#### Abstract

We present a spectral study of the black hole candidate MAXI J1348-630 during its 2019 outburst, based on monitoring observations with Insight-HXMT and Swift. Throughout the outburst, the spectra are well fitted with power-law plus disk-blackbody components. In the soft-intermediate and soft states, we observed the canonical relation $L \propto T_{\text {in }}^{4}$ between disk luminosity $L$ and peak colour temperature $T_{\text {in }}$, with a constant inner radius $R_{\text {in }}$ (traditionally identified with the innermost stable circular orbit). At other stages of the outburst cycle, the behaviour is more unusual, inconsistent with the canonical outburst evolution of black hole transients. In particular, during the hard rise, the apparent inner radius is smaller than in the soft state (and increasing), and the peak colour temperature is higher (and decreasing). This anomalous behaviour is found even when we model the spectra with self-consistent Comptonization models, which take into account the up-scattering of photons from the disk component into the power-law component. To explain both those anomalous trends at the same time, we suggest that the hardening factor for the inner disk emission was larger than the canonical value of $\approx 1.7$ at the beginning of the outburst. A more physical trend of radii and temperature evolution requires a hardening factor evolving from $\approx 3.5$ at the beginning of the hard state to $\approx 1.7$ in the hard intermediate state. This could be evidence that the inner disk was in the process of condensing from the hot, optically thin medium and had not yet reached a sufficiently high optical depth for its emission spectrum to be described by the standard optically-thick disk solution.

[^0]
## 1. INTRODUCTION

A black hole binary (BHB) consists of a black hole (BH) and a companion star. Depending on the mass of their donor stars, BHBs are classified as high mass X-ray binaries (HMXBs; $\mathrm{M}_{2} \geq 10 M_{\odot}$ ) or low mass X-ray binaries (LMXBs; $\mathrm{M}_{2} \leq 1 M_{\odot}$ ). Matter is transferred from the companion star to the compact object mainly through stellar winds in HMXBs, and Roche-lobe overflow in LMXBs (Charles \& Coe 2006), with the formation of a geometrically thin, optically thick accretion disk (Shakura \& Sunyaev 1973).

Roche-lobe fed BHBs tend to be transient, alternating between outburst and quiescence. In the "canonical" interpretation, outbursts are due to disk instabilities (Lasota 2001). Outbursts are typically divided into several spectral states (e.g., Fender et al. 2004; Remillard \& McClintock 2006; Motta et al. 2009). At the beginning, the source rises in the hard state (HS), dominated by a hard power-law component in the Xray band, and with a flat-spectrum radio core attributed to a steady compact jet. The power-law component extends to $>100 \mathrm{keV}$ and originates from inverse Compton scattering in a hot corona or the base of the jet. The accretion disk is usually thought to be truncated and does not dominate the X-ray emission. In an X-ray hardness-intensity diagram (HID), the source at this point is rising along the right branch. Next, a transient BHB generally switches to the intermediate state
(IMS). The soft thermal emission from the disk component gradually becomes significant, as the disk extends inward; the source moves along the top horizontal branch in the HID. Normally, the IMS can be further divided into the hard intermediate state (HIMS) and soft intermediate state (SIMS). The spectra of the SIMS are slightly softer than the HIMS, and the so-called type-B QPO would appear in the SIMS. When the jet turns off and the spectra are softer and dominated by the disk emission, the transient enters the high/soft (or thermal dominant) state (SS, top left section of the HID). In this state, the type-B QPO disappears and the inner disk is thought to reach the innermost stable circular orbit (ISCO). After several weeks or months, transient BHBs decline through an IMS (lower horizontal branch of the HID) and finally back to the low/hard state with a restarted jet, completing a counterclockwise q-shaped track in the HID (Belloni et al. 2005; Belloni \& Motta 2016; Remillard \& McClintock 2006).
This simplified outburst outline may suggest that the physical evolution of disk, jet and corona are all connected, and produce the common behaviour in all BHBs. However, this may not always be the case. In this paper, we illustrate and discuss one example of X-ray outburst in a recently discovered BH candidate, MAXI J1348-630, in which the evolution of the fitted disk parameters is different from the canonical scenario. This suggests that there are still important aspects of the outburst cycle that differ from source to source and require more accurate modelling.

MAXI J1348-630 was discovered with the Monitor of Allsky X-ray Image (MAXI; Matsuoka et al. 2009) Gas Slit Camera (GSC) on 2019 January 26 (Yatabe et al. 2019). The initial discovery triggered a flurry of follow-up observations: with the Hard X-ray Modulation Telescope (Insight-HXMT) (Chen et al. 2019), the Neil Gehrels Swift Observatory (Swift) (Kennea \& Negoro 2019), INTEGRAL (Lepingwell et al. 2019) and the Neutron star Interior Composition Explorer (NICER) (Sanna et al. 2019) in the X-ray bands; with the $50-\mathrm{cm}$ T31 telescope (Denisenko et al. 2019), the Las Cumbres Observatory 2-m and 1-m robotic telescopes (Russell et al. 2019a) and the Southern African Large Telescope (Charles et al. 2019) in the optical bands; with the Australia Telescope Compact Array (Russell et al. 2019b), MeerKAT (Carotenuto et al. 2019) and the Murchison Widefield Array (Chauhan et al. 2019) in the radio bands. A distance of $\sim 2.2 \mathrm{kpc}$ was estimated from the HI absorption (Chauhan et al. 2020), or of $\sim 3.39 \mathrm{kpc}$ from the dust scattering ring around the source (Lamer et al. 2020).
The optical counterpart brightened by at least $\sim 2.8 \mathrm{mag}$ at the beginning of the outburst (Denisenko et al. 2019; Russell et al. 2019a), as expected for an LMXB. There is no dynamical mass measurement for the compact object. Its identification as a BH candidate is supported by its radio detection (Russell et al. 2019b; Carotenuto et al. 2019), the strong broadband noise and "power color" in its power spectrum (Sanna et al. 2019), its optical/X-ray (Russell et al. 2019a) and radio/X-ray (Russell et al. 2019b) correlations. The main outburst lasted for about four months, with a peak flux of $\sim 4$ Crab in the $2-20 \mathrm{keV}$ band (Tominaga et al. 2020), followed by several re-brightenings (e.g., Russell et al. 2019c; Negoro et al. 2019; Al Yazeedi et al. 2019; Pirbhoy et al. 2020; Zhang et al. 2020a). A compact, steady radio jet was detected in the initial HS (Russell et al. 2019b; Carotenuto et al. 2019), and bright radio flaring marked the hard-to-soft state transition (Carotenuto et al. 2019; Chauhan et al. 2019). Low-frequency quasi periodic oscillations (QPOs) were detected in the hard and intermediate states (Chen et al. 2019; Sanna et al. 2019;

Jana et al. 2019, 2020; Belloni et al. 2020; Zhang et al. 2020b, Huang et al., in prep). The inner disk radius and temperature in the SS, and the X-ray luminosity at the state transitions are consistent with a $\sim 10-M_{\odot}$ stellar BH (Tominaga et al. 2020; Jana et al. 2020), with large uncertainties function of BH spin, viewing angle and source distance. The long-term monitoring suggested that the hard X-rays and the optical emission changed simultaneously, and both leaded the soft X-rays by about 8-12 days (Weng et al. 2021).

