## ABSTRACT

*Euclid* will provide deep NIR imaging to  $\sim 26.5$  AB magnitude over  $\sim 59 \text{ deg}^2$  in its deep and auxiliary fields. The Cosmic DAWN survey complements the deep *Euclid* data with matched depth multiwavelength imaging and spectroscopy in the UV–IR to provide consistently processed *Euclid* selected photometric catalogs, accurate photometric redshifts, and measurements of galaxy properties to a redshift of  $z \sim 10$ . In this paper, we present an overview of the survey, including the footprints of the survey fields, the existing and planned observations, and the primary science goals for the combined data set.

**Key words.** Surveys; Catalogs; Galaxies: high-redshift; Galaxies: evolution; Galaxies: luminosity function, mass function

## 1. Introduction

The *Euclid* mission (Laureijs et al. 2011; Euclid Collaboration: Mellier et al. 2024; Euclid Collaboration: Cropper et al. 2024; Euclid Collaboration: Jahnke et al. 2024) is designed to constrain the properties of dark matter and dark energy through weak lensing, galaxy cluster counts, and clustering measurements. The majority of the six year mission will be spent carrying out a wide area imaging and spectroscopic survey (the Euclid Wide Survey: EWS; Euclid Collaboration: Scaramella et al. 2022) covering roughly  $14\,000 \text{ deg}^2$  of the extragalactic sky. The EWS will measure the shape and colour of billions of galaxies from imaging observations in a single broad visible band ( $I_{\text{E}}$ ) and three near-infrared (NIR) bands ( $Y_{\text{E}}, J_{\text{E}}, H_{\text{E}}$ ) with expected depths of  $25 \text{ AB}$  ( $10\sigma$  for extended sources) and  $24.5 \text{ AB}$  ( $5\sigma$  for point sources) respectively. The spectroscopic component of EWS will measure redshifts for around thirty million galaxies with emission line fluxes of  $2 \times 10^{-16} \text{ erg cm}^{-2} \text{ s}^{-1}$  at  $1.6 \mu\text{m}$ . Redshifts for the remaining galaxies will be measured photometrically by combining ground-based optical photometry with the *Euclid* data.

*Euclid* will also devote 17% of the primary mission time to obtaining deeper observations needed for calibration, control of systematic effects, and characterising the galaxy sample from the EWS. The six *Euclid* auxiliary fields (EAFs; CDFS, COSMOS, SXDS, VVDS, AEGIS, and GOODS-N, see Sect. 2 for details) each have extensive UV–NIR imaging observations and large catalogues of spectroscopic redshift measurements. Three large ( $10\text{--}20 \text{ deg}^2$ ) Euclid Deep Fields (EDFs; EDF-North, EDF-South, and EDF-Fornax) were also selected for observations two mag deeper than the EWS. Consistent processing and photometric measurements from the *Euclid* and ancillary data in the EAFs and EDFs is essential for calibrating photometric redshift measurements and quantifying biases in shape measurements from the broader EWS.

The Cosmic DAWN Survey (DAWN) is a  $59 \text{ deg}^2$  multi-wavelength imaging survey of the EDFs and EAFs with comparable depth to the *Euclid* data. *Spitzer*/IRAC data cover all the DAWN fields at  $3.6$  and  $4.5 \mu\text{m}$  (Euclid Collaboration: Moneti et al. 2022) and incorporate the single largest allocation of *Spitzer* observing time (Capak et al. 2016). The Hawaii Twenty deg $^2$  Survey (H20; Euclid Collaboration: Zalesky et al. 2024) provides Subaru Hyper Suprime-Cam optical data and CFHT MegaCam UV data for EDF-N and EDF-F. The Hyper Suprime-Cam Subaru Strategic Survey (HSC-SSP Aihara et al. 2018a) provides optical data for COSMOS, SXDS, VVDS, and AEGIS. Additional UV–optical data for EDF-F and EDF-S will also be provided by Vera C. Rubin Observatory (Ivezic et al. 2019). The CFHT large area U-band deep survey (CLAUDS; Sawicki et al. 2019) and the ongoing Deep Euclid U-band Survey (DEUS) program provide additional CFHT MegaCam UV data in COSMOS, SXDS, EDF-N, and GOODS-N.

