(Dated: 22 January 2021)

The axion, a hypothetical elementary pseudoscalar, is expected to solve the strong CP problem of QCD and is also a promising candidate for dark matter. The most sensitive axion search experiments operate at millikelyin temperatures and hence rely on instrumentation that carries signals from a system at cryogenic temperatures to room temperature instrumentation. One of the biggest limiting factors affecting the parameter scanning speed of these detectors is the noise added by the components in the signal detection chain. Since the first amplifier in the chain limits the minimum noise, low-noise amplification is of paramount importance. This paper reports on the operation of a flux-driven Josephson parametric amplifier (JPA) operating at around 2.3 GHz with added noise approaching the quantum limit. The JPA was employed as a first stage amplifier in an experimental setting similar to the ones used in haloscope axion detectors. By operating the JPA at a gain of 19 dB and cascading it with two cryogenic amplifiers operating at 4 K, noise temperatures as low as $120\,\mathrm{mK}$ were achieved for the whole signal detection chain.

I. INTRODUCTION

Axions are spin-0 particles that emerge as a result of the Peccei-Quinn mechanism which was originally proposed as a solution to the strong CP problem of quantum chromodynamics^{1,2}. They were also identified as viable candidates for all or a fraction of the cold dark matter in our universe³⁻⁵. It is possible to detect axions upon their conversion to microwave photons, using resonant cavities immersed in high magnetic fields⁶. Since the axion mass is unknown, these detectors employ a mechanism to scan different frequencies corresponding to different axion masses. The scanning rate of such detectors scales with $1/T_{\rm sys}^2$, where $T_{\rm sys}$ is the system noise background characterized in units of temperature. It can be decomposed as $T_{\text{sys}} = T_{\text{cav}} + T_{\text{add}}$, where the first term denotes the noise temperature accompanying the signal itself and the second one denotes the noise added by the signal detection chain. Throughout this work, noise temperature refers to the added noise unless otherwise stated. In order to reduce T_{cav} , the cavity is cooled to millikely in temperatures. If the first amplifier has sufficiently high gain (G_1) , its noise temperature (T_1) will be the dominant contribution to $T_{\rm add}$ as given by the well-known relation⁷: $T_{\text{add}} = T_1 + \frac{T_{\text{rest}}}{G_1}$ where T_{rest} is the noise temperature of the whole chain except the first amplifier. Amplifiers based on Josephson junctions

including microstrip superconducting quantum interference device amplifiers (MSA) and JPA have already been shown to be capable of gains higher than 30 dB, and noise temperatures approaching the quantum limit^{8,9}. While an MSA has an internal shunt resistor used for biasing which hinders noise performance^{10,11}, by design the JPA requires no resistive element to operate. Several experiments presently searching for dark matter axions have already adopted the JPA as the first amplifier^{12–14}. In this work, the frequency coverage, gain and noise properties of a flux-driven JPA for use in an axion dark matter experiment operating around 2.3 GHz are investigated.

The power spectral density of the noise accompanying a signal measured in an impedance matched environment can be given as 15 :

$$S_n(f,T) = hf \left[\frac{1}{\exp\left(\frac{hf}{k_BT}\right) - 1} + \frac{1}{2} \right]$$
 (1)

where h is Planck's constant and k_B is Boltzmann's constant. The first term in the brackets is the mean number of quanta at frequency f at the bath temperature T and the second term is the contribution from zero-point fluctuations. The lower limit on noise temperature for linear phase-insensitive amplifiers is given by 16 $T_Q = \lim_{T\to 0} S_n(f,T)/(k_B) = hf/(2k_B)$ which is about 55.2 mK at 2.3 GHz. Using a 2.3 GHz flux-driven JPA $T_{\rm add} \approx 120$ mK is achieved. This corresponds to a $T_{\rm sys} \approx 190$ mK for an axion haloscope experiment running at a bath temperature of 50 mK. The lower bound for $T_{\rm sys}$ is given by the standard quantum limit 17 $T_{\rm SQL} = 2T_Q$ which is about 110 mK at 2.3 GHz.