In this paper, we present detailed results of our study of the outburst evolution with Insight-HXMT. The broad energy band and large effective area at high energy make InsightHXMT an ideal instrument to study the spectral and timing evolution of X-ray transients, especially for bright sources, such as MAXI J1348-630, which may suffer from pile-up in other X-ray telescopes. We describe observations and data analysis in Section 2, we model the spectral state evolution in Section 3, and discuss the results in Section 4.

## 2. OBSERVATIONS AND DATA REDUCTION

Insight-HXMT is the first Chinese X-ray observatory, launched on 2017 June 15 (Zhang et al. 2020). It carries three telescopes with high time resolutions and large effective areas: the Low Energy (LE) telescope with an effective area of $384 \mathrm{~cm}^{2}$ at $1-15 \mathrm{keV}$ (Chen et al. 2020); the Medium Energy (ME) telescope with $952 \mathrm{~cm}^{2}$ at $5-30 \mathrm{keV}$ (Cao et al. 2020); the High Energy (HE) telescope with $5100 \mathrm{~cm}^{2}$ at $20-250 \mathrm{keV}$ (Liu et al. 2020). Each telescope carries large and small field-of-view (FOV) detectors, in order to facilitate the background analyses. The small FOV detectors (LE: $1.6^{\circ} \times 6^{\circ}$; ME: $1^{\circ} \times 4^{\circ}$; HE: $1.1^{\circ} \times 5.7^{\circ}$ ) have low probability of source contamination, thus are applicable to observe point sources.

Insight-HXMT started to observe MAXI J1348-630 on 2019 January 27 (MJD 58510), one day after its discovery, and monitored it until the end of the main outburst on May 30. We obtained 59 observations, each divided into sub-exposures (a total of 171 individual sub-exposures). The exposure time of each observation varied between $10-150 \mathrm{ks}$, with a total exposure time of 1500 ks .

We extracted and analyzed the data with the Insight-HXMT Data Analysis software ${ }^{13}$ (HXMTDAS) V2.04. We used only data from the small FOV detectors. We created good time intervals with the following selection criteria: (1) pointing offset angle $<0.04^{\circ}$; (2) elevation angle $>10^{\circ}$; (3) geomagnetic cutoff rigidity $>8 \mathrm{GV}$; (4) at least 300 s away from the crossing of the South Atlantic Anomaly. The LE, ME and HE background spectra are taken from the blind detectors because the spectral shape of the particle background is the same for both the blind and the small field-of-view detectors (Liao et al. 2020a; Guo et al. 2020; Liao et al. 2020b). We created background spectra with the lebkgmap, mebkgmap and hebkgmap tasks in HXMTDAS, and response files with lerspgen, merspgen and herspgen.

The Swift X-Ray Telescope (XRT) also monitored the main outburst, with 43 observations ${ }^{14}$, each with a typical exposure time of $\sim 1 \mathrm{ks}$. We reprocessed the Swift/XRT data with the XRTPIPELINE software (calibration database version 20191017) and extracted spectra with xselect v 2.4 g . In most observations, the count rates are very high, above $100 \mathrm{ct} \mathrm{s}^{-1}$.

[^1]To mitigate that, we only used data taken in windowed timing mode; even in this mode, the pile-up effect cannot be ignored and the source core should be excluded from spectral extraction. Thus, we used annular source regions (Tao et al. 2018) with an outer radius of 20 pixels and an inner radius adjusted to have a count rate below $100 \mathrm{ct} \mathrm{s}^{-1}$. The background regions were chosen as annuli centered on the source, with an outer radius of 110 pixels and an inner radius of 90 pixels. Heavily absorbed sources (column densities of about $10^{22} \mathrm{~cm}^{-2}$ and above) observed in windowed timing mode can show a spurious emission bump in the low energy spectrum, below 1 keV . To reduce this problem, we only included grade0 events when extracting the spectrum ${ }^{15}$ and ignored energies below 0.6 keV . We generated ancillary response files with the xrtmkarf task in the FTOOLS package (Blackburn 1995).

We used the FTOOLS task grppha to rebin both sets of spectra (from Insight-HXMT and Swift) to a minimum of 20 counts per bin, and we fitted them in Xspec (Arnaud 1996) with the $\chi^{2}$ statistics. We added a systematic uncertainty of $2 \%$ to the Insight-HXMT spectra.

## 3. RESULTS

### 3.1. Light Curve, Hardness Ratio and HIDs

The Insight-HXMT/LE $2-10 \mathrm{keV}$ light-curve shows (Figure 1, panel a) an outburst peak at MJD 58522, when the LE count rates reached $\sim 2400$ ct s $^{-1}$, followed by a gradual decline down to a count rates of $2 \mathrm{ct} \mathrm{s}^{-1}$ on its last observation of the source (MJD 58617). The evolution is consistent with the $S$ wift/XRT light-curve (Figure 1, panel b), with the added bonus that the Insight-HXMT/LE observations have higher cadence and no pile-up issues even at outburst peak.
We define a hardness ratio HR1 from the ratio of the $4-$ 10 keV over the $2-4 \mathrm{keV}$ count rates in Insight-HXMT/LE, and a hardness ratio HR2 for the $4-10 \mathrm{keV}$ over $0.5-4 \mathrm{keV}$ rates in Swift/XRT. Both HR1 and HR2 clearly show (Figure 1, panels $\mathrm{c}, \mathrm{d}$ ) evolution and a sequence of transitions, corresponding to various outburst stages. The difference between HIMS and SIMS is defined by the detection of a Type-B QPO in the latter, from MJD 58522 to MJD 58528 and again very briefly from MJD 58539 to MJD 58540 (Belloni et al. 2020; Zhang et al. 2020b, Huang et al., in prep.). InsightHXMT/LE's data show very clearly that the transition from HIMS to SIMS corresponds to the peak count rates. From MJD 58528 to MJD 58596 is the SS, during which the flux decays exponentially (Figure 1, panel a). The decay timescale is 32 days. The reverse transition from the SS to the IMS and then HS starts on MJD 58596. Combining the intensities and hardness ratios, we obtain the typical q-shaped evolutionary track expected for a BHB outburst (Figure 2), with consistent results between Insight-HXMT/LE and Swift/XRT. For comparison, we also plot the HID from $M A X I / \mathrm{GSC}^{16}$; see Tominaga et al. (2020) for the MAXI results.

