### **Abstract:**

**Recently, a signature of high-temperature superconductivity above the liquid nitrogen temperature (77 K) was reported for La3Ni2O<sup>7</sup> under pressure. This finding immediately stimulates intense interest in the possible high-***T<sup>c</sup>* **superconducting mechanism in double-layer nickelates. Interestingly, the pressure-dependent phase diagram inferred from transport measurements indicates that superconductivity under high pressure emerges from the suppression of a density-wave-like transition at ambient pressure, which is similar to hightemperature superconductors. Therefore, clarifying the exact nature of the density-wave-like transition is important for determining the mechanism of superconductivity in double-layer nickelates. Here, nuclear magnetic resonance (NMR) spectroscopy of <sup>139</sup>La nuclei was performed to study the density-wave-like transition in a single crystal of La3Ni2O7. The temperaturedependent <sup>139</sup>La NMR spectrum and nuclear spin-lattice relaxation rate (1/***T1***) provide unambiguous evidence for a spin-density-wave (SDW) transition with a transition temperature**  *TSDW* **of ~ 150 K. Furthermore, the anisotropic splitting of the NMR spectrum suggests a possible double spin stripe with magnetic moments along the** *c* **axis. In addition, the present NMR**  **measurements also revealed spatial inhomogeneity of magnetism due to inner apical oxygen vacancies. All these results will be helpful for building a connection between superconductivity and magnetic interactions in double-layer nickelates.**

The origin of high-temperature superconductivity remains a conundrum in condensed matter physics  $[1, 2]$ . The discovery of superconductivity up to 15 K in infinite-layer nickelate NdNiO<sub>2</sub> thin films has drawn extensive interest for the pursuit of high- $T_c$  superconducting mechanisms in nickelate materials [3]. Recent resonant inelastic X-ray scattering (RIXS) experiments revealed significant antiferromagnetic interactions in superconducting  $Nd_{1-x}Sr_xNiO_2$  thin films [4]. Moreover, muon spin rotation/relaxation (μSR) experiments also reveal intrinsic magnetism in a series of superconducting infinite-layer nickelate thin films [5]. All these results are similar to those of cuprate superconductors [6-13], suggesting the key role of antiferromagnetic interactions in superconducting infinite-layer nickelates [14]. Very recently, a signature of high-temperature superconductivity at approximately 80 K was observed for the double-layer nickelate  $La_3Ni_2O_{7-\delta}$  under high pressure [15]. Although characterization of the superconducting state is still limited due to the high-pressure environment, these findings have stimulated wide discussions on the electronic correlations and possible high- $T_c$ mechanism [16-31].

Experimentally, a density-wave-like transition at approximately 150 K was previously observed in La<sub>3</sub>Ni<sub>2</sub>O<sub>7- $\delta$ </sub> at ambient pressure [32-37]. Due to the absence of detectable magnetic and charge ordering below 150 K in earlier experiments, the exact nature of this density-wave-like transition has not been determined [38]. In contrast, a similar density-wave-like transition has also been observed in the trilayer nickelate  $La_4Ni_3O_{10}$ , in which an intertwined density wave with both charge and spin order is experimentally revealed below the transition temperature  $(\sim 136 \text{ K})$  [39]. Considering the similar band structures observed by angle-resolved photoemission spectroscopy (ARPES) [40, 25], understanding the different experimental results of density-wave-like transitions between  $La_3Ni_2O_{7-\delta}$ and  $La_4Ni_3O_{10}$  is not straightforward. More importantly, recent high-pressure transport measurements indicate that the density-wave-like transition in  $La_3Ni_2O_{7-\delta}$  is continuously suppressed as the pressure increases and finally disappears when high- $T_c$  superconductivity occurs [15, 41, 42]. These results suggest an important correlation between superconductivity and density-wave-like order. Therefore, identifying the exact nature of the density-wave-like transition is a prerequisite for understanding the high-*T<sup>c</sup>* superconductivity in La3Ni2O7-δ under high pressure. Nuclear magnetic resonance (NMR) is a sensitive local probe for detecting both spin and charge orders in high-*T<sup>c</sup>* superconductors [43, 44]. Here, we performed a systematic NMR measurement on  $^{139}$ La nuclei in a single crystal of La<sub>3</sub>Ni<sub>2</sub>O<sub>7-δ</sub>. Our results provide clear evidence for a spin-density-wave (SDW) transition at  $\sim$  150 K.