II. FLUX-DRIVEN JPA

The equivalent circuit diagram of the tested device is shown in Figure 1. It consists of a superconducting quantum interference device (SQUID) attached to the end of a coplanar waveguide $\lambda/4$ resonator that is coupled via a capacitor (C_c) to the transmission line for the signal input and output. The SQUID acts as a variable inductor whose value depends on the magnetic flux passing through its loop. In the setup, a superconducting coil is used to provide the necessary DC flux (ϕ) through the SQUID loop in order to tune the resonance frequency (f_r) . Parametric amplification is achieved by modulating the flux through the SQUID using a pump signal. The pump tone is provided by a separate transmission line inductively coupled to the SQUID. The JPA is operated in the three-wave mixing mode¹⁸ where the pump (f_n) , the signal (f_s) , and the idler (f_i) frequencies satisfy the relation $f_p = f_s + f_i$. The signal input and output share the same port. A circulator is used to separate them. Since the $\lambda/4$ resonator only allows odd harmonics, there is no measurable pump leakage to the output line. This prevents the stronger pump tone from saturating the rest of the amplifiers in the chain ¹⁹. Figure 2 shows a schematic for the axion search experimental setup.

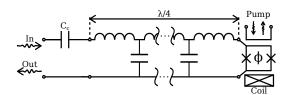

FIG. 1: Equivalent circuit diagram of the JPA sample. The JPA was fabricated by photolithography of a Nb layer, deposited on a 0.3 mm thick Si substrate. The SQUID was placed on top of the Nb layer by E-beam lithography followed by shadow evaporation^{20,21}. The sample was attached to a printed circuit board (PCB) and the transmission lines were bonded with Al wires. The PCB was fixed onto a gold plated copper structure and placed inside a superconducting coil. The whole structure was covered tightly with a lead shield and attached to the mixing-chamber (MC) plate using a gold plated copper rod.

III. MEASUREMENTS

When there is no pump tone present, the JPA can be modeled as a resonator with a well-defined quality factor and resonance frequency which are functions of flux. The resonance frequency is estimated from the frequency domain phase response using a parameter fit²². The phase response is obtained by doing a transmission S-parameter measurement using a vector network analyzer (VNA) in the configuration as shown in Figure 2. The resonance

frequency was measured as a function of the coil current (see Figure 3). It was found that the minimum observable resonance frequency was at 2.18 GHz and the maximum was 2.309 GHz. The lower bound is due to the frequency band of the circulators which spans from 2.15 GHz to 2.60 GHz. At the lower frequencies, the JPA becomes much more sensitive to flux noise due to a higher $\frac{\partial f_r}{\partial \phi}$. This work mainly focused on operation with frequencies above 2.2 GHz.

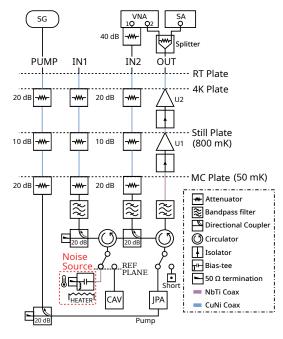

FIG. 2: The experimental setup used in all the characterization measurements. SG, VNA, and SA stand for the signal generator, vector network analyzer, and spectrum analyzer, respectively. During this work, the switch that selects between the cavity and the noise source was always kept at the position shown in the figure. The ports IN2 and OUT were used to directly measure the JPA characteristics, bypassing the cavity. The microwave short element shown next to the JPA was used to bypass the JPA for calibration measurements. U1 and U2 are HEMT amplifiers with noise temperatures of 1.5 K and 5 K, respectively.

During the experiments, the MC plate temperature was stabilized at $50 \pm 1\,\mathrm{mK}$. With the temperature fixed, the frequency response of the JPA is determined by three experimental variables: the coil current (i_b) , the pump frequency (f_p) , and the pump power (P_p) . The measurements shown in this work had i_b confined to the region where the flux through the SQUID loop is given by $-0.5\phi_0 < \phi < 0$, where ϕ_0 is the magnetic flux quantum. Therefore, f_r can be unambiguously converted to ϕ or i_b . All experiments began with a transmission measurement, with the resonance frequency tuned to 2.18 GHz. This becomes the baseline measurement to be used for the duration of the experiment. When the result was compared to a separate measurement, in which a microwave

short was put in place of the JPA, it was found that the baseline obtained via such an off-resonance measurement was at most $0.2\,\mathrm{dB}$ lossier than an ideal mirror. The JPA gain (G_J) was estimated by dividing the transmission magnitude response with the baseline's magnitude response.