### 3.2. Spectral Analysis

Not all observations provide enough signal-to-noise for detailed spectral modelling. For Insight-HXMT, we do not model the hard-state data from the fading stage (after MJD 58617). The observation on MJD 58510 (2019 January 27) is also not used, because its effective exposure time is too short (200 s). All Insight-HXMT observations used for spectral

[^2]analysis are listed in Table 1. We also discard LE data in the $7-10 \mathrm{keV}$ band, because its systematic error is twice as large as in the $1-7 \mathrm{keV}$ band (Li et al. 2020). The energy bands used for LE, ME and HE fitting are $1-7 \mathrm{keV}, 10-35 \mathrm{keV}$ and $35-150 \mathrm{keV}$, respectively. For Swift/XRT, we use all available observations (Table 2), and fit the spectra in the $0.6-10 \mathrm{keV}$ band. All errors represent the $90 \%$ confidence range for a single parameter, unless otherwise stated.

### 3.2.1. diskbb+cutoffpl model

For a typical BHB, the continuum consists of a non-thermal component from the corona and a multicolor blackbody component from the disk. The power-law component dominates in the HS, the disk component in the SS. In the IMS, both components may give a significant contribution. Thus, we tried fitting the spectra with a single broad-band non-thermal component (cutoffpl for Insight-HXMT and powerlaw for Swift), a single disk blackbody (disk.bb) and a twocomponent model (diskbb+cutoffpl for Insight-HXMT and diskbb+powerlaw for Swift). For Insight-HXMT, we included a free energy-independent multiplicative factor (constant) to account for slightly different normalizations of LE, ME and HE.

The reason we used an exponential roll-off model for In-sight-HXMT but a simple power-law model for Swift is that the cut-off energy is $>60 \mathrm{keV}$ and cannot be constrained in the $0.6-10 \mathrm{keV}$ XRT energy band. For the HS and HIMS, we used F-tests to determine whether the thermal component was significant. For the Swift spectra in the SIMS and SS, we fixed the power-law photon index $\Gamma$ to the constant "canonical" value of 2.5 because the power-law tail in those states is very weak and its slope is unconstrained over the small XRT energy band.

Another possible source of X-ray emission that, in principle, we should be concerned about, for the LE (given its large field of view), is scattered emission from the dust ring discovered by Lamer et al. (2020). Such structure is located at a distance of $\sim 2 \mathrm{kpc}$ from us, it has an apparent angular radius on the sky of $\sim 40^{\prime \prime}$ ( $\sim 20 \mathrm{pc}$ ), and scatters X-ray photons into our line of sight with a time delay of $\sim 400 \mathrm{~d}$ from the original time of emission from MAXI J1348-630 (Lamer et al. 2020). However, our observations cover only the first $\sim 100$ days of the outburst, during which that particular scattering structure is not relevant. In principle, there may be other scattering rings already appearing within the first $\sim 100$ days, caused by dust located at smaller angular distances from our line of sight to the source. Scaling from the results of Lamer et al. (2020), and assuming those other putative dust structures are also located at $\sim 2 \mathrm{kpc}$, we estimate that a scattering ring visible after a time delay of $\sim 100$ days would have a radius of $\sim 17^{\prime}$ (a little larger than the Swift/XRT field of view), or a radius of $\sim 12^{\prime}$ (Swift/XRT field of view) for a time delay of $\sim 50$ days. We searched for such rings of scattered emission in the Swift images but found no evidence. Thus, we can plausibly assume that the X-ray photons detected in our spectra are all from direct emission.

We modelled the absorption with t.babs, with abundances from Wilms et al. (2000). Initially, we kept the column density $N_{\mathrm{H}}$ free at every epoch. Later, we repeated the modelling with a fixed value of $N_{\mathrm{H}}$ for the whole outburst (as discussed in Section 3.3).

Both disk and power-law components are needed for all observations, except for the last three Swift observations near the end of the main outburst given the lower statistics. Four

Figure 1. (a) Insight-HXMT/LE $2-10 \mathrm{keV}$ light-curve. (b) Swift/XRT $0.5-10 \mathrm{keV}$ light-curve; we avoid pile-up problems by using an annular source extraction region, then correct the count rates with the ancillary response function. (c) Insight-HXMT/LE hardness ratio, defined as the ratio of $(4-10 \mathrm{keV}) /(2-4 \mathrm{keV})$ count rates. (d) Swift/XRT hardness ratio, defined as the ratio of $(4-10 \mathrm{keV}) /(0.5-4 \mathrm{keV})$ count rates. Vertical lines mark the onset of different states: hard state (HS), hard-intermediate state (HIMS), soft-intermediate state (SIMS), soft state (SS), and intermediate state (IMS) in the decline phase.
representative spectra for different state, obtained from In-sight-HXMT, are shown in Figure 3. The spectral evolution is shown in Figure 4, and the spectral parameters are summarized in Tables 1 (Insight-HXMT) and 2 (Swift). Most spectra can be well described by two continuum components, except for some Insight-HXMT observations in the SS and SIMS with reduced $\chi^{2}$ larger than 1.5 . Upon closer inspection, we find that the large values of $\chi^{2}$ come mainly from some narrow residuals in LE and the residuals in different observations have a similar structure, which may be due to some systematic uncertainties in calibration. As we focus on the evolution of the broad continuum components, the narrow residuals only have minor impact on the parameter determination.
The results from Insight-HXMT and Swift show a good consistency in the evolution for most parameters, especially for the disk parameters. However, we also note that $N_{\mathrm{H}}$ values in some Swift observations are larger than those obtained from Insight-HXMT, even after we adopt $N_{\mathrm{H}}$ derived from the $0.6-$ 10 keV band fits (see above). The photon index ( $\Gamma$ ) is smaller in some Swift spectra; this may be due to the different energy bands of the two satellites ( $1-150 \mathrm{keV}$ for Insight-HXMT and $0.6-10 \mathrm{keV}$ for Swift). We also test the fits by fixing Swiftderived $\Gamma$ at the value of 2 , and find that the other parameters change only slightly. Moreover, our results are consistent with previously published results: Bassi et al. (2019) analyzed the Swift spectra from MJD 58517 and 58519, and obtained similar disk temperatures ( $T_{\text {in }}$ ) to ours. Our results also agree with $T_{\text {in }}$ derived from the MAXI/GSC spectra during the whole main outburst and justify their assumption about $\Gamma$ (Tominaga et al. 2020). The spectral evolution is also consistent with the NICER results from Zhang et al. (2020b) except for the disk normalization in the IMS at the end of the outburst. We also note that an extra gaussian model is added in their spectral
fitting in order to account for the extra residuals below 3 keV after MJD 58603. The residuals may be due to the instrumental effects and the use of the gaussian model may affect the determination of the disk normalization.

