ABSTRACT

The Asymptotic Giant Branch (AGB) is the terminal phase of red giant evolution with timescales of millions of years and a total mass lost from the star that is a significant fraction of the initial mass. Investigation of one of these stars, WISEA J173046.10-344455.5, a kpc in the direction of the center of the Galaxy, reveals a cool oxygen rich star with a dust shell of black-body temperature 1305 K.

Keywords: Stars: circumstellar matter – stars: variables: general – stars: mass-loss – infrared: stars

1. INTRODUCTION

It will soon be 50 years since astrophysicists first evolved stellar models of low and intermediate mass stars beyond core helium burning to the double shell source phase. They encountered a number of phenomena not seen in simpler structures: thermal pulses and convective troughs which mixed burning products to the surface, terminal mass loss leading to the exposure of hot cores (and planetary nebulae), a powerful observational constraint in the form of the initial final mass relation, an instability region in the cool HR diagram and a rapid luminosity evolution (1 mag per million years).

Unsurprisingly, infrared observations have proved illuminating of this phase of evolution. The Magellanic Clouds have proved a valuable laboratory [\(Meixner et al.](#page-4-0) [2008;](#page-4-0) [Cioni](#page-4-1) [2004;](#page-4-1) [Frogel et al.](#page-4-2) [1990\)](#page-4-2). Much complexity remains to be explored, and Gaia's Galactic distances can be expected to provide a solar metallicity contrast with what has been discovered there.

Among the problems still challenging AGB evolution are hydrodynamic treatment of stellar and circumstellar structure, single star loss winds and binary mass transfer. AGB stars are the stellar site for the main s-process (slow neutron capture process), with ¹³C being the major neutron source via ${}^{13}C(\alpha,n){}^{16}O$ [\(Gallino et al.](#page-4-3) [1998;](#page-4-3) [Karakas](#page-4-4) [2019\)](#page-4-4), with challenges to develop a quantitative treatment. We can expect progress with the advance of more powerful observations at high spatial and spectral resolution.

The optical transient AT2019gac was discovered on 27 May, 2019 by the MASTER Global Robotic Net $(MASTER OT J173045.95-344454.7)^1$ $(MASTER OT J173045.95-344454.7)^1$ $(MASTER OT J173045.95-344454.7)^1$, with a discovery magnitude of 16.5. Rather than discard it as a nonsupernova on the basis of the spectrum, we pursued it as a long period variable (LPV) star. This was spatially identified with WISEA J173046.10-344455.5 (2MASS J17304612-3444551), henceforth J173046. The 2MASS and WISE color images are shown in Figure [1,](#page-1-0) illustrating the redness of the object. Infrared spectroscopy and photometry show that it is a luminous asymptotic giant branch (AGB) star with a large, thick, and cool circumstellar shell, located in a region a kpc from the Sun towards the Galactic Centre, that has been actively forming stars in the last 0.1 to 1 Gyr.

2. OPTICAL SPECTRUM AND DISTANCE

J173046 has a very red color $(i - z = 3.84$ from SkyMapper data; [Wolf et al.](#page-5-0) [2018\)](#page-5-0). SkyMapper z images also show a decline in brightness of ∼ 0.5 mag over the period 1 August, 2014 to 14 March, 2018. The op-

Figure 1. Color images of WISEA J173046.10-344455.5. Left: 2MASS $J/H/K_s$ (spatial resolution 1"/pixel - logarithmic scaling). Right: WISE $W1/W2/W3$ (spatial resolution $1.375''/pixel$ - linear scaling). Colors for each filter are blue/green/red correspondingly. The length scales and orientations are shown. The object is significantly redder than field stars.

tical spectrum was obtained on June 13, 2019 with the WiFeS spectrograph [\(Dopita et al.](#page-4-5) [2007\)](#page-4-5) on the ANU 2.3m telescope at Siding Spring Observatory. A standard star was observed (Feige 110), the data were reduced using PyWiFeS software [\(Childress et al.](#page-4-6) [2014\)](#page-4-6), and the spectrum (longward of 750 nm) is shown in Figure [2.](#page-1-1) Shortward of this, the spectrum is non-existent at the flux limit.

Figure 2. WiFeS spectrum of AT2019gac. The spectrum is a late M star, showing TiO bandheads and atomic absorption lines.

