#### Abstract

We investigate the infall properties in a sample of 11 infrared dark clouds（IRDCs） showing blue－asymmetry signatures in $\mathrm{HCO}^{+} J=1-0$ line profiles．We used JCMT to conduct mapping observations in $\mathrm{HCO}^{+} J=4-3$ as well as single－point observations in $\mathrm{HCO}^{+} J=3-2$ ， towards 23 clumps in these IRDCs．We applied the HILL model to fit these observations and derived infall velocities in the range of $0.5-2.7 \mathrm{~km} \mathrm{~s}^{-1}$ ，with a median value of $1.0 \mathrm{~km} \mathrm{~s}^{-1}$ ， and obtained mass accretion rates of $0.5-14 \times 10^{-3} \mathrm{M}_{\odot} \mathrm{yr}^{-1}$ ．These values are comparable to those found in massive star forming clumps in later evolutionary stages．These IRDC clumps are more likely to form star clusters． $\mathrm{HCO}^{+} J=3-2$ and $\mathrm{HCO}^{+} J=1-0$ were shown to trace infall signatures well in these IRDCs with comparable inferred properties． $\mathrm{HCO}^{+} J=4-3$ ，on the other hand，exhibits infall signatures only in a few very massive clumps，due to smaller opacties．No obvious correlation for these clumps was found between infall velocity and the $\mathrm{NH}_{3} / \mathrm{CCS}$ ratio．

## 1 INTRODUCTION

Mass accumulation by inward gravitational motions is a basic step in models of star formation (e.g. Larson 1969; Anglada et al. 1987; Bonnell et al. 2001; Motte et al. 2018). Infall motions often are revealed in observations with moderate optical depth molecular lines, which show blue-shifted self-absorption dips at frequencies where optically thin lines peak, produced by the temperature gradients of dense cores and the infalling gas (e.g. Walker et al. 1986; Wu \& Evans 2003). Multiple transitions of many molecules such as $\mathrm{CS}, \mathrm{CO}, \mathrm{H}_{2} \mathrm{CO}, \mathrm{HCO}^{+}, \mathrm{HCN}, \mathrm{CH}_{3} \mathrm{CN}$, and $\mathrm{C}_{3} \mathrm{H}_{2}$ have been investigated to search for infall signatures in various environments in low mass star forming regions (e.g. Myers et al. 1995; Mardones et al. 1997; Tafalla et al. 1998; Keown et al. 2016), as well as massive star forming regions (e.g. Zhang et al. 1998; Wu \& Evans 2003; Fuller et al. 2005; Velusamy et al. 2008; Barnes et al. 2010; Qin et al. 2016).

The comparisons of different tracers including multiple transitions of the same tracer have been made through both observations and simulations, to explore which tracers are more efficient to reveal infall signatures in what kind of sources. Higher- $J$ transitions, such like $J=3-2$ and $J=4-3$, of HCN and $\mathrm{HCO}^{+}$are considered as good tracers for dense clusters based on their infall asymmetries in lines generated in numerical simulations (Chira et al. 2014). Observationally, HCN $J=3-2$ has been considered as a very good infall tracer in a dense clump sample associated with $\mathrm{H}_{2} \mathrm{O}$ masers (Wu \& Evans 2003). The $J=1-0$ transition of HCN was found to have the strongest infall signatures (Stahler \& Yen 2010) in simulations although the line shapes depend on the viewing angle (Smith et al. 2012). Compared to $\mathrm{HCN}, \mathrm{HCO}^{+}$changes less drastically in abundances in chemical models at temperatures ranging from 10 K to 40 K (Vasyunina et al. 2012), which is the temperature range of dark clouds. Thus, $\mathrm{HCO}^{+}$is potentially better for comparing infall in different star forming environments as it is less affected by chemistry. Among $\mathrm{HCO}^{+}$, the lowest transition, $\mathrm{HCO}^{+}$ $J=1-0$, showed the most blue-asymmetric profiles towards a sample of 77 candidate high mass protostellar objects (HMPOs) (Fuller et al. 2005), which is consistent with the results of numerical simulations that $\mathrm{HCO}^{+} J=1-0$ is a better indicator of collapse in high mass star formation (Smith et al. 2013) where the gas is not dense enough to excite the higher- $J$ transitions.

Being cold and dense, infrared Dark Clouds (IRDCs) are believed to represent the initial conditions of massive star formation and the formation of the associated stellar clusters (e.g. Carey et al. 2000; Rathborne et al. 2006; Peretto \& Fuller 2009; Motte et al. 2018). Some pilot $\mathrm{HCO}^{+}$observations towards two massive IRDCs have revealed that the clumps/cores in there are undergoing rapid collapse (Peretto et al. 2013; Contreras et al. 2018). Considering IRDCs are at an earlier stage than HMPOs or UCHII massive clumps, it raises the question of what molecular or ion line tracers can best trace infall in IRDCs? Specifically, will lower- $J$ transitions with smaller critical density (like $\mathrm{HCO}^{+} J=1-0$ ) reveal infall signature better, or higher- $J$ transitions are needed to probe collapse in these IRDCs? In addition, it is important to understand the properties of infall in the IRDC phase compared with infall in more evolved regions.