As show in Figure 4, the parameters show a clear evolution between different states, which also justifies the classification of the spectral states. In the rising phase, the inner disk temperature ( $k T_{\text {in }}$ ) decreases from 0.75 to 0.5 keV in the HS, and increases to 0.75 keV in the HIMS. Then, it gradually decreases in the SIMS and SS, and suddenly decreases in the IMS and HS at the end of the outburst. The disk normalization ( $N_{\text {disk }}$ ) has an increasing trend in the HS and slightly decreases in the HIMS in the rising phase, then keeps nearly constant in the SIMS and SS. In the IMS and HS at the end of the outburst, $N_{\text {disk }}$ gradually decreases. $\Gamma$ is small in the HS and gradually increases from 1.5 to 2.1 in the HIMS. $\Gamma$ then stays at 2.3 in the SIMS and SS, and decreases in the IMS and HS at the end of the outburst. $E_{\text {cut }}$ ranges around 70 keV in the HS, and then slightly increases. However, as the power-law component is weak in the SS and the source count rate is low during the fading stage, $E_{\text {cut }}$ can not be well constrained since the SS. $N_{\mathrm{H}}$ also evolves in the outburst. $N_{\mathrm{H}}$ in the SS is larger than that in the HS, increasing from 0.7 to $1 \times 10^{22} \mathrm{~cm}^{-2}$. We are aware that there is often a degeneracy between the fitted values of $N_{\mathrm{H}}, T_{\mathrm{in}}$ and $N_{\text {disk }}$. We will examine and discuss the behaviour of those parameters under the assumption of a constant $N_{\mathrm{H}}$ in Section 3.3.

The relative disk contribution to the unabsorbed flux increases from less than $10 \%$ in the HS to above $60 \%$ in the SS, and then decreases to below $10 \%$ in the HS at the end of the outburst. The relations between the disk luminosity $\left(L_{\text {disk }}\right)$ and the inner disk color temperature ( $T_{\text {in }}$ ) during the SIMS and SS are shown in Figure 5. $L_{\text {disk }}$ is proportional to $T_{\text {in }}^{3.63 \pm 0.11}$ and

Figure 2. Top panel: HID based on the data from Insight-HXMT/LE. Red points mark the observations with Type-C QPOs, cyan points those with typeB QPOs, and four blue circles marked with 'a', 'b', 'c' and 'd' corresponding to the four observations in Figure 3. Middle panel: HID from Swift/XRT. Bottom panel: HID from MAXI/GSC.
$T_{\mathrm{in}}^{4.3 \pm 0.3}$ for Insight-HXMT and Swift, respectively, consistent with $L_{\text {disk }} \propto T_{\text {in }}^{4}$ expected from a standard thin disk extending to the ISCO (Makishima et al. 1986). For other states, $L_{\text {disk }}$ and $T_{\text {in }}$ deviate significantly from the relationship of $L_{\text {disk }} \propto T_{\text {in }}^{4}$.

### 3.2.2. diskbb+nthcomp+nthcomp model

We find that, in the HS and the IMS, there is a bulge or a change of slope around $20-40 \mathrm{keV}$ in the spectra, when fitted with a single power-law component. This may be evidence of an additional Comptonization component. By analogy with the two Comptonizing regions assumed in the model of García et al. (2021), we also tried a double Comptonization model. First, we tried with two nthcomp components (this Section), then with one nthcomp and one thermal comptonization component (Sections 3.2.3 and 3.2.4). In all our modelling, we fixed the seed photon temperature of nthcomp at $0.1 \mathrm{keV}^{17} \mathrm{An}$ additional diskbb component was also included, because it is statistically significant (F-test null probability $<0.01$ ) both in the HS and the IMS. As shown in Figure 6 top panel, the diskbb plus two nthcomp model improved the spectral fits significantly, both in the $20-40 \mathrm{keV}$ region and in the shape of the down-up around 100 keV . The two Comptonization component have different best-fitting values of $k T_{\mathrm{e}}$. The higher temperature is greater than 40 keV , and may come from the region of the corona closer to the disk. The lower temperature is less than 15 keV , and may come from the outer, cooler part of the corona. The detailed interpretation will be discussed in Guan et al. (in prep). The peak disk temperature and normalization are shown in the top panel of Figure 7: $N_{\text {disk }}$ is consistent with that obtained with the simpler model (Section 3.2.1), while $k T_{\text {in }}$ is about 0.05 keV lower, during the HS. The best-fitting values of the parameters and their uncertainties are shown in Table 3.

### 3.2.3. simplcut $*$ diskbb+nthcomp model

A simple addition of separate diskbb and power-law or Comptonization components, as we have done so far, does not self-consistently account for the disk photons that are upscattered into the harder component(s). This loss of photons reduces the fitted normalization of the disk emission in the HS (Yao et al. 2005). As a consequence, the fitted disk radius may appear smaller than the true radius. To avoid this problem, we re-fitted the spectra with a self-consistent thermal Comptonization model, s impl cut (Steiner et al. 2017), convolved with disk.b.b. We kept the scattering fraction as a free parameter in our fits, and fixed the reflection fraction to zero. We constrained the $k T_{\mathrm{e}}$ parameter to a positive value to ensure that the Compton kernel used by simplcut is nthcomp (Steiner et al. 2017). We also included an additional nthcomp component in the HS and IMS. The bestfitting parameter values are summarized in Table 4; peak colour temperature and normalization of the disk are shown in the middle panel of Figure 7; a representative spectrum is shown in Figure 6 bottom panel. As expected, $N_{\text {disk }}$ is now a factor of 2 larger in the HS and IMS (both at the beginning and at the end of the outburst) than what we had estimated previously; however, it still shows the anomalous increasing trend in the initial HS. Likewise, $T_{\text {in }}$ still shows the anomalous decreasing trend in that state.

[^3]

Figure 3. Four representative spectra for different states of MAXI J1348-630, obtained from Insight-HXMT observations 021400200201 (panel a, HS); 021400200701 (panel b, HIMS); 021400201701 (panel c, SIMS); 021400202801 (panel d, SS). The blue symbols for LE ( $1.0-7.0 \mathrm{keV}$ ), the green symbols for ME ( $10.0-35.0 \mathrm{keV}$ ), and the red symbols for $\mathrm{HE}(35.0-150.0 \mathrm{keV})$. The diskbb and cutoffpl components are plotted in magenta dashed and cyan dash-dotted lines, respectively.

