Abstract. The current status of the experimental searches for rare alpha and beta decays is reviewed. Several interesting observations of alpha and beta decays, previously unseen due to their large half-lives $(10^{15}-10^{20}~{\rm yr})$, have been achieved during the last years thanks to the improvements in the experimental techniques and to the underground locations of experiments that allows to suppress backgrounds. In particular, the list includes first observations of alpha decays of ¹⁵¹Eu, ¹⁸⁰W (both to the ground state of the daughter nuclei), ¹⁹⁰Pt (to excited state of the daughter nucleus), ²⁰⁹Bi (to the ground and excited states of the daughter nucleus). The isotope ²⁰⁹Bi has the longest known half-life of $T_{1/2} \approx 10^{19}~{\rm yr}$ relatively to alpha decay. The beta decay of ¹¹⁵In to the first excited state of ¹¹⁵Sn ($E_{exc} = 497.334~{\rm keV}$), recently observed for the first time, has the Q_{β} value of only (147 ± 10) eV, which is the lowest Q_{β} value known to-date. Searches and investigations of other rare alpha and beta decays (⁴⁸Ca, ⁵⁰V, ⁹⁶Zr, ¹¹³Cd, ¹²³Te, ^{178m2}Hf, ^{180m}Ta and others) are also discussed.

1 Introduction

From the theoretical and experimental points of view, a very interesting topic of nuclear physics is the study of nuclear instability, which played so far an important role in the foundation and development of nuclear physics. In fact, it can offer information about the nuclear structure, the nuclear levels and the properties of nuclei. In the last hundred years a lot of experimental and theoretical studies have been performed and the knowledge of the nuclear

 $^{^{}m a}$ e-mail: pierluigi.belli@roma2.infn.it

matter becomes more and more determined. In particular, the first two processes ever studied were α and β decays (actually, the generic word β decay consists of β^- , β^+ and electron capture, ε). Generally, α and β decays are also accompanied by emission of γ quanta, conversion electrons and e^+e^- pairs and/or by emission of subsequent atomic radiation, X-rays and/or Auger and Coster-Kronig electrons

More recently, other forms of radioactive decays have been considered, as:

- the cluster decays, where a nuclide decays by emitting nuclides heavier than α particle (from ¹⁴C to ³⁴Si); about 40 nuclides from ²²¹Fr to ²⁴²Cm can decay in such a way to isotopes close to ²⁰⁸Pb ("lead radioactivity") with partial half-lives in the range 10³ 10²⁰ yr [1,2]. The cluster decay was theoretically predicted in 1980 [3] and experimentally observed for the first time in 1984 [4,5].
- the 2β decay, which is a transformation of nucleus (A,Z) into (A,Z+2) with simultaneous emission of two electrons. The two-neutrino 2β decay is the rarest nuclear decay ever observed in several nuclei with the half-lives $T_{1/2}^{2\nu 2\beta^-} \approx 10^{18} 10^{24} \text{ yr } [6,7,8]$. On the contrary, the neutrinoless 2β decay is forbidden in the Standard Model of particle physics (SM) since the process violates the lepton number by two units and is possible if the neutrino is a massive Majorana particle. Typically the most sensitive experiments give only half-life limits on the decay at level of $\lim T_{1/2}^{0\nu 2\beta^-} \approx 10^{24} 10^{26} \text{ yr.}$ Investigations of the double beta plus processes, such as double electron capture (2ε) , electron capture with positron emission $(\varepsilon\beta^+)$ and double positron decay $(2\beta^+)$ are also on-going [6,9].
- the spontaneous fission occurs when a heavy nucleus fragments itself in two (or, with lower probabilities, in more than two) nuclides. It is theoretically possible for many nuclei with A>100, but it has been observed for several isotopes starting from 232 Th. The measured partial half-lives range from 10^{-3} s of 264 Hs to 10^{19} yr of 235 U.
- nucleon, di-nucleon, tri-nucleon ... emission occurs in short living isotopes in about forty isotopes with half-lives from ps to s.
- higher-order electromagnetic phenomena, accompanying β decay, shell-electron capture, and α decay, are [10,11]: i) internal bremsstrahlung; ii) ionization and excitation of the electron cloud; iii) internal e^+e^- pair production (IPP). They are much less intense than the first-order processes; for example, in the case of the internal bremsstrahlung about one photon is produced per 100 β decays. The first estimates of the contribution of the IPP process was reported in Ref. [12,13,14] and in Ref. [11] for the β and the α decays, respectively. The IPP in the α decay has been measured for ²¹⁰Po, ²³⁹Pu, and ²⁴¹Am (see Ref. [15] for a recent measurement and references therein).
- α decay corresponds to a very asymmetric spontaneous fission, where a nucleus (A,Z) transforms into (A-

4, Z-2) with the ejection of a $^4{\rm He}$ nucleus (α particle). Most nuclei with A>140 are potential $\alpha-{\rm emitters}$. The lightest $\alpha-{\rm emitter}$ is $^{105}{\rm Te}$ ($T_{1/2}=0.6~\mu{\rm s},~Q_{\alpha}=5.1~{\rm MeV})^1$. However, among the naturally occurring $\alpha-{\rm emitting}$ nuclides only those with either A>208 or $A\approx 145$ have $\alpha-{\rm half}$ -lives short enough to be detected; the lightest one is the $^{142}{\rm Ce}$ nuclide. Considering all the α unstable nuclei, the partial $\alpha-{\rm half}$ -lives range from $10^{-8}~{\rm s}$ of $^{217}{\rm Ac}$ to $10^{19}~{\rm yr}$ of $^{209}{\rm Bi}$. The α decay rate is an exponentially increasing function of Q_{α} . Thus, the α decay is preferentially to the ground state of the daughter nucleus, since decays to excited states necessarily have smaller values of Q_{α} (on the contrary, for β decay the Q_{β} dependence is weaker).

 β decay can occur in nuclei where the neutron-to-proton ratio is not optimal. In this process the parent and the daughter nuclei have the same atomic mass: an electron (positron) plus an electron anti-neutrino (neutrino) are emitted; the nucleus transforms from (A,Z) into (A,Z+1) or (A,Z-1). In first approximation the β decay rate is proportional to the fifth power of Q_{β} . The β -decay half-lives range from 10^{-3} s of e.g. 35 Na to 10^{16} yr of 113 Cd (the longest to date observed β decay).

The purpose of this paper is to review the current status of the experimental searches for rare alpha and beta decays. Several interesting observations of alpha and beta decays, previously unseen due to their large half-lives $(10^{15}-10^{20}~\rm yr)$ or/and very low branching ratios $(10^{-3}-10^{-8})$, have been achieved just during the last years thanks to the improvements in the experimental techniques and to the underground locations of the experiments that allows to suppress backgrounds.

2 The rare α decays

The interest to the more than 100 years old phenomenon of α decay [16] is still great, both from the theoretical and the experimental sides. In fact, it can offer information about both the nuclear structure and the fusion–fission reactions since the α decay process involves sub-barrier penetration of α particles through the barrier, caused by the interaction between the α and the nucleus.

The description of α decay as a process of quantum tunnelling through an energy barrier (a process not possible from the point of view of classical physics) in 1928 by Gamow [17] and Gurney and Condon [18] was a great success of the quantum mechanics. It naturally explained the exponential dependence of the probability of the α decay on the released energy Q_{α} , already known empirically since 1911 as the Geiger-Nuttall law [19]. The energy releases in naturally occurring α -decaying nuclides are in the range from 1.9 MeV (144 Nd) to 4.9 MeV (234 U), while more energetic α particles are present in chains of 232 Th, 235 U, 238 U decay (with the highest value of $Q_{\alpha}=8.954$

 $^{^1}$ There are also few light nuclei which decay with emission of α particle: $^5{\rm He},~^5{\rm Li},~^6{\rm Be},~^8{\rm Be},$ with half-lives $10^{-22}-10^{-16}$ s.

MeV for ²¹²Po in the ²³²Th chain). The released energy is shared between the α particle, E_{α} , and the daughter nuclear recoil, E_d , in good approximation as: $E_{\alpha} = Q_{\alpha} \times (A_m - 4)/A_m$, $E_d = Q_{\alpha} \times 4/A_m$ (A_m is the mass number of the mother nucleus). It means that for typical values $A_m \simeq 200$ and $Q_{\alpha} \simeq 5$ MeV, the recoiled daughter has energy $\simeq 100$ keV. Such recoils are well observed e.g. in experiments to search for dark matter with bolometers where U/Th chains are still present in tiny amounts creating background but also serving as a calibration points (see e.g. [20]).

Various theoretical models are continuously developed or improved, see e.g. [21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31] and refs. therein, in particular motivated by the searches for stable or long-lived superheavy isotopes [32,33] and the prediction of their half-lives. One can find in the list of approaches: cluster model [34], generalized density-dependent cluster model [35,36], modified two-potential approach for deformed nuclei by constructing the microscopic doublefolding potential [30], density-dependent cluster model using a two-potential approach [31], density-dependent M3Y effective interaction [37,38], generalized liquid drop model [39], unified model for α decay and α capture [40,41]. In particular, the inclusion of nuclear deformation in the α decay calculations is important since most of the α emitters have deformed shapes; this has been accounted in various way [40,42,43,44,45,46,47,48,49,50]. Recently, the effective radial potential between the axially symmetric deformed daughter nucleus and the α particle has been considered as sum of the deformed Woods–Saxon nuclear potential, of the deformed Coulomb potential, of the centrifugal potential, and also taking into account the quadrupo and the hexade-capole deformation parameters of the daugh ter nucleus [51]. The effects of the orientation and of the deformed surface diffuseness on the effective potential, transmission coefficient, and assault frequency were significant, suggesting that the inclusion of a more accurate description of the deformed surface diffuseness instead of an average form, and analysis of its effect on a wide range of α decays within different models can be interesting. On the other hand, experimentalists require the possibility of evaluating the expected half-lives during the planning and the design of an experiment, especially when α decays of super-heavy elements or of nuclei very far from the stability line are investigated; both processes are very rare and difficult to observe. Thus, simple and accurate empirical formulas are still developed and used. Presently, more accurate atomic mass values lead to a more exact definition of the Q_{α} values of the ground-state-to-ground-state α transitions; in addition, more precise definitions of the value of the angular momentum of the emitted α particle (related to factual values of the ground-state spins) lead to a more rigorous determination and description of the α decays half-lives. See Ref. [52] for a recent review on various microscopic and phenomenological models of α decay which successfully reproduce experimentally measured half-lives.

Recently the detection of naturally long-lived $\alpha-$ decaying nuclides has become a hot subject. Improvements

in the experimental sensitivity, especially related with the use of super-low-background set-ups located in underground laboratories, have led during the last decade to discovering new α decays which were not observed previously because of their extremely long half-lives or small branching ratios.

The process of α decay can be accompanied by emission of γ quanta when the decay goes to excited levels of a daughter nucleus or/and the daughter in the ground state is also unstable. Thus, a possible strategy to detect rare α decay is to look for the γ rays following the α decay. This can be accomplished by using e.g. an ultra-low background germanium detector in an underground laboratory, as the Gran Sasso National Laboratory [LNGS, 3600 m water equivalent (w.e.)] of Istituto Nazionale di Fisica Nucleare (INFN), Italy (for an ultra-pure Os sample with natural isotopic composition see for example Ref. [53]).

A collection of half-lives (or limits) on α decays of all the naturally occurring nuclides with $Q_{\alpha} > 0$ is reported in Table 1. The Table also shows the theoretical half-life values (from the ground state to the ground state, g.s. to g.s., transitions) calculated with the cluster model of Ref. [54,55] and with the semiempirical formulae [56] based on the liquid drop model and the description of the α decay as a very asymmetric fission process. The approaches [54, 55,56] were tested with a set of experimental half-lives of almost four hundred α emitters and demonstrated good agreement between calculated and experimental $T_{1/2}$ values, mainly inside a factor of 2–3. In some cases, when there is a difference between spins and parities of the parent and the daughter nuclei, and the emitted α particle has non-zero angular momentum l, one has to take into account the additional hindrance factor, calculated in accoordance with Ref. [57] (for the lowest possible l value). In addition, we also report in Table 1 the results obtained by the semiempirical formulae of Ref. [24] which also were successfully tested with about four hundred experimental α decays and which take into account non-zero l explicitly.

In the following a systematic discussion on long–living isotopes is carried out.

3 Investigations of rare α decays

A systematic discussion on long-living isotopes is given in the following.

Note that the four naturally occurring isotopes, 232 Th, 234 U, 235 U, and 238 U, are well known to experimentalists working in the low background field, because they are present at different levels in many materials. Moreover, they are the progenitors of long radioactive decay chains, which supply the bulk of the heat production in our planet [58]. Their decay parameters and their half-lives are well established (see Table 1); thus, they will not be considered in the following.

3.1 $^{209}\mathrm{Bi}\ \alpha\ \mathrm{decay}$

The attempts to detect α decay of ²⁰⁹Bi began in 1949. The used experimental technique exploited bismuth-loaded

and with $Q_{\alpha} > 0$ are considered. The α decays to excited levels of the daughter nucleus are also reported if they were observed. The nuclide with the lowest experimental $T_{1/2}$ reported in this table is ²³⁴U with the measured total half-life of $(3.44 \pm 0.01) \times 10^5$ yr. The limits, where not specified, are at 90% C.L. The ground state to the ground state transition is supposed if not stated explicitly. Table 1: Collection of partial half-lives (or limits) on α decays. Only nuclides with natural abundance (δ) greater than zero (i.e. naturally present in nature)

⁹ Partial $T_{1/2}$ for decay to g.s. from the total half-life $4.468(6) \times 10^9$ yr [70] and branching $b = 79.0 \pm 0.27\%$.

nuclear emulsions. The alpha activity of 209 Bi was not observed in the first experiment of Ref. [59], and only a lower limit on the half-life $T_{1/2} > 3 \times 10^{15}$ yr was set. Further experiments claimed detection of this decay with half-life at level of $T_{1/2} \sim 2 \times 10^{17}$ yr [60,61]. However, as shown in Fig. 1, the performances (first of all, a rather poor energy resolution) of the emulsion detection technique was rather poor at that time.

Fig. 1: Distributions of track lengths (on the X-axis) from 0 $\mu \rm m$ to 18 $\mu \rm m$ in a blank emulsion plate with area 4.2 cm² over 100 days (upper panel), and in the Bi-loaded emulsion with area 4.5 cm² over 100 days (lower panel). On the Y-axis is given the number of tracks per interval of track lengths 1 $\mu \rm m$. There is a peculiarity in the data accumulated with the Bi-loaded emulsion which was interpreted by authors at that time as α decay of ²⁰⁹Bi with a half-life $T_{1/2}=2\times 10^{17}$ yr. Figure taken from Ref. [61].

This interpretation was not confirmed by other investigations where half-life limits at the level of $T_{1/2} > 2 \times 10^{18}$ yr [85] and $T_{1/2} > 10^{19}$ yr [86] were set. The alpha decay to the first $3/2^+$ excited level of the daughter 205 Tl ($E_{exc} = 203.7$ keV) was searched by using a low-background highpurity germanium (HPGe) γ spectrometry [87]; however, the experimental sensitivity, $T_{1/2} > 3 \times 10^{19}$ yr, was not enough to detect the process.

The α decay of ²⁰⁹Bi was detected for the first time in 2003 using Bi₄Ge₃O₁₂ (BGO) low temperature scintillating bolometers [88]. The principle of the low temperature scintillating bolometer operation is schematically shown in Fig. 2.

Two crystals with mass 45.7 g and 91.2 g cooled down to 20 mK were utilized in the experiment carried out in a surface laboratory. The α particles were separated from the events induced by cosmic rays thanks to the high quenching of the scintillation signal for α particles (we refer reader to work [89] where quenching in scintillation detectors is reviewed). Fig. 3 shows the scatter plots of light-versus-heat signals measured during a $^{241}\mathrm{Am}$ calibration run. The energy release of $[3137\pm1(\mathrm{stat})\pm2(\mathrm{syst})]$ keV was measured that is in agreement with the Q_{α} of

Fig. 2: Simplified scheme of the low temperature scintillating bolometer. The scintillating bolometer (BGO crystal, light-grey box) and the optical bolometer (germanium disk, bold-grey bar) face each other in an Ag-coated light-reflecting copper cavity cooled to milli-Kelvin temperature. Heat sensors made from neutron transmuted doped germanium (NTD-Ge, small grey boxes in contact with the bolometers) convert the temperature rise in the BGO crystal and germanium disk into voltage signals. Figure taken from Ref. [88].

 $^{209} \rm Bi:$ 3137.3(0.8) keV [63]. The half-life of $^{209} \rm Bi$ was determined as $T_{1/2}=(1.9\pm0.2)\times10^{19}$ yr.

The observation was confirmed using a much more massive 889-g BGO scintillating bolometer operated at the LNGS underground laboratory [84]. The experiment not only measured the half-life to the ground state transition with higher accuracy $T_{1/2}=(2.04\pm0.08)\times10^{19}$ yr, but also observed the α decay of 209 Bi to the first excited level of 205 Tl with a half-life $T_{1/2}=(1.4\pm0.2)\times10^{21}$ yr. The pure α + recoil and α + recoil + γ (conversion electron) events were clearly separated in the light channel of the detector thanks to the large enough energy of the γ rays and conversion electrons emitted in the de-excitation of the 204 keV level, and comparatively high energy resolution in the light channel (see Fig. 4).

The experiments where α decay of 209 Bi was searched

The experiments where α decay of ²⁰⁹Bi was searched for (observed) are summarized in Table 2. It should be stressed that ²⁰⁹Bi has 100% isotopic abundance [62], which facilitates the success of the experiments.

3.2 The α decay of 190 Pt and other platinum isotopes

The $^{190}{\rm Pt}^{-186}{\rm Os}$ system is an interesting tool to investigate the chronology and evolution of geo- and cosmochemistry samples (see e.g. Refs. [90,91]). All the six naturally occurring isotopes of platinum are potentially unstable in relation to α decay (see Table 1). However, only for one of them, the $^{190}{\rm Pt}$ (with the largest energy release: $Q_{\alpha}=3268.6(6)~{\rm keV}),$ this process was experimentally observed to-date, with the first successful measurement in 1921 [92]. The natural abundance of $^{190}{\rm Pt}$ is very low: $\delta=(0.012\pm0.002)\%$ [62]. This aspect and the rather high cost of platinum, probably explains the lack of experimental results.

