(Received )

A small spheroid settling in a quiescent fluid experiences an inertial torque that aligns it so that it settles with its broad side first. Here we show that an active particle experiences such a torque too, as it settles in a fluid at rest. For a spherical squirmer, the torque is  $\mathbf{T}' = -\frac{9}{8}m_f(\mathbf{v}_s^{(0)} \wedge \mathbf{v}_g^{(0)})$  where  $\mathbf{v}_s^{(0)}$  is the swimming velocity,  $\mathbf{v}_g^{(0)}$  is the settling velocity in the Stokes approximation, and  $m_f$  is the equivalent fluid mass. This torque aligns the swimming direction against gravity: swimming up is stable, swimming down is unstable.

## 1. Introduction

The motion of small plankton in the turbulent ocean is overdamped (Visser 2011). Accelerations play no role, and hydrodynamic forces and torques can be computed in the Stokes approximation. Turbulence rotates these small organisms, yet they manage to navigate upwards towards the ocean surface. Gyrotactic organisms make use of gravity to achieve this. These bottom-heavy swimmers experience a gravity torque that tends to align against the direction of gravity, so that they swim upwards (Kessler 1985; Durham *et al.* 2013; Gustavsson *et al.* 2016). Also density or shape asymmetries give rise to torques in the Stokes approximation that can change the swimming direction (Roberts 1970; Jonsson 1989; Roberts & Deacon 2002; Candelier & Mehlig 2016; Roy *et al.* 2019).

Larger organisms accelerate the surrounding fluid as they move, and this changes the hydrodynamic force the swimmer experiences (Wang & Ardekani 2012; Khair & Chisholm 2014; Chisholm *et al.* 2016; Redaelli *et al.* 2022*b,a*). Three different mechanisms cause such fluid-inertia effects, a non-zero slip velocity (Oseen problem with non-dimensional parameter  $Re_p$ , the particle Reynolds number), velocity gradients of the disturbance flow (Saffman problem, shear Reynolds number  $Re_s$ ), and unsteady fluid inertia (with parameter  $Re_pSl$ , where  $Sl$  is the Strouhal number).

Fluid inertia gives rise to hydrodynamic torques. For a passive spheroid in spatially inhomogeneous flow, there are  $Re_s$ -corrections to Jeffery's torque (Subramanian & Koch 2005; Einarsson *et al.* 2015; Rosén *et al.* 2015). A passive spheroid settling in a quiescent fluid experiences an inertial torque, a  $Re_p$ -effect. This Khayat-Cox torque tends to align the particle so that it settles with its broad side down (Brenner 1961; Cox 1965; Khayat & Cox 1989; Klett 1995; Dabade *et al.* 2015; Menon *et al.* 2017; Lopez & Guazzelli 2017; Kramel 2017; Gustavsson *et al.* 2019; Jiang *et al.* 2021; Cabrera *et al.* 2022). For a passive sphere, spherical symmetry ensures that the Khayat-Cox torque vanishes.

In this paper, we show that a small spherical squirmer experiences an inertial torque analogous to the Khayat & Cox torque when it settles in a quiescent fluid. Using asymp-

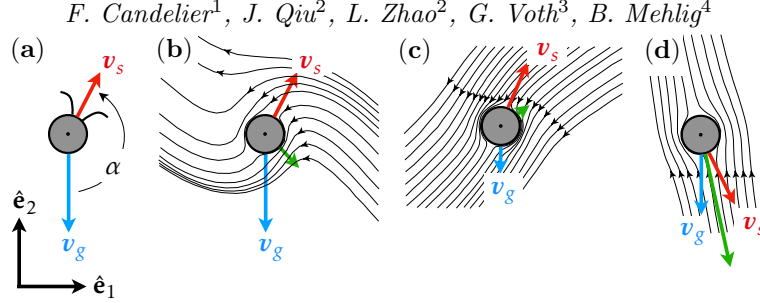

FIGURE 1. (a) Squirmer with swimming velocity  $\mathbf{v}_s$  and settling velocity  $\mathbf{v}_g$ , see Section 2. Gravity points in the negative  $\hat{\mathbf{e}}_2$ -direction. (b,c,d) Disturbance flow created by a squirmer with  $B_2 = 0$  (schematic). Shown are the flow lines in the frame that translates with the body. The centre-of-mass velocity  $\dot{\mathbf{x}}$  is shown in green.