**Fig. 1.** Illustration of the dark matter overdensity,  $\delta_{\text{DM}} \equiv \rho_{\text{DM}}/\bar{\rho}_{\text{DM}} - 1$ , at redshifts  $4.3 < z < 5.3$  in a  $5^\circ \times 5^\circ$  region from the cosmological simulation of Rácz et al. (2021). The large circle encloses a  $10 \text{ deg}^2$  region, which is equivalent to the area covered by the smallest EDF. The small rectangles and circle are comparable to the areas of the CANDELS and COSMOS surveys, respectively. The DAWN survey has both the depth and large area coverage needed to study rare overdensity peaks (orange) and cosmic voids (blue) and place strong constraints on the overall cosmological distribution of dark matter. The scale bar shows the angular size for a proper distance of  $20 \text{ Mpc}$  at  $z = 5$ .

The combination of depth, area, and wavelength coverage makes DAWN an excellent data set for studying galaxy evolution and robustly characterising the  $z > 4$  galaxy population. Deep rest-frame UV–near-IR data are critical for estimating photometric redshifts and physical parameters (e.g., stellar mass, star-formation rate) of galaxies. Robustly characterizing the  $z > 4$  galaxy population requires multiwavelength data that cover observed wavelengths from the near-UV ( $0.3 \mu\text{m}$ ) to near-IR ( $3\text{--}5 \mu\text{m}$ ) and are deep enough to detect faint ( $z_{\text{AB}} \sim 26$ ) galaxies. Large fields ( $\gtrsim 10 \text{ deg}^2$ ) are needed to identify rare sources in the high-redshift Universe, probe cosmologically significant volumes ( $\sim 1 \text{ Gpc}^3$ ), and making them contiguous allows one to study the evolution of large-scale structure with cosmic time. Existing deep fields with similar depth and wavelength coverage such as the CANDELS fields (Grogin et al. 2011; Koekemoer et al. 2011) and COSMOS deep field (Scoville 2007) are prone to small number statistics and cosmic variance due to the scale of variations in the underlying dark matter (DM) density field at high redshifts (see Fig. 1).

The COSMOS field has shown the power of multiwavelength data sets spanning large areas of the sky. The DAWN survey aims to expand on the legacy of COSMOS by providing value added

catalogues with consistently measured *Euclid* selected multi-wavelength photometry and physical properties in the EDFs and EAFs; an area 30× larger than the COSMOS field. By including *Spitzer*/IRAC data needed to probe the rest-frame optical at  $z > 4$ , the DAWN catalogues are optimized for high-redshift and galaxy evolution science and are thus complimentary to the official *Euclid* catalogues. This paper describes the fields, observations, and science goals of the DAWN survey. A companion paper ([Euclid Collaboration: Zalesky et al. 2024](#)) provides the first DAWN survey catalogue of the pre-launch data in EDF-N and EDF-F. Future DAWN data releases (including EDF-S and the EAFs) will follow each of the *Euclid* data releases.

Section 2 describes the fields covered by the DAWN survey. Sections 3 and 4 summarise the broad-band imaging and spectroscopic observations (respectively) in each field. The main science goals of the survey are discussed in Section 5 and Section 6 provides a summary of the survey.

## 2. Survey fields

The DAWN survey covers each of the EDFs and EAFs. The center coordinates and area of each field are presented in Table 1, and Fig. 2 shows their positions on an all-sky map. The following subsections give a brief summary of the EDFs and EAFs. Consult the *Euclid* overview paper ([Euclid Collaboration: Melier et al. 2024](#)) for more details.

### 2.1. *Euclid* Deep Fields

The deepest observations from the *Euclid* mission focus on three fields: Euclid Deep Field North (EDF-N), Euclid Deep Field Fornax (EDF-F), and Euclid Deep Field South (EDF-S). The locations of EDF-N and EDF-S were strategically chosen to maximise their observability throughout the duration of the *Euclid* mission. Each field will receive *Euclid* imaging observations that are 2 mag deeper than the EWS, which is essential for calibration of the bias introduced by noise in weak lensing measurements. The depth and area (see Table 1 & 2) of the EDFs make them the primary fields for galaxy evolution and high-redshift science from the *Euclid* mission.