Recently, in a $\mathrm{HCO}^{+} J=1-0$ mapping survey towards a sample of 27 IRDCs (Peretto et al. in preparation), a significant fraction presented infall signatures in their line profiles. In this paper, we report our follow-up study on a sub-sample of these IRDCs, all of which show infall signatures in $\mathrm{HCO}^{+} J=1-0$ in at least one clump in the IRDCs. We mapped 11 IRDCs with $\mathrm{HCO}^{+} J=4-3$, and made single-point observa-
(JCMT). The aims of the study are to use multiple $\mathrm{HCO}^{+}$transitions to fit and constrain models of infall motion, to understand infall properties in IRDCs, and to investigate if higher- $J$ transitions of $\mathrm{HCO}^{+}$can also probe infall and reveal infall properties well in these $\mathrm{HCO}^{+} J=1-0$ selected IRDCs .

The organization of the rest of the paper are the follow: We describe source selection and observations in sect. 2. The observational results and and data analysis are presented in sect. 3. We discuss infall tracers and infall properties of IRDCs in sect. 4, and summarise our conclusions in sect. 5.

## 2 TARGET SELECTION AND SPECTROSCOPIC OBSERVATIONS

The sources in this work are a sub-sample of an IRAM $30 \mathrm{~m} \mathrm{HCO}^{+} J=1-0$ survey towards 27 IRDCs (Peretto et al. in preparation). The parent sample was selected to span a range of geometries and a factor of $\sim 100$ in mass range from $\sim 200$ to $\sim 2 \times 10^{4} \mathrm{M}_{\odot}$, to cover a representative sample of IRDCs. From the parent sample we selected 11 IRDCs who show blue asymmetry indicative of infall in $\mathrm{HCO}^{+} J=1-0$ in at least one clump. We made follow-up higher- $J \mathrm{HCO}^{+}$observations and we fit multiple transitions with models, in order to study infall properties in these candidate infalling IRDCs. The basic information of the sources are listed in Table 1.

All the sources have been mapped in $\mathrm{HCO}^{+} J=1-0$ with IRAM 30 m telescope (half power beam width (HPBW): $29 " ; \eta_{m b}=0.75$ ). Since $\mathrm{N}_{2} \mathrm{H}^{+} J=1-0$ has been found in good agreement with $\mathrm{H}^{13} \mathrm{CO}^{+} J=1-0$ in both velocity and line width (Fuller et al. 2005), we use $\mathrm{N}_{2} \mathrm{H}^{+} J=1-0$, which was observed simultaneously with $\mathrm{HCO}^{+} J=1-0$, to locate the central velocity of the cloud and to identify infall signature for all the $\mathrm{HCO}^{+}$transitions. The IRAM 30 m observations and data reduction of $\mathrm{HCO}^{+} J=1-0$ and $\mathrm{N}_{2} \mathrm{H}^{+} J=1-0$ of the 27 IRDCs will be presented in a separated paper (Peretto et al. in preparation).

Eleven IRDCs were mapped in $\mathrm{HCO}^{+} J=4-3$ with Heterodyne Array Receiver Programme (HARP) ${ }^{1}$ (Buckle et al. 2009) (HPBW:: $14 " ; \eta_{m b}=0.63$ ) on the 15 m James Clerk Maxwell Telescope (JCMT) ${ }^{2}$ on Mauna Kea, Hawaii during August and September 2016 (Project M16BP081), and August 2017 (Project M17BP087). The Auto-Correlation Spectral Imaging System (ACSIS) spectrometer was used. Maps of $180^{\prime \prime}$ by $180^{\prime \prime}$ (except one source SDC18.624, whose map size is $240^{\prime \prime} \times 180^{\prime}$ ) were made with RASTER scans with $\mathrm{T}_{\text {sys }}$ ranging from 364 K to 613 K (with an average of 443 K ), under weather Band 3 and Band 4 with $0.08<\tau_{225 G H z}<0.20$.

Single-point observations were carried out in $\mathrm{HCO}^{+} J=3-2$ towards the $\mathrm{HCO}^{+} J=4-3$ peak positions with JCMT RxA3m frontend and ACSIS backend ${ }^{3}$ (HPBW: 20"; $\eta_{m b}=0.57$ ) from April to June 2018 under Project M18AP073. No $\mathrm{H}^{13} \mathrm{CO}^{+} J=3-2$ observations were available due to a low LO current at 260 GHz . The molecule line frequencies are listed in Table 2. Each position was observed in position-switching mode (GRID) for an integration time of 300 s in weather Band $4\left(0.12<\tau_{225 \mathrm{GHz}}<0.2\right)$. An off-position (+600", +600 ") (J2000) from the observed position was also observed. The system temperatures ranged from 778 K to 1356 K , with an average of 988 K . For both the HARP and RxA3m observations, ACSIS was configured

[^0]to cover 250 MHz wide windows, 8192 channels in each window, resulting to a velocity resolution of $\sim$ $0.02 \mathrm{~km} \mathrm{~s}^{-1}$ for HARP and $\sim 0.03 \mathrm{~km} \mathrm{~s}^{-1}$ for RxA3m. All data the HARP and RxA3 observations were smoothed with a Gaussian kernel which has the FWHM equals 5.9 channels, resulting a velocity resolution of $0.15 \mathrm{~km} \mathrm{~s}^{-1}$ and $0.20 \mathrm{~km} \mathrm{~s}^{-1}$ for HARP and RxA3, respectively. The telescope pointing was checked before observing a new source and was checked every 1-1.5 hours, by observing one or more calibration sources in $\mathrm{CO}(2-1)$ at 234.591 GHz and $\mathrm{CO}(3-2)$ at 350.862 GHz for RxA 3 m and HARP, respectively. The uncertainty in the flux calibration is estimated to be about $10 \%$.

