamada et al., 2016).

Word and entity embeddings in general are promising approaches to deal with learning semantic representations of data. Moreover, recent research deals with finding ways to exploit the structure of these representations to explain why a specific answer is output by a neural network. Being able to explain neural networks is a first step towards designing accountable machine learning systems that humans can trust for solving the most crucial problems (e.g.medical diagnosis or legal advice). By carefully designing the learning criteria and structure of embeddings, it is conceivable that a semantic representation can be interpreted in terms of a formal conceptualization defined *a priori*.

3 Semantic Neural Networks

We define a Semantic Neural Network (SNN) as an artificial neural network architecture that encodes knowledge. Two main semantic elements are encoded from the Knowledge Base. First, the graph structure of the Knowledge Base (i.e. entity classes and their relations) is directly represented in the architecture of a SNN. Second from a Knowledge Base KB, the information about which instances belong to which entity classes and their specific relations are encoded into the weights of the SNN. By design, the architecture of the SNN is built to represent each specific entity class and relation in a clearly recognizable structure (a set of neurons with a pre-designed connection pattern). This allows a semantic meaning to be attached to an activation of the SNN in terms of the classes and relations defined in the Knowledge Base.

The purpose of the SNN is to provide a semantic representation of the input data that can be used as component inside a larger deep learning architecture, to solve a related learning problem L. If the knowledge represented in KB is useful for solving the problem L, then the representation provided by the SNN should be richer than plain bag-of-words or general purpose embeddings. With the same computational power (same number of parameters), a deep learning architecture using a SNN is expected to achieve equal or better performance than using other representations not specifically designed to exploit the knowledge in KB. Furthermore, the SNN architecture provides a semantic explanation for the model's predictions.

A SNN is built based on a specific Knowledge Base KB which is of interest for solving a related learning problem L. Figure 1 shows a schematic representation of the process for constructing, training and using an SNN in an arbitrary learning problem L. First, given the problem L to solve, a relevant Knowledge Base KB is chosen. The entity classes and relations of KB are used to define the architecture of the SNN (Section 3.1). Then, training instances are

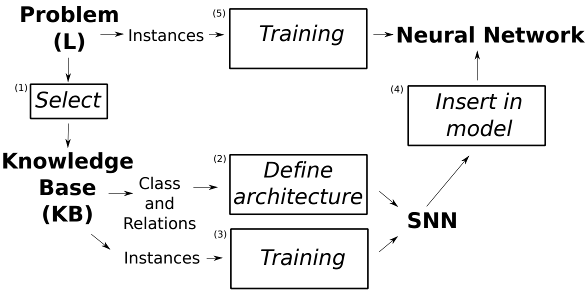

Figure 1: The process for constructing and using a SNN for a specific learning problem (L) and a suitable Knowledge Base (KB). The SNN is first defined and pre-trained based on KB, and then used in a larger neural network trained specifically for L.

extracted from KB and used to pre-train the SNN weights (Section 3.2.1). Afterwards, the SNN is included in a deep learning model (which can contain other components such as extra layers). Finally, this larger model is trained on instances from L using standard optimization techniques and loss functions suitable for the problem L (Section 3.2.2).

Different Semantic Neural Networks can be trained on different Knowledge Bases ahead of time and reused for many related problems. In this sense, SNNs are similar to pre-trained word embeddings, since a SNN trained for a commonly used Knowledge Base (i.e., DBPedia or WordNet) could be useful in solving different problems. However, pre-trained SNNs can (and should) be fine-tuned on a specific problem L after deciding a convenient deep learning architecture for this problem.

3.1 Architecture of the Semantic Neural Network

The architecture of a Semantic Neural Network (SNN) is composed of several instances of two simple structures: **entity blocks** and **relation blocks**. For each class of the knowledge base, an entity block is created, and for each relation, a corresponding relation block.

An **entity block** is a computational graph with a single input variable and a single output variable. The input dimension and shape is determined by the specific application, a sensible default consists of a single one-hot encoding layer when using a bag-of-words representation, but an alternative input could be a general-purpose word embedding representation. The output dimension is a fixed size dense vector of small dimension (e.g., 10). The input and output are connected by a linear matrix operator. Additionally, a one-dimensional indicator neuron is connected to the output layer through a dot product operator with a sigmoid activation function. The purpose of the indicator is to signal when the activation of the output is large in absolute value. This is interpreted as the importance of the corresponding concept in a particular input text.

A **relation block** is a similar computational graph, but with an input variable whose size is twice the entity output size. Thus, the relation input shape corresponds with the output shape of the two entity blocks that will be connected. The outputs from each incoming entity block are concatenated, forming a single vector, which is then connected through a linear matrix operator to the output variable. An identical indicator neuron is connected to the output variable.

The overall architecture of an SNN consists of several entity blocks, one for each class in the knowledge base, and several relation blocks, one for each relation defined. The entity blocks are all connected to a single input (e.g., a bag of words representation). Every relation block is connected to the respective outputs of the entity blocks that represent the classes for which the relation is defined. Figure 2 shows a schematic representation of an example SNN built from a knowledge base in the cinematic domain (specifically the Internet Movie Database, IMDB).

The input size of the SNN is the size of some vocabulary chosen before hand. This vocabulary should include the common terms in the knowledge domain(s) of interest. An additional input dimension can be added to account for unknown words (those not present in the vocabulary at the moment of training).

3.2 Training the Semantic Neural Network

The training procedure for a SNN is divided in two phases, each of which solves a different learning problem. In the first phase, which we call “structured pre-training”, the parameters of the entity and relation blocks are adjusted. The learning objective for this phase consists of predicting to which instance of the knowledge base the sample of natural text refers. In the second phase, in order to deal with the original natural language process-

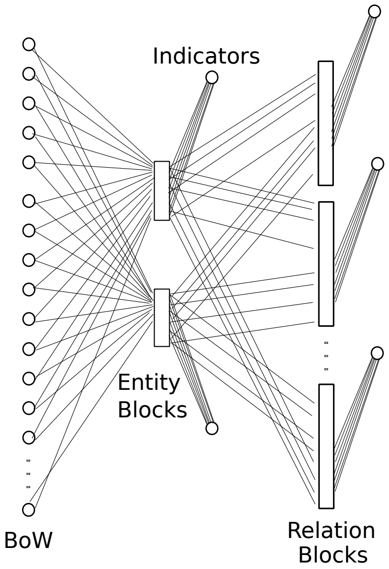

Figure 2: Schematic representation of a Semantic Neural Network, for an example knowledge domain in the film industry. The input layer consists of a bag of words (BOW) representation. The middle layer contains all the entity blocks (Movie and Person in this example) and the final layer contains all the relation blocks. The indicator outputs are one-dimensional sigmoid neurons.

ing problem, a standard training is performed. In this phase, the parameters of the rest of the network are adjusted. The internal parameters of the SNN can either be frozen, or optionally, adjusted together with the rest of the network in a post-optimization phase.

3.2.1 Structured Pre-Training

During the structured pre-training step, a knowledge base is used to extract random instances and adjust the SNN parameters. This knowledge base is the same as that chosen for designing the architecture, i.e., to choose the entities and relations which are represented in the SNN blocks. A random instance of this knowledge base is a tuple (e_i, r, e_j) which asserts the relation r between entities e_i and e_j. In this instance, e_i and e_j are assumed to have a natural text label associated (e.g., a name, description, tag, etc.).

The SNN learns to represent natural text in a manner which resembles the entity extraction process. Note that no natural text is associated to the label of the relation. Hence, in order for the SNN to accurately predict that relation $r(e_1, e_2)$ is true for a specific pair of entities e_1, e_2, but false for another pair of entities, the "list" of pairs of entities that hold in each relation must be encoded in the W_r weights of the corresponding relation block. Furthermore, in order to differentiate the relations, the SNN needs to learn to differentiate the entities implicitly because there is no requisite to define the specific learning objective, namely representing different entities and their corresponding encodings.

3.2.2 Unstructured Training

After the pre-training phase is completed, standard training proceeds. In this phase, given the characteristics of the learning problem, the training is performed. For example, if the problem consists of text classification (i.e., opinion mining, topic detection, etc.), then the training examples consist of pairs of single-hot encoded text and the corresponding class label. The exact parameters of the training depend on the problem characteristics, and are thus left unspecified in this proposal. During this training phase, the parameters of the SNN are frozen, i.e., they remain unchanged throughout the training procedure. The reason for this is that the parameters of the SNN have already been adjusted, and the rest of the parameters are randomly initialized. Therefore, allowing the training algorithm to change the SNN parameters would destroy the learned mappings.

After the standard training, a final phase of finetunning can be optionally performed. In this final phase, all the parameters, both those of the SNN and those of the rest of the network, are allowed to change. In this phase, only small parameter updates are expected to happen, since the network should have converged in the previous phase.

4 Experimental Analysis

To analyze the behavior of the SNN, we selected a classic NLP problem and a suitable knowledge base. The selected problem is opinion mining in movie reviews, using the dataset from Pang and Lee (2004). The corpus contains 1000 positive and 1000 negative movie reviews written in English. For building the knowledge base, raw data from IMDB[2] was processed obtaining a graph representation with 2 classes (*Person* and *Movie*), 11 relations and a total 27,044,985 tuples. Table 1 summarizes the statistics of the knowledge base.

The SNN obtained from the IMDB knowledge base has the structure shown in figure 3. The input

writer	3 256 270

Table 1: Summary statistics of the knowledge base built from IMDB data.

size is 267,178 (number of unique words in a standard English dictionary), the output size of each entity block is 10, and of each relation block is 20. The total number of indicator outputs is 14 (total number of concepts present in the IMDB knowledge base). Hence, the total number of trainable parameters in the SNN is 5,350,873.

The pre-training phase is executed for 10 epochs, each one with 100 batches, and each batch comprising 100 training examples. This cycle was repeated three times, first only with entities, then only with relations, and finally with both entities and relations. Hence, a total of 300,000 training examples were used in the pre-training phase. The final validation accuracy was 0.976 for the entities cycle, 1.00 for the relations cycle and 0.987 for the combined cycle. Since there are far fewer different relation types than actual entities, convergence is expected earlier when only training with relations.

4.1 Evaluating in the Opinion Mining Problem

The performance of the pre-trained SNN was evaluated by including it as an internal component in a larger neural network. This neural network was applied to the original problem of classifying movie reviews. The architecture of this extended neural network consists of a single-hot encoding input which is connected to the SNN. The output of the SNN is connected to three sequential dense layers with ReLU activation. A final dense layer with sigmoid layer was used, since the movie reviews problem is a binary classification problem. This network had an additional 141,361 trainable parameters.

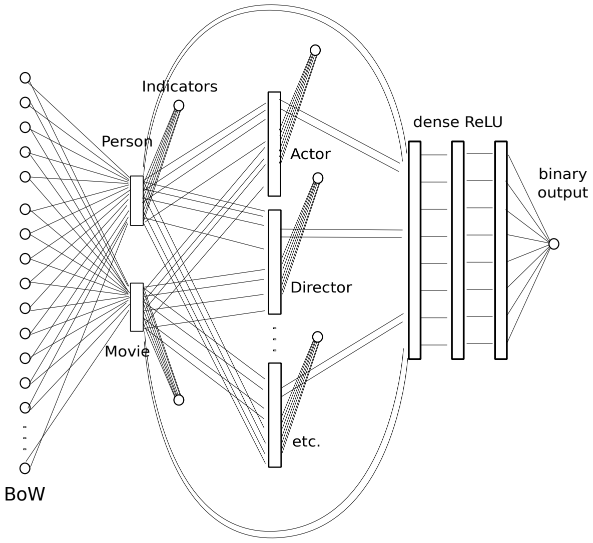

Figure 3: Schematic representation of the Semantic Neural Network trained in IMDB. Not all relation blocks are shown, given space constraints.

Training was performed only on these new parameters for 10 epochs, using 100 batches each one with 100 samples per epoch. After this process, the SNN parameters were unfrozen, and a fine-tune training was performed with all 5,491,981 parameters.

This final training was performed for 50 epochs, until convergence was achieved. The validation accuracy obtained at this point was 0.702. Finally, an independent test set was used to measure test accuracy, obtaining 67.82% precision in the movie reviews problem.

For comparison purposes, a fully-connected feed forward neural network, with 4 dense ReLU layers and a total of 5,494,681 trainable parameters was also trained from scratch in the movie review corpus. This network achieved a test accuracy of 64.47% in the same test set used for testing the SNN. Hence, with roughly the same number of trainable parameters the SNN obtains a small, but statistically significant advantage ($p \approx 10^{-39}$). Results are summarized in Table 2.

5 Discussion

The experimental results obtained show that using a SNN provides some benefits over a stan-

Model	Parameters	Accuracy
SNN + 3 ReLU	5,491,981	**67.82**
4 Dense ReLU	5,494,681	64.47

Table 2: Comparison of performance in the opinion mining problem between different SNN-based architectures.

dard architecture. No comparison has been performed with more advanced architectures, such as Long Short Term Memory (LSTM) or Convolutional (CNN) networks. However, the purpose of SNNs is not to compete with, but rather to complement existing architectures with a new type of component that is knowledge-aware. Hence, the fact that the SNN performs effectively when combined with more traditional architectures encourages its use with other state-of-the-art deep learning components.

The most significant advantage of using a SNN is that it provides a semantic interpretation of the network's behavior. The one-dimensional indicators used for guiding the SNN training could potentially act as a signaller for the high-level concepts that are being activated in any given example. By looking at the activation patterns inside the SNN, it may be possible to obtain an explanation of the network's prediction for a given example, in terms of the concepts in the knowledge base learned. Figure 4 presents an illustrative example in the context of the NLP problem presented in Section 4.

Another advantage of SNNs is that once pretrained with a given knowledge base, they can be reused in many different architectures. In a sense, SNNs can be seen as feature extractors or representational components that are associated with a given knowledge domain. It is also conceivable to use multiple SNNs trained in different knowledge domains in the same neural network. This provides a strategy for knowledge integration, when different and possible incompatible knowledge domains are considered relevant for a particular problem. This opens the door to new strategies for transfer learning, from a more semantic perspective, where the transferred or reused knowledge can be tied to a particular domain.

In our experimental setup we used a small natural language dataset, since our purpose was not to obtain state-of-the-art results in the opinion mining problem, but rather to illustrate the design of the SNN and explain its main architectural characteristics. We demonstrated that the SNN model provides effective support to learning approaches for resolving NLP problems.

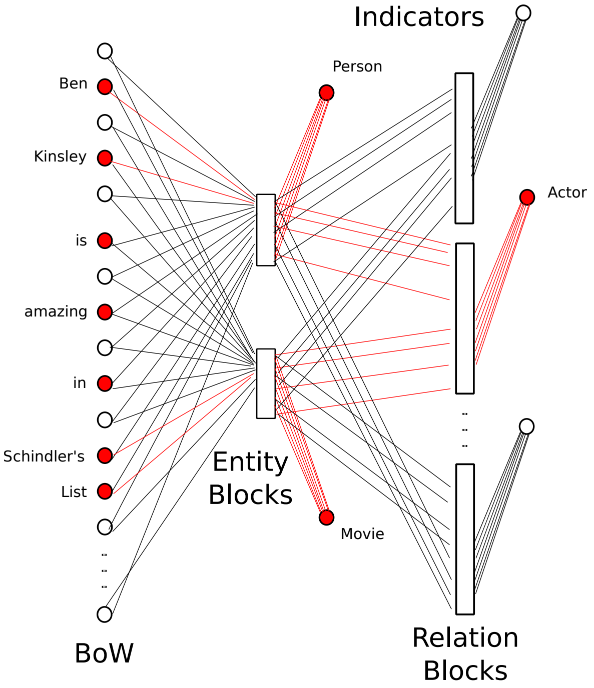

Figure 4: Illustrative example of a Semantic Neural Network activation in response to a particular input.

6 Conclusions and Future Work

In this paper, we present Semantic Neural Networks (SNNs), which allow the inclusion of explicit semantic knowledge in traditional neural networks without affecting performance. This knowledge is extracted from available knowledge bases, built by domain experts. We considered that the SNN is a first step towards raising the abstraction level in neural networks and building semantically-aware architectures that can be self-explained. A possible line of future research consists of combining multiple SNNs for multiple knowledge domains in a single problem, and studying how the different representations output by each network can be merged. Further, in the current design, the core of the SNN is a simple linear operation. In future works, we will explore other, more complex operations, which will potentially improve accuracy. It is also necessary to compare the performance of SNN-powered architectures with other state-of-the-art deep learning architectures, such as LSTMs, CNNs and different embedding strategies. Finally, the SNN internal structure has a semantic meaning attached to each neuron block. This opens the door for the design of interpretation models that can automatically output an explanation of a neural networks response in terms of human-defined concepts.

Toponym Detection in the Bio-Medical Domain: A Hybrid Approach with Deep Learning

Alistair Plum, Tharindu Ranasinghe, Constantin Orăsan
Research Group in Computational Linguistics, University of Wolverhampton, UK
{a.j.plum, t.d.ranasinghehettiarachchige, c.orasan}@wlv.ac.uk

Abstract

This paper compares how different machine learning classifiers can be used together with simple string matching and named entity recognition to detect locations in texts. We compare five different state-of-the-art machine learning classifiers in order to predict whether a sentence contains a location or not. Following this classification task, we use a string matching algorithm with a gazetteer to identify the exact index of a toponym within the sentence. We evaluate different approaches in terms of machine learning classifiers, text pre-processing and location extraction on the SemEval-2019 Task 12 dataset, compiled for toponym resolution in the bio-medical domain. Finally, we compare the results with our system that was previously submitted to the SemEval-2019 task evaluation.

1 Introduction

The task of toponym resolution (TR) is a topic in natural language processing (NLP) which is aimed at extracting locations from texts. TR includes the sub-tasks of detecting, disambiguating and finally resolving and assigning coordinates to the proper location in the text. The first step is to detect a location in a text, which can be carried out by more simple means of gazetteer lookup or named entity recognition (NER) (Piskorski and Yangarber, 2013). Next, each detected location that is ambiguous needs to be distinguished and the correct location chosen (Leidner et al., 2004). The final step involves assigning coordinates or applying some other meta-information to clearly distinguish each proposed location (Smith and Crane, 2001; Leidner et al., 2004).

TR can involve many challenges, caused by cases that are not trivial to resolve. This includes, for example, locations contained in phrases such as *London Bus Company*, which contains *London* but refers to an organisation and should therefore not be marked as a location. Furthermore, locations can be contained in other types of phrases, such as genome sequences mentioned in bio-medical texts, as seen in the SemEval-2019 data (Weissenbacher et al., 2019). For example, the location *Henan* in the string *A/Tree sparrow/Henan/4/04* could be omitted from the results, as it is part of the name of a genome. Similar problems can occur where a location might be detected in a character sequence denoting a chemical.

The increasing availability of online resources has been beneficial to TR. On the one hand large-scale geographical databases, such as GeoNames[1], make information about many different locations easily and freely available. On the other hand, readily available mapping services, such as Google Maps[2], allow users to visualise these locations. Although some of these services, such as GeoNames, have been used since the beginnings of TR (Smith and Crane, 2001; Leidner et al., 2004), they are more complete today. A lack of training and evaluation data also existed for some time, mainly reflected by the fact that no standard corpora existed up until a certain period (Leidner, 2004) and that advanced learning techniques could not be used (Smith and Crane, 2001).

Geographic information contained in texts is highly useful and, therefore, the areas where TR is applied are diverse. In the past, TR has been used to catalogue digital libraries (Larson, 1996; Hill et al., 1999) and to make information retrieval techniques spatially aware (Clough,

[1] http://www.geonames.org/

[2] http://www.google.com/maps

2005). A more specialised area included the automatic tracking of biological specimens from different places around the world (Beaman and Conn, 2003). Today, the possible uses range from analysing social media texts (Ireson and Ciravegna, 2010) to news streams (Lieberman and Samet, 2012), where locations of large-scale activity and problematic regions are mapped, respectively. A further example is the bio-medical domain, where the spreading of viruses can be tracked by analysing texts that mention locations (Weissenbacher et al., 2019). However, as the areas of application are varied, the effectiveness of toponym resolvers is also said to vary among different types of text (Gritta et al., 2018).

This paper presents further research into TR, or to be more precise the detection of toponyms. Moreover, this research was carried out in the context of SemEval-2019 Task 12: Toponym Resolution (Weissenbacher et al., 2019) and aimed specifically at subtask 2, which deals only with the detection of toponyms. To the best of our knowledge, prior work on exploring how a machine learning classifier can be used together with relatively simple string matching to detect locations in texts has been limited. Previously, we explored the use of machine learning classifiers to predict a location within short word windows in the context of SemEval-2019 Task 12 (Plum et al., 2019).We employ our system submitted to the SemEval-2019 task as a baseline and make use of the same dataset, consisting of texts from the bio-medical domain Plum et al. (2019). While the system serving as a baseline was reasonably competitive in terms of precision, it did not achieve a high recall. The neural network architectures that are used for this research are novel to this type of task even though some of the architectures have been used for sentence classification tasks like sentiment analysis, spam detection and so on.

The rest of the paper is structured as follows. We present related work in the field first (Section 2), followed by the methodology employed (Section 3). This section includes a description of the dataset, system and network architectures. Section 4 presents the overall results, which are split into classifier results at the sentence level, i.e. disregarding the indexes and therefore not comparable to the SemEval evaluation (Section 4.1) and the overall results at the word level, where explicit indexes are retrieved in order to be evaluated according as in SemEval (Section 4.2). Finally, in Section 5 we come to general conclusions about the project.

2 Related Work

Detecting and resolving locations or toponyms has undergone some changes in its approach. The topic was first dealt with more extensively towards the late 1990s and early 2000s (Larson, 1996; Hill et al., 1999; Smith and Crane, 2001; Leidner et al., 2004). These earliest approaches were aimed mainly at using geographical information for information retrieval, as well as catalogue searches in digital libraries. While the first of these approaches used named entity tagging, as well as specially constructed gazetteers to detect (Larson, 1996; Hill et al., 1999), others went beyond this and used a combination of methods to disambiguate. Smith and Crane (2001) used NE tagging and a gazetteer to detect locations, and disambiguated these using information gathered beforehand. This information, ”local” and ”document” context, is said to include co-occurring words and other locations mentioned throughout the text, respectively. The authors also use ”world knowledge” gathered from other sources, which mainly includes meta information such as coordinates, size, corresponding political entities and so on (Smith and Crane, 2001). Similarly, Leidner et al. (2004) used a combination of simple heuristics, linguistic cues, co-occurrence statistics and discourse information to detect locations and assign coordinates.

TR has shifted from the methods of earlier approaches and followed the trend of using machine learning techniques. Whereas in the past learning techniques lacked data (Smith and Crane, 2001), this is no longer the case. Approaches using machine learning with (indirect) supervision include Hu and Ge (2009) and Speriosu and Baldridge (2013). Hu and Ge (2009) make use of hierarchical structures ensuing from geographical relations, an approach said to perform in an accuracy range of 73.55 to 85.38 percent on an Australian news corpus. Speriosu and Baldridge (2013) on the other hand, present their text-driven approach, which uses context information to resolve toponyms. The classifiers themselves are trained mainly on semi-automatically generated data, obtained primarily from locations tagged in Wikipedia. While the aforementioned approach relies on the availability of gazetteers, a gazetteer-independent approach has been brought forward by DeLozier et al. (2015). This approach, which also relies on a machine learning classifier to disambiguate toponyms, solely uses NER techniques to detect locations, and is said to perform on a state-of-the-art level on the TR-CoNLL (Leidner, 2006) and Civil War corpora (DeLozier et al., 2015).

Most recently, Gritta et al. (2018) have presented a survey of the current state of TR, which they refer to as geoparsing. While the two terms are essentially synonymous, the authors use geoparsing (or geoparsers) to refer to fully fledged end-to-end systems. These include CLAVIN[3], the Edinburgh Parser (Tobin et al., 2010; Grover et al., 2010), Topocluster (DeLozier et al., 2015) and GeoTxt (Karimzadeh et al., 2019). These systems are said to perform at state-of-the-art levels, and are tested on the Local Global Corpus, as well as a corpus compiled by the authors, which is based on Wikipedia and GeoNames data (Gritta et al., 2018). However, it should be mentioned that Topocluster and CLAVIN apply learning techniques. The Edinburgh Parser and GeoTxt rely on NER and heuristics to rank possible candidates.

The evaluation of toponym resolvers is carried out on specifically created datasets or corpora. Leidner (2004) was the first to raise awareness for the need of a gold standard for these purposes. To this end, the paper describes the ongoing effort to create such a corpus, including a custom markup language (TRML) and editor (TAME) (Leidner, 2004). Later, Leidner (2006) describes the resulting corpus of the previous efforts. It is based on news articles, with $6,980$ human-annotated instances of toponyms. The corpus, utilising the CoNLL format, is still used today (DeLozier et al., 2015; Gritta et al., 2018). However, recently concerns have been raised again concerning the availability of datasets for toponym resolution or geoparsing by both Gritta et al. (2018) and Karimzadeh and MacEachren (2019). Gritta et al. (2018) have contributed their own dataset compiled from Wikipedia. In addition, Karimzadeh and MacEachren (2019) present their tool GeoAnnotator which has been developed to aid the compilation of such corpora. The tool is said to not only be useful for the creation of large-scale corpora on a collaborative basis, but also versatile enough to be used for other applications of NLP.

Our System described in Plum et al. (2019) that was submitted to SemEval-2019 Task 12 will serve as the baseline. The approach uses GATE with ANNIE to detect all the occurrences of locations in a text, using custom gazetteers based on GeoNames. Several gazetteers were tested and the best results achieved with a gazetteer of locations with a population of $15,000$ people or more. Following the string matching, two neural network models are used to classify five-word windows around the matched location. For each window a prediction is made whether a real location is contained or not. The method is reported to have a significant drawback, since a five-word context is not enough to carry out proper classification, as the location itself could, for instance, be a multi-word expression. Furthermore, the gazetteer matching carried out beforehand severely limits the overall recall of the approach, as it is not able to detect locations that are written across line-breaks, or are simply not contained in the gazetteer. In contrast to this system, the approach proposed in this paper predicts locations on a sentence-by-sentence basis, then attempts to retrieve the correct index of each location by using a gazetteer lookup.

3 System Description

This section describes the system we developed for detecting toponyms in bio-medical texts. Our approach is based on our system submitted to SemEval-2019 Task 12, described in Plum et al. (2019). It differs mainly in the order of the processing stages, as well as in the architectures that were used. The previous system matches location names using a gazetteer, followed by a machine learning classifier to predict whether the matched location is a proper location or not (Plum et al., 2019). In the present approach, we use a machine learning classifier to predict whether a sentence contains a relevant location first, and on this preselection we perform a gazetteer lookup to identify the specific index range of each location. We also use spaCy NER[4] to compare the effectiveness of the gazetteer.

The approach for the system is split into three steps, which are explained in the following three sections. The first step deals with the preparation of the texts from the dataset. This involves cleaning noisy sections of text and outputting an input

[3] https://clavin.bericotechnologies.com/about-clavin/.

[4] Version 2.1.3, available at https://spacy.io/

file for the machine learning classifier containing all texts split into sentences. Next, each classifier is trained and run in order to obtain predictions at the sentence level. Finally, the output from the classifier is used in conjunction with a gazetteer lookup algorithm (and later spaCy NER) in order to determine the exact indexes of the detected locations.

3.1 Dataset

To ensure comparability with the baseline system, we work with the same dataset from SemEval-2019 Task 12. This dataset is made up of 150 journal articles from PubMed Central and are from the domain of epidemiology (Weissenbacher et al., 2019). As mentioned previously, the main idea behind detecting locations in texts from this domain is to track the spreading of viruses (Weissenbacher et al., 2019). The articles were downloaded as PDFs and converted to plain text using a pdf-to-txt tool by the organisers of the task. The toponyms were manually disambiguated by the organisers and subsequently annotated using the Brat annotator (Stenetorp et al., 2012). Two texts of the training set were removed, as they were unreadable, probably caused by PDF to text conversion problems. Apart from this, we work with the same training and test splits as supplied by the organisers, which are 73 and 45 texts, respectively. It should be pointed out that we had to adjust the annotations of some of the training texts, as these were carried out on texts using CRLF-type line breaks[5] and did not match the indexes read by our system, as it used LF-type line breaks, which lead to the indexes being offset.

The texts had to be prepared for the classification task. As some parts of the texts had been deemed irrelevant by the organisers of SemEval-2019 Task 12 (Weissenbacher et al., 2019), we had to remove these. This includes the references and acknowledgement sections of each article. We also had to remove certain character strings which are specific to texts from the bio-medical domain. Finally, the texts had to be split into sentences and stored with further information in order to be classified in the next step.

3.1.1 Text Cleaning

The cleaning of the texts is performed in two steps. First, all line breaks are removed and replaced with spaces. This is mainly to deal with sentence splitting and string matching problems that could occur over line breaks. For instance, a line break character between *New* and *York* would lead to this location to be detected as *York*, not as *New York*. The line breaks have to be replaced by one space, as the annotations take line breaks into account and add these to the index range of a location. It should be mentioned that this requires the texts to use LF-type line breaks, as any other type would require a different number of replacement characters. For this dataset, it was ensured that all files conform to this standard.

Next, we carry out more methods to clean the texts. Using the guidelines set out by the task organisers and a brief analysis carried out by Plum et al. (2019), we determined that certain parts of the texts are not relevant for detection. This includes references and certain character and word strings that describe biological genome sequences. As these often include toponyms that were excluded from annotation in the SemEval-2019 task, these could also be disregarded. In order to remove all irrelevant parts but retain indexing consistency, we use regular expressions to find and replace certain text sequences with an equivalent number of spaces. As before, we replace each character with a space in order to ensure that the indexes match up with the annotations.

We wanted to test the effectiveness of our cleaning methods. Therefore, we tested our methods with both types of text: texts where only the line breaks have been removed and texts that have been completely cleaned. During testing it was clear that the performance was better on fully cleaned texts, due to the reduction in seemingly random strings that could be detected (i.e. the string *[..] ACG GGG* ***MA*** *AUA UGC [..]* could produce the match *MA*, as in the U.S. state *Massachusetts*).

3.1.2 Sentence Splitting

As the identification of locations primarily happens at the sentence level, each individual text needs to be split into sentences. We use spaCy in order to complete this task. The sentences are then output to a CSV file, containing information on each sentence's text id, as well as its own specific index range. This information is necessary at the stage of identifying the exact index range of

[5] CRLF-type line breaks are commonly used in text files created with Microsoft DOS/Windows operating systems. This type of line break uses two characters to denote the end of a line. LF-type line breaks are commonly used on UNIX/Linux-based operating systems, and only use one character to denote the end of a line.

a location and then producing the annotation files for the SemEval evaluation script. For the machine learning training file, a separate column indicating whether or not a location is contained in the sentence is also included.

3.2 Sentence Level Location Identification

Once the texts have been pre-processed, we run a binary classification on the sentences, predicting whether a sentence contains a location, or not. Table 1 shows some examples from the training dataset which is used for this classification task.

Out of the $17,535$ sentences in the training set, only $2,117$ sentences contain locations. This means that the dataset is highly unbalanced, thus making the classification task quite difficult. The increased difficulty was also caused by the language used. As an example, in the row with the ID PMC2857219, shown in Table 1, the sentence contains *Korea* and is not annotated as a location since it is a part of an organisation name. Also, in the row with the ID PMC2857219, *US* is not annotated as a location, as it functions as an adjective to the word soldier. General named entity recognisers such as spaCy or gazetteer matching could possibly falsely detect that these sentences contain a proper location as defined for this task. Furthermore, sentences similar to ID PMC5837706, shown in 1, caused difficulties, as the text in the sentence was not clear. Considering all of these issues, we need an intelligent classifier that detects whether a sentence contains a location or not, by considering the words that appear in the sentence.

We use five different recurrent network architectures to perform the binary classification task on the sentences: pooled Gated Recurrent Unit (GRU) (3.2.1), stacked Long Short-Term Memory (LSTM) with attention (3.2.2), LSTM and GRU with attention (3.2.3), 2D convolution with pooling (3.2.4) and GRU with capsule (3.2.5). Each classifier was run on prepared and cleaned text (as explained in Section 3.1.1). These models were successfully applied to a number of classification tasks such as GRU for sequence labeling Chung et al. (2014), LSTM for semantic similarity and word analogy Coates and Bollegala (2018), and GRU with capsule for toponym detection Plum et al. (2019). Their success in these tasks inspired us to try them for our problem.