EDF-N covers a 20 deg $^2$  circular region centered on the North Ecliptic Pole (NEP) in the constellation Draco. Due to its proximity to the ecliptic pole, EDF-N has perennial visibility by

*Euclid* allowing for regularly repeated observations throughout the mission. EDF-F is a 10 deg $^2$  circular region in the constellation Fornax. EDF-S covers a 23 deg $^2$  elongated region in the southern constellation Horologium.

### 2.2. *Euclid* Auxiliary Fields

The EAFs focus on well studied galaxy deep fields (COSMOS, AEGIS, SXDS, VVDS, CDFS, and GOODS-N) and will receive observations from *Euclid* that are four to five times deeper than the EWS. Due to the large amount of existing multiwavelength data in these fields, the EAFs will be essential for calibrating photometric redshift estimates and the effect of colour gradients in galaxies on shear measurements for the EWS.

The COSMOS EAF ([Scoville 2007](#)) has deep multiwavelength observations from X-ray to radio and an extensive spectroscopic database. The COSMOS2020 catalogue ([Weaver et al. 2022](#)) provides the most up-to-date compilation of photometry, photo-zs, and stellar mass estimates. The Chandra Deep Field South (CDFS) EAF lies within EDF-F and contains one of the deepest observations from by the *Chandra* X-ray observatory along with complementary observations from UV to radio. Two EAFs lie within the XMM Large Scale Structure (XMM-LSS) Survey field ([Clerc et al. 2014](#)): the Subaru/XMM-Newton Deep Survey (SXDS; [Sekiguchi et al. 2004](#)) and the VIMOS VLT Deep Survey (VVDS; [Le Fèvre et al. 2005a](#)). The SXDS EAF overlaps with the UKIRT Infrared Deep Sky Survey (UKIDSS; [Lawrence et al. 2007](#)) UDS field which has extensive spectroscopic coverage from UDSz program ([Bradshaw et al. 2013](#); [McLure et al. 2013](#); [Maltby et al. 2016](#)). The VVDS EAF focuses on the VVDS-02h field which includes a total area of 0.61 deg $^2$  from the VVDS Deep survey and 512 arcmin $^2$  from the VVDS Ultra-Deep Survey ([Le Fèvre et al. 2005b](#); [Le Fevre et al. 2013](#)). The Great Observatories Origins Deep Survey North (GOODS-N; [Dickinson et al. 2003](#)) EAF is centered on the Hubble Deep Field which contains some of the deepest observations obtained by HST along with complementary observations from the ground and space. The All-Wavelength Extended Groth Strip International Survey (AEGIS; [Davis et al. 2007](#)) EAF is a multiwavelength survey field with low Galactic extinction and observations covering X-ray to radio wavelengths. AEGIS, CDFS, COSMOS, GOODS-N, and SXDS were all targeted as part of the Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey (CANDELS; [Grogan et al. 2011](#), 0.2 deg $^2$  in total) and have also been observed by JWST through the CEERS ([Bagley et al. 2023](#), 100 arcmin $^2$ ), JADES ([Eisenstein et al. 2023](#), 45 arcmin $^2$ ), PRIMER ([Dunlop et al. 2021](#), 378 arcmin $^2$ ), NGDEEP ([Bagley et al. 2024](#), 10 arcmin $^2$ ), and COSMOS-Web ([Casey et al. 2023](#), 0.54 deg $^2$ ) surveys.

## 3. Image data

The core data set of the DAWN Survey is deep space-based near-IR imaging in the *Euclid* EDFs and EAFs coupled with deep wide area *Spitzer*/IRAC data. Figure 3 shows an example of the image data in EDF-N. Figures A.1 and A.2 show the footprints of the UV-near-IR image data in the EDFs and EAFs, respectively. Table 2 provides limiting magnitudes for each band and field and Fig. 4 compares the depths with model spectra of galaxies at a range of redshifts. The rest of this section summarises the UV-mid-IR imaging observations and archival data that comprise the DAWN survey data set.