otic matching, we calculate the torque to leading order in the particle Reynolds number

$$\text{Re}_p = au_c/\nu, \quad (1.1)$$

where  $u_c$  is a velocity scale,  $a$  is the radius of the squirmer, and  $\nu$  is the kinematic viscosity of the fluid. The calculation shows that the inertial torque does not vanish for a spherical swimmer because swimming breaks rotational symmetry. We describe how the torque aligns the squirmer, and compare its effect with gyrotactic torques, and with the Khayat-Cox torque for a nonspherical passive particle.

## 2. Model

We consider a steady spherical squirmer, an idealised model for a motile microorganism developed by Lighthill (1952) and Blake (1971). In this model, one imposes an active axisymmetric tangential surface-velocity field of the form

$$(B_1 \sin \theta + B_2 \sin \theta \cos \theta) \hat{\mathbf{e}}_\theta, \quad (2.1)$$

with parameters  $B_1$  and  $B_2$ , and where  $\theta$  is the angle between the swimming direction (unit vector  $\mathbf{n}$ ) and the vector  $\mathbf{r}$  from the particle centre to a point on its surface. The tangential unit vector at this point is denoted by  $\hat{\mathbf{e}}_\theta$ . One distinguishes two types of squirmers depending on the parameter  $\beta = B_2/B_1$  (Lauga & Powers 2009): ‘pushers’ ( $\beta < 0$ ) and ‘pullers’ with  $\beta > 0$ . In the Stokes limit, a squirmer moving with velocity  $\dot{\mathbf{x}}$  in a fluid at rest experiences the hydrodynamic force

$$\mathbf{F}'^{(0)} = 6\pi\varrho_f\nu a \left( \frac{2}{3}B_1\mathbf{n} - \dot{\mathbf{x}} \right). \quad (2.2)$$

Here the superscript denotes the Stokes approximation, and  $\varrho_f$  is the mass density of the fluid. Following Candelier *et al.* (2019), we use a prime to indicate that this is the hydrodynamic force on the squirmer, due to the disturbance it creates.

Plankton tends to be slightly heavier than the fluid. Therefore we allow the squirmer to settle subject to the buoyancy force

$$\mathbf{F}_g = \frac{4\pi}{3}a^3(\varrho_s - \varrho_f)\mathbf{g}, \quad (2.3)$$

where  $\varrho_s$  is the mass density of the squirmer, and  $\mathbf{g}$  is the gravitational acceleration. In the overdamped limit, the steady centre-of-mass velocity of the squirmer is determined by the zero-force condition  $\mathbf{F}'^{(0)} + \mathbf{F}_g = \mathbf{0}$ . This yields  $\dot{\mathbf{x}} = \frac{2}{3}B_1\mathbf{n} + \frac{2}{9}\left(\frac{\varrho_s}{\varrho_f} - 1\right)\frac{a^2}{\nu}\mathbf{g} \equiv \mathbf{v}_s^{(0)} + \mathbf{v}_g^{(0)}$ . Again, the superscript denotes the Stokes limit. In this limit, the squirmer experiences no torque in a fluid at rest,  $\mathbf{T}'^{(0)} = \mathbf{0}$ .

### 3. Inertial torque

Assume that the swimmer swims with swimming velocity  $\mathbf{v}_s$  and settles with settling velocity  $\mathbf{v}_g$ . The angle between  $\mathbf{v}_s$  and  $\mathbf{v}_g$  is denoted by  $\alpha$ , as shown in Fig. 1(a). Symmetry dictates the form of the inertial torque  $\mathbf{T}'$ . It has the units mass  $\times$  velocity<sup>2</sup>. Since the torque is an axial vector, it must be proportional to the vector product between the two velocities. The torque can therefore be written as

$$\mathbf{T}'^{(1)} = Cm_f (\mathbf{v}_s \wedge \mathbf{v}_g), \quad (3.1)$$

where  $m_f = \frac{4\pi}{3}a^3\rho_f$  is the equivalent fluid mass,  $C$  is a non-dimensional constant, and the superscript indicates that this is the first inertial correction to the torque. Eq. (3.1) says that torque vanishes when the swimmer swims against gravity [ $\alpha = \pi$  in Fig. 1(a)], and when it swims in the direction of gravity ( $\alpha = 0$ ). Bifurcation theory implies that one of these fixed points is stable, the other one unstable. The sign of the coefficient  $C$  determines which of the two is the stable fixed point.

