We report the first mass measurement of the proton-halo candidate 22 Al performed with the LEBIT facility's 9.4 T Penning trap mass spectrometer at FRIB. This measurement completes the mass information for the lightest remaining proton-dripline nucleus achievable with Penning traps. 22 Al has been the subject of recent interest regarding a possible halo structure from the observation of an exceptionally large isospin asymmetry [Phys. Rev. Lett. **125** 192503 (2020)]. The measured mass excess value of ME = 18 093.6(7) keV, corresponding to an exceptionally small proton separation energy of $S_p = 99.2(1.0)$ keV, is compatible with the suggested halo structure. Our result agrees well with predictions from sd-shell USD Hamiltonians. While USD Hamiltonians predict deformation in 22 Al ground-state with minimal $1s_{1/2}$ occupation in the proton shell, a particle-plus-rotor model in the continuum suggests that a proton halo could form at large quadrupole deformation. These results emphasize the need for a charge radius measurement to conclusively determine the halo nature.

INTRODUCTION

Nuclei at, and near, the boundaries of nuclear existence serve as excellent probes for evaluating nuclear models given their exotic nature [1–3]. Halo nuclei are one such example; seated at or near the nuclear driplines, their mass distribution extends far beyond the compact core, creating their so-called 'halo' structure. Efforts to identify, study, and model these nuclei have provided critical evaluations of nuclear forces (see [4–6] for reviews).

Studies of proton halo structures are often limited, compared to neutron halos, as their formation is suppressed by the confining effect of the Coulomb barrier. Additional complications arise from low production cross-sections for nuclei approaching the proton dripline. Precision measurements of these nuclei are of particular

importance as the proton drip line is sufficiently well known compared to that for neutrons, offering a unique probe of nuclear forces.

²²Al was first proposed as a proton-halo candidate resulting from an exceptionally small proton separation energy extrapolated from systematic trends in the mass region [7] and from calculations of isospin-symmetry breaking effects in the sd-shell region [8]. Recent excitement pointing to a halo structure in the first 1⁺ state of ²²Al stems from an observed isospin asymmetry of $\delta_{\beta} = 2.09(96)$ in the Gamow-Teller β^+ transition from the first excited 1⁺ state of 22 Si and with its mirror 22 O β^- transition [9]. This is by far the largest asymmetry reported for low-lying states. Results, however, contain significant uncertainties propagating from its unmeasured mass. The presence of an s-wave halo in ²²Al should favor deformation by increasing the proton $1s_{1/2}$ — $0d_{5/2}$ quadrupole coupling. In fact, relativistic meanfield calculations [10] and data evaluation [11] support large quadrupole deformation of about $\beta_2 > 0.2$ in 22 Al.

Due to the role of weak binding in the emergence of halo structures, precise knowledge of the binding energy—and consequentially mass—is paramount [3, 12]. In quantum mechanics, the halo can be seen as a leakage of the valence nucleon wave function, which itself depends exponentially on the nucleon separation energy. Precise mass information is also required to extract nuclear charge radii from isotope shift measurements [13]. Since the current mass value of ²²Al is based purely on extrapolation of systematic trends of mass values of nearby isotopes [7], there is a clear need for a first, precise mass measurement of ²²Al.

EXPERIMENTAL METHOD AND ANALYSIS

At the Facility for Rare Isotope Beams (FRIB), the proton-rich ²²Al isotope was produced by projectile fragmentation: a ³⁶Ar primary beam was sent through the FRIB linear accelerator, ultimately impinging upon a ¹²C target of about 8 mm thickness. The cocktail beam was then sent to the Advanced Rare Isotope Separator [14] for separation. Two aluminum degraders of thicknesses 3287 μ m and $1015 \mu m$, followed by a $1003 \mu m$ 2.67 mrad aluminum wedge prepared the beam for stopping in the Advanced Cryogenic Gas Stopper (ACGS) [15]. Following mass separation with a magnetic dipole, the extracted 30-keV energy beam showed highest beta activity at A=22 and was sent to the Low Energy Beam Ion Trap (LEBIT) facility. There, the continuous beam was delivered to the Cooler-Buncher [16], allowing ions to cool for 10 ms. Ion bunches were purified with a coarse time-of-flight gate before injection into the 9.4 T Penning trap mass spectrometer [17]. In the trap, nearby contaminants were cleaned using the Stored Waveform Inverse Fourier Transform (SWIFT) technique [18].