3.2.1 Pooled GRU

This model takes pre-trained fasttext embeddings (Mikolov et al., 2018) as a matrix for the input which is comprised of the vertically stacked embedding vectors corresponding to the words present in the sentence. The matrix can be thought of as a sequence of embedded words. Each of these embedding vectors is fed to the bi-directional GRU (Chung et al., 2014) at their respective timestep. The final timestep output is fed into a max pooling layer and an average pooling layer in parallel (Scherer et al., 2010). Following this, the outputs of the two pooling layers are concatenated and connected to a dense layer (Huang et al., 2017) activated with a sigmoid function. Additionally, there is a spatial dropout (Tompson et al., 2015) between the embedding layer and the bi-directional GRU layer to avoid over-fitting.

The network was trained using adam optimiser (Kingma and Ba, 2015), with a reduced learning rate once learning stagnates. This model has been discussed in Kowsari et al. (2019) as a common model to perform text classification tasks.

3.2.2 Stacked LSTM with Attention

As with the previous model, this model takes pre-trained fasttext embeddings (Mikolov et al., 2018) as an input. Each of these embedding vectors are then fed into a bi-directional LSTM (Schuster and Paliwal, 1997). The output of this layer is again fed into a bi-directional LSTM (Schuster and Paliwal, 1997) with self attention (Vaswani et al., 2017). Finally, the output is connected to two dense layers that are (Huang et al., 2017) activated first with a relu function, and then with a sigmoid function.

Again, this network was trained using adam optimiser (Kingma and Ba, 2015), with a reduced learning rate once learning stagnates. We adopted this model from the Toxic Comment Classification Challenge in Kaggle[6].

3.2.3 LSTM and GRU with Attention

This architecture applies a spatial dropout to the embedding layer (Tompson et al., 2015). The output is then fed in parallel to a bi-directional LSTM-layer (Schuster and Paliwal, 1997) with self attention and a bidirectional GRU-layer (Chung et al., 2014) with self attention

Table 1: Example rows in the training set. Sentences containing a location are represented with 1 in the *loc?* column and 0 otherwise. The *location* column contains the explicit location names contained in the sentence.

(Vaswani et al., 2017). The output from the bi-directional GRU-layer is fed into an average pooling layer and a max pooling layer. The output from these layers and the output of the bi-directional LSTM-layer are concatenated and connected to a dense layer with relu activation. After that, a dropout (Srivastava et al., 2014) is applied to the output and connected to a dense layer activated with a sigmoid function.

While this network was also trained using adam optimiser (Kingma and Ba, 2015), it was trained with a cyclical learning rate (Smith, 2017) this time. Plum et al. (2019) has used this model to predict whether a word window contains a location or not.

3.2.4 2D Convolution with Pooling

The fourth architecture takes a different approach than the previous architectures by using 2D convolution layers (Wu et al., 2018), rather than LSTM- or GRU-layers. The outputs of the embedding layers are connected to four 2D convolution layers (Wu et al., 2018), each with max pooling layers. The outputs of these are concatenated and connected to a dense layer activated with a sigmoid function after applying a dropout (Srivastava et al., 2014).

This network also uses adam optimiser (Kingma and Ba, 2015) and a reduced learning rate once learning stagnates. This model has been used in the Quora Insincere Questions Classification Kaggle competition[7].

3.2.5 GRU with Capsule

Most of the previous architectures rely on a pooling layer. However, this architecture uses a capsule layer (Hinton et al., 2018) rather than pooling layers. After applying a spatial dropout (Tompson et al., 2015) the output of the embedding layer is fed into a bi-directional GRU-layer (Chung et al., 2014). The output is then connected to a capsule layer (Hinton et al., 2018). The output of the capsule layer is flattened and connected to a dense layer with relu activation, a dropout (Srivastava et al., 2014) and batch normalisation applied, and re-connected to a dense layer with sigmoid activation.

The capsule network was trained using adam optimiser (Kingma and Ba, 2015), with a reduced learning rate once learning stagnates. This model has been used in Plum et al. (2019) to predict whether a word window contains a location or not.

3.3 Word Level Location Identification

The location predictions made by the ML-classifier at the sentence level are passed as a CSV file to the string matching script. It runs through each sentence, matching locations from a gazetteer. For matching the strings we use a fast and efficient Aho-Corasick algorithm (Aho and Corasick, 1975). The implementation used is available for the Python programming language[8]

We use a large gazetteer that is comprised of the full list of all locations from the GeoNames database[9]. The main idea behind this is that we want to achieve the highest chance of detecting

[7] https://www.kaggle.com/c/quora-insincere-questions-classification

[8] https://github.com/WojciechMula/pyahocorasick/

[9] http://www.geonames.org/, last accessed 21.05.2019

every location. However, as the gazetteer is so large, is causes a lot of ”noise” during the string matching, including partial matches and numbers that have no meaning. In order to combat this, we apply several filters after finding matches, in order to exclude certain results. We consciously avoided removing anything from the gazetteer itself, as this would be either time-consuming (manual) or could falsely remove desired locations (automatic). Therefore, we use filters to remove all matches with numbers (i.e. *717, 7Palms, 50da*), strings shorter than three characters which are not both uppercase (i.e. *Bl, b1, al* but not *AL, CA, NY*), sub-string matches (i.e. *London* in *Londonderry*) and all lowercase strings (which are usually fragments of location names left in the database, as in *paseo caribe*). The resulting tables are sorted by index, and duplicates removed. Where matches overlap in terms of indexing, we give preference to the longest match. This ensures that in sentences such as *I live in New York*, we detect only *New York* and not *York* (as these are separate entries in the gazetteer).

For comparison purposes, we also employ spaCy to detect locations in the sentences at this stage. We used the standard English web corpus and the spaCy NER algorithm.

4 Results

As our system operates at two levels, we first present the results of location prediction at the sentence level using the five different recurrent network architectures. Next, we present the results of the prediction at the word level. These results are also regarded as our final results, as these predictions yielded the index range of each location, which were evaluated with an evaluation script. The evaluation script that was utilised was the one provided for SemEval-2019 Task 12.

4.1 Sentence Level Prediction

Results of the sentence level predictions for the test set are shown in Table 2. We use precision and recall to evaluate the results. The third model described, LSTM and GRU with Attention, provided the best results for the cleaned text. Despite the dataset being quite unbalanced, the model reported good precision and recall scores of 0.852 and 0.853, which provided a high F1 score, too.

As this is the best model, we use these predictions as the basis for our word level predictions, which are described in the next section. It should be mentioned that we did run some word level predictions on the output of the other classifiers, but as expected the results were always much lower, due to the decreased starting point.

4.2 Toponym Identification

As mentioned previously, we regard the word level predictions as the overall result of the system. The evaluation was carried out in accordance with parameters set out for SemEval-2019 Task 12, featuring strict and overlap categories on macro and micro levels. For the strict measure, predicted locations are only considered as correct if the text span matches the gold standard exactly. For the overlap measure, predictions are considered to be correct if they share a common span of text with the gold annotations. The python script was made available on Bitbucket[10] by the SemEval-2019 Task 12 organizers.

Table 3 shows the results for both the string matching method using gazetteers to extract the locations with a custom script for indexes, as well as the spaCy NER algorithm (only considering locations) and the baseline system submitted to SemEval-2019. Our best results were achieved in the overlap macro classes, and are highlighted in bold. Overall, while we were not able to beat the best precision score of Plum et al. (2019), we came quite close. Nonetheless, we were able to improve the recall significantly, as well as the overall f-score.

The trade-offs that each approach brings with it should become clear when regarding the results.The approach using the GeoNames gazetteer detects a higher number of locations overall. This is due to the simplistic string matching method backed by such a large gazetteer, and comes at the cost of overall precision. The spaCy NER algorithm is much more precise, but is more limited in terms of recall. We find it most likely that this approach does not tag many locations as such, because the texts are still quite noisy, and because we did not train it on our dataset. Due to the small size and unbalanced nature of our dataset, we did not consider training spaCy any further. In the future, given an appropriate dataset from the bio-medical domain, this could perhaps lead to better results.

Baseline - Micro	.816	.339	.479	.893	.365	.518

Table 3: Results for the word level classification. We report the same measures as previously, for the categories described in Section 4. Results are shown for both approaches (bold indicates the best set of results).

5 Conclusion

We have presented a system for toponym detection based on a recurrent network and gazetteer lookup. The approach is novel in that we use the recurrent network to predict whether a sentence contains a location, from which we later extract the exact location by more simpler means. This eliminates the need for a more extensive sequence labelling task, which would require more elaborately annotated training data. Our approach was able to improve on the baseline system presented at SemEval-2019 Task 12 on the same dataset. Albeit not at the same level of precision.

The main conclusion of this paper is that using a hybrid approach, where a machine learning approach is mixed with more traditional gazetteer lookup methods, seems to introduce too many areas where performance is lost. Both in this paper and in Plum et al. (2019) the machine learning or rather neural network architectures on their own perform quite well. However, performing a gazetteer lookup before or after lowers the result significantly. Of course, in both cases these lookups provide necessary information for the system to work, as they provide the index range of each location. The fact that our system performed better in terms of precision when using the popular spaCy NER algorithm, shows that simple gazetteer lookup lacks precision and is probably too simple.

In the future, we would like to introduce an end-to-end system entirely based on machine learning or recurrent network architectures. One emerging approach is to use BERT (Devlin et al., 2018) for token classification which is a fine-tuning model that wraps the BERT model and adds a token-level classifier on top of the BERT model. The recent release of BioBERT (Lee et al., 2019) makes it easier to apply BERT for NER in the bio-medical domain. While a lot more research has been focused on these kind of architectures, we hope to explore tasks other than only sequence labelling. To this end, our aim is to also explore the use of word and context embeddings further.

Combining SMT and NMT Back-Translated Data for Efficient NMT

Alberto Poncelas, Maja Popović, Dimitar Shterionov,
Gideon Maillette de Buy Wenniger and **Andy Way**
School of Computing, DCU, ADAPT Centre
{firstname.lastname}@adaptcentre.ie

Abstract

Neural Machine Translation (NMT) models achieve their best performance when large sets of parallel data are used for training. Consequently, techniques for augmenting the training set have become popular recently. One of these methods is back-translation (Sennrich et al., 2016a), which consists on generating synthetic sentences by translating a set of monolingual, target-language sentences using a Machine Translation (MT) model.

Generally, NMT models are used for back-translation. In this work, we analyze the performance of models when the training data is extended with synthetic data using different MT approaches. In particular we investigate back-translated data generated not only by NMT but also by Statistical Machine Translation (SMT) models and combinations of both. The results reveal that the models achieve the best performances when the training set is augmented with back-translated data created by merging different MT approaches.

1 Introduction

Machine translation (MT) nowadays is heavily dependent on the quantity and quality of training data. The amount of available good-quality parallel data for the desired domain and/or language pair is often insufficient to reach the required translation performance. In such cases, it has become the norm to resort to back-translating freely available monolingual data as proposed in (Sennrich et al., 2016a). That is, one can translate a set of sentences from language L2 into L1 with an already trained MT system for the language pair L2→L1. Then create a synthetic parallel corpus from L1 to L2, with the source (L1) side being the translated text and the target side being the monolingual data. Back-translation has been shown to be beneficial not only for MT but also for other NLP tasks where data is scarce, e.g. automatic post-editing (APE) (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018). However, the effects of various parameters for creating back-translated (BT) data have not been investigated enough as to indicate what are the optimal conditions in not only creating but also employing such data to train high-quality neural machine translation (NMT) systems.

The work presented in Poncelas et al. (2018) draws an early-stage empirical roadmap to investigating the effects of BT data. In particular, it looks at how the amount of BT data impacts the performance of the final NMT system. In Sennrich et al. (2016a) and Poncelas et al. (2018), the systems used to generate the BT data are neural. However, it has been noted that often different paradigms can contribute differently to a given task. For example, it has been shown that applying an APE system based on NMT technology improves statistical machine translation (SMT) output, but has lower impact on NMT output (Bojar et al., 2017; Chatterjee et al., 2018).

In this work we assess the impact of different amounts of BT data generated by two different types of MT systems – NMT and SMT. Our contribution is two-fold: (i) we provide a systematic comparison of the BT data by building NMT systems with a combination of SMT and NMT BT data and (ii) we identify the effects of BT data that originates from SMT or NMT on the end-quality of the trained NMT system. We aim to answer the question: "What is the best choice for BT data?"

Proceedings of Recent Advances in Natural Language Processing, pages 922–931,
Varna, Bulgaria, Sep 2–4 2019.

2 Preparatory Study: the Effect of Back-Translation when Controlling for the Amount of Training Effort

A typical assumption made when training NMT models, is that when more training data is used, more training effort is warranted. Based on this assumption when training NMT systems what is normally kept constant is the amount of training epochs rather than the amount of training effort in the form of steps/mini-batches. Nevertheless, when adding back-translated data to the training set, while keeping the amount of epochs the same, the effective amount of training increases. It could then be questioned whether the extra training effort in itself does not partly explain the positive effect of back-translation. For this reason, we seek to answer the question: "Does the effect of back-translation change when we control for the amount of training effort, by keeping the total amount of steps/mini-batches constant?". To answer this question we compare the performance of systems trained on purely authentic data to those trained on authentic plus synthetic data, while keeping either the number of steps/mini-batches or the number of epochs constant in both settings:

1. Models trained with 1M auth + 2M synth sentences using the default settings, including 13 training epochs.
2. Models trained on 1M auth data only, trained either:
   (a) using the default settings, including 13 training epochs.
   (b) Trained for 39 epochs, to obtain a same amount of training effort as for the 1M auth + 2M synth sentences model.

When increasing the epochs to 39, we take appropriate measures to keep the starting point and speed of decay of the learning rate constant for the amount of training steps/epochs.[1]

The results of these experiments indicate that training a model on authentic data with $1/3$ of the amount of the total parallel data (authentic + synthetic) for an additional 26 epochs to account for the extra training effort is not required as no significant improvement has been observed. Based on the outcome of these experiments we chose the rest of our experiments.

3 Using Back-Translation from Different Sources

The work of (Sennrich et al., 2016a) showed that adding BT data is beneficial to achieve better translation performances. In this work we compare the details related to the translation hypotheses originating from SMT and NMT back-translated training data as well as combine the data from those two different sources. To the best of our knowledge, this has not been investigated yet.

We compare German-to-English translation hypotheses generated by systems trained (i) only on authentic data, (ii) only on synthetic data, and (iii) on authentic data enhanced with different types of BT data: SMT, NMT. We exploit two types of synthetic and authentic data combinations: (a) randomly selected half of target sentences back-translated by SMT and another half by NMT system, and (b) joining all BT data (thus repeating each target segment).

The translation hypotheses are compared in terms of four automatic evaluation metrics: BLEU (Papineni et al., 2002), TER (Snover et al., 2006), METEOR (Banerjee and Lavie, 2005) and CHRF (Popović, 2015). These metrics give an overall estimate of the quality of the translations with respect to the reference (human translation of the test set). In addition, the translation hypotheses are analyzed in terms of five error categories, lexical variety and syntactic variety.

4 Related Work

A comparison between MT models trained with synthetic and with authentic data that originate from the same source has been presented in Poncelas et al. (2018). They show that while the performances of models trained with both synthetic and authentic data are better than those of models trained with only authentic data, there is a saturation point beyond which the quality does not improve by adding more synthetic data. Nonetheless, models trained only with synthetic (BT) data perform very reasonably, with evaluation scores being close to those of models trained with only authentic parallel data. In fact, when appropriately selected, BT data can be used to enhance NMT

[1] This is implemented by changing the start of the learning rate decay from epoch 8 to epoch 22 $(= 7 * 3 + 1)$ and changing the decay factor from 0.5 to $\sqrt[3]{0.5} = 0.7936$. This way, the learning rate decay starts after the same amount of data when using the 1M auth dataset $(7 \times 3M)$ and the decay rate is maintained at 0.5 for each $3M$ sentences from this point onwards.

models (Poncelas et al., 2019).

Edunov et al. (2018) confirmed that synthetic data can sometimes match the performance of authentic data. In addition, a comprehensive analysis of different methods to generate synthetic source sentences was carried out. This analysis revealed that sampling from the model distribution or noising beam outputs out-performs pure beam search, which is typically used in NMT. Their analysis shows that synthetic data based on sampling and noised beam search provides a stronger training signal than synthetic data based on argmax inference.

One of the experiments reported in Burlot and Yvon (2018) is comparing performance between models trained with NMT and SMT BT data. The best Moses system (Koehn et al., 2007) is almost as good as the NMT system trained with the same (authentic) data, and much faster to train. Improvements obtained with the Moses system trained with a small training corpus are much smaller; this system even decreases the performance for the out-of-domain test. The authors also investigated some properties of BT data and found out that the back-translated sources are on average shorter than authentic ones, syntactically simpler than authentic ones, and contain smaller number of rare events. Furthermore, automatic word alignments tend to be more monotonic between artificial sources and authentic targets than between authentic sources and authentic targets.

Burlot and Yvon (2018) also compared training BT data with authentic data in terms of lexical and syntactic variety, segment length and alignment monotony, however they did not analyze the obtained translation hypotheses. In (Vanmassenhove et al., 2019) it is shown that MT systems trained on authentic and on backtranslated data lead to general loss of linguistic richness in their translation hypotheses.

5 Experimental Settings

For the experiments we have built German-to-English NMT models using the Pytorch port of OpenNMT (Klein et al., 2017). We use the default parameters: 2-layer LSTM with 500 hidden units. The models are trained for the same number of epochs. As the model trained with all authentic data converges after 13 epochs, we use that many iterations to train the models (we use the same amount of epochs). As optimizer we use stochastic gradient descent (SGD), in combination with learning rate decay, halving the learning rate starting from the 8th epoch.

In order to build the models, all data sets are tokenized and truecased and segmented with Byte-Pair Encoding (BPE) (Sennrich et al., 2016b) built on the joint vocabulary using 89500 merge operations. For testing the models we use the test set provided in the WMT 2015 News Translation Task (Bojar et al., 2015). As development set, we use 5K randomly sampled sentences from development sets provided in previous years of WMT.

6 Data

The parallel data used for the experiments has been obtained from WMT 2015 (Bojar et al., 2015). We build two parallel sets with these sentences: *base* (1M sentences) and *auth* (3M sentences). We use the target side of *auth* to create the following datasets:

- *SMTsynth*: Created by translating the target-side sentences of *auth*. The model used to generate the sentences is an SMT model trained with *base* set in the English to German direction. It has been built using the Moses toolkit with default settings, using GIZA++ for word alignment and tuned using MERT (Och, 2003)). The language model (of order 8) is built with the KenLM toolkit (Heafield, 2011) using the German side of *base*.

- *NMTsynth*: Created by translating the target-side sentences of *auth*. The model used to generate the sentences is an NMT model (with the same configuration as described in Section 5 but in the English to German direction) trained with the *base* set.

- *hybrNMTSMT*: Synthetic parallel corpus combining *NMTsynth* and *SMTsynth* sets. It has been built by maintaining the same target side of *auth*, and as source side we alternate between *NMTsynth* and *SMTsynth* each 500K sentences.

- *fullhybrNMTSMT*: Synthetic parallel corpus combining all segments from *NMTsynth* and *SMTsynth* sets (double size, each original target sentence repeated twice with both an NMT and SMT back-translation-generated translation).

7 Experiments

In our experiments, we build models on different portions of the datasets described in Section 6. First, we train an initial NMT model using the *base* data set. Then, in order to investigate how much the models benefit from using synthetic data generated by different approaches, we build models with increasing sizes of data (from the data sets described in Section 6).

The models explored are built with data that ranges from 1M sentences (built with only authentic data from *base* data set) to 4M sentences (consisting on 1M sentences from *base* and 3M sentences generated artificially with different models). We also include the models built with the *fullhybrNMTSMT* set. As this set contains duplicated target-side sentences, the largest model we build contains 7M sentences in total but only 4M distinct target-side sentences.

8 Results

8.1 Controlling the Amount of Training Effort

Table 1 shows the effect of controlling the amount of training effort when using back-translation. It can be observed that increasing the number of epochs from 13 to 39 when using just the 1M base training set does not increase the performance over using just 13 epochs (i.e. not compensating the relatively smaller training set with more epochs), rather it deteriorates it. From these results we conclude that there is no reason to believe that the positive effects of using back-translation is caused by an effectively larger training effort, rather than by the advantage of the larger training set itself. We therefore also conclude that it is reasonable to keep the number of epochs constant across experiments, rather than fixing the amount of training effort as measured by steps/mini-batches, and we do the former throughout the rest of the paper.

8.2 Addition of Synthetic Data from SMT and NMT Models

Table 2 shows the results of the performance of the different NMT models we have built. The subtables indicate the size of the data used for building the models (from 1M to 4M lines). In each column it is indicated whether *base* has been augmented with the *auth*, *SMTsynth*, *NMTsynth*, *hybrNMTSMT*, or *fullhybrNMTSMT* data set.

The results show that adding synthetic data has a positive impact on the performance of the models as all of them achieve improvements when compared to that built only with authentic data *1M base*. These improvements are statistically significant at p=0.01 (computed with multeval (Clark et al., 2011) using Bootstrap Resampling (Koehn, 2004)). However, the increases of quality are different depending on the approach followed to create the BT data.

First, we observe that models in which SMT-generated data is added do not outperform the models built with the same size of authentic data. For example, the models built with 4M sentences (1M authentic and 3M SMT-produced sentences, in cell *+ 3M SMTsynth*) achieve a performance comparable to the model trained with smaller number of sentences of authentic data (such as *+ 1M auth* cell, 2M sentences).

Models built by using NMT-created data have a better performance than those built with data generated by SMT. When performing a pairwise comparison between models using an equal amount of either SMT or NMT-created data, we observe that the latter models outperform the former by around one BLEU point. In fact, the performance of models using NMT-translated sentences is closer to those built with authentic data, and some *NMTsynth* models produce better translation qualities. This is the case of *+1M NMTsynth* model (according to all evaluation metrics) or *+3M NMTsynth* (according to BLEU).

Our experiments also include the performance of models augmented with a combination of SMT- and NMT- generated data. We see that adding *hybrNMTSMT* data, with one half of the data originating from SMT and the other half from NMT models, have performances similar to those models built on authentic data only. According to some evaluation metrics, such as METEOR, the performance is better than *auth* models when adding 1M or 2M artificial sentences (although none of these improvements are statistically significant at p=0.01). For these amount of sentences, it also outperforms those models in which only SMT or only NMT BT data have been included.

The models extended with synthetic data that perform best are *fullhybrNMTSMT* models. Furthermore, they also outperform authentic models when built with less than 4M distinct target-sentences according to BLEU, METEOR

(showing statistically significant improvements at p=0.01) and CHRF1. Despite that, when using large sizes of data (i.e. adding 3M synthetic sentences) the models built with SMT-generated artificial data have the lowest performances whereas the performance of the other three tends to be similar.

8.3 Further Analysis

In order to better understand the described systems, we carried out more detailed analysis of all translation outputs. We analyzed five error categories: morphological errors, word order, omission, addition and lexical errors, and we compared lexical and syntactic variety of different outputs in terms of vocabulary size and number of distinct POS n-grams. We also analyzed the sentence lengths in different translation hypotheses, however no differences were observed, neither in the average sentence length nor in the distribution of different lengths.

Automatic Error Analysis

For automatic error analysis results, we used Hjerson (Popović, 2011), an open-source tool based on Levenshtein distance, precision and recall. The results are presented in Table 3.

	error class rates↓				
training	morph	order	omission	addition	mistranslation
1M *base*	2.8	9.8	12.0	4.8	29.1
1M *base* + 1M *auth*	2.7	9.5	11.4	4.9	28.2

1M *base* + 3M *fullhybrNMTSMT*	2.5	9.7	10.8	4.8	27.7

Table 3: Results of automatic error classification into five error categories: morphological error (morph), word order error (order), omission, addition and mistranslation.

It can be seen that morphological errors are slightly improved by any additional data, but it is hard to draw any conclusions. This is not surprising given that our target language, English, is not particularly morphologically rich. Nevertheless, for all three corpus sizes, the numbers are smallest for the full hybrid system, being comparable to the results with adding authentic data.

As for word order, adding SMT data is not particularly beneficial since it either increases (1M and 2M) or does not change (3M) this error type. NMT systems alone do not help much either, except a little bit for the 3M corpus. Hybrid systems yield the best results for this error category for all corpus sizes, reaching or even slightly surpassing the result with authentic data.

Furthermore, all BT data are beneficial for reducing omissions, especially hybrid which can be even better than the authentic data result.

As for additions, no systematic changes can be observed, except an increase for all types of BT data. However, it should be noted that this error category is reported not to be very reliable for comparing different MT outputs (see for example (Popović and Burchardt, 2011)).

The mostly affected error category is mistranslations. All types of additional data are reducing this type of errors, especially the hybrid BT data for 1M and 2M, even surpassing the effect of adding authentic data. As for the 3M corpus, the improvement in this error category is similar to the one by authentic data, but the best option is to use NMT BT data alone.

In total, the clear advantage of using hybrid systems can be noted for mistranslations, omissions and word order which is the most interesting category. This error category is augmented by adding BT SMT data or not affected by adding BT NMT data, but combining two types of data creates beneficial signals in the source text.

Lexical and Syntactic Variety

Lexical and syntactic variety is estimated for each translation hypothesis as well as for the human reference translation. The motivation for this is the observation that machine-translated data is generally lexically poorer and syntactically simpler than human translations or texts written in the original language (Vanmassenhove et al., 2019). We want to see how different or similar our translation hypotheses are in this sense, and also how they relate to the reference.

Lexical variety is measured by vocabulary size (number of distinct words) in the given text, and syntactic variety by number of distinct POS n-grams where n ranges from 1 to 4. The results are shown in Figure 1.

First of all, it can be seen that none of the

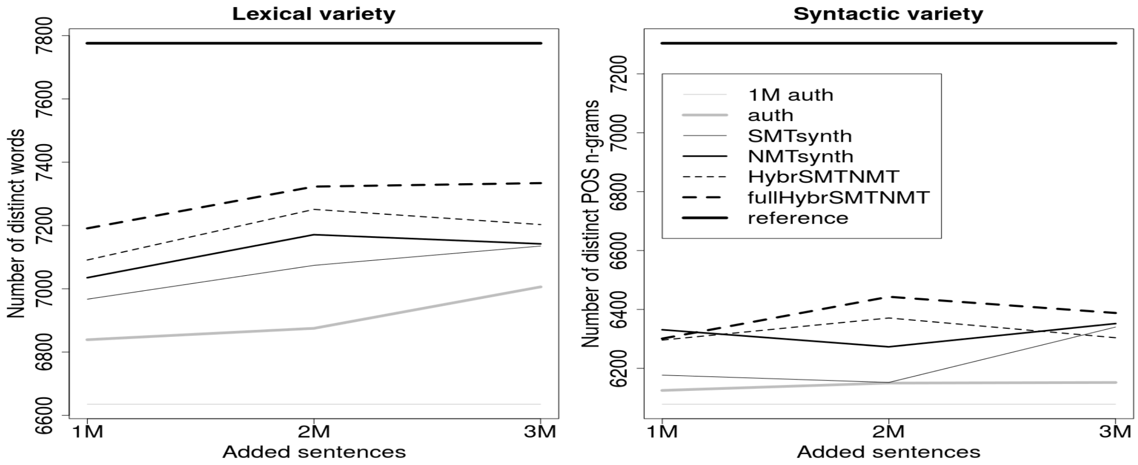

Figure 1: Lexical variety and syntactic variety for all translation hypotheses and for human reference translations.

translation hypotheses reaches the variety of the reference translation (the black line on the top). The difference is even more notable for the syntax, where the differences between translation hypotheses are smaller and the difference between them and the reference is larger than for vocabulary.

Furthermore, it can be seen that for authentic data (thin gray line on the bottom and thick gray line) the variety increases monotonically with adding more text.

Lexical variety is increased by all synthetic data, too, even more than by authentic data, however, for the NMT and hybrid synthetic data the increase for the 3M corpus is smaller than for smaller corpora.

The increase of syntactic variety is lower both for authentic and for synthetic data than the increase of lexical variety. For 1M and 2M corpus, syntactic variety is barely increased by SMT synthetic data whereas NMT and hybrid data are adding more new instances. For the 3M corpus, however, all synthetic methods yield similar syntactic variety, larger than the one obtained by adding authentic data.

Word/POS 4-gram Precision and Recall

Whereas the increase of lexical and syntactic varieties is a positive trend in general, there is no guarantee that the MT systems are not introducing noise thereby. To estimate how many of added words and POS sequences are sensible, we calculate precision and recall of word and POS 4-grams when compared to the given reference translation. The idea is to estimate how much the translation hypotheses are getting closer to the reference. We take word 4-grams instead of single words because it is not only important that a word makes sense in isolation, but also in a context. Of course, it is still possible that some of the new instances are valid despite being different from the given single reference.

The results of precision and recall for word/POS 4-grams are are shown in Figure 2. Several tendencies can be observed:

- hybrid BT data is especially beneficial for the 1M and 2M additional corpora, for 1M even outperforming the authentic additional data, especially regarding word 4-grams;
- NMT BT is the best synthetic option for the 3M additional corpus, however not better than adding 3M of authentic data. This tendency is largest for POS 4-gram precision.
- SMT BT data achieves the lowest scores, especially for POS 4-grams; this is probably related to the fact that it produces less grammatical BT sources, which are then propagated to the translation hypotheses. The differences are largest for the 3M additional corpus, which is probably the reason of diminished effect of the hybrid BT data for this setup.

Overall tendencies are that the hybrid BT data is capable even of outperforming the same amount of authentic data if the amount of added data does not exceed the double size of the baseline authentic data. For larger data, a deterioration can be ob-

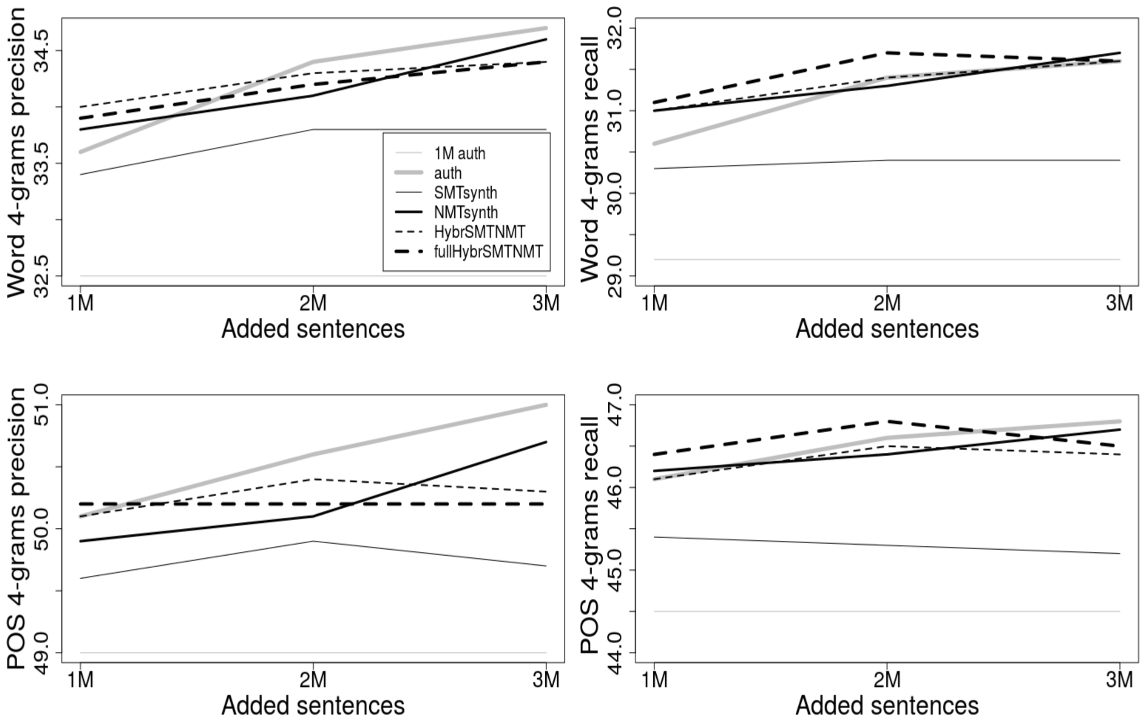

Figure 2: Word/POS 4-gram precision and recall for all translation hypotheses.

served for the SMT BT data, leading to saturation of hybrid models.

Further work dealing with mixing data techniques is necessary, in order to investigate refined selection methods (for example, removing SMT segments which introduce noise).

9 Conclusion and Future Work

In this work we have presented a comparison of the performance of models trained with increasing size of back-translated data. The artificial data sets explored include sentences generated by using an SMT model, and NMT model and a combination of both. Two mixing strategies are explored: randomly selecting one half of the source segments from the SMT BT data and the other half from the NMT BT data, and using all BT source segments thus repeating each target segment.