The HARP and RxA3m data reduction were undertaken using the Starlink (Currie et al. 2014) software package SMURF, KAPPA, and GAIA. Each integration was first visually checked. The data were converted to spectral cubes and baselines were subtracted before been written out as FITS format files using standard Starlink routines (Jenness et al. 2015).

All data were converted from the antenna temperature scale $\mathrm{T}_{A}^{*}$ to main-beam brightness temperature $\mathrm{T}_{m b}$ using $\mathrm{T}_{m b}=\mathrm{T}_{A}^{*} / \eta_{m b}$, where main beam efficiencies are listed in Table 2, as well as the noise levels and the velocity resolutions.

## 3 RESULTS

### 3.1 Infall Signature Statistics

We have mapped $\mathrm{HCO}^{+} J=4-3$ towards 11 IRDCs, which are presented as a contour map overlaid on the emission image of $\mathrm{HCO}^{+} J=1-0$ in Figure 4 through Figure 14 in Appendix.1. The $\mathrm{HCO}^{+} J=4-3$ data have been convolved with the IRAM 30 m beam size. We identified 23 dense clumps based on $\mathrm{HCO}^{+} J=4-$ 3 emission peaks in the maps. These are labelled A through D in the figures. The coordinates of these peaks are tabulated in Table 4.

The position of the $\mathrm{HCO}^{+} J=4-3$ peaks generally agree well with $\mathrm{HCO}^{+} J=1-0$ peaks. An exception is $\mathrm{SDC} 28.333+0.063$, in which $\mathrm{HCO}^{+} J=4-3$ peaks at two positions (B and C in the figure) without corresponding $\mathrm{HCO}^{+} J=1-0$ peaks. These two clumps may be very small in size and smoothed out by the much larger beam size in IRAM 30 m telescope, or these regions may have quite different physical conditions leading to unusual $\mathrm{HCO}^{+} J=4-3$ to $\mathrm{HCO}^{+} J=1-0$ ratio.

We present the spectra of all three transitions towards the peak positions in Appendix.1. As seen from these spectra, infall signatures can be recognized in most of these clumps, and vary among different transitions. We categorised the profile signatures into five types that suggest different kinematic statuses: (1) double peaks with blue strong, an example can be seen in $\mathrm{HCO}^{+} J=3-2$ in SDC18.624-0.070B (see Figure 4); (2) a blue profile with a shoulder, e.g. the profile of $\mathrm{HCO}^{+} J=4-3$ in SDC18.624-0.070B (see Figure 4); (3) symmetric profile, e.g. $\mathrm{HCO}^{+} J=3-2$ in SDC18.624-0.070A (see Figure 4); (4) a red profile with a shoulder, e.g. $\mathrm{HCO}^{+} J=1-0$ in SDC18.888-0.476A (see Figure 5); (5) double peaks with red strong, e.g. $\mathrm{HCO}^{+} J=3-2$ in SDC18.888-0.476A (see Figure 5). We summarize the the line profiles of different $\mathrm{HCO}^{+}$ transitions for the 23 IRDC clumps in Table 3.

A double peak with a blue peak stronger profile is the best infall signature that indicates infall is ongoing and can be fitted to derive the infall properties. A blue peak with a red shoulder is also an infall signature, although less dramatic, it can still be used to derive infall parameters through modelling. Both profiles are called blue profiles. It is clear both from spectra or from Table 3 that $\mathrm{HCO}^{+} J=1-0$ has the best performance in revealing infall in these IRDCs, with 12 out of 23 showing a double peak profile with blue peak strong, and 5 with a blue peak with a shoulder. This is not surprising given this sample has been selected bias to showing the blue asymmetry in $\mathrm{HCO}^{+} J=1-0 . \mathrm{HCO}^{+} J=3-2$ presents a less prominent, yet still comparable, ability to reveal blue profiles, 11 out of 23 having double peaks with the blue peak stronger, and 3 blue peak with a red shoulder profiles. $\mathrm{HCO}^{+} J=4-3$ only presents profiles with double peaks and the blue peak stronger in 3 clumps, and shows a blue peak with a shoulder in 13 clumps. It is less sensitive in revealing infall in this IRDC sample. More discussion to compare the ability of the 3 transitions to reveal infall will be given in sect.4.