**Fig. 2.** A Mollweide projection of the Galactic foreground reddening –  $E(B - V)$  – on the celestial sphere from the Planck Collaboration: Aghanim et al. (2016) generated using the dustmaps Python package (Green 2018). The coordinates of each of the EAFs are indicated with black squares and the EDFs are highlighted with red stars. The solid blue line shows the ecliptic. The dotted blue lines indicate continuous viewing zone (CVZ) for the Euclid mission at  $\pm 87.5^\circ$ . The dot-dashed blue lines indicate ecliptic latitudes of  $\pm 54^\circ$  which is the expected boundary for the CVZ of the Roman space telescope (Foley et al. 2018). The dashed blue lines show the CVZ for JWST at  $\pm 85^\circ$ . The locations of the north and south ecliptic poles are indicated with the text NEP and SEP, respectively.

**Fig. 3.** An example of the image data quality from the DAWN MegaCam, HSC, IRAC programs in EDF-N. The top panel shows a *riz* colour image ( $2' \times 1'$ ) and the bottom row shows a zoom-in ( $20'' \times 20''$ ) of the highlighted region in each band of the DAWN data.

**Table 2.** Expected photometric depths for each of the fields covered by the DAWN survey. Unless noted below, depths are quoted as  $5\sigma$  limiting magnitudes (AB) in 2'' empty apertures.

Instrument / Band	EDF-N	EDF-F	EDF-S	COSMOS	SXDS	VVDS	AEGIS	GOODS-N
CFHT MegaCam / $u$	26.4	26.4	–	27.7	27.6	27.4	27.0	26.6

Notes: The *Spitzer* IRAC depths are average values measured from the image data from [Euclid Collaboration: Moneti et al. \(2022\)](#). *Euclid* depths are those expected for point sources by the end of the mission. Expected depths for Rubin data from [Foley et al. \(2018\)](#). The  $u$  band depths in SXDS and VVDS are from [Sawicki et al. \(2019\)](#) and depths in AEGIS are from [Gwyn \(2012\)](#). Subaru HSC and CFHT MegaCam depths for COSMOS are from [Weaver et al. \(2022\)](#). HSC depths for SXDS, VVDS, and AEGIS are the average over each field provided by [Aihara et al. \(2022\)](#).

### 3.1. *Euclid* Space Telescope observations

*Euclid* is a Korsch telescope with a 1.2 m mirror providing an effective collecting area of 1 m<sup>2</sup> ([Racca et al. 2016](#)) and two instruments: the *Euclid* visible imager (VIS; [Euclid Collaboration: Cropper et al. 2024](#)) has one broad visible band ( $I_{\text{E}}$ ) that covers 530–920 nm with a 0''.1 pixel scale; the Near-Infrared Spectrometer and Photometer (NISP; [Euclid Collaboration: Jahnke et al. 2024](#)) has three bands— $Y_{\text{E}}$ ,  $J_{\text{E}}$ , and  $H_{\text{E}}$ —covering 949.6–1212.3 nm, 1167.6–1567.0 nm, and 1521.5–2021.4 nm (respectively; [Euclid Collaboration: Schirmer et al. 2022](#)) with a pixel scale of 0''.3. VIS and NISP share a common field of view (FoV) of 0.53 deg<sup>2</sup>.

*Euclid* observations in the EDFs and EAFs are the primary motivation for the DAWN survey. The EDFs will each receive more than 40 visits with a final depth that is 2 mag deeper than the EWS. The EAFs will be covered by 1–4 *Euclid* FoVs with varying depths listed in Table 2.

### 3.2. *Spitzer*/IRAC observations

The *Spitzer* Space Telescope ([Werner et al. 2004](#)) Infrared Array Camera (IRAC; [Fazio et al. 2004](#)) is an imaging camera with four channels centered at 3.6, 4.5, 5.8, and 8.0  $\mu\text{m}$  (referred to as channels 1–4, respectively). Each channel has a 5''.2  $\times$  5''.2 FoV and a pixel scale of 1''.2.