LEBIT uses Penning trap mass spectrometry to determine an ion's mass relative to a well-known calibrant through measurements of their cyclotron frequencies, ν_c :

$$R = \frac{\nu_{c,\text{calib}}}{\nu_c} = \frac{q_{\text{calib}}(m - m_e q)}{q(m_{\text{calib}} - m_e q_{\text{calib}})}, \quad (1)$$

where m and q are the ion atomic mass and charge state respectively. Electron binding energies are negligible as they are orders of magnitude smaller than the measurement precision.

Initial measurements were performed with the well-established Time-of-flight Ion Cyclotron Resonance (TOF-ICR) technique in use at LEBIT [19–21]. The achievable precision is determined in part by excitation duration, which defines the frequency selectivity and scales linearly with duration. Because of its half-life of ≈ 85 ms [22], excitation times of 50 and 75 ms were used for ²²Al. A much longer 500 ms excitation was used for ²³Na. Figure 1(a) shows one TOF-ICR resonance spectrum obtained for ²²Al⁺.

Additional measurements were performed with the recently implemented Phase Imaging Ion Cyclotron Resonance (PI-ICR) technique [23] at LEBIT. A 'two-phase' approach is used, measuring the magnetron (ν_{-}) and reduced cyclotron (ν_{+}) frequencies independently. After evolving for a duration $t_{\rm acc}$, the final phase $\phi_{\rm final}$ of the ions relative to a reference location $\phi_{\rm ref}$ determines the frequency:

$$\nu_{\pm} = \frac{(\phi_{\text{final},\pm} - \phi_{\text{ref}}) + 2\pi n}{2\pi t_{\text{acc}}}.$$
 (2)

n is the number of full revolutions undergone by the ions during $t_{\rm acc}$, and is known sufficiently, so long as the frequency uncertainty is less than $1/t_{\rm acc}$. The ion's cyclotron frequency is found by $\nu_c = \nu_+ + \nu_-$ as described in [24]. Similar to the restrictions for TOF-ICR, $t_{\rm acc}$ was set to 50 ms for $^{22}{\rm Al}^+$, and 150 ms for $^{23}{\rm Na}^+$. Figure 1(b) shows an example of a final phase spot for $^{22}{\rm Al}^+$ with $t_{\rm acc}$ = 50 ms.

FIG. 1. (a) Observed 75 ms ²²Al⁺ TOF-ICR resonance and fit, containing approximately 350 detected ions. (b) Observed 50 ms PI-ICR beam spot resulting from reduced cyclotron motion, containing approximately 50 detected ions. The spot is fit to a 2D (polar) Gaussian. The black arrow shows the direction of motion.

A number of systematic uncertainties in \bar{R} have been shown to scale linearly with the difference in mass of the calibrant ion and the ion of interest. This includes shifts due to magnetic field inhomogeneities, deviations in the axial alignment of the Penning trap with the magnetic field, and distortions of the electrostatic trapping potential [25]. Mass dependent shifts for TOF-ICR measurements are known to add an uncertainty of $\delta \bar{R} \approx 2 \times 10^{-10}/u$ [26], which is negligible compared to the statistical uncertainty. Additional contributions, such as those from isobaric contaminants [27] and space charge effects [25], were mitigated by in-trap beam purification with SWIFT and by limiting the number of ions in the trap to less than five at a time. Furthermore, studies of non-linear temporal magnetic field instabilities show a contribution to the uncertainty in \bar{R} by no more than 1×10^{-9} [28] over the course of one hour, which is greater than the duration of any of the measurements performed.