Some findings from previous work (Burlot and Yvon, 2018) are confirmed, namely that in terms of overall automatic evaluation scores, SMT BT data reaches slightly worse performance than NMT BT data. Our main findings are that mixing SMT and NMT BT data further improves over each data used alone, especially if full hybridisation is used (using two sources for each target side). These data can even reach better performance than adding the same amount of authentic data, mostly by reducing the number of mistranslations, and increasing the lexical and syntactic variety in a positive way (introducing useful new instances).

However, if the amount of synthetic data becomes too large (three times larger than the authentic baseline data), the benefits of hybrid system start to diminish. The most probable reason is the decrease in grammaticality introduced by SMT BT data which becomes dominant for the larger synthetic corpora.

The presented findings offer several directions for the future work, such as exploring efficient strategies for mixing SMT and NMT data for different authentic/synthetic ratios and investigating morphologically richer target languages.

Abstract

One of the challenges during a task-oriented chatbot development is the scarce availability of the labeled training data. The best way of getting one is to ask the assessors to tag each dialogue according to its intent. Unfortunately, performing labeling without any provisional collection structure is difficult since the very notion of the intent is ill-defined.

In this paper, we propose a hierarchical multimodal regularized topic model to obtain a first approximation of the intent set. Our rationale for hierarchical models usage is their ability to take into account several degrees of the dialogues relevancy. We attempt to build a model that can distinguish between subject-based (e.g. medicine and transport topics) and action-based (e.g. filing of an application and tracking application status) similarities. In order to achieve this, we divide set of all features into several groups according to part-of-speech analysis. Various feature groups are treated differently on different hierarchy levels.

1 Introduction

One of the most important goals of task-oriented dialogue systems is to identify the user intention from the user utterances. State-of-the-art solutions like (Chen et al., 2017) require a lot of labeled data. User's utterances (one or several for a dialogue) have to be tagged by the intent of the dialogue.

This is a challenging task for a new dialogue collection because the set of all possible intents is unknown. Giving a provisional hierarchical collection structure to assessors could make the intent labeling challenge easier. The resulting labels will be more consistent and better suitable for model training.

Simple intent analysis is based on empirical rules, e.g. "question" intent contains phrase "what is # of #" (Yan et al., 2017). More universal and robust dialogue systems should work without any supervision or defined rules. Such systems can be implemented with automatic extraction of the semantic hierarchy from the query by multi-level clustering, based on different semantic frames (capability, location, characteristics etc.) in sentences (Chen et al., 2015). In our work intents represent a more complex entity which combine all intentions and objectives.

Many previous works take advantage of hierarchical structures in user intention analysis. In paper (Shepitsen et al., 2008) automatic approach through hierarchical clustering for document tagging is used. However, this approach does not take advantage of peculiar phrase features, such as syntax or specific words order. Syntactic parsing of intention was applied in (Gupta et al., 2018) to decompose client intent. This hierarchical representation is similar to a constituency syntax tree. It contains intentions and objects as tree elements and demands deep analysis of every sentence. Attempt to extract subintents along with main intent can be found in paper (Tang et al., 2018), but as proved below it is not necessary to apply neural networks for precise and efficient retrieval of multi-intent, especially in unsupervised task.

We propose a hierarchical multimodal regularized topic model as a simple and efficient solution for accurate approximation of the collection structure. The main contribution of this paper is the construction of a two-level hierarchical topic model using different features on the first and second levels. To the best of our knowledge, this is the first work that investigates that possibility. We introduce a custom evaluation metric which measures the quality of hierarchical relations between topics and intent detection.

The hierarchy structure helps to make a provisional clustering more interpretative. Namely, we require first level topics to describe the dialogue subject and the second level topics to describe the action user is interested in. We accomplish this by incorporating information about part-of-speech (PoS) tags into the model.

This paper is organized as follows. Section two describes popular approaches to an unsupervised text classification. Section three describes our reasoning behind our choices of model architecture. Section four briefly reviews our preprocessing pipeline and introduces several enhancements to the existing NLP techniques. We demonstrate the results of our model in section five. We conclude our work in section six.

2 Text clustering approaches

2.1 Embeddings approaches

The simplest way to build a clustering model on a collection of text documents includes two steps. On the first step, each document is mapped to a real-valued vector. On the second step, one of the standard clustering algorithms is applied to the resulting vectors.

There are many methods to build an embedding of a document. The simplest way is the tf-idf representation. Logistic regression on the tf-idf representation is quite a strong algorithm for the text classification problem. This algorithm is respectable baseline even in deep neural networks research (Park et al., 2019). However, the direct use of the tf-idf representation leads to poor results in the clustering problem because of the curse of dimensionality. Dimensionality reduction methods could be used to improve clustering quality: PCA or Uniform Manifold Approximation and Projection (UMAP, McInnes et al. (2018)).

Another popular approach makes use of different word embeddings (Esposito et al., 2016). First of all, each word is mapped to a real-valued vector. Then the document representation is derived from the embeddings of its words. The most popular embedding models belong to the word2vec family (Mikolov et al., 2013b): CBOW, Skip-gram and their modifications (Mikolov et al. (2013a)). For correct representation word2vec models should be trained on a large collection of documents, for example, Wikipedia. Further improvement in quality of clustering models with embeddings can be achieved through fine-tuning. Similar to the tf-idf approach dimensionality reduction is often employed for the clustering problem (Park et al., 2019). Several averaging schemes can be used to aggregate word embeddings: mean, where all words contribute equally to the document, or idf-weighted, where rare words have a greater contribution than frequent words.

2.2 Topic modeling

Another approach to text clustering problem is topic modeling. The topic model simultaneously computes words and document embeddings and perform clusterization. It should be noted that in some cases topic model-based embeddings outperform traditional word embeddings, (Potapenko et al., 2017). The probability of the word w in the document d is represented by formula below:

$$p(w \mid d) = \sum_{t \in T} p(w \mid t) p(t \mid d) = \sum_{t \in T} \phi_{wt} \theta_{td}$$

where matrix Φ contains probabilities ϕ_{wt} of word w in topic t, matrix Θ contains probabilities θ_{td} of topic t in document d.

Probabilistic Latent Semantic Analysis (pLSA) (Hofmann, 2000) is the simplest topic model which describes words in documents by a mixture of hidden topics. The Φ and Θ distributions are obtained via maximization of the likelihood given probabilistic normalization and nonnegativity constraints:

$$L(\Phi, \Theta) = \sum_{d \in D} \sum_{w \in W} n_{dw} \log p(w|d) \;\to\; \max_{\Phi,\Theta}$$

$$\sum_{w \in W} \phi_{wt} = 1, \;\phi_{wt} \geq 0$$

$$\sum_{t \in T} \theta_{td} = 1, \;\theta_{td} \geq 0$$

This optimization problem can be effectively solved via EM-algorithm or its online modifications (Kochedykov et al., 2017).

Latend Dirichlet Allocation (LDA) (Blei et al., 2003) model is an extension of pLSA with a prior estimation of the Φ and Θ, widely used in topic modelling. However, as a solution for both pLSA and LDA optimization problem is not unique, each solution may have different characteristics.

Additive Regularization of Topic Models (ARTM) (Vorontsov and Potapenko, 2015) is non-bayesian extension of likelihood optimization task, providing robustness of the solution by applying different regularizers. Each regularizer is used to pursue different solution characteristics. For example, many varieties of LDA can be obtained from ARTM model by using certain smoothing regularizer; pLSA model is an ARTM model without regularizers. Furthermore, documents can contain not only words but also terms of other modalities (e.g. authors, classes, n-grams), which allow us to select specific for our task language features. In this case, instead of a single Φ matrix, we have several Φ_m matrices for each modality m. Resulting functional to be optimized is the sum of weighted with α_m coefficients modalities likelihoods with regularization terms:

$$\sum_m \alpha_m L(\Phi_m, \Theta_m) + R(\cup_m \Phi_m, \Theta) \rightarrow \max_{\Phi,\Theta}$$

3 Multilevel clustering

Our goal is to build a topic model with topics corresponding to the user's intents. We use the following operational definition of intent: two dialogues (as represented by user's utterances) are said **to have the same intent** if both users would be satisfied with the essentially same reaction by the call centre operator. This definition, while inherently problematic, allows us to highlight several important practical problems:

- Simple bag-of-words (BoW) approach isn't sufficient. Compare: "I want my credit card to be blocked. What should I do¿' and "My credit card is blocked, what should I do¿'.
- In some cases, the intent of conversation is not robust to a single word change. "I want to make an appointment with cardiologist" and "I want to make an appointment with neurologist" are considered to have the same intent since they require the user to perform a virtually identical set of actions. However, "Payment of state duty for a passport" and "Payment of state duty for vehicle" are vastly different.

To account for the BoW problem we add an n-gram modality and p_{tdw} smoothing regularizer (Skachkov and Vorontsov, 2018) for all tokens. The p_{tdw} smoothing regularizer respects the sequential nature of text, making the distributions $p(t|d, w)$ more stable for w belonging to a same local segment. In a way, $p(t|d, w)$ distribution could be interpreted as the analogue for context embeddings in topic modeling world. $p(t|d, w)$ distribution isn't used directly for topic representation, but it is used on the E-step of EM-algorithm for ϕ_{wt} and θ_{td} recalculation.

In order to obtain more control over intent robustness we propose to use a two-level hierarchical topic model. The first level is responsible for coarse-grained similarity, while the second one could take into account less obvious but important differences.

The hierarchical ARTM model consists of two different ARTM models for each level, which are linked to each other. The first level of the hierarchical model can be any ARTM model. The second level is built using regularizer from (Chirkova and Vorontsov, 2016) which ensures that each first-level topic is a convex sum of second-level topics. Various methods could be employed to ensure that each parent topic is connected to only a handful of relevant children topics: one can use either interlevel sparsing regularizer (Chirkova and Vorontsov, 2016) or remove "bad" edges according to EmbedSim metric (Belyy, 2018).

3.1 Distinct hierarchy levels

Building a two-level clustering model is a difficult task due to the inaccuracy of clustering algorithms. Provided that documents in the model first-level clusters are already similar to each other (as they should be), further separation could be complicated (especially if we attempt to subdivide each cluster by the same algorithm). In practice, the second-level clusters tend to repeat first-level clusters at smaller scale instead of demonstrating some meaningful differences. In order to make our model able to distinguish new dissimilarities in clusters on the second level, we adjust algorithm at the second level: in broad strokes, we base the second level of model on different features.

In the context of our problem, separation based on the functional purpose of the model tokens is proposed. We divide all words and n-grams into two groups based on the PoS analysis: "thematic" and "functional". The "functional" group consists of the verb words and n-grams that contain at least one verb. The "thematic" group consists of the nouns and adjectives and n-grams that contain at least one noun and have no verbs. Inspired by multi–level (Tang et al., 2018) and multi–syntactic (Gupta et al., 2018) phrases annotation, among with hierarchical partition, our approach is essential for client goal and subgoals extraction.

The purpose of the first hierarchy level is to determine the conversation subject (the entities the dialogue is about). Hence, at the first level of the hierarchy thematic tokens should have a noticeably higher weight than functional tokens. The purpose of the second level of hierarchy, by contrast, is to determine client intent concerning particular objects (e.g. what action the client is trying to perform). Functional tokens should have higher impact over thematic ones. The tokens unrelated to these two groups are used on both levels and serve as a connection between the layers.

4 Preprocessing

We use standard preprossessing pipeline consisting of tokenization, lemmatization, part-of-speech tagging, n-grams extracting, named entity recognition and spell checking. In this section we describe some details of preprocessing algorithms since the preprocessing is very important for any morphologically rich languages such as Russian.

Data prepossessing pipeline consists of many parts, therefore each part must be relatively fast. That is why we don't use some great powerful approaches such as (Devlin et al., 2018) for NER.

4.1 N-grams extracting

Conventional approach in surpassing the bag-of-word hypothesis of the model is by adding n-grams or collocations into the model. To extract n-grams we use TopMine algorithm (El-Kishky et al., 2014) based on a words co-occurrences statistics.

However, we found it beneficial to implement some modifications. First change alters gathering and usage of word co-occurrences statistics: TopMine differentiates between sequences (w_1, w_2) and (w_2, w_1), which is not desirable for synthetic languages with less strict word order compared to English. To make it better suited to the Russian language, we use multisets as containers for collocations instead of sequences. Second change modifies the extraction process: while the original version of TopMine extracts only disjoint collocations and won't detect sub-collocations (e.g. if n-gram "support vector machines" is extracted, n-gram "support vector" will not be extracted), our modification will extract every high-scoring collocation at the cost of increased memory usage.

4.2 Named entity recognition

There are a lot of references to the speakers' names, company/product names, streets, cities in the dialogue collection. It makes sense to take into account some entities in a special way.

For the named entity recognition problem (NER) different methods are commonly used: rule-based, machine-learning-based or neural-networks-based. We used neural network from Arkhipov et al. (2017) pretrained on a PERSONS-1000 (Vlasova et al. (2014)) for our experiments. We replace all person related tokens by the $\langle \mathrm{PERSON} \rangle$ tag.

4.3 Spell checking

Errors and typos in client utterances are common in the dialogue collection. The simplest way to deal with this problem is to apply a spell checking algorithm. We use Jamspell[1] algorithm for spell checking since its fastness.

We make some modifications to adapt the Jamspell model to our case. First of all, the language model used to select the best correction candidates should be trained on the collection for clustering. This modification takes into account the collection specificity and collection specific words won't be treated as unknown.

Also the set of candidates can be extended. According to the statistics of Yandex search engine[2] word merging error is one of the most popular typos in the dialogues. Hence, we add candidates that are obtained via splitting a word in two.

5 Experiments

We use two dialogue datasets from the Russian call-centres ($\sim 90K$ dialogues in each) in our experiments. The first dataset is collected from client dialogues with various public services. The second dataset is conversation logs of ISP tech support. All dialogues are between a user and a call agent, mean length of a single dialogue is six utterances. Both datasets are proprietary.

5.1 Scoring metric

There are several approaches for measuring the quality of topic model, especially its interpretabil-

[1] Jamspell github

[2] Yandex search errors statistics (on Russian)

ity. The usual procedure involves evaluating the list of most frequent topic words by human experts. However, this approach suffers from several fundamental limitations (Alekseev, 2018). Therefore we choose to employ a different method.

For each dataset, we collect a set of dialogue pairs to score our model. Following the reasoning outlined in the section 3, we generated a number of (d_1, d_2) pairs (where d_i is a dialogue) and asked three human experts to label them. To measure the quality of the model, we compare these labels to the labels predicted by model.

The following list summarizes our approach for model estimation and labeling guidelines for human experts:

- `0`: d_1 and d_2 have nothing in common. Such objects should correspond to the different first-level topics.
- `1`: both d_1 and d_2 are related to the same subject, but there are significant differences. Such dialogues should correspond to the same first-level topic, but to the different second-level topics.
- `2`: d_1 shares an intent with d_2. Such dialogues should correspond to the same first-level and second-level topics.
- `?`: it is impossible to determine the intent for at least one of the dialogues.

We select the best model according to the accuracy metric on a given labeled pairs. Three sets of pairs are used for the estimation ($\sim 12K$ and $\sim 1.5K$ for the first dataset, $\sim 1.5K$ for the second dataset). All model hyperparameters are tuned according to the accuracy on a $12K$ dataset ("1-big"). Two other sets are used to control overfitting ("1-small" and "2-small"). Notably, the good performance on 2-small dataset implies that the model generalizes beyond the initial training dataset.

The same preprocessing procedures are used for both datasets. All tokens are lemmatized, stop-tokens are deleted, simple entities (e-mails, websites e.t.c) are replaced by their tags. Operator utterances are deleted from the dialogue document (they are not informative in our datasets; for example, there are many cases where operator fails to reply at all). Finally, each document is a concatenation of one dialogue user utterances from a single dialogue.

5.2 Baselines

As one of the baselines, we use the following procedure. First, we convert raw texts into real-valued vectors using pretrained embeddings or tf-idf scores in a way described in 2.1. Second, we cluster this dataset via K-Means algorithm. Third, we treat each cluster as a separate collection and perform K-Means algorithm again. As a result, we obtain both first-level and second-level clusters.

Another baseline models are hierarchical topic model without any additional regularizers and hierarchical topic model with Φ and Θ smoothing for both levels. For K-Means based algorithms we tune embeddings dimensionality and both level cluster number. For topic modeling based algorithms we tune both level topics number. As shown in table 1 regularized topic model outperforms K-Means approaches at two out of the three pair sets.

	1-big	1-small	2-small
hKmeans (tf-idf)	0.568	0.593	**0.649**
hKmeans (emb.)	0.615	0.638	0.641
hPLSA	0.603	0.675	0.633
hARTM	**0.636**	**0.683**	0.631

Table 1: Baselines accuracy

5.3 Proposed model perfomance

We use several NLP-based techniques described in 4 to improve main model quality. We start with the hPLSA model. For each problem we test a few approaches and choose the best one. We add all main features one by one, e.g. we choose the best method for extracting n-grams and use it on the next step. We conduct all the experiments in the following order:

1. including additional n-gram modality, choosing between the based and modified n-grams extracting methods, tuning modality weights and topics number;
2. adding p_{tdw} smoothing at the first model level for all tokens, tuning regularizer coefficient and topics number;
3. replacing person related named entities, choosing between the dictionary-based and rnn-based methods;
4. typo correction, choosing between the base and modified algorithm

	1-big	1-small	2-small
hPLSA	0.603	0.675	0.633
+ n-grams base	0.612	0.634	0.633
+ n-grams mod.	**0.635**	**0.674**	**0.655**
+ ptdw smooth.	**0.64**	**0.678**	**0.66**
+ NER dict.	0.634	0.661	0.635
+ NER NN	**0.64**	**0.68**	**0.662**
+ Jamspell	0.635	0.674	0.655
+ mod. Jamspell	**0.657**	**0.686**	**0.663**

Table 2: NLP techniques quality improvement

As the table 2 demonstrates our n-grams extraction method outperforms traditional TopMine algorithm in this task. Replacing persons by a tag does not lead to a great improvement of the quality. Our analysis of hPLSA cluster top-tokens shows that only 3% of the top-tokens are related to persons. After the NER preprocessing the proportion of named entities in top tokens reduces to 0.3%. And at the same time spellchecking improves the performance on all three pair sets. It should be noted that standard Jamspell algorithm leads to a quality decrease.

Finally, we apply feature grouping schemes proposed in 3.1. The results (table 3) turned out to be reassuring. There is a noticeable performance boost for all of the pair sets.

	1-big	1-small	2-small
featured hARTM	0.657	0.686	0.663
+ groups	**0.667**	**0.715**	**0.672**

Table 3: Grouping feature quality improvement

Further, we represent some examples of the model performance. All example texts from examples were translated from Russian to English. In the table 4 all subtopics of the topic "Tariff plan" are presented. Each subtopic described by the characteristic question.

In the table 5 we demonstrate top documents corresponding to the "How do I switch from credit to advance payment?" subtopic.

6 Conclusion

In this paper, we report a success in formalizing the clustering process suitable for unsupervised inference of user intents.

The realization that any intent consists of two crucial parts: the entity relevant to the user's request and the action user wishes to perform helped us to choose a two-level hierarchical model as our main tool. This leads us to design a custom quality metric which takes into account several degrees of the dialogues relevancy.

Tariff plan
How to change the tariff plan?
When did the tariff change happen?
How often can I change my tariff plan?
When will the changes take effect when the tariff is changed?
Why can't I change the tariff?
Why was the tariff plan changed without my knowledge?
Why there are no available tariff plans for the transition?

Table 4: Subtopics of topic "Tariff plan"

How do I switch from credit to advance payment?
How do I switch from credit to advance payment?
Hi. Tell me can we change the credit system of payment to advance? Well thanks!
I need to change my payment from credit to advance.
How to disable credit payment system?
Hello. Change the payment system from credit to advance!
Good morning. How to change the payment system from credit to normal?
Disable the credit payment system.

Table 5: Top documents of subtopic "How do I switch from credit to advance payment?"

Our next step was to devise a PoS-based feature separation and to leverage n-grams, named entities and spellchecking. This allowed us to construct a hierarchical multimodal regularized topic model which outperforms all baseline models.

Acknowledgments

We thank our colleagues Alexey Goncharov and Konstantin Vorontsov from Machine Intelligence Laboratory who provided expertise that greatly assisted the research. We thank Evgeny Egorov for comments that greatly improved the manuscript.

Abstract

Lexical resources such as WordNet (Miller, 1995) and FrameNet (Baker et al., 1998) are organized as graphs, where relationships between words are made explicit via the structure of the resource. This work explores how structural information from these lexical resources can lead to gains in a downstream task, namely frame identification. While much of the current work in frame identification uses various neural architectures to predict frames, those neural architectures only use representations of frames based on annotated corpus data. We demonstrate how incorporating knowledge directly from the FrameNet graph structure improves the performance of a neural network-based frame identification system. Specifically, we construct a bidirectional LSTM with a loss function that incorporates various graph- and corpus-based frame embeddings for learning and ultimately achieves strong performance gains with the graph-based embeddings over corpus-based embeddings alone.

1 Introduction

Frames are common scenarios, expressed by their typical participants and the predicates which evoke them. The INFECTING frame, where someone transmits an illness, has participants INFECTED_ENTITY and INFECTION_CAUSE and is evoked by predicates *infect* and *give*. A single predicate can evoke one or more frames; *give*, for instance, can evoke INFECTING (*give someone a cold*) or GIVING (*give someone a present*). The disambiguation of which frame is evoked in context is the task of *frame identification* (FrameID), which is, in essence, a word sense disambiguation task where the senses are frames (Das et al., 2010).

The FrameNet resource (Baker et al., 1998) provides concrete definitions of frames, predicates, and participants (called *frame elements*) and is structured as a hierarchical graph. Frames towards the top of the hierarchy are more abstract (ex. INTENTIONALLY_ACT), while frames lower in the hierarchy are more granular (ex., SUBMITTING_DOCUMENTS). FrameNet's graph structure captures the relationship between frames, their predicates, and their frame elements, such that a single frame can be connected to multiple frames via different relationships (Baker and Ellsworth, 2017). Given the structure of the resource, it is surprising that the graph is not used in current FrameID systems, as the relationships in the FrameNet graph have been previously shown as relevant to frame prediction, especially in cases of unseen predicates (Das et al., 2014).

This work leverages FrameNet's graph structure to boost the performance of neural architectures for FrameID. Specifically, we construct frame embeddings from the FrameNet graph structure and use them as input to a neural network. Although frame embeddings are often used in neural architectures for FrameID, prior work only learns these embeddings from frame-annotated corpus data (Hartmann et al., 2017; Hermann et al., 2014). To our knowledge, this is the first work to incorporate embeddings composed from the FrameNet graph structure itself, thus incorporating all frame, frame element, and predicate relationships that could otherwise be missing from corpus data. We expand our frame graphs with knowledge from another lexical resource, WordNet, to achieve further gains in performance.

Our paper is structured as follows. Section 2 describes prior work in graph embedding models and FrameID. We define our model in Section 3, and

Section 4 focuses on the FrameNet and WordNet graphs, while Sections 5 and 6 explain how we use the FrameNet knowledge base to build graph embeddings. Section 7 outlines our experiments, and Section 8 gives results and further analysis of the model performance.

2 Background

2.1 Graph Embeddings

Graph algorithms, especially random walk algorithms, have been applied to prediction tasks such as word sense disambiguation (Agirre et al., 2014), measuring semantic similarity and relatedness between words (Agirre et al., 2010), and entity linking (Guo et al., 2011). These algorithms traverse over the relations and nodes in a large knowledge base such as WordNet (Miller, 1995) or taxonomies built from Wikipedia links (Cucerzan, 2007) to uncover relationships between the nodes in the knowledge base. However, the effectiveness of shallow neural networks in learning word similarity, as shown by the popular Word2Vec and GloVe models (Mikolov et al., 2013; Pennington et al., 2014), rapidly replaced traditional graph-based methods for word similarity and prediction tasks. Word representations learned in these models, called *embeddings*, provide the latent features of a word in context as low-dimensional vectors. Recent work has sought to incorporate the best of graph algorithms and embeddings by learning representations for words over a neural network while using the structural information found in knowledge bases (Goikoetxea et al., 2015; Faruqui et al., 2015).

Our method for constructing graph embeddings follows the work of Goikoetxea et al. (2015) who use random walks to build a synthetic corpus based on entries in WordNet. In this corpus, a word's contexts are the other words in the knowledge base that it is related to. They use the corpus to generate embeddings for words with CBOW and Skipgram models.

2.2 Neural Architectures for Frame Identification

The first work to use embeddings for FrameID used the WSABIE algorithm to project frames and predicate contexts into the same shared space (Hermann et al., 2014). The authors then apply a pairwise loss to minimize the distance between the frames and their predicate instances. Subsequent FrameID models followed, including a system that constructed frame embeddings using the Word2Vec model (Botschen et al., 2017). More recent state-of-the-art models use contextualized embeddings of frames in the BERT framework (Sikos and Padó, 2019) or joint models with semantic dependencies and frames (Peng et al., 2018). All of these prior neural architectures construct frame embeddings directly from annotated corpora, meaning the frame embeddings that are used to make predictions in the model are limited to frames that are seen in the corpora.

3 Frame Identification Model

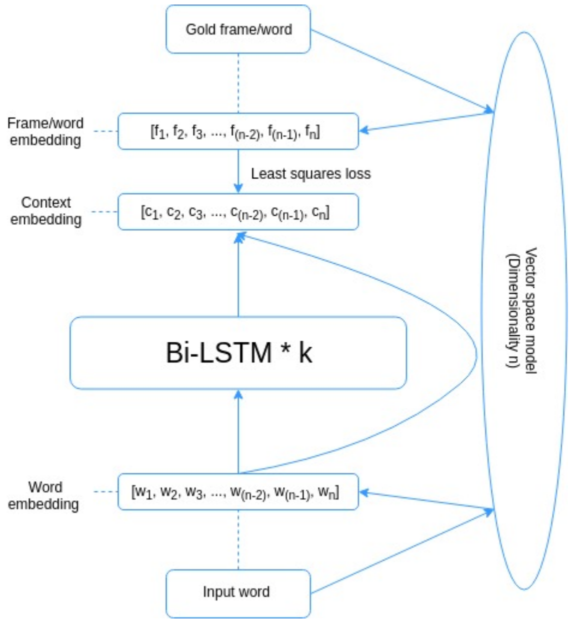
This section describes the overall architecture of our FrameID model. We adopt a bidirectional recurrent neural network (Bi-LSTM) that accepts as input different embeddings that represent frames and predicates. This allows us to measure the effectiveness of the pre-trained embeddings (corpus-based, graph-based and combined) for an apples-to-apples comparison within the same setting. The components of our neural network include:

- an input embedding layer; the network can allow two embedding inputs per word – the embeddings from separate sources (corpus/graph-based) are concatenated;
- bidirectional recurrent layers; the forward and backward states are concatenated;
- an output vector with the same dimensionality as the frame embeddings;
- an objective function that compares the final output and the gold frame embeddings; at those steps that do not introduce frame-evoking predicates the network attempts to reconstruct the embedding for the input word itself, so that "infect" should result in the embedding of INFECTING, but "the" should just be reconstructed to the embedding of "the".

At evaluation time, output vectors are compared via cosine similarity to the frame embeddings, where the label for the closest frame is selected as the model's prediction. Figure 1 shows the architecture of the network.

4 FrameNet as a Graph

As described above in Section 1, FrameNet has a structure which connects frames via different semantic relations. Relations in the knowledge base include *Inheritance*, an *is-a* relation akin



Gold frame/word
Frame/word embedding
$[f_1, f_2, f_3, ..., f_{(n-2)}, f_{(n-1)}, f_n]$
Least squares loss
Context embedding
$[c_1, c_2, c_3, ..., c_{(n-2)}, c_{(n-1)}, c_n]$
Bi-LSTM * k
Word embedding
$[w_1, w_2, w_3, ..., w_{(n-2)}, w_{(n-1)}, w_n]$
Input word
Vector space model
(Dimensionality n)

Figure 1: Bi-LSTM for FrameID. The diagram shows a model with one embedding layer, but combining with an additional embedding source is done trivially via concatenation. The embeddings used for the input and the gold frames can either come from the same or a different vector space. The size of the word/frame embeddings is **n**; **k** is the number of hidden layers.

to hypernymy in WordNet (e.g., REVENGE inherits from REWARDS_AND_PUNISHMENTS), *Using*, which connects a concrete frame to a related, but more abstract frame (e.g. SPEED uses the MOTION frame), and *Subframe*, where the parent frame is a more complex event that subsumes the child frame(s) (e.g. CRIMINAL_PROCESS subsumes ARREST). See Ruppenhofer et al. (2006) for a more detailed description of all possible relation types.

This network of relations is used as the basis of our graph. We construct a graph where each frame is a node, and we build edges between frames according to the available relational information in FrameNet. Frame elements (FEs) are also nodes that are connected to their frames. Some FE nodes, such as AGENT, are widely connected in the graph since they are linked to a diverse set of frames. In order to have a single FE node be distinctive to a single frame, the FE nodes are given unique identifiers. For the unique identifier, the frame name is prepended to the name of the FE together with a colon separator, such as HIRING::EMPLOYEE. However, these unique FE nodes are further connected to their abstract counterparts with an *is-a* relation (REVENGE::AVENGER *is-a* AVENGER), which preserves the connectedness of the FE in FrameNet and also provides some connectivity between frames that share the same FE.

4.1 Extending the FrameNet graph

We empirically find that, on its own, the graph described above does not form a dense enough graph structure. This is due to the fact that few frames can be connected through short paths since some frames contain little to no relations to others and FrameNet FEs are often very specific to particular types of scenarios.

To overcome this limitation, we mapped FrameNet to the WordNet lexical resource. WordNet groups synonymous words of the same part-of-speech category into concept clusters called *synsets* and provides lexical relations between word senses and the relations between synsets. Its dense semantic network provides a rich representation of the ecology of lexical meaning, especially when associated resources are brought into play. This allows for connecting concepts that might not be linked via lexico-semantic relations but nevertheless are mutually dependent due to contextual co-occurrence.

Mapping FrameNet predicates with the Predicate Matrix The mapping process is done in two steps. First, the verbal predicates in FrameNet are connected to their corresponding synsets in WordNet. Since one word can be mapped to several senses in WordNet, this mapping is far from straightforward. We map FrameNet predicates and WordNet synsets through an auxiliary resource called the Predicate Matrix (De Lacalle et al., 2014), which aimed to automatically extend the predicate mappings from SemLink (Palmer, 2009). Within the Predicate Matrix, predicates from a FrameNet frame are linked to concept nodes, which are also connected to a corresponding WordNet synset. Via these synsets, we now have access to WordNet's semantic network, where words are interconnected through lexico-semantic relations such as hypernymy, antonymy, meronymy, as well as through other relations expressing relatedness.

Lexical fillers for FrameNet FEs via Wikipedia and BabelNet The second step in the mapping process is the automatic expansion of FrameNet by extracting typical fillers for FrameNet FEs.

For instance, SELLER is strongly linked to lexical items such as *cashier* or *salesman*, both available in WordNet. While the Predicate Matrix aligns the predicates in FrameNet to WordNet synsets, we additionally align these candidate fillers from WordNet to the FEs they instantiate in FrameNet. Aligning FrameNet's FEs with WordNet is made possible by an automatically created extension of FrameNet (Bryl et al., 2012). The method used by the authors relies on a machine learning model linking nominal lexical fillers for the FEs in the authors' FrameNet reference corpus to Wikipedia pages. The BabelNet resource (Navigli and Ponzetto, 2010) provides mappings between Wikipedia pages and the corresponding WordNet synsets, which are mapped to the frame-FE tuples. Because the process is automated, the correspondences are inevitably noisy. However, it provides a significant expansion of words are not directly given by the FrameNet lexicon but nevertheless intuitively related to the concepts in the frame; e.g., a *cashier* and *salesman* are implicitly related to the COMMERCE_SELL frame. In this sense, this step incorporates more world knowledge into a frame's graph.

5 The FrameNet Graph as a Pseudo-Corpus

Once the nodes in FrameNet and WordNet are aligned, the resulting graph structure is leveraged to produce a large corpus of artificial sentences on which a vector space model can be trained. We follow the methodology of Goikoetxea et al. (2015) for the generation of a pseudo-corpus, where each line contains a sequence of node identifiers visited during one random walk of the algorithm as it moves along the graph. This is done with the UKB tool[1] and its "ukb_walkandprint" functionality. The *wemit_prob* parameter is set to 0.5, which means that in half the cases it emits a dictionary key associated with the node ID generated along the random walk, i.e., half the "words" in the artificial sentences are either predicates or frames corresponding to synsets, as established in the mapping process.