Fig. 3: Scatter plot of light-versus-heat signals measured with a 91-g BGO scintillating bolometer during a 241 Am calibration run over 114 h. The α events (black dots) are separated from β and γ events (gray dots) thanks to a much lower scintillation light yield of the BGO scintillator to α particles. The insets show energy spectra of the 241 Am calibration source and the energy region where the peak of 209 Bi is observed. Figure taken from Ref. [88].

Fig. 4: (Color online) Scatter plot of light-versus-heat signals measured with a 889-g BGO scintillating bolometer over 374.6 h. The population of events in the right lower corner (blue dots) is due to detection of α particles plus recoils after the α decay of ²⁰⁹Bi to the ground state of the daughter nuclei. The events above the main population (red dots) are due to the mixed α + recoil + γ (conversion electron) events corresponding to the α decay of ²⁰⁹Bi to the first 3/2⁺ 204 keV excited level of ²⁰⁵Tl. Figure taken from Ref. [84].

$3.2.1^{190} \mathrm{Pt} \ \alpha \ \mathrm{decay}$

In Ref. [92] and in subsequent works the half-life of 190 Pt was determined to be in the range of $(3.2-10) \times 10^{11}$ yr for the decay to the ground state of 186 Os (see review [93] and Refs. therein); the recommended half-life value for

this transition was: $T_{1/2}^{\alpha}=(6.5\pm0.3)\times10^{11}$ yr [94], but recently a laboratory measurement of the α decay half-life of ¹⁹⁰Pt has been performed using a low background Frisch grid ionization chamber. The resulting half-life is (4.97 \pm 0.16) $\times10^{11}$ yr, with a total uncertainty of 3.2% [80].

Table 2: Limits and half-lives from experiments on the α decay of ²⁰⁹Bi. The abbreviation "LT" denotes low temperature.

Level of	$T_{1/2} (yr)$	Experimental technique	Reference (year)
daughter nucleus			
g.s. $1/2^+$	$> 3 \times 10^{15}$	Bi-loaded nuclear emulsion	[59] (1949)
g.s. $1/2^+$	$=2.7\times10^{17}$	Bi-loaded nuclear emulsion	[60] (1951)
g.s. $1/2^+$	$=2 \times 10^{17}$	Bi-loaded nuclear emulsion	[61] (1952)
g.s. $1/2^+$	$> 2 \times 10^{18}$	Bi-loaded nuclear emulsion	[85] (1958)
g.s. $1/2^+$	$> 10^{19}$	Bi-loaded nuclear emulsion	[86] (1972)
g.s. $1/2^+$	$= (1.9 \pm 0.2) \times 10^{19}$	Bi ₄ Ge ₃ O ₁₂ LT scintillating bolometers	[88] (2003)
g.s. $1/2^+$	$= (2.04 \pm 0.08) \times 10^{19}$	Bi ₄ Ge ₃ O ₁₂ LT scintillating bolometer	[84] (2012)
$203.7 \text{ keV } 3/2^+$	$> 3 \times 10^{19}$	HPGe γ spectrometry	[87] (2000)
$203.7 \text{ keV } 3/2^+$	$= (1.4 \pm 0.2) \times 10^{21}$	Bi ₄ Ge ₃ O ₁₂ LT scintillating bolometer	[84] (2012)

This result is in good agreement with the half-life obtained using the geological comparison method of (4.78 \pm 0.05) $\times 10^{11}$ yr. In such methods the Pt–Os system is considered and the isotopic abundances are measured inside either ores or meteorites of known age (calibrated by different techniques, mainly by $^{238}{\rm U}$); thus, the standard method of the radiometric dating allows the evaluation of the half-life of the $^{190}{\rm Pt}$ parent.

In Fig. 5 the ¹⁹⁰Pt half-life measurements as a function of time are shown. In general the most recent direct counting method results do not agree well with each other, whereas the most recent half-lives determined using the geological comparison method are consistent with each other. The source of the discrepancy is still unclear and further direct counting measurements could be very useful for the interpretation of the results.

Fig. 5: (Color online) ¹⁹⁰Pt half-life measurements as a function of time. For the interpretation of the references to colour in this figure legend see Ref. [80]. Direct counting method (blue circle), geological comparison method (green cross), semiempirical calculation model (teal square) and the result from Ref. [80] (red cross) are shown. Figure taken from Ref. [80].

The $^{190}{\rm Pt}$ α decay was observed only to the g.s. of $^{186}{\rm Os}$ and to the first excited state. In fact, the first excited level of the daughter nuclide $^{186}{\rm Os}$ $(J^{\pi}=2^+)$ has

a quite low energy: $E_{exc}=137.2$ keV [95], and the energy available to the α particle in the decay to this level: $Q_{\alpha}^{*}=3131.4(6)$ keV, is not much lower than that in the g.s. to g.s. transition. Theoretical estimates of the corresponding half-life [81] gave values in the range of $T_{1/2}^{\alpha}=10^{13}-10^{14}$ yr. This $^{190}{\rm Pt}\to^{186}{\rm Os}(2_{1}^{+})$ decay was in fact discovered through the observation of the 137.2 keV γ quantum emitted in the deexcitation of the $^{186}{\rm Os}^{*}$ nucleus with a well shielded ultra-low background HPGe detector even using a Pt sample of 42.5 g with natural isotopic composition [81]; the measurements were performed at the LNGS.

In addition to the 190 Pt decay, the γ quanta can be emitted in the α decays of other Pt isotopes: (1) when excited levels of the daughter Os nuclei are populated; (2) when the daughter Os isotopes are unstable and further decay with emission of some γ quanta, as in the case of 195 Pt and 198 Pt; in Ref. [81] the $T_{1/2}$ limits for these latter decays were determined for the first time.

Part of the spectrum accumulated with the Pt sample in comparison with the background in the energy range of $100-700~{\rm keV}$ is shown in Fig. 6.

The 137.1 keV peak can be explained with the α decay of $^{190}\mathrm{Pt}$ to the first excited level of $^{186}\mathrm{Os}$, whose excitation energy is (137.159 \pm 0.008) keV [94]. If populated, this level deexcites with the emission of a γ quantum. Using the area of the 137 keV peak, the corresponding partial half-life for the transition to the first excited level of $^{186}\mathrm{Os}$ can be calculated as:

$$T_{1/2}(^{190}\text{Pt} \to ^{186}\text{Os}(2_1^+, 137.2 \text{ keV})) = \frac{\ln 2 \cdot N_{190} \cdot \varepsilon \cdot t}{S \cdot (1+\alpha)},$$
(1)

where $N_{190}=1.84\times 10^{19}$ is the number of the ¹⁹⁰Pt nuclei in the Pt sample, ε is the efficiency to detect the full energy γ ray with the HPGe detector (3.0%), t=1815.4 h is the measurement time, $S=(132\pm 17)$ counts is the area of the peak and α is the coefficient of conversion of γ quanta to electrons for the given nuclear transition.

The full peak efficiency at 137 keV was calculated with the EGS4 [96] and, for crosscheck, also with GEANT4 [97] simulation packages. It was validated through a volumi-

Fig. 6: (Color online) Energy spectrum of the Pt sample with mass of 42.5 g measured for 1815 h in the (100 – 700) keV energy interval (upper part), and in more detail around the 137 keV region (lower part). The background spectrum (measured for 1046 h but normalized here to 1815 h) is also shown (filled histogram). Peak at 137 keV after α decay of $^{190}{\rm Pt} \rightarrow ^{186}{\rm Os}(2^+_1)$ is clearly visible in the Pt spectrum being absent in the background [81]. Figure taken from Ref. [81].

nous $(7.0 \times 1.1 \text{ cm})$ water source with several radioactive isotopes dissolved, among them ^{57}Co with gamma quanta of 136.5 keV. The disagreement between the experimental and the calculated efficiencies was 6% (0%) with EGS4 (GEANT4). However, because of a more complicated geometry of the Pt sample in comparison with the simple cylindrical shape of the water source, the systematic uncertainty in the efficiency was conservatively estimated as 20%.

Summing all the systematic uncertainties in squares, the following value for the half-life of α decay ¹⁹⁰Pt \rightarrow ¹⁸⁶Os(2⁺₁) was obtained [81]:

$$T_{1/2}(^{190}\text{Pt} \to ^{186}\text{Os}(2_1^+, 137.2 \text{ keV})) =$$
 (2)

$$2.6^{+0.4}_{-0.3}(\mathrm{stat.}) \pm 0.6(\mathrm{syst.}) \times 10^{14} \mathrm{\ yr.}$$

This value reported in Ref. [81] was calculated using the old value of the natural abundance of $^{190}\mathrm{Pt}$ equal to 0.014%, from the previous recommendations [98]. Thus, using the new recommended value of 0.012% [62], the recalculated half-life is: $T_{1/2}=(2.2\pm0.6)\times10^{14}$ (see Table 1).

It should be noted that $^{192}{\rm Ir},$ present in the Pt sample, emits also γ rays with energy of 136.3 keV, however, with very low yield: I=0.183% [95]. Taking into account that the area of the most intensive (I=82.80%) peak of $^{192}{\rm Ir}$ at 316.5 keV is (619 \pm 32) counts (and considering

also the different efficiencies of 2.3% at 137 keV^2 and 5.5%at 316 keV), contribution of ¹⁹²Ir to the 137 keV peak is 0.6 counts; this does not change the $T_{1/2}$ value presented in Eq. (2). Gamma rays with energies close to 137 keV are emitted in some other nuclear processes (see e.g. [99]), and this could give an alternative explanation of the peak observed in the Pt experimental spectrum; however, usually additional γ rays are also emitted in such decays, and their absence allows us to exclude these effects. For example, 181 Hf $(T_{1/2} = 42.4 \text{ d } [95])$, which could be created in result of cosmogenic activation of Pt, emits 136.3 keV (I = 5.85%) and 136.9 keV (I = 0.86%) γ quanta but also 133.0 keV γ quanta should be emitted with much higher yield of I = 43.3% which, however, are absent in the experimental data. Other example could be the 136.6 keV (I = 0.012%) γ rays from ²³⁵U but peak at 143.8 keV (I = 10.96%) is absent. The contributions from the nuclides of the U/Th natural radioactive chains: ²¹⁴Pb $(E_{\gamma} = 137.5 \text{ keV}, I < 0.006\%)$ and ²²⁸Ac $(E_{\gamma} = 137.9 \text{ keV})$ keV, I = 0.024%) are calculated to be negligible using the

data on U/Th pollution in the Pt sample. The $^{181}\mathrm{W}$ $(T_{1/2}=121.2~\mathrm{d}),$ other possible cosmogenic contamination of Pt, cannot be estimated in the above-described way because its 136.3 keV γ rays are the most intensive with yield of I=0.0311%. The $^{181}\mathrm{W}$ induced activity in Pt was calculated with the COSMO code [100]; the result was 1.5 decays per day per kg of $^{nat}\mathrm{Pt}.$ Taking into account the time of measurements (75.6 d), the small mass of the used Pt sample (42.5 g) and the low yield of these γ rays, the contribution from $^{181}\mathrm{W}$ to the 137 keV peak is estimated also to be negligible (5 \times 10 $^{-5}$ counts).

In conclusion, analysing other possible sources of the 137 keV peak, no real alternative that could mimic α decay $^{190}\mathrm{Pt} \to ^{186}\mathrm{Os}(2^+_1)$ was found. The old scheme of the $^{190}\mathrm{Pt}$ α decay [94,95] and the updated scheme which follows the observation of the $^{190}\mathrm{Pt} \to ^{186}\mathrm{Os}(2^+_1)$ transition is presented in Fig. 7.

In the process of $^{190}{\rm Pt}$ α decay other excited levels of $^{186}{\rm Os}$ could be populated too. Because the probability of α decay exponentially decreases with the decrease of the energy, we consider here only the possible transition to the next excited level of $^{186}{\rm Os}$ $(J^\pi=4^+)$ with $E_{exc}=434.1$ keV. If this level is populated, two γ quanta are emitted in its deexcitation with energies of $E_{\gamma 1}=296.9$ keV and $E_{\gamma 2}=137.2$ keV. Both peaks were present in the energy spectrum of Ref. [81]. While the 137 keV peak can be explained by the $^{190}{\rm Pt} \rightarrow ^{186}{\rm Os}(2^+_1)$ α decay, the 296 keV peak is related with $^{192}{\rm Ir}$.

The contribution to the 296 keV peak from 192 Ir can be estimated using its nearby peak at 316.5 keV. Taking into account that the area of the 316 keV peak is (619 ± 32) counts, the yields $I_{316}=82.80\%$ and $I_{296}=28.67\%$ [95], one could expect (193 ± 10) counts from 192 Ir. At the same time, in the real Pt spectrum area of the 296 keV peak is $S=200\pm23$ counts. The difference between these two values (7 ± 25) counts is consistent with 0 and, in accor-

 $^{^2}$ The efficiency for the 137 keV peak of $^{192}\mathrm{Ir}$ is lower than that for the single 137 keV γ quantum because of summing effects for $^{192}\mathrm{Ir}$ γ quanta emitted in cascade.

Fig. 7: Old (a) and new (b) schemes of the α decay of ¹⁹⁰Pt. The energies of the levels and the deexcitation γ quantum are given in keV [94,95]. Figure taken from Ref. [81].

dance with the Feldman-Cousins procedure [101], results in the limit: S < 48 counts at 90% C.L. To be conservative, when deriving the $T_{1/2}$ limits for the Pt α decays, the used values for efficiencies were obtained with the code giving systematically lower efficiency. Substituting in Eq. (1) the value of the electron conversion coefficient $\alpha = 0.095$ [94] and the efficiency $\varepsilon = 7.1\%$ for the 296 keV γ quanta, the following half-life limit was obtained [81]:

$$T_{1/2}(^{190}\text{Pt} \to ^{186}\text{Os}(4_1^+, 434.1 \text{ keV})) >$$

> $3.6 \times 10^{15} \text{ yr at } 90\% \text{ C.L.}$

3.2.2 $T_{1/2}$ limits on α decays of other Pt isotopes

The data collected in Ref. [81] also allowed the search for the α decays of other Pt isotopes related with the emission of γ quanta. Here only transitions to the lowest excited levels of the daughter Os isotopes are considered as the most probable. In the case of ¹⁹⁵Pt and ¹⁹⁸Pt, the daughter Os nuclei are unstable, and the search for γ quanta related with their decays gives the possibility to look for the g.s. to g.s. transitions of Pt to Os. In general, no such decays were seen, and only limits on the corresponding half-lives were determined.

Following the procedure described above, limits on α decays of other primordial platinum isotopes were obtained by the analysis of the energy spectra in the regions of interest. A summary of all the obtained results is given in Table 3.

The theoretical estimations for the half-lives of the α decay of the Pt isotopes are reported in the last column of Table 3. The approaches [54,55,56,24] have already been mentioned above. The ground state of all Pt isotopes has spin and parity $J^{\pi}=0^+$, with the exception of ¹⁹⁵Pt with $J^{\pi}=1/2^-$. We consider here the transitions to the daughter levels with $J^{\pi}=2^+$ and 4^+ (9/2⁻ for ¹⁹⁵Pt \rightarrow ¹⁹¹Os g.s.). Because of the difference between the spins of the initial and of the final nuclear states, the emitted α particle will have non-zero angular momentum: values of l=2 or l=4 are the most preferable among the allowed ones by the selection rules for the transitions with $\Delta J^{\Delta\pi}=2^+$

or 4^+ , respectively. Thus, in the $T_{1/2}$ estimation with [54, 55], we take into account the hindrance factors of HF = 1.9 for l=2 and HF = 9.0 for l=4, calculated in accordance with Ref. [57]. The results of the calculations are given in Table 3. For the α decay ¹⁹⁰Pt \rightarrow ¹⁸⁶Os(2⁺, 137.2 keV) we also report the results of Ref. [102] with $T_{1/2}=1.6\times10^{13}$ yr and of Ref. [103] with $T_{1/2}=2.6\times10^{13}$ yr.

From the theoretical results, it is clear that the observation of other Pt α decays presented in Table 3 is out of reach of current experimental possibilities, probably with the exception of the 190 Pt \rightarrow 186 Os(4⁺, 434.1 keV) decay. The latter will need 3 orders of magnitude higher sensitivity which, however, could be possible by using enriched 190 Pt instead of natural Pt with $\delta(^{190}$ Pt) = 0.012%.

3.3 The α decay of osmium isotopes

All the seven naturally occurring Os isotopes are potentially unstable in relation to α decay (see Table 1 for energy releases and abundances). However, only for two of them (with the highest Q_{α} values) the process was experimentally observed or indication of its existence obtained.

For 184 Os, only limits were known previously: $T_{1/2} > 2.0 \times 10^{13}$ yr [75,104] obtained with nuclear emulsions, and $T_{1/2} > 5.6 \times 10^{13}$ yr [105] with proportional counter measurements of Os sample enriched in 184 Os to 2.25%. However, recently an indication on α decay of 184 Os was found in geochemical measurements [78] where an excess of the daughter 180 W was measured in meteorites and terrestrial rocks; the half-life was determined to be $T_{1/2} = (1.12 \pm 0.23) \times 10^{13}$ yr. This experimental value is in good agreement with theoretical calculations: $T_{1/2} = 2.6 \times 10^{13}$ yr [106] and $T_{1/2} = 1.3 \times 10^{13}$ yr [107] (see also Table 1).

yr [106] and $T_{1/2}=1.3\times 10^{13}$ yr [107] (see also Table 1). The decay of ¹⁸⁶Os with $T_{1/2}=(2.0\pm 1.1)\times 10^{15}$ yr was observed in a direct experiment with a semiconductor detector and an Os sample enriched in ¹⁸⁶Os at 61.27% [79]. Theoretical estimations, e.g. the recent ones $T_{1/2}=2.7\times 10^{15}$ yr [108] and $T_{1/2}=(2.8-3.5)\times 10^{15}$ yr [109], are in good agreement with this experimental value (see also Table 1).

Table 3: Summary of $T_{1/2}$ results on Pt α decays. The limits are at 90% C.L. Theoretical half-lives are calculated in accordance with the prescriptions of [54,55] and [56] taking into account additional hindrance factors. For ¹⁹⁵Pt and ¹⁹⁸Pt (and for ¹⁹²Pt all states), the experimental $T_{1/2}$ limits are valid for the α decays to all the states of the daughter Os nuclei while the theoretical estimations are given for the g.s. to g.s. transitions.

^a The value of Ref. [81] has been re-calculated using the new recommended value of the natural abundance of ¹⁹⁰Pt 0.012% [62], instead of 0.014% used at that time.