Additional systematic effects were accounted for in the TOF-ICR measurements by performing offline measurements of 23 Na⁺ with 22 Ne⁺ as an isobaric stand-in for 22 Al⁺. Both these ions' masses are very well known. The ions were produced using an offline plasma ion source operated with high-purity neon gas at LEBIT. Experimental conditions were matched as closely as possible to those with 22 Al, and the total trapping times remained unchanged. All system settings were not modified following the experiment. The systematic uncertainty was determined to be $\delta \bar{R}_{\rm TOF} = -1(2) \times 10^{-8}$.

With the increased sensitivity of PI-ICR, a number of additional systematic effects are present. Extensive systematic investigations performed at other facilities [29–31] show that these are dominated by many of the same as listed above for TOF-ICR. PI-ICR specific effects are also largely determined by the electrostatic trapping field harmonicity, magnetic field alignment, and count rate dependent frequency shifts [32]. These are mitigated by using smaller total trapping times, maintaining the same spot location on the MCP, and limiting the MCP count rate to ≈ 2 ions per shot respectively. A magnetic field misalignment will result in an elliptical projection of the ion motion. This was accounted for by imaging this projection and fitting the result to an ellipse. The acquired fit is shown in Fig. 1(b). ²³Na and ²²Ne were also used to calculate a systematic uncertainty for PI-ICR, maintaining the accumulation times and angular locations respectively. The systematic uncertainty was determined to be $\delta \bar{R}_{\rm PI} = 0(2) \times 10^{-8}$.

RESULTS

A total of four TOF-ICR and three PI-ICR measurements were taken over the course of approximately 16 hours. The TOF-ICR measurements resulted in a weighted average of $\bar{R}_{\rm TOF} = 1.04406876(6)$, and for the PI-ICR measurements $\bar{R}_{\rm PI} = 1.044068841(14)$. A summary of these measurements is shown in Fig. 2. Combined, these results yield $\bar{R} = 1.044068837(14)$, corresponding to a mass excess of 18 093.6(7) keV and a proton separation energy of 99.2(1.0) keV.

FIG. 2. Measured frequency ratios of $^{22}\text{Al}^+$ relative to $^{23}\text{Na}^+$. Blue points and uncertainty region correspond to TOF-ICR measurements, red points and uncertainty region correspond to PI-ICR measurements. Dashed black lines indicate the combined TOF-ICR and PI-ICR result. All uncertainties are shown to 1σ .

DISCUSSION

Shell Model with USD Hamiltonians

The low-lying structure for the nuclei around 22 Al can be described within the sd ($0d_{5/2}, 0d_{3/2}, 1s_{1/2}$) model space. Several "universal" sd-shell (USD) Hamiltonians have been developed over the last 40 years [33], [34], [35]. They are all obtained by starting with a set of two-body matrix elements (TBME) obtained with nucleon-nucleon potentials renormalized to the sd model space. The singular-valued de-

composition (SVD) method is then used to constrain linear-combinations of TBME to obtain lower uncertainties for binding energies and excitation energies. The lastest SVD-type fit from 2020 was based on Hamiltonians that included the Coulomb and isospin-dependent strong interactions treated explicitly [35], and provide absolute binding energies for all sd shell nuclei relative to that of ¹⁶O. This resulted in two Hamiltonians: USDC starting with the Bonn-A [36] interaction, and USDI starting with the VS-IMSRG method [37], [38]. The rms deviation between the experimental and calculated energies for both USDC and USDI was 140 keV. The results for $S_p(^{22}\text{Al})$ are 40 keV (USDC) and 30 keV (USDI) which are in reasonable agreement with experiment. The calculated spectrum of the mirror nucleus ²²F is in excellent agreement with experiment (see Fig. 3).

FIG. 3. Experimental levels of 22 F up to 5 MeV compared to the results obtained from the USDC and USDI Hamiltonians. The calculated levels of 22 Al are also shown. The horizontal lines in the figure are proportional to the J value for positive parity states. For the experiment shown on the left-hand side, the levels with unknown J are shown by black dots. Levels with uncertain J are indicated by the red lines ending with a black dot.