The UKB tool uses a particular dictionary format for the creation of pseudo-corpora. Each line is constructed as follows: a key, often a predicate, begins the entry, followed by its associated WordNet synsets. The result looks like the following:

employment 13968092-n:9 00584367-n:9 01217859-n:6 00947128-n:1

where the synset number is given along with a letter after the synset ("-n"), which signifies the POS category and the number (":9") is the number of instances of this specific sense found in a reference corpus. The *ukb_walkandprint* functionality requires this dictionary for the emission of lexical items from the visited nodes along the random walks. In the case when *wemit_prob* is set to a non-zero value, the tool will pick, with probability *wemit_prob*, one dictionary key associated with the current WordNet synset. The dictionary provides information on what items belong to which synset. If the *dict_weight* parameters are provided, the tool will also take into consideration the count-based weights for each predicate-synset pairing and emit a predicate according to the available probability distribution.

Incorporating FrameNet frames into the UKB dictionary Because the graph now includes frames and FE relations, which are outside of the WordNet lexicon, those need to be included in the dictionary as well. Therefore, we add the frame IDs to the dictionary. This is done in two ways; first, the frames are added as keys corresponding to the synsets to which they have been mapped - below, the frame RENTING is mapped:

Renting 02208537-v:1 02460619-v:1 02208903-v:2

Second, frames are added as values of lexical items that evoke them, as per the information encoded in the FrameNet database. For instance, the predicate *hire.v* is evoked by the RENTING frame:

hire.v Renting:0 02208537-v:0 02460619-v:1 02409412-v:33 Hiring:34[2]

A frame ID can be emitted whenever a connected synset node is visited during a random walk, or if a frame node is visited, it might emit a lexical item connected to the frame as a key in the dictionary. Thus the pseudo-corpus includes both references to specific frames and frame-evoking expressions whose use is contextualized with respect to particular frames. The weights for the frames in the dictionary are calculated by summing up the weights

[1] http://ixa2.si.ehu.es/ukb/

[2] Note that because we are interested in obtaining representations for lexical units (i.e. *lemma.pos* items), the dictionary is modified to include morphological information per each key.

for the lemma-synset pairs mapped to the frames-as-values.

Augmenting the Graph with Wikipedia With the graph and dictionary in place, *ukb_walkandprint* is used to generate 200 million random walks. This pseudo-corpus is then concatenated to a lemmatized and POS-tagged Wikipedia dump (where each word is transformed to a *lemma.pos* lexical item), so that the embeddings can be trained on natural language text in addition to the graph-generated artificial sentences. This is a naive method to combine graph and text information, in that the model is never trained on both kinds of information in one and the same sentence, but it nevertheless allows it to encode real-text syntagmatic information within the lexical space projected from the graph structure. The Wikipedia data is approximately the same size as the pseudo-corpus.

6 Frame Embeddings

Graph embeddings of frames We now have a pseudo-corpus composed from the FrameNet/WordNet graph structure, as described in Section 5. These graph representations are constructed for all the frames in the FrameNet lexicon. We use the popular Word2Vec tool[3] to generate embeddings from the pseudo-corpus. This model uses negative sampling to learn word representations, and we apply the Skipgram variant of the model where a single word is used to predict its neighboring terms in the immediate context. This produces a large inventory of graph embeddings for frames in FrameNet and lexical items, all located in the same space.

Corpus embeddings of frames To compare the graph embeddings with frame embeddings learned from a corpus, we took the freely available embeddings from Sikos and Padó (2018), in which the authors generated frame embeddings using the Word2Vec tool. Specifically, the authors took lemmatized sentences from the FrameNet annotated data and replaced each predicate (e.g., **say.v**) with the frame it evokes:

FrameNet sentence	Officials **say.v** he left
Frame evoked	STATEMENT
Embedding Input	official STATEMENT he left

This resulted in sentences of frames in context, so the example input above would not only produce an embedding for the frame STATEMENT, but also embeddings for the context words such as *official*. In addition to training embeddings on this frame corpus, the authors also provide embeddings based on the original FrameNet annotated corpus. This is important in our case, as we can use the embeddings trained on the original corpus at the input step and the embeddings trained on the frames corpus at the output.

7 Experiments

7.1 Model Setup

The inputs to our model are frame and lexical unit embeddings with 300 dimensions, and the Bi-LSTM has 1 recurrent layer. Each LSTM cell is of size 200, with 0.2 dropout applied to all its sublayers during training. We use the Adam optimizer with a least squares loss function. The training sentences are presented in batches of 128.

The graph that we use for generating the training data for the embedding models consists of 129,101 nodes and 1,146,508 edges. The nodes correspond predominantly to WordNet synsets, with the rest being frame and FE IDs. The synset and FE IDs can be part of the pseudo-corpus or can be omitted from it, depending on the parametrization of the *ukb_walkandprint* command. Depending on this choice, the embeddings will either contain representations of synsets and FEs, or will not, since they are not present as keys in the UKB dictionary.

The graph embeddings were produced by the Word2Vec tool in the Skipgram variant, which has many hyperparameters that can be tuned. We use the following hyperparameters to generate the graph embeddings: size=300; window=15; sample=1e-7; negative=5; iter=7.

7.2 Datasets

We use the annotated data from the FrameNet v1.5 full text annotations to train our models. Sentences are drawn from the balanced BNC corpus[4], and overall there are over 11k frame-evoking predicates with their frames manually annotated. Standard training, development and test splits are defined by Das et al. (2014), where 39 documents are used in training with over 15k target predicates, 16

documents for development with over 4,500 target predicates, and 23 documents for testing with 4,458 target predicates.

7.3 Evaluation Metrics

Standard FrameID systems are evaluated via several different metrics, and we evaluate our models on the most common types. "Full Lexicon" evaluation uses knowledge of the FrameNet lexicon, so that for each predicate we classify the most likely frame given the list of all possible frame candidates for that predicate. "Ambiguous" only runs evaluation on predicates that can evoke multiple frames, thus making the evaluation more challenging by removing predicates that can only evoke one frame. "No Lexicon" reports only results from the classifier, where all frames in the FrameNet database are considered possible candidates. Finally, "Unseen" is the most challenging, as it only evaluates predicates that were not seen in the training data and also does not incorporate knowledge from the lexicon.

8 Results

Results of our models are given in Table 1. The best performing model combines graph-based embeddings with corpus-based embeddings for frame prediction, where strong gains are seen over the basic model that uses corpus-based embeddings alone. "Unseen" results in particular show the largest performance gains, where the combined graph- and corpus-based embeddings allow the model to generalize over new predicates.

The model that uses the popular GloVe embeddings (Pennington et al., 2014) at the input step performs worse than the model that uses the FN corpus embeddings at input and output. This indicates that learning the mapping between predicates and frames is much easier if their corresponding representations are drawn from identical data. The graph-based embeddings are somewhat better than those based solely on the FrameNet annotated corpus; the difference is especially pronounced in the evaluations without the lexicon. However, the graph embedding model that does not incorporate WordNet synsets and FrameNet FEs seems to perform the worst, indicating that those resources provide a strong conceptual skeleton for situating the embeddings of frames and lexical items. What is clear from the results, then, is that both corpus-based and graph-based embeddings contribute to frame prediction and that a richer structure underlying the graph-based embeddings is crucial for improved accuracy.

Our model underperforms compared to other embedding frameworks from Hermann et al. (2014) and Botschen et al. (2018), which can be explained through an examination of the input representation methods used by the different models, as well as their disambiguation strategies. The model by Hermann et al. (2014) constructs an input representation that encodes the syntactic dependency relations found within the predicate context by concatenating the embeddings for the arguments and learning a mapping to a lower-dimensional space. In this way it is similar to our recurrent neural network, but instead of learning the syntactic information implicitly, it feeds it directly, which potentially gives it an advantage. In our experimental setup this could be remedied by training a syntactic dependency parser that shares hidden layer parameters with the FrameID module. Since the FrameNet corpus is not annotated with such data, sequential transfer learning can be employed in order to train on two different signals at different stages (Ruder, 2019).

The Botschen et al. (2018) model is most significantly different from ours in two respects: it uses multimodal embedding representations at the input (textual + visual), and it employs a softmax classifier at the output step, whereas we use MSE as a loss function. Prior work has shown that the first option is more powerful in the context of word sense disambiguation tasks (Popov, 2017). The two classification approaches can be combined, however, in a multitask learning setting to boost accuracy with respect to both (Popov, 2019). Since our main goal in this paper has been to demonstrate the benefits of embedding FrameNet concepts using a graph model, we leave the task of improving the accuracy of the framework for future work.

Nevertheless, our Bi-LSTM does perform well compared to the Das et al. (2014) system, and we get strong results in the "No Lexicon" condition, suggesting the model is able to successfully learn frame categories without any knowledge from the lexicon. The "Unseen" metric shows a complementarity between the graph- and corpus-based embeddings, which further suggests that the two sources of information encode very different lexical and world knowledge.

8.1 Linguistic Analysis

We proceed with a qualitative comparison of frame performance to establish which frames have a boost in performance with graph or corpus-based knowledge. To discriminate the best performing frames within each model, we assign a ranking function for frame performance. We run this ranking function over each model to obtain a ranked list of its best performing frames.

Ranking combines the accuracy of each individual frame $Acc(F_i)$ with an added weight for the frequency of the frame in the corpus $Freq(F_i)$ to obtain an overall rank score $Rank(F_i)$. $Acc(F_i)$ is defined as the number of correctly predicted instances of the frame over the total number of instances. $Freq(F_i)$ is the total number of frame instances over the total number of all frame instances in the test corpus. The $Freq(F_i)$ weight ensures that frames with higher counts in the corpus are ranked higher than frames that have few instances, so therefore a frame with a perfect score will receive a higher rank when there are 80 instances of that frame than a perfect score with only a single instance.

We define $Rank(F_i)$ of a single frame as:

$$Rank(F_i) = Acc(F_i) + Freq(F_i) \tag{1}$$

We then apply the ranking formula to all frames F in the test data and select the 20 highest ranked frames. The highest ranking frames for each model are given in Table 2 and Table 3. Table 2 gives frames that perform better with graph-based knowledge, including AWARENESS, TIME_VECTOR, GOAL, and DEPARTING. Interestingly, AWARENESS and TIME_VECTOR both have a large number of predicates, where AWARENESS has predicates *comprehend.v*, *know.v*, and *understand.v*, and TIME_VECTOR contains mostly function words such as *after.prep*, *before.prep*, and *since.adv*. Both frames have frame elements that appear in multiple related frames, including EXPRESSOR and COGNIZER, which appear in AWARENESS and other frames relating to mental activity, and LANDMARK_EVENT in the TIME_VECTOR frame, which also appears in the closely related TEMPORAL_COLLOCATION frame. This suggests that their graph structures are large but the knowledge in these frame graphs are tied to a specific domain.

Alternatively, Table 3 shows frames that perform better in the corpus-based model, including ORIGIN, LEADERSHIP, and NATURAL_FEATURES. Their predicates are mostly restricted to one sense – ORIGIN, for instance, has predicates *jamaican.n*, *canadian.n*, and *french.a*, while NATURAL_FEATURES has predicates *mountain.n* and *continent.n*. However, their frame elements are more likely to appear across different domains. LOCALE is a frame element of the NATURAL_FEATURES frame, and it appears in POLITICAL_LOCALES which has many politically-related predicates and politically-related frames, all relatively unrelated to the concept of NATURAL_FEATURES. ENTITY is a frame element of the ORIGIN frame, and it appears in AGING and EVENTIVE_AFFECTING frames – both are also only loosely related to the concept of an ORIGIN. Frames that perform better under the corpus-based model, then, have frame elements and related frames that are more spread out and distantly connected in the graph, so it is perhaps not too sur-

Top 20 frames in graph- versus corpus-based frame embedding models. Frames in **bold** are not in the top 20 of the other model, and thus have benefited from knowledge found in either the graph (Table 2) or corpus (Table 3).

9 Conclusion

Our results here demonstrate that neural networks can achieve a significant boost when combining representations learned from corpus data with representations learned from knowledge graphs. Many frames that perform poorly in pure corpus-based models improve in the graph-based models. The graph-based model seems to learn better when there is a large set of domain-specific knowledge extracted from the frame's graph. Alternatively, corpus models provide benefits to frames whose graph structures are more diffuse, suggesting the corpus knowledge is better at helping the model to narrow down the sense of the predicate by using the contextual cues found in the annotated data. By combining both embedding types, we achieve strong gains where the combined model can draw advantages from both graph- and corpus-based embeddings.

Abstract

This paper introduces several improvements over the current state of the art in *knowledge-based* word sense disambiguation. Those innovations are the result of modifying and enriching a knowledge base created originally on the basis of WordNet. They reflect several separate but connected strategies: manipulating the shape and the content of the knowledge base, assigning weights over the relations in the knowledge base, and the addition of new relations to it. The main contribution of the paper is to demonstrate that the previously proposed knowledge bases organize linguistic and world knowledge suboptimally for the task of word sense disambiguation. In doing so, the paper also establishes a new state of the art for knowledge-based approaches. Its best models are competitive in the broader context of supervised systems as well.

1 Introduction

Word sense disambiguation (WSD) is a longstanding task in natural language processing (NLP), which has been approached through several broad families of computational techniques. While supervised learning models typically achieve the highest accuracy scores, problems related to the lack of gold corpora, data sparseness and suboptimal granularity of the computational lexicons have plagued the field and prevented significant breakthroughs. This paper presents results achieved with *knowledge-based word sense disambiguation* (KBWSD) algorithms as an alternative pathway. It builds on previous work in the subfield and demonstrates that KBWSD can achieve accuracy scores near and in some cases even at the state-of-the-art, as a rule dominated by supervised approaches. Moreover, the experimental results indicate that in-depth analysis of knowledge representation and knowledge enrichment hold significant promises – both as an alternative to supervised WSD, able to sidestep data-related issues, and as a source of potentially powerful new training signals.

The contribution of the article is fourfold. Firstly, it presents a novel strategy for constructing knowledge bases used in KBWSD, showing that a structure centered on word senses rather than on synsets can be more effective for this particular task. Secondly, another novel approach to structuring the graph is explored in using word and synset embedding models in order to assign weights to relation arcs in the knowledge graph. Thirdly, a number of avenues for the enrichment of the semantic network used for KBWSD are pursued, thus linking WordNet to external resources. Finally, a new state of the art *for KBWSD* is established, which is competitive even when compared with supervised systems.

The paper is structured as follows: the next section presents related work; section 3 deals with some preliminary experiments aimed at replicating previous work described in the literature, but in a slightly modified setting; section 4 outlines several strategies for improving the structure of the knowledge base used for KBWSD; the penultimate section reports on our core experimental work, and the final section concludes the paper.

2 Related Work

State-of-the-art results in the broader field of WSD have been recently summarized in the Unified Evaluation Framework[1] (UEF) by Raganato et al. (2017a), which focuses on the *all-words*

[1] http://lcl.uniroma1.it/wsdeval

disambiguation task based on WordNet 3.0 (Fellbaum, 2012). The top-performing systems in UEF, across supervised and knowledge-based ones, are an SVM model – an extension of the popular IMS system (Zhong and Ng, 2010), and a recurrent neural network model – context2vec (Melamud et al., 2016), with F1 scores on the concatenation of all evaluation corpora ranging between 69% and 69.7%. The supervised models are trained either on the SemCor corpus (Miller et al., 1993) or jointly on SemCor and the semi-automatically constructed OMSTI corpus (Taghipour and Ng, 2015). Very recently deep learning approaches have produced results above the 70% threshold (Luo et al., 2018a,b).

KBWSD has attracted a lot of interest from researchers over the years, since, at least notionally, it does not require any training data or additional resources beyond a computational lexicon and in some cases a knowledge base (KB). Furthermore, if the latter resources are designed in such a way so as to be domain-independent, this could provide a big advantage in dealing with data of heterogeneous origins. One of the earliest popular KBWSD methods is due to Lesk (1986); it takes the dictionary definitions of word senses for target words that occur together in a shared context and calculates the degree of overlap between them, seeking to maximise the latter metric. KBWSD systems, however, typically perform less well than supervised models, due to a number of hurdles, such as: the non-trivial issue of how to structure a KB and what to put inside it; how to explore a KB most effectively; how to integrate various pieces of knowledge into a holistic representation of meaning.

One of the most successful KBWSD approaches has been to use algorithms from the *Random Walks on Graph* family in order to obtain sense representations over particular textual contexts. For instance, Mihalcea (2005) constructs a subgraph with the possible word senses in a context and then runs *PageRank* (Page et al., 1999) over it in order to calculate the most prominent senses. Agirre and Soroa (2009) present an influential update on this method, within the UKB tool for WSD[2]. In addition to the *static* version of PageRank (Spr; introduced in Agirre and Soroa (2008)), which also constructs a sub-graph from the WordNet semantic network as a preliminary step, they put forward *Personalized PageRank*, in which the whole KB is used, with the context words serving to inject probability mass into all candidate word senses. The final state of the PageRank vector over the graph indicates which are the most relevant concepts in the particular context. Two variants are described: *Ppr* and *Ppr_w2w*, where the second one is modified so as to put additional emphasis on connected concepts and away from the target senses themselves. The second strategy is used to prevent competing but related word senses from bolstering each other inordinately, but also makes the algorithm significantly slower. Another related KBWSD system is *Babelfy*, which uses a *Random Walk with Restart* algorithm (Moro et al., 2014).

Two discussion points regarding Random Walks on Graph approaches are central in the context of this article: *knowledge base enrichment* and *algorithm parametrization*. Simov et al. (2016) have shown that the addition of new relation sets to the baseline WordNet 3.0 semantic network can have significant positive effects on the performance of the PageRank algorithm. Adding relations extracted from the manually disambiguated word sense glosses, for instance, is a major improvement; including dependency-based relations between manually disambiguated words from SemCor has also led to big error reductions. Therefore the enrichment and structural optimization of the KBs is clearly one possible avenue for the improvement of KBWSD accuracy. On the issue of optimal parameters selection, Agirre et al. (2018) have proposed an updated default parametrization for using the UKB system for PageRank KBWSD. They consider various possible changes: changing the length of the context under consideration, the number of iterations, the value of the damping factor, the use of word sense frequency information from WordNet, etc. This new default configuration yields much higher accuracy scores on the UEF evaluation data sets – in fact those are the best reported results for a KBWSD system that we are aware of. They are significantly above the challenging most frequent sense (MFS) baseline, and are not very far even from the accuracy scores reported for supervised systems.

3 Preliminary Experiments

Following the impressive improvements achieved via parameter optimization in Agirre et al. (2018)

[2] http://ixa2.si.ehu.es/ukb/

and the observations by Simov et al. (2016) that KB extension can lead to significant improvements over using just the baseline WordNet relations, we undertook to combine the contributions of these two lines of research. In these preliminary experiments, version 3.2 of the UKB system has been used, which is set by default to the parameters described in Agirre et al. (2018). The immediate aim of the experimentation was to ascertain whether this optimized parametrization generates analogous positive effects when an extended KB is used in conjunction with the PageRank algorithm.

We have performed an exhaustive combination and evaluation of the relation sets presented in Simov et al. (2016). In several cases we have been able to obtain improvements over the results reported in Agirre et al. (2018). In addition to reusing these sets of relations, we have decided to further enrich the knowledge graph by assigning weights to the relation arcs, making use of a synset embedding model in order to calculate node similarities. We have constructed such a model following the methodology described in Goikoetxea et al. (2015): using the UKB system's random walk function to produce an artificial corpus of node sequences, then training a Skip-gram model (Mikolov et al., 2013) over it. Thus, for each relation in the KB of the kind `(synset_1, synset_2)` its weight is set to the value of the cosine similarity function between the two synsets. The best results for the two types of setting – without and with weights – are reported in Table 1, in lines 9 and 10 respectively. Merely reusing the additional relation sets leads to an improvement of 0.9%. Setting the relation weights via the embedding model produces further gain of 0.4%.

4 Improving the Knowledge Base

In this section we present further changes to the knowledge base in order to improve accuracy. These modifications can be summed up as follows:

- Changing the shape of the graph by representing nodes in terms of word senses
- Defining weights on the knowledge graph arcs via embedding models
- Extraction of new relations from different external sources

We present each of these in turn.

4.1 Sense-Based vs. Synset-Based WSD

When constructing the KB, the UKB system generalizes lexical meaning in a number of ways. One of these is the use of synset IDs as nodes in the semantic network. Here is an example of a relation as represented in the KB distributed together with the UKB system:

```
u:00007846-n v:04618781-n s:derivation
```

where `u:00007846-n` and `v:04618781-n` represent two nodes in the KB and where there exists a relation between them. The source of this connection is a derivational relation encoded in WordNet. `00007846-n` is the identifier[3] for the synset including the following senses[4]:

```
person%1:03:00::, individual%1:03:00::,
someone%1:03:00::, somebody%1:03:00::,
mortal%1:03:00::, soul%1:03:00::
```

The second node corresponds to the following synset:

```
personhood%1:07:00::
```

As made apparent by this example, the derivational relation holds only between two of these senses[5]:

```
u:person%1:03:00::-n
        v:personhood%1:07:00::-n
                         s:derivation
```

We have exploited this original representation in order to construct the new KB format. The biggest open question we have been faced with is how to represent the synonymy relation. The first option considered was representing it in the same way as in the WordNet distribution:

```
00007846-n person%1:03:00::-n
00007846-n individual%1:03:00::-n
00007846-n someone%1:03:00::-n
00007846-n somebody%1:03:00::-n
00007846-n mortal%1:03:00::-n
00007846-n soul%1:03:00::-n
```

This approach was our first choice. The relation representation in the KB follows the distinction between *lexical relations* holding among senses and *semantic relations* holding among synsets. After several experiments with this new representation of the KB it became clear that the novel format does not lead to improved accuracy.

Subsequently, we have excluded the synset identifiers from the representation of the KB. In

[3] This identifier is formed out of the original identifiers in WordNet. The original part-of-speech prefix is deleted and a part-of-speech suffix is added in its place.

[4] A sense in WordNet is defined as a combination of a lemma and a concept represented by a synset.

[5] This is how derivational and other kinds of lexical relations are represented in the original distribution of WordNet.

order to do this, a decision had to be made on how to represent the semantic and the synonymy relations. The option to represent them via calculating complete Cartesian products seems unrealistic. Hence our decision to utilize another source of information encoded in the distribution of WordNet – the ordering of the senses within each synset, which are supposed to represent their relative lexicographic importance. The main node for each synset is thus represented by the first sense in it. All remaining senses are mapped to this node, which is taken to be representative for the synset. All the semantic relations are mapped to the central nodes as well. The lexical relations are represented as before – between the corresponding word senses.

The above synset is now represented as follows:

```
person%1:03:00::-n individual%1:03:00::-n
person%1:03:00::-n someone%1:03:00::-n
person%1:03:00::-n somebody%1:03:00::-n
person%1:03:00::-n mortal%1:03:00::-n
person%1:03:00::-n soul%1:03:00::-n
```

The sense-centric experiments reported in the article have been performed using this format of the KB.

The next step in transforming the KB is the construction of a set of relations extracted from external sources, such as the ones described in Simov et al. (2016). Included in those is the set of external relations distributed together with the UKB system. This set is constructed on the basis of a WordNet gloss corpus, in which some of the words used in the gloss for each synset are annotated with the appropriate word senses from WordNet. Each constructed relation holds between the synset associated with the gloss and the synset of the corresponding sense in the annotation. It is relatively easy to reproduce this type of relation on the basis of the gloss corpus.

The relations represented in the **GraphRelSC** set are extracted from the SemCor corpus. This set of relations includes two types of nodes: for the semantically annotated words and for the nodes in the dependency tree of the corresponding sentence. The dependency analyses of the sentences are not part of the original annotation of SemCor. Thus, those cannot be reused for the construction of sense-based relations. The good news is that we do not need to have the actual dependency annotation, because in **GraphRelSC** the nodes corresponding to the dependency nodes are numbered with the numerical IDs of the documents, the sentences, and the words in the original corpus. Thus, through a simple mapping we have been able to substitute the synset identifiers with the actual sense annotations in the corpus. In Table 1 this new set of relations is referred to as **SC**.

In addition to **GraphRelSC**, we have extracted a set of co-occurrence relations from each sentence in SemCor. This new set of relations is called **SCR**. We have not been able to reconstruct the **WN30gl** set of relations because the mapping from it to the original annotation is not straightforward. Similarly, we have decided not to use the third set of relations, **WN30glCon**.[6]

4.2 Relation Weighting

Each relation in the KB can be assigned an individual weight. These weights are exploited within the ranking algorithms implemented in the UKB system. The original sets of relations do not assign any weights to the arcs. In our preliminary experiments we have assigned each relation a weight determined by the similarity of its associated nodes. This similarity is derived by calculating the cosine similarity of the vector representations for the corresponding nodes.

In order to assign weights, then, appropriate embedding models are necessary to provide vector representations. In the case of the preliminary experiments, we have used a synset embedding model constructed via random walks along the WordNet KB[7]. This is not the case with the new format of the KB where the nodes are represented as senses in WordNet. A direct construction of sense embeddings is also an option, which has not been realized for the purposes of this paper, and will be addressed in future research. Here we use pretrained embeddings.

Each word sense in WordNet is connected to a lemma and a synset. Thus, we could use either the synset embeddings, or the lemma (word) embeddings, or some combination between them. The first option has been disregarded since it does not distinguish between the various senses in the synonym sets. We have performed experiments with pretrained word embeddings such as GoogleNews[8] and Glove[9] (the 300-dimensional version),

[6] All new sets of relations, as well as the lexicon, available at `http://bultreebank.org/en/resources/`.

[7] All embedding models referred to here are also made accessible at `http://bultreebank.org/en/resources/`.

[8] `https://code.google.com/archive/p/word2vec/`

[9] `https://nlp.stanford.edu/projects/`

also with lemma embeddings trained analogously to the synset embeddings (see Goikoetxea et al. (2015) on how to generate pseudo corpora from WordNet and subsequently train embedding models on them).

For instance, for the sense `person%1:03:00::-n`, the associated list of synset and lemma IDs includes `00007846-n` and `person`. In the case when only a lemma embedding is available, the corresponding vector is used. In the case of multi-word expressions like `physical_object%1:03:00::-n`, the average of the vectors for the different component words is calculated. In the case when there are both a synset and a lemma embedding available, the concatenation of the two vectors is considered. The following embeddings have been used in the current work:

- **GoogleNews.** A word embedding model trained over 100 billion running words. The vectors are of size 300.
- **Glove.** Word embeddings trained over global contexts, as described in Pennington et al. (2014).
- **WN30WN30glConOne**. Synset and lemma embeddings trained by Simov et al. (2017).
- **WN30WN30glConOneWiki**. In this case a lemmatized Wikipedia corpus has been added to the pseudo corpus, in order to balance information from the knowledge graph with actual text data.

The weights associated with the different word senses in the new lexicon, which also play an important role for the optimal performance of the UKB system, are the same as those associated with synset identifiers in the original lexicon in the UKB distribution. This is so because the frequencies have been originally determined on the basis of sense occurencies in "various semantic concordance texts" (according to the documentation, quoted in Agirre et al. (2018)). Consequently, the conjunction of lemma and synset ID in the lexicon provides a unique mapping to a singular word sense, regardless of the structure of the KB.

4.3 Linking WordNet to VerbNet and FrameNet

VerbNet (Schuler, 2005) and FrameNet (Baker et al., 1998) are structured lexical resources which provide information that is, from a theoretical point of view, complementary to that within WordNet. While the latter's semantic network is a rich representation of lexical semantics, the former give more insight into sentential semantics.

VerbNet classes bring together verbs that share the same syntactic subcategorization and semantic valency patterns. Membership in a VerbNet class does not necessarily indicate that the lexical items have a similar meaning (although that is often the case), but that they share some kind of structurally analogous behaviour, which is certainly a kind of information that is not present in WordNet. For instance, the verb *buy* is in the same class as *hire, lease, rent*, but in the same class are also the verbs *catch, choose, pluck, slaughter*[10].

FrameNet organizes lexical knowledge around particular procedural scenarios called *frames* (Fillmore, 1968). An example of a FrameNet frame would be *Commerce_buy*[11], which specifies *frame elements*, i.e. participants and specifications of the situation, such as *Buyer*, *Goods*, *Seller*, *Means*, *Money*, etc. A frame is activated by certain *lexical units*, in this case *buy, buyer, client, purchase (noun), purchase (verb), purchaser*. Frames can be linked with one another, through relations like *Inherits from, Is used by*, etc.

As part of the effort to complement already existing relation sets for KBWSD, the WordNet semantic network has been partially connected to those of VerbNet and FrameNet. The Predicate Matrix resource[12] (De Lacalle et al., 2014, 2016), which automatically maps the WordNet, VerbNet, FrameNet, PropBank and MCR indices, has been used to obtain most of the cross-mappings; in the case of VerbNet, some of the verbs have already been mapped to WordNet senses, but Predicate Matrix can be used to extend the coverage of the mapping. In this way all WordNet sense identifiers that could be mapped to predicates in VerbNet classes and FrameNet frames have been organized in structures that reflect this kind of membership in the external resources. This has been done in a way that is similar to the one described earlier in relation to graphically connecting the various word senses in a synset. That is, the word sense

Table 1: Accuracy scores on the UEF data sets with different KBs. Only the results for the Ppr_w2w mode of the PageRank algorithm are reported. The synset-based models use KBs where the nodes are represented by synset IDs in WordNet; sense-based models use the new KB configurations described in the paper; the *+w* subscript means that a model takes into account relation weights. **WN** stands for the original WordNet relations; **GL** – the relations from the annotated gloss corpus; **SC** – the relations from the automatically parsed SemCor corpus; **VNM** – the sense groupings from VerbNet; **FNM** – the sense groupings from FrameNet; **FNR** – the links between FrameNet predicate senses and role-type senses. All experiments use the default parametrization from Agirre et al. (2018), with the exception of the cases marked with a subscript *ctx=num*, where the context windows have been changed to include *num* words. The best result (line 14) is achieved for contexts with 10, 15, 25 and 30 words. **SNE** stands for *Senseval* and **SME** stands for *SemEval*.

Table 2: The state of the art across WSD systems. The dagger symbol indicates that the result is reported in the UEF (Raganato et al., 2017a). * Luo et al. (2018a,b) do not report accuracy on SME07 since it is used as a development set; this is also true for Raganato et al. (2017b), which however does report the result. The KBWSD models in the table (ours and those by Agirre and Moro) are deterministic, i.e. they would always produce the same results with particular KBs, as no actual training is involved.

in a class/frame with the highest associated frequency of use is promoted to main node status that stands in for the whole structure, then all the rest of the senses are connected to it by setting a connection weight according to their respective frequencies (including a +1-count smoothing). The verb class hierarchy and inter-frame connection relations are also included in the new subgraph.

Additionally, the automatically created FrameNet extension[13] by Bryl et al. (2012), which

[13] `https://dh.fbk.eu/technologies/wordnet-sense-repository-framenet-extension`

maps FrameNet roles to WordNet synsets, has been used to add links between predicate word senses grouped in frames and role-filling word senses. These new relations are weighted in accordance with the numbers provided by the generated sense repository, which correspond to frequencies of use in an automatically tagged corpus. The procedures described above should provide higher inter-predicate connection density (the class/frame membership relations) in the KB and also more syntagmatically oriented relations (the FrameNet role senses mapped to frame lexical unit senses).

5 Experiments

In this section we provide several empirical points of view to the currently presented project of extending and optimizing the knowledge graph used for WSD. First we examine how the reconfiguration of the graph in terms of word senses compares with the synset-based graph and show that the new structure outperforms the previous one. In parallel with that we demonstrate that the introduced KB extensions lead to significant improvements over the baseline graphs. We also provide our own contribution to the optimal parametrization of the UKB system.

KB permutations Table 1 shows the various combinations of KB relations, KB structuring and parametrization of the UKB system. Several noteworthy observations come to the fore:

1. By comparing lines 1&2, 6&7, 9&11, it becomes clear that the KBs structured around word senses perform better than those where nodes are represented by synset IDs.
2. The addition of relations extracted from the VerbNet-WordNet-FrameNet (gold and automatic) mappings does improve the baseline results over the WN relations (lines 3-5). VNM builds over WN accuracy, FNM builds over WN+VNM, while FNR does not seem to decisively improve results (though on some data sets it does help – SNE-3 and SME-07).
3. The addition of the gloss and SemCor relations has a very significant effect on accuracy when compared to using just the baseline WN relations (lines 6-14).
4. The VN-FN relations do not seem to reliably improve accuracy when added to the gloss and SemCor relations, in fact they improve accuracy only on one data set (SME-15) and in the rest of the cases bring it down (line 13).
5. The default parameters from Agirre et al. (2018) are indeed a good optimization of the UKB system. We have been able to improve the result with the best KB only in one case, which we report here, and the improvement is not very big (0.1%; line 14). The result nevertheless indicates that there is space for optimizing the interaction between KB and algorithm.