The process of α decay can be accompanied by the emission of γ quanta when the decay goes to excited levels of a daughter nucleus (see Table 4) or/and the daughter in the ground state is also unstable (as in case of $^{189}\mathrm{Os}$ and $^{192}\mathrm{Os}$ here). Thus, a possible strategy to detect such rare α decays is to look for the γ rays following the α decay. An ultra-pure Os sample with natural isotopic composition is currently under measurements at LNGS underground laboratory with a low-background Broad Energy germanium (BEGe) detector [53]. This scheme was already used to search for double beta processes in $^{184}\mathrm{Os}$ and $^{192}\mathrm{Os}$ nuclides [110].

3.4 ¹⁸⁰W and other W nuclides

The alpha decay is energetically allowed for all the five natural isotopes of tungsten (see Table 1 where characteristics of the isotopes are given). The α activity of tungsten with half-life $T_{1/2}=2.2\times\delta\times10^{17}$ yr (where δ is the isotopic abundance of isotope) was postulated in an early experiment by using the nuclear emulsion technique [111, 75]. The authors considered two possible explanations of the detected tracks with an energy of ~ 3 MeV: 1) the activity should be attributed to a rare, and as yet undiscovered, tungsten isotope (the assumption, however, was

called into question in [75]); 2) the activity is due to the alpha decay of 180 W. Because the comparatively high Q_{α} value for ¹⁸⁰W, the result of Refs. [111,75] could be attributed to α decay of $^{180}\mathrm{W}$ with a half-life 2.6×10^{14} yr [112]. However, the observation in Refs. [111,75] was not supported by the work [113], in which a cadmium tungstate (CdWO₄) crystal scintillator (mass of 20.9 g) was simultaneously used as α source and as detector of the α decay events. After 193 h of measurements the limit: $T_{1/2} > 1.0 \times 10^{15}$ yr, was established. A similar restriction $(T_{1/2} > 9.0 \times 10^{14} \text{ yr})$ was also obtained in the experiment over 66.7 h with a ionization counter (1200 cm² area) and a thin (83 mg/cm²) sample of W (79 mg total mass) enriched in 180 W at 6.95% [73]. These bounds were improved in the measurements with two scintillators: CdWO₄ (mass of 452 g, running time of 433 h), and ¹¹⁶CdWO₄ enriched in ¹¹⁶Cd to 83% (91.5 g, 951 h) [114].

In 2003, the α decay of $^{180}\mathrm{W}$ was detected for the first time [112] in the Solotvina 2β experiment using $^{116}\mathrm{CdWO_4}$ scintillator enriched in the isotope $^{116}\mathrm{Cd}$; the half-life $T_{1/2}=(1.1^{+0.9}_{-0.5})\times 10^{18}$ yr was measured. Because of quenching of the light yield for α particles in scintillators [89], the peak is shifted to lower energies in γ energy scale. The discrimination of the events caused by α particles from those from β/γ 's (thanks to the different shapes of their light

Table 4: Naturally occurring Os isotopes (with J^{π} value for the ground state), their abundances δ [62], the expected energy release Q_{α} [63], and the states of W daughters which could be populated in the α decays accompanied by γ quanta emission.

signals) allowed to extract the α energy spectrum from all the accumulated events. The simultaneous coincidence of three conditions: (1) the peak is observed at the expected energy in γ scale, (2) it is associated with α events, (3) the deduced half-life is in agreement with theoretical calculations, allowed to conclude that the peak is related with $^{180}\mathrm{W}$ α decay and not with other phenomena. The α peak of $^{180}\mathrm{W}$ detected in the experiment is shown in Fig. 8.

The observation of $^{180}\mathrm{W}$ decay was confirmed with low temperature CaWO₄ scintillating bolometers $(T_{1/2}=(1.8\pm0.2)\times10^{18}~\mathrm{yr}$ [77] and $T_{1/2}=(1.59\pm0.05)\times10^{18}~\mathrm{yr}$ [76]). Fig. 9 shows some advantages of the cryogenic scintillating bolometers technique (high energy resolution and efficient particle discrimination). The decay was further observed in the low background measurements with conventional scintillation detectors: CaWO₄ $(T_{1/2}=$

Fig. 8: (Color online) Part of the α spectrum measured with the $^{116}{\rm CdWO_4}$ detector over 2975 h together with the fitting curve (solid line).  $(1.0^{+0.7}_{-0.3})\times10^{18}~\rm{yr}$ [115]) and ZnWO₄ $(T_{1/2}=(1.3^{+0.6}_{-0.5})\times10^{18}~\rm{yr}$ [116]).

Fig. 9: Part of the α spectrum measured with the CaWO₄ low temperature scintillating bolometer in the experiment of Ref. [77]. The α peak of ¹⁸⁰W is visible in the data thanks to the particle discrimination and the energy resolution of the used technique. Figure taken from Ref. [77].

The most stringent limits for the g.s. to g.s. α decays of other W isotopes were set at level of $T_{1/2} > 10^{21} - 10^{22}$ yr by using CaWO₄-based low temperature scintillating bolometers [77], while for the decay of ¹⁸³W to the excited level of ¹⁷⁹Hf ($E_{exc}=375~{\rm keV}$) the strongest limit $T_{1/2} > 6.7 \times 10^{20}$ yr was obtained in Ref. [117] by using a conventional room temperature ZnWO₄ scintillation detector.

The results on α decay of natural tungsten isotopes are summarized in Table 5, while the theoretical predictions are reported in Table 1.

The α decay of ¹⁸⁰W to the first 2⁺ 88.3 keV excited level of ¹⁷⁶Hf is not observed yet. The detection of the decay could be realized by specific high resolu-

tion scintillators or by scintillation bolometric technique with tungstate crystal scintillators. The discrimination of α + recoils (decay to the ground state) and α + recoils + γ (conversion electrons) (decay to the excited level) events would be a challenge for such a kind of experiments because of the small energy of the excited level, and the typically rather poor energy resolution in the light channel of scintillating bolometers. In fact, possible detectors for such experiments are CaWO₄, ZnWO₄, CdWO₄; in particular, ZnWO₄ and CdWO₄ scintillators have the advantage of very high level of radio-purity [118]; but they have only modest energy resolution for alpha particles because of the anisotropy of their scintillation response [112,119] which is a disadvantage for an accurate particle discrimination. The CaWO₄ scintillator, despite typically with higher radioactive contamination [118], might provide the best energy resolution of all tungstate scintillators for α particles [115].

3.5 178m2 Hf lpha decay

The nuclear isomer $^{178m2}\mathrm{Hf}$ is an excited state of $^{178}\mathrm{Hf}$ with unique combination of high excitation energy (E_{exc} = 2446.09(8) keV) and long half-life $(T_{1/2} = 31(1) \text{ yr})$ [120]. The latter is related with the high spin, $J^{\pi} = 16^+$, and high projection of the total angular momentum on the symmetry axis, K = 16 of the isomer (for the ground state $J^{\pi} = 0^+$, K = 0). The de-excitation of the ¹⁷⁸m²Hf usually occurs through isomeric transitions to $^{178}\mathrm{Hf}$ states with lower energies, lower spins and K=8, K=0 values. However, its decay is energetically possible also through α decay to ¹⁷⁴Yb (difference in energies between ¹⁷⁸m²Hf and the ground state of ¹⁷⁴Yb is: $Q_{\alpha} = 4530 \text{ keV}$), β^{-} decay to ¹⁷⁸Ta ($Q_{\beta^{-}} = 606 \text{ keV}$), electron capture to ¹⁷⁸Lu $(Q_{\varepsilon} = 349 \text{ keV})$ and spontaneous fission $Q_{SF} \simeq 100 \text{ MeV})$ [63]. In 1980, only limits for these possible decays were established [121]: $T_{1/2}(\alpha) > 6 \times 10^8$ yr (branching ratio: $b.r. < 5 \times 10^{-8}$), $T_{1/2}(\beta^{-}) > 1 \times 10^{4} \text{ yr } (b.r. < 3 \times 10^{-3})$, $T_{1/2}(\varepsilon) > 3 \times 10^3 \text{ yr} (b.r. < 1 \times 10^{-2}), T_{1/2}(\text{SF}) > 1 \times 10^9 \text{ yr}$ $(b.r. < 3 \times 10^{-8}).$

In the work of 2007 [122], a thin source with a number of 178m2 Hf nuclei equal to 2.8×10^{13} was inserted between two solid-state track detectors CR-39. In the measurement of about 1 year duration, 307 excess α counts (in comparison with background measurements) were observed and the half-life was deduced as: $T_{1/2}(\alpha) = (2.5 \pm 0.5) \times 10^{10}$ yr. Despite the largest energy release, the decay goes not directly to the ground state of 174 Yb because of the suppression due to the large spin variation $(16^+ \rightarrow 0^+)$, but to few excited 174 Yb levels; as the theoretical estimations show, the most probable transition is to the 6^+ excited level at $E_{exc} = 526$ keV [122].

It is interesting to note that the high excitation energy and the long half-life of 178m2 Hf lead to the hope of creating a γ ray laser (graser) and even to the creation of non-conventional nuclear weapon (the so-called "isomeric bomb" with 1.33 GJ stored in 1 g of pure 178m2 Hf, which is equivalent to 315 kg of trinitrotoluene) [123,124]. It was

supposed that the energy release can be triggered by external flux of particles as γ rays and neutrons.

In 1999, Collins et al. reported evidence for accelerated decay of 178m2 Hf irradiated by X rays with an end point at $\simeq 90~{\rm keV}$ [125]. In this and subsequent experiments, the Collins' group observed an increase of the intensities of different γ peaks emitted in the 178m2 Hf decay by $\simeq 2-6\%$; the effect was seen for the 213, 217, 426, 495 keV γ peaks, and also new peaks at 130 and 2457 keV of unknown origin were detected. However, (1) in different measurements different peaks were enhanced, (2) other groups did not observe the effect, (3) the experimental results of Collins et al. contradicted the theoretical estimations by orders of magnitude (see reviews [124,126,127] and one of the last works [128] and Refs. therein).

It should be noted, however, that the theoretical analyses concerned the isomeric transition in the decay of 178m2 Hf, while it would be useful to analyse also the possible enhancement of both the other two decays: $^{178\hat{m}^2}\mathrm{Hf}$ β^- decay and electron capture. In one of their experiments Collins et al. observed (at 6.5σ level) a new γ peak at 2457.20(22) keV. A ^{178m2}Hf sample was irradiated at the SPring-8 synchrotron radiation source by monochromatic X rays with energy range 9.555 - 9.575 keV [129]. The sum of the energies of ^{178m2}Hf and X rays: 2446.09(8) +9.575 = 2455.67(8) keV, is lower than the energy of the new line by 1.54(23) keV (that was outside of calibration uncertainty) and its appearance cannot be explained by X ray capture. It is interesting to note that 174Yb, daughter nuclide in the $^{178m^2}$ Hf α decay, has an excited level at 2457(3) keV with spin (14^+) [130] with the central value coinciding with the energy of the new line. This coincidence is very curious, however, even if supposing that the 2457 keV level of ¹⁷⁴Yb was populated in enhanced $^{178m2}\mathrm{Hf}~\alpha$ decay, it is impossible to suggest a mechanism of direct deexcitation of the 2457 keV level to the ground state of 174 Yb.

3.6 151 Eu α decay

Both $^{151}\mathrm{Eu}$ (natural abundance 47.81(6)% [62]) and $^{153}\mathrm{Eu}$ (52.19(6)%) have positive energy release to α decay, Q_α : 1964.5(11) keV and 272.1(20) keV, respectively [63]; thus, they are potentially α radioactive. The low Q_α of the $^{153}\mathrm{Eu}$ α decay implies a very long expected half-life far from the current experimental sensitivity, while the estimated half-life for the $^{151}\mathrm{Eu}$ has been explorable in recent years. It was measured for the first time in 2007 [131] with a $\mathrm{CaF}_2(\mathrm{Eu})$ scintillator $(T_{1/2}=(5^{+11}_{-3})\times 10^{18}~\mathrm{yr})$ and recently measured more precisely with a $\mathrm{Li}_6\mathrm{Eu}(\mathrm{BO}_3)_3$ low-temperature scintillating bolometer as $T_{1/2}=(4.6\pm1.2)\times 10^{18}~\mathrm{yr}$ [71].

The first evidence [131] was obtained with a low background europium-doped calcium fluoride, CaF₂(Eu), scintillator (370 g mass) optically coupled through 10 cm long TETRASIL-B light guide to low background PMT; both the scintillation crystal and the light guide were wrapped by PTFE tape. This detector was installed deep underground at LNGS in the low-background DAMA/R&D

set-up, where an event-by-event data acquisition system recorded the amplitude and the arrival time of the events; in particular, the signals from the PMT were also recorded – over a time window of 3125 ns – by a 160 MSa/s Transient Digitizer. The energy scale and the energy resolution of the CaF₂(Eu) detector for γ quanta were measured with 22 Na, 133 Ba, 137 Cs, 228 Th and 241 Am sources, while the response to α particles was studied from 1 MeV to 5.25 MeV by using a collimated 241 Am α source and a set of absorbers. The dependence of the α/β ratio (i.e. ratio of energy of α particle measured by the scintillator in γ scale to its real energy) versus the energy of α particles was derived; in particular, $\alpha/\beta=0.128(19)$ at the energy of 151 Eu α peak in γ scale was 245(36) keV.

The precise concentration of Eu in the CaF₂(Eu) crystal was determined by Inductively Coupled Plasma - Mass Spectrometry analysis (ICP-MS, Agilent Technologies model 7500a) to be: $(0.4\pm0.1)\%$; the uncertainty also takes into account the uncertainty in the sample preparation procedure.

The data of the low background measurements with the CaF₂(Eu) detector were analyzed by several approaches (time-amplitude analysis, pulse shape discrimination, removing double pulses, etc.); the presence of radioactive isotopes in the detector was studied as well. In particular, to discriminate the events from α decays inside the crystal from the $\gamma(\beta)$ background, the optimal filter method was applied and the energy dependence of the shape indicators was measured. The discrimination was rather low, however this procedure allowed to test the nature of the events in the energy distribution of Fig. 10-left. In the low energy part of the energy distribution measured in the low background set-up for 7426 h (shown in Fig. 10right), a peculiarity at the energy near 250 keV is present which gives an indication on the existence of the process; furthermore, the pulse-shape discrimination analysis has allowed to clarify the nature of events on the $\approx 250 \text{ keV}$ peak. In fact, as it can be seen on the bottom curve of Fig. 10-right, this effect is present in the α component of the spectrum (solid line), while absent in the $\gamma(\beta)$ component (dashed line). In this way, the half-life of 151 Eu relatively to the α decay to the ground state of 147 Pm was evaluated: $T^{\alpha}_{1/2}(g.s. \to g.s.) = (5^{+11}_{-3}) \times 10^{18}$ yr. Theoretical half-lives for 151 Eu α decay calculated in different model frameworks are in the range of $(0.3-3.6)\times10^{18}$ vr; in particular, the ¹⁵¹Eu half-life measured value was well in agreement with the calculations of Refs. [56, 132].

As mentioned above, several years later in Ref. [71], the α decay of $^{151}\mathrm{Eu}$ to the ground state of $^{147}\mathrm{Pm}$ was remeasured by using a 6.15 g Li₆Eu(BO₃)₃ crystal operated as a scintillating bolometer. Germanium Neutron Transmutation Doped thermistors were used as temperature sensors coupled to the crystal and to the light detector (a high purity Ge wafer 44.5 mm diameter and 300 μ m thickness); the crystal was surrounded by a reflecting foil to maximize the light collection efficiency.

The light vs bolometer signals were used for each event to significantly reduce the γ/β events in the energy dis-

Fig. 10: Left: energy distribution measured with the CaF₂(Eu) scintillator for 7426 h in the low background DAMA/R&D set-up (points). The energy distributions, obtained by applying the pulse-shape discrimination (PSD) technique, are shown by dashed line for $\gamma(\beta)$ component and solid line for α component. (Inset) The fit of the total spectrum by simulated models in 90 – 2200 keV energy interval is shown by solid line. The most important components of $\gamma(\beta)$ background are also shown. Right: low energy part of the energy distribution (points) and its $\gamma(\beta)$ (dashed line) and α (solid line) components obtained by applying the PSD. The peculiarity on the left of the ¹⁴⁷Sm peak can be attributed to the α decay of ¹⁵¹Eu with the half-life $T_{1/2} = 5 \times 10^{18}$ yr [131]. Figure taken from Ref. [131].

Fig. 11: Zoom of the α energy spectrum around the region of interest. Two peaks are visible: ¹⁴⁷Sm at 2311 keV and one at 1949 keV, interpreted as ¹⁵¹Eu. In the inset the full y-scale plot is shown. The dashed lines represent the detector response function, while the solid line is the sum of the response functions of the two peaks [71]. Figure taken from Ref. [71].

tribution; in Fig. 11 the best-fit α energy spectrum is

shown from 1.2 MeV to 4 MeV; the best-fit Q-value of the $^{151}\mathrm{Eu}~\alpha$ transition is $[1948.9\pm6.9(stat.)\pm5.1(syst.)]$ keV with an energy resolution (full width at half maximum, FWHM): (65±7) keV. The best-fit number of $^{151}\mathrm{Eu}$ events corrected for the event selection efficiency was derived to be: (37.6±7.5) counts giving: $T_{1/2}^{\alpha}(g.s.\to g.s.)=[4.62\pm0.95(stat.)\pm0.68(syst.)])\times10^{18}$ yr, which is in agreement with the first observation [131] and predictions of nuclear theory using the Coulomb and proximity potential model.

$3.6.1~^{151}{\rm Eu}~\alpha$ decay to the first excited level of the $^{147}{\rm Pm}$ and limits on the $^{153}{\rm Eu}~\alpha$ decay

In addition to the decay of 151 Eu to the 147 Pm ground state, also the first excited level of 147 Pm $(5/2^+, E_{exc}=91 \text{ keV})$ can be populated³; its corresponding Q_{α} value is 1.873 MeV.

Still in Ref. [131] a study on such a process was performed. In particular, taking into account the α/β ratio, the energy of α particles, which is 1.823 MeV, corresponds in the used CaF₂(Eu) detector to 234 keV in the γ scale. Then, in a subsequent deexcitation process of the excited ¹⁴⁷Pm level, some particles will be emitted: either single gamma quantum ($E_{\gamma}=91~{\rm keV}$) with a probability of 33%, or conversion electron plus cascade of X rays and

³ Higher ¹⁴⁷Pm levels could be populated too, but the probabilities for such α decays are much lower because of the exponential dependence on the energy release.