### 3.2.4. diskir+nthcomp model

As a further test, we also modelled our spectra with the Comptonization model diskir (Gierliński et al. 2009), with an additional nthcomp in the HS and IMS. We fixed the values of $f_{\text {in }}, r_{\text {irr }}, f_{\text {out }}$ and $\log r_{\text {out }}$ at $0.1,1.2,0.001$ and 5 , respectively; different choices of those default values do not strongly affect the other X-ray fitting parameters. Based on the two ranges of $k T_{\mathrm{e}}$ found in our previous fits with the double nthcomp model (Section 3.2.2), we expect to find a hotter and a colder corona also with the diskir+nthcomp model. We assumed that the hotter coronal emission is associated with diskir, because it comes from a region closer to the inner disk, and the cooler component is modelled by nt hcomp. Accordingly, we constrained the $k T_{\mathrm{e}}$ parameter of nth comp to be $<15 \mathrm{keV}$ in our fits, to avoid a fitting degeneracy with the $k T_{\text {e }}$ parameter in diskir. We find that $T_{\text {in }}$ is significantly lower than estimated with the simple diskbb model (Section 3.2.1), and $N_{\text {disk }}$ is several times larger, both at the beginning and at the end of the outburst, more in agreement with what we expect from the evolution of the inner disk radius, at all stages except for the initial HS. In the initial state, we find
again an anomalous increase of $N_{\text {disk }}$ and a decrease of $T_{\text {in }}$. However, the reduced $\chi^{2}$ values of our diskir+nthcomp fits are much worse than those obtained from the double nthcomp fits or from the simplcut plus nthcomp fits. On closer inspection, we noticed that diskir does not reproduce well the spectral curvature above $\approx 50 \mathrm{keV}$. Thus, we consider the diskir+nthcomp parameters less reliable than those obtained with the models described in the previous sections.

### 3.3. Parameter evolution assuming constant $N_{\mathrm{H}}$

In all the modelling described so far, we have always kept $N_{\mathrm{H}}$ as a free parameter. Its best-fitting value remains approximately constant throughout the SIMS and SS, but is lower in the initial and final HSs. We cannot rule out that this is a physical effect: for example, accretion disk winds may contribute to the absorbing column in the SS. However, more plausibly, the apparent change in $N_{\mathrm{H}}$ is only a fitting artifact, related to a degeneracy in the fit parameters. Thus, we need to study how the other parameters vary when we assume a constant $N_{\mathrm{H}}$. For this analysis, we selected the simplcut*disk.b.b+nthcomp model (Section 3.2.3) as

Figure 4. Evolution of Insight-HXMT (blue points) and Swift (magenta points) spectral parameters. From top to bottom: the inner disk color temperature ( $T_{\text {in }}$ ), the square root of the normalization of the diskbb model $\left(N_{\text {disk }}=\left(r_{\text {in }} / D_{10}\right)^{2} * \cos \theta\right)$, the hydrogen absorption column density $\left(N_{\mathrm{H}}\right)$, the power-law photon index $(\Gamma)$ and the exponential roll-off energy ( $E_{\text {cut }}$ ).

Figure 5. Disk flux versus inner disk temperature of the SIMS (blue symbols) and the SS (red symbols) for Insight-HXMT (left panel) and Swift (right panel). The flux is in units of $\mathrm{erg} \mathrm{cm}^{-2} \mathrm{~s}^{-1}$, and $k T_{\text {in }}$ is in units of keV . The dashed lines represent the best fitting relation.

Figure 6. Top panel: spectral model and residuals for the Insight-HXMT spectra from observation 021400200201 (first available observation in the HS), fitted with a tbabs* (diskbb+nthcomp+nthcomp) model and free $N_{\mathrm{H}}$ (which in this case takes the value of $\approx 7.3 \times 10^{21} \mathrm{~cm}^{-2}$ ). See Table 3 for the fit parameters. The blue datapoints in the residuals are for the LE ( $1.0-7.0 \mathrm{keV}$ ), the green datapoints for the ME ( $10.0-35.0 \mathrm{keV}$ ), and the red datapoints for the HE ( $35.0-150.0 \mathrm{keV}$ ). The spectral components are described in the plot legend. Bottom panel: same as the top panel, but this time the model is tbabs* (simplcut*diskbb+nthcomp) (best-fitting $N_{\mathrm{H}} \approx 7.2 \times 10^{21} \mathrm{~cm}^{-2}$ ). See Table 4 for the fit parameters.
the most physical choice, based on our detailed comparison of alternative models (Sections 3.2.1-3.2.4). We determined the median value of $N_{\mathrm{H}}$ during the SIMS, $N_{\mathrm{H}} \approx 8.9 \times 10^{21} \mathrm{~cm}^{-2}$. We froze $N_{\mathrm{H}}$ at that value for every epoch. We also fixed the seed photon temperature of nt hcomp at 0.1 keV ; we verified that the parameter evolution trends do not change if we link the seed photon temperature instead to $T_{\text {in }}$ of diskbb. The best fitting parameter values are shown in Figure 8. Two representative spectra, one from the HS and one from the SIMS, are shown in Figure 9.
The only significant differences between the free- $N_{\mathrm{H}}$ and fixed $-N_{\mathrm{H}}$ are in the initial and final stages of the outburst. In the initial HS, the peak colour temperature decreases from $\approx 0.45 \mathrm{keV}$ to $\approx 0.35 \mathrm{keV}$. This decline is less dramatic than we found from the free- $N_{\mathrm{H}}$ fit, but it is still significant, at a time when the canonical outburst evolution predicts a temperature increase. The temperature trend reverses and becomes consistent with a standard disk evolution from the beginning of the HIMS. At the same time, the apparent inner radius $r_{\text {in }}$ increases by a factor of 2 in the initial HS-a more moderate

Figure 7. Disk parameter evolution in the framework of different models. In all panels, the blue datapoints are the results from diskbb+cutoffpl. Top pair of panels: the magenta datapoints in the HS and IMS at the beginning of the outburst come from the diskbb+nthcomp+nthcomp model. Middle pair of panels: magenta datapoints are from simplcut*diskbb+nthcomp and green datapoints from simplcut*diskbb. Bottom pair of panels: magenta datapoints are from diskir+nthcomp and green datapoints from diskir.
increase than what we found with a free $N_{\mathrm{H}}$, but still significant, in a stage where $r_{\text {in }}$ is supposed to decrease. Again, the trend reverses from the beginning of the HIMS. The photon index of the comptonized component increases during the initial HS but remains $\lesssim 2$ until the beginning of the HIMS; its behaviour is not substantially affected by the choice of $N_{\mathrm{H}}$.

In the IMS and HS at the end of the outburst, the choice of a fixed $N_{\mathrm{H}}$ leads to a moderate increase in the apparent radius by a factor of $\approx 1.5$ (Figure 8 ), associated with a decrease in colour temperature. This trend is consistent with the canonical evolution, and removes the contradictory behaviour (radius and temperature simultaneously decreasing) previously inferred in our free- $N_{\mathrm{H}}$ modelling.
In summary, the results of our modelling with fixed $N_{\mathrm{H}}$ showed a canonical end of the outburst but an anomalous evolution of the disk component in the hard rising phase. We verified that the same trend is found with the other models previously considered (Sections 3.2.1, 3.2.2, 3.2.4), when we refit them at fixed $N_{\mathrm{H}}$. We will propose a physical interpretation for the anomalous initial phase in Section 4.

## 4. DISCUSSION

Based on the hardness ratios (Figure 1), the HIDs (Figure 2) and the spectral parameters (Figure 4), we have shown that MAXI J1348-630 completed a typical BHB outburst evolution cycle from MJD 58510 to MJD 58617. It was detected first in the HS, went through a hard-to-soft transition to reach the SS, before returning to the HS.