Inertial torques can be understood as a consequence of advection of fluid momentum. In the frame translating with the swimmer, far-field momentum is advected by the transverse disturbance flow generated by the swimmer. At non-zero  $\text{Re}_p$ , the head of the swimmer – the north pole of the axial velocity field (2.1) – experiences more drag than its rear, because some of the momentum imparted to the fluid by the head is advected to the trailing end, in the direction transverse to gravity. So when  $\mathbf{v}_s$  is not co-linear with  $\mathbf{v}_g$  there is an inertial torque which rotates the swimmer so that  $\mathbf{v}_s$  becomes closer to anti-parallel with  $\mathbf{v}_g$ . Comparing with Eq. (3.1), this means that the coefficient  $C$  must be negative. Note that the mechanism described above is the same that creates Khayat-Cox torques on non-spherical passive particles sedimenting in quiescent fluid. For a fibre, for example, the far-field momentum is advected by the transverse flow along the fibre, leading to a torque that aligns the fibre perpendicular to gravity (Khayat & Cox 1989).

### 4. Perturbation theory for the coefficient $C$

The inertial torque is computed from

$$\mathbf{T}'^{(1)} = \int_{\mathcal{S}} \mathbf{r} \wedge (\boldsymbol{\sigma}^{(1)} d\mathbf{s}), \quad (4.1)$$

where  $\sigma_{mn}^{(1)} = -p^{(1)}\delta_{mn} + 2\mu S_{mn}^{(1)}$  are the elements of the stress tensor  $\boldsymbol{\sigma}^{(1)}$  with pressure  $p^{(1)}$ ,  $S_{mn}^{(1)}$  are the elements of the strain-rate tensor of the disturbance flow, and  $\mu = \rho_f \nu$  is the dynamic viscosity. The integral goes over the particle surface  $\mathcal{S}$ ,  $\mathbf{r}$  is the vector from the particle centre to a point on the particle surface, and  $d\mathbf{s}$  is the outward surface normal at this point. In the Stokes approximation the torque vanishes,  $\mathbf{T}'^{(0)} = \mathbf{0}$ , as mentioned above.

The disturbance stress tensor is determined by solving the steady Navier-Stokes equations for the incompressible disturbance flow  $\mathbf{w}$ ,

$$-\text{Re}_p \dot{\mathbf{x}} \cdot \nabla \mathbf{w} + \text{Re}_p \mathbf{w} \cdot \nabla \mathbf{w} = -\nabla p + \Delta \mathbf{w}, \quad (4.2)$$

with boundary conditions  $\mathbf{w} = \dot{\mathbf{x}} + (B_1 \sin \theta + B_2 \sin \theta \cos \theta) \hat{\mathbf{e}}_\theta$  for  $|\mathbf{r}| = 1$ , and  $\mathbf{w} \rightarrow \mathbf{0}$  as  $|\mathbf{r}| \rightarrow \infty$ . Here we assumed that the swimmer has no angular velocity. We non-dimensionalised Eq. (4.2) using the radius  $a$  of the swimmer as a length scale, and with the velocity scale  $u_c = v_g^{(0)}$ . Forces are non-dimensionalised by  $\mu a u_c$ , and torques by  $\mu a^2 u_c$ . The acceleration terms on the l.h.s. of Eq. (4.2) are singular perturbations of the

r.h.s., the Stokes part (Hinch 1995). We use matched asymptotic expansions in  $\text{Re}_p$  to determine the solution for small  $\text{Re}_p$ . Near the squirmer, one expands

$$\mathbf{w}_{\text{in}} = \mathbf{w}_{\text{in}}^{(0)} + \text{Re}_p \mathbf{w}_{\text{in}}^{(1)} + \dots \quad \text{and} \quad p_{\text{in}} = p_{\text{in}}^{(0)} + \text{Re}_p p_{\text{in}}^{(1)} + \dots \quad (4.3)$$