### 3.2 Infall Velocity Calculations

To derive the infall parameters, we adopted the HILL model (De Vries \& Myers 2005) to fit the spectral lines. The HILL model is based on the precursor 'two-layer' model (Myers et al. 1996), which has been

Table 3: The Numbers of Clumps Profile Signatures.

| Profile Signatures | $\mathrm{HCO}^{+} J=1-0$ | $\mathrm{HCO}^{+} J=3-2$ | $\mathrm{HCO}^{+} J=4-3$ |
| :--- | :---: | :---: | :---: |
| Double Peaks with Blue Strong | 12 | 11 | 3 |
| Blue Profile with Shoulder | 5 | 3 | 13 |
| Symmetric | 2 | 4 | 2 |
| Red Profile with Shoulder | 3 | 1 | 1 |
| Double Peaks with Red Strong | 0 | 4 | 2 |

factor of $\sim 2$ (De Vries \& Myers 2005). The HILL model assumes a hill shape excitation temperature profile across the cloud, where the centre has the peak excitation temperature $T_{P}$ (De Vries \& Myers 2005). The brightness temperature of the molecular line is:

$$
\begin{align*}
\Delta T_{B}(v)=\left(J\left(T_{P}\right)-J\left(T_{0}\right)\right)\left[\left(1-e^{-\tau_{f}(v)}\right) /\right. & \left./ \tau_{f}(v)-e^{-\tau_{f}(v)}\left(1-e^{-\tau_{r}(v)}\right) / \tau_{r}(v)\right]  \tag{1}\\
& +\left(J\left(T_{0}\right)-J\left(T_{b}\right)\right)\left[1-e^{-\tau_{r}(v)-\tau_{f}(v)}\right]
\end{align*}
$$

where $T_{B}$ is the brightness temperature defined as $T_{B}=\left(c^{2} / 2 \nu^{2} k\right) I_{v}$, and $I_{\nu}$ is the specific intensity. The excitation temperature at the outer edges of the core is $T_{0}$. The optical depth $\tau_{f}$ is the optical depth where has the excitation temperature rising along the line of sight and $\tau_{r}$ is the opposite, with a velocity dispersion of $\sigma$ for the entire cloud. We developed a Python fitting code which consists five parameters, i.e. HILL5 model, based on equation Eq. $1^{4}$ using Python package LMFIT ${ }^{5}$, which also provides error estimates. HILL5 is the HILL model with five free parameters, which are optical depth $\tau$, infall velocity $V_{\mathrm{in}}$, systematic velocity $V_{\mathrm{LSR}}$, velocity dispersion $\sigma$, and excitation temperature $T_{\text {ex }}$. HILL5 is considered as the most robust model among the HILL models (De Vries \& Myers 2005), and has been applied to calculate infall velocities in various objects such as IRDCs (e.g. Contreras et al. 2018), low mass cores (e.g. Maureira et al. 2017), and massive starless clumps (e.g. Calahan et al. 2018).

We applied the HILL5 model to fit $\mathrm{HCO}^{+} J=1-0,3-2$, and 4-3 spectral lines towards the peak positions as listed in Table 4. Fitted lines are plotted in red in Figure 4 through Figure 14. The fitted infall velocities are listed in Table 4. We exclude clumps (SDC18.888-0.476A, SDC24.618, and SDC35.429) which have red-asymmetries for all transitions.

In some sources (e.g. SDC25.166-0.306C), although the blue-asymmetric profile look differently for different transitions, the derived infall velocities are similar ( $\Delta V_{i n}<0.2 \mathrm{~km} \mathrm{~s}^{-1}$ ). A possible explanation is that the line has different optical depth, as listed in Table 4, which causes the differences in the line profiles, even with similar infall velocities.

### 3.3 Clump Sizes and Line Luminosities from $\mathrm{HCO}^{+} J=4-3$ maps

$\mathrm{HCO}^{+} J=4-3$ traces the densest part of the cloud among the three transitions, thus can be used to define the compact, very dense regions in these IRDCs. We obtained the effective angular diameter $\left(\theta_{\text {transition }}\right)$

[^1]Table 4: Infall velocities fitted by HILL at Peak Positions of $\mathrm{HCO}^{+} J=4-3$

[^2]size of the dense clumps by measuring the area of the contour at the intensity half of the peak intensity of $\mathrm{HCO}^{+} J=4-3$, following the method used in Wu et al. (2010), with the equation:
\[

$$
\begin{equation*}
\theta_{\text {transition }}=2\left(\frac{A_{1 / 2}}{\pi}-\frac{\theta_{\text {beam }}^{2}}{4}\right)^{1 / 2} \tag{2}
\end{equation*}
$$

\]

where $A_{1 / 2}$ is the area within the contour of half-peak intensity and $\theta_{\text {beam }}$ is the angular beam size.
$R_{\text {transition }}$ is the equivalent spatial radius of the clumps, and is calculated as $R_{\text {transition }}=\theta_{\text {transition }} D / 2$,

The line luminosity is then calculated as:

$$
\begin{equation*}
L^{\prime}=23.5 \times 10^{-6} \times D^{2} \times\left(\frac{\pi \times \theta_{\text {transition }}^{2}}{4 \ln 2}\right) \times\left(\frac{\theta_{\text {transition }}^{2}+\theta_{\text {beam }}^{2}}{\theta_{\text {transition }}^{2}}\right) \times \int T_{m b} \mathrm{dv} \mathrm{~K} \mathrm{~km} \mathrm{~s}{ }^{-1} \tag{3}
\end{equation*}
$$

where $T_{m b} d v$ is the integrated intensity at the peak position, $D$ is in kpc and $\theta$ in $\operatorname{arcsecond}$ (Wu et al. 2010). The calculated clump angular sizes, spacial sizes $R$, and the line luminosities for $\mathrm{HCO}^{+} J=4-3$ are listed in Table 5.