J173046 has also been observed by ESA's Gaia satellite [\(The Gaia Collaboration et al.](#page-5-1) [2016\)](#page-5-1). Its parallax in DR2 is 0.921 ± 0.258 mas = $1086(+422, -238)$ pc. [\(The](#page-5-2) [Gaia Collaboration et al.](#page-5-2) [2018;](#page-5-2) [Bailer-Jones et al.](#page-4-7) [2018\)](#page-4-7) We neglect the DR2 parallax offset of -0.08 mas [\(Stassun](#page-5-3)) [& Torres](#page-5-3) [2018\)](#page-5-3). The source catalog gives passband magnitudes of $m_G = 16.07 \pm 1.1$ and $m_{RP} = 14.1 \pm 1.05$, with the variability derived from the mean error in the fluxes. J173046 is not flagged as a variable in Gaia DR2; however, the are 135 g band magnitude measurements yielding a 0.066 mag standard error on the mean. If it is a LPV, more observations are required to find a period.

126 [\(Kharchenko et al.](#page-4-8) [2013\)](#page-4-8). Their distances from the J173046 is located in a region with a number of young star clusters: Collinder 133, ESO 392-13 and Ruprecht Sun range from 0.8 to 2.3 kpc, their reddening from $E(B - V) = 0.11 - 0.82$ mag, and their ages from 0.9–8 \times 10⁸ years.

3. IR SPECTROSCOPY & PHOTOMETRY

3.1. Spectroscopy

The steep rise in Figure [2](#page-1-1) demands an infrared spectrum. This was observed with the SofI (Son of ISAAC) near infrared (NIR) spectrometer [\(Moorwood et al.](#page-5-4) [1998\)](#page-5-4) at the Nasmyth A focus of the ESO 3.5-m New Technology Telescope (NTT) at the European Southern Observatory (ESO) in La Silla (Chile), as a commensal observation in the program 0103.B-0504(B) (observation date 25 August 2019). Both the GBF and GRF grisms were used with a $1^{\prime\prime}$ slit width, for a spectral range of 918-2518 nm and a spectral resolution $R \sim 600$. The A0 star HIP79473 was also observed as a telluric standard and flux calibrator. The data were reduced in the standard manner, with flat-fielding, extraction of the spectrum from the A-B pair observations, wavelength calibration, and combination of all frames for each object. Telluric correction and flux calibration were performed using an A0V stellar spectral template (from the ESO stellar library of [Pickles](#page-5-5) [1998\)](#page-5-5). The GBF and GRF spectra were combined, showing excellent flux calibration at the boundary wavelength (1600 nm), as seen in Figure [3.](#page-2-0) The spectrum was re-dispersed to the range 940-2410 nm, with 0.5 nm steps.

3.2. Photometry

J173046 has also been observed by NASA's WISE satellite [\(Wright et al.](#page-5-6) [2010;](#page-5-6) [Cutri et al.](#page-4-9) [2013\)](#page-4-9), and has 2MASS photometry [\(Skrutskie et al.](#page-5-7) [2006\)](#page-5-7). Combining these with SkyMapper i and z data, we can plot the spectral energy distribution (SED), shown in Figure [4.](#page-2-1) A black-body curve was fitted to the photometric points, yielding a best-fit temperature of 1305 K. The excess flux at the WISE W3 band can be attributed to silicate emissions at $\sim 10 \mu$ m.

Computing the integrated flux of the fitted blackbody, we obtain $F_{BB} = 1.47 \times 10^{-8}$ erg cm⁻² s⁻¹. Equating the luminosity of a black-body of radius R and temperature T with that derived from the observed flux at distance D (found above), we obtain the relationship:

Figure 3. NIR Spectrum of AT2019gac. Note the noisy regions between the atmospheric windows, designated with ⊕ symbol (1330-1450 nm and 1770-1990 nm). Spectral features include the VO bandheads in the J band, plus CO in H and K bands. Pa γ is identified in emission.

Figure 4. Spectral energy distribution from SkyMapper, 2MASS and *WISE* photometry. The flux units are 10^{-10} erg cm⁻² s⁻¹ μ m⁻¹. The curve is a 1305 K black-body.

$$
R = \frac{D}{T^2} \sqrt{\frac{F_{BB}}{\sigma}} \tag{1}
$$

where σ is the Stefan-Boltzmann constant.

From this we derive the radius of the dust shell $R = 455(+177, -101)$ \mathcal{R}_{\odot}^{N} and luminosity $L =$ $540(+1340, -210)$ \mathcal{L}_{\odot}^{N} (the uncertainties are from the range of Gaia distances). Given the solar bolometric magnitude of 4.75, this equates to M_{Bol} = $-2.1(+0.6,-1.3).$

4. DISCUSSION

4.1. Spectral Type and the Dust Shell

The features of the spectrum (the broad bumps in the H and K spectral regions and the molecular features in the J band) are similar to a late-class M star, however with a different general slope. Inspecting the IRTF IR spectral library of cool stars [\(Rayner et al.](#page-5-8) [2009\)](#page-5-8), we noticed a striking similarity to IRAS01037+1219 (WX Psc). This is classed as a variable of type M (OH/IR) , i.e. a Mira at the very late stage of AGB evolution, with a highly dusty shell, extreme mass loss rate and OH maser emission. A search of the 1612 MHz OH blind survey of the galactic bulge region by [Sevenster](#page-5-9) [et al.](#page-5-9) $(1997)^2$ $(1997)^2$ $(1997)^2$ did not show a match.