To investigate the gain behavior, a sweep over the parameters i_b , f_p , P_p was made and the maximum gain was measured at each point. After each i_b tuning step, the resonance frequency is estimated by performing a phase measurement and applying a parameter fit. With the detuning defined as $\delta = f_p/2 - f_r$, the equigain contours had a minimum in necessary pump power around $\delta = 0$, as shown in Figure 4a. It was observed that for resonance frequencies above 2.299 GHz the minimum starts to shift to lower detunings which is attributed to pump-induced shifts in resonance frequency²². Figure 4b shows that the slice of $\delta = 0$ can be used to achieve peak gains of up to 30 dB along the frequency range of the device.

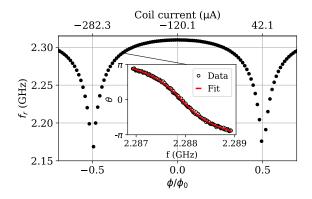

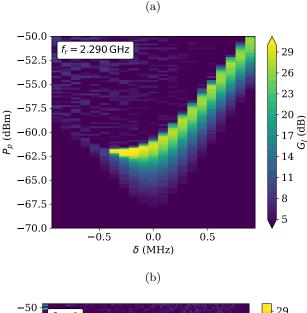

FIG. 3: Resonance frequency versus flux obtained by sweeping the coil current and measuring the phase response at each step. One period corresponds to a current of $324.4\,\mu\text{A}$. The inset shows the fit performed to estimate the resonance frequency for each applied flux.

To investigate noise temperature, a methodology similar to the well-known Y-factor method²³ was used. A $50\,\Omega$ cryogenic microwave terminator was used as the noise source. A bias-tee was attached in front for improved thermalization of its inner conductor. These two components were fixed onto a gold-plated copper plate along with a ruthenium oxide temperature sensor and a $100\,\Omega$ resistor functioning as a heater. This plate was then fixed onto the MC plate so that the dominant thermalization was through a thin copper wire attached to the MC plate. The noise source was connected to the switch input using a superconducting coaxial cable, which provides thermal isolation while minimizing losses. Using a PID controller, the terminator temperature could be adjusted from 50 mK to 1 K without affecting the MC plate temperature. The noise power generated by the noise source was measured using a spectrum analyzer

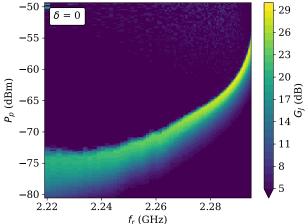

FIG. 4: (a) Maximum gain measured as a function of detuning and pump power for a flux bias corresponding to $f_r = 2.29 \,\text{GHz}$. (b) Maximum gain as a function of frequency and pump power with $f_p = 2 f_r$.

(SA) with 1 kHz resolution bandwidth after being amplified by the JPA and the rest of the signal detection chain. The power spectra were recorded at noise source temperatures (T_s) of 60, 120 and 180 mK. The power values were converted into power spectral densities (PSD) by dividing them with the noise bandwidth corresponding to the SA settings used. Before each PSD measurement, the JPA gain and passive resonance were measured. From these measurements, it was concluded that there were neither gain changes nor resonance shifts. From the obtained PSD values $S(T_s)$, a fit was done to a function of the following form independently for each frequency bin (see Figure 5):

$$S(T_s) = (2G_J - 1)\frac{G_L G_{\text{tot}}}{G_J} (S_n(T_s) + rk_B T_n + \gamma) \quad (2)$$