As discussed in Sec. V of [35], a special consideration for proton-rich nuclei is the Thomas-

Ehrman shift (TES). For example, the $1/2^+$ excited state in ¹⁷F is shifted down by 0.376 MeV compared to its energy in the mirror nucleus ¹⁷O. Single-particle states with low- ℓ values that are loosely bound (in this case $\ell=0$ for the $1s_{1/2}$ which is bound by only 0.105 MeV in ¹⁷F) are lowered in energy relative to those with high- ℓ values. The reason is that the low- ℓ states are extended in size, and the kinetic energy of the extended wavefunctions decreases. As discussed in [35], the TES depends on the separation energy of the specific state and the related spectroscopic factors. It is a many-body effect that cannot be corrected simply by a modification of single-particle energies in the Hamiltonian. In the ²²Al mass region there are excited states that have a significant $\ell=0$ spectroscopic factor with a TES as high as -0.75 MeV (see Fig. 12 of [35]).

A key feature for all of the USD Hamiltonians is the increase in the $1s_{1/2}$ — $0d_{5/2}$ single-particle energy gap from 0.9 MeV at N=8 to 4.0 MeV at N=14 (see Fig. 4 in [39]). This shift has been attributed to three-body interactions between the valence neutrons and the core nucleons [40] and it is contained in VS-IMSRG Hamiltonian for the sd shell [41]. Taking into account the TES, the proton $1s_{1/2} - - 0d_{5/2}$ gap changes from 0.5 MeV at Z=8 to about 3.5 MeV at Z=14. The calculated proton $1s_{1/2}$ occupations for the 4^+ and 3^+ states of 2^2 Al are 0.29 and 0.38, respectively.

The 3^+ state in the mirror nucleus 22 F is only 0.072 MeV above the 4^+ ground-state. The TES from the larger $1s_{1/2}$ occupation of the 3^+ state could result in a 3^+ ground-state for 22 Al, as suggested by [42, 43]. However, the calculated β^+ decay properties of 22 Al are more consistent with a 4^+ ground-state assignment. It will be important to measure the spin-parity and the moments of the 22 Al ground-state to better characterize the structure.

Particle-plus-Rotor Model

Based on the small proton separation energy of about 0.1 MeV measured in 22 Al, one can also investigate the possible presence of a ground-state halo structure using the particle-plus-rotor model (PRM) including couplings to continuum states. The motivation for using this model is to investigate the possible interplay between weak binding, which enhances the occupation of s-waves, and deformation via the $s_{1/2}-d_{5/2}$ quadrupole coupling, which lowers the proton $1s_{1/2}$ shell. Here, one wants to test how the presence of deformation affects the formation of a halo structure.

We assume that only couplings between the angular momentum j_r associated with the rotational motion of ²¹Mg and the angular momentum j of the weakly-bound valence proton play a role in the particle-plus-rotor dynamic $(\vec{j}_r + \vec{j} = \vec{j}_{PRM})$, while the angular momentum J_i coming from the structure of ²¹Mg can be ignored for our purpose. This approximation is justified by the fact that, except for one well-bound neutron in $0d_{5/2}$, all nucleons in ²¹Mg are expected to be paired and coupled to 0^+ . It follows that in this picture, the low-lying multiplets $(1,2,3,4,5)^+$ and $(2,3)^+$ of ²²Al are associated with $j_{PRM}^{\pi} = 5/2^+$ and $1/2^+$, respectively, and the states within each multiplet are degenerate.

In the PRM [44], the core-nucleon interaction is represented by a Woods-Saxon potential with quadrupole deformation controlled by the deformation parameter β_2 , and the wave function is expanded in terms of channel wave functions defined by the quantum numbers (n, l, j, j_r) where (n, l, j) are the usual shell quantum numbers for the valence particle. Each channel wave function is expanded using the Berggren basis to account for continuum couplings, and the coupled-channel equations obtained are solved exactly by direct diagonalization.