A soft component consistent with a thermal model is significantly detected in our spectral fitting at all epochs, including in the initial HS, although it is only contributing a relatively small fraction of flux in that state, compared with the power-law component (Figure 10). What is the origin of this component, especially in the HS? The question is still open. Negoro et al. (2001) argued that the soft variable component of Cyg X-1 in the HS can be explained by highly variable Xray shots. Alternatively, from wide-band Suzaku observations of Cyg X-1, Yamada et al. (2013) showed that in addition to two Comptonized components there are two types of low energy components seen around 1 keV : a variable soft component and the Wien tail of a static disk. For MAXI J1348-630, we argue that this component always comes from the disk, throughout the outburst. The reason we suggest this interpretation is that its model parameters evolve smoothly and continuously from the initial HS to the SS, when it becomes the dominant component. There is little doubt (also by analogy with other BHBs) that the thermal component in the SS is associated with an optically thick disk, extending down to ISCO. Before then, during the outburst evolution from HS to SS, we do not see any transition or discontinuity that could suggest the appearance of the disk component and the disappearance of a different source of soft emission. Thus, the disk scenario is the simplest explanation consistent with the data, although we cannot rule out alternative ones.
As we pointed out earlier, MAXI J1348-630 shows two physically distinct Comptonization components. The nthcomp component (which we may interpret as the classical corona) dominates the broadband spectrum at the beginning of the outburst; the simplcut*diskbb component dominates the SIMS and SS. Physically, this means that the disk does not reach ISCO in the initial HS, and the comptonized disk emission cannot be the dominant component in that state. Later, during the SIMS and SS, the disk radius settles at a constant value consistent with ISCO, and dominates
the emission.
As outlined so far, this outburst scenario may appear similar to any other canonical outburst. However, this is not the case. The best-fitting disk parameters show a peculiar behavior in the initial HS. $N_{\text {disk }}$ starts out even smaller than in the SS, then increases until it reaches a peak (whose value is model dependent), and finally decreases (as expected) until the disk reaches ISCO. The reason this is apparently unphysical is that if the inner disk radius was really as small or smaller than ISCO in the HS, the thermal component would already dominate the X-ray emission at that stage (which is not the case). Similarly, $T_{\text {in }}$ starts out much hotter than expected for a truncated hard-state disk (e.g., Fender et al. 2004; Remillard \& McClintock 2006; Done et al. 2007), then decreases towards more plausible values (also model-dependent and very much coupled with the $N_{\text {disk }}$ behaviour), and finally increases until it reaches the expected $L_{\mathrm{X}}$ vs $T_{\mathrm{in}}^{4}$ relation. A (model-dependent) irregular behaviour is also observed in the HS at the end of the outburst, with $N_{\text {disk }}$ either constant or decreasing again, and $T_{\text {in }}$ either constant or slightly increasing, at odds with the expectations of a retreating inner disk.

Most BHB outbursts follow the canonical evolution: large and decreasing $N_{\text {disk }}$, low and increasing $T_{\text {in }}$ in the initial HS, then a constant $N_{\text {disk }}$. For example, MAXI J1659-152 (Muñoz-Darias et al. 2011; Yamaoka et al. 2012), XTE J1550-564 (Rodriguez et al. 2003), XTE J1908+094 (Tao et al. 2015; Zhang et al. 2015) and MAXI J1535-571 (Tao et al. 2018). However, the anomalous behaviour seen in the initial HS of MAXI J1348-630 is far from rare (even though it is rarely discussed). Previous examples include several outbursts of GX 339-4 (Dunn et al. 2008; Nandi et al. 2012), of GRO J1655-40 (Done et al. 2007; Debnath et al. 2008), of XTE J1650-500 (Gierliński \& Done 2004) and a few other cases illustrated by Dunn et al. (2011).

A partial explanation for the initial low value of $N_{\text {disk }}$ is that a significant fraction of the seed disk photons are upscattered into the power-law component (Yao et al. 2005). This effect is accounted for when we replaced the independent disk-blackbody plus power-law components with the self-consistent Comptonization models diskir and simplcut*diskbb. Those models provide the intrinsic disk normalization (and, hence, inner radius) before Compton scattering. However, even with those two models, $N_{\text {disk }}$ is smaller than expected in the initial HS (in particular, smaller than in the SS). The difference between the best-fitting $N_{\text {disk }}$ from diskir and simplcut*diskbb comes from the different Compton kernel in the two models, and from the effect of coronal irradiation of the disk (included in diskir but not in simplcut*diskbb). Simulations suggest (Yao et al. 2005) that the detailed geometry of the corona affects the apparent disk flux: an incorrect approximation for the scattering region may be the reason why $N_{\text {disk }}$ appears too small. Quantitative discussions on how $N_{\text {disk }}$ depends on the geometry of the corona is beyond the scope of this work.

However, the fact that the anomalous behavior appears simultaneously in $N_{\text {disk }}$ and $T_{\text {in }}$, and that the two parameters are strongly coupled, suggests that additional processes are in play, such as changes in color correction factor $f$ in different states (originally proposed by Soria et al. 2008 and Dunn et al. 2011). The fitted peak color temperature $T_{\text {in }}$ is equal to $f T_{\text {eff }}$, where $T_{\text {eff }}$ is the peak effective temperature (i.e., a more physical measure of the true disk emission). Conversely, the fitted normalization $N_{\text {disk }} \propto r_{\text {in }}^{2} \propto R_{\mathrm{in}}^{2} / f^{4}$, where $r_{\text {in }}$ is the ap-

Figure 8. Evolution of $T_{\mathrm{in}}, \sqrt{N_{\text {disk }}}\left(\propto r_{\mathrm{in}}\right)$ of diskbb and $\Gamma$ of simplcut in the case of free $N_{\mathrm{H}}$ (magenta datapoints) and fixed $N_{\mathrm{H}}$ (blue datapoints). Model A ( simplcut*diskbb+nthcomp) is used for all spectra before the first transition to the SS; Model B (simplcut*diskbb) is used for all spectra subsequent to that transition. $N_{\mathrm{H}}$ is fixed at $8.9 \times 10^{21} \mathrm{~cm}^{-2}$.