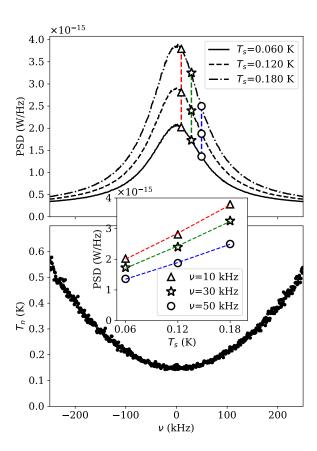

FIG. 5: The upper plot shows the set of power spectra obtained during a noise temperature measurement performed for a tuning at $f_r = 2.305 \,\text{GHz}$ with $f_p = 2f_r$. The offset ν is defined as $\nu = f - f_r$ where f is the center of the frequency bin at which the power was measured using the spectrum analyzer. T_s is the temperature of the noise source. The inset shows three vertical slices which were fit with Equation (2). The lower plot shows the estimated noise temperature of the whole chain as a function of ν .

where $S_n(T_s)$ is the noise PSD of the source, $G_{\rm tot}$ is the total gain seen from the reference plane, G_L is the loss factor between the $50\,\Omega$ terminator and the reference plane and T_n is the noise temperature. The reference plane is at the end of the superconducting cable connected to the noise source (see Figure 2). Here, r and γ are factors that are explained in Appendix A.

Since the amplifier needs to be tuned along with the cavity during the axion experiment, the noise temperature was investigated at different frequencies. The measurements were done in 5 MHz steps from 2.28 to 2.305 GHz. At each step, the pump power and resonance frequency were tuned such that the JPA gain was about

20 dB. From these measurements (Figure 6) a minimum noise temperature of 120 mK was observed at 2.28 GHz.

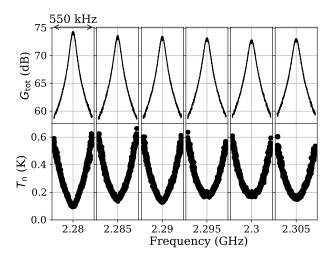

FIG. 6: Total gain and the noise temperature of the whole chain for 6 tuning points with $19.3 \pm 0.5\,\mathrm{dB}$ JPA gain. Both quantities were estimated from noise temperature measurements. The small variations along tuning frequencies were mainly attributed to the losses due to the microwave components before the JPA.

Another important characteristic is the saturation that occurs when a narrowband signal is applied. For stable and predictable operation the JPA must be operated away from the effects of saturation. A common way to quantify the saturation of an amplifier is to determine the input power at which the gain is reduced by $1 \, dB \, (P_{1dB})$. The $P_{1\text{dB}}$ was measured at $\delta = 0$ for different frequencies and different pump powers corresponding to different gains. It is evident from the results (see Figure 7) that an axion-like signal with an expected power of $-180 \, \mathrm{dBm}$ is far from saturating the device. While saturation from narrowband signals is avoidable to a certain extent, it was observed that thermal noise at the input can also saturate and alter the behavior of the device. For frequencies below 2.28 GHz with gains above 23 dB, the device started showing saturated behavior with thermal noise when the noise source temperature was raised above 120 mK, which was done to measure noise temperature. While this does not necessarily mean that the device is unusable below these frequencies, it renders the direct measurement of the noise temperature using a noise source unreliable for these frequency and gain regions.

IV. CONCLUSION

In conclusion, a flux-driven JPA, tunable in the range 2.2 to 2.305 GHz was demonstrated and determined to be operational for use in axion search experiments. The added noise temperatures of the receiver chain were measured using a noise source at a location as close as pos-

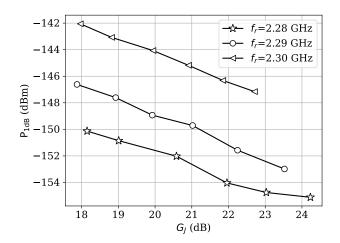

FIG. 7: Saturation measurements for three different f_r . Each measurement was done by sweeping the signal powers from the VNA and observing at which input power the gain reduces by 1 dB. The horizontal axis corresponds to the unsaturated gain measured with the lowest signal power available from VNA.

sible to the origin of the axion signal. With an added noise temperature of $120\,\mathrm{mK}$ the system was shown to reach $T_\mathrm{sys} \approx 1.7T_\mathrm{SQL}$. This is the first record of T_sys below $2T_\mathrm{SQL}$ for an axion haloscope setup operating below $10\,\mathrm{GHz}$. The saturation input power for the JPA was observed to be more than adequate for an axion-like signal. Currently, the tested JPA is being used as part of a KSVZ^{24,25} sensitive axion search experiment at the Center for Axion and Precision Physics Research (CAPP). The system is taking physics data with a scanning speed that has been improved more than an order of magnitude. We expect that further optimization of the JPA design could result in improved instantaneous bandwidth and tuning range.