Comparison with state-of-the-art models Table 2 situates our best result in the context of the state-of-the-art results in WSD at large. Again, several observations are worth pointing out:

1. The combination of UKB with our best-performing graph comfortably beats the WN 1st sense heuristic, which is not the case for many WSD systems.
2. The model significantly outperforms all KB-WSD models reported in the UEF, including the improved parametrization of Agirre et al. (2018), whose results we have improved upon with 1.7%.
3. Our result is at this point very close to the top-performing WSD systems, regardless of whether they are supervised or not. This has typically not been the case for KBWSD systems. For one data set (SME-13) the present model achieves the highest result of all[14] and for another one (SME-15) it is better than all but the two leading supervised systems.

Improvements with *static PageRank* Finally, in table 3 we show the performance of three different versions of the PageRank algorithm, as implemented in the UKB system and described in Agirre and Soroa (2009). The results with the static version have been very significantly improved in comparison to the results reported in Agirre et al. (2018). The static mode performs better than the WN 1st sense heuristic when used with the specified graphs. The difference between the *w1* and *w2* models is as follows: with *w1* weights are set via a combination of **WN30WN30glConOne** embeddings for synsets and lemmas, and with *w2* – via a combination of

[14] SME-13 contains sense annotations of nouns only; with its extensive taxonomic network, WordNet is a powerful tool for representing nominal meaning. More detailed analysis is required to ascertain the real reasons for the high accuracy scores.

Knowledge base	**Spr**	**Ppr**	**Ppr_w2w**
WN+GL$_{\text{synsets}}$(Agirre et al., 2018)	57.7	**65.6**	67.3
WN+GL+SC$_{\text{senses+w1}}$	65.5	65.2	**68.9**
WN+GL+SC$_{\text{senses+w2}}$	66.5	65.1	68.0
WN+GL+SC+SCR$_{\text{senses+w2}}$	**66.6**	65.1	68.1

Table 3: Comparison between different PageRank versions (accuracy measured on all UEF test data sets). **Spr** stands for *static* mode, **Ppr** is *Personalized PageRank*, **Ppr_w2r** is *Ppr with emphasis on neighbouring concepts*. *w1* denotes weights set via the combination of **WN30WN30glConOne** embeddings for synsets and lemmas; *w2* denotes the combination of **WN30WN30glConOneWiki** embeddings.

WN30WN30glConOneWiki embeddings, again for synsets and for lemmas. The **SCR** relation set, which is built on the basis of co-occurrences of word senses in SemCor, contributes positively to the best static model. Compared with previous state-of-the-art results when using static PageRank, here we can see an improvement of nearly 9%.

Bearing in mind that the static version of the algorithm is much faster than the personalized ones, these results should also be interpreted as important, as they demonstrate that KB improvement might be even more beneficial for less sophisticated methods that nevertheless offer a good tradeoff in terms of speed of execution.

6 Conslusion

We have presented results from a series of experiments with a KBWSD system with state-of-the-art default parametrization and have shown that accuracy can be further improved through the manipulation and extension of the KB. The present models achieve the highest reported accuracy scores for a KBWSD system that we are aware of; they also enter in the close orbit of the highest-scoring supervised systems, achieving a new state of the art on the Semeval-13 data set.

Further improvement to the content of the KB is certainly possible. Based on the reported experiments, an intuition emerges that the relation weighting schema has to have a dynamic character. This would correspond to the promotion and demotion of semantic features within context. The current implementation relies on the PageRank algorithms to maintain this kind of dynamics. The experiments also demonstrate that the different weighting schemata improve the performance of different algorithms, which suggests complex patterns of interaction between algorithm and graph structure. The current schemata do not distinguish between different kinds of relations. The difference between paradigmatic and syntagmatic relations necessitates different weighting approaches. Using the cosine similarity measure over the entire embedding space seems to be a suboptimal blanket strategy. In our future research we plan to train relation embeddings, following the approach for generating pseudo corpora, as in the case of training synset and lemma embeddings.

Additionally, we plan on further investigating strategies for generalizing knowledge from external resources such as VerbNet and FrameNet, as well as other ones which can be mapped to WordNet, such as PropBank (Kingsbury and Palmer, 2002) and the OntoNotes sense groupings (Snow et al., 2007). As has been demonstrated, structuring a lexico-semantic graph in an optimal way can make a big difference. Detailed error analysis and sophisticated linguistic theory should be employed in order to capture the principles underlying a good knowledge base.

Are Ambiguous Conjunctions Problematic for Machine Translation?

Maja Popović and Sheila Castilho

Abstract

The translation of ambiguous words still poses challenges for machine translation. In this work, we carry out a systematic quantitative analysis regarding the ability of different machine translation systems to disambiguate the source language conjunctions "but" and "and". We evaluate specialised test sets focused on the translation of these two conjunctions. The test sets contain source languages that do not distinguish different variants of the given conjunction, whereas the target languages do. In total, we evaluate the conjunction "but" on 20 translation outputs, and the conjunction "and" on 10. All machine translation systems almost perfectly recognise one variant of the target conjunction, especially for the source conjunction "but". The other target variant, however, represents a challenge for machine translation systems, with accuracy varying from 50% to 95% for "but" and from 20% to 57% for "and". The major error for all systems is replacing the correct target variant with the opposite one.

1 Introduction

Ambiguous words are often difficult to translate automatically, even by the state-of-the-art neural machine (NMT) systems. Whereas the NMT approach significantly improved fluency (grammar) of MT outputs compared to the previous state-of-the-art statistical phrase-based (PBMT) models, adequacy (meaning preservation) is still often problematic (Castilho et al., 2017; Klubička et al., 2018). Adequacy is even more problematic for ambiguous words which have two or more meanings depending on the context.

Therefore, ambiguity of nouns, verbs and pronouns has been investigated extensively in recent years (Guillou et al., 2018; Müller et al., 2018; Rios Gonzales et al., 2017, 2018). However, to the best of our knowledge, no results for ambiguity of conjunctions have been reported so far. The only work dealing with conjunctions and machine translation (Huang, 1983) explores conjunction scope for rule-based MT systems and does not address the ambiguity. It should be noted, though, that the conjunction ambiguity is more structural than lexical: it is mainly related to certain aspects of grammar involving the arrangement of words and word types. Therefore, the conjunction ambiguity is related more to fluency than it is to adequacy.

In this work, we present the results of quantitative analysis addressing machine translation of two potentially ambiguous conjunctions, "but" and "and". The analysis of the conjunction "but" is carried out for {English,French}-into-{Spanish,German,Serbian,Croatian} translation directions, and the conjunction "and" is analysed on {English,Portuguese}-into-{Serbian,Croatian} outputs. Evaluation is carried out on specialised test sets[1] designed for evaluating translation of these ambiguous conjunctions. Instead of comparing the translation output with a reference human translation, our evaluation is based on presence or absence of the correct target language conjunction variant in the translation output. For a small number of sentences with both or with none of the target variants (about 1-2%), manual inspection is carried out.

2 Related Work

Lexical ambiguity as a challenge for machine translation has received a lot of attention in recent years. Rios Gonzales et al. (2017) and Rios Gonzales et al. (2018) focus on ambiguous German nouns, while Guillou et al. (2018) and Müller et al. (2018) investigate ambiguous English pronouns. Broader linguistic evaluations presented in Burchardt et al. (2017) and Klubička et al. (2018) also include ambiguity, but conjunctions are not mentioned in any context.

Syntactic ambiguity for rule-based English-to-Bulgarian machine translation is investigated in Pericliev (1984), but these ambiguities are not related to conjunctions. Ambiguity of conjunctions "and" and "or" is investigated for requirement specifications in Sharma et al. (2014) and for legal texts in Adams and Kaye (2006), however without any relation to (either human or machine) translation.

The first work dealing with conjunctions and machine translation is described in Huang (1983). It explores conjunction scope for English parser to be used in rule-based MT systems, but it does not address the ambiguity. Another work related to conjunctions and machine translation is the work of Xu et al. (2014), who proposes using conjunctions for Chinese sentence segmentation in order to achieve better translation quality. Some problems with translating conjunctions by phrase-based machine translation systems involving South Slavic languages are mentioned in Popović and Arčan (2015), but without any systematic quantitative analysis.

To the best of our knowledge, our work represents the first experiments related to ambiguous conjunctions and machine translation. We report the results of an extensive evaluation showing that certain conjunction ambiguities pose a challenge to the state-of-the-art machine translation systems.

3 Ambiguity of "But" and "And"

3.1 Conjunction "But"

In some languages, there are two possible variants of the conjunction "but". One variant, but_1, can be used after either a positive or a negative clause. The other variant, but_2, is used after a negative clause when expressing a contradiction. The first clause in the sentence must contain a negation marker, and the second part of the sentence must contradict the first part of the sentence.

Three examples can be seen in Table 1. The sentences on the left have the same context, same or similar meaning, and contain similar words as

	En-Hr	59.4	40.6
Subtitles	En-Sr	62.2	37.8
	Pt-Hr	60.4	39.6

Table 4: Distribution of sentences with two types of conjunctions "and" in different publicly available parallel corpora.

the sentences on the right. Nevertheless, the conjunction "but" in all sentences on the left should be translated into but_1 and in those on the right as but_2. This also illustrates the previously mentioned structural nature of conjunction ambiguity.

Generally, sentences with the first variant, but_1, can be found more frequently in the data. Table 2 presents the distribution of the two types of sentences with the conjunction "but" found in publicly available data for several language pairs in two domains: news and subtitles.

3.2 Conjunction "And"

Some target languages, such as Serbian and Croatian, distinguish two variants of the conjunction "and". The first variant, and_1, is used to connect non-contrasting actions or ideas, for example to indicate that one action follows another in the chronological order, or that one idea is the expected result of another. The second variant, and_2, is used to indicate that the two connected facts are different: it introduces a new or different meaning, that is, it introduces an idea that is different or opposite to the idea that is desired, expected or stated previously. Both variants are used to start a new sentence or clause that continues or adds to a previous sentence or clause, however and_2 is adding some new, different or unexpected facts.

Four examples can be seen in Table 3. Similarly to the examples for the conjunction "but", the sentences on the left have similar meaning and contain similar words as the sentences on the right, but all "ands" on the left should be translated into and_1 and those on the right into and_2.

Table 4 presents the distribution of the two types of conjunction "and" in publicly available news and subtitles data. Again, the first variant, and_1, is more frequent, although the difference is smaller than between the two variants of the conjunction "but".

4 Experimental Set-Up

4.1 Test Sets

In order to estimate a system's capability to translate ambiguous conjunctions, evaluation is performed on specialised test sets specifically designed for the conjunctions "but" and "and" and their two variants.

The test sets are created semi-automatically using the multilingual subtitles corpora[2] (Tiedemann, 2012). Only short segments (up to 20 words) were included, all noise was removed, and rare named entities which could introduce additional effects were avoided or replaced. Thus, about 1000 source sentences in English and in French were prepared for the conjunction "but", and 250 source sentences in English and in Portuguese for conjunction "and". Detailed corpus statistics are presented in Table 5.

It should be noted that although the test sets were created using a bilingual corpus, the resulting test sets do not contain any reference translations. The reason for this is twofold: on the one hand, bilingual manual filtering of noisy and complex

	and_2	206	2651	691	12.9
	and_1	52	566	248	10.9
Portuguese	all	250	2763	908	11.0
	and_2	199	2218	767	11.1
	and_1	51	546	264	10.7

Table 5: Statistics of the test sets for (a) conjunction "but" and (b) conjunction "and": number of sentences, number of running words, vocabulary size and average sentence length.

content would be very time and resource consuming. On the other hand, reference translations are not really needed, because we are interested only in conjunction disambiguation, therefore, checking the conjunction in the translation hypothesis is sufficient.

In order to encourage and enable future research on the topic, the developed test sets are made publicly available.[3]

4.2 MT Outputs

The English and the French test sets for the conjunction "but" were translated into four target languages that distinguish the two variants but_1 and but_2 in the same way, namely Spanish, German, Serbian and Croatian. The English and the Portuguese test sets for the conjunction "and" were translated into Serbian and Croatian. For all translation directions, two publicly available on-line systems, "Google Translate"[4] and "Bing Translator"[5] are used. All on-line translations were generated between 26th and 30th April 2019.

In addition to this, for English-to-German and English-to-Serbian translation, two internal systems trained on much smaller amounts of data from the news domain were available. Two English-to-German systems, one NMT and one PBMT, are trained on one million parallel sentences from the WMT[6] data. Two English-to-Serbian systems, also one NMT and one PBMT, are trained on the SETimes corpus (Tyers and Alperen, 2010) containing about 200k sentence pairs.

In total, the conjunction "but" is analysed on 20 MT outputs, and the conjunction "and" on 10 MT outputs.

4.3 Evaluation

The majority of sentences are checked automatically, however for a small number of sentences a manual inspection is needed. For each sentence, there are four possible outcomes of the automatic evaluation:

- only the correct conjunction is found
  ⇒ correct
- only the opposite conjunction is found
  ⇒ incorrect
- both conjunctions are found
  ⇒ manual inspection

[3] https://github.com/m-popovic/evaluating-ambiguous-conjunctions-MT

[4] https://translate.google.com/

[5] https://www.bing.com/translator

[6] http://www.statmt.org/wmt17/

- none of the two conjunctions are found

  ⇒ manual inspection

Manual inspection is carried out in the following way: if the structure of a sentence with additional or without any conjunctions is correct, then the sentence is considered correct.

All errors which are not related to the conjunction choice are ignored, both by automatic and by manual evaluation.

5 Results

The results for both conjunctions and all language pairs are presented in the form of percentage of sentences automatically identified as correct ("aut."), identified as correct after both automatic check and manual inspection ("full"), and automatically identified as incorrect because the source conjunction is translated into the opposite conjunction ("opposite").

5.1 Conjunction "But"

The results for the source conjunction "but" can be seen in Table 6.

Target variant *but*$_1$: Recognising the target conjunction but_1 is generally not problematic: the percentage of correct sentences is almost 100% for all on-line systems, and close to 100% even for the scarce-data $setimes$ systems. Apparently, there is no correlation between this accuracy and the amount of the training data, because the two wmt systems have lower accuracies than the two $setimes$ systems. These lowest accuracies are still very high, i.e. close to 90%.

Target variant *but*$_2$: For this variant, the situation is, however, different. On-line systems translate it correctly in 73-95% of cases, and the predominant problem for the rest of the cases is translating it into the opposite variant but_1 (5-25%). The four scarce-data systems are struggling much more with this variant, PBMT systems more than NMT ones. In addition, the influence of the amount of data is obvious, since $setimes$ systems are performing much worse than wmt systems. For these four systems, replacing but_2 with but_1 is the most frequent problem too, but there were more sentences requiring manual inspection than for the on-line systems.

Both target variants: Manual inspection revealed that this is generally not problematic for any of the systems and language pairs: it can happen if "however", "yet" or similar words that can be translated as but_1 are present in the source sentence.

None of the two target variants: Only a small number of such sentences are generated by on-line systems when translating from English if the English sentence has a structure "not only X, but Y, too". In these cases, the sentence is paraphrased in the way "not only X, Y too". For the French source, a number of other sentence structures are paraphrased, and the majority of these paraphrases are correct. An example can be seen in Table 7.

As for the scarce-data systems, manual inspection revealed that the wmt NMT system left many sentences untranslated, of which mainly those requiring the conjunction but_2. However, a number of those requiring the conjunction but_1 were also left untranslated. As for PBMT systems, many of the sentences in the output used a possible translation for but_1 such as "however", which is of course not correct for sentences requiring but_2. A number of PBMT sentences had a number of other error types and a low fluency in general. Apart from this, when translating from English into Serbian and Croatian, $Google$ and $Bing$ often translated "but" as "except", which is not a possible option for any of the source sentence structures.

5.2 Conjunction "And"

The results for the source conjunction "and" can be seen in Table 8.

Target variant *and*$_1$: Similarly to the translation of "but", the target variant and_1 is not really problematic for any of the systems, with almost all accuracies close to 100% and all larger than 92%. Also, there is apparently no correlation between this accuracy and the amount of the training data, since the $Bing$ system has the lowest accuracy and it is certainly trained on more data than the two $setimes$ systems.

Target variant *and*$_2$: This target variant is definitely problematic, and much more challenging than but_2: the highest accuracy is 56.3%. Similarly to the conjunction "but", the predominant problem is replacing and_2 with and_1. Also, the accuracies are lower for the scarce-training $setimes$ systems. Nevertheless, one curiosity can be noted: the PBMT $setimes$ system better disambiguates the conjunction "and" than the NMT $setimes$ system. Given that NMT systems are generally more sensitive to the scarcity of training data (Koehn and Knowles, 2017) than PBMT

source (en gloss)	It is not a star **but** a crystal.
output (es)	No es una estrella, es un cristal.
output (de)	Es ist kein Stern, es ist ein Kristall.
output (en gloss)	It's not a star, it's a crystal.

Table 7: Example of correct translation without any of the two conjunction variants (mostly occurring in French-to-Spanish and French-to-German on-line systems).

systems, disambiguating the conjunction "and" is probably more sensitive to the amount of the training data than disambiguating the conjunction "but". More experiments on systems trained on different training data sizes should be carried out in the future.

Both target variants: Manual inspection revealed that all sentences with both "and" variants are correct: the affected source sentences contain "too", "as well" or similar, which can be correctly translated as and_1. Three examples can be seen in Table 9.

None of the two target variants: A small number of sentences containing "neither" were correctly paraphrased in the target language so that it does not need any of the two "and" variants. These cases are found only in translations generated by on-line systems. An example can be seen in Table 10.

6 Summary and Outlook

We present a targeted evaluation of 20 translation outputs regarding their performance in lexical choice for the ambiguous source conjunction "but", and 6 (10) systems regarding the source conjunction "and". For the source conjunction "but", we observe that all systems almost perfectly recognise the target conjunction but_1, whereas accuracies for the other target variant but_2 are lower, and depend on the model (NMT performs better than PBMT), as well as on the amount of training data. For on-line systems trained on large amounts

		and_2			and_1		
language		correct		opposite	correct		opposite
pair	system	aut.	full	(and_1)	aut.	full	(and_2)

source:	I can swim well **and so** do you.
output (hr) :	ja mogu plivati dobro, **a i** ti.
output (en gloss):	I can swim well, and_2 and_1 you.
source:	Holly travels a lot, **and** her sister, **too**.
output (hr)	Holly puno putuje, **a i** njena sestra.
output (en gloss):	Holly travels a lot, and_2 and_1 her sister.
source:	John likes burger, **and** he likes fish, **too**.
output (hr)	John voli hamburger, **a** voli **i** ribu.
output (en gloss):	John likes burger, and_2 likes and_1 fish.

Table 9: Examples of correct translations into Croatian with both target variants of "and".

source	I don't want you here, **and neither** does my wife.
output (hr)	Ne želim te ovdje, **kao ni** moja žena.
output (en gloss)	I don't want you here, **as not** my wife.

Table 10: Example of correct translation into Croatian without any of the two conjunction variants.

of data, accuracies range from 73% to 94%, and for the systems trained on small amounts between 50% and 60%. The errors for all systems are mostly caused by replacing the conjunction but_2 with the alternative conjunction but_1.

As for the conjunction "and", its first variant and_1 is also not problematic, even for the systems trained on small amounts of data. The variant and_2 is, however, much more challenging than but_2, with the highest accuracy of 56.3%. In addition, disambiguation of this conjunction seems to be more sensitive to the training data scarcity for NMT than for PBMT. More systematic experiments including both models and different sizes of the training corpus should be carried out in the future to better understand this finding.

In addition to this, there are many other directions for future work. The current study is focused on only two ambiguous conjunctions and only two target language variants for each of them. More conjunctions and ambiguities should be investigated in the future, as well as more source and target languages. Quantitative analysis of correlation between the conjunction disambiguation and overall performance should be a part of future work, too. Also, improving a MT system by, for example, adding more parallel data containing "difficult" target conjunction variants should be investigated as well.

7 Acknowledgements

We would like to thank Alberto Poncelas and Pintu Lohar for providing PBMT and NMT translation outputs for English-to-German and English-to-Serbian. Abstract

We present a live cross-lingual system capable of producing shallow semantic annotations of natural language sentences for 51 languages at this time. The domain of the input sentences is in principle unconstrained. The system uses single training data (in English) for all the languages. The resulting semantic annotations are therefore consistent across different languages. We use CoNLL Semantic Role Labeling training data and Universal dependencies as the basis for the system. The system is publicly available and supports processing data in batches; therefore, it can be easily used by the community for research tasks.

1 Introduction

In this work, we present a major outcome in our journey to build a system capable of producing semantic annotations for domain and language unconstrained natural language sentences. Currently, we rely on the Semantic Role Labeling (SRL) annotation scheme (Gildea and Jurafsky, 2002). The SRL goal is to determine semantic relationships (*semantic roles*) of given *predicates* (see examples in Figure 1). Verbs, such as "believe" or "cook", are natural predicates but certain nouns can be accepted as predicates as well (see the third line in the example). The semantic roles are specific for each predicate; however, the meaning of the roles is mostly shared across predicates. The core roles are denoted by *A0* (usually Agent), *A1* (usually Patient) and *A2*. Additional roles are modifier arguments (*AM-**), restriction arguments (*R-**) and others. We selected SRL because we believe that the annotations are simple enough to be generalized for different languages and target domains but at the same time expressive enough to bring a useful insight into the sentence semantics.

(1) [He]$_{\text{A0}}$ believes [in what he plays] $_{\text{A1}}$.

(2) Can [you] $_{\text{A0}}$ cook [the dinner] $_{\text{A1}}$?

(3) [The nation‘s] $_{\text{AM-LOC}}$ largest [pension]$_{\text{A1}}$ fund,

Figure 1: Three examples of shallow semantic annotations: 1) and 2) are examples of verb predicates and 3) of a noun predicate.

In order to be able to produce semantic annotations for more languages, we employ the *cross-lingual* SRL. Cross-lingual SRL takes the training data from a source language (usually English) and builds a language independent model that can be applied to target languages. The advantage of the cross-lingual SRL is that it ensures coherent annotation for all supported languages because it trains on single training data for all the languages. This does not apply to the monolingual SRL where the tagsets and annotation guidelines change with every training dataset.

In our approach, we heavily depend on Universal Dependencies (UD) (Nivre et al., 2016). They are the primary means to transfer the learned rules from one language to another. With universal dependencies, we can create language independent parse trees. It means that sentences with the same syntactic structure share (in theory) the same parse trees for all (supported) languages. We train our machine learning model on the UD trees to capture the syntactic patterns required for semantic role labeling. We do not use any lexical information or any other language dependent features. Our only information for SRL comes from UD trees. Thus, the resulting model can be applied to any of the supported languages.

The system we present in this paper is a web-based application written in Java – see the screen-

Proceedings of Recent Advances in Natural Language Processing, pages 967–972,
Varna, Bulgaria, Sep 2–4 2019.

shots in Figures 3 and 2. The system allows a user to input a natural language sentence in any of the 51 languages. The system outputs SRL annotations (predicates and corresponding semantic roles) of the input sentences. The semantic roles are associated with syntactic tree nodes. The video demonstration of the system is available here: `https://www.youtube.com/watch?v=8QPKCegHT_c`. The system itself can be accessed at the following address: `http://liks.fav.zcu.cz/ulsana`. We intend to support the system for public use for several years.

2 Related Work

Approaches to cross-lingual SRL can be divided into three main categories: **1)** *Annotation projection* methods attempt to transfer annotations from one language to another and then they train an SRL system on the transferred annotations. **2)** *Model transfer* approaches are designed to use language-independent features to train a universal model which can be applied to languages that support the designed features. **3)** Methods based on *unsupervised training* require no annotated data; however, the models have difficulties in assigning meaningful labels to predicate arguments.

Annotation projection Padó and Lapata (2009) transfer annotations to a target language via word alignments obtained from parallel corpora. Annesi and Basili (2010) use a similar approach and extend it with an HMM model to increase the transfer accuracy.

Model transfer Kozhevnikov and Titov (2013) use cross-lingual word mappings and cross-lingual semantic clusters obtained from parallel corpora, and cross-lingual features extracted from unlabelled syntactic dependencies to create a cross-lingual SRL system. In (Kozhevnikov and Titov, 2014), they try to find a mapping between language-specific models using parallel data automatically.

Unsupervised SRL Grenager and Manning (2006) deploy unsupervised learning using the EM algorithm based upon a structured probabilistic model of the domain. Lang and Lapata (2011) discover arguments of verb predicates with high accuracy using a small set of rules. A split-merge clustering is consequently applied to assign (nameless) roles to the discovered arguments. Titov and Klementiev (2012) propose a superior argument clustering by using the Chinese restaurant process.

Our approach belongs among the model transfer approaches. Most of the other state-of-the-art approaches to SRL rely on lexical features (e.g. word lemmas). In the cross-language scenario, such features require bilingual models (e.g. word mapping via machine translation or bilingual clusters). In our demonstration application, we show a multi-language model that is capable of producing annotations for many languages. Therefore, we omit all bilingual features including the lexical features from our model.

3 System Description

In this section, we describe the core of the cross-lingual system we use in our demo. The system is described in our original paper (Pražák and Konopik, 2017) in full details. Here, we explain only the basic principles. The system described in (Pražák and Konopik, 2017) is available for five languages only. In this demo, we extended the system for 51 languages.

3.1 Training Dataset and Annotation Conversion

We train our system on UD parse trees. However, there are no such training data that would contain SRL annotations on UD trees. Therefore, we proposed an algorithm to convert existing SRL annotations built on SD[1] trees.

The conversion process is by no means straightforward. The main source of complications stems from different approaches to choose head words for syntactic phrases in UD trees. To solve this issue, we proposed optimization algorithms that attempt to select the most appropriate heads for UD trees which would cover the same phrases as the heads in original SD trees. In many cases, there is no such word in UD trees which could be used as the new head. In such cases, we choose the head that minimizes the annotation error. The details of the proposed conversion algorithms are presented in the original paper – Section 4.

In our application, we use the CoNLL 2009 English dataset (Hajič et al., 2009). The corpus

Figure 2: Application screenshot

includes syntactic dependencies (from the Penn Treebank [TB]) and semantic dependencies (from PropBank [PB] and NomBank [NB]).

3.2 Universal Dependencies Parser

Our system requires syntactic trees in the UD annotation scheme. We rely on the freely available tool UDPipe (Straka et al., 2016). It contains pretrained models for all the languages we support in our application. We use models provided with parsers based on UD. The algorithms were developed on UD v1.2 models based on UD 2.0 were also added, and they achieve better results (about +1% of labeling accuracy).

3.3 Classifier & Features

We train a supervised system based upon the Maximum Entropy classifier using the Brainy tool (Konkol, 2014). We use separate models for verb and non-verb predicates.

All features employed in our system are syntactic:

- *Predicate-argument distance* – the distance between the locations of a predicate and an argument in a sentence.
- *POS* – part-of-speech of the predicate, the argument and their parent nodes.
- *Dependency relation* – dependency tree relation of the predicate, the argument and their parent nodes.
- *Directed path* – dependency tree path from the predicate to the argument including the indication of the dependency directions.
- *Undirected path* – the list of relations from the predicate to the argument.
- *Verb voice* – indication of active/passive voice.
- *Other syntactic features* – `feats` column in CoNLL 2009 format with additional information about the words.
- *Bigram features* – predicate-argument bigrams of the part-of-speech and the dependency relations.

The dependency path features are encoded as a probability of a word being a predicate argument (or having a specific role) given the path. These features are more general, and the resulting vectors have a smaller dimension. Also, the cost function is smoother, and thus the model is easier to train.

3.4 Web Application Description

We created a Java web UI for the SRL annotation and its visualization. We use *TikZ* for visualization of the trees. The *TikZ* output is converted to *SVG* which is then shown in the browser. The application takes its input either in plain text or in various CoNLL formats. Input can be a single sentence or a file with sentences separated by new lines. On the input, a user has to select an input language (one of 51 supported languages) because syntactic parsers are language-dependent and the application cannot determine the language automatically at this time. The application can parse the sentences syntactically and semantically. After these steps (if requested) the annotations are visualized in the SVG format and showed in the browser. The user can download analyzed sentences in *svg*, *pdf* or raw *CoNLLu* format.

3.5 Application Use Cases

Research Experiments The primary purpose of our application is to help the researchers to get familiar with the capabilities of cross-lingual semantic processing. We also want to demonstrate the power and limitations of Universal Dependencies. Users can work with examples entered into the input field, but they can also use the batch processing feature. In this way, users can obtain SRL annotations of larger corpora that can be used in the consequent research.

Language Learning The application can also help users who are learning a new language. Our application shows the structure of a sentence and the basic roles of the main phrases in the sentence. In this way, users can more easily understand the semantic structure of the sentence.

Translation Cross-lingual SRL can be used either in the machine or human translation. When translating a sentence, we aim to preserve the semantic structure of the sentence. We can achieve that by studying both structures of the source and target input sentences.

3.6 Known issues

- Parser errors – Since our system relies solely on syntactic features, it is very sensitive to parser errors. When the sentences match the domain of training data of UD annotations (mostly news domain) the parse trees are generally quite correct. We produce mostly correct SRL annotations with correct parser trees. However, our system is usually unable to classify correctly when the parse trees contain significant errors.

- Visualizing complex relations – Our system sometimes struggles with visualizing complex relations. It those circumstances the resulting visualization can be confusing.

4 Future Work

In future work, we plan to adopt the end-2-end approach to Semantic Role Labeling. We intend to attach the SRL annotation after UD parsing and use a global cost function to optimize the UD parsing and the SRL annotation simultaneously. In order to apply the end-2-end approach, we might have to switch to the SyntaxNet[2] UD parser. We expect to be able to produce more robust SRL annotations with one global optimization function.

Next, we plan to focus on lexical features. We want to stay with the idea of one model for many languages. Therefore, we need to use cross-lingual embeddings as lexical features.

5 Conclusion

We have created a semantic role labeling system with a massively multilingual model. A single model can be used for SRL in 51 different languages. The system supports large inputs, and therefore it can be used to annotate entire datasets for various NLP tasks.

Abstract

Fake news detection and closely-related fact-checking have recently attracted a lot of attention. Automatization of these tasks has been already studied for English. For other languages, only a few studies can be found (e.g. (Baly et al., 2018)), and to the best of our knowledge, no research has been conducted for West Slavic languages. In this paper, we present datasets for Czech, Polish, and Slovak. We also ran initial experiments which set a baseline for further research into this area.

1 Introduction & Motivation

Fake news is designed to incite agitation against an individual or a group of people. Its aim is to influence and manipulate public opinion on targeted topics. Fake news detection, including fact-checking, which can be used as the first step of a detection system, are currently receiving a lot of attention in the research community and journalism.

This attention is apparent from the rise of fact-checking websites that verify mainly political claims (see the list of signatories of the code of principles of the International Fact-Checking Network[1]). Research related to these tasks is on the rise in a variety of fields, including natural language processing, machine learning, knowledge representation, databases, and journalism (Thorne and Vlachos, 2018).

The automation of these tasks or their parts would greatly benefit journalism and perhaps help the public to verify the credibility of various media. It is evident that fact-checking needs external knowledge or detailed context. However, in order to achieve the goal of a robust automatic fact-checking system, we must first find a way how to evaluate such a system. For English, there are publicly available datasets that researchers can use to evaluate their systems. However, no systematic research has been conducted in West Slavic languages yet; thus we establish a common ground for further research by providing large datasets for fact-checking in Czech, Polish, and Slovak languages including initial experiments which reveal the complexity of the task. We set a baseline which uses standard machine learning approach, and set an upper bound which uses manually created external knowledge.

2 Related Work

This section presents a brief overview of related work, for a more detailed survey, please refer, for example to Thorne and Vlachos (2018).

For the development of the first fact-checking systems, Vlachos and Riedel (2014) manually labeled a dataset and defined fact-checking as the assignment of a truth Boolean value to a claim made in a particular context. They also discussed baseline approaches to fact-checking.

Wang (2017) presented a dataset of 12.8K manually labeled statements from the Politifact[2] website. He experimented with logistic regression, support vector machines, Long Short-Term Memory neural networks (LSTM), and convolutional neural networks (CNN). He then introduced a modified neural network architecture integrating text with other meta-data. He performed similar experiments to our work on English dataset with six labels achieving 27.7% accuracy as the best result.

Tacchini et al. (2017) showed that fake news

could be detected based on user likes. Using an adaptation of a Boolean label crowdsourcing algorithm, they were able to detect hoaxes with 99% accuracy. Their dataset consists of 15.5K posts (58% fake news, 42% real news) with over 2,300K likes from 900K users.

Jin et al. (2017) focused on detecting fake news on Twitter related to the U.S. presidential elections. They labeled the data according to the Snopes[3] website. They analysed tweets of followers of the presidential candidates.