This inner expansion is matched, term by term, to an outer expansion

$$\hat{\mathbf{w}}_{\text{out}} = \hat{\mathcal{T}}_{\text{reg}}^{(0)} + \text{Re}_p (\hat{\mathcal{T}}_{\text{reg}}^{(1)} + \hat{\mathcal{T}}_{\text{sing}}^{(1)}) + \dots \quad (4.4)$$

Here  $\hat{\mathcal{T}}_{\text{reg}}^{(0,1)}$  are regular terms in the outer expansion, while  $\hat{\mathcal{T}}_{\text{sing}}^{(1)}$  is singular in  $\mathbf{k}$ -space, proportional to  $\delta(\mathbf{k})$  (Meibohm *et al.* 2016). The outer solution is obtained by replacing the boundary condition on the surface of the squirmer by a singular source term in Eq. (4.2), a Dirac  $\delta$ -function (Schwartz 1966) with amplitude  $\mathbf{F}^{(0)} = -6\pi(\frac{2}{3}B_1\mathbf{n} - \dot{\mathbf{x}})$ . Since the non-linear term (quadratic in  $\mathbf{w}$ ) is negligible far from the particle, the resulting equation can be solved by Fourier transform, yielding explicit expressions for  $\hat{\mathcal{T}}_{\text{reg}}^{(0,1)}$  and  $\hat{\mathcal{T}}_{\text{sing}}^{(1)}$  which serve as boundary conditions for the inner problems.

The inner problem to order  $\text{Re}_p^0$  is the homogeneous Stokes problem

$$-\nabla p_{\text{in}}^{(0)} + \Delta \mathbf{w}_{\text{in}}^{(0)} = \mathbf{0}, \quad \nabla \cdot \mathbf{w}_{\text{in}}^{(0)} = \mathbf{0}, \quad (4.5a)$$

with boundary conditions

$$\mathbf{w}_{\text{in}}^{(0)} = \dot{\mathbf{x}} + (B_1 \sin \theta + B_2 \sin \theta \cos \theta) \hat{\mathbf{e}}_\theta \quad \text{for } |\mathbf{r}| = 1, \quad \mathbf{w}_{\text{in}}^{(0)} \sim \mathcal{T}_{\text{reg}}^{(0)} \quad \text{as } |\mathbf{r}| \rightarrow \infty. \quad (4.5b)$$

This problem is solved in the standard fashion using Lamb's solution (Happel & Brenner 1965). The  $\text{Re}_p^1$ -order inner problem is inhomogeneous:

$$-\nabla p_{\text{in}}^{(1)} + \Delta \mathbf{w}_{\text{in}}^{(1)} = -\text{Re}_p \dot{\mathbf{x}} \cdot \nabla \mathbf{w}_{\text{in}}^{(0)} + \text{Re}_p \mathbf{w}_{\text{in}}^{(0)} \cdot \nabla \mathbf{w}_{\text{in}}^{(0)}, \quad \nabla \cdot \mathbf{w}_{\text{in}}^{(1)} = 0, \quad (4.6a)$$

$$\mathbf{w}_{\text{in}}^{(1)} = \mathbf{0} \quad \text{for } |\mathbf{r}| = 1 \quad \text{and} \quad \mathbf{w}_{\text{in}}^{(1)} \sim \mathcal{T}_{\text{reg}}^{(1)} + \mathcal{T}_{\text{sing}}^{(1)} \quad \text{for } |\mathbf{r}| \rightarrow \infty. \quad (4.6b)$$