The DAWN survey covers the Euclid Deep Fields with uniform *Spitzer*/IRAC imaging data at 3.6 and 4.5  $\mu\text{m}$  from two dedicated programs: the *Euclid*/WFIRST *Spitzer* Legacy Survey (SLS; [Capak et al. 2016](#)) that covers EDF-N and EDF-F; and a dedicated program to observe EDF-S ([Scarlata et al. 2019](#)). The

dedicated observations of the deep fields are supplemented by previous observations extracted from the archive. Observations of the EAFs are also compiled from the archive. All available data in the *Euclid* fields have been uniformly reduced and are described in detail in [Euclid Collaboration: Moneti et al. \(2022\)](#).

### 3.3. HSC optical observations

Hyper Suprime-Cam (HSC; [Miyazaki et al. 2018](#)) is a wide-field optical imaging camera at the prime focus of the 8.2 m Subaru telescope on Maunakea, Hawaii. With a 1''.5 diameter FOV and a 0''.168 pixel scale combined with the large collecting area of Subaru, HSC is an efficient instrument for deep surveys covering large areas of the sky.

#### 3.3.1. H20

The Hawaii Twenty deg<sup>2</sup> Survey (H20) covers two 10 deg<sup>2</sup> fields in the EDF-N and EDF-F with the Subaru HSC *griz* bands. Observations of each field were obtained using a seven point flower petal pattern with one central pointing surrounded by the remaining six spread over a circle with a radius of 1.1 deg (see Fig. A.1). Pointings are executed using a standard five point dither pattern with a throw of 120''. The target exposure times are 1.1, 2.5, 4.1, and 4.8 hours per pointing for the *griz* bands, respectively. As these observations are still ongoing, we defer a full accounting of the total number of exposures to a future publication describing the final DAWN data release.

**Fig. 4.** Top panel: Throughput curves for the photometric bands in the DAWN survey. Bottom panel: Photometric sensitivity limits for the EDFs at  $5\sigma$  with HSC, MegaCam, IRAC, *Euclid* and *Rubin* (see Tab. 2 for details). The solid coloured lines show throughputs and depths for EDF-N and EDF-F data from MegaCam, HSC, and IRAC. The dotted lines show the same for EDF-S coverage from Rubin (expected) and IRAC. *Euclid* NISP depths are shown with solid lines for all three fields since they are identical. The greyscale lines show FSFS (Conroy et al. 2010; Conroy & Gunn 2010) model spectra for galaxies at a range of redshifts (see legend). The model spectra are normalized to stellar masses of  $M^*$  galaxies at the respective redshift based on Weaver et al. (2023) and Stefanon et al. (2021) which have values of  $\log M_\star = 10.65, 10.24, 10.0, 9.5$  for redshifts  $z = 4, 6, 8, 10$ ; respectively. All models assume a Chabrier (2003) IMF, a delayed exponential star-formation history with  $\tau = 2$  Gyr, Solar metalicity, and Calzetti et al. (2000) dust with  $A_V = 0.2$ .

### 3.3.2. HSC-SSP

The Hyper Suprime-Cam Subaru Strategic Program (HSC-SSP; Aihara et al. 2018a) is a 330 night *grizy* band imaging survey of the extragalactic sky. HSC-SSP is a three tier ‘wedding cake’ survey composed of a  $1400 \text{ deg}^2$  wide layer, a  $26 \text{ deg}^2$  deep layer covering four fields, and a  $3.5 \text{ deg}^2$  ultra-deep layer covering COSMOS and SXDS. The extended COSMOS field and XMM-LSS, which encompasses SXDS and VVDS, were both observed as part of the deep survey. A single pointing centered on the AEGIS field was also observed to the depth of the wide survey for photo- $z$  calibration. The HSC-SSP observing strategy is discussed in Aihara et al. (2018a) and details of the data reduction are described in Bosch et al. (2018) and Aihara et al. (2018b, 2019, 2022).