Auger electrons with a probability of 67% (coefficient of conversion for this transition is equal to 2.06 [133]). Since all these low-energy particles are effectively absorbed inside the crystal, the full energy observed by the CaF₂(Eu) detector was equal to (325 ± 33) keV. Such a peak, which should be on the right slope of the ¹⁴⁷Sm peak, is not evident in the experimental data (see Fig. 10-right). Fitting the background spectrum with a model consisting of two peaks (¹⁴⁷Sm and the peak searched for) plus an exponential function, the obtained upper limit on the α decay of ¹⁵¹Eu to the first excited level of ¹⁴⁷Pm was determined as: $T_{1/2}^{\alpha}(g.s. \rightarrow 5/2^+) \geq 6 \times 10^{17}$ yr at 68% C.L. This limit was one order of magnitude higher than the one reported in Ref. [134] where 91 keV γ rays were searched for from a sample of Li₆Eu(BO₃)₃ crystal measured with a ultra-low background HPGe γ spectrometer deep underground.

Some years later, in Ref. [72], the α decay of $^{151}{\rm Eu}$ to the first excited level of $^{147}{\rm Pm}$ was searched for at the HADES underground laboratory (about 500 m w.e.). A sample of high-purity europium oxide of natural isotopic composition and 303 g mass was measured over 2232.8 h with a high-energy-resolution ultra-low background HPGe detector (40 cm³) with sub-micron dead-layer. The half-life limit reached in this way was $T_{1/2}^{\alpha}(g.s. \rightarrow 5/2^+) \geq 3.7 \times 10^{18}$ yr at 68% C.L., approaching the theoretical predictions.

Fig. 12: Simplified scheme of the α decay of 153 Eu. The γ ray produced by the transition following the β decay of 149 Pm is highlighted. Figure taken from Ref. [72].

For completeness, we also remind that in the latter work from the same data a new half-life limit for decay of 153 Eu was also determined by studying the γ radiations associated to the β decay of the daughter nucleus, 149 Pm, as shown in Fig. 12. The energy spectrum measured in the experiment over 2232.8 h with the Eu₂O₃ sample in the energy interval 278–298 keV is shown in Fig. 13; there

Fig. 13: The energy spectrum measured in the experiment of Ref. [72]. The fit of the spectrum in the energy interval 282-290 keV is shown by solid line. The expected γ peak at 285.9 keV from β decay of ¹⁴⁹Pm, see Fig. 12, is shown by the dashed line. The area of the peak corresponds to the half-life of ¹⁵³Eu $T_{1/2}=5.5\times10^{17}$ yr excluded at 68% C.L. The background spectrum is normalized to the time of measurements with the sample. Figure taken from Ref. [72].

is no evidence for the peak and new half-life limit for the decay of 153 Eu was set to $\geq 5.5 \times 10^{17}$ yr at 68% C.L.

3.7 The α decay of samarium isotopes

Samarium has seven naturally occurring isotopes (see Table 1). The natural Sm contains three radioactive isotopes: $^{147}\mathrm{Sm}$ (abundance 15.00%), $^{148}\mathrm{Sm}$ (abundance 11.25%) and $^{149}\mathrm{Sm}$ (abundance 13.82%), which have long half-lives of 1.06(1) \times 10¹¹ yr, 7(3) \times 10¹⁵ yr, and > 2 \times 10¹⁵ yr, respectively. Potentially, other two isotopes can decay by emitting α particles: $^{150}\mathrm{Sm}$ and $^{152}\mathrm{Sm}$.

For completeness let us mention that the α decay from various excited states of samarium isotopes were investigated by thermal neutrons and resonance neutrons [135, 136, 137, 138]. While the α decay from the ground states have long life-times, the decay from highly excited states is fast. The use of resonance neutrons allows to excite a number of discrete levels, but it is complicated because of the very small cross sections involved and the large γ -ray yield in competitive reactions, in fact the ratio $\sigma(n,\alpha)/\sigma(n,\gamma)$ is in the range of 10^{-5} – 10^{-9} . The measurements regard the α widths, and the values measured correspond to lifetimes of few ns ($\Gamma \times \tau = h/2\pi$).

3.7.1 $^{147}\mathrm{Sm}~\alpha$ decay

To precisely know the half-life of ¹⁴⁷Sm is important because this isotope – due to its long half-life – is considered

as a cosmochronometer; the dating method is based on the relative abundance of $^{143}\mathrm{Nd}$ to $^{144}\mathrm{Nd}$ [139], with the first isotope deriving from the α decay of $^{147}\mathrm{Sm}$. The $^{147}\mathrm{Sm}$ isotope is therefore suitable for dating ancient ores and meteorites.

Since the pioneering studies in 1933 by Hevesy et al. [140] and in 1934 by Curie and Joliot [141], many measurements of α radioactivity of ¹⁴⁷Sm have been performed (more than 30 measurements are available). Recently, a last high precision investigation of the α decay of the $^{147}\mathrm{Sm}$ isotope $(J^{\pi}=7/2^{-})$ into the ground and first excited states of 143 Nd was performed by using α spectrometry and γ spectroscopy [68]. To measure the α activity a low-background twin Frisch-grid ionization chamber (TF-GIC) was used [142]. When no source is present the obtained background in the energy region (1-9) MeV was of (10.9 ± 0.6) counts per day; the main contribution was from the daughters of 222 Rn (218 Po, 214 Po and 210 Po). There were also small contributions from ²²⁰Rn, coming from the ²³²Th decay chain (²²⁰Rn, ²¹⁶Po and ²¹²Po). The background activity fell to (8.3 ± 0.7) counts per day in the same energy region after the first 12 days of operation due to the radon daughters decay.

The measured $^{147}\mathrm{Sm}$ peak shows the expected maximum at 2.28 MeV. All events above 2.5 MeV were from Th and U contaminations, the majority of which are above 5 MeV. The energy resolution of the peak was $\sigma_E=16.76(88)~\mathrm{keV}$.

The combined half-life value of 147 Sm on the four measured samples is $T_{1/2} = (1.0787 \pm 0.0095 (\text{stat.}) \pm 0.0244 (\text{systr}))$ gion of interest of the expected signal. The γ spectrum \times 10^{11} yr. The quoted systematic uncertainty is the combination of the uncertainty of the detector efficiency and the uncertainty on the isotopic abundance. The systematic uncertainty is dominated by the precision on the activity of the calibration source which is 2.2%. In Fig. 14 the half-life values [143] plotted as a function of year are shown as reported in Ref. [68].

For a historical report on half-life measurements of $^{147}\mathrm{Sm}$ see also Ref. [143].

An updated critical review and data analysis of the whole set of half-life-values obtained over time is available in Ref. [145]. In that paper the recommended value for the α -decay half-life of $^{147}\mathrm{Sm}$ isotope is $(1.063\pm0.005)\times10^{11}$ yr. In particular the authors applied also a one-parameter, semi-empirical model for α emission from nuclei, developed in the framework of the quantum mechanical tunneling mechanism through a Coulomb-plus-centrifugal-plus-overlapping potential barrier, and evaluated a value of $(1.082\pm0.030)\times10^{11}$ yr.

There is a finite probability of α decay into the excited state of ¹⁴³Nd; this leads to a de-excitation through the emission of γ radiation. The excited state transitions have been studied using low background γ spectroscopy [68] and data were published only relatively to the first excited state $E_1 = 742.05(4)$ keV [146] (because of the lower Q_{α} values and potential total angular momentum changes). The samples of Sm₂O₃ were measured in a ultra-low background HPGe [147]. The measured spectrum shows few prominent peaks. These peaks are due to contamination

Fig. 14: The half-life values of ¹⁴⁷Sm [143] plotted as a function of year are shown as reported in Ref. [68]. The red circular points are the original published results. The blue circular points are the adjusted half-life values, by the method described in Ref. [143]. The weighted mean (uncertainties in squared braces) is calculated in Ref. [68] using the method described in Ref. [144] with the adjusted half-life values.

from natural radioactive sources like Th and U decay chains as well as 40 K. The peak at 2614.5 keV corresponds to the decay of 208 Tl. The positron annihilation line from muon interactions is visible at 511 keV. The presence of natural radioactivity makes a Compton continuum in the tregion of interest of the expected signal. The γ spectrum measured in Ref. [68] is shown in Fig. 15.

Fig. 15: The γ spectrum from 50.74 g of Sm₂O₃, with a combined runtime of 62.91 d [68]. Figure taken from Ref. [68].

The region of interest (ROI) around 742 keV is shown in Fig. 16.

The fit gave a background estimate in the ROI of 336(11) counts, while the measured number in the ROI was 352 counts. The analysis resulted in a lower half-life limit of $T_{1/2} > 3.1 \times 10^{18}$ yr (at 90% C.L.). The the-

Fig. 16: The ROI (between the two red vertical lines) in the γ spectrum for a potential α decay of ¹⁴⁷Sm into the first excited state of ¹⁴³Nd at 741.98(4) keV [68]. The line at 727.2 keV is most likely from ²¹²Bi decay from the thorium decay chain. The efficiency at 742 keV was estimated to be 5.5%. Figure taken from Ref. [68].

oretical prediction for this decay mode, taken from the Viola-Seaborg relation between the Q_{α} value and half-life [27], gives an expected value for the half-life of the order of 10^{24} yr. This is considered a rough estimate as the change in total angular momentum is not taken into account, but would modify the expected half-life even longer. The small Q_{α} value is also expected to have an important impact on the half-life. To reach the predicted half-life region lower background and larger exposure (mass, time) will be needed.

3.7.2 $^{148}\mathrm{Sm}~\alpha$ decay

Some measurements to study the alpha decay of $^{148}\mathrm{Sm}$ were performed in the past by two groups, and the half-lives were measured with quite large uncertainties: $(8\pm2)\times10^{15}$ yr [148] and $(7\pm3)\times10^{15}$ yr [149] due to a rather small signal-to-background ratio.

Recently, the half-life of the α decay of ¹⁴⁸Sm was measured at LNGS with improved accuracy by using a ZnWO $_4$ scintillating bolometer doped with Sm, isotopically enriched in $^{148}{\rm Sm}$ to 95.54% [69]. A ZnWO $_4$: $^{148}{\rm Sm}$ cylindrical crystal with a mass of 22.014 g was used as low temperature scintillating bolometer. Defining the light yield as the ratio of the energy measured in the light detector to the energy measured in the ZnWO₄: ¹⁴⁸Sm crystal, it results that alphas have a low light yield and can be discriminated from the beta/gamma events. The measured activity of (745.4 \pm 0.5) mBq/kg for $^{147}\mathrm{Sm}$ was deduced from the peak at 2310.5 keV. The smaller peak just below 2 MeV was identified as related to the ¹⁴⁸Sm alpha decay and was found consistent with the expected decay energy. In order to evaluate the 148 Sm Q-value and its half-life, a simultaneous unbinned and extended likelihood fit to the alpha energy spectrum was done by using the response function.

The best fit value for the energy transition of the $^{148}\mathrm{Sm}$ alpha decay was (1987.3 \pm 0.5) keV, in agreement with the recommended value at (1986.8 \pm 0.4) keV [63]. The computed energy resolution for the $^{148}\mathrm{Sm}$ peak was (4.7 \pm 0.5) keV (FWHM). Finally, taking into account the ratio of the atomic concentration of $^{148}\mathrm{Sm}/^{147}\mathrm{Sm}$ and the number of events in the two peaks, the obtained half-life was $T_{1/2}=(6.4^{+1.2}_{-1.3})\times10^{15}$ yr [69].

The quoted uncertainties include both the statistical and the systematic contributions derived from the fit. The measured half-life is in agreement with the previously reported values [148,149]. Furthermore, it is in agreement with evaluation based on the cluster model [54,55] and the semi-empirical formulae in Ref. [150], giving 5.6×10^{15} yr and 8.0×10^{15} yr, respectively.

The method has the potential to improve the sensitivity by three orders of magnitude, if the isotope mass is increased to few grams (it is less than 2 mg in this measurement).

3.7.3 The α decay of other Sm isotopes

The 149 Sm is predicted to decay, but no decays have ever been observed. It is considered to undergo α decay to 145 Nd with a half-life over 2×10^{15} yr, as reported in Ref. [149].

Recently a study on the extremely long-lived α -decaying nuclei within a generalized density-dependent cluster model involving the experimental nuclear charge radii was performed [23] and calculations within the UMADAC model [151,21] and the analytic formulas given by Royer [150] are available. These three calculations give for the half-life of ¹⁴⁹Sm: 5.8×10^{18} yr, 3.1×10^{19} yr, 6.5×10^{18} yr, respectively (see also Table 1).

3.8 144 Nd and 146 Nd lpha decay

Neodymium has seven isotopes present in nature; five of them can in principle be unstable undergoing an α decay. Some isotopes (146 Nd, 148 Nd, and 150 Nd) can undergo $2\beta^-$ decay; in particular, the $2\nu 2\beta^-$ decay of 150 Nd to the ground state and to the first excited level of 150 Sm was measured in several direct experiments in the ranges: $T_{1/2}(g.s. \rightarrow g.s.) = (0.7 - 1.9) \times 10^{19}$ yr, and $T_{1/2}(g.s. \rightarrow 0^+, 740.5 \text{ keV}) = (0.47 - 1.4) \times 10^{20}$ yr, respectively [152]. Only a limit of $T_{1/2} > 3 \times 10^{18}$ yr is reported for the $2\beta^-$ decay of 148 Nd [153] (g.s. to g.s. transition).

The isotopes 143 Nd, 145 Nd, and 148 Nd have either pos-

The isotopes ¹⁴³Nd, ¹⁴⁵Nd, and ¹⁴⁸Nd have either positive low Q_{α} values: (520.7 ± 7.4) keV, (1576.0 ± 2.1) keV, and (599.0 ± 3.6) keV, respectively, or low natural abundances: 12.173(26)%, 8.293(12)%, and 5.756(21)%, respectively [62]; thus, they are classified as "stable" nuclei. Some attempts to measure their α decay by a gridded ionization chamber have been done for the ¹⁴⁵Nd isotope, resulting in a limit on the half-life $> 6 \times 10^{16}$ yr [66].

The half-life of the α decay of the ¹⁴⁴Nd isotope to ¹⁴⁰Ce has been adopted in Ref. [65] to be: $(2.29 \pm 0.16) \times$

 10^{15} yr; the Q_{α} value is (1903.2 ± 1.6) keV [63]. This halflife is the unweighted average of the measured half-lives: $(2.65 \pm 0.37) \times 10^{15} \text{ yr } [154], (2.4 \pm 0.3) \times 10^{15} \text{ yr } [73],$ 2.2×10^{15} yr [75], and 1.9×10^{15} yr [66]. Three of them have been obtained in the decade 1950-1960 using either a large cylindrical ionization counter accommodating samples [73], or nuclear emulsion technique [75], or gridded ionization chambers [66]. A relatively more recent measurement was done in 1987 by using a cylindrical proportional counter with a cathode source area of 1550 cm² [154]. The counting volume was enclosed by a brass cylinder, 10 cm in diameter and 63 cm long. The gold-plated tungsten anode wire had 50 μ m diameter. The source material was deposited on the inside of a thin stainless steel sheet with an area of approximately 1550 cm². The used gas was a mixture of 90% of Ar and 10% of CH₄. The pressure was regulated at a few percent above atmospheric pressure. The spectrum obtained with a source of isotopically enriched Nd_2O_3 in ^{144}Nd at 97.5% is shown in Fig. 17. The $^{144}{\rm Nd}~\alpha$ peak at $E_{\alpha}=1.8~{\rm MeV}$ is clearly visible, together with a continuous background extending to about 8.8 MeV. This background is due to ²³²Th and its daughters, with its last member ²¹²Po contributing to the energy spectrum between 6.8 and 8.8 MeV. The obtained half-life is: $T_{1/2} = (2.65 \pm 0.37) \times 10^{15} \text{ yr } [154].$

Fig. 17: Energy spectrum measured for 100 hours of data taking by a cylindrical proportional counter with a cathode source containing 144 Nd enriched at 97.5% [154]. The background above 2 MeV is due to the 232 Th and its daughters. Figure taken from Ref. [154].

The nuclide ¹⁴⁶Nd is considered to be stable, however, according to the atomic mass evaluation [63] it has a positive Q_{α} value: (1182.4±2.2) keV with respect to α decay. The decay to the ground state is expected to be accompanied by α decay into the first excited 2_1^+ state of ¹⁴²Ce.

This state would de-excite via the emission of 641.282(9) keV γ quanta. The first search ever for its α decay into the first excited state of ¹⁴²Ce by the detection of the 641.282 keV γ quanta was performed by using a low background HPGe detector and a sample of neodymium, enriched in ¹⁴⁶Nd at 97.20(1)% [67]. The measurements were done at the Felsenkeller Underground Lab of VKTA Rossendorf [67].

The measured spectrum of the HPGe with the enriched Nd sample around the energy region of interest after 144 hours of data taking is reported in Fig. 18. The most prominent line in this region is the 609.3 keV line from $^{214}\mathrm{Bi}$ from the natural decay chain of $^{238}\mathrm{U}$, while no significant signal is present at the energy of the expected transition. Hence, the region has been fitted with a flat background and a Gaussian peak and the lower limit on the half-life of this decay mode has been determined to be $T_{1/2}(0^+ \to 2_1^+) > 1.6 \times 10^{18}$ yr at 90% CL [67].

Fig. 18: Energy spectrum, measured by HPGe with the Nd sample enriched in ¹⁴⁶Nd at 97.20(1)% around the expected gamma energy of the first excited state transition. No peak is seen in the ROI. The identified peaks (blue) have been subtracted before fitting the background. Figure taken from Ref. [67].

The theoretical estimates of the half-life for the α decay of $^{146}{\rm Nd}$ to the ground state of $^{142}{\rm Ce}$ are in the region of about 10^{31-36} years (see also Table 1), and even longer for the transition to the first excited state [67], thus far from the experimental sensitivities.

3.9 The α decay of gadolinium and hafnium isotopes

All six naturally abundant isotopes of Hf and the three isotopes of Gd are unstable (at least, potentially) with respect to α decay (see Table 1). It is very peculiar that no measurements of the half-lives of the α decay of gadolinium and hafnium isotopes are reported after 1961 (in their

ground states; see Section 3.5 on $^{178m^2}$ Hf). In particular, the α decay of two nuclides, 152 Gd and 174 Hf, have been firstly observed in 1959 by using nuclear emulsions [155] and remeasured with higher accuracy in 1961 [73]. In the latter measurement a cylindrical ionization counter was used, and the samples – enriched in the isotopes of interest – were deposited uniformly over a substrate of metallic sheets which fitted concentrically into the counter. The total active area was 1200 cm² and the typical thickness of the samples was between 10 and 100 $\mu g/cm^2$.