## **Site-selective <sup>139</sup>La NMR**

As shown in Fig. 1a, the structure of  $La_3Ni_2O_{7-\delta}$  at ambient pressure crystallizes into an orthorhombic phase (space group Amam) with a corner-connected  $NiO<sub>6</sub>$  octahedral layer separated by a La–O fluorite-type layer stacking along the *c* axis [36]. The La sites inside the corner-connected  $NiO<sub>6</sub>$  octahedral layer are defined as  $La(1)$ , and the other La sites in the La-O fluorite-type layer are defined as  $La(2)$ . In previous  $139La NMR$  measurements of polycrystalline samples, the quadrupole frequencies (v<sub>O</sub>) of these two La sites were found to be quite different, with 2.2 MHz for La(1) and 5.6 MHz for La(2) [37, 45, 46]. This is useful for obtaining site-selective  $^{139}$ La NMR spectra of single crystals. As shown in the inset of Fig. 1d, one piece of a La<sub>3</sub>Ni<sub>2</sub>O<sub>7-δ</sub> single crystal with a size of  $\sim$  2  $mm \times 1$  mm was selected for <sup>139</sup>La NMR measurement (see Sec. S1 in the Supplementary Materials for detailed sample information,). The full NMR spectra with magnetic fields (*B*) perpendicular and parallel to the *ab* plane were measured. The nuclear spin number for <sup>139</sup>La nuclei is 7/2. In principle, due to nonzero quadrupole interactions, there should be seven NMR transition lines for each La(1) and La(2) site. As shown in Fig. 1(b) and 1(c), only one set of sharp <sup>139</sup>La NMR peaks with  $v_0 \sim 2.2$  MHz is well resolved and assigned to La(1) sites. In contrast, the NMR signal from the La(2) site contributes a broad background to the full NMR spectrum, suggesting that the  $La(2)$  site is strongly inhomogeneous. This inhomogeneity might be related to the low superconducting volume suggested by very recent *ac* susceptibility measurements on single crystals from the same batch [47]. However, the origin of such an inhomogeneity requires additional microscopic characterization of the structure and ingredients. In the following, we will only focus on the sharp NMR signals for the La(1) sites. In addition, we also found that there is an unexpected splitting on each La(1) NMR transition line above the density-wave-like transition temperature ( $\sim 150$  K), which is well resolved with  $B/\sqrt{c}$ , as shown in Fig. 1d. The twinning due to the orthorhombic structure, which should not split with *B*//*c*, can be excluded from our angle-dependent NMR spectra (see Sec. S2 in the Supplementary Materials). Therefore, the splitting of the NMR spectrum with *B*//*c* suggested a more complicated structural modulation beyond the perfect structure with the space group Amam [48]. In fact, the nearest neighboring sites to  $La(1)$  are the four inner apical oxygens. Therefore, the NMR spectrum of  $La(1)$ should be very sensitive to the presence of inner apical oxygen vacancies, which provides a natural explanation for the NMR splitting of La(1). As shown in Fig. 1e, La(1)a and La(1)b are attributed to La(1) without inner apical oxygen vacancy and with a single inner apical oxygen vacancy at the nearest neighboring sites, respectively. By considering a random distribution of inner apical oxygen vacancies, the ratio of oxygen vacancies at the inner apical oxygen site is estimated to be approximately 20% (see Sec. S3 in the Supplementary Materials). This result is also consistent with recent results from multislice electron ptychography [49], suggesting the key role of inner apical oxygen vacancies in the superconducting properties of  $La_3Ni_2O_{7-\delta}$  single crystals.