These IRDC clumps have $\mathrm{HCO}^{+} J=4-3$ sizes ranging from 0.17 pc to 0.73 pc , with a mean size of 0.33 pc and a median size of 0.28 pc . These sizes are comparable to clump sizes of higher- $J$ transitions found in later stages massive clumps. For example, The half-peak clumps' sizes of $\mathrm{HCN} J=3-2$ towards some UCHII clumps (Wu et al. 2010) have a mean and median size of 0.32 pc and 0.26 pc , respectively. The derived line luminosity of $\mathrm{HCO}^{+} J=4-3$ ranges $0.2-18 \mathrm{~K} \mathrm{~km} \mathrm{~s}^{-1} \mathrm{pc}^{2}$, with a mean and median value of $4.1 \mathrm{~K} \mathrm{~km} \mathrm{~s}^{-1} \mathrm{pc}^{2}$ and $2.6 \mathrm{~K} \mathrm{~km} \mathrm{~s}^{-1} \mathrm{pc}^{2}$, respectively.

### 3.4 Clump Mass and Mass Accretion Rate

Assuming all the mass within the beam is uniformly distributed and contributing to the infall motions and the peak regions are spherical, following Calahan et al. (2018) the mass accretion rate is calculated as:

$$
\begin{align*}
\dot{M} & =4 \pi R^{2} \rho v_{i n}=\frac{3 M v_{i n}}{R} \\
& =3068 \frac{M_{\odot}}{M y r}\left(\frac{M}{1000 M_{\odot}}\right)\left(\frac{v_{i n}}{1 k m s^{-1}}\right)\left(\frac{1 p c}{R}\right), \tag{4}
\end{align*}
$$

The infall velocities used to calculate the mass accretion rates for these IRDCs are from the modelling of $\mathrm{HCO}^{+} J=1-0$ observations. We use the column density maps from Peretto et al. (2016) to calculate the mass then the average volume density of the clumps within the IRAM $\mathrm{HCO}^{+} J=1-0$ beam to match the radius from infall observations, to estimate the mass accretion rates. Peretto et al. (2016) derived the column density maps of the sources from Herschel $160 \mu \mathrm{~m}$ and $250 \mu \mathrm{~m}$ observations obtained as part of the Hi-GAL survey (Molinari et al. 2016) and they estimate an uncertainty of $\sim 50 \%$ in the column density (Peretto et al. 2016).

The assumption that all mass within the beam will contribute to infall profile could lead to an overestimate of the averaged volume density within the beam due to the foreground and background emission along the light of sight, therefore an overestimate on the mass accretion rate. The averaged column density within the beam, as well as the derived mass accretion rate of the sources are listed in Table 5.

Note that the above mass estimated from the column density map within the IRAM beam is a beamsize defined mass. Here we want to estimate the physical mass of these clumps by calculating the total dust masses above $4 \sigma$ of the Herschel map. Based on the radiative transfer equation, following Hildebrand (1983), the flux density of the dust core is related to its mass in the form of

$$
\begin{align*}
S_{\nu} & =\kappa_{\nu} B_{\nu}\left(T_{\mathrm{d}}\right) \Omega \mu m_{\mathrm{H}} N_{\mathrm{tot}} \\
& =\frac{\kappa_{\nu} B_{\nu}\left(T_{\mathrm{d}}\right) M_{\Omega}}{D^{2}} \tag{5}
\end{align*}
$$

wherein $S_{\nu}$ is the flux density at the frequency $\nu . \Omega$ is the solid angle of the core or selected area. $B_{\nu}\left(T_{\mathrm{d}}\right)$ is

Table 5: The derived parameters of IRDC clumps.

Notes: ${ }^{a}$ The physical parameters are from $\mathrm{HCO}^{+} J=4-3$ observations. The clump size and $R_{\text {transition }}$ are determined from half peak intensity of $\mathrm{HCO}^{+} J=4-3$ observations. For some sources, the sizes of half intensity contours are smaller than the beam size that the sources are unresolved. Thus, we can not calculate their sizes and masses. ${ }^{b}$ The physical parameters are from Herschel $160 \mu \mathrm{~m}$ and $250 \mu \mathrm{~m}$ observations, see sect. 3.4 for details. ${ }^{c}$ The physical parameters are derived from $\mathrm{HCO}^{+} J=4-3$ observations, see sect. 3.4 for details.
is the average molecular weight, $m_{\mathrm{H}}$ is the mass of the hydrogen atom, and $\kappa_{\nu}$ is the dust opacity, which is assumed to be related to the frequency in the form $\kappa_{\nu}=\kappa_{230 \mathrm{GHz}}(\nu / 230 \mathrm{GHz})^{\beta}$. The reference value $\kappa_{230 \mathrm{GHz}}=0.009 \mathrm{~cm}^{2} \mathrm{~g}^{-1}$, is adopted from dust model for the grains with coagulation for $10^{5} \mathrm{yr}$ with accreted ice mantles at a density of $10^{6} \mathrm{~cm}^{-3}$ (Ossenkopf \& Henning 1994). $D$ is the source distance. In calculation, we used the $\mathrm{NH}_{3}$ kinetic temperature (Xie et al. 2021 in press) to approximate the dust temperature. The total core mass which covers the regions above $4 \sigma$ in the dust emission map have been calculated using equation 5, and the result is shown in Table 5. The derived masses of these IRDC clumps range from 250 to $3400 \mathrm{M}_{\odot}$, with a mean mass of $770 \mathrm{M}_{\odot}$ and a median mass of $490 \mathrm{M}_{\odot}$. They are massive enough to form massive star clusters.