Yang et al. (2018) used a dataset of 20K news (12K fake news, 8K real news) for fake news detection. They used a modified convolutional neural network trained using the title, images and text of the news articles, making use of both explicit and latent features to detect fake news. They achieved F_1-measure of 92% overcoming a baseline LSTM text-based model by 3%. They presented a thorough analysis of the dataset, including text style and image resolution.

In this paper we present the following novel contributions:

1. The availability of multi-lingual data for non-English languages is lacking. Our paper addresses this need.

2. The dataset also contains reasoning for labeling each claim - this can be used in future research, e.g. argumentation mining.

3. The claims are also labeled by Political party affiliations - this may facilitate fine-grained analysis.

3 Dataset

We provide three datasets for fact-checking - one for each language downloaded from the following fact-checking websites.

- Czech (https://demagog.cz/)
- Polish (http://demagog.org.pl/)
- Slovak (http://www.demagog.sk/)

Each dataset contains claims of politicians[4] annotated with one of four classes: FALSE, TRUE, UNVERIFIABLE, and MISLEADING. The labels have the following meaning:

- FALSE These statements are not in line with publicly available numbers or information. It may also be a situation where the calculation method of the indicator differs, but none of these sources confirms the number or claim in question.

- TRUE Statement using the right information in the right context.

- UNVERIFIABLE If it is not possible to find the source of the claim, or it is not possible to confirm or refute it based on the available information.

- MISLEADING These are statements that use correct facts, but in a wrong or incomplete context, or are being torn out or otherwise distorted from the original context. These are inappropriate or disproportionate comparisons.

The labels are manually annotated by the authors of the corresponding language websites. The dataset also contains information about the speaker and his or her political affiliation. The reasoning[5] for the given label is also included in the dataset. The data were downloaded from the respective websites in April 2018. The following example has been translated into English.

[3] https://www.snopes.com/

[4] Other publicly active people such as journalist are included in the dataset as well.

[5] Including external knowledge.

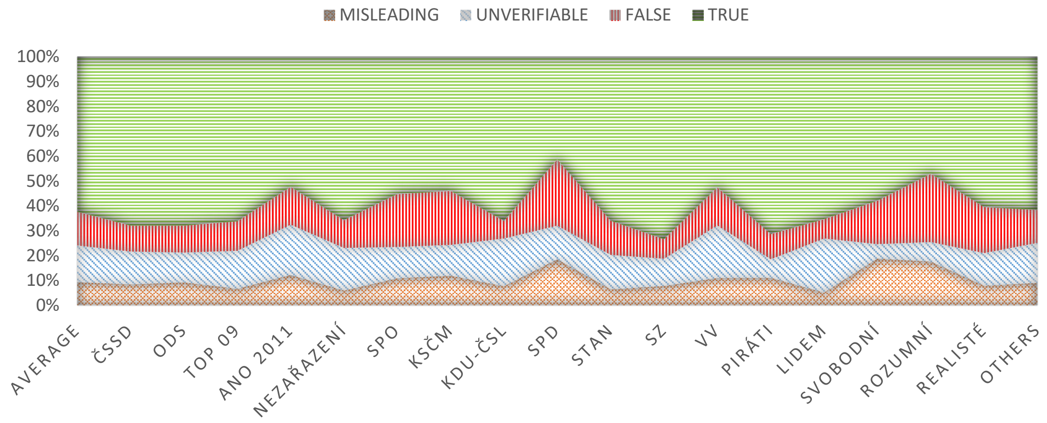

Figure 1: Czech Political Parties Statistics

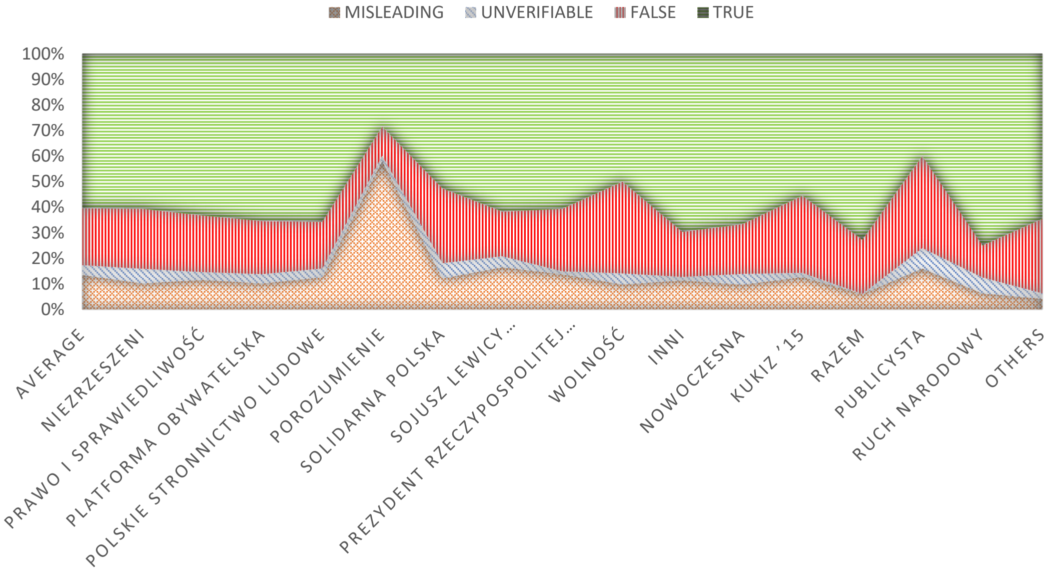

Figure 2: Polish Political Parties Statistics

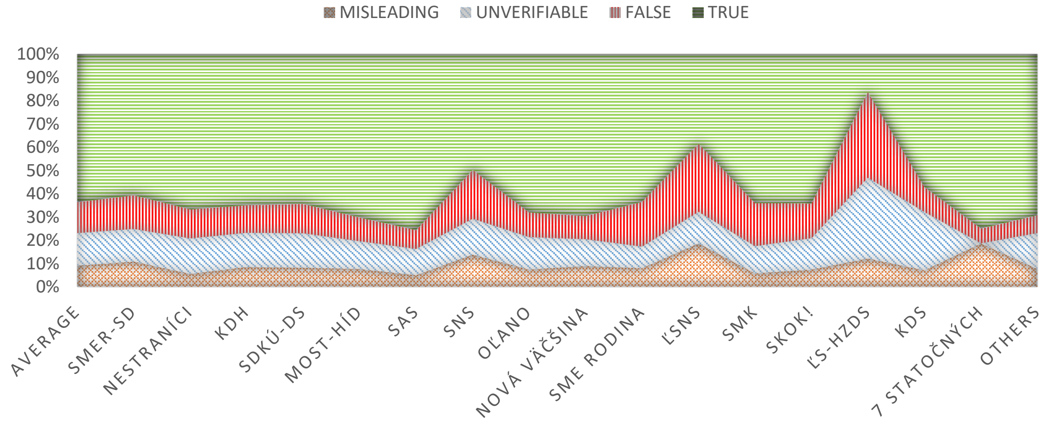

Figure 3: Slovak Political Parties Statistics

> Miloš Zeman (SPO) → FALSE
> CLAIM: "The Swedes have seven million inhabitants."
> REASONING: Sweden has according to the latest official data from November 2017 10,113,000 inhabitants.

The data distribution, according to the labels, is shown in Table 1. Table 2 shows the median and the average number of words in a claim.

We compare the label distribution among selected political parties with the most claims. Figures 1, 2, and 3 show the average label distribution and the distribution for the selected political parties sorted by a number of claims for Czech, Polish, and Slovak languages. Note that the labels *Nezařazení* for Czech, *Niezrzeszeni* for Polish, and *Nestraníci* for Slovak represent claims of people without any political party affiliation. The `Other` label is the average of the rest[6] of the political parties present in the dataset [7].

It is clear that the claims of some political parties often tend to be truth compared to other parties. This phenomenon can be observed for all three languages. The opposite applies to the Czech parties *SPD*, *Rozumní*, Polish party *Porozumienie* and Slovak party *LS-HZDS*. However, the inconsistency of `UNVERIFIABLE` label across languages was more surprising. We believe that it is caused by differences in labeling i.e. that in the Polish dataset the `UNVERIFIABLE` label is used only under stringent rules in comparison with the other two languages.

4 Experiments

We performed identical classification experiments for each language to allow a comparison for future research. The main goal of these experiments is to illustrate the complexity of the task and to set a baseline for these datasets.

We use 10-fold cross-validation for the evaluation of both balanced and imbalanced datasets. We also perform binary experiments only with `FALSE` and `TRUE` classes. The input for the classifier is either the text of a claim or a text of a claim supplemented by the reasoning text. Experiments using the reasoning text set up an upper bound of performance that can be achieved with an automatic approach. Our evaluation metrics are macro-average F_1 score and accuracy.

The reasoning text often contains words or phrases which are strictly related to the assigned label, for example, *Výrok je pravdivý* (The statement is true) for the `TRUE` label or *Výrok nelze ověřit* (The statement is unverifiable) for the `UNVERIFIABLE` label. We call these words *give-away words* as they alone will be a sufficient source of information for the classifier. In other words, the reasoning text in a large number of cases de facto contains the label.

We removed these words from the reasoning text and repeated the experiments with the modified reasoning text. The list of removed give-away words was manually selected from the words with highest label occurrence ratio[8]. All words were selected only if they occurred at least 20 times in the corresponding label class. Finally, we manually chose words and removed them from the reasoning text, see Table 3 that contains examples of the removed give-away words. For Czech, we removed $9,601$ words out of $1,552,878$, for Slovak, we removed $9,147$ words out of $2,146,465$ and for Polish, we removed 573 words out of $367,435$. The complete list of the removed words is available at `http://nlp.kiv.zcu.cz/projects/fact-checking`.

Czech	Polish	Slovak
nepravdivý	fałszywą	nepravdivý
pravdivíy	prawdziwą	pravdivý
neověřitelný	nieweryfikowalną	neoverite'ný
neodpovídá	manipulację	nevieme

Table 3: Examples of give-away words.

4.1 Models Settings

The preprocessing includes tokenization using NLTK *TreebankWordTokenizer* (Bird et al., 2009), text lowercasing, removing HTML tags and entities. No other preprocessing steps are employed. We use Logistic Regression classifier from the LIBLINEAR library (Fan et al., 2008) with penalty parameter $C = 1$ and L2 regularization (see Fan et al. (2008) for detailed description), along with

[6] The rest of the parties that had fewer claims than the selected parties. In the Czech dataset, this includes the `null` value used for people who changed parties over time.

[7] The dataset is available for research purposes at `http://nlp.kiv.zcu.cz/projects/fact-checking`

[8] The number of occurrences of words for a given label divided by the total frequency. We selected words with a ratio ≥ 0.8 for the `TRUE` label, and words with a ratio ≥ 0.6 for the other three labels.

		Czech		Polish		Slovak	
Dataset	Labels	Macro F_1	Accuracy	Macro F_1	Accuracy	Macro F_1	Accuracy

* dataset only with claim

† dataset with both claim and reasoning.

‡ dataset with both claim and reasoning without give-away words.

Table 5: Results of logistic regression classification.

unigram and bigram features. Experiments with the reasoning are performed on a combination of the claim text and the reasoning text. First, the reasoning text and the claim text are concatenated, and then we extract the unigram and bigram features. These features are used as an input to the classifier.

4.2 Results

We report results for the experiments for all three languages, including results of a random and majority class classification in Table 4.

In Table 5 we show the results for the Logistic Regression classifier on the balanced and imbalanced datasets for the following text combinations:

- claim
- claim & reasoning
- claim & reasoning without give-away words

On the balanced dataset we can see that using only unigrams and bigrams as features is not enough for the classifier as the results are only slightly better than the majority baseline; thus more sophisticated methods are needed to extract the information contained in the reasoning part of the dataset.

We can see that the results achieved on both claim and reasoning are very high (F_1 0.87, accuracy 0.91 for Czech) confirming our hypothesis that in ideal conditions this task could be solved by a machine learning algorithm. In the case of using only the claim on the balanced binary dataset, accuracy drops to 0.57, 0.55, and 0.58 for Czech, Polish, and Slovak, respectively. Polish appears as the most challenging language as the results are lower compared to the other two languages. One reason could be a smaller size of the Polish dataset (see Table 2).

In the case of experiments with the *give-away words*, results are still much higher than in experiments where only the claim was used (F_1 0.53, accuracy 0.72 for Slovak). We observed the highest performance drop for experiments with all four labels, especially for Czech, in comparison to the experiments with the original reasoning text. The performance of the Polish model was least affected. This was caused by the low number of removed words (573 words out of 367,435 in total) for Polish. Thus the assumption that the reasoning contains only give-away words is false; leading us to believe that some information about the validity of the claim is contained in the reasoning.

5 Conclusion

This paper represents the initial research of fact-checking in Czech, Polish, and Slovak languages.

- We presented datasets for fact-checking in three West Slavic languages and provided them to the research community.
- We ran initial experiments which revealed baseline results for further research.

It is clear that this task is very challenging. However, we showed that when a machine learning approach uses label reasoning in addition to the claim, it can perform very well. Although such human-written reasoning rather sets a performance upper bound, the way to go forward might include generating such reasoning automatically using external data.

Abstract

Many Natural Language Processing (NLP) tasks depend on using Named Entities (NEs) that are contained in texts and in external knowledge sources. While this is easy for humans, the present neural methods that rely on learned word embeddings may not perform well for these NLP tasks, especially in the presence of Out-Of-Vocabulary (OOV) or rare NEs. In this paper, we propose a solution for this problem, and present empirical evaluations on: a) a structured Question-Answering task, b) three related Goal-Oriented dialog tasks, and c) a Reading-Comprehension task[1], which show that the proposed method can be effective in dealing with both in-vocabulary and OOV NEs.

1 Introduction

We come across Named Entities (NEs) in many Natural Language Processing (NLP) tasks. In tasks such as Question-Answering (QA) and goal-oriented dialog, NEs play a crucial role in task completion. Examples include QA systems for retrieving information about courses offered at a university, and dialog systems that perform restaurant reservation, flight ticket booking, and so on. In many cases, these tasks also involve interaction with external knowledge sources such as DataBases (DB) which could have a large number of NEs. In these tasks NEs include people's names, restaurant names, locations etc.

There has been a lot of interest in building neural methods for NLP tasks. Past work has developed multiple methods for addressing the unique challenges to neural methods posed by NEs. One straightforward method is to add each and every NE (including those in the DB) to the vocabulary. This method has been evaluated for only synthetic or small tasks (Neelakantan et al., 2015). For real world tasks, especially those with large DBs, this causes an explosion in the vocabulary size and hence the number of parameters to learn. There is also the problem of not being able to learn *good* neural embeddings for individual NEs, as individual NEs (e.g., a particular phone number) generally occur only a few times in a dataset. Another previously proposed method is to encode all the NEs with random embeddings and keep them fixed throughout (Yin et al., 2015), but here we lose the meaning associated with the neural embeddings and risk interference and correlation with others in unexpected ways.

A third method is to first recognize the NE-type with either NE taggers (Finkel et al., 2005) or entity linkers (Cucerzan, 2007; Guo et al., 2013), and then replace them with NE-type tags. For example, all location names could be replaced with the tag *NE_location*. This prevents the explosion in vocabulary size; however, the system loses the ability to distinguish and reference different NEs of the same type. There is also the possibility of new NEs arising during the test time. In fact, many of the Out-Of-Vocabulary (OOV) words that arise during test time in many NLP tasks (e.g. Bordes and Weston (2016)) are NEs. Furthermore, in many scenarios it is easier and accurate to work with the actual exact values of NEs rather than neural embeddings, like providing a phone number to a user or searching for a faculty name over a DB. None of the above neural methods have the ability to work with exact NE values.

[1] We create extended versions of dialog bAbI tasks 1,2 and 4 and OOV versions of the CBT test set - https://github.com/IBM/ne-table-datasets/

Proceedings of Recent Advances in Natural Language Processing, pages 980–993,
Varna, Bulgaria, Sep 2–4 2019.

In this paper, we propose a novel neural method that addresses all the aforementioned issues. There are three aspects to our method.

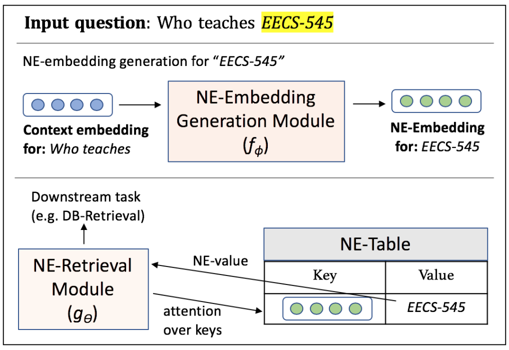
- On-the-fly-generation: Neural embeddings for the NEs are generated on the fly using their context information. This avoids the explosion in vocabulary size, while still providing meaningful and distinguishable neural embeddings for the different NEs.
- Key-Value-Table: The generated embeddings are stored in a table (*NE-Table*), with embeddings as the keys (key-embeddings) and exact NEs as the values (NE-values).
- On-the-fly-Retrieval: The NE-values can later be retrieved from the *NE-Table* by attending over the key-embeddings, providing the ability to interact with exact NE values.

We demonstrate our method on a reading-comprehension task, a simple structured Question-Answering (QA) task, and three goal-oriented dialog tasks. Our method achieves 10% increase in accuracy for Reading-Comprehension, 19% increase for structured-QA and around 90% increase for goal-oriented dialog tasks, with respect to their corresponding baselines.

2 NE-Table: A Neural Key-Value Table for Named Entities

Our proposed method (Figure 1) has three aspects.

On-the-fly-generation. Neural embeddings for the NEs are generated on the fly using their context information (shown as the *NE-Embedding Generation Module* in Fig 1), instead of adding them to the vocabulary. The context information depends on the task. For a dialog task, the context is the full dialog so far, including the present utterance which has the NE in it. For the QA task, context is the sentence in which the NE appears. For the Reading Comprehension task, the sentence where the NE occurs or potentially the full story can be used as the context. The context could also include the NE-type information when available. The *NE-Embedding Generation Module*, denoted (f_ϕ), takes the context embedding as input and outputs the NE-Embedding. For our purposes, f_ϕ is an multi-layer perceptron (MLP). The problem of explosion in vocabulary size is avoided, as NEs are not part of the vocabulary and the NE-Embeddings are generated on the fly. Our proposed method also generates unique embeddings for different NEs with the same NE-type. This is better than replacing a NE with its NE-type as that results in all NEs with the same NE-type having the same embedding and hence, losing the ability to distinguish different NEs with the same NE-type. The generated NE-Embeddings are meaningful as they are learned from the context, in comparison to fixed random embeddings and can also be used as the learned neural embedding for that NE word from thereon.



Input question: Who teaches EECS-545
NE-embedding generation for "EECS-545"

NE-Embedding for: EECS-545
Downstream task (e.g. DB-Retrieval)
NE-Retrieval Module (g_θ)
NE-value
attention over keys
NE-Table
Key
Value
EECS-545

Figure 1: For input question - *Who teaches EECS-545*, the *NE-Embedding Generation Module* (f_ϕ) takes the context embedding as input and generates a NE-Embedding for the NE *EECS-545*. The NE-Embedding is stored in *NE-Table* with its actual value *EECS-545*. The *NE-Retrieval Module* (g_θ) performs attention over the keys in *NE-Table* to retrieve the NE-value. We show a simple example here to illustrate f_ϕ and g_θ. Depending on the task, the context can vary and the *NE-Table* can have more entries.

Key-Value-Table. As discussed in the previous section, there are many scenarios where it is easier and more accurate to work with the exact values of NEs rather than their neural embeddings, like providing a phone number to a user or searching for a faculty name over a DB. For this purpose, the generated NE-Embedding, along with its exact NE value is stored in a table, *NE-Table*, as a key-value pair, with the embedding as key (key-embedding) and the exact NE as value (NE-value).

On-the-fly-Retrieval. The NE-value can later be retrieved from the *NE-Table* by performing attention over the key-embeddings in the *NE-Table*. This is performed by the *NE-Retrieval Module* (g_θ) shown in Figure 1. For our purposes, g_θ is an MLP. The input to *NE-Retrieval Module* also depends on the task. For dialog task, the dialog state vector is used, which has the information of the dialog so far. For QA task, the encoding of the input question is used. For Reading Comprehension task, the full story is used as input to the retrieval module. The retrieved NE-value can be used in the output utterance (e.g. providing a phone number) or to do an exact match over values in a DB (e.g. searching for a faculty name in a DB).

While the matching of a NE-value retrieved from the *NE-Table*, with other NEs in the DB is performed through exact value match, the actual retrieval of that NE from the *NE-Table* happens using attention in the neural embedding space (using a dot product in our experiments). This allows the training of the *NE-Retrieval Module* using the supervision obtained from the downstream module (e.g., a DB retrieval module) that uses the retrieved NE-value. This also provides supervision for training the *NE-Embedding Generation Module*. Our intuition is that, this would encourage the *NE-Embedding Generation Module* to generate embeddings for the NEs such that the embeddings have relevant and enough information to allow the *NE-Retrieval module* to attend and retrieve them correctly when required later.

Since the embeddings are generated on the fly using the context, the above method works equally well for new NEs that come during test time as it would for the NEs present in the training data. We show examples for *NE-Table* for the dialog and Reading Comprehension task in Figure 2. A new, separate *NE-Table* is created for each data instance based on the task. For example, in the dialog task, each dialog will have its own separate *NE-Table*. Only the NEs that have appeared in the dialog so far will be present in its corresponding *NE-Table*. The same NE occurring in different dialogs will have different dialog-context-dependent embeddings in their corresponding *NE-Table*. Similarly, for the reading comprehension task, each story will have a separate *NE-Table* with the NEs present in that story and for the QA task, each question will have a separate *NE-Table*. Note that, a NE that occurs multiple times in the same dialog/story/question will also have multiple unique embeddings in the *NE-Table* because of differing contexts as shown in Figure 2 (right).

3 Experiments and Results

We evaluate our proposed method on three types of tasks: a reading-comprehension task, a structured-QA task and three goal-oriented dialog tasks. Our proposed method is generic and can be added to the state-of-the-art approaches for these tasks. But instead of implementing 3 separate specialized neural architectures, we chose the end-to-end memory network architecture from Sukhbaatar et al. (2015) as the base architecture for our tasks. This allows us to evaluate the advantage gained by adding our method to the base architecture instead of trying to get state-of-the-art performance in a particular task/dataset.

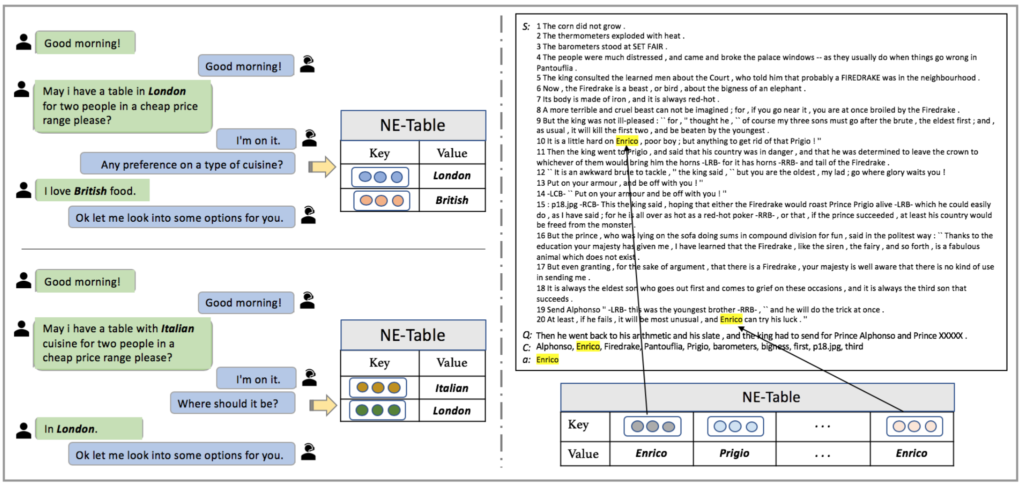
Model	Validation	Test
W/O-NE-Table (BoW)	49.55	41.69
W/O-NE-Table (LSTM)	49.40	41.10
With-NE-Table (BoW)	57.05	51.28
With-NE-Table (LSTM)	55.75	51.08

Table 1: Results (accuracy %) on CBT-NE dataset

3.1 Reading Comprehension Task

The Children's Book Test dataset (CBT), built from children's books from ProjectGutenberg, was introduced by Hill et al. (2015) to test the role of memory and context in language processing and understanding. Questions are formed by enumerating 21 consecutive sentences, where the first 20 sentences form the *story* (S), and a *word* (a) is removed from the 21st sentence, which then implicitly becomes the *query* (q). The specific task is to predict the correct answer word (a) from a set of 10 candidate words (C) present in the story or the query. We test our method on the NE questions subset of the CBT dataset.

We use the Window memory architecture proposed by Hill et al. (2015) for the CBT dataset as our baseline. In Memory Networks (Sukhbaatar et al., 2015), each complete sentence of S is encoded and represented in a separate memory slot. For the CBT, this setting would yield exactly 20 memories for S. In Window memory, instead of a full sentence from the story, a phrase is encoded and represented in a separate memory slot. Each phrase s corresponds to a window of text from the story S centred on an individual mention of a candidate c in S. The window is constructed as span of words $w_{i-(b-1)/2}$ ... w_i ... $w_{i+(b-1)/2}$ where b is window size and $w_i \in C$ is an instance of one of the candidate words in the question. We perform two baseline evaluations: encoding the windows using a) Bag-of-Words (BoW) and b) LSTM (Hochreiter and Schmidhuber, 1997).



Good morning!

Good morning!

May i have a table in ***London*** for two people in a cheap price range please?

I'm on it.

Any preference on a type of cuisine?

I love ***British*** food.

Ok let me look into some options for you.

Good morning!

Good morning!

May i have a table with ***Italian*** cuisine for two people in a cheap price range please?

I'm on it.

Where should it be?

In ***London***.

Ok let me look into some options for you.

S: 1 The corn did not grow .
2 The thermometers exploded with heat .
3 The barometers stood at SET FAIR .
4 The people were much distressed , and came and broke the palace windows -- as they usually do when things go wrong in Pantouflia .
5 The king consulted the learned men about the Court , who told him that probably a FIREDRAKE was in the neighbourhood .
6 Now , the Firedrake is a beast , or bird , about the bigness of an elephant .
7 Its body is made of iron , and it is always red-hot .
8 A more terrible and cruel beast can not be imagined ; for , if you go near it , you are at once broiled by the Firedrake .
9 But the king was not ill-pleased : `` for , '' thought he , `` of course my three sons must go after the brute , the eldest first ; and , as usual , it will kill the first two , and be beaten by the youngest .
10 It is a little hard on Enrico , poor boy ; but anything to get rid of that Prigio ! ''
11 Then the king went to Prigio , and said that his country was in danger , and that he was determined to leave the crown to whichever of them would bring him the horns -LRB- for it has horns -RRB- and tail of the Firedrake .
12 `` It is an awkward brute to tackle , '' the king said , `` but you are the oldest , my lad ; go where glory waits you !
13 Put on your armour , and be off with you ! ''
14 -LCB- `` Put on your armour and be off with you ! ''
15 : p18.jpg -RCB- This the king said , hoping that either the Firedrake would roast Prince Prigio alive -LRB- which he could easily do , as I have said ; for he is all over as hot as a red-hot poker -RRB- , or that , if the prince succeeded , at least his country would be freed from the monster .
16 But the prince , who was lying on the sofa doing sums in compound division for fun , said in the politest way : `` Thanks to the education your majesty has given me , I have learned that the Firedrake , like the siren , the fairy , and so forth , is a fabulous animal which does not exist .
17 But even granting , for the sake of argument , that there is a Firedrake , your majesty is well aware that there is no kind of use in sending me .
18 It is always the eldest son who goes out first and comes to grief on these occasions , and it is always the third son that succeeds .
19 Send Alphonso '' -LRB- this was the youngest brother -RRB- , `` and he will do the trick at once .
20 At least , if he fails , it will be most unusual , and Enrico can try his luck . ''

Q: Then he went back to his arithmetic and his slate , and the king had to send for Prince Alphonso and Prince XXXXX .

a: Enrico

Figure 2: *Left:* **Two dialogs from bAbI task-1**. A user (in green) chats with a dialog system (in blue) to book a table. Each dialog has its own separate *NE-Table* and a separate NE-Embedding is generated for the NE *London* though it appears in both dialogs. *Right:* **Question from CBT** . NE *Enrico* (highlighted in yellow) occurs twice in the context *S*, where a separate NE-Embedding is generated for each occurrence.

For each NE[2], the corresponding window is fed to an LSTM to create the context embedding. The context embedding is used as input to *NE-Embedding Generation Module* (f_ϕ), as shown in Figure 1, to generate the corresponding NE-Embedding, which is added to the *NE-Table*. The NE-Embeddings are also added to window memory, in place of the NEs. The query (q) embedding is used to attend over the memory (list of encoded window memory slots) to get relevant information from the memory. The internal state generated is given as input to the *NE-Retrieval Module* (g_θ), for retrieving the correct NE answer (a). Table 1 shows that replacing the baseline with our method achieves higher performance on both BoW and LSTM baseline models, across both validation and test sets. We use a window size of 5 as in Hill et al. (2015). We think that since the window size is small, both BoW and LSTM models perform similarly. We provide model training and hyper-parameter details in the Appendix.

To further evaluate the impact of OOV NEs, we created additional OOV test sets by replacing NEs in the test set with new NEs not present in the train and validation sets. We generate 5 such OOV test sets with varying percentage of OOV NEs (20%, 40%, 60%, 80% and 100%). Figure 3 shows the comparison of our model with the baselines on OOV test-sets. The baseline models perform poorly as OOV% increases, decreasing to as low as 5% from 41%. We observe only a slight reduction in accuracy for the NE-Table models from 51% to 46% because the new entities are also part of the windows, used to generate NE-Embeddings. These experiments illustrate that our model performance is robust to OOV NEs.

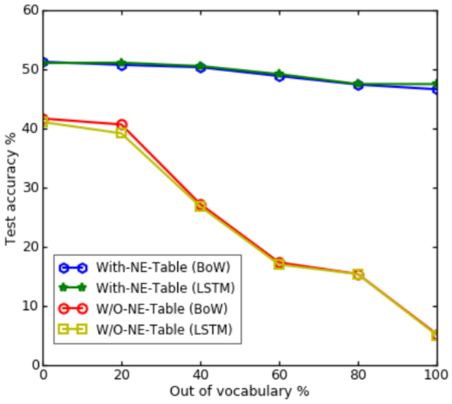

Figure 3: Results on CBT-NE OOV test sets

The next two tasks, structured-QA and goal-oriented dialog involve retrieval from an external DB. This is performed by the *DB-Retrieval Module* (h_ψ), which uses a multiple-attention based neural retrieval mechanism. We describe this next and then present results on the 2 tasks.

[2] The NEs present in the story are identified by the Stanford Core NLP NER system (Manning et al., 2014).

3.2 Multiple-Attention Based Neural Retrieval Mechanism

In both structured-QA and goal-oriented dialog tasks, the external information is present in a single database table, where each row corresponds to a new entity of interest and the columns correspond to the different attributes associated with it. For example, in our structured-QA (which is about course offerings at a university) DB, each row corresponds to a course and the columns correspond to course attributes, such as course number, course name, instructor name, etc. Each column of the table has a column heading, which labels the attribute of that column. These headings are also part of the vocabulary. While the non-NEs present in the DB are part of the vocabulary and represented by their learned neural embeddings, the NEs are not part of the vocabulary and are represented by their exact values.

The *DB-Retrieval Module* performs attention over both attributes(columns) as well as rows to select the final cell(s) in 3 steps. In step 1, the column(s) that the final cell(s) belong to are selected by attention over the column heading embeddings. For the question *Who teaches EECS545?*, step 1 selects the column *'instructor name'*. In step 2, separate attention is performed over the column headings to select the columns, which are used to represent the rows (to retrieve the final cell) and column *'course number'* is selected. Step 3 is to do attention over the rows. For each non-NE column selected in step 2, the cell embeddings are added together along each row, to generate an embedding for each row. Attention is performed over these row embeddings to select row(s). For each NE-column selected in step 2, a NE-value is retrieved from the *NE-Table* to do an exact match search over that NE-column to select matching row(s). The intersection of these matching row(s) gives the final set of selected row(s), and their intersection with the set of column(s) selected in step 1 gives the retrieved cell(s). For our example, only one column is selected to represent the rows: *'course number'*, which is a NE-column. Therefore, a NE value is retrieved from the *NE-Table* (EECS545) and an exact match search is done over the *'course number'* column.