#### **Evidence for an SDW transition at 150 K**

Next, we systematically studied the temperature-dependent evolution of NMR central transition lines, which are sensitive to magnetic transitions. As shown in Fig. 2, the central NMR lines exhibit a remarkable change below 150 K with magnetic fields applied along different crystalline axes. When an external magnetic field *B* is applied along the (001) direction, the central NMR lines exhibit significant broadening below 150 K, as shown in Fig. 2(a). However, when an external magnetic field *B* is applied along the (110) direction, the central NMR lines clearly split below 150 K, as shown in Fig. 2(b), which is a hallmark of magnetic transition. By further checking the field-dependent broadening and splitting (see Sec. S4 in the Supplementary Materials), we conclude that an SDW transition occurs below 150 K. The temperature-dependent broadening and splitting are shown in Fig. 2(c) and (d), which exhibit a second-order SDW transition with a transition temperature  $T_{SDW}$  of  $\sim 150$ K. This result is also consistent with recent μSR and RIXS experiments [50, 51]. In addition, it should be noted that the SDW transition produces quite different hyperfine fields at  $La(1)a$  and  $La(1)b$  (Fig. 2(c)), which implies the possible role of inner apical oxygen in magnetism. Based on a recent density functional theory calculation [52], the magnitude of magnetic moments is strongly affected by the absence of inner apical oxygens in  $La_3Ni_2O_7$ . This finding is in line with our present observation (see the next section for more discussion). Furthermore, the temperature-dependent nuclear spin-lattice relaxation rate  $(1/T_I)$  also confirms the SDW transition at ~150 K. As shown in Fig. 3(a), the temperature-dependent  $1/T_I T$  of La(1)a and La(1)b exhibit similar SDW transitions at  $\sim$  150 K, which is quite consistent with previous NMR investigations of polycrystalline samples [37,46]. Interestingly, the present NMR measurements of single crystals reveal additional site-dependent behavior for 1/*T1T* above 150 K. For La(1)a, the critical behavior of spin fluctuations due to the SDW transition can extend much above  $T_{SDW}$  up to 200 K, which has not been observed in previous La(1) NMR results on polycrystalline samples [37,46]. However, for La(1)b, a similar critical behavior appears only within a narrow temperature range of a few Kelvins around the *TSDW*. Moreover, the overall temperaturedependent behaviors for La(1)a and La(1)b are also different above 150 K. All these results suggest that the nature of fluctuating magnetic moments above the SDW transition is also strongly affected by the inner apical oxygens, which might also be pivotal for superconductivity under pressure. More theoretical investigations are needed to clarify the site-dependent spin susceptibility of  $La_3Ni_2O_7$ , which is beyond the scope of the present study. Below 150 K, the  $1/T_I T$  of both La(1)a and La(1)b are strongly suppressed as the temperature decreases to 50 K. This behavior is well understood by the formation of the SDW order. Moreover, the stretched exponent, which is extracted from the fitting of  $T_I$  decay and depicts the inhomogeneity of  $T_I$ , shows a continuous decrease below 150 K (Fig. 3(b)). This indicates inhomogeneous spin dynamics in the SDW state. This might be related to the abovementioned inner apical oxygen vacancies. Below 50 K, additional spin dynamics appear in the temperature-dependent  $1/T_I T$  and lead to field-dependent peak behavior at lower temperatures (Fig. 3(c)). This field-dependent behavior can be ascribed to the dynamic slowing down of fluctuating magnetic moments, which is usually observed in glassy magnetism [12, 53-55]. Considering the sensitivity of magnetism to inner apical oxygens, whether the observed glassy spin dynamics are intrinsic or extrinsic is still unclear.

#### **Possible magnetic structure**

Finally, we discuss the possible magnetic structure based on the present NMR results. In a previous study on the trilayer nickelate  $La_4Ni_3O_{10}$ , an intertwined density wave with both spin and charge order was observed at ambient pressure [39]. Considering the similar band structures in both  $La<sub>3</sub>Ni<sub>2</sub>O<sub>7</sub>$  and  $La<sub>4</sub>Ni<sub>3</sub>O<sub>10</sub>$  [25, 40], a similar intertwined density wave order might also be shared in  $La<sub>3</sub>Ni<sub>2</sub>O<sub>7</sub>$ . However, the temperature-dependent  $139$ La NMR satellites, which are sensitive to charge ordering [55, 56], do not show any signature for charge ordering at approximately 150 K (see Sec. S5 in the Supplementary Materials). Therefore, we believe that if there is any charge order accompanied by an SDW order in  $La_3Ni_2O_7$ , the order should be very weak and beyond the sensitivity of the present NMR measurements. Below, we only consider pure SDW models to explain our NMR results. By careful in-plane rotation, two orthorhombic domains were identified by the present NMR measurements (see Sec. S6 in the Supplementary Materials). Furthermore, all these NMR spectra with magnetic fields along different directions (Fig. 2 and Fig. S8) can be used to constrain the possible magnetic structure below 150 K. As shown in Fig. 4(a), by considering an approximate square lattice of Ni, a double spin stripe model with a wavevector  $q = (\pi/2, \pi/2)$  is finally proposed to account for the present NMR results, which are quite consistent with recent RIXS and neutron scattering experiments [51, 57]. Here, we consider an antiferromagnetic coupling between the neighboring Ni-O planes in each bilayer, and the spin polarization is along the out-of-plane direction. According to this model, the hyperfine fields transferred at La sites from the nearest neighboring Ni sites can explain the <sup>139</sup>La NMR spectra shown in Fig. 2 and Fig. S8. More discussion on the possible magnetic structure can be found in the supplementary materials (see Sec. S7 in the Supplementary Materials). It should be emphasized that the transferred hyperfine fields at La sites are quite different for La(1)a and La(1)b. Based on the results of hyperfine fields, we can estimate the magnetic moments at Ni sites, which are approximately 0.08 Bohr magneton ( $\mu_B$ ) for Ni with inner apical oxygen and 0.018  $\mu_B$  for Ni without inner apical oxygen (see Sec. S8 in the Supplementary Materials). This result suggests that the inner apical oxygen is helpful for stabilizing static magnetic moments at Ni sites in the SDW state.