The average and mean value of the mass accretion rates are $7.5 \times 10^{-3} \mathrm{M}_{\odot} \mathrm{yr}^{-1}$ and $4.8 \times 10^{-3} \mathrm{M}_{\odot} \mathrm{yr}^{-1}$,

HMPOs or UCHII regions, as seen in Table 6. Given that the infall velocity derived from the two-layer model will be underestimated by a factor of 2 compared to HILL5 model, the mass accretion rates in these IRDCs are not very different to those in HMPOs or UCHII regions.

The Kelvin-Helmholtz timescale, which is the time it takes for a star to radiate away its total kinetic energy, reflects how long a star can sustain its luminosity by gravitational contraction. An empirical form of Kelvin-Helmholtz timescale $t_{K H}$ can be written as (Li 2002):

$$
\begin{equation*}
t_{K H} \approx 19 M y r\left(\frac{M_{*}}{M_{\odot}}\right)^{-2.5} \tag{6}
\end{equation*}
$$

where $\mathbf{M}_{*}$ is the stellar mass. For a star sufficiently massive, $t_{K H}$ can be too short for a star to even reach the main sequence (Li et al. 2003; Klaassen \& Wilson 2007). For example, an $8 \mathrm{M}_{\odot}$ stellar mass, the lower end of massive stars, has a Kelvin-Helmholtz timescale of 0.1 Myr. The mass accretion rate has to be high enough to allow mass accumulated within 0.1 Myr to be more than $8 \mathrm{M}_{\odot}$, so that the massive star will survive to main-sequence. Our measured accretion rate of $5 \times 10^{-3} \mathrm{M}_{\odot} \mathrm{yr}^{-1}$ in these IRDC clumps corresponds to the infall of $\sim 500 \mathrm{M}_{\odot}$ in 0.1 Myr . According to equation Eq. 6 , for any stellar mass $\mathrm{M}_{*}$ $\lesssim 26 \mathrm{M}_{\odot}$, the current infall rate can provide enough accretion within its Kelvin-Helmholtz time, but more massive stars will be hard to reach main-sequence. Therefore, these IRDC clumps can form massive stars, but are more likely to form star clusters rather than a single massive star.

## 4 DISCUSSION

### 4.1 Infall tracers for IRDCs

Some works have claimed that $\mathrm{HCO}^{+} J=4-3$ is likely more sensitive to trace infall than $\mathrm{HCO}^{+} J=1-0$ in massive star forming regions, especially for denser regions (Tsamis et al. 2008; Purcell et al. 2006; Klaassen et al. 2012). While in a survey towards a large sample of HMPOs, $\mathrm{HCO}^{+} J=1-0$ has been found to have more prominent infall signatures, i.e. double peaks with self-absorbed dip, than $\mathrm{HCO}^{+} J=4-3$ lines (Fuller et al. 2005), suggesting lower- $J \mathrm{HCO}^{+}$transitions could be a better infall tracer in these regions. Very limited such studies have been done on IRDCs (e.g. Wyrowski et al. 2016). Based on our survey with multiple $\mathrm{HCO}^{+}$lines towards a sample of 23 clumps, we can evaluate their ability in revealing infall in IRDCs.

As seen from Table 3, the surveys with three $\mathrm{HCO}^{+}$transitions at least imply that in infall candidates selected by $\mathrm{HCO}^{+} J=1-0, \mathrm{HCO}^{+} J=4-3$ is not more sensitive, not even comparable, in detecting infall in IRDCs. These results suggest $\mathrm{HCO}^{+} J=4-3$ may not be optically thick enough to reveal infall in these IRDCs, as also indicated by the opacity derived from HILL model in Table 4 and Figure 2.
$\mathrm{HCO}^{+} J=3-2$ has been found to have comparable ability to $\mathrm{HCO}^{+} J=1-0$ to study infall in later stages of massive star forming regions like HMPOs (Fuller et al. 2005; Reiter et al. 2011; Klaassen et al. 2012), and we find a similar trend for $\mathrm{HCO}^{+} J=3-2$ in IRDCs. As well as the line profiles, we also compare the derived infall velocities of the three $\mathrm{HCO}^{+}$transitions as presented in Table 4. The infall velocities derived from $\mathrm{HCO}^{+} J=1-0$ are slightly larger than those from $\mathrm{HCO}^{+} J=3-2$ overall, while the weighted average of both transitions are similar $\left(1.02 \pm 0.03 \mathrm{~km} \mathrm{~s}^{-1}\right.$ for $\mathrm{HCO}^{+} J=1-0$ and $0.89 \pm 0.01 \mathrm{~km} \mathrm{~s}^{-1}$ for $\mathrm{HCO}^{+} J=3-$