Figure 9. Left panel: spectral model and residuals for the Insight-HXMT spectra from observation 021400200201 (first available observation in the HS), fitted with a tbabs* (simplcut*diskbb+nthcomp) model and $N_{\mathrm{H}}$ fixed to the median value in the SIMS $\left(N_{\mathrm{H}}=8.9 \times 10^{21} \mathrm{~cm}^{-2}\right)$. The fit in the soft X-ray band is not as good as the one obtained with free (lower) $N_{\mathrm{H}}$, shown in the bottom panel of Figure 6. Colors and symbols are the same as in Figure 6. Right panel: same as in the left panel, for the spectrum from observation 021400201701 (SIMS). Here the fixed value of $N_{\mathrm{H}}=8.9 \times 10^{21} \mathrm{~cm}^{-2}$ provides an excellent fit to the soft band.
parent radius, and $R_{\text {in }}$ is the physical radius. The canonical value of the hardening factor is $f \approx 1.7$ (Shimura \& Takahara 1995; Shafee et al. 2006). The change of $f$ (for any reason) would lead to simultaneous variations of both $T_{\text {in }}$ and $N_{\text {disk }}$ (even after the correction of the lost soft photons in inverse Compton scattering), and may drive the observed anomalous behaviors. Hardening factors as high as $\approx 3$ in the initial phase of an outburst were suggested by Dunn et al. (2011) to explain the anomalously low values of $R_{\text {in }}$ in some of the BH
transients in their sample.
We tested this hypothesis for MAXI J1348-630 by estimating what values of $f$ are needed to make the apparent temperature and radius evolution in the initial HS consistent with their expected physical evolution (Figure 10). First, we assumed that $T_{\text {eff }}$ is constant in that state, then we assumed that $R_{\text {in }}$ is constant. In both cases, the inferred values of $f$ are to be taken as lower limits, as even higher values would be needed to produce an increasing $T_{\text {eff }}$ or a decreasing $R_{\mathrm{in}}$. We repeated
this exercise first with the set of model parameters derived with free $N_{\mathrm{H}}$ (Section 3.2.2), and then with the parameters derived with fixed $N_{\mathrm{H}}$ (Section 3.3). The more regular evolution of the $f$ parameter in the fixed- $N_{\mathrm{H}}$ scenario (Figure 10, bottom panels) is an indication that this constraint is preferable to the free- $N_{\mathrm{H}}$ scenario (Figure 10, upper panels); however, the qualitative trend is the same in the two cases. The values of $f$ quoted below refer to the fixed $-N_{\mathrm{H}}$ case. Imposing a constant $T_{\text {eff }}$ in the initial HS requires $f \approx 2$; however, this is not high enough to offset the anomalous behaviour of the inner radius, as $R_{\text {in }}$ is still unphysically increasing (Figure 10, bottom left panel). By contract, imposing a constant $R_{\text {in }}$ in the HS requires an initial $f \approx 3.5$, declining smoothly to $f \approx 1.7$ in the HIMS (Figure 10, bottom right panel). With this choice of $f$, the anomalous temperature evolution is also normalized, as $T_{\text {eff }}$ now increases with time during outburst rise. The subsequent evolution in the HIMS can be described as the continuing increase of $T_{\text {eff }}$ and decrease of $R_{\text {in }}$ down to ISCO at constant $f$, in agreement with the standard outburst model. In this scenario, the transition between HS and HIMS can be defined as the time when the incipient inner disk (condensing from the cooling corona) has reached a sufficiently high effective optical thickness to be described by the standard ShakuraSunyaev solution. The transition between HIMS and SIMS is when the optically thick inner disk has reached ISCO.

What could produce the initial high value of $f$, later declining to the standard value? One of the physical parameters that determine the value of $f$ are the relative values of free-free absorption and electron scattering coefficients. From textbook radiation theory (Rybicki \& Lightman 1979), we note (see also Soria et al. 2008) that in the region of the disk where the opacity is dominated by electron scattering rather than freefree absorption, the emerging flux at frequency $\nu$ is reduced by a factor $\left(\alpha_{\nu}^{\mathrm{ff}} / \alpha^{\mathrm{es}}\right)^{1 / 2}<1$, where $\alpha_{\nu}^{\mathrm{ff}}$ is the free-free absorption coefficient and $\alpha^{\text {es }}$ is the electron scattering coefficient. If we impose that the disk is radiatively efficient, i.e. that it dissipates all the gravitational energy without advection, the color temperature of the emerging radiation must increase by a factor $\left(\alpha^{\mathrm{es}} / \alpha_{\nu}^{\mathrm{ff}}\right)^{1 / 8}>1$ compared with the effective temperature of blackbody emission with the same flux. From the standard disk solution (Shakura \& Sunyaev 1973; Frank et al. 2002) and the expression for the scattering and free-free absorption coefficients, it follows that the hardening factor $f \sim\left(\alpha^{\mathrm{es}} / \alpha_{\nu}^{\mathrm{ff}}\right)^{1 / 8} \propto n_{e}^{-1 / 8}$, where $n_{e}$ is the electron density. For a disk around a $10-M_{\odot} \mathrm{BH}$, with an accretion rate $\approx 0.1 \mathrm{Ed}-$ dington, at a radius $\approx 10$ times $R_{\mathrm{ISCO}}$, the characteristic electron density in equilibrium is $n_{e} \sim 10^{22} \mathrm{~cm}^{-3}$. But the inner disk around MAXI J1348-630 was far from equilibrium (for a given accretion rate) at the start of the outburst. We speculate that it was still in the process of condensing from the hot corona (Liu et al. 2007; Taam et al. 2008; Meyer-Hofmeister et al. 2009; Liu et al. 2011; Qiao \& Liu 2017). Although already optically thick and radiatively efficient, its density may have been a few orders of magnitude below the equilibrium value. An increase in $n_{e}$ by three orders of magnitudes corresponds to a decrease of $f$ by a factor of 2 , which would explain the initial odd behaviour of disk normalization and color temperature. We further speculate that the transition to the HIMS corresponds to the moment when the inner disk structure reaches the equilibrium configuration. Other effects that determine the value of $f$ include Comptonization near the disk surface (Shimura \& Takahara 1993): we expect that a
cooling/collapse of the hot corona during the evolution from harder to softer states will reduce the amount of up-scattering suffered by emerging disk photons and therefore also reduce the value of $f$. More detailed modelling of such evolution is beyond the scope of this work.

## 5. CONCLUSIONS

We presented the X-ray spectral behaviour of the BH candidate MAXI J1348-630 during its main outburst in 2019, based on Insight-HXMT and Swift observations. The source was discovered in the HS, then transited to the SS, and finally returned to the HS, consistent with the typical outburst of BHBs. Throughout the outburst, the spectra are well described by a model consisting of a disk component and either one or two power-law-like components. In the SIMS and SS, the disk properties are consistent with the standard model ( $R_{\text {in }} \approx R_{\text {isco }}, L_{\text {disk }} \propto T_{\text {in }}^{4}$ ). Instead, in the initial HS (first week of Insight-HXMT observations), the disk behaviour appears odd, with a increasing disk normalization and a decreasing color temperature. The canonical model of outburst evolution predicts an initial decrease of the disk normalization, as the inner disk radius moves closer to ISCO, and a corresponding temperature increase.