Appendix A: Noise Temperature Estimation

The output PSD from a component with its input connected to a matched source can be written as:

$$S_{\rm O} = GS_{\rm in} + S_{\rm added} \tag{A1}$$

where S_{in} is the source PSD, G is the power gain of the component, and S_{added} is the noise added by it. The noise temperature (T_n) is a measure of the added noise at the output of a component. By convention, it is defined as if it is for noise entering the device itself: $T_n = S_{\text{added}}/(k_B G)$. The entire detection chain (see Figure 8), from the reference plane to the spectrum analyzer,

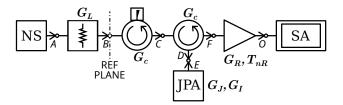

FIG. 8: The simplified model used for the noise temperature estimations conducted in this work. Bold letters denote the power gains of components. The reference plane marks the input of the detector chain. Arrows denote the flow of power entering the nodes shown with a small circle. G_L is a composite gain factor for everything between the noise source and the reference plane. G_c is the circulator gain factor. G_J is the signal and G_I is the idler gain for the JPA. The amplifier gain G_R and noise temperature T_{nR} contain the effects of all elements after the last circulator, including SA noise. For simplicity, circulators are assumed to have complete rotational symmetry with respect to their ports and to be completely identical to each other.

can be described as a single composite component with $G = G_{\text{tot}}$ and noise temperature T_n .

The noise temperature can be defined for a situation similar to the experimental one where a narrowband axion signal with power A is present. This signal enters the chain from a source connected to the reference plane. Assuming the source is thermalized to the MC plate with the temperature T_f , then the defining relation for T_n can be written as:

$$S_O = G_{\text{tot}}(\underbrace{A\delta(f - f_s) + S_n(T_f)}_{S_{\text{in}}} + k_B T_n)$$
 (A2)

where S_O is the PSD at the output, $G_{\rm tot}$ is the total power gain for the signal from the reference plane, S_n is the noise coming from the source itself. The main idea here is that if one has a reliable estimate of T_n , and understands the source environment well $(S_n(T_f))$, it is straightforward to estimate A without the precise knowledge of $G_{\rm tot}$. This is possible since S_O can be easily measured at two frequencies f_s and f_s' using a spectrum analyzer. Provided that $|f_s - f_s'|$ is small enough so that T_n is approximately the same for both frequencies, A can be estimated from these two measurements. This approach forms the basis of the analysis methods applied in axion dark matter search experiments^{26–29}.

The detection chain consists of passive components, the JPA and the HEMT amplifiers. Each one of these adds noise in a different way. A passive component at physical temperature T_f has $S_{\rm added} = (1 - G)S_n(T_f)$. The HEMT amplifier noise is usually estimated from measurements. The JPA adds noise by two main mechanisms. The first one is by amplifying the input noise at the idler mode onto the signal mode. The second one

is via the losses or other dissipation mechanisms inside or before the sample. Ideally, the latter can be made zero, whereas the former will approach to the half-photon added noise in the limit of a $0\,\mathrm{K}$ bath temperature.