The energy spectrum collected after 109.3 hours using the enriched gadolinium oxide sample is reported in Fig. 19. The peak of the α particles due to the ^{152}Gd decay is well evident and corresponds to the half-life of $T_{1/2} = (1.08 \pm 0.08) \times 10^{14} \text{ yr } [73]$. The authors verified, by repeating the measurement adding samarium oxide to the sample, that there was no contamination in the peak due to α particles from samarium decay [73]. Fig. 19 also shows the energy spectrum collected in 236 hours with a sample of $100~\mu\text{g/cm}^2$ containing the enriched hafnium oxide sample and a weak reference source of ^{210}Po . The measured half-life of ^{174}Hf was $T_{1/2} = (2.0 \pm 0.4) \times 10^{15}$ yr [73].

The half-lives measured in this experiment are still the reference ones, as reported in the table values [70]. It is our opinion that a more precise determination of them is recommended by exploiting the present technologies and facilities. No measurements of the α decay of the other naturally occurring isotopes of gadolinium and hafnium have been performed until now at our knowledge.

4 Search for very long living α decays

The α decay of some isotopes shown in Table 1 has neither been observed, nor any attempts to get lower limit on the half-life have been performed, to our knowledge. The theoretical estimations of their half-life is far from any reasonable experimental sensitivity (see Table 1). These isotopes are: ^{165}Ho , four isotopes of dysprosium (^{158}Dy , ^{160}Dy , ^{161}Dy , ^{162}Dy), two of neodymium (^{143}Nd , ^{148}Nd), two of gadolinium (^{154}Gd , ^{155}Gd), two of thallium (^{203}Tl , ^{205}Tl), five of erbium (^{164}Er , ^{166}Er , ^{167}Er , ^{168}Er , ^{170}Er), ^{152}Sm , ^{197}Au , five isotopes of mercury (^{198}Hg , ^{199}Hg , ^{200}Hg , ^{201}Hg , ^{202}Hg), the two isotopes of lutetium (^{175}Lu , ^{176}Lu), all of them because of their low Q_{α} values (see Table 1).

Moreover, no attempt for half-life measurements has been done for 150 Sm, 169 Tm, the two isotopes of rhenium (185 Re, 187 Re), of tantalum (180m Ta, 181 Ta), of iridium (191 Ir, 193 Ir), and 196 Hg, either. In particular, 187 Re is undergoing β decay.

In the following, we review the cases of those isotopes for which measurements on their decay were performed, setting lower limits on $T_{1/2}$.

4.1 $^{142}\mathrm{Ce}~\alpha$ decay

The cerium isotopes 136 Ce, 138 Ce, and 142 Ce, with natural abundances 0.185(2)%, 0.251(2)%, and 11.114(51)%,

Fig. 19: Energy spectra collected with the enriched samples of 152 Gd (Top) and 174 Hf (Bottom) by the large cylindrical ionization counter of Ref. [73]. The peaks due to the α particles from the decay of 152 Gd, 174 Hf and 210 Po, used as reference, are evident. Figures taken from Ref. [73].

respectively, [62] are good candidates for 2β decay; competitive experimental results are reported in Ref. [156, 157, 64, 158, 159, 160]. Moreover, the $^{142}\mathrm{Ce}$ isotope can decay to the ground state of $^{138}\mathrm{Ba}$ with emission of an α particle. The corresponding energy release is equal to (1303.5 ± 2.5) keV [63], thus the expected energy of the α particle is $E_{\alpha}=1267$ keV. The decay has not yet been observed and only experimental limits have been set. Firstly a limit was set in the sixties: $T_{1/2}^{\alpha} \geq 5 \times 10^{16}$ yr [73] by using a large cylindrical ionization counter, accommodating samples up to 1200 cm² in area.

A more stringent limit has been achieved by using a more sensitive set-up [64] at LNGS. In this experiment the used detector was a CeF₃ crystal scintillator $(2 \times 2 \times 2 \text{ cm}^3, \text{ mass of } 49.3 \text{ g})$ [64], that served as source and de-

tector simultaneously. The crystal was directly coupled to two low radioactive (to enhance the sensitivity to such rare events) PMTs, working in coincidence. The detector was surrounded by Cu bricks and sealed in a low radioactive Cu box continuously flushed with high purity nitrogen gas (stored in bottles deeply underground for a long time to allow the decaying of short/medium half-lives cosmogenic isotopes) to avoid presence of residual environmental radon. The Cu box was surrounded by a passive shield made of 10 cm of high purity Cu, 15 cm of low radioactive lead, 1.5 mm of cadmium and 4-10 cm polyethylene (paraffin) to reduce the external background. The whole shield was closed inside a Plexiglas box, also continuously flushed by high purity nitrogen gas. The performances of this CeF₃ crystal scintillator were investigated [64]. In particular, the relative light output for α particles as compared with that for β particles (or γ rays), named α/β ratio, was measured at various α energies either by α 's, collimated and attenuated by mylar foils, from a ²⁴¹Am source or by peaks due to internal contamination of the CeF₃ crystal itself. The dependence can be written as [64]:

$$\alpha/\beta = 0.084 + 1.09 \times 10^{-5} E_{\alpha}$$

where E_{α} is in keV. Finally, the possibility of a pulse-shape discrimination between α particles and γ quanta, and the radioactive contamination of the crystal were also studied [64].

Fig. 20: Low energy part of the background spectra measured for 2142 h in the low background set-up with the CeF₃ scintillator after the rejection of the PMT noise and the double pulses [64]. The spectrum contains at least 99% of $^{142}\mathrm{Ce}~\alpha$ peak. The fit of the spectrum is shown by solid line, the simulated α peak of $^{142}\mathrm{Ce}$ corresponding to half-life $T_{1/2}=5\times10^{16}$ yr is shown by dashed line as reference. Figure taken from Ref. [64].

Considering the natural abundance, the number of $^{142}\mathrm{Ce}$ nuclei in the CeF3 crystal was $1.67\times10^{22}.$ The search for the $^{142}\mathrm{Ce}$ α decay was performed by using the energy spectrum obtained by discarding the double pulses, that identify events due to known background from radioactive isotopes, such as those due to the following chains: $^{212}\mathrm{Bi} \to ^{212}\mathrm{Po} \to ^{208}\mathrm{Pb},$ and $^{220}\mathrm{Rn} \to ^{216}\mathrm{Po} \to ^{212}\mathrm{Pb}.$ Taking into account the α/β ratio, the α peak of $^{142}\mathrm{Ce}$ can be expected at the energy $(127\pm7)~\mathrm{keV}$ (with FWHM = 53 keV), where the experimental α spectrum contains at least 99% of α events. A fitting procedure was applied to search for the $^{142}\mathrm{Ce}$ α decay. The best fit in the (60–165) keV energy interval gives a peak's area equal to (-790 ± 1010) counts and leads to $\mathrm{lim}\,S=972$ counts at 90% C.L. Thus, the lower bound on the half-life of the $^{142}\mathrm{Ce}$ α decay is [64]:

$$T_{1/2}^{\alpha} \ge 2.9 \times 10^{18} \text{ yr at } 90\% \text{ C.L.}$$
 (3)

A part of the experimental distribution together with the fitting curve is presented in Fig. 20. The simulated α peak of $^{142}\mathrm{Ce}$ with $T_{1/2}=5\times10^{16}~\mathrm{yr}$ (that is also the half-life limit of Ref. [73]) is shown as reference. The present experimental limit is still much lower than the existing theoretical estimates, which are in the range of $\approx 10^{27}~\mathrm{yr}$ [161,56,54], as shown in Table 1.

4.2 The α decay of dysprosium isotopes

Five of the seven natural dysprosium isotopes are potentially unstable undergoing α decay. Furthermore, the transitions to the excited levels of daughter nuclei are allowed for all the isotopes. Characteristics of the possible alpha decays are presented in Table 1. In Ref. [162] a search for α decay of the dysprosium isotopes to the excited levels of the daughter gadolinium isotopes was realized by analysing the low background energy spectrum measured by a low background HPGe γ detector with a purified 322 g Dy₂O₃ sample for 2512 h. No peculiarities, that could be interpreted as γ peaks from α decays of the dysprosium isotopes to the lowest excited levels of the daughter nuclei, were observed in the energy spectrum measured with HPGe spectrometer; thus, only limits were set on these decays. As an example in Fig. 21 is shown a part of the energy spectrum accumulated by the HPGe spectrometer.

The results for the various decay modes are summarized in Tables 1 and 6 for the g.s. to g.s. transitions and for the transitions to the lowest excited levels of the daughter nuclei, respectively. In these Tables are given also the theoretical estimates that were calculated by using the approach used in [56].

As shown in the Table 6, the theoretical estimates disfavour realistic observations of alpha decays of all naturally abundant dysprosium isotopes to the excited levels of daughter nuclei. At the same time the detection of the 156 Dy decay to the ground state of 152 Gd (supposing one will apply crystal scintillators from dysprosium enriched in 156 Dy) looks possible. In fact, a half-life 6.8×10^{24} yr was estimated by using the approach of Ref. [56]. The strong

Table 6: Characteristics of possible alpha decays of dysprosium isotopes to the lowest excited levels of the daughter nuclei [162].

Alpha decay	Excited level	Detection	$\lim S$	Experimental	Theoretical

Fig. 21: (Color online) A part of the energy spectrum measured by the HPGe spectrometer with a Dy₂O₃ sample for 2512 h. An expected γ peak from α decay of ¹⁵⁶Dy to the first excited level of ¹⁵²Gd corresponding to the half-life $T_{1/2}=3.8\times 10^{16}$ yr (excluded at 90% C.L.) is shown by the solid line [162]. Figure taken from Ref. [162].

advantage of scintillation methods is an almost 100% detection efficiency to alpha particles and pulse-shape discrimination capability [112,131].

As far as we know, there was only one attempt many years ago to measure the half-life of the α decay of the $^{156}\mathrm{Dy}$ to the ground state of $^{152}\mathrm{Gd}$. It was done by using Ilford C2 emulsion plates in contact with the dysprosium sample [74]. The absence of α tracks gave a rough estimate of the half-life lower limit: $T_{1/2} > 10^{18}$ yr [74]. To our

knowledge no attempt was made to investigate the α decay of the other Dy isotopes – also disfavoured by the lower Q_{α} values with respect to $^{156}{\rm Dy}$ (see Table 1) – to the ground state of the daughter nuclei.

In conclusion, the development of enrichment methods for dysprosium isotopes and of radiopure crystal scintillators containing Dy is mandatory to observe α activity of natural dysprosium.

4.3 The α decay of erbium isotopes

Erbium has six naturally occurring isotopes (see Table 1). They are stable, but potentially all of them can decay emitting α particles [70], in particular: ¹⁶²Er is considered to undergo α decay to ¹⁵⁸Dy (with a half-life larger than 1.40 $\times 10^{14}$ yr).

The only experimental data are available from Ref. [75], where the α activity was studied for some elements. To detect the α particles, Ilford plates were used (with the element impregnated in emulsions or mixed in a gel form). After the development, the plates were screened with a Leitz-Ortholux microscope. Only traces fully contained in the plates were considered in order to evaluate the energy. All the experimental parameters were considered (effects on the preparation of the emulsions, the fixing bath, the post treating bath, humidity etc.). The mass of the element impregnated in the emulsions was around 5-20 mg in 800 mg of emulsion, in order to have a negligible variation of the emulsion density. In case of gel the density was determined by measuring it. Also some blank measurements were performed without impregnating the emulsion with the element under study. Most of the traces are due to radioactive contaminants. Some radioactive impurities (Sm, Th, U, Po, etc.) were present in traces in the examined samples, so the measurements were performed in two energy intervals (1.5-2.5) MeV and (2.5-3.7) MeV, where the first interval is more affected by the Sm impurity (it is present at level of $10^{-4}-10^{-5}$). Twenty-three elements were examined and for 19 of them no alpha activity was found. For these elements only a lower limit for life-time was set.

In Table 4 of Ref. [75] a lower limit value around 10^{17} is quoted for the Er element, value that is at level of sensitivity of the applied experimental approach.

Considering that from the theory-phenomenology of the α decay (Gamow, Royer, Viola-Seaborg etc.), the smaller the value of the energy released in the decay the larger the half-life of the decay becomes. The shortest half-life (in principle the first for which one could hope to reach a suitable experimental sensitivity) is that of the $^{162}{\rm Er}$ isotope (see Table 1). Considering its natural abundance (0.139(5)%), the limit of Ref. [75] corresponds to $T_{1/2} > 1.4 \times 10^{14}$ yr, which is in fact the value quoted in Ref. [70].

In literature no other experimental determination is at hand, and certainly with the updated advanced experimental techniques presently available this limit could be strongly improved. However, the modeling estimates seem to set the half-life of these decays to very high values, as reported in Table 1 and e.g. in Ref. [23], where the quoted calculated values are in the range $(10^{28}-10^{30})$ for 162 Er and even $(10^{39}-10^{41})$ for 164 Er.

4.4 The α decay of ytterbium isotopes

Ytterbium has seven naturally occurring isotopes (see Table 1).

They are stable, but potentially all of them can decay emitting α particles [70], in particular: ¹⁶⁸Yb is considered to undergo α decay to ¹⁶⁴Er (with a half-life over 1.3×10^{14} yr).

The only experimental data are available from Ref. [75] obtained with the same experimental approach already described in the Er case.

In case of Yb, in Table 4 of Ref. [75] a lower limit around 10¹⁷ is quoted, a value that is at the level of sensitivity of the applied experimental approach.

Therefore, considering that for Yb isotopes (see Table 1) the highest Q_{α} value is that of the ¹⁶⁸Yb isotope (natural abundance 0.123(3)%), the limit of Ref. [75] corresponds to a $T_{1/2} > 1.3 \times 10^{14}$ yr, which is in fact the value quoted in Ref. [70]. Also in case of Yb isotopes the theoretical estimates seem to set the life-time of these decays to higher values. The quoted calculated values (see Table 1 and e.g. Ref. [23]) are in the range $(10^{23} - 10^{25})$ for ¹⁶⁸Yb.

4.5 Search for α decay of lead isotopes

After the discovery of the α decay of ²⁰⁹Bi in 2003 [88], the lead is considered to be the heaviest stable element.

As shown in Table 1, lead has four naturally occurring isotopes with Q_{α} larger than zero and, therefore, potentially unstable undergoing α decay. Given the theoretical predictions for the half-lives, there is no possibility to observe their α decays with the present sensitivities. Moreover, let us stress the important role of ²⁰⁴Pb in lead geochronology as a standard reference [168].

Fig. 22: Light-heat scatter plot measured over 586 h. The two horizontal axes are calibrated for α and β/γ , respectively. Figure taken from Ref. [83].

Fig. 23: Energy spectrum of α particles in the PbWO₄ experiment. The two bands are the ROI for ²⁰⁴Pb and ²⁰⁶Pb decays. Figure taken from Ref. [83].

A possible evidence of the α decay of ^{204}Pb was reported in the fifties [74], by using Ilford C2 emulsion plates in contact with the enriched (at 27.0%) sample of ^{204}Pb . However, such measurement was reconsidered on the basis of more accurate mass determination of the parent and daughter nuclei, leading to a half-life limit for the α decay of ^{204}Pb to $T_{1/2} > 1.4 \times 10^{17}$ yr.

In 2013 new limits on the α decay of naturally occurring Pb isotopes were obtained in Ref. [83], by using a 454.1 g PbWO₄ crystal as a bolometer at LNGS un-

derground laboratory. The crystal was grown using low background ancient Roman lead. The scintillation light of the bolometer was detected by a Ge absorber working as a bolometer. The scatter plot of the events in the plane light vs heat is reported in Fig. 22; the horizontal axes are calibrated for α and β/γ , respectively. The separation shown in Fig. 22 allows the rejection of the background and the selection of the α particles, whose energy spectrum is reported in Fig. 23. New upper limits on the half-lives of the four natural lead isotopes have been estimated in the range of $T_{1/2} > 1.4 \times 10^{20} - 2.6 \times 10^{21}$ yr at 90% C.L. with PbWO₄ scintillating bolometer [83] (see also Table 1).

5 The rare β decays

Another hot field of interest in nuclear physics is the investigation of nuclear beta decays (weak interaction processes inside the nuclei), and in particular the study of rare and highly forbidden beta decays. Beta radiation was observed long time ago [16]; however, our knowledge of this phenomenon still can be and should be improved. Most of the beta decay transitions, which are observed in nature, are of allowed type, or in few cases transitions with low level of forbiddenness. More recently rare beta decays of long-living nuclides are under investigation. They are beta decay (β^- or β^+/ε) transitions suppressed by low Q_β value and/or high level of forbiddenness due to the large change in spin and parity; thus they correspond to long half-lives.

The β decays is well approximated by a point-like interaction vertex, since the massive W^{\pm} boson has ≈ 80 GeV/c² mass while the decay energy (≈ 1 MeV) is small. In addition to the general information, which can be derived by the experiments as shown later in this paper, two arguments are intriguing topics:

- 1) the very accurate determination of the shape of the beta spectrum at the end-point, in order to get information on the neutrino mass with direct and modelindependent approach;
- -2) the investigation of the role of the axial-vector coupling, g_A .

For the first case the most suitable nuclei/transitions are those with as low as possible Q-value and allowed, but 1st (2nd, ...) forbidden could be manageable as well; at present the exploited candidates are: 3 H ($Q_{\beta}=18.594(8)$ keV) and 187 Re ($Q_{\beta}=2.469(4)$ keV). As regards the axial-vector coupling, the value $g_A=1.27$ extracted from the partially conserved vector current hypothesis holds for bare nucleons only; on the other hand, in the $0\nu2\beta$ decay rate $\lambda \propto (g_A)^4$, thus, a possible – even small – quenching of g_A can play a strong impact on the sensitivities of the present and future $0\nu2\beta$ experiments. This quenching from the free-nucleon value can arise from nuclear medium effects and/or from nuclear many-body effects. Moreover, the effective value of g_A can also depend on the energy scale of the process and it can be different for β

and 2β decays (for exhaustive reviews see Refs. [169,170]). A good probe to study the effective value of g_A can be the β decay of the ¹¹³Cd isotope (4th forbidden non-unique, $Q_{\beta} = (323.83 \pm 0.27) \text{ keV } [63]$).