The input to the *DB-Retrieval Module* depends on the task. For the dialog task, the dialog state vector is used, which has the information of the dialog so far. For the QA task, the encoding of the input question is used. All the attention operations in our experiments are performed through dot product followed by a sigmoid operation, which allows for multiple selections. Additional details and further explanation of the retrieval mechanism with examples are provided in Appendix. Note that *NE-Table* can potentially be used with other neural retrieval mechanisms. The multiple-attention mechanism described above is only one of the several neural retrieval mechanisms (Yin et al., 2015).

3.3 Structured-QA from DB

The task here is to retrieve an answer (single cell in a table) from DB in response to structured one line questions. We used the details of course offerings at a university to create structured Question-Answer (QA) pairs. The DB is a single table of 100 rows (Courses) and 4 columns (Course Number, Course Name, Department, Credits)[3], where course numbers and course names are treated as NEs. The QA pairs are generated through random sampling from the DB, following the format -

```
Q: Col-1-type Col-1-value Col-2-type ?
A: Col-2-value
```

with the following being a specific example:

```
Q: Course Number EECS545 Credits ?  A: 4.
```

500 QA pairs were created and split randomly between training and test set (400-100), where the random split results in some NEs (OOV) in the test set, not present in the training set. The task was specifically constructed to be simple to show the impact of OOV NEs on the model performance and evaluate our proposed method.

The experiments were performed with two models. Both models use a Recurrent Neural Network (RNN) to encode the question and use the multiple-attention based neural retrieval mechanism to retrieve answers. The baseline model (*W/O-NE-Table*) does not distinguish NEs from normal words, and all words (including NEs) that occur in questions and DB are part of the vocabulary. The *With-NE-Table* model uses our proposed method and builds *NE-table* (course numbers and course names are the NEs in this task). In the *With-NE-Table* model, when a NE word is encountered, the hidden state of the RNN at the previous time step (word) is used as input to the *NE-Embedding Generation Module* (f_ϕ). The

[3] number of unique course numbers - 100, unique course names - 96, unique dept names - 10 and unique credits - 4

Model	Retrieval accuracy (%)
W/O-NE-Table	81.0
With-NE-Table	100.0

Table 2: Results on structured-QA task

NE-Embedding generated by f_ϕ is then fed back to the RNN to continue encoding the question. The generated NE-Embedding is also stored in the *NE-Table* associated with this question. The final hidden state of the RNN obtained after encoding the full question is provided as input to the *DB-Retrieval Module* (h_ψ).

For our example, both models perform attention over the column headings to identify the correct column *Credits* required for the answer. Then, both models attend over column headings to find the column *Course Number* used for representing the rows. For *W/O-NE-Table* model, since all course numbers are part of vocabulary, each row is represented by neural embeddings associated with course numbers and attention is done over the row embeddings. For *With-NE-Table* model, since course numbers are NEs, each row is represented with exact course number values. A neural attention over *NE-Table* is performed to return the NE value, *EECS545*, which is then used to perform an exact match with the course number values. We provide model training details in Appendix.

Table 2 shows the retrieval accuracy for both models. While the test accuracy for *With-NE-Table* is 100%, it drops to 81% for *W/O-NE-Table* model. Further analysis shows that out of the 19% drop, 11% is due to OOV NEs encountered at test time. These OOV NEs are in the DB, and hence are part of the vocabulary for the *W/O-NE-Table* model, but have random embeddings which did not change during the training time (as they were never encountered during the training). The rest 8% drop can be attributed to the model's inability to learn good embeddings for unique NEs that were rarely seen during training. However, these issues do not pose a problem for our *With-NE-Table* model, since we generate embedding for a NE on the fly for each question based on the context. This solves both problems: a) whether an NE occurred rarely or b) it was not present in training data at all. The *With-NE-Table* model should also easily scale to large datasets with any number of NEs without drop in performance.

3.4 Goal-Oriented Dialog Tasks

The Dialog bAbI tasks dataset was introduced by Bordes and Weston (2016) as a testbed to break down the strengths and shortcomings of end-to-end goal-oriented dialog systems The task domain is restaurant reservation and there are 5 tasks - Task 1: Issuing API calls, Task 2: Updating API calls, Task 3: Displaying Options, Task 4: Providing extra information and Task 5: Conducting full dialogs (combination of tasks 1-4). The system is evaluated in a retrieval setting. At each turn of the dialog, the system has to select the correct response from a list of possible candidates.

In the original bAbI tasks, DB-Retrieval is bypassed by providing all possible system utterances with all combinations of information *pre*-retrieved from the DB in a large candidate response list. We extend the original testbed and propose a new testbed, which is closer to real-world restaurant reservation, by adding an actual external DB so that the system can also be tested on the ability to retrieve the required information from the DB. We evaluate our method on extended versions of task 1,2 and 4[4].

For our experiments, we use an end-to-end memory network similar to Bordes and Weston (2016), except that we encode sentences using an RNN, while they use BoW encoding. The encoded sentences, which are part of the dialog history, are stored in the memory and the query (last user utterance) embedding is used to attend over the memory to get relevant information from the memory. The generated internal state is used to select the candidate response, and is also given as input to the *DB-Retrieval Module* (h_ψ). The DB is used to identify the NEs along with their types (if a word is present in a NE-column in the DB it is a NE; the column where it appears gives its NE-type).[5]

The experiments are performed on two models:

- *W/O-NE-Table* model (the baseline model) - All input words including NEs are part of the vocabulary. For NEs, however, their embedding given to the sentence encoder RNN is the sum of the NE word embedding and the embedding associated with its NE-type.

[4] Task 3 requires to learn to sort. Bordes and Weston (2016) achieve close to 0% accuracy on it.Therefore, we decided to skip tasks 3 and 5 (task 5 includes task 3 dialogs) to focus on evaluating our proposed method.

[5] This simple method (based on exact match) though works for this dataset, is not very effective, as plural or abbreviated NEs will not match.

- *With-NE-Table* model (uses our proposed method) - When an NE is encountered in the dialog, the last hidden state of the RNN encoding the sentence is used as input to the *NE-Embedding Generation Module* (f_ϕ). The NE-Embedding generated is stored in the *NE-Table*. The generated NE-Embedding and the embedding associated with its NE-type are fed to the RNN.

Note that both the models have access to the information whether a given word is a NE and its NE-type. Supervision is provided for candidate response selection and all attention operations performed during *DB-Retrieval*, for both models.

3.4.1 Extended Dialog bAbI Tasks 1 and 2

In the original bAbI task 1, the conversation between the system and the user involves getting information necessary to issue an *api_call*. In task 2, the user can ask the system to update his/her preferences (cuisine, location etc.). The system has to take this into account and make an updated *api_call*. In our extended version, once the system determines that the next utterance is an *api_call*, the system also has to actually retrieve the restaurant details from the DB (rows) which match user preferences. The system is evaluated on having conversation with the user, issuing *api_call* and retrieving the correct information from DB. The DB is represented as a single table, where each row corresponds to a unique restaurant and columns correspond to attributes, e.g. cuisine, location etc.

Both *W/O-NE-Table* and *With-NE-Table* models, first select the four relevant (cuisine, location, price range and number of people) columns to represent each row (restaurant). The *W/O-NE-Table* model then selects the rows using attention over the row embeddings obtained through the combined (additive) representation of the four selected attributes. The *With-NE-Table* model splits the row selection into two simpler problems. For cuisine and location (which are NEs), one NE value each is retrieved from the *NE-Table* and an exact match is performed in the DB. The neural embeddings of the non-NE attributes (price range and number of people) are added to perform attention for selecting rows. The final retrieved rows are the intersection of the rows selected by NE column and non-NE column based selections.

The results for tasks 1 and 2 are shown in Table 3. The *With-NE-Table* model achieves close to 100% accuracy in both tasks, while *W/O-NE-Table* performs poorly. During DB retrieval, for the *With-NE-Table* model, two NEs are chosen from the *NE-Table* and exact matching is done over different cuisines and locations in the DB, but embeddings for these NEs are learned for *W/O-NE-Table*. This results in poor DB-Retrieval for *W/O-NE-Table* for less frequent/ OOV location/cuisine values. Both models perform well in *Per-dialog* accuracy as it does not involve DB retrieval[6]. The Per-Dialog accuracy is high for both models on the normal test set. However, for task 1 OOV-test set, *W/O-NE-Table* model is affected by OOV-NEs (90.3%), while *With-NE-Table* model performance is robust (99.0%).

Model	DB-Retrieval	Per-Dialog	Per-Dialog + DB-Retrieval
Task 1			
W/O-NE-Table	10.2 (7.0)	100 (90.3)	10.2 (6.7)
With-NE-Table	98.5 (99.0)	98.8 (99.0)	**97.3 (98.0)**
Task 2			
W/O-NE-Table	0.8 (1.0)	100 (100)	0.0 (0.1)
With-NE-Table	99.6 (99.8)	100 (99.9)	**99.2 (99.7)**
Task 4			
W/O-NE-Table	0.0 (0.0)	100 (100)	0.0 (0.0)
With-NE-Table	100 (100)	100 (100)	**100 (100)**

Table 3: Results for extended bAbI tasks 1, 2 and 4. % accuracy for Test and Test-OOV (given in parenthesis). *DB-Retrieval* : Retrieval accuracy for rows (task 1,2 - *all* restaurants matching user preferences) and a particular cell (task 4 - restaurant phone number/address). *Per-Dialog* : Percentage of dialogs where every dialog response is correct. Training details and hyperparameter values are provided in Appendix.

3.4.2 Extended Dialog bAbI Task 4

The original task 4 starts at the point where a user has decided a particular restaurant. The system is given information (location, phone number, address etc.) about *only* that restaurant as part of the dialog history and the user can ask for its phone number, address or both. For a given user request e.g. address, the task is to select the correct response with the restaurant's address from a list of candidate responses. These candidate responses have phone number and address information for all the restaurants mentioned in the DB.

In our extended version, even though the user

[6] The system responses in tasks 1/2/4 do not contain any NEs, but the system still needs to understand user utterances which might have NEs.

has decided a particular restaurant, its corresponding information is not provided as part of dialog history. This makes the task harder but more realistic. Now, the system needs to search for phone number/address for the restaurant from the full DB while in the original task, the phone number/address is already provided as part of dialog history. In the extended version, the NEs in candidate responses are replaced with their NE-type tags. For example, *Suvai_phone* is replaced with *NE_phone*. The system has to select the candidate with correct NE-type tag and then replace the tag with the actual NE-value retrieved from the DB, similar to Williams et al. (2017). This setting is closer to how a human agent would do this task.

For *With-NE-Table* model, the restaurant name that appears in the dialog would be stored in *NE-Table*. When the user asks for information such as phone number, the restaurant name stored in *NE-Table* is selected and used for retrieving its phone number from the DB. In *W/O-NE-Table* model, all input words (including NEs) are part of vocabulary and phone number is selected by neural embedding attention over all restaurants names.

The results for task 4 are shown in Table 3. We observe that both models perform well in Per-dialog accuracy. The *W/O-NE-Table* model fails in DB-retrieval (0%) because it needs to learn neural embeddings for all restaurant names, while *With-NE-Table* performs well (100%) as it uses our proposed method to generate NE-Embeddings on the fly and use the actual NE values later for exact value matching over restaurant names in the DB.

4 Related Work

NE in QA: Neelakantan et al. (2015) and Yin et al. (2015) transform a natural language query to a program that could run on DBs, but those approaches are only verified on small or synthetic DBs. Other papers dealing with large Knowledge Bases (KB) usually rely on entity linking techniques (Cucerzan, 2007; Guo et al., 2013), which links entity mentions in texts to KB queries. Recently, Liang et al. (2016) extended end-to-end neural methods to QA over KB, which could work for large KB and large number of NEs. However, their method still relies on entity linking to generate a short list of entities linked with text spans in the questions, in advance. Yin et al. (2015) propose 'Neural Enquirer', a neural network architecture similar to the neural retrieval mechanism used in this work, to execute natural language queries on DB. They keep the randomly initialized embeddings of the NEs fixed as a method to handle NEs and OOV words.

NE in Dialog: There has been a lot of interest in end-to-end training of dialog systems (Vinyals and Le, 2015; Serban et al., 2016; Lowe et al., 2015; Kadlec et al., 2015; Shang et al., 2015; Guo et al., 2017). Among recent work, Williams and Zweig (2016) use an LSTM model that learns to interact with APIs on behalf of the user; Dhingra et al. (2017) use reinforcement learning to build the KB look-up in task-oriented dialog systems. But the look-up actions are defined over each entity in the KB and is therefore hard to scale up. Most of these papers actually do not discuss the issue of handling NEs though they are present. Williams et al. (2017) propose Hybrid Code Networks and achieve state-of-the-art on Facebook bAbI dataset, but approach involves a developer writing domain-specific software components.

NE in Reading Comprehension and Others: For certain tasks such as Machine Translation and summarization, neural copying mechanisms (Gulcehre et al., 2016; Gu et al., 2016) have been proposed for handling OOV words. Our *NE-Table* method can be used along with such copying mechanisms for cases like dialog generation.

5 Conclusion and Future work

In this paper, we proposed a novel method for handling NEs in neural settings for NLP tasks. Our experiments on the CBT dataset illustrate that the models with *NE-Table* perform better than models without *NE-Table*, and clearly outperform the baseline models on the OOV test sets. We observe similar results for our experiments on the structured-QA task and goal-oriented bAbI dialog tasks. We also show that our method can be used for NEs in the external DB provided. Overall, these experiments show that the proposed method can be useful for various NLP tasks where it is beneficial to work with actual NE values, and/or it is hard to learn good neural embeddings for NEs.

In future, we are interested in testing the proposed method with retrieval mechanisms such as 'Neural Enquirer' (Yin et al., 2015), which can work with multiple tables. We are also interested in exploring the use of pre-trained embeddings: word2vec (Mikolov et al., 2013), ELMo (Peters et al., 2018) etc., to bootstrap our learned NE-embeddings. We are also interested in evaluating our proposed method on tasks that are more unstructured and requires more free-form generation, e.g. machine translation and dialog generation.

A Model Training and Hyperparameter Details

A.1 Reading Comprehension - CBT

The hyperparameters used for baseline *W/O-NE-Table* models are as follows: hops = 1, embedding_size = 100, batch_size = 16. The *W/O-NE-Table (LSTM)* model uses an LSTM for encoding windows with hidden_units = 100. The entire model is trained using stochastic gradient descent (learning rate = 0.05), minimizing a standard cross-entropy loss between predicted answer $\hat{a}$ and the correct answer a. We use the same embedding matrix for encoding both story and the query.

For our *With-NE-Table* models, we use the same hyper-parameters as mentioned above. The *With-NE-Table (LSTM)* model uses separate LSTM cells for a) generating the context embedding for *NE-Embedding Generation Module* (f_ϕ) and b) encoding the windows.

A.2 Structured-QA

Both the *With-NE-Table* and *W/O-NE-Table* models use the following hyperparameters : embedding_size = 20, batch_size = 16. The RNN used for encoding the sentences has hidden_units = 20. The model is trained using Adam (learning rate = 0.01, epsilon = 1e-8). Supervision is provided for DB-Retrieval attentions and standard cross-entropy loss is used.

A.3 bAbI dialog tasks

Both the *With-NE-Table* and *W/O-NE-Table* models use the following hyperparameters : hops = 3, embedding_size = 40, batch_size = 16. The RNN used for encoding the sentences has hidden_units = 40. The model is trained using Adam (learning rate = 0.001, epsilon = 1e-8). Supervision is provided for both the candidate response selection and DB-Retrieval attentions and standard cross-entropy loss is used.

B Extended dialog bAbI tasks' examples

B.1 Original dialog bAbI task 1:

U: Hi !

S: Hello, what can I help you with today?

U: I'd like to book a table for six people in an expensive price range with British food.

S: I'm on it.

S: Where should it be?

U: In London.

S: Ok, let me look into some options for you.

S: api_call British, London, Six, Expensive

B.2 Extended dialog bAbI task 1:

U: Hi !

S: Hello, what can I help you with today?

U: I'd like to book a table for six people in an expensive price range with British food.

S: I'm on it.

S: Where should it be?

U: In London.

S: Ok, let me look into some options for you.

S: api_call

S (Retrieved Information):

B.3 Original dialog bAbI task 2:

U: Hi !

S: Hello, what can I help you with today?

U: I'd like to book a table for six people in an expensive price range with British food in London.

S: Ok, let me look into some options for you.

S: api_call British, London, Six, Expensive

U: Instead, could it be Indian cuisine.

S: Sure, is there anything else to update?

U: No.

S: Ok, let me look into some options for you.

S: api_call Indian, London, Six, Expensive

B.4 Extended dialog bAbI task 2:

U: Hi !

S: Hello, what can I help you with today?

U: I'd like to book a table for six people in an expensive price range with British food in London.

S: Ok, let me look into some options for you.

S: api_call

S (Retrieved Information):

{The_Place, british, london,...}
The_Fancy_Pub, british, london, ...}

U: Instead, could it be Indian cuisine.

S: Sure, is there anything else to update?

U: No.

S: Ok, let me look into some options for you.

S: api_call

S (Retrieved Information):

{Suvai, Indian, london, ...}
{Madras_Masala, Indian, london, ...}

B.5 Original dialog bAbI task 4:

DB Information given :
Name:The_Place, Cuisine:British,
Location:London, Price Range:Expensive,
Rating:7, Phone:The_Place_phone,
Address:The_Place_address, Availability:six

U: Hello

S: Hello, what can I help you with today?

U: I'd like to book a table at The_Place.

S: Great, let me do the reservation.

U: May I have the address of the restaurant.

S: Here it is, The_Place_address.

B.6 Extended dialog bAbI task 4:

DB Information given : Entire DB

U: Hello

S: Hello, what can I help you with today?

U: I'd like to book a table at The_Place.

S: Great, let me do the reservation.

U: May I have the address of the restaurant.

S: Here it is, NE_address.

S: The_Place_address *(*retrieved information)

C Multiple-attention based neural retrieval mechanism

Figure 4 shows the schematic of the entire retrieval process. In order to retrieve a particular cell from the table, the system needs to find the correct column and row corresponding to it. The *DB-Retrieval Module* (h_ψ) does that by generating 3 different attention key embeddings (vectors): Attention over Columns for Columns (*ACC*), Attention over Columns for Rows (*ACR*), Attention over Rows for Rows (*ARR*).

The column(s) that the final retrieved cell(s) belong to, are selected by matching *ACC* key embeddings with the neural embeddings of the column headings (Course Number, Instructor, Credits etc). A separate *ACC* key embedding is generated for every column heading and matched with its embeddings to provide attention scores for all the columns. For the example, *Who teaches EECS545?*, the system would want to retrieve the name of the *Instructor*. Therefore, the *Instructor* column heading alone will have high attention score and be selected. In our experiments, the attention scores are computed through dot products followed by a sigmoid operation, which allows for multiple selections.

Now that the column(s) are chosen, the system has to select row(s), so that it can get the cell(s) it is looking for. Each row in the table contains the values (EECS545, Machine Learning, Scott Mathew etc) of several attributes (Course Number, Course Name, Instructor etc). But we want to assign attention scores to the rows based on particular attributes that are of interest (*Course Number* in this example). The column/attribute headings that the system has to attend to for selecting these relevant attributes are obtained by matching *ACR* (Attention over Columns for Rows) key embeddings with the neural embeddings of the different column headings.

The last step in the database retrieval process is to select the relevant rows using the *ARR* (Attention over Rows for Rows) key embedding. *ARR* is split into two parts *ARR NE* and *ARR non-NE*. In a general scenario, *ACR* can select multiple columns to represent the rows. For each selected column that is a NE column, a separate NE-value is retrieved from the *NE-Table* using a separate *ARR NE* embedding for each of them. These NE values are used to do exact match search along the corresponding columns (in the NE row representations) to select the matching rows. For the non-NE columns that are selected by *ACR*, their neural embeddings are combined together along each row to get a fixed vector representation for each row in the DB (weighted sum of their embeddings, weighted by the corresponding column attention

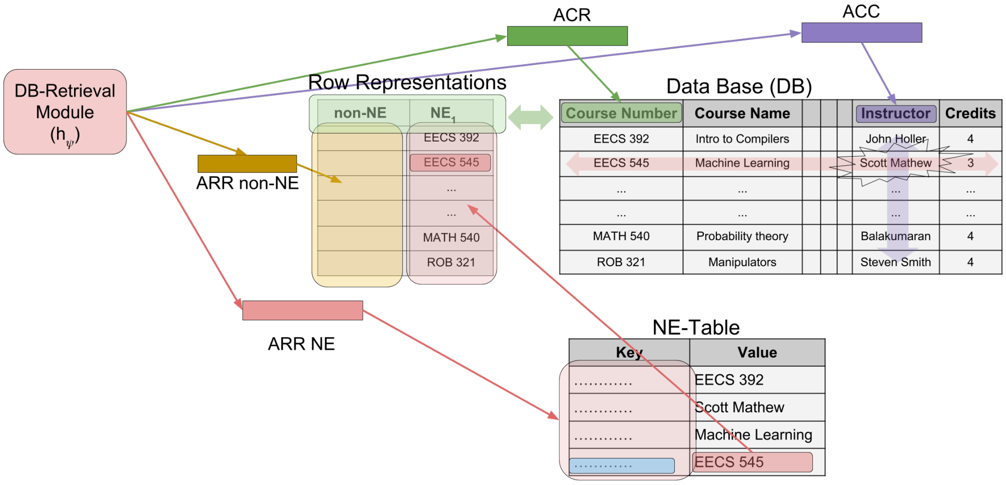

Figure 4: Multiple-attention based neural retrieval mechanism. The *DB-Retrieval Module* attends to the relevant rows and columns of the DB by generating attention key embeddings *ACC*, *ACR* and *ARR*.

scores). *ARR non-NE* is then used to match these representations for selecting rows. The intersection of the rows selected in the NE row representations and the non-NE row representations is the final set of selected rows.

In short, the dialog system can use neural embedding matching for non-NEs, exact value matching for NEs and therefore a combination of both to decide which rows to attend to. Depending on the number of columns and rows we match with, we select zero, one or more output cells. For our running example, *ARR NE* is used to match with the keys in the *NE-Table* to select the row corresponding to *EECS 545* and the value *EECS 545* is returned to do an exact match over the NE row representations (represented by the course number values). This gives us the row corresponding to *EECS 545* and hence the cell *Scott Mathew*. We could use our *NE-Table* idea with potentially many types of neural retrieval mechanisms to retrieve information from the DB. The multiple-attention based retrieval mechanism, described above, is only one such possible mechanism.

D Goal oriented dialog tasks: extended results

D.1 Extended results for tasks 1 and 2

The detailed results for task 1 and task 2 are shown in Table 4.

With-NE-Table: For issuing an *api_call* in tasks 1 and 2, four argument values are required - cuisine, location, price range and number of people. We consider cuisine and location to be NEs. So whenever cuisine and location names occur in the dialog, a NE key is generated on the fly and is stored in the *NE-Table* along with the NE values.

- ACC: For tasks 1 and 2, ACC is not required as we are interested in retrieving rows.
- ACR: ACR is used to select the columns required to represent the rows. These are four columns - NE columns (cuisine and location) and non-NE columns (price range and number of people)
- ARR-non-NE: Each row in the DB is represented by weighted vector (embedding) sum of its price range and number of people (embeddings). The model returns the relevant rows using attention on the non-NE columns embeddings.
- ARR-NE: The model attends over the *NE-Table* by matching (dot product) its generated key with the keys present in the *NE-Table* to retrieve NE values. The selected NE values are then matched (exact-match) with cuisine and location values in DB to retrieve the relevant rows.
- The final retrieved rows are the intersection of the rows selected by ARR-non-NE and ARR-NE.

W/O-NE-Table: *ACR* is used to attend to the four relevant columns. However, each row is rep-

Task	Model	ACR	ARR non-NE	ARR NE	DB-Retrieval	Per-response	Per-Dialog	Per-Dialog + DB-Retrieval
Task 1	W/O-NE-Table	100 (100)	9.0 (6.9)	-	10.2 (7)	100 (98.2)	100 (90.3)	10.2 (6.7)
	With-NE-Table	99.4 (98.1)	96.9 (96.7)	100,100 (100,100)	98.5 (99.0)	99.8 (99.8)	98.8 (99)	97.3 (98.0)
Task 2	W/O-NE-Table	100 (100)	8.6 (7.6)	-	0.8 (1.0)	100 (100)	100 (100)	0.0 (0.1)
	With-NE-Table	100 (100)	99.1 (99.8)	100,100 (100,100)	99.6 (99.8)	100 (100)	100 (100)	99.2 (99.7)

Table 4: Results for extended dialog bAbI task 1 and 2. Accuracy % for Test and Test-OOV (given in parenthesis). ARR non-NE columns are price and number of people. ARR NE columns are cuisine and location. DB-Retrieval %: Retrieval accuracy for rows (task 1,2) and a particular cell (task 4). Per-Dialog %: Percentage of dialogs where every dialog response is correct. Per-Dialog + DB-Retrieval %: Percentage of dialogs where every dialog response and information from DB retrieval are correct.

Model	ACR	ACC	ARR non-NE	ARR NE	DB-Retrieval	Per-response	Per-Dialog	Per-Dialog + DB-Retrieval
W/O-NE-Table	100 (100)	100 (100)	0.0 (0.0)	-	0.0 (0.0)	100 (100)	100 (100)	0.0 (0.0)
With-NE-Table	100 (100)	100 (100)	-	100 (100)	100 (100)	100 (100)	100 (100)	100 (100)

Table 5: Results for extended dialog bAbI task 4. Accuracies in % for Test and Test Out-Of-Vocabulary (given in parenthesis). DB-Retrieval %: Retrieval accuracy for rows (task 1,2) and a particular cell (task 4). Per-Dialog %: Percentage of dialogs where every dialog response is correct. Per-Dialog + DB-Retrieval %: Percentage of dialogs where every dialog response and information from DB retrieval are correct.

resented by the combined neural embedding representation of all four attribute values, cuisine, location, price range and number of people. *ARR non-NE* is used to retrieve the relevant rows.

From Table 4, we can see that both the models perform well in selecting the relevant columns, but the model *W/O-NE-Table* performs poorly in retrieving the rows, while *With-NE-Table* performs very well. This results in *With-NE-Table* model achieving close to 100% accuracy in DB retrieval while *W/O-NE-Table* performs poorly.

This is because, in the *With-NE-Table* model, the task of retrieving rows is split into two simpler tasks. The NEs are chosen from the *NE-Table*, and then exact matching is used (which helps in handling OOV-NEs as well). The non-NEs, price range and number of people, have limited set of possible values (low, moderate or expensive for price range and 2,4,6 or 8 for number of people respectively). This allows the system to learn good neural embeddings for them and hence have high accuracy in *ARR non-NE*. Whereas in *W/O-NE-Table* model, *ARR non-NE* involves the neural representations of cuisine and location values as well, where a particular location and cuisine value will occur only a few number of times in the training dataset. In addition to that, new cuisine and location values can occur during the test time (Test OOV dataset, performance shown in parenthesis).

For the dialog part (which does not involve the DB retrieval aspect) of extended tasks 1 and 2, the system utterances do not have any NEs in them. However, the user utterances contain NEs (cuisine and location that the user is interested in) and so the system has to understand them in order to select the right system utterance. The accuracy in performing the dialog (by selecting responses from candidate set) is similar for both the models on the normal test set. However, in the OOV-test set, for task 1, where the system has to maintain the dialog state to track which attribute values have not been provided by the user yet, *W/O-NE-Table* model seems to get affected, while the *With-NE-Table* model is robust to that. While *W/O-NE-Table* gets a Per-Dialog accuracy of 90.3% in the OOV-test set, *With-NE-Table* is able to get 99%.

D.2 Extended results for task 4

Detailed results for task 4 are shown in Table 5.

With-NE-Table: In task 4, the user tells the system the restaurant in which he/she wants to book a table. The restaurant name, which is a NE, is stored in the *NE-Table* along with it's generated key. When the user asks for information about the restaurant such as, phone number, the NE restaurant name stored in the *NE-Table* is selected and used for retrieving its corresponding phone number from the DB. For this particular case, *ACC* attends over the column *Phone* and *ACR* attends over *Restaurant Name*. Since the column selected

Task	Model	Evaluation	Task 1	Task 2	Task 4
Original bAbI tasks	Baseline(MemN2N + match-type + RNN-encoding)	Per-Dialog	100 (100)	99.9 (50.6)	100 (100)
Extended bAbI tasks	With-NE-Table	Per-Dialog + DB-Retrieval	97.3 (98.0)	99.2 (99.7)	100 (100)

Table 6: Performance comparison of our model in the extended dialog bAbI tasks, with a baseline model in the original bAbI tasks. Accuracies in % for Test and Test Out-Of-Vocabulary (given in parenthesis).

by *ACR* is a NE column, the NE value (here the actual restaurant name given by the user) is retrieved using *ARR NE* from the *NE-Table*. The retrieved NE value is used to do an exact match over the DB column selected by *ACR* to select the rows. The cell that intersects the selected row and the column selected by *ACC* is returned as the retrieved information and used to replace the NE type tag in the output response.

W/O-NE-Table: Here, all input words (including NEs) are part of the vocabulary and for NEs, their embedding given to the sentence encoder is the sum of the NE word embedding and the embedding associated with its NE-type. The candidate response retrieval (dialog) is same as the above model and the column attentions are also similar. However, the models differ with respect to attention over rows. Since NEs are not treated special here, attention over rows happens through *ARR non-NE*. For this task, when *ACR* is selected correctly (restaurant name), each row will be represented by the neural embedding representation of its restaurant names. *ARR non-NE* generates a key to match these neural embeddings to attend to the row corresponding to the restaurant name mentioned by the user.

E Comparison with original dialog bAbI tasks

We choose the best model (MemN2N + match-type features) from (Bordes and Weston, 2016) (they use match-type features for dealing with entities) and update the baseline model by using RNN encoding for sentences (similar to *With-NE-Table*). Note that we achieve higher accuracy for our updated baseline model for original bAbI tasks than reported in (Bordes and Weston, 2016), which we attribute to the use of RNN for encoding sentences (they use BoW encoding).

For match-type features, (Bordes and Weston, 2016) add special words (*R_CUISINE*, *R_PHONE* etc.), for each KB entity type (cuisine, phone, etc.) to the vocabulary. The special word (e.g. *R_CUISINE*) is added to a candidate if a cuisine (e.g. Italian) appears in both dialog and the candidate. For each type, the corresponding type word is added to the candidate representation if a word is found that appears 1) as a KB entity of that type, 2) in the candidate, and 3) in the input or memory. For example, for a task 4 dialog with restaurant information about *RES1*, *only* one candidate *"here it is RES1_phone"* will be modified to *"here it is RES1_phone R_PHONE"*. Now, if the user query is for the restaurant's phone number, using match-type features essentially reduces the output search space for the model and allows it to attend to specific candidates better. Hence, match-type features can only work in a retrieval setting and will not work in a generative setting. Our *With-NE-Table* model will work in both retrieval and generative settings.

Table 6 compares the performance of the *With-NE-Table* model in the extended bAbI tasks with that of a baseline method on the original bAbI tasks. Note that extended dialog bAbI tasks require the dialog system to do strictly more work compared to the original dialog bAbI tasks. Though not a strictly fair comparison for our model, we observe that the performance of our *With-NE-Table* model in extended bAbI tasks is as good as the performance of updated baseline model in original bAbI tasks. In addition to that, for bAbI task 2 OOV test set, *With-NE-Table* model performance in the extended bAbI task, is actually much higher compared to the baseline model on the original bAbI task (99.7% vs 50.6%).

Enhancing Unsupervised Sentence Similarity Methods with Deep Contextualised Word Representations

Abstract

Calculating Semantic Textual Similarity (STS) plays a significant role in many applications such as question answering, document summarisation, information retrieval and information extraction. All modern state of the art STS methods rely on word embeddings one way or another. The recently introduced contextualised word embeddings have proved more effective than standard word embeddings in many natural language processing tasks. This paper evaluates the impact of several contextualised word embeddings on unsupervised STS methods and compares it with the existing supervised/unsupervised STS methods for different datasets in different languages and different domains.

1 Introduction

Measuring Semantic Textual Similarity (STS) is calculating the degree of semantic equivalence between two snippets of text (Agirre et al., 2016). Earlier, STS tasks largely focused on similarity between short texts such as abstracts and product descriptions (Li et al., 2006; Mihalcea et al., 2006). Recently, STS tasks at the International Workshops on Semantic Evaluation (SemEval) focused on measuring STS between full sentence pairs. The introduction of competitive STS tasks led to the development of standard datasets like the SICK corpus (Bentivogli et al., 2016) and standardised the similarity score as a numerical value between 1 and 5 (Agirre et al., 2014).