We showed that part of the apparent initial deficit of photons in the disk normalization is caused by the upscattering of thermal photons into the Comptonized component. This is why self-consistent Comptonization models such as diskir and simplcut*diskbb are preferable to the simpler disk-blackbody plus power-law model, when a corona is still present. However, even after accounting for such photon transfer, the initial odd trend of $N_{\text {disk }}$ and $T_{\text {in }}$ persists. We showed that the coupled evolution of those two quantities can be phenomenologically described with an effective hardening factor about 2 times higher at the start of the observations than in the rest of the outburst (where we assume a canonical value of 1.7). We argued that this change in hardening factor reveals a real and perhaps rarely observed phase of disk evolution. A higher-than-usual color correction is theoretically expected from an optically thick, radiatively efficient disk annulus (in the region where scattering opacity dominates) if the electron density is much lower than the equilibrium value (given by the solutions of the standard disk equation). We speculated that at the start of our observations, the inner part of the standard thin disk was still in the process of condensing from the previous geometrically thick hot corona. Its density was still increasing (implying a decreasing hardening factor) until it reached the equilibrium value; this happened as the system switched from the HS to the HIMS.

In conclusion, the outburst rise in BHBs is often empirically simplified as the inward motion of the inner truncation radius of a standard disk, replacing the geometrically thick, hot scattering region (with a well defined, sharp boundary between the two regions). In this system, and perhaps in others, we may have seen instead the gradual condensation of the hot scattering region into a thin standard disk, during the initial HS. Once this part of the disk reached its equilibrium, we also saw a canonical evolution for a few days (the short transition phase identified as HIMS), with the inner radius moving further inwards until it reached ISCO, where it remained throughout the SS.

This work made use of data from the Insight-HXMT mission, a project funded by China National Space Administra-

Figure 10. Comparison between apparent and physical evolution of disk temperature and radii, as a function of hardening factor $f$, as well as the evolution of the bolometric flux percentage (R) for the diskbb and simplcut components. Top left panel: blue datapoints represent the apparent evolution ( $k T_{\text {in }}$ ( keV ), $\sqrt{N_{\text {disk }}}(\mathrm{km})$ ) in the model described in Section 3.2.3, for free $N_{\mathrm{H}}$. Magenta datapoints represent the physical evolution $\left(k T_{\text {eff }}(\mathrm{keV}), \sqrt{N_{\text {disk }}}{ }^{\prime}(\mathrm{km})\right.$ ), if $f$ is chosen in such a way to keep $k T_{\text {eff }}$ constant in the initial HS. The evolution of $f$ is also plotted (red datapoints). Top right panel: as in the top left panel, but this time $f$ is defined in a way to keep ${\sqrt{N_{\text {disk }}}}^{\prime}$ constant in the HS. Bottom left panel: as in the top left panel, but for fixed- $N_{\mathrm{H}}$ fitting (Section 3.3). Bottom right panel: as in the top right panel, but for fixed- $N_{\mathrm{H}}$ fitting. We suggest (Section 5) that the bottom right panel represents the most physical conditions, as $k T_{\text {eff }}$ is now increasing during outburst rise, and $f$ is decreasing smoothly from $\approx 3.5$ to the canonical value of $\approx 1.7$.

## Table 1

Log of the Insight-HXMT observations, and best-fitting parameters when the spectra are modelled with [diskbb+cutoffpl].
Error ranges represent the $90 \%$ confidence limit for one interesting parameter, with the $\chi^{2}$ fitting statistics.
HS - hard state; HIMS - hard intermediate state; SIMS - soft intermediate state; SS - soft
state.

| ObsID | Observed date (day) | Exposure time (ks) | ExposureID | $\begin{gathered} N_{\mathrm{H}} \\ \left(10^{22} \mathrm{~cm}^{-2}\right) \end{gathered}$ | $\begin{gathered} k T_{\mathrm{in}} \\ (\mathrm{keV}) \end{gathered}$ | $N_{\text {disk }}$ | $\Gamma$ | $\begin{gathered} E_{\mathrm{cut}} \\ (\mathrm{keV}) \end{gathered}$ | State |

Note. $-N_{\mathrm{H}}$ is the absorption column density in units of $10^{22}$ atoms $\mathrm{cm}^{-2} ; k T_{\text {in }}$ is the inner disk color temperature in units of keV; $N_{\text {disk }}$ is the normalization of the diskbb model; $\Gamma$ is the photon index of the cutoffpl model; $E_{\text {cut }}$ is the e-folding energy of exponential rolloff in units of keV .
${ }^{a}$ The error reaches the limit of parameter.
Table 2
Log of the Swift/XRT observations, and best-fitting parameters when the spectra are modelled with [diskbb+powerlaw].
Error ranges represent the $90 \%$ confidence limit for one interesting parameter, with the $\chi^{2}$ fitting statistics.

Note. - $\Gamma$ is the photon index of the powerlaw model.
${ }^{a}$ The photon index $(\Gamma)$ is assumed to be constant at the canonical value.
Table 3
Best-fitting parameters for the Insight-HXMT spectra in the hard and intermediate states, modelled with [diskbb+nthcomp+nthcomp].
Error ranges represent the $90 \%$ confidence limit for one interesting parameter, with the $\chi^{2}$ fitting statistics.

| ExposureID | $\begin{gathered} N_{\mathrm{H}} \\ \left(10^{22} \mathrm{~cm}^{-2}\right) \end{gathered}$ | $\begin{gathered} k T_{\text {in }} \\ (\mathrm{keV}) \end{gathered}$ | $N_{\text {disk }}$ | $\Gamma_{1}$ | $\begin{gathered} k T_{\mathrm{el}} \\ (\mathrm{keV}) \end{gathered}$ | $\Gamma_{2}$ | $\begin{gathered} k T_{\mathrm{e} 2} \\ (\mathrm{keV}) \end{gathered}$ | $\chi^{2} / \mathrm{dof}$ |

Note. $-{ }^{a}$ The temperature went below the lower limit and we fixed it at that limit.

## Table 4

Best-fitting parameters for the Insight-HXMT spectra in the hard and intermediate states, modelled with [simplcut*diskbb+nthcomp].
Error ranges represent the $90 \%$ confidence limit for one interesting parameter, with the $\chi^{2}$
fitting statistics.

| ExposureID | $\begin{gathered} N_{\mathrm{H}} \\ \left(10^{22} \mathrm{~cm}^{-2}\right) \end{gathered}$ | $\begin{gathered} k T_{\mathrm{in}} \\ (\mathrm{keV}) \end{gathered}$ | $N_{\text {disk }}$ | $\Gamma_{1}$ | $\begin{gathered} k T_{\mathrm{e} 1} \\ (\mathrm{keV}) \end{gathered}$ | frac | $\Gamma_{2}$ | $\begin{gathered} k T_{\mathrm{e} 2} \\ (\mathrm{keV}) \end{gathered}$ | $\chi^{2} /$ dof |

Note. $-\Gamma_{1}$ is the photon power law index of simplcut; $k T_{\mathrm{e} 1}$ is the electron temperature of simplcut in units of keV; frac is the scattered fraction; $\Gamma_{2}$ is the asymptotic power-law photon index of nthcomp; $k T_{\mathrm{e} 2}$ is the electron temperature of nthcomp in units of keV .
${ }^{a}$ The temperature went below the lower limit and we fixed it at that limit.