To solve Eqs. (4.6), we make the ansatz  $\mathbf{w}_{\text{in}}^{(1)} = (\mathbf{w}_p + \mathcal{T}_{\text{sing}}^{(1)}) + \mathbf{w}_h$ , where  $\mathbf{w}_p$  is a particular solution, and  $\mathbf{w}_h$  is the homogeneous solution of Eqs. (4.6). For the pressure we write  $p_{\text{in}}^{(1)} = p_p^{(1)} + p_h^{(1)}$ . We first determine the particular solution  $\mathbf{w}_p$  and  $p_p^{(1)}$  using Fourier transform. Then  $\mathbf{w}_h$  and  $p_h^{(1)}$  are determined using Lamb's solution. The boundary condition for  $\mathbf{w}_h$  is  $\mathbf{w}_h = -\mathbf{w}_p - \mathcal{T}_{\text{sing}}^{(1)}$  on the particle surface. Having obtained  $\mathbf{w}_{\text{in}}^{(1)}$ , we compute the torque from Eq. (4.1). The torque comes from the particular solution of the first-order inner problem. For a passive spherical particle, spherical symmetry ensures that the particular solution does not contribute to the torque. Swimming breaks spherical symmetry, and this is the reason that torque does not vanish. Given  $p^{(1)}$  and  $\mathbf{w}_{\text{in}}^{(1)}$ , we can determine the inertial correction to the stress tensor,  $\sigma^{(1)}$ . Integrating it over the particle surface as specified in Eq. (4.1), we find to leading order in  $\text{Re}_p$

$$\mathbf{T}'^{(1)} = -\frac{3\pi}{2} \text{Re}_p (\mathbf{v}_s^{(0)} \wedge \mathbf{v}_g^{(0)}). \quad (4.7)$$

In dimensional units, this corresponds to  $\mathbf{T}'^{(1)} = -\frac{9}{8} m_f (\mathbf{v}_s^{(0)} \wedge \mathbf{v}_g^{(0)})$ . The coefficient  $C = -\frac{9}{8}$  is negative, as predicted by the argument summarised in Section 3. So a spherical organism swimming downwards experiences a torque that tends to turn it upwards, causing the organism to swim against gravity.

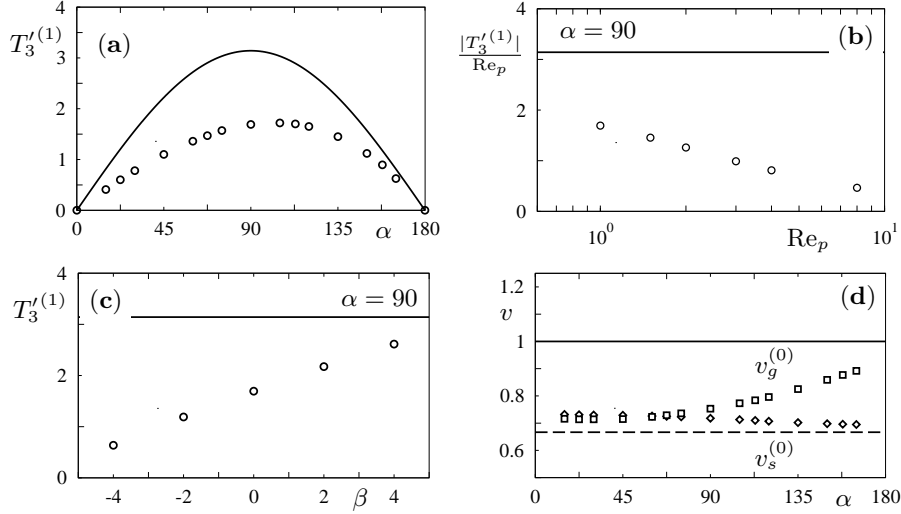

FIGURE 2. (a) Non-dimensional inertial torque  $\mathbf{T}^{(1)} = T_3^{(1)} \hat{\mathbf{e}}_3$  on a spherical squirmer. Shown is the theory, Eq. (4.7) (solid line), in comparison with direct numerical-simulation results (Section 5,  $\circ$ ). The torque was non-dimensionalised with the factor  $\mu a^2 u_c$ , where  $u_c = v_g^{(0)}$ . The angle  $\alpha$  is defined in Fig. 1(a). Parameters:  $B_1 = 1$ ,  $B_2 = 0$ ,  $v_s^{(0)} = 2/3$ ,  $v_g^{(0)} = 1$ , and  $Re_p = 1$ . (b) Non-dimensional torque for  $\alpha = 90$  as a function of  $Re_p$ , other parameters same as in panel (a). Also shown is the theory, Eq. (4.7). (c) Non-dimensional torque for  $\alpha = 90$  as a function of  $\beta = B_2/B_1$ , other parameters the same as in panel (a). (d) Non-dimensional swimming speed ( $\diamond$ ) and settling speed ( $\square$ ) from direct numerical simulations for the same parameters as in panel (a). Also shown are the Stokes estimates for  $v_s^{(0)}$  (dashed line) and  $v_g^{(0)}$  (solid line).