Some rare β decays $(T_{1/2}) > 10^{10}$ yr) are poorly investigated; for some of them the β decay is not yet observed, as in the case of 50 V, 123 Te, and 180m Ta. The interest in β decays increased in the recent past because sometimes they cause significant backgrounds in searches for and investigations of rare effects, like solar neutrinos (e.g. $^{14}{\rm C}$ in Borexino [171]), double beta (2 β) decay (e.g. $^{39}{\rm Ar},~^{42}{\rm Ar}/^{42}{\rm K}$ in GERDA [172], $^{113}{\rm Cd}$ in $^{106}{\rm Cd}$ double beta decay experiments) or dark matter experiments, especially based on Ar (e.g. $^{39}{\rm Ar}, ^{42}{\rm Ar}/^{42}{\rm K}$ in DarkSide [173]). While in the above-mentioned cases β decays constitute one of the main features in the measured spectra, other single β decays create not so large, but noticeable, backgrounds in many experiments: ⁴⁰K, ⁹⁰Sr/⁹⁰Y, ¹³⁷Cs, ²¹⁴Bi and others. Quite often their energy spectra have not-allowed shape and are classified as forbidden (unique or non-unique), and sometimes they are not well studied. For example, $^{2\dot{1}4}$ Bi is one of the main backgrounds in 2β experiments due to its high energy release, $Q_{\beta} = 3270 \text{ keV}$; in 19.1% of the cases it decays to the ground state of 214 Po with change in spin and parity $1^- \to 0^+$, $\Delta J^{\Delta\pi} = 1^-$, classified as 1-forbidden non-unique (1 FNU); however, to our knowledge, theoretical calculations of its shape appeared only recently [174], after Ref. [175] which drew attention to this problem. In addition, it was not well measured experimentally. Its shape in graphical form can be found only in old papers (see [176,177,178]), from which it could be concluded that it is not far from the allowed. It is clear that the good knowledge of the shapes of single β decays is very important for a proper fitting of experimental spectra and correct estimation of weak effects possibly present there.

After a summary of the classification of single β decays and shapes of their energy spectra, we review recent achievements in studies and searches for rare β processes.

A collection of partial half-lives (or limits) on β decays of all the naturally occurring nuclides with $Q_{\beta} > 0$ is reported in Table 7.

decay modes in brackets) are reported. Only nuclides with natural abundance greater than zero (i.e. naturally present in nature) and with $Q_{\beta} > 0$ are Table 7: Collection of partial half-lives (or limits) on rare β decays. The branching fractions for the considered decay channel (and, if present, for other considered. The nuclide with the lowest experimental total $T_{1/2}$ reported in this table is $^{40}\mathrm{K}$ with the measured total half-life of $(1.248\pm0.003)\times10^9$ yr. The limits, when not specified, are at 90% C.L.

The results in Refs. [190,183] are given for $g_A = g_V = 1.0$.

^a The 2β decay of ⁴⁸Ca is observed with $T_{1/2} = (6.4^{+1.4}_{-1.1}) \times 10^{19}$ yr [206].

^b Decay to the 131 keV excited level of ⁴⁸Sc (the most probable).

. The 2β decay of $^{96}{\rm Zr}$ is observed with $T_{1/2}=(2.3\pm0.2)\times10^{19}~{\rm yr}$ [207].

^d Decay to the 44 keV excited level of 96 Nb (the most probable).

^e Decay to the first excited level ($E_{exc} = 497 \text{ keV}$) of ¹¹⁵Sn. The average of the most precise measurements is reported. f The α decay is also energetically possible. See Table 1.

5.1 The shapes of β spectra

The beta decays are classified as allowed or forbidden with some level of forbiddenness depending on the change in spin J and parity π between parent and daughter nuclei, as reported in Table 8.

For unique decays, the rate of decay and the shape of the energy spectrum are defined by only one nuclear matrix element. The shape of the β spectrum in general is described as:

$$\rho(E) = \rho_{allowed}(E) \times C(E),$$

where

$$\rho_{allowed}(E) = F(Z, E)WP(Q_{\beta} - E)^2$$

is the distribution for the allowed spectrum; W(P) is the total energy (momentum) of the β particle; F(Z,E) is the Fermi function:

$$F(Z, E) = const \cdot P^{2\gamma - 2} \exp^{(\pi s)} |\Gamma(\gamma + is)|^2,$$

where: $\gamma = \sqrt{1 - (\alpha Z)^2}$; $s = \alpha ZW/P$; $\alpha = 1/137.036$ is the fine structure constant; Z is the atomic number of the daughter nucleus $(Z > 0 \text{ for } \beta^- \text{ and } Z < 0 \text{ for } \beta^+ \text{ decay})$; Γ is the gamma function; W is given in $m_e c^2$ units and P in $m_e c$ units.

Finally, C(E) is an empirical correction factor depending on the energy E of the β particle and is often written as:

$$C(E) = C_1(E)$$
 for FNU decays
= $C_1(E) \cdot C_2(E)$ for FU decays

The function $C_1(E)$ is often parametrized in one of the two possible forms:

either
$$C_1(E) = 1 + a_1/W + a_2W + a_3W^2 + a_4W^3$$

or $C_1(E) = 1 + b_1P^2 + b_2Q^2$,

where Q is the momentum of (anti)neutrino, in $m_e c$ units. The correction factor $C_2(E)$ is parametrized differently for each FU degree:

$$\begin{split} C_2 &= P^2 + c_1 Q^2 & \text{for 1 FU} \\ C_2 &= P^4 + c_1 P^2 Q^2 + c_2 Q^4 & \text{for 2 FU} \\ C_2 &= P^6 + c_1 P^4 Q^2 + c_2 P^2 Q^4 + c_3 Q^6 & \text{for 3 FU} \\ C_2 &= P^8 + c_1 P^6 Q^2 + c_2 P^4 Q^4 + c_3 P^2 Q^6 + c_4 Q^8 & \text{for 4 FU} \end{split}$$

Sometimes alternative forms are used: for 1 FU it is $C_2 = Q^2 + \lambda_2 P^2$, for 2 FU it is the analogous expression with λ_2, λ_4 , and so on, where λ_i are the Coulomb functions calculated in Ref. [208].

The coefficients a_i, b_i, c_i above reported should be evaluated theoretically (they are mixture of products of phase space factors with different nuclear matrix elements) or extracted from experimental measurements. Compilations of the experimental a_i, b_i, c_i can be found in Ref. [209,210, 211,212].

As examples, the left panels of Fig. 24 show the β spectra for ³⁹Ar and ⁴²Ar in comparison with the allowed shapes. In both cases $\Delta J^{\Delta\pi}=2^-$, so such decays are classified as 1 FU; the correction factor is given as $C(E)=Q^2+\lambda_2 P^2$.

The middle panels of Fig. 24 show the β spectra of 42 K (daughter of long-living 42 Ar), measured in few experiments. For the transition 42 K \rightarrow 42 Ca (ground state, probability 81.90%), which is also 1 FU, the correction factor is $C(E) = (Q^2 + \lambda_2 P^2)(1 + aW)$. The transition 42 K \rightarrow 42 Ca (excited level with $E_{exc} = 1525$ keV, 17.641%) is classified as 1 FNU ($\Delta J^{\Delta\pi} = 0^-$), and $C(E) = 1 + a_1/W + a_2W + a_3W^2$. The values of a, a_i and the references to the original works can be found in Ref. [211].

The right panels show the spectra of 40 K and 137 Cs decays. For 40 K \rightarrow 40 Ca (g.s., 89.28%, $\Delta J^{\Delta\pi} = 4^-$, 3 FU); the correction factor is $C(E) = P^6 + c_1 P^4 Q^2 + c_2 P^2 Q^4 + c_3 Q^6$ with $c_1 = c_2 = 1, c_3 = 7$ as measured in Ref. [213]. For 137 Cs \rightarrow 137 Ba (g.s., 5.3%, $\Delta J^{\Delta\pi} = 2^+$, 2 FNU) the correction factor is $C(E) = 1 + a_1/W + a_2W + a_3W^2$ with $a_1 = 0, a_2 = -0.6060315, a_3 = 0.0921520$ as measured in Ref. [214].

This is a demonstration that the forbidden β spectra can significantly deviate from the allowed shapes, and this has to be taken into account in the simulations of the response of the detectors. It should be also noted that sometimes even decays that are classified as allowed have deviations from the allowed shape, as in the case of 14 C, where in the theoretical description the first order terms mutually compensate each other and only the second order terms determine the $T_{1/2}$ and the shape.

6 Investigations of rare β decays

In the following various experimental results on rare beta decay will be presented considering that the careful determination of the shape, of the end-point behaviour of the beta spectrum as well as accurate Q_{β} value determination are crucial

Five naturally occurring isotopes, 40 K, 87 Rb, 138 La, 176 Lu, and 187 Re, β unstable and with long half-lives (as reported in Table 7), are not considered in the following since their decay parameters are well established (very often they create undesirable background in the investigations of rare effects such as 2β decay, dark matter, etc.). In fact 40 K, despite the low natural abundance, produces a very distinctive γ ray of 1460.851 keV following its decay; this allowed a precise determination of its half-life. A similar situation is for 138 La, whose signature of the decay is rather peculiar giving γ rays of 1435.795 keV and 788.744 keV (see e.g. Ref. [215]), and for 176 Lu, producing during its β decay γ rays at 306.78, 201.83 and 88.34 keV. On the contrary, 87 Rb and 187 Re are not accompanied by γ radiation; however, they have large natural abundances (see Table 7), that facilitated the study of their decay.

Table 8: Classification of β decays on the basis of the change in spin J and parity π between the parent and the daughter nuclei.

$\Delta J^{\Delta\pi}$	$\Delta\pi$		for bid denness
$0^+, 1^+$		- allowed;	
$0^-, 1^-, 2^+, 3^-, 4^+, \dots$		forbidden non-unique (FNU);	ΔJ
$2^-, 3^+, 4^-, \dots$	$(-1)^{\Delta J-1}$	- forbidden unique (FU);	$\Delta J - 1$

Fig. 24: Shapes of the β spectra of ^{39,42}Ar, ⁴²K, ⁴⁰K and ¹³⁷Cs. The calculated allowed spectra (black curves) are reported for comparison with the expected spectra on the basis of the degree of forbiddenness. Figure taken from Ref. [175].

6.1 The highly forbidden β decay of 48 Ca

In the case of 48 Ca, the double β decay channel competes with the ordinary single β decay channels. In addition, the single β decay of 48 Ca can populate few excited levels of 48 Sc (see Fig. 25).

Fig. 25: The single (and double) β decay of $^{48}\mathrm{Ca}.$ Figure taken from Ref. [216].

The mechanism of the ordinary β decay of ⁴⁸Ca results from two features of the decay. Firstly, the large change in

angular momentum ($\Delta J = 4, 5, \text{ or } 6$) between the initial and final nuclear states, and secondly the energy release which is small. The experimentally measured Q_{β} value for the 6^{th} -forbidden ground-state-to-ground-state transition is (279 ± 5) keV [63]. With this value, the Q_{β} values for the 4^{th} -forbidden branches are evaluated to be 148 keV (5⁺) and 27 keV (4^+) with an uncertainty of 5 keV each one. The probability of β decay is determined by the change $\Delta J^{\Delta\pi}$ (an increase in ΔJ by 1 unit leads to the increase of $T_{1/2}$ by ~ 3 orders of magnitude) and by the energy release $(T_{1/2} \sim 1/Q_{\beta}^5)$. The transition to the 131 keV level is estimated as the most probable and, after some initial studies by Warburton [217] and by Aunola, Suhonen, and Siiskonen [181], a value $T_{1/2} = (2.6 - 7.0) \times 10^{20}$ yr was estimated [182]. The process is not yet observed; however, it should be noted that the second order process - two neutrino 2β decay to ⁴⁸Ti – is faster in this case, as already underlined; it was already observed with $T_{1/2} = 6.4 \times 10^{19}$ yr [206]. The shape of 48 Ca β spectrum was calculated in Ref. [183].

The potentiality of the β – γ coincidence technique was exploited to search for the ordinary highly forbidden β decay (see e.g. Ref. [216]). In fact, e.g. after a ⁴⁸Ca β decay, a γ quantum of 131 keV is expected from the excited nuclear level of ⁴⁸Sc and, subsequently, γ quanta of 984, 1037 and 1312 keV are emitted when the daughter ⁴⁸Sc decays to the excited nuclear levels of ⁴⁸Ti.

In Ref. [216], by using a 1.11 kg CaF₂(Eu) scintillator partially surrounded by low background NaI(Tl) detectors, the process was investigated by searching in the experimental data for the β decay of the daughter nuclei 48 Sc to 48 Ti with $T_{1/2}=43.7$ h. With large probability (89.98%) the decay goes to the excited 6^+ level of 48 Ti with excitation energy 3333 keV. In this case the emitted electron has energy up to 656 keV, and three γ quanta are emitted as well with energies 1037, 1312 and 984 keV [218]. In the remaining 10.02% of the cases the daughter nucleus ⁴⁸Sc decays to ⁴⁸Ti level with energy 3508 keV (electron energy up to 482 keV); the subsequent emitted γ quanta are listed in Fig. 25. Thus, the coincidence technique can be used to determine the half-life of the β decay of ⁴⁸Ca since the ⁴⁸Ca–⁴⁸Sc chain is in equilibrium. With this procedure a limit of $T_{1/2} > 2.4 \times 10^{18}$ yr (at 90% C.L.) [216] was obtained for the highly forbidden β decay

However, the best experimental limit $T_{1/2} > 2.5 \times 10^{20}$ yr was obtained with a 400 cm³ HPGe detector and 24.558 g of enriched ⁴⁸CaF₂ powder, by looking for γ rays following β^- transitions of ⁴⁸Ca [180]. The obtained limit is not far from the above mentioned theoretical estimations.

6.2 Electron capture and β decay of 50 V

⁵⁰V can decay both through electron capture to ⁵⁰Ti with energy release of $Q(\varepsilon) = 2207.6(4)$ keV and through β^- decay to ⁵⁰Cr with $Q(\beta^-) = 1038.06(30)$ keV [63] (see Fig. 26). In both cases the change in spin for the g.s. to g.s. transitions is $6^+ \to 0^+$, and transitions to the first 2^+ excited levels of ⁵⁰Ti (1553.8 keV) or ⁵⁰Cr (783.3 keV) are more probable (by orders of magnitude). With $\Delta J^{\Delta\pi} = 4^+$ these decays are classified as 4th-forbidden non-unique. ⁵⁰V is one of the only 3 nuclei where β processes with $\Delta J^{\Delta\pi} = 4^+$ were measured (the other two are ¹¹³Cd and ¹¹⁵In).

Fig. 26: Scheme of the $^{50}{\rm V}$ decay. Energies are in keV. Data are from [219,63,184].

The low natural abundance of 50 V ($\delta = 0.250(10)\%$ [62]) and the large expected half-lives make its experimental investigations rather difficult. Different approaches

were used to search for $^{50}{\rm V}$ decay. On the first stages, Geiger counters and proportional counters with thin V-containing foils were applied to look for X rays emitted in result of electron capture and for electrons emitted in β^- decay. Later on, NaI, Ge(Li) and HPGe detectors and massive V sources were used to look for the 783 and 1554 keV γ rays; these techniques were more sensitive than the previous ones.

To our knowledge, the first search for the decay of 50 V was performed in 1949 [220]; a thin-walled beta counter and also photographic plates were used; the activity was not observed ($T_{1/2}$ limits were not reported). The summary of the subsequent experiments is given in Table 9. Early reports on positive observations of electron capture and β^- at level of $T_{1/2} \sim 10^{14} - 10^{16}$ yr [221,222,223] were not supported in later investigations. The detection of the 783 keV γ peak expected in 50 V β^- decay by Simpson et al. in 1989 [224] with $T_{1/2}(\beta^-) = (8.2^{+13.1}_{-3.1}) \times 10^{17}$ yr was quite uncertain and not confirmed in the subsequent investigations; the best known limit obtained in a recent experiment [184] is $T_{1/2}(\beta^-) > 1.9 \times 10^{19}$ yr.

On the contrary, the 1554 keV γ peak, expected in the electron capture branch of the 50 V decay, is confidently observed in all experiments since 1984, with the recent, most accurate result of $T_{1/2}(\varepsilon) = (2.67^{+0.16}_{-0.18}) \times 10^{17}$ yr [184].

The half-life of the 50 V was calculated in nuclear shell model by Nishimura in 1979 [185] as: $T_{1/2}(\varepsilon)=1.5\times 10^{16}$ yr, $T_{1/2}(\beta^-)=9.04\times 10^{17}$ yr, which is in disagreement with the experimental values. Recent calculations of Haaranen et al. [186] for the electron capture branch: $T_{1/2}(\varepsilon)=(5.13\pm 0.07)[(3.63\pm 0.05)]\times 10^{17}$ yr given for $g_A=1.00[1.25]$ is in good agreement with the measured value [184]. The predicted value for β^- decay $T_{1/2}(\beta^-)=(2.34\pm 0.02)[(2.00\pm 0.02)]\times 10^{19}$ yr [186] is not far from the best achieved limit 1.9×10^{19} yr [184], that gives hope to observe the effect in near future.

The shape of $^{50}{\rm V}~\beta^-$ spectrum was calculated in Ref. [183].

Recently, an YVO₄ crystal (5 cm³, $\oslash 1.8 \times 2$ cm, mass of 22 g) was tested as cryogenic scintillating bolometer [232]; the light yield for beta/gamma particles was measured to be (59.4 \pm 0.1) keV/MeV and for alpha particles 9 – 12 keV/MeV (dependent on the energy). The full width at half of maximum (FWHM) for the 661 keV line of ¹³⁷Cs was determined to be (9 \pm 2) keV. The sensitivity of the measurements of the YVO₄ scintillating bolometer with an additional detector registering the 783 keV γ quantum was estimated at level of $T_{1/2} \sim 1 \times 10^{20}$ yr which could allow the observation of ⁵⁰V β ⁻ decay for the first time and the measurement of its β ⁻ shape.

6.3 96 Zr β decay

The situation of 96 Zr is analogous to the case of 48 Ca (the decay scheme is shown in Fig. 27): the single β decay to 96 Nb is possible, but not yet observed ($T_{1/2} > 3.8 \times 10^{19}$ yr [191] for the most probable transition to the 44 keV excited level), while $2\nu 2\beta$ decay has been already measured

Table 9: Summary of the investigations of ⁵⁰V decay.

with $T_{1/2}=(2.3\pm0.2)\times10^{19}$ yr [207]. The shape of the $^{96}{\rm Zr}$ β spectrum was calculated in Ref. [183].

LNGS 3600 m w.e.

Fig. 27: Decay scheme for the A=96 triplet showing the energy position of 96 Zr with respect to its neighbor 96 Nb and 96 Mo; the energies are in keV. Figure taken from Ref. [233].