Full treatment of the emission and absorption of the star and shell would require radiative transfer code like DUSTY [\(Ivezic et al.](#page-4-10) [1999\)](#page-4-10), but this is beyond the scope of this paper. To determine the extinction (and thus the stellar magnitude), we can model the spectrum using a late M stellar template plus a standard dust extinction curve. We also include a contribution from the blackbody emission modeled by the SkyMapper, 2MASS and WISE data. Our model is thus:

$$
F_{\lambda} = \alpha T_{\lambda} a_{\lambda} + \beta B_{\lambda} \tag{2}
$$

where F_{λ} is the observed spectrum, T_{λ} is the template spectrum, B_{λ} is the black-body contribution and a_{λ} is the wavelength-dependent absorption from the circumstellar shell. α and β are arbitrary scaling constants to be fitted.

We selected 8 stellar templates from the IRTF library with spectral type M7III to M9III. We modeled the extinction using both the [Cardelli et al.](#page-4-11) [\(1989\)](#page-4-11) (CCM) and the [Calzetti et al.](#page-4-12) [\(2000\)](#page-4-12) (CAL) curves, with the black-body temperature fixed at 1305 K, as derived from the SED fit. The best fit was with the template IRAS21284-0747 (HY Aqr), spectral type M8-9III. Both forms of the extinction curve gave similar results; the CCM extinction model gave sightly better fit, with an $E(B-V) = 3.06$. This translates to a V band extinction $A_V \approx 9.5$ mag (using the standard CCM factor $R_V = 3.1$). Allowing the black-body temperature to vary in the fit produced almost no change.

The plot of this fit is shown in Figure [5.](#page-3-0) The fit broadly reproduces the features of the NIR spectrum; the broad peaks in the H and K and the molecular features in the J band combined with the steep decline in flux towards shorter wavelengths. The detailed flux levels are somewhat different, however this can be ascribed to (a) the differences in extinction between the

² <http://cdsarc.u-strasbg.fr/viz-bin/cat/J/A+AS/122/79>

dust shell and the CCM model and (b) differences in detail between the template and the stellar spectra. The circumstellar shell and the stellar emission contribute roughly equal amounts of flux over the NIR range.

At the effective wavelength of the 2MASS K_s filter (2159 nm), we fitted an extinction factor of 0.37 $(= 1.1 \text{ mag})$; with the range of *Gaia* distances the 2MASS magnitude $(K_s = 4.92 \pm 0.02)$ translates to $M_K = -6.15 \pm 0.6.$

Figure 5. Model of a M8-9III stellar template fit to the IR spectrum of J173046 with an extinction $E(B-V)=3.06$ (CCM law), plus a contribution from the circumstellar shell black-body emission at 1305 K. The plot shows the observed spectrum (black), the template spectrum (green), the circumstellar shell absorption factor (red) and the black-body contribution (dashed black), with the best fit model (blue). Fluxes are in arbitrary units and normalized.

4.2. Comparison with Surveys

The most comprehensive study of cool star SEDs is the SAGE survey of the Magellanic Clouds [\(Meixner et al.](#page-5-10) [2006\)](#page-5-10). [Woods et al.](#page-5-11) [\(2011\)](#page-5-11) assigns 13 classifications to point sources, and J173046 fits O-AGB better than a Young Stellar Object (YSO) in this system; that is to say, it is an oxygen rich (M type) AGB star at the faint end of Woods's bolometric luminosity function. Without a firm period measurement, it is not possible to tell to which of four sequences of [Wood](#page-5-12) [\(2000\)](#page-5-12) of variable red giants J173046 belongs.

We can also compare this object to the study by [Wood](#page-5-13) [\(2015\)](#page-5-13) of variability of luminous red giants in the Large Magellanic Cloud (LMC). The Weisenheit reddening free magnitude of the object is

$$
W_{JK} = K - 0.686 (J - K)
$$
 (3)

This has a value of 2.33; at the distance of the LMC $(m - M = 18.45)$, this translates to $W_{JK} = 10.8$, which is within the range for Wood's Figure 10 plot. Since there is an unknown contribution from the LMC's stars' circumstellar shells, we can only say that W_{JK} and K are plausible for AGB LPVs.