Fig. 1: The infall velocity comparisons among the three transitions: $J=1-0, J=3-2$, and $J=4-3$. The diagonal line indicates where the infall velocities are equal. The black markers indicate the weighted average of infall velocities.
the infall velocity does not change much, agreeing with the hypothesis that infall velocity is consistent within these layers or regions. The infall velocities of $\mathrm{HCO}^{+} J=4-3$, on the other hand, are much smaller. The weighted average infall velocity of $\mathrm{HCO}^{+} J=4-3\left(0.67 \pm 0.05 \mathrm{~km} \mathrm{~s}^{-1}\right)$ is more than 1.5 times smaller than what is derived from $\mathrm{HCO}^{+} J=1-0$, with a similar result been found with another study using the two-layer model towards an IRAS source (Barnes et al. 2010). Excluding the non-fitted and/or the negative values in Table 4, the median values of infall velocities for $\mathrm{HCO}^{+} J=1-0,3-2$, and 4-3 are $0.97,0.94$, and $0.74 \mathrm{~km} \mathrm{~s}^{-1}$, respectively. The comparisons between pairs of transitions of $\mathrm{HCO}^{+}$are shown in Figure 1, which suggests that the infall velocity of $\mathrm{HCO}^{+} J=3-2$ is comparable to that of $\mathrm{HCO}^{+} J=1-0$, while both are larger than those of $\mathrm{HCO}^{+} J=4-3$. The opacities derived from the HILL5 model for all three transitions are also listed in Table 4, and are compared between every two transitions for each clumps in Figure 2. It is clear to see that the opacities calculated from $\mathrm{HCO}^{+} J=1-0$ and $3-2$ are comparable and both are much higher than the values from $\mathrm{HCO}^{+} J=4-3$. This is consistent with RADEX (van der Tak et al. 2007) modelling for $10^{4}-10^{5} \mathrm{~cm}^{-3}$ at temperatures from 15 to 30 K . The detailed modelling is beyond the scope of this observational work and will be presented in future works.

### 4.2 Infall properties of IRDCs

Different infall tracers, especially lower- $J$ and higher- $J \mathrm{HCO}^{+}$or HCN transitions normally trace different parts or layers of dense star forming clumps. For massive clumps at different evolutionary stages, like UCHII regions, HMPOs and IRDCs, we will need different infall tracers to best probe the collapsing regions in the clumps, as argued in Wu \& Evans (2003) that infall profile will best be revealed when the opacity of the source and the critical density of the tracer can be well matched. Therefore, the infall properties may be compared for samples at different evolutionary stage as long as the best infall tracers are used to model the kinematic information of infall.

Under this assumption, we find that the infall velocities of IRDCs obtained in this work are in general consistent with the values in other massive star forming regions. For example, an infall velocity of $\sim 1.5 \mathrm{~km} \mathrm{~s}^{-1}$ for $\mathrm{HCO}^{+} J=3-2$ was obtained using HILL5 model towards an IRDC (Contreras et al.

XIE J. J. et al.

Notes: The references are: (1) Fuller et al. (2005); (2) Klaassen \& Wilson (2007); (3) Churchwell et al. (2010); (4) Calahan et al. (2018); (5) Traficante et al. (2018); (6) Giannetti et al. (2015). ${ }^{a}$ The numbers in the parentheses are the numbers of infall candidates versus the total numbers of the sources. The infall velocity derived from two-layer model has been found about a factor of 2 smaller than calculated from the HILL5 model (De Vries \& Myers 2005; Barnes et al. 2010).

Fig. 2: The optical depth comparisons among the three transitions: $J=1-0, J=3-2$, and $J=4-3$. The diagonal line indicates where the optical depths are equal. The black markers indicate the weighted average of optical depths. Despite the scattering of the optical depths of $\mathrm{HCO}^{+} J=3-2$ and $\mathrm{HCO}^{+} J=1-0$, they are similar and both are higher than those of $\mathrm{HCO}^{+} J=4-3$.
$\sim 1.4 \mathrm{~km} \mathrm{~s}^{-1}$. In Table 6, we listed infall velocities as well as mass accretion rates obtained from some other studies towards HMPOs and UCHII regions, to compare with our results. Considering infall velocities calculated from two-layer model are generally a factor of 2 less than obtained from the HILL model, the derived infall velocity and therefore the mass accretion rate of these IRDCs (with a median of $1.0 \mathrm{~km} \mathrm{~s}^{-1}$ ) is actually comparable to those calculated from HMPOs (Fuller et al. 2005) or UCHII regions (Klaassen \& Wilson 2007), which is interesting as this suggests that although these molecular line tracers may origin from different parts/layers of the clumps, they imply that infall velocities are within a similar range for these different samples.

### 4.3 Infall velocities and the $\mathrm{NH}_{3}$ to CCS ratio

Some works have argued that the ratio of the column densities of $\mathrm{NH}_{3}$ and CCS could be an indicator of chemical evolution in low mass and high mass star formation (e.g. Suzuki et al. 1992; Sakai et al. 2008).