Recently single and double beta decay Q values among the triplet $^{96}\mathrm{Zr}, ^{96}\mathrm{Nb},$ and $^{96}\mathrm{Mo}$ have been determined in Ref. [233] by means of high-precision mass measurements using the JYFLTRAP mass spectrometer at the IGISOL facility of the University of Jyväskylä [234, 235]; in particular, the energy of the decay has been measured as $Q_{\beta}(^{96}\mathrm{Zr}) = 163.96(13)$ keV.

This single beta decay is of special importance being the main branch fourfold unique forbidden, which is an alternative decay path to the ⁹⁶Zr double beta decay; thus, its observation can provide one of the most direct tests of the neutrinoless double beta decay nuclear-matrix-element calculations, as these can be simultaneously performed for both decay paths with no further assumptions. In the latter reference the theoretical single beta decay rate has been re-evaluated using a shell-model approach, which also indicates ⁹⁶Zr single beta decay life-time reachable in near future for an experimental verification; in fact, for the most probable transition to the 44 keV excited level the value: $T_{1/2} = 11 \times 10^{19}$ yr, has been estimated. The uniqueness of the decay also supports the relevance of a dedicated experiment which could allow an investigation into the origin of the quenching of the axial-vector coupling constant q_A .

6.4 113 Cd β decay

The isotope $^{113}\mathrm{Cd}$ is one of only three nuclei (the two others are $^{50}\mathrm{V}$ and $^{115}\mathrm{In})$ with four-fold forbidden β decays that can be practically investigated. The high order of forbiddenness, together with rather low energy of the decay: $Q_{\beta}=323.83(27)~\mathrm{keV}$ [63], leads to a large half-life: in the range of $\sim 10^{16}~\mathrm{yr}.$

After a number of unsuccessful attempts since 1940 (see [236,237] and references in Ref. [238]), the β activity of $^{113}\mathrm{Cd}$ was detected for the first time in 1970 [238] by

using a sample of cadmium oxide enriched in the isotope ^{113}Cd installed in a proportional counter. The experiment has measured the ^{113}Cd half-life as $T_{1/2} = (9.3 \pm 1.9) \times 10^{15}$ yr. The β spectrum of ^{113}Cd was observed for the first time with the help of a small 0.27 cm³ CdTe detector in Ref. [239], as reported in Fig. 28.

Fig. 28: Low-energy spectrum from the CdTe detector 16 mm diameter and 2 mm thick, with an active area of 1.33 cm², measured over 87.4 h live time. The increase in counts below 320 keV is ascribed to the β decay of $^{113}{\rm Cd}$ with half-life $T_{1/2}\sim 10^{16}$ yr. Figure taken from Ref. [239].

Both the half-life and the spectral shape of 113 Cd were investigated by using CdWO₄ low temperature bolometer in Refs. [240,241]. Further improvement of the accuracy was achieved with a CdWO₄ crystal scintillator at the Solotvina underground laboratory [242] and in the experiment [243] with a CdZnTe detector.

The most accurate measurement of the $^{113}\mathrm{Cd}~\beta$ decay was realized in the experiment [193] at the LNGS underground laboratory by using the same CdWO₄ crystal scintillator as in Ref. [242] (to minimize its cosmogenic activation, the crystal has been stored underground at the Solotvina laboratory after the experiment [242], and then was transported in a thick-wall iron container to the LNGS laboratory). The shape of the spectrum was precisely measured, and the half-life of ¹¹³Cd was determined as $T_{1/2} = (8.04 \pm 0.05) \times 10^{15} \text{ yr [193]}$. The high accuracy of the experiment was achieved thanks to the deeper experimental site, the better discrimination capability between the photomultiplier noise and the scintillation events, the larger exposure, and the lower level of background. In addition, in the experiment [193] the energy resolution was slightly better than that in the Solotvina experiment [242]. A summary of the experiments for the β decay of ¹¹³Cd is given in Table 10.

Fig. 29: The analytical beta spectrum of 113 Cd obtained after de-convolution of the experimental β spectrum [193], with uncertainties (upper panel). Uncertainties of different origin and the cumulative uncertainties of the spectrum are shown in the upper panel (lower panel).

As noted in Refs. [244, 245, 190], the investigations of the spectral shape of non-unique forbidden β decays have the potential to give an estimate of the weak interaction coupling constants g_A and g_V by comparing a theoretical shape with the experimental spectrum. The approach provides an important possibility to solve the g_A problem of the neutrinoless double beta decay [246,247,248,170]. However, the spectrum measured in [193] and utilized in the work [244] to estimate the g_A constant, was without systematic uncertainties which limited the capability of the approach to find the most suitable nuclear models and to estimate g_A . We have re-analyzed the data of the experiment [193] by adding the systematic uncertainties. Besides, we have corrected the energy scale of the β spectrum by taking into account that the beta-decay energy measured in [193] $(Q_{\beta} = [344.9 \pm 0.2(\text{stat}) \pm 21(\text{syst})] \text{ keV})$ is substantially higher than the current table value: $Q_{\beta} =$ 323.83(27) keV [63]. We ascribe this excess to the quenching of the scintillation light efficiency of the CdWO₄ scintillator for gamma quanta (used to calibrate the detector energy scale). The quenching is a well known effect in scintillation detectors (see, e.g., [89,249]). In case of β particles the effect is related to the non-proportionality in the scintillation response [250], which is present also in CdWO₄ crystal scintillators [251]. Thus, we have transformed the energy spectra measured in [193] to obtain the beta-spectrum endpoint at the table value of ¹¹³Cd. The result is presented in Fig. 29 together with the estimated systematic uncertainties. The main sources of the system-

Table 10: Half-lives (limits) relatively to β decay of ¹¹³Cd.

atic uncertainties are due to the PMT noise (the effect is essential at low energies), and ambiguity of the background model subtracted from the experimental data.

6.5 115 In β decay

$6.5.1~^{115} {\rm In}~eta~{ m decay}$ to the ground state of $^{115} { m Sn}$

 $^{115} \mathrm{In}$ is present in nature with a large abundance of $\delta = 95.719(52)\%$ [62]. However, it is unstable in relation to beta decay to $^{115} \mathrm{Sn}$, with $Q_{\beta} = (497.489 \pm 0.010)$ keV [63]. It has one of the longest half-lives of the observed single β^- decays; this is due to the large difference in spin between the parent $(9/2^+)$ and the daughter nuclei $(1/2^+$ for the ground state of $^{115} \mathrm{Sn}$). With $\Delta J^{\Delta\pi} = 4^+$, the decay is classified as 4-fold forbidden non-unique, similar to that of $^{113} \mathrm{Cd}$.

The 115 In half-life was measured for the first time in 1950 as $T_{1/2} = (6 \pm 2) \times 10^{14}$ yr [236] with the subsequent results as: $\approx 1 \times 10^{14}$ yr [252], $(6.9 \pm 1.5) \times 10^{14}$ yr [253], $(5.1 \pm 0.4) \times 10^{14}$ yr [237]. Currently, the recommended value $T_{1/2} = (4.41 \pm 0.25) \times 10^{14}$ yr was obtained in 1978 [195,196]; no results have been published since then.

While for $^{113}\mathrm{Cd}$ the shape of the β spectrum was measured in a rather large number of works, on the contrary the shape of ¹¹⁵In was measured only in [196]⁴. This experiment, done with liquid scintillator (LS) loaded by In at 51.2 g/L, had a number of drawbacks: the measurements were performed at sea level (thus the background was quite high); the quenching of low energy electrons, which is rather strong for LS, was not taken into account; the energy resolution was not known exactly; and the energy threshold was quite high (around 50 keV). Recently, this decay was measured again in ultra-low background conditions with a scintillating $LiInSe_2$ bolometer $((8 \times 15 \times 19) \text{ mm}^3, 10.2 \text{ g})$ at the Modane underground laboratory [254]. The shape of the spectrum was obtained with $\simeq 20$ keV energy threshold; a preliminary value of the half-life is $T_{1/2} = (2.9 \pm 0.1 (stat.)) \times 10^{14} \text{ yr. Theo-}$ retical calculations of the 115 In β shape can be found in Refs. [244, 245, 190].

$6.5.2^{115} \text{In} \rightarrow^{115} \text{Sn}^* \beta \text{ decay}$

Until 2005, the $^{115}\text{In} \rightarrow ^{115}\text{Sn}$ decay was considered as 100% g.s. to g.s. transition, but in 2005 also the decay to the first excited level of $^{115}\mathrm{Sn}$ ($E_{exc}=(497.334\pm$ 0.022) keV [255]) was observed for the first time [256, 257]. A sample of metallic indium (mass of 929 g) was measured for 2762 h with 4 HPGe detectors ($\simeq 225 \text{ cm}^3 \text{ each}$) installed deep underground at LNGS. The branching ratio of the decay was estimated as $b.r. = (1.18 \pm 0.31) \times 10^{-6}$ which corresponds to the partial half-life $T_{1/2} = (3.73 \pm$ $0.98) \times 10^{20}$ yr [256]. The atomic mass difference Δm_a between 115 In and 115 Sn (equal to the energy release Q_β in $^{115} \mathrm{In}~\beta$ decay) at the time of measurements [256] was known with quite low accuracy: $Q_{\beta} = (499 \pm 4) \text{ keV } [258];$ however, in 2009 it was measured with extremely high accuracy of 10 eV: $Q_{\beta} = (497.489 \pm 0.010) \text{ keV } [259].$ Taking into account that the energy of the ¹¹⁵Sn first excited level was known as $E_{exc} = (497.334 \pm 0.022)$ keV [255], the energy release in the decay $^{115}\text{In} \rightarrow ^{115}\text{Sn}^*$ was equal to $Q_{\beta}^* = (155 \pm 24) \text{ eV}$, that is the lowest known Q_{β} value among the observed β decays (the next one is $Q_{\beta}=(2.467\pm0.002)$ keV for $^{187}{\rm Re}$ [63]). The observation [256] was confirmed in measurements of In sample (2566 g) at the HADES underground laboratory with 3 HPGe detectors; slightly more precise values of half-life were obtained: $T_{1/2} = (4.1 \pm 0.6) \times 10^{20} \text{ yr [197]}$ and $T_{1/2} = (4.3 \pm 0.5) \times 10^{20} \text{ yr } [198].$

Very recently the energy of the excited 115 Sn level was precisely remeasured in two experiments. In the first one, a 30 mg Sn target enriched at 70% in 114 Sn (the natural isotopic abundance of 114 Sn is: $\delta(^{114}$ Sn) = 0.66% [62]) was irradiated by cold neutrons; the excited 115 Sn level was populated in the 114 Sn(n, γ) 115 Sn reaction. The result is: $E_{exc} = (497.316 \pm 0.007)$ keV, that leads to $Q_{\beta}^* = (173 \pm 12)$ eV [261].

In the second one, a 230 mg Sn sample enriched in $^{115}{\rm Sn}$ to 50.7% (natural isotopic abundance: $\delta(^{115}{\rm Sn})=0.34\%)$ was irradiated by a proton beam. The $^{115}{\rm Sb}$ radioactive isotope, created in the $^{115}{\rm Sn}({\rm p,n})^{115}{\rm Sb}$ reaction, decays with $T_{1/2}=32$ min to $^{115}{\rm Sn}$ populating the 497 keV level with $\simeq96\%$ probability. The measurements gave an even more precise value $E_{exc}=(497.342\pm0.003)$ keV leading to $Q_\beta^*=(147\pm10)$ eV [260]. It is important to note that also the energy of the $^{115}{\rm Cd}$ 492 keV

 $^{^4}$ A crude measurements of the $^{115}{\rm In} \to ^{115}{\rm Sn}~\beta$ shape were done in [253].

 γ quantum was measured in this experiment as $E_{\gamma} = (492.350 \pm 0.003)$ keV, which is in excellent agreement with the table value: (492.351 ± 0.004) keV $[255]^5$. This 115 Cd γ peak is at the distance of only 5 keV from the 497 keV peak of the 115 Sn, which increases the credibility of the obtained Q_{β}^* value.

The decay scheme of $^{115}\text{In} \rightarrow ^{115}\text{Sn}$ is shown in Fig. 30.

Fig. 30: Scheme of the 115 In decay. The energies are in keV. The data are from [259,255,260].

The half-life for the $^{115}{\rm In} \rightarrow ^{115}{\rm Sn}^*$ decay was calculated in [197,262] as a function of the Q^*_β value, however for $Q^*_\beta \simeq 150$ eV there is a disagreement by $\simeq 1$ order of magnitude which could be related to atomic effects, essential for such low energies and not accounted for in the calculations. The shape of the $^{115}{\rm In} \rightarrow ^{115}{\rm Sn}^*$ spectrum ($\Delta J^{\Delta\pi} = 3^+$, classified as 2-fold forbidden unique) was calculated in [263]. Deviations from the theoretical shape could be used to limit (or to measure) the neutrino mass [256,257], however, taking into account the high $T_{1/2}$ and the low Q^*_β , such measurements will be extremely difficult.

There are also other nuclides which are candidates for the lowest Q_{β}^* value in their decays to excited levels of daughter nuclei: ⁷⁷As, ⁷⁹Kr, ¹⁰⁹In, ¹¹¹In, ¹¹⁵Cd, ¹³¹I, ¹³⁵Cs, ¹⁴⁶Pm, ¹⁴⁹Gd, ¹⁵⁵Eu, ¹⁵⁹Dy, ¹⁶¹Ho, ¹⁸⁸W, and ¹⁸⁹Ir [264,265,266,267] (see also the recent review [169] and an additional list of candidates in [268]); these decays are not observed yet and their Q_{β} values are known currently with a low accuracy (\simeq 1 keV or worse). Precise measurements of the atomic mass differences and possibly of the energies of the excited levels are needed in all these cases. Because of the evident restriction: $m_{\nu} \leq Q_{\beta}$, if – luckily – an extremely low Q_{β}^* value will be measured for one of these candidates, say, $Q_{\beta}^* = 1$ eV, one can soon obtain an interesting limit on neutrino mass: $m_{\nu} \leq 1$ eV.

6.6 123 Te electron capture

 $^{123}\mathrm{Te}$ (a naturally occurring isotope of Te) has an isotopic abundance of (0.89 \pm 0.03) % [62] and a Q-value

of 51.91(7) keV [63]. Because of the large spin difference between the parent and the daughter nuclei, the electron capture occurs primarily from the L and M shells [269,95] while the capture from the K shell is suppressed by about three orders of magnitude.

It is a second forbidden unique electron capture. It should occur to the ground state of ¹²³Sb. This process, although expected to occur, has never been experimentally observed. Measurements in an old work [237] concentrating on the detection of the 26.1 keV photons of the K X-rays from 123 Sb resulted in a half-life $T_{1/2}=(1.24\pm$ $0.10) \times 10^{13}$ yr. However, in Ref. [270] it was found that the real value is 6 orders of magnitude larger: $T_{1/2} = (2.4)$ ± 0.9) × 10¹⁹ yr. Later, also this result was found incorrect, and only a limit was set for electron capture of ¹²³Te from the K shell as $T_{1/2} > 5.0 \times 10^{19}$ yr [204]. The observation of Ref. [270] was explained with the electron capture in 121 Te; this unstable isotope was created in the TeO₂ crystals, used in the measurements, through neutron capture by ¹²⁰Te while the crystals were at sea level. The natural abundance of ¹²⁰Te is very small, $\delta = 0.09\%$ [62], and this is a good demonstration how even a tiny effect may mimic another rare effect. Taking into account the predicted K electron capture branching ratio, the corresponding lower limit on the ¹²³Te electron capture half-life is $T_{1/2} > 9.2$ $\times 10^{16}$ yr, which can be theoretically interpreted only on the basis of a strong suppression of the nuclear matrix elements.

Considering the improved sensitivity of present TeO₂ thermal detectors, this limit could be improved orders of magnitude by CUORE apparatus [271,272]. Being the source part of the active volume, a signal corresponding to the total binding energy of the captured electron can be measured with almost 100% efficiency. Moreover, the excellent energy resolution is a useful tool to distinguish externally generated γ rays from X-rays and electron cascades. For the (suppressed) K-capture a line at 30.5 keV is expected, while for the most probable L3 capture (L1 and L2 intensities are about one and three orders of magnitude lower than L3 [95]) the line should appear at 4.1 keV. Finally, the M transitions are all beyond any possible detection capability given their too small energy release (of the order of keV). In addition, in a high granularity array like CUORE, background events have a high chance of generating energy depositions in multiple crystals, while a genuine electron capture process is most likely a singlecrystal event. Other possible backgrounds can come from the electron capture of 121 Te and ^{121}m Te, both generated via neutron activation of the naturally occurring $^{120}\mathrm{Te}.$ The neutron flux in the underground location of CUORE, however, is small enough to assume the in situ activation to be negligible, while the activity generated between the growth of the crystals and the storage underground is expected to have already decayed by many orders of magnitude (and could anyway be tagged thanks to its wellknown time-dependence).

The experimental measurement of the ¹²³Te half-life has important theoretical implications: very low rates are predicted if a strong (up to six orders of magnitude [269])

 $^{^{5-115}\}mathrm{Cd}$ was produced in the reaction $^{114}\mathrm{Cd}(n,\gamma)^{115}\mathrm{Cd}$ with the Cd target enriched in $^{114}\mathrm{Cd}$ to 99% (natural isotopic abundance: $\delta(^{114}\mathrm{Cd})=28.8\%).$

suppression of the nuclear matrix element is generated by the cancellation between particle–particle and particle–hole correlations. An experimental study of this effect would be a severe test of the nuclear models that are used to calculate the matrix elements for rare electroweak decays [205].

An alternative search for the second forbidden electron capture of $^{123}\mathrm{Te}$ was performed with CdZnTe semiconductor detectors [273] setting a lower half-life limit (for ε from the K shell) of $T_{1/2}>3.2\times 10^{16}$ yr (95% C.L.). The study was performed within a pilot project for the COBRA experiment. A more sensitive experiment could only be done with a setup using a larger amount of CdZnTe detectors.