## 5. Direct numerical simulations

We solved the three-dimensional Navier-Stokes equations for the incompressible flow using an immersed-boundary method (Peskin 2002). The interaction between squirmer and fluid was implemented by the direct-force method (Uhlmann 2005): in order to satisfy the boundary condition (2.1), the algorithm calculates the predicted fluid velocity on the surface of the squirmer. Based on the mismatch between the predicted velocity and Eq. (2.1), an appropriate immersed-boundary force is applied to the fluid phase to maintain the boundary conditions (2.1) on the surface of the squirmer. We implemented the improved algorithm described in (Kempe & Fröhlich 2012; Breugem 2012; Lambert *et al.* 2013), because it is more precise for nearly-neutrally buoyant particles. We used a cubic computational domain of side length  $L = 20a$  with periodic boundary conditions. This is large enough to account for convective inertia for  $Re_p > 1$ . The computational domain was discretised using a cubic mesh with resolution  $\Delta x$ . The Navier-Stokes equations were integrated using a second-order Crank-Nicholson scheme for the time-integration (Kim *et al.* 2002) with time step  $\Delta t$ , while the motion of the squirmer was integrated using a second-order Adams-Bashforth method (Hairer *et al.* 2000).

The numerical simulation of solid-body motion in a fluid is challenging at small  $Re_p$ . The mesh resolution  $\Delta x$  must be fine enough to resolve the shape of the body, so that the viscous stresses near its surface are accurately represented (Andersson & Jiang 2019). In addition, the time step  $\Delta t$  must be small enough to resolve the viscous diffusion of the disturbance,  $\Delta t < \Delta x^2/\nu$ . In Appendix A we briefly describe our convergence checks. We found that our algorithm fails to converge for  $Re_p$  smaller than unity. In the following we discuss our numerical results for  $Re_p \geq 1$ .

To determine the torque, we froze the orientation of the squirmer at a given angle  $\alpha$ , but allowed the squirmer to translate. It was initially at rest. We measured the centre-of-mass velocity and the torque after the transient, when the disturbance flow was fully established. Figure 2(a) shows the numerical results for the inertial torque on a spherical squirmer for  $\text{Re}_p = 1$ , in comparison with the theory (4.7). The remaining parameter values used in the simulations are quoted in the Figure caption. Although the theory is valid for  $\text{Re}_p \ll 1$ , it nevertheless agrees qualitatively with the numerical results for  $\text{Re}_p = 1$ . This is encouraging, because it allows us to draw qualitative conclusions about the effects of the torque on small plankton (Section 6). Panel (a) shows that the theory overestimates the amplitude of the torque by a factor of two, but that its angular dependence is roughly the same. We note, however, that the numerical results exhibit an asymmetry in their dependence on  $\alpha$ . Since the small- $\text{Re}_p$  theory yields a symmetric angular dependence of the torque, we attribute the asymmetry to higher-order  $\text{Re}_p$ -corrections. Panel (b) confirms that the difference between theory and numerical simulation increases for larger  $\text{Re}_p$ , as expected.

The small- $\text{Re}_p$  theory (4.7) says that the torque is independent of  $\beta$ . Panel (c) shows that this is not the case for the numerical results at  $\text{Re}_p = 1$ . This suggests, again, that higher- $\text{Re}_p$  corrections matter at  $\text{Re}_p = 1$ , and that they exhibit a  $\beta$ -dependence. Another indication that higher-order  $\text{Re}_p$ -corrections may be important comes from measuring settling and swimming speeds in the numerical simulations. We extracted the swimming speed using  $\dot{\mathbf{x}} = v_s \mathbf{n} - v_g \hat{\mathbf{e}}_2$ . Solving for  $v_s$  gives  $v_s = \dot{\mathbf{x}} \cdot \hat{\mathbf{e}}_1 / (\mathbf{n} \cdot \hat{\mathbf{e}}_1)$ . Fig. 2(d) compares the measured swimming and settling speeds. The settling speed is substantially smaller than the Stokes estimate, consistent with a significant  $\text{Re}_p$ -correction. The swimming speed is much closer to the Stokes estimate. This is because the data shown is for  $\beta = 0$ , and the known  $\text{Re}_p$ -corrections to the swimming speed (Khair & Chisholm 2014),