### 3.3.3. Archival HSC data

Additional HSC observations were extracted from the archive where available. The HEROES (Taylor et al. 2023a) and AKARI-NEP (Oi et al. 2021) programs both obtained *grizy* observations in EDF-N. Various PI-led programs at the University of Hawaii provide supplementary data for the COSMOS (see Hu et al. 2016; Tanaka et al. 2017, for details) and GOODS-N fields.

### 3.4. MegaCam ultraviolet observations

MegaCam (Boulade et al. 2003) is an optical wide-field imaging camera mounted at the prime focus of the 3.6 m Canada France Hawaii Telescope (CFHT) on Maunakea, Hawaii. MegaCam has a  $1^\circ \times 1^\circ$  FoV and a pixel scale of  $0''.187$ . Over its lifetime, MegaCam has had two different *u* band filters: an original *u*\* filter that was discontinued in 2015 due to a red leak around 5000 Å and a new bluer *u* filter that has been in use since then (Sawicki et al. 2019).

The H20 team conducted a dedicated MegaCam *u* band imaging survey in EDF-N and EDF-F. Observations were obtained in a  $4 \times 4$  grid with a total area coverage of  $13.7 \text{ deg}^2$  in each field. In the EDF-N the ongoing 240-hour Deep Euclid U-band Survey (DEUS; PIs: Arnouts and Sawicki) will reach a depth of  $u = 27$  AB over  $\sim 10 \text{ deg}^2$  when completed; the DEUS data taken to date were shared by the DEUS team and used in making the *u* band mosaic for this field. The third Euclid Deep Field, EDF-S, has not been observed by MegaCam as it is not accessible from Maunakea. Planned observations of EDF-S by the Rubin observatory are discussed in Sect. 3.6.

A variety of programs provide MegaCam observations of the EAFs. The CFHT Large Area U-band Deep Survey (CLAUDS; Sawicki et al. 2019) performed dedicated observations using the *u* band in the COSMOS EAF. CLAUDS and the MegaCam Ultra-deep Survey: *u*\* band Imaging (MUSUBI; Wang et al. 2022) survey provide *u*\* band in XMM-LSS and COSMOS. Observations of the AEGIS EAF were obtained through the CFHT Legacy Survey (CFHTLS) (Gwyn 2012) in the *u*\* band with deep imaging in the CFHTLS-D3 field covering  $1 \text{ deg}^2$  and shallower data in the larger CFHTLS-W3 field covering  $7 \text{ deg}^2$ . Archival *u*\* band observations of GOODS-N (PI: L. Cowie) were extracted from the Canadian Astronomy Data Centre<sup>1</sup> (CADC) and reduced in the same manner as the data obtained by the H20 team.

### 3.5. *K* band observations

Ground-based observations in the *K* band provide supplementary data to fill in the wavelength gap between the *Euclid* NISP and *Spitzer*/IRAC data. Various programs have obtained *K* band data in the DAWN fields which we briefly summarise here and provide relevant citations where available. The UltraVISTA program (McCracken et al. 2012; Moneti et al. 2023) performed

<sup>1</sup> <http://www.cadc-ccda.hia-iha.nrc-cnrc.gc.ca/>

$K_s$  band observations of the COSMOS field using VIRCAM on the 4 m VISTA telescope at Cerro Paranal Observatory in Chile. Deep observations of  $20 \text{ deg}^2$  in EDF-S have been executed through the EDFS-Ks program (PI M. Nonino). The VIDEO (Jarvis et al. 2013) and VEILS (Hönig et al. 2017) surveys provide VIRCAM  $K_s$  data in XMM-LSS and CDFS. Additional  $K$  band observations from the UKIRT WFCAM also exist in SXDS from UKIDSS UDS (Lawrence et al. 2007).