Fig. 3: Infall velocities versus the logarithm of the ratio of the column density of $\mathrm{NH}_{3}$ to that of CCS .
we have tested to see if there is any correlation between the obtained infall velocity and the logarithm of the ratio of the column density of $\mathrm{NH}_{3}$ to that of CCS. To best match the resolution of the $\mathrm{NH}_{3}$ and CCS survey (HPBW~45") (Xie et al. 2021, in press), we use the infall velocities derived from $\mathrm{HCO}^{+} J=1-$ 0 (HPBW~30"). The results are shown in Figure 3. For the IRDCs in our sample, we see no obvious correlation between infall velocities and the logarithm of the ratio of the $\mathrm{NH}_{3}$ column density to the CCS column density.

## 5 CONCLUSIONS

We summarise our main conclusions as the following:

1. We investigate the infall properties in a sample of 11 IRDCs which present infall line profiles in a $\mathrm{HCO}^{+} J=1-0$ survey by Peretto et al. (in prep). A total of 23 clumps were identified in $\mathrm{HCO}^{+} J=4-3$ maps of theses IRDCs and they were observed in $\mathrm{HCO}^{+} J=3-2$ using JCMT. The sizes and line luminosities of these IRDC clumps in $\mathrm{HCO}^{+} J=4-3$ were calculated.
2. We compare the infall signatures traced by the three transitions of $\mathrm{HCO}^{+}$towards the peaks of the 23 IRDC clumps and found that $\mathrm{HCO}^{+} J=3-2$ can trace infall signature well in this $\mathrm{HCO}^{+} J=1-0$ selected sample, while $\mathrm{HCO}^{+} J=4-3$ shows the least blue asymmetric profiles in these IRDCs.
3. We used the HILL model to fit infall parameters based on the three $\mathrm{HCO}^{+}$transitions profiles for the identified IRDC clumps. The infall velocities derived from $\mathrm{HCO}^{+} J=1-0$ range from 0.5 to $2.7 \mathrm{~km} \mathrm{~s}^{-1}$, with a median of $1.0 \mathrm{~km} \mathrm{~s}^{-1}$, which are similar to the values derived from $\mathrm{HCO}^{+} J=3-2$ and are more than 1.5 times larger than the values derived from $\mathrm{HCO}^{+} J=4-3$.
4. The infall velocities and the mass accretion rates in the IRDC clumps in our survey are comparable to
5. No prominent correlation between the infall velocities and the ratio of $\mathrm{NH}_{3}$ column density to CCS column density has been found in this sample.

## Appendix. 1 Observational Positions of RxA3m of $\mathrm{HCO}^{+} J=3-2$ on the emission map of

 $\mathbf{H C O}^{+} J=1-0$ with $\mathbf{H C O}^{+} J=4-3$ contours.

Fig. 4: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for SDC18.624. The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. A and B are the observed positions of $\mathrm{HCO}^{+} J=3-2$. The spectra are fitted with HILL model. The black emission profiles are from the data, while the red lines represent the fitted profiles. The grey dot at the corner of the emission map represents the IRAM beam size.

SDC18.888-0.476

Fig. 5: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for SDC18.888. The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. A and B are the observed positions of $\mathrm{HCO}^{+} J=3-2$. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 6: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for $\operatorname{SDC} 22.373$. The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. A and B are the observed positions of $\mathrm{HCO}^{+} J=3-2$. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 7: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for SDC 23.367 . The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. A and B are the observed positions of $\mathrm{HCO}^{+} J=3-2$. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 8: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for SDC 24.489 . The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. A and B are the observed positions of $\mathrm{HCO}^{+} J=3-2$. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 9: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for SDC 24.618 . The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. A and B are the observed positions of $\mathrm{HCO}^{+} J=3-2$. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 10: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for $\operatorname{SDC} 25.166$. The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. $\mathrm{A}, \mathrm{B}$, and C are the observed positions of $\mathrm{HCO}^{+} J=3-2$. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 11: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for SDC28.333. The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. A, B, C, and D are the observed positions of $\mathrm{HCO}^{+} J=3-2$. Note that at B position, $\mathrm{HCO}^{+} J=1-0$ shows no strong emission, despite B position is the emission peak for $\mathrm{HCO}^{+} J=4-3$ and $\mathrm{HCO}^{+} J=3-2$ also shows strong emission. The reasons are unknown yet. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 12: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for SDC35.429. The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 13: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for SDC35.527. The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. $\mathrm{A}, \mathrm{B}$, and C are the observed positions of $\mathrm{HCO}^{+} J=3-2$. The grey dot at the corner of the emission map represents the IRAM beam size.

Fig. 14: The integrated intensity map of $\mathrm{HCO}^{+} J=1-0$ overlaid with $\mathrm{HCO}^{+} J=4-3$ contours at $0.5,0.8$, and 1.0 of the maximum of the integrated intensity in $\mathrm{K} \mathrm{km} \mathrm{s}^{-1}$ for $\operatorname{SDC} 35.745$. The maximum of the integrated intensity has been stated in Table 5 as the biggest value of $\int T_{M B} d v$ for the source. The grey dot at the corner of the emission map represents the IRAM beam size.