Having a good STS metric is crucial for many natural language processing applications such as information retrieval (IR) (Majumder et al., 2016), text summarisation (Aliguliyev, 2009; Steinberger and Jezek, 2004), question answering (Mohler et al., 2011) and text classification (Rocchio, 1971). Semantic similarity also contributes to many semantic web applications like community extraction, ontology generation and entity disambiguation (Li et al., 2006), and it is also useful for Twitter search (Salton et al., 1997), where it is required to accurately measure semantic relatedness between concepts or entities (Xu et al., 2015). STS is not limited only to natural language processing. For example in Biomedical Informatics, it can be used to compare genes (Ferreira and Couto, 2010).

Given the growing importance of having a good STS metric and as a result of the SemEval workshops, researchers have proposed numerous STS methods. Most of the early approaches were based on traditional machine learning and involved heavy feature engineering (Béchara et al., 2015). With the advances of word embeddings, and as a result of the success neural networks have achieved in other fields, most of the methods proposed in recent years rely on neural architectures (Tai et al., 2015; Shao, 2017). Neural networks are preferred over traditional machine learning models as they generally tend to perform better than traditional machine learning models. They also do not rely on explicit linguistics features which have to be extracted before the ML model is learnt. Determining the best linguistic features for calculating STS is not an easy task as it requires a good understanding of the linguistic phenomenon and relies on researchers' intuition. In addition, calculating these features is usually not an easy task, especially for languages other than English. Therefore, in contrast to traditional ML methods, models based on neural networks can be easily applied to other languages.

However, the biggest challenge that the neural based architectures face when applied to STS tasks is the small size of datasets available to train them. As a result, in many cases the networks can-

Proceedings of Recent Advances in Natural Language Processing, pages 994–1003,
Varna, Bulgaria, Sep 2–4 2019.

not be trained properly. Given the amount of human labour required to produce datasets for STS, it is not possible to have high quality large training datasets. As a result researches working in the field have also considered unsupervised methods for STS. Recent unsupervised approaches use pretrained word/sentence embeddings directly for the similarity task without training a neural network model on them. Such approaches have used cosine similarity on sent2vec (Pagliardini et al., 2018), InferSent (Conneau et al., 2017), Word Mover's Distance (Kusner et al., 2015), Doc2Vec (Le and Mikolov, 2014) and Smooth Inverse Frequency with GloVe vectors (Arora et al., 2017). While these approaches have produced decent results in the final rankings of shared tasks, they have also provided strong baselines for the STS task.

Word vectors are used to determine a representation of a sentence in approaches like Word Mover's Distance (Kusner et al., 2015) and Smooth Inverse Frequency (Arora et al., 2017). The main weakness of word vectors is that each word has the same unique vector regardless of the context it appears. For an example, the word ”play” has several meanings, but in standard word embeddings such as Glove (Pennington et al., 2014), FastText (Mikolov et al., 2018) or Word2Vec (Mikolov et al., 2013) each instance of the word has the same representation regardless of the meaning which is used. However, contextualised word embedding models such as ELMo (Peters et al., 2018), BERT (Devlin et al., 2018) etc. generate embeddings for a word based on the context it appears, thus generating slightly different embeddings for each of its occurrence. The recent applications in areas such as question answering and textual entailment show that contextualised word embeddings perform better than the traditional word embeddings (Devlin et al., 2018).

This paper explores the performance of several contextualised word embeddings in three unsupervised STS methods - cosine similarity using average vectors, Word Mover's Distance (Kusner et al., 2015) and cosine similarity using Smooth Inverse Frequency (Arora et al., 2016). The rest of the paper is organised as follow. Section 2 contains information about the settings of the experiments carried out in this paper including the datasets employed here and the different contextualised word embedding models explored. Each of the contextualised word embedding models against each method are evaluated in Section 4. Further experiments are conducted on Spanish sentence similarity and Bio-medical sentence similarity to observe the portability of the model to other languages and domains in section 5. Section 6 would briefly describe the related work done for STS. The paper finishes with conclusions.

2 Settings of the Experiments

2.1 Data Sets

The experiments presented in this paper were carried out using several datasets which will be explained in next subsections. In order to prove the portability of the approaches, the proposed architectures were also tested on an English Biomedical STS dataset. In addition, the language independence of the method is tested by applying it to a Spanish STS dataset.

2.1.1 English-English STS Data Set

For the experiments carried out on English STS, we used the SICK dataset. (Bentivogli et al., 2016). The SICK data contains 9927 sentence pairs with a 5,000/4,927 training/test split which were employed in the SemEval tasks. Each pair is annotated with a relatedness score between 1 and 5, corresponding to the average relatedness judged by 10 different individuals. Table 1 shows a few examples from the SICK training dataset.

Sentence Pair	Similarity
1. A little girl is looking at a woman in costume. 2. A young girl is looking at a woman in costume.	4.7
1. A person is performing tricks on a motorcycle. 2. The performer is tricking a person on a motorcycle.	2.6
1. Someone is pouring ingredients into a pot. 2. A man is removing vegetables from a pot.	2.8
1. Nobody is pouring ingredients into a pot. 2. Someone is pouring ingredients into a pot.	3.5

Table 1: Example sentence pairs from the SICK training data

2.1.2 Spanish-Spanish STS Data Set

For the Spanish STS experiments we used the dataset provided for Spanish STS subtask in SemEval 2015 Task 2 (Agirre et al., 2015). The training set has 1250 sentence pairs annotated with a relatedness score between 0 and 4. There were two sources for test set - Spanish news and Spanish Wikipedia dump having 500 and 250 sentence pairs respectively. Both datasets were annotated with a relatedness score between 0 and 4. Table 2 shows few pairs of sentences with their similarity score. As can be seen, this dataset is significantly smaller than the English dataset presented in the previous section. The effect of this is discussed in more detail below.

Sentence Pair	Similarity
1. Ams, los misioneros apunten que los nmberos d’infectaos puen ser shasta dos o hasta cuatro veces ms grandess que los oficiales. 2. Los cadveres de personas fallecidas pueden ser hasta diez veces ms contagiosos que los infectados vivos.	0.6
1. Desde Colombia, el presidente Juan Manuel Santos dijo que convers por telfono con Humala sobre el tema y que entregara al detenido a las autoridades peruanas a ms tardar el viernes. 2. El presidente de Colombia, Juan Manuel Santos, haba anunciado horas antes que Orellana, que se encuentra detenido, ser entregado a las autoridades peruanas sentre hoy y maanas.	3.2
1. La polica abati a un canbal cuando devoraba a una mujer Matthew Williams, de 34 aos, fue sorprendido en la madrugada mordiendo el rostro de una joven a la que haba invitado a su hotel. 2. La polica de Gales del Sur mat a un canbal cuando se estaba comiendo la cara de una mujer de 22 aos en la habitacin de un hotel.	2
1. Ollanta Humala se rene maana con el Papa Francisco. 2. El Papa Francisco mantuvo hoy una audiencia privada con el presidente Ollanta Humala, en el Vaticano.	3

Table 2: Example sentence pairs from the Spanish STS training data

2.1.3 Bio-medical STS Data Set

In-order to see the performance of our baseline in a complete different domain we used the biomedical English STS dataset provided in Sogancioglu et al. (2017). The dataset comprises 100 sentence pairs, which were evaluated by five different human experts that judged their similarity and gave scores ranging from [0,4]. To represent the similarity between two sentences we took the average of these scores. Table 3 shows few examples in the dataset. A dataset as small as this one can not be used by to train a supervised ML method, requiring alternative approaches such as unsupervised methods.

Sentence Pair	Similarity
1. It has recently been shown that Craf is essential for Kras G12D-induced NSCLC. 2. It has recently become evident that Craf is essential for the onset of Kras-driven non-small cell lung cancer.	4
1. Up-regulation of miR-24 has been observed in a number of cancers, including OSCC. 2. In addition, miR-24 is one of the most abundant miRNAs in cervical cancer cells, and is reportedly up-regulated in solid stomach cancers.	3
1. These cells (herein termed TLM-HMECs) are immortal but do not proliferate in the absence of extracellular matrix (ECM) 2. HMECs expressing hTERT and SV40 LT (TLM-HMECs) were cultured in mammary epithelial growth medium (MEGM, Lonza)	1.4
1.The up-regulation of miR-146a was also detected in cervical cancer tissues. 2. Similarly to PLK1, Aurora-A activity is required for the enrichment or localisation of multiple centrosomal factors which have roles in maturation, including LATS2 and CDK5RAP2/Cnn.	0.2

Table 3: Example sentence pairs from the Bio-medical dataset

2.2 Contextualised Word Representations

In order to use words in machine learning models, words have to be represented with a numerical form. Over the years researches have used many word representations like bag of words, one hot encoded vectors etc. But the recent neural models like word2vec (Mikolov et al., 2013) and Glove (Pennington et al., 2014) provide better representations to the words considering its context too. We call them *standard word representations* in this research. Their main weakness is that every word has a unique word embedding regardless of the context it appears. As an example the word ’bank’ in two sentences - “I am walking by the river bank” and “I deposited money to the bank” would have the same embeddings which can be confusing for machine learning models. The recent introduction of contextualised word representations solved this problem by providing vectors for words considering their context too. In this way the word ’bank’ in above sentences have two different embeddings. As a result, contextualised word embeddings perform better than standard word embeddings in many natural language processing tasks like question answering, textual entailment etc. (Devlin et al., 2018). The following contextualised words representation models were considered for the experiments.

2.2.1 ELMo

ELMo introduced by Peters et al. (2018) use bidirectional language model (biLM) to learn both word (e.g., syntax and semantics) and linguistic context. After pre-training, an internal state of vectors can be transferred to downstream natural language processing tasks. We used the ’original’ pre-trained model provided in Peters et al. (2018) which was trained on the 1 Billion Word Benchmark (Chelba et al., 2013), approximately 800M tokens of news crawl data from WMT 2011. Using the model we represented each word as a vector with a size of 3072 values.

2.2.2 BERT

BERT was introduced in Devlin et al. (2018). It is based on a bidirectional transformer architecture rather than a unidirectional transformer used in Open AI GPT (Radford et al., 2019). In contrast to ELMo which uses a shallow concatenation layer (Devlin et al., 2018), BERT employs a deep concatenation layer. As a result BERT is considered a very powerful embedding architecture. We used pre-trained 'bert-large-uncased' model and represented each word as a 4096 lengthened vector.

2.2.3 Stacked Embeddings

Stacked Embeddings are obtained by concatenating different embeddings. According to Akbik et al. (2019) stacking the embeddings can provide a powerful embeddings to represent words. We represent the stacked embeddings in section 4 with '+' between the used models. As an example if the model name says ELMo + BERT, it is a stacked embedding of ELMo and BERT. For ELMo + BERT model we used pre-trained 'bert-large-uncased' model and 'original' pre-trained ELMo model to represent each word as a 4096 + 3072 vector.

2.2.4 Flair

Flair is another type of popular contextualised word embeddings introduced in Akbik et al. (2018). It takes a different approach by using a character level language model rather than the word level language model used in ELMo and BERT. The recommended way to use Flair embeddings is to stack pre-trained 'news-forward' embeddings and pre-trained 'news-backward' embeddings with Glove (Pennington et al., 2014) word embeddings (Akbik et al., 2018). We used the stacked model to represent each word as a 4196 lengthened vector.

2.3 Standard Word Representations

In order to compare the results of contextualised word embeddings, we used a standard word representation model in each experiment as a baseline. In this research we used word2vec embeddings (Mikolov et al., 2013) pre-trained on Google news corpus. We represented each word as a 300 lengthened vector using this model.

3 Experiments

This section describes the actual methods used to calculate the STS score between a pair of sentences and their variants we used. Each experiment was conducted using all three contextualised word embedding models - ELMo, BERT and Flair and one standard word representation model - word2vec (Mikolov et al., 2013).

3.1 Cosine Similarity on Average Vectors

The first unsupervised STS method that we used to estimate the semantic similarity between a pair of sentences, takes the average of the word embeddings of all words in the two sentences, and calculates the cosine similarity between the resulting embeddings. This is a common way to acquire sentence embeddings from word embeddings. Obviously, this simple baseline leaves considerable room for variation. We have investigated the effects of ignoring stopwords and computing an average weighted by tf-idf in particular and reported them in the 4 section.

3.2 Word Mover's Distance

The second baseline that we have considered is Word Mover's Distance introduced by Kusner et al. (2015). Word Mover's Distance uses the word embeddings of the words in two texts to measure the minimum distance that the words in one text need to "travel" in semantic space to reach the words in the other text as shown in Figure 1. Kusner et al. (2015) says that this is a good approach than vector averaging since this technique keeps the word vectors as it is through out the operation. We have investigated the effects of considering/ ignoring stop words before calculating the word mover's distance.

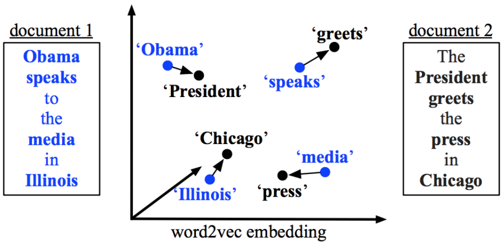

Figure 1: The Word Mover's Distance between two documents

3.3 Cosine Similarity Using Smooth Inverse Frequency

The third and the last unsupervised STS method we have considered is to acquire sentence embeddings using Smooth Inverse Frequency proposed by Arora et al. (2016) and then calculate the cosine similarity between those sentence embeddings. Semantically speaking, taking the average of the word embeddings in a sentence tends to give too much weight to words that are quite irrelevant. Smooth Inverse Frequency tries to solve this problem in two steps.

1. Weighting: Smooth Inverse Frequency takes the weighted average of the word embeddings in the sentence. Every word embedding is weighted by $\frac{a}{a+p(w)}$, where a is a parameter that is typically set to 0.001 and $p(w)$ is the estimated frequency of the word in a reference corpus.

2. Common component removal: After that, Smooth Inverse Frequency computes the principal component of the resulting embeddings for a set of sentences. It then subtracts their projections on first principal component from these sentence embeddings. This should remove variation related to frequency and syntax that is less relevant semantically.

As a result, Smooth Inverse Frequency downgrades unimportant words such as *but, just*, etc., and keeps the information that contributes most to the semantics of the sentence. After acquiring the sentence embeddings for a pair of sentences, the cosine similarity between those two vectors were taken to represent the similarity between them.

4 Evaluation on English SemEval Data

This section describes the evaluation results of English SemEval data for all the unsupervised STS methods we described above.

All the experiments were evaluated using the three evaluation metrics normally employed in the STS tasks: Pearson correlation (τ), Spearman correlation (ρ) and Mean Squared Error (MSE). Following sub-sections will discuss the results in detail.

4.1 Cosine Similarity on Average Vectors

Vector averaging results are shown in Table 4. Since we calculated the similarity as the cosine similarity between two vectors our predicted similarity lies between ∈ [0,1]. Since the GOLD standards are between ∈ [1,5] we re-scaled the predictions to be ∈ [1,5] in order to allow comparison.

Following variations were considered and reported in each sub-table.

1. All the word vectors were considered for averaging. Results are shown in table 4a.

2. All the word vectors except the vectors for stop words were considered for averaging. Table 4b shows the results.

3. All the word vectors were weighted from its tf-idf scores and considered averaging. Results are shown in table 4c

4. Stop words were removed first and remaining word vectors were weighted from its tf-idf scores and considered averaging. Table 4d shows the results.

As shown in table 4 the contextualised word vectors did not perform better than the standard word embeddings in all the variations. The only model that came close to word2vec performance was ELMo. All the contextualised word embedding models we considered have more than 3000 dimensions for the word representation which is significantly higher than the number of dimensions for the word representation we had for standard embeddings - 300. As the vector averaging model is highly dependent on the number of dimensions that a vector can have, the curse of dimensionality might be the reason for the poor performance of contextualised word embeddings.

4.2 Word Mover's Distance

The results for the Word Mover's Distance is shown in 5. Following variations were considered and reported in each sub-table.

1. Considering all the words to calculate the Word Mover's Distance. Results are shown in 5a

2. Removing stop words before calculating the Word Mover's Distance. Table 5b shows the results.

As depicted in table 5a contextualised word representations could not improve Word Mover's method too over standard word representations. Since the travelling distance is dependent on number of dimensions, the curse of dimensionality might be the reason for the poor performance of contextualised word representations in this scenario too.

Embedding	τ	ρ	MSE
Word2vec	**0.732**	**0.624**	**1.664**
ELMo	0.655	0.592	1.863
Flair	0.632	0.559	3.348

ELMo + BERT	0.619	0.565	1.299

(b) Considering all the word vectors removing stop words

Table 5: Word moving distance results for SICK training set

4.3 Cosine Similarity Using Smooth Inverse Frequency

Table 6 shows the results for the Smooth Inverse Frequency method. As shown there, all the contextualised word representations have improved the results significantly over the standard word representations. Since the first principle component is removed in the process, curse of dimensionality has not affected this method. The stacked embeddings of ELMo and BERT provided the best results to the experiment. Also, it is important to notice that the Smooth Inverse Frequency using the stacked embeddings of ELMo and BERT showed the best results from all three methods for all three evaluation metrics.

As shown in the above tables, contextualised word embeddings did not improve the results of vector averaging and word movers distance. But contextualised word embeddings showed a great improvement over standard word embeddings in Smooth Inverse Frequency STS method which also provided the best results among the considered unsupervised STS methods.

Embedding	τ	ρ	MSE
Word2vec	0.734	0.632	0.604
ELMo	0.740	0.654	0.593
Flair	0.731	0.634	0.601
BERT	0.746	0.661	0.456
ELMo + BERT	**0.753**	**0.669**	**0.446**

Table 6: Smooth Inverse Frequency results for SICK training set

4.4 Further Experiments and Results

As shown in the above section Smooth Inverse Frequency with ELMo and BERT stacked contextualised word representations provided the best result. However, since we used the cosine similarity between two vectors, the predictions of our model are constrained to follow the cosine curve and are thus not suited for these evaluation metrics. For this reason, we applied a parametric regression step to obtain better-calibrated predictions. We trained a regression model on the SICK train data and predicted on the SICK test data. This calibration step served as a minor correction for our restrictively simple similarity function. However, this regression calibration improved the Pearson correlation by 0.01 for the SICK test set.

Our unsupervised method had 0.762 Pearson correlation score, whilst the best result in the International Workshop on Semantic Evaluation 2014 Task 1 had 0.828 Pearson correlation (Marelli et al., 2014). Our approach would be ranked on the ninth position from the top results out of 18 participants, and it is the best unsupervised STS method among the results. Our method even outperformed systems that rely on additional feature generation (e.g. dependency parses) or data augmentation schemes. As an example, our method is just above the UoW system which relied on 20 linguistics features fed in to a Support Vector Machine and obtained a 0.714 Pearson correlation (Gupta et al., 2014). Compared to these complex approaches our simple approach provides a strong baseline to STS tasks.

5 Portability of the Method to Other Languages and Domains

Our approach has the advantage that it does not rely on language dependent features and it does not need a training set as the approach is unsupervised. As a result, the approach is easily portable to other languages and domains given the availability of ELMo and BERT models in that particular language or domain. In order to observe how well the method performs in other languages and domains we applied it to Spanish STS dataset and Biomedical STS dataset described in section 3.

5.1 Spanish STS

We run all the unsupervised STS methods described in section 2 on the Spanish STS dataset explained in section 2.1.2. For the ELMo embeddings we used Spanish ELMo embeddings provided in Che et al. (2018), while for the BERT embeddings we used "BERT-Base, Multilingual Cased" [1] model which has been built on the top 100 languages with the largest Wikipedias which includes Spanish language too.

The predictions from the experiment were rescaled to lie $\in$ [0,4] as the GOLD standards. Organisers have used only one evaluation metric in this Spanish STS task: Pearson correlation (τ) against the predictions and GOLD standard. They have calculated Pearson correlation for each test set: Spanish news and Spanish wiki, separately and has taken the weighted average to give the final rankings in the leader board. We took the same procedure in order to evaluate our approach with the other approaches in the task. Also we applied parametric regression step we did to English-English STS experiment to obtain better-calibrated predictions. Parametric regression step improved the Pearson correlation by 0.01 for both Wikipedia and Newswire datasets.

From the experiments, Smooth Inverse Frequency with ELMo and BERT stacked embeddings gave the best results, similar to the English STS experiments we conducted. Our approach had 0.660 Pearson correlation for Wikipedia dataset, 0.547 Pearson correlation for Newswire dataset and 0.570 weighted mean from both of them. The best performing model that participated in SemEval 2015 task 2, had 0.705 Pearson correlation for Wikipedia, 0.683 for Newswire and 0.690 weighted mean (Agirre et al., 2015). Our approach would rank fifth out of 17 team in the final results, which is the best result for an unsupervised approach. As with the English model, this one also surpasses other complex supervised models. As an example RTM-DCU-1stST.tree uses a supervised machine learning algorithm with Referential Translation Machines(Biici and Way, 2014) and our fairly simple unsupervised approach outperform them by a significant margin. Comparing the results we can safely assume that our approach works well with Spanish language STS too.

5.2 Bio-Medical STS

In order to evaluate our approach in a different domain, we experimented it on Bio-medical STS dataset explained in 2.1.3. As in the previous experiments we applied all unsupervised approaches mentioned. We used ELMo embeddings trained on a biomedical domain corpora (e.g., PubMed abstracts, PMC full-text articles) (Peters et al.,

[1] https://github.com/google-research/bert

2018) and BioBERT: BERT embeddings trained on biomedical domain corpora (Lee et al., 2019). We did not apply Parametric regression step to this dataset since there was not enough data for the training. The predictions from the experiment were re-scaled to lie $\in$ [0,4] as the GOLD standards. Organisers have used only one evaluation metric in this Bio-medical STS task: Pearson correlation (τ) against the predictions and GOLD standard.

Same as English and Spanish experiments, Smooth Inverse Frequency with ELMo and BERT stacked embeddings performed best with this dataset too. It had 0.680 Pearson correlation, whilst the best performing method had 0.836 Pearson correlation. This would rank our approach seventh out of 22 teams in the final results of the task (Sogancioglu et al., 2017). It should be also noted that it outperforms many complex methods that sometimes uses external tools too. As an example, the UBSM-Path approach is based ontology based similarity which uses METAMAP (Aronson, 2001) for extracting medical concepts from text and our simple unsupervised approach outperform them by a significant margin. UBSM-Path only has 0.651 Pearson correlation. Comparing the results we can safely assume that our approach works well in bio medical domain too.

6 Related Work

Given that a good STS metric is required for a variety of natural language processing fields, researchers have proposed a large number of such metrics. Before the shift of interest in neural networks, most of the proposed methods relied heavily on feature engineering. With the introduction of word embedding models, researchers focused more on neural representation for this task.

There are two main approaches which employ neural representation models: supervised and unsupervised. Unsupervised approaches use pre-trained word/sentence embeddings directly for the similarity task without training a neural network model on them while supervised approaches uses a machine learning model trained to predict the similarity using word embeddings. ConvNet (He et al., 2015), Skip Thought vectors (Kiros et al., 2015), Dependency Tree-LSTM (Tai et al., 2015) and Siamese Neural Networks (Mueller and Thyagarajan, 2016) can be considered as the most successful architectures employed for calculating STS. These supervised approaches always suffer from less training data problem which is common in STS tasks. As a result the researches have also considered unsupervised approaches.

The three unsupervised STS methods explored in this paper: Cosine similarity on average vectors, Word Mover's Distance and Cosine similarity using Smooth Inverse Frequency are the most common unsupervised methods explored in STS tasks. Apart from them cosine similarity of the output from Infersent (Conneau et al., 2017), sent2vec (Pagliardini et al., 2018) and doc2vec (Le and Mikolov, 2014) have been used to represent the similarity between two sentences. All these approaches relies on pre-trained sentence embeddings.

7 Conclusions

This paper experimented three unsupervised STS methods namely cosine similarity using average vectors, Word Mover's Distance and cosine similarity using Smooth Inverse Frequency with contextualised word embeddings for calculating semantic similarity between pairs of texts and compared them with other unsupervised/ supervised approaches. Contextualised word embeddings could not improve cosine similarity using average vectors and Word Mover's Distance methods, but the results when using Smooth Inverse Frequency method were improved significantly with contextualised word embeddings, instead of standard word embeddings. Further more we learned that stacking ELMo and BERT provides a strong word representation rather than individual representations of ELMo and BERT. The results indicated that calculating cosine similarity using Smooth Inverse Frequency with stacked embeddings of ELMo and BERT is the best unsupervised method from the available approaches. Also, our approach finished on the top half of the final results list surpassing many complex and supervised approaches.

Our approach was also applied in the Spanish STS and Bio-medical STS tasks, where our simple unsupervised approach finished on the top half of the final result list in both cases. Therefore, given our results we can safely assume that regardless of the language or the domain cosine similarity using Smooth Inverse Frequency with stacked embeddings of ELMo and BERT will provide a simple but strong unsupervised method for STS tasks.

Abstract

Calculating the Semantic Textual Similarity (STS) is an important research area in natural language processing which plays a significant role in many applications such as question answering, document summarisation, information retrieval and information extraction. This paper evaluates Siamese recurrent architectures, a special type of neural networks, which are used here to measure STS. Several variants of the architecture are compared with existing methods.

1 Introduction

Measuring Semantic Textual Similarity (STS) is the task of calculating the similarity between a pair of texts using both direct and indirect relationships between them (Rus et al., 2013). Originally, the work on STS largely focused on similarity between short texts such as abstracts and product descriptions (Li et al., 2006; Mihalcea et al., 2006). The introduction of the STS tasks at the International Workshops on Semantic Evaluation (SemEval) lead to an increase of the interest that the field received from the research community. The SemEval tasks also led to the development of standard datasets like the SICK corpus (Bentivogli et al., 2016) and standardised the similarity score as a numerical value between 1 and 5 (Agirre et al., 2014).

Having a good STS metric is very important in many natural language processing (NLP) applications. As an example, for certain types of question answering systems, having an accurate STS component is the key to success since the questions with similar meanings can be answered similarly (Majumder et al., 2016). STS is also important in translation memories retrieval and matching (Gupta et al., 2014b). Translation memories help translators by finding in the database they maintain previously translated sentences, which are similar to the one to be translated, and retrieving their translations. Hence, accurate STS methods are beneficial for translation memory.

Given the growing importance of having a good STS metric and as a result of the SemEval workshops, researchers have proposed numerous STS methods. Most of the early approaches were based on traditional machine learning and involved heavy feature engineering (Béchara et al., 2015). With the advances of word embeddings, and as a result of the success neural networks have achieved in other fields, most of the methods proposed in recent years rely on neural architectures (Tai et al., 2015; Shao, 2017). Neural networks are preferred over traditional machine learning models as they generally tend to perform better than traditional machine learning models. They also do not rely on linguistic features which means they can be easily applied to languages other than English. The architecture employed in this paper is a special class of neural networks called *Siamese neural networks*. These networks contain two or more identical sub-networks. The networks are identical in the sense that they have the same configuration with the same parameters and weights. In addition, parameter updating is mirrored across these sub-networks.

Siamese networks are popular among tasks that involve finding similarity or a relationship between two comparable things. They have been proven successful in tasks like signature verification (Bromley et al., 1993), face verification (Chopra et al., 2005), image similarity (Koch et al., 2015) and have been re-

Proceedings of Recent Advances in Natural Language Processing, pages 1004–1011,
Varna, Bulgaria, Sep 2–4 2019.

cently used successfully in sentence similarity (Neculoiu et al., 2016). Siamese architectures are good in these tasks because, when the inputs are of the same kind, it makes sense to use a similar model to process similar inputs. In this way the networks will have representation vectors with the same semantics, making them easier to compare pairs of sentences. Given that the weights are shared across sub networks there are fewer parameters to train, which in turn means they require less training data and less tendency to over-fit. Given the amount of human labour required to produce datasets for STS, Siamese neural networks can prove the ideal solution for the STS task.

This paper explores the performance of several architectures which use Siamese neural networks for STS. The rest of the paper is organized as follows. Section 2 briefly describes several approaches used to measure sentence similarity focusing more on Siamese neural networks. Section 3 contains information about the settings of the experiments carried out in this paper including the datasets employed here and the different architectures explored. The architectures are evaluated in Section 4. The paper finishes with conclusions.

2 Related Work

Given that a good STS metric is required for a variety of NLP fields, researchers have proposed a large number of such metrics. Before the shift of interest in neural networks, most of the proposed methods relied heavily on feature engineering. A typical example is (Gupta et al., 2014a) which employed 20 linguistic features fed into a support vector machine regressor. The top system (Zhao et al., 2014) in task 1 in SemEval 2014 has used seven types of features including text difference measures, common text similarity measures etc. (Zhao et al., 2014). Then they have fed it in to several learning algorithms like support vector machine regressor, Random Forest, Gradient boosting etc (Zhao et al., 2014). With the introduction of word embedding models, researchers focused more on neural representation for this task. Many of the leading teams in the STS task at Semeval 2017 used some kind of neural network architecture which employed word embeddings (Shao, 2017). As an example, Maharjan et al. (2017) used an ensemble of traditional machine learning models and deep learning models in their top performing system at Semeval 2017 STS task.

There are two main approaches which employ neural representation models: supervised and unsupervised. Unsupervised approaches use pretrained word/sentence embeddings directly for the similarity task without training a neural network model on them. Such approaches have used cosine similarity on sent2vec (Pagliardini et al., 2018), InferSent (Conneau et al., 2017), Doc2Vec (Le and Mikolov, 2014) and smooth inverse frequency with GloVe vectors (Arora et al., 2017).

Supervised approaches use neural networks to project word embeddings to fixed dimensional vectors which are trained to capture the semantic meaning of the sentence. Recently, many neural network architectures have been used to calculate sentence similarity. He et al. (2015) propose an elaborate convolutional network (ConvNet) variant which infers sentence similarity by integrating various differences across many convolutions at varying scales.

Kiros et al. (2015) propose the skip-thoughts model, which extends the skip-gram approach of word2vec from the word to sentence level. This model feeds each sentence into an Recurrent Neural Network (RNN) encoder-decoder with Gated Recurrent Unit (GRU) activations. They attempt to reconstruct the immediately preceding and following sentences. For the sentence similarity task, they obtain skip-thought vectors for sentence pairs. Then a separate classifier is trained using features derived from differences and products between skip-thought vectors for each pair of sentences.

Tai et al. (2015) propose Tree-LSTMs (Long short-term memory) which generalize the order-sensitive chain-structure of standard LSTMs to tree-structured network topologies. Each sentence is first converted into a parse tree using a separately trained parser, and the Tree-LSTM composes its hidden state at a given tree node from the corresponding word as well as the hidden states of all child nodes. The hope is that by reflecting syntactic properties of a sentence, the parse tree structured network can propagate necessary information more efficiently than a sequentially restricted architecture. The output from Tree-LSTM can be used for sentence similarity task as the same way as Kiros et al. (2015), where representations of the input sentences are now produced by Tree-LSTMs rather than skip-thoughts.

Our proposed model also represents sentences using neural networks whose inputs are word vectors learned separately from a large corpus. But unlike the models proposed by Kiros et al. (2015) and Tai et al. (2015) the sole target of our objective function is to calculate sentence similarity. In order to have an objective function that solely focus on similarity we need an architecture which is capable of handling two sentences parallelly. To do that we use a special kind of neural network architecture: Siamese neural network architecture.

Siamese recurrent neural networks have been recently used in STS tasks. The MALSTM architecture (Mueller and Thyagarajan, 2016) uses two identical LSTM networks trying to project zero padded word embeddings of a sentence to fixed sized 50 dimensional vectors using Manhattan distance as the similarity function between 2 sub networks. Mueller and Thyagarajan (2016) report that it performs better than other neural network models like Tree-LSTM (Tai et al., 2015). This inspired us to use this model and extend it. This research proposes new variants of the MALSTM architecture for predicting STS [1].

3 Settings of the Experiments

3.1 Data Sets

The experiments presented in this paper were carried out using the SICK dataset (Bentivogli et al., 2016) and SemEval 2017 Task 1 dataset (Cer et al., 2017) which we will refer as STS2017 dataset.

The SICK data contains 9927 sentence pairs with a 5,000/4,927 training/test split which were employed in the SemEval tasks. Each pair is annotated with a relatedness score between [1,5] corresponding to the average relatedness judged by 10 different individuals. In order to generate more training data we used thesaurus-based augmentation (Miller, 1992) and added 10,022 additional training examples. Evaluation was done with the SICK test data. Mueller and Thyagarajan (2016) uses the same thesaurus-based data augmentation in their research.

The STS2017 test datset had 250 sentence pairs annotated with a relatedness score between [1,5]. As the training data for the competition, participants were encouraged to make use of all existing data sets from prior STS evaluations including all previously released trial, training and evaluation data [2]. Once we combined all datasets from prior STS tasks we had 8277 sentence pairs for training.