$$\mathbf{v}_s = \frac{2}{3} B_1 \mathbf{n} \left[ 1 - \frac{3\beta}{20} \text{Re}_p + \left( \frac{\beta}{8} + \frac{11987}{470400} \beta^2 \right) \text{Re}_p^2 + \dots \right], \quad (5.1)$$

vanish for  $\beta = 0$ .

## 6. Conclusions

We showed that a spherical squirmer settling in a fluid at rest experiences an inertial torque, and computed the torque using matched asymptotic expansions. The calculation is similar to that of Cox (1965) for the inertial torque on a nearly spherical, passive particle settling in a quiescent fluid. This torque vanishes for a passive sphere, a consequence of spherical symmetry. A spherical swimmer experiences an inertial torque because swimming breaks this symmetry. The torque causes the squirmer to align with gravity so that it swims upwards. In other words, this torque acts just like Kessler's gyrotactic torque for bottom-heavy organisms.

For plankton, the effect of the inertial torque is much smaller than the gyrotactic torque, at least for spherical shapes. We can see this by comparing the corresponding reorientation times. This time scale is defined as  $\tau_I = \frac{1}{2} (8\pi\mu a^3) / T_{\max}$ , where  $8\pi\mu a^3$  is the rotational resistance coefficient for a sphere (Kim & Karrila 2013), and  $T_{\max}$  is the maximal magnitude of the torque. For the inertial torque, one obtains  $\tau_I = 8\nu / (3v_s^{(0)} v_g^{(0)})$  (this and all following expressions are quoted in dimensional units). The reorientation time for the gyrotactic torque is  $\tau_G = 3\varrho_s \nu / (\varrho_f g h)$  (Pedley & Kessler 1987), where  $h$  is the offset between the centre-of-mass and the geometrical centre of the squirmer, and  $g = |\mathbf{g}|$ . The ratio of these time scales is  $\tau_I / \tau_G \sim g h / v_s^{(0)} v_g^{(0)}$ , assuming  $\varrho_s \approx \varrho_f$ . Taking  $h \sim 10^{-7}$  m [Table 1 in (Kessler 1986)], we see that swimming and settling speeds

need to be of the order mm/s for the reorientation times to be comparable. For small plankton, typical speeds tend to be much smaller (Kessler 1986). For larger organisms, however, the inertial torque can be significant. With typical values for a small copepod (Titelman & Kjørboe 2003),  $v_s = 1$  mm/s,  $v_g = 0.2$  mm/s, as well as  $\nu = 10^{-6}$  m<sup>2</sup>/s, one finds an inertial reorientation time of the order of  $\tau_I \sim 10$  s. Kolmogorov times for ocean turbulence range from  $\tau_K = \sqrt{\nu/\mathcal{E}} = 100$  s for dissipation rate per unit mass  $\mathcal{E} = 10^{-6}$  cm<sup>2</sup>/s<sup>3</sup> to  $\tau_K = 1$  s for  $\mathcal{E} = 10^{-2}$  cm<sup>2</sup>/s<sup>3</sup>. So the non-dimensional reorientation parameter  $\Psi = \tau_I/\tau_K$  (Durham *et al.* 2013) ranges from 0.1 for weak turbulence to 10 for strong turbulence. The Reynolds number is of order  $\text{Re}_p \sim 1$  for speeds of the order of 1 mm. This means that the  $\text{Re}_p$ -perturbation theory does not strictly apply, but we can nevertheless conclude that for weak turbulence, the inertial torque can have a significant effect on the angular dynamics of the organism.