The above shell model calculations using the USD family of interactions, predict a fairly limited occupation of the $\pi 1s_{1/2}$ shell in ²²Al and

are not indicative of any significant deformation. Consequently, we first assume spherical symmetry for 21 Mg ($\beta_2=0$) and adjust the potential to reproduce the experimental binding energy of 22 Al and use the energy spectra of 21 Mg to fix the $1s_{1/2}$ shell at about 200 keV above the $0d_{5/2}$ shell, respectively, which will be understood as Nilsson orbits for $\beta_2 \neq 0$. These s.p. energies differ from those in magic nuclei to account for the absence of residual interaction in the PRM. We obtain a diffuseness d=0.67 fm, a radius $R_0=3.2$ fm, a depth $V_0=54.8$ MeV, a spin-orbit coupling $V_{\rm so}=3.62$ MeV, and a WS Coulomb potential radius $R_c=3.0$ fm.

The potential is then deformed by varying β_2 , and the ground-state energy of ²²Al together with the norms of channel wave functions are calculated. Results are shown in Fig. 4. Both

FIG. 4. Energy of the 21 Mg+p system (top panel), and norms of channel wave functions for $j_{\text{PRM}} = 5/2^+$ (middle panel) and $1/2^+$ (lower panel) as a function of the quadrupole deformation parameter β_2 .

prolate $(\beta_2 > 0)$ and oblate $(\beta_2 < 0)$ deformations are shown to lower the energy, suggesting that a weakly-bound valence proton pushes the system to deform.

For a small deformation ($|\beta_2| < 0.1$) qualitatively compatible with shell model calculations, the weight of the channel wave function $(j_r = 2)1s_{1/2}$ remains relatively low compared to other channels built on the $0d_{5/2}$ shell. In this scenario, the presence of a s-wave halo would thus be unlikely. However, for a significant prolate deformation $\beta_2 > 0.1$, the $1/2^+$ PRM state associated with the $(2,3)^+$ multiplet in 22 Al becomes the ground state. This state is dominated by the s-wave channel and shown in Fig. 4 (lower panel) and would likely support a halo structure. While such large quadrupole deformations are not supported by the shell model, relativistic mean-field calculations [10] and data evaluation [11], however, predict deformations of $\beta_2 = 0.284$ and 0.226, respectively. Using the latter estimate as a guess and readjusting the core-proton potential to match the experimental binding energy by lowering the potential depth does not affect the results significantly.

CONCLUSIONS

In summary, the first precision mass measurement of ²²Al is reported. The exceptionally small proton separation energy observed at 99.2(1.0) keV agrees with extrapolations by the 2020 Atomic Mass Evaluation as well as predictions made with the sd-shell USD Hamiltonians. Such a small nucleon separation energy is one such benchmark allowing for halo formation. The shell model, reproducing the experimental result within uncertainties, suggests a very small $1s_{1/2}$ orbital occupation. In the PRM, this small $1s_{1/2}$ occupation translates in a small deformation parameter and no halo structure. Conversely, the observation of a halo state would indicate strong continuum-induced deformation similar to the suspected situation in ²⁹F [45]. Both models are constrained by a 4⁺ ground state assignment for ²²Al, though it remains unmeasured [22, 46]. Ultimately, the charge radius and nuclear spin, which can be determined from the hyperfine structure measurements by laser spectroscopy, are needed to conclusively determine the halo nature of the ²²Al ground state and to resolve the confusion surrounding its structure.

This work was conducted with the support of Michigan State University and the National Science Foundation under Grants No. PHY-1102511, PHY-1126282, PHY-2111185, and PHY-2238752. This material is based upon work supported by the U.S. Department of Energy, Office of Science, Office of Nuclear Physics and used resources of the Facility for Rare Isotope Beams (FRIB) Operations, which is a DOE Office of Science User Facility under Award Number DE-SC0023633, and under the FRIB Theory Alliance Award No. DE-SC0013617. Thank you to Witek Nazarewicz for his fruitful discussions and input towards the presented theoretical work.