4.3. Mass Loss

Although we tend to associate thick dust shells with the terminal maximum luminosity phase of AGB evolution, it is quite possible from the point of view solely of the mass budget for a low luminosity AGB star to supply the requisite dust. A low or intermediate mass star may lose as much as $0.3 \mathcal{M}_{\odot}^{\mathbf{N}}$ of gas at the time of the helium flash; after that the [Reimers](#page-5-14) [\(1977\)](#page-5-14) mass loss rate for a one solar mass star with the parameters we find here is of order 10^{-5} $\mathcal{M}^{\mathbf{N}}_{\mathbf{\odot}}$ yr⁻¹. [Lebzelter & Wood](#page-4-13) [\(2005\)](#page-4-13) have studied variable red giants in 47 Tuc with a luminosity $\log L/\mathcal{L}_{\odot}^{\mathbf{N}}=3.15$, considerably below the tip of the redgiant branch (RGB) at $\log L/\mathcal{L}_{\odot}^{\mathbf{N}}=3.35$. Models that have undergone mass loss reproduce observed periodluminosity relations and they show that mass loss of the order of 0.3 $\mathcal{M}_{\odot}^{\mathbf{N}}$ occurs along the RGB and AGB. They show that stars evolve up the RGB and first part of the AGB pulsating in low order overtone modes, then switch to fundamental mode at high luminosities.

Assuming an dust absorption coefficient of 0.4 cm² gm⁻¹ [\(Chini et al.](#page-4-14) [1991\)](#page-4-14) and a gas to dust ratio of 100, we can compute the gas mass required to give $A_V = 9.5$ mag; this is $M_{Gas} = 4.9 \times 10^{-5} \mathcal{M}_{\odot}^N$. Thus there is ample dust to provide an optically thick shell.

4.4. Possible Origin of the Transient

The transient was at least 1.5 mag visually brighter than its minimum (given the limiting magnitude of 17.9 for the MASTER network), but had faded over the 90 day period between discovery and our IR observation (our estimate from the IR spectrum is $K_S = 5.9$ mag, below that of the 2MASS catalog of 4.92 mag). The cause of the transient is not known; this could be intrinsic, e.g. the prototypical AGB LPV (Mira) has been shown to have X-ray flares on a 1-2 day timescale [\(Karovska et al.](#page-4-15) [2005\)](#page-4-15) and the symbiotic Mira V407 Cyg produced a nova outburst [\(Munari et al.](#page-5-15) [2011\)](#page-5-15). Extrinsically, the dust shell may not be uniform (e.g. [Tatebe](#page-5-16) [et al.](#page-5-16) [2008;](#page-5-16) [Paladini et al.](#page-5-17) [2012\)](#page-5-17), possibly caused by companions, stellar asymmetry, asymmetric dust emission or dust clumps.

5. CONCLUSION

The transient AT2019gac is identified with the very red object WISEA J173046.10-344455.5. The color is due to the late spectral type of the central red giant with some foreground reddening, but notably to a circumstellar shell of warm dust. This shell has an estimated temperature of 1305 K, a luminosity of 540 $\mathcal{L}_{\odot}^{\mathbf{N}}$ and a radius of 455 \mathcal{R}_{\odot}^{N} . From the observed extinction, the gass mass is $4.9 \times 10^{-5} \mathcal{M}_{\odot}^N$. On the basis of our observations, J173046 is a mass losing, LPV, AGB star, whose initial mass would have been comparable to the turnoff masses of the star clusters of its region in the Galaxy.

With a WISE W4 mag of 1.34, J173046 would repay spectroscopy at $3-30\mu m$ to investigate this shell in detail. We are only now beginning to get a good sample of Galactic LPV luminosities thanks to Gaia (e.g. [Lebzel](#page-4-16)[ter et al.](#page-4-16) [2019\)](#page-4-16).

ACKNOWLEDGMENTS

We thank the reviewer for their constructive report, which much improved the paper. This paper is based on observations collected at the European Organisation for Astronomical Research in the Southern Hemisphere under ESO program 0103.B-0504(B). We thank Purple Mountain Observatory, Nanjing, PRC for its support of this program.

This work presents results from the European Space Agency (ESA) space mission *Gaia*. *Gaia* data are being processed by the Gaia Data Processing and Analysis Consortium (DPAC). Funding for the DPAC is provided by national institutions, in particular the institutions participating in the Gaia MultiLateral Agreement (MLA) .

This publication makes use of data products from the Wide-field Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles, and the Jet Propulsion Laboratory/California Institute of Technology, funded by the National Aeronautics and Space Administration (NASA) and from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the NASA and the National Science Foundation.

The national facility capability for SkyMapper has been funded through ARC LIEF grant LE130100104 from the Australian Research Council, awarded to the University of Sydney, the Australian National University, Swinburne University of Technology, the University of Queensland, the University of Western Australia, the University of Melbourne, Curtin University of Technology, Monash University and the Australian Astronomical Observatory. SkyMapper is owned and operated by The Australian National University's Research School of Astronomy and Astrophysics.