Some motile microorganisms are non-spherical (Berland *et al.* 1995; Faust & Gullede 2002; Smayda 2010). It has been suggested that this can give additional contributions to the torque (Qiu *et al.* 2022). Since the boundary conditions are different, and since swimming breaks fore-aft symmetry, these additional contributions may be different from the Khayat-Cox torque for passive particles. However, we expect that the torque is still determined by the same physical mechanism, advection of fluid-momentum transverse to gravity. This may give rise to terms proportional to  $\sin(2\alpha)$ , whereas the torque is proportional to  $\sin(\alpha)$  for the spherical swimmer. To make these speculations definite, one could compute the inertial torque for a nearly spherical swimmer in perturbation theory. A second open question is to determine the inertial torque for bottom-heavy, non-spherical organisms, the analogue of the inertial torque on passive particles with mass-density asymmetries (Roy *et al.* 2019).

More generally, although the small- $\text{Re}_p$  perturbation theory may become quantitatively inaccurate for Reynolds numbers of order unity – where the torque begins to make a significant difference – the results tell us which non-dimensional parameters matter, and how to reason about the effect of boundary conditions, and the symmetries of the problem. The calculation illustrates the conceptual insight that the inertial torque comes from fluid motion transverse to the direction of gravity. Fluid momentum in this direction is advected along the swimmer by the transverse fluid velocity, resulting in a torque. In our case, the boundary conditions are different from those for passive particle, and so is the symmetry of the problem, because swimming breaks fore-aft symmetry. Nevertheless, the fundamental mechanism generating the torque is the same.

## Appendix A. Details regarding the direct numerical simulations

To find out the required mesh and time resolution, we considered two test cases at  $\text{Re}_p = 1$ : a passive sphere settling under gravity, and a neutrally buoyant swimmer with  $\beta = 0$ . To check convergence as the mesh resolution increases, we changed  $2a/\Delta x$  ranging from 16 to 48, keeping  $\nu\Delta t/\Delta x^2 = 0.58$  constant. Settling and swimming speeds reached a plateau when we increased the mesh resolution  $2a/\Delta x$ . The settling speed varied about 0.1% and swimming speed varied about 1% when we changed  $2a/\Delta x$  from 36 to 48.

FIGURE 3. Convergence tests changing mesh resolution  $\Delta x$  (left column) and changing integration-time step  $\Delta t$  (right column). Settling speed of a passive sphere (first row), compared with the experimental data of Maxworthy, extracted from Fig. 4 of (Vesey II & Goldenfeld 2007). Swimming speed of neutrally buoyant spherical squirmer with  $\beta = 0$ , compared with Eq. (5.1), (Khair & Chisholm 2014), second row. The third row shows the inertial torque.

We then checked for convergence as the step size  $\Delta t$  was reduced, for fixed  $2a/\Delta x = 36$ . Again, both settling and swimming speeds reached plateaus as  $\nu\Delta t/\Delta x^2$  decreased. When we halved  $\nu\Delta t/\Delta x^2$  from 0.58 to 0.29, the settling and swimming speeds varied about 1% and 2%, respectively. Therefore, we used  $2a/\Delta x = 36$  and  $\Delta t = 0.58\Delta x^2/\nu$  for our numerical simulations at  $Re_p = 1.0$  that are shown in the main text. At these parameter values, the simulated settling speed of a passively settling particle is about 3% larger than the measurement of Maxworthy, taken from Fig. 4 of (Vesey II & Goldenfeld 2007). The swimming speed of the squirmer is about half a percent larger than the theoretical value  $v_s^{(0)} = 2B_1/3$ . The convergence for the inertial torque was slightly worse. The torque varied about 0.5% when we changed  $2a/\Delta x$  from 36 to 48 for  $\nu\Delta t/\Delta x^2 = 0.58$ , and it varied about 4% when we halved  $\nu\Delta t/\Delta x^2$  from 0.58 to 0.29 for  $2a/\Delta x = 36$ . We also performed convergence checks for  $Re_p = 0.32$ , reducing the particle Reynolds number by increasing  $\nu$ . We found that the values of  $\Delta x$  and  $\Delta t$  quoted above are too large for the numerical scheme to converge at this Reynolds number. Therefore we only show results for  $Re_p \geq 1$  in the main text.