In summary, the present NMR study successfully identified an SDW transition at  $\sim$ 150 K and strongly constrained the possible magnetic structure of the bilayer nickelate  $La_3Ni_2O_7$  at ambient pressure. A double spin stripe model with magnetic moments along the *c*-axis is proposed to account for the observed <sup>139</sup>La NMR spectra. These results strongly suggest a possible twist of the SDW and superconductivity under pressure, but further experiments are needed to clarify this picture. In addition, the role of the inner apical oxygen in magnetic properties was also revealed by site-selective <sup>139</sup>La NMR, which might also be important for superconductivity under pressure.

# **Figures**

FIG. 1 (a) Sketch of the crystal structure of La<sub>3</sub>Ni<sub>2</sub>O<sub>7</sub>. (b) and (c) Full NMR spectra of <sup>139</sup>La nuclei with spin number  $I = 7/2$  for external fields  $B \parallel c$  and  $B \parallel (110)$ ; (d) The central line of <sup>139</sup>La above the SDW transition temperature. The inset shows the single crystal of  $La_3Ni_2O_7$  used for the present NMR study; (e) Illustration of La(1)a without an inner apical oxygen vacancy and La(1)b with a single inner apical oxygen vacancy.

**FIG. 2** Temperature dependence of the <sup>139</sup>La central transition lines for the (a)  $B \parallel c$  axis and (b)  $B \parallel c$ (110) direction. (c) Temperature-dependent linewidth for the  $La(1)a$  and  $La(1)b$  sites. (d) Temperature-dependent magnetic splitting  $(\Delta f)$  of the La(1)b site for B  $\parallel$  (110). The dash lines in (c) and (d) represent the SDW transition temperature at  $\sim$  150 K.

**FIG. 3** (a) Temperature dependences of  $1/T_1T$  for both the La(1)a and La(1)b sites for *the B*  $\parallel$  *c* axis. The value of  $T_1$  is extracted by fitting with the following formula  $m(t) = m_0 + m_1[\frac{1}{\alpha}]$  $\frac{1}{84}e^{-\left(\frac{t}{T}\right)}$  $\left(\frac{t}{T_1}\right)^r$ + 3  $rac{3}{44}e^{-\left(\frac{6t}{T_1}\right)}$  $\left(\frac{6t}{T_1}\right)^r$  $+\frac{75}{36}$  $rac{75}{364}e^{-\left(\frac{15t}{T_1}\right)}$  $\frac{15t}{T_1}\big)^r$  $+\frac{1225}{1716}$  $\frac{1225}{1716}e^{-\left(\frac{28t}{T_1}\right)}$  $\frac{28t}{T_1}\big)^r$ ], where  $r$  is the stretch exponent. (b) The temperaturedependent stretch exponent  $r$  of <sup>139</sup>La. (c) Field and temperature dependence of  $1/T_1T$  for La(1)(a).

**FIG. 4** (a) Illustration of the double spin stripe model, as well as the transferred hyperfine fields at the La(1) sites. (b-c) The evolution of the NMR spectra before and after the SDW transition. When the external field (*B*) is parallel to the *c*-axis, the hyperfine field  $h_f$  at the La(1) sites is perpendicular to the external field  $h_0$ . The effective external field at the La(1) sites is expressed as  $h_{eff} = \sqrt{h_f^2 + h_0^2}$ , where  $h_0$  is the applied external field and  $h_f$  is the transferred hyperfine field. Only spectral line broadening can be observed in this case. In contrast, when  $B \parallel (110)$ , the effective external field at the La(1) sites is expressed as  $h_{eff} = h_0 \pm h_f$ . A clear spectral splitting can be observed in this case.