Using the model shown in Figure 8, it is straightforward to write a relation for the output PSD. For clarity, the explicit frequency dependence of the thermal noise S_n and of the gains will be omitted. Also, the approximation $S_n(f,T)\approx S_n(f_p-f,T)$ will be denoted with the shorthand $S_{nf}=S_n(f,T_f)$. This approximation has less than 30 ppm error given that $|2f-f_p|<100\,\mathrm{kHz}$. Note that $100\,\mathrm{kHz}$ is the typical bandwidth for the JPA tested in this work. Furthermore, the transmission characteristics of the microwave components will be assumed to not vary on a scale of $100\,\mathrm{kHz}$. Using the gain symbols for components as shown in Figure 8, the power flow at each node in terms of their PSD is written as:

$$S_{B} = G_{L}S_{A} + (1 - G_{L})S_{nf}$$

$$S_{C} = G_{c}S_{B} + (1 - G_{c})S_{nf}$$

$$S_{D} = G_{c}S_{C} + (1 - G_{c})S_{nf}$$

$$S_{E} = G_{J}S_{D} + G_{I}S_{D} + G_{J}S_{j}$$

$$S_{F} = G_{c}S_{E} + (1 - G_{c})S_{nf}$$

$$S_{O} = G_{R}(S_{F} + k_{B}T_{nR})$$
(A3)

The idler gain is denoted by G_I , and is substituted using $G_I = G_J - 1^{30}$ in the following derivations. As shown in Equation (A3), the idler contribution to the noise appears as G_IS_D . The symbol S_i denotes an unknown noise density added at the JPA stage which does not contribute to the quantum limit but rather contains losses or other mechanisms of stationary noise. Note that the noise propagating back from the later stages is also included in S_j . The output S_O can be written for two cases. In the first case, the noise source is operational at temperature T_s , and in the second case, a signal source at temperature T_f is connected to the reference plane. The former case describes the measurement situation, whereas the latter case is only used to define T_n in terms of the parameters in the model. For the first case, i.e. $S_A = S_n(T_s)$, the output PSD can be written as:

$$S_O^{(1)} = \underbrace{G_R G_c^3 G_L(2G_J - 1)}_{G_{\text{noise}}} [S_n(T_s) + S_\alpha]$$
 (A4)

$$S_{\alpha} = \lambda^{(1)} S_{nf} + \frac{G_J S_j}{(2G_J - 1)G_c^2 G_L} + \frac{k_B T_{nR}}{G_c^3 G_L (2G_J - 1)}$$
(A5)

$$\lambda^{(1)} = \beta_l + \frac{\beta_c}{G_L} + \frac{\beta_c}{G_c G_L} + \frac{\beta_c}{G_c^2 G_L}$$
 (A6)

$$\beta_{\bullet} \equiv \frac{1}{G_{\bullet}} - 1 \tag{A7}$$

The output for the second case, where $S_B = A\delta(f - f_s) + S_{nf}$, is written as:

$$S_O^{(2)} = \underbrace{G_J G_c^3 G_R}_{G_{c-1}} [S_B + k_B T_n]$$
 (A8)

$$k_B T_n = \lambda^{(2)} S_{nf} + \frac{S_j}{G_c^2} + k_B \frac{T_{nR}}{G_c^3 G_J}$$
 (A9)

$$\lambda^{(2)} = \left[\frac{G_J - 1}{G_J} + \left(\beta_c + \frac{\beta_c}{G_c} \right) \frac{2G_J - 1}{G_J} + \frac{\beta_c}{G_c^2} \right]$$
 (A10)

Here, the unknowns are S_j , T_{nR} and G_R . It is clear from Equations (A9) and (A10) that T_n approaches T_Q as expected in the limits of $G_J \gg 1$, $G_c \to 0$, and $G_L \to 0$. Using Equations (A4), (A5) and (A9), $S_O^{(1)}$ can be rewritten as:

$$S_O^{(1)} = \frac{G_{\text{tot}}}{r} (S_n(T_s) + rk_B T_n + \gamma)$$

$$r = \frac{G_J}{G_L(2G_J - 1)}$$

$$\gamma = \left(\lambda^{(1)} - r\lambda^{(2)}\right) S_{nf}$$
(A11)

This relation is used to perform a fit with $G_{\rm tot}$ and T_n as the fit parameters. For the estimations, the parameters G_L and G_c were taken as $-0.05\,{\rm dB}$, and $-0.4\,{\rm dB}$ respectively. Some typical values for r and γ/k_B can be found in Table I.

TABLE I: Calculated r and γ/k_B for typical component losses and $T_f=50\,\mathrm{mK}.$