Although the decay schemes for 123 Te and 123 Sb are known, the mass difference of 123 Te and 123 Sb, which governs the half-life of ¹²³Te, was not well known. It was recently measured [274] with a direct and high precision measurement. Since the expected mass difference, i.e. Qvalue, between the parent and the daughter nucleus is close to the energetic region of the total electron binding energies for Te, accurate and precise data are required. All the attempts of determining the half-life concern the ground state of neutral ¹²³Te. However, in stars nuclides are ionized leading to a certain charge-state distribution, which depends on the temperature of the stellar interior. The decay energy for the electron capture from ionic ground states is expected to be smaller than that for neutral states. This substantially increases the half-life of ionized ¹²³Te. In addition, it was noted that in hot stellar conditions the nuclei with populated excited states can undergo electron capture, whose strength depends on the excitation energy, the mass difference between the neutral parent and daughter atoms, the ionic charge state, and the astrophysical conditions [275, 276, 277]. Such a possibility was verified [278] for long-lived beta-emitters. The mass difference between ionic states depends on the mass difference of the neutral atoms and the excitation energy of the nuclear state, which can be populated in the stellar environment. Accurate knowledge of the former is important for the capture process, especially for small decay energies close to the binding energy of K-electrons equal to 30.49 keV for the electron capture in ¹²³Te.

The basic processes involved in heavy element nucle-osynthesis are the slow (s) and rapid (r) neutron capture processes, and, to a lower extent, the p process. The sprocess forms nuclides along the "valley of stability", over relatively long time periods during the helium burning phase of stellar evolution. Tellurium is unique in that, it is the only element with three s-only isotopes (122,123,124 Te) and they offer a unique opportunity to test s-process systematics [279].

In particular an investigation of the decay-branches, attributed to the electron capture from excited states – impossible under terrestrial conditions – can shed light on the production and depletion of tellurium isotopes in stars. The role of the electron-capture process from excited states of ¹²³Te in stellar conditions is discussed in Ref. [274]. Based on reliable data the impact on the effective decay rate of ¹²³Te in stellar conditions has been investi-

gated and revealed dramatic changes in electron capture probabilities of this pure s-process nuclide, which exceeds the terrestrial value by many orders of magnitude. Thus the terrestrially nearly stable nuclide 123 Te becomes radioactive in stars. This can lead to a depletion of 123 Te in the s-process nucleosynthesis.

6.7 180m Ta β decay

It is interesting to note that 180m Ta has some peculiar features. In fact, to our knowledge it is: i) the only nuclide present in nature in the isomeric state; ii) one of the rarest naturally occurring isotopes; iii) the longest lived metastable state; iv) the heaviest nuclide among the nine odd-odd nuclei present in nature.

Tantalum is present in nature in two isotopes, the stable $^{181}\mathrm{Ta}$ and the excited level, $^{180m}\mathrm{Ta}$ ($\delta=0.012\%$ [62]), at $E_{exc}=77$ keV. The ground state of $^{180}\mathrm{Ta}$ is unstable, since it quickly decays with $T_{1/2}\simeq 8.1$ h by electron capture and β^- with branching ratios 85(3)% and 15(3)%, respectively.

Fig. 31: The decay schema of $^{180m}\mathrm{Ta}.$ Figure modified from Ref. [280].

 180m Ta has a high spin of 9^- , while the ground state has a spin of 1^+ . Due to the high spin difference, the isomeric transition to the ground state is very slow, and the decay of 180m Ta can also occur by electron capture and β^- decay into excited levels of 180 Hf and 180 W, respectively. The decay scheme is shown in Fig. 31. The transitions are towards the level with the lowest spin difference, that is the 6^+ levels of 180 Hf and 180 W. Afterward an electromagnetic cascade down to the ground state occurs. The transitions can be classified as $\Delta J^{\Delta\pi}=3^-$, so they are 3-fold forbidden non-unique (see Table 8). The half-lives in relation to the isomeric transition (which occurs mainly by conversion electrons), the ε and β^- channels were calculated recently as: $T_{1/2}({\rm IT})=8.0\times 10^{18}~{\rm yr},$ $T_{1/2}(\varepsilon)=1.4\times 10^{20}~{\rm yr},$ $T_{1/2}(\beta^-)=5.4\times 10^{23}~{\rm yr}$ [202], respectively.

Table 11: Recent results on 180m Ta half-lives in the electron capture and β^- channels. They have been obtained by γ -spectrometry using the different detectors reported in the first column. Only the results obtained after 1980 are included in the Table; for a complete list see Ref. [280]. The two experiments in Ref. [281,282] have been performed using enriched Tantalum.

Detector	Lower half-life limits			Year, reference
	arepsilon	eta^-	Total	
Ge(Li), enriched Ta	$5.6 \times 10^{13} \text{ yr}$	$5.6 \times 10^{13} \text{ yr}$	$2.8 \times 10^{13} \text{ yr}$	1981 [281]
HPGe, enriched Ta	$3.0 \times 10^{15} \text{ yr}$	$1.9 \times 10^{15} \text{ yr}$	$1.2 \times 10^{15} \text{ yr}$	1985 [282]
HPGe	$1.7 \times 10^{16} \text{ yr}$	$1.2 \times 10^{16} \text{ yr}$	$7.2 \times 10^{15} \text{ yr}$	2006 [283]
Sandwich HPGe	$4.45 \times 10^{16} \text{ yr}$	$3.65 \times 10^{16} \text{ yr}$	$2.0 \times 10^{16} \text{ yr}$	2009 [284]
Sandwich HPGe	$2.0 \times 10^{17} \text{ yr}$	$5.8 \times 10^{16} \text{ yr}$	$4.5 \times 10^{16} \text{ yr}$	2017 [280]
HPGe	$2.0 \times 10^{17} \text{ yr}$	$1.7 \times 10^{17} \text{ yr}$	$9.0 \times 10^{16} \text{ yr}$	2018 [201]

The decay of 180m Ta (through electron capture and β^{-}) has not yet been observed; thus, 180m Ta is considered a quasi-stable nuclide. By the way, kinematically it can also decay via α emission with $Q_{\alpha} = (2101.6 \pm 2.5)$ keV (see Table 1), but this decay is strongly disfavoured compared with the ε/β^- channels.

Several measurements have been performed in the past to look for electron capture and β^- decay of 180m Ta; they are summarized in Table 11.

Well established limits were set in the recent work of Ref. [280] as: $T_{1/2}(\varepsilon)>2.0\times 10^{17}~\rm{yr}$ and $T_{1/2}(\beta^-)>5.8\times$ 10^{16} yr (90% C.L.). The total half-life is $T_{1/2} > 4.5 \times 10^{16}$ yr (90% C.L.) [280].

The measurements [280] were performed in the HADES laboratory in Belgium, where the atmospheric μ flux is reduced by a factor 5000 compared to the surface. The used detectors were made of two coaxial HPGe detectors, Ge6 and Ge7, placed with their end-caps faced each other (sandwich detector system). The sample, placed between the two HPGe detectors, was made of six 2 mm thick disks with 100 mm diameter of high purity Tantalum of natural isotopic composition. The total mass was 1500.33 g, corresponding to 180 mg of $^{180m}\mathrm{Ta}.$

Some examples of the collected energy spectra accumulated in the total time of 176 days are reported in Fig. 32. The β^- channel was studied by the γ peak at 234.0 keV; two background peaks are also present in the fit region coming from contaminations of ²¹²Pb and ²²⁴Ra. As concerning the electron capture channel, it was studied by means of the γ peaks at 215.4 keV and 332.3 keV; also in this case two background γ peaks from ²²⁸Ac are included in the fit. The other γ peaks expected by 180m Ta decay were not used either for the presence of higher background or of lower detection efficiency.

Recently, the results from the Kamioka Underground Observatory (2700 m w.e.) were reported [201]. In this experiment, a sample of Ta with mass of 863 g was measured with HPGe detector for 8597 h. Only limits were set as: $T_{1/2}(\varepsilon) > 2.0 \times 10^{17} \text{ yr}, \ T_{1/2}(\beta^-) > 1.7 \times 10^{17} \text{ yr}, \text{ and total } T_{1/2} > 9.0 \times 10^{16} \text{ yr (which are currently the best)}.$

In conclusion, no signal was observed for either decay mode and new limits were set, as reported in Table 11. Improvements in the sensitivity of the experiments can be expected by using much lower background set-ups, in a deeper underground site and possibly with enriched sam-

6.8 222 Rn β decay

The 222 Rn isotope is known to undergo α decay in 100% of the cases ($Q_{\alpha} = 5590 \text{ keV}$, $T_{1/2} = 3.82 \text{ d}$). However, it was recently noted [249] that single β decay (1 FU) is also energetically possible with $Q_{\beta} = (24 \pm 21) \text{ keV}^6$. After the β decay of ²²²Rn, one should observe a chain of α and β decays which is different from that following its α decay. Looking for these chains in a BaF₂ crystal scintillator polluted by $^{226}\mathrm{Ra}$, only a limit on the half-life of the $^{222}\mathrm{Rn}$ β decay was set: $T_{1/2}(\beta) > 8.0$ yr [249]. This search was performed using a 1.714 kg BaF₂ detector installed deep underground at LNGS in the low background DAMA/R&D set-up.

The β decay to the ground state $^{222}{\rm Rn}(0^+) \rightarrow ^{222}{\rm Fr}(2^-)$ occurs with change in spin and parity: $\Delta J^{\Delta\pi} = 2^-$, and thus it is classified as first forbidden unique.

The compilation of Log ft values in Ref. [285] gives the average value Log $ft = 9.5 \pm 0.8$ for all known 216 first forbidden unique β decays. Using the LOGFT tool at the National Nuclear Data Center [286], the central value Log ft = 9.5 corresponds to a half-life 4.8×10^5 yr for $Q_{\beta}=24~{\rm keV}$; thus, considering the uncertainties in the Q_{β} value, the half-life is $6.7\times 10^4~{\rm yr}$ for $Q_{\beta}=45~{\rm keV}$ and $2.4\times 10^8~{\rm yr}$ for $Q_{\beta}=3~{\rm keV}$.

The β decay of $^{222}{\rm Rn}$ leads to a chain of subsequent

decays:

The first attempt to experimentally search for the β decay of ²²²Rn was performed in Ref. [249]; this is due,

 $^{^{6}}$ $^{222}\mathrm{Rn}$ is an example of rare β decay, despite its short halflife, because of a rather low branching ratio.

Fig. 32: Three energy spectra measured by HPGe detectors used in the experimental set-up of Ref. [280]. Top: ROI for the β^- channel of 180m Ta decay. Middle and bottom: ROI for the electron capture channel. The best fit is shown in blue (online) and the best fit with the signal peak set to the 90% C.L. half-life limit is shown in red (online). Figures taken from Ref. [280].

in particular, to the small half-life relatively to α decay (3.82 d [287]), the low Q_{β} value (typically below the en-

ergy threshold) and the background level at low energies. The live time was 101 h considering the quite-high activity of ²²⁶Ra (parent of ²²²Rn): 13.4 Bq in the used BaF₂ crystal. The possibility of pulse-shape analysis to discriminate between α and β/γ events, and the knowledge of the expected energies and time differences between events give the possibility to search for the peculiar chain in the accumulated data. However, due to the high total event rate in the BaF₂ detector (75 counts/s), it was not feasible to look for events with $T_{1/2}=14.2$ m ($^{222}{\rm Fr}$ β decay) because of the many events of other origin; at most, we should have restricted to the α decay of ²²²Ra with $T_{1/2} = 38.0$ s. Moreover, also the α decay of ²¹⁴Po with $T_{1/2} = 164.3 \ \mu s$ could not be considered because of the 1.65 ms dead time in the measurements resulting in a very low efficiency and in a low sensitivity. Thus, practically, only the decay chain: $^{222}{\rm Fr} \rightarrow ^{222}{\rm Ra} \rightarrow ^{218}{\rm Rn}$ was considered by searching for the following sequence of events: (1) an event in the energy window [30, 2207] keV (222 Fr Q_{β} + FWHM $_{\beta}$) and with β time shape; (2) next event at [2109, 2623] keV (²²²Ra $E_{\alpha} \pm \text{ FWHM}_{\alpha}$ in γ scale), with α time shape and in the time interval [1.65 ms, 1.65 ms + 5×38 s]; (3) last event at [2398, 2946] keV (218 Rn $E_{\alpha} \pm \text{FWHM}_{\alpha}$ in γ scale), with α time shape and in the time interval [1.65 ms, 1.65 ms + $5 \times 35 \text{ ms}$].

The energy spectrum of the last events in the chain is shown in Fig. 33 - top; it obviously contains also additional events of other origin due to the high counting rate in the used ${\rm BaF_2}$.

Fig. 33: (Color online) Top: Energy spectrum of possible events of $^{218}\mathrm{Rn}~\alpha$ decay in the chain $^{222}\mathrm{Fr} \to ^{222}\mathrm{Ra} \to ^{218}\mathrm{Rn}$: experimental data and maximal effect consistent with the data. Bottom: Fit of the selected data by sum of the background model built from α peaks of isotopes in U/Th chain together with the excluded $^{218}\mathrm{Rn}~\alpha$ peak. Figure taken from Ref. [249].

The limit on $T_{1/2}^{\beta}$ of $^{222}{\rm Rn}$ was conservatively calculated using the formula:

$$\lim T_{1/2}^{\beta} = \varepsilon \cdot t \cdot R^{\alpha} \cdot T_{1/2}^{\alpha} / \lim S,$$

and the values $\lim S=1.3\times 10^5,\, \varepsilon=0.849$ (taking into account the time and energy intervals used and the efficiency for the pulse-shape discrimination), t=101 h, $R^\alpha=13.4$ Bq (the same activity can be considered for $^{222}\mathrm{Rn}$ as for $^{226}\mathrm{Ra}$ being $^{222}\mathrm{Rn}$ in equilibrium with $^{226}\mathrm{Ra}$), $T^\alpha_{1/2}=3.8235$ d for $^{222}\mathrm{Rn}$. The result was: $T^\beta_{1/2}(^{222}\mathrm{Rn})>122$ d at 90% C.L.

A more realistic estimate was obtained by fitting the spectrum with the sum of (1) some model that represents the background and (2) a gaussian with known center and width that corresponds to the $^{218}\mathrm{Rn}$ peak searched for. The isotopes in the $^{232}\mathrm{Th}$ and $^{238}\mathrm{U}$ chains randomly give contributions to the data of Fig. 33 due to the large time interval used in the selection ($\simeq 5 \times 38$ s) and to the high counting rate. Thus, one can build the background model from the α peaks of the nuclei in the U/Th chains. The fit of the data in the energy interval (2110 – 3260) keV with this background model and the expected gaussian peak of $^{218}\mathrm{Rn}$ gave as area in the region of interest $S=(3023\pm1476)$ counts and, in accordance with the Feldman-Cousins procedure [101], the limit on the area was $\lim S=5444$ counts at 90% C.L., giving [249]:

$$T_{1/2}^{\beta}(^{222}\text{Rn}) > 8.0 \text{ yr at } 90\% \text{ C.L.}$$

7 Prospects for future experiments and conclusions

The most important requirements for the detectors used for the investigation of rare α and β decays are: 1) high detection efficiency; 2) particle discrimination ability; 3) low background; 4) high energy resolution; 5) large amount of the isotope of interest. Moreover, the lowest possible energy threshold is requested for the β decay studies. It should be stressed that the characteristics 2 and 3 are, to some extent, interrelated for α decay experiments: the particle discrimination allows to suppress the background caused by γ quanta (β particles, cosmic muons) of α detectors. However, the background caused by other α emitters should be reduced by minimizing the naturally occurring α active nuclides, and by applying α detectors with high energy resolution. On the other hand, a low level of β background is required in the β decay experiments.

The development and use of scintillation detectors containing an isotope of interest look like promising techniques to investigate rare α and β decays, first of all thanks to their high detection efficiency, to their particle discrimination ability and to their reasonable energy resolution. For example, the α decay of the two naturally occurring thallium isotopes (203 Tl, 205 Tl) can be studied by massive ultra low background NaI(Tl) scintillators, which contain Tl as activator [288]. In addition, low temperature scintillating bolometers look like a promising detection technique as well taking into account their better

energy resolution, their low energy threshold and their particle discrimination ability. A typical energy resolution of bolometers is several keV and almost 100% discrimination between α particles and β particles (γ quanta) could be achievable. The recent observations of rare alpha decays (e.g., of ^{151}Eu , ^{180}W , ^{209}Bi) confirm this.

While low temperature scintillating bolometers look like a good technique to investigate α and β decays to the ground states of daughter nuclei, HPGe γ spectrometry is a favorable technique to study the α and β decays to excited levels owing to their excellent energy resolution, the low background achieved with the HPGe technique, and the possibility of long time operation (see the review [289] and the original works [256,81,231]).

The next issue that should be addressed is the use of isotopically enriched materials for rare α and β decay search. In most of the cases the isotopes of interest have very low isotopic abundances. Therefore, the production of crystals scintillators or samples for HPGe γ spectrometry from isotopically enriched materials is requested for the next generation experiments aiming at the discovery of α decay half-lives at the level of $T_{1/2} \sim 10^{19} - 10^{26}$ yr. It should be noted that the production of crystal scintillators from enriched isotopes is already well developed for double beta decay experiments (see the review [290] and the original works [291, 292, 293, 294, 295, 296, 297]).

An interesting experimental approach for the future could also be the study of the α decay rates as a function of the temperature. There are some theoretical predictions that the α decay rate could change at low temperatures (approximately of liquid helium) if atoms of radionuclides are incorporated into metal. The effect can be explained by the plasma model of Debye applied to the quasi-free electrons in the metallic samples [298, 299]. There is an indication of such an effect for alpha active ²¹⁰Po [300,301]. However, there are also theoretical considerations where the effect is considered to be very small, if present at all [302]. A possible option of the experiment could be the measurement of the α decay of ¹⁹⁰Pt to the excited level of daughter nuclide at room and at low temperature by using a low background HPGe detector. An advantage of such approach is the incorporation of α active platinum atoms in platinum metal, which exclude any surface location of radioactive atoms, or localization of radioactive atoms in dielectric (oxide, carbonate, etc.) micro inclusions, etc. A better possibility to look for the dependence of alpha decay on temperature could be with a 226 Ra source ($T_{1/2}=1600$ yr). 226 Ra decays with probability of ≈ 5.6 % to the 186.2 keV level of 222 Rn, and this gamma peak is well-known (usually it is present in all background spectra). Thus, using an external target contaminated with ²²⁶Ra and changing its temperature, one would be able to measure a weak change of the decay rate with a HPGe detector. This method avoids changing the temperature of the used detector.

In conclusion, in the recent past many interesting observations of rare α and β decays, previously unseen due to their long half-lives ($10^{15}-10^{20}$ yr) or small branch-

ing ratios $(10^{-3}-10^{-8})$ have been achieved thanks to the improvements in the experimental techniques, to the use of underground location and to background suppression techniques. The experimental status of such rare decays has been described in this paper and future possibilities have also been underlined.