### 3.6. Future Rubin observations

The Vera Rubin Observatory will perform repeated observations over  $18\,000 \text{ deg}^2$  to identify optical transients, study dark energy and dark matter, map the Milky Way, and characterise the population of Solar System objects through the 10 year Legacy Survey of Space and Time (LSST) survey (Ivezić et al. 2019). In addition to the main LSST program, Rubin will also observe a set of deep drilling fields with more frequent visits that will ultimately have much deeper data in the  $ugrizy$  bands than the main survey. Although the specific fields for the deep drilling survey have not been finalised at this time, they will likely include EDF-S, CDFS, COSMOS, and XMM-LSS. When available, these data will also be incorporated into the DAWN survey data set.

## 4. Spectroscopic follow-up

Spectroscopic follow-up is essential for precise redshift measurements, confirming objects of interest, and photo- $z$  calibration. Extensive spectroscopic surveys have already been conducted in the EAFs and will be summarised along with the DAWN catalogue release for those regions. This section provides a brief summary of ongoing spectroscopic follow-up in the EDFs.

### 4.1. Keck DEIMOS

The H20 team in Hawaii is conducting an ongoing spectroscopic survey of high-redshift galaxies in the EDF-N and EDF-F using the Deep Extragalactic Imaging Multi-Object Spectrograph (DEIMOS; Faber et al. 2003) on the 10 m Keck II telescope. The survey, so far, has focused on Lyman break galaxies (Steidel et al. 1996), also known as ‘dropout’ galaxies, selected using observed optical colours. Specifically, the program has focused on targeting Ly- $\alpha$  emission in overdensities of  $g$  band dropout galaxies at  $z \sim 4$ . See Murphree et al. (in prep.) for a full description of the colour selection criteria, overdensity calculations, and results.

High- $z$  galaxies in protoclusters are scientifically interesting and convenient observationally since a large number of galaxies can be observed in a single mask. These observations increase the number of high-redshift spec- $z$  measurements which have immediate impact in achieving the science goals of the DAWN survey and help to improve redshift estimates derived from the photometry.

### 4.2. Hobby-Eberly Telescope VIRUS IFU

The Texas-Euclid Survey for Lyman-Alpha (TESLA; Chávez Ortiz et al. 2023) is a spectroscopic survey targeting a  $10 \text{ deg}^2$  region in the center of EDF-N to generate a large sample ( $\sim 50\,000$ ) of Ly- $\alpha$  emitting galaxies (LAEs) at redshifts  $z = 2\text{--}3.5$  to explore how the physical properties of LAEs correlate with emerg-

ing Ly- $\alpha$  emission. The combination of these spectra with the deep H20 imaging allows redshift identification of TESLA-identified emission lines via spectral-energy distribution (SED) fitting, and subsequent analyses including the study of the physical properties of identified LAEs. TESLA spectroscopic data is acquired by the Visible Integral-field Replicable Unit Spectrograph (VIRUS; Hill et al. 2018) instrument atop the Hobby-Eberly Telescope. The VIRUS instrument has a wavelength coverage of  $3500\text{--}5500 \text{ Å}$  with a resolving power of  $R \sim 800$  making the VIRUS instrument optimal for detecting Ly- $\alpha$  emission from galaxies at redshifts  $z = 1.9\text{--}3.5$ , as well as O II-emitting galaxies at  $z < 0.5$ .

## 5. Science goals

The DAWN survey’s deep NIR imaging from *Euclid*, complemented by matched-depth UV to IR data, facilitates a wide array of scientific analyses. Sharing similarities in wavelength coverage and depth with prior surveys like CANDELS (Grogin et al. 2011) and COSMOS (Scoville 2007), DAWN stands out due to its significantly larger area coverage—thirty times that of the COSMOS field. This expanded scope opens up numerous new analytical possibilities. The primary scientific goals of the DAWN survey revolve around understanding galaxy formation and evolution, particularly in the high-redshift Universe. This section outlines the core objectives for the survey team, although the dataset will support a multitude of other research endeavors as well.

### 5.1. UV luminosity functions and mapping reionization

The Epoch of Reionisation (EoR) marks the period of ‘cosmic dawn’ in which light from the first galaxies ionised the predominately neutral intergalactic medium (IGM) allowing this radiation to stream freely throughout the Universe. Although observations of the cosmic microwave background (CMB) (Planck Collaboration: Aghanim et al. 2020), high- $z$  quasars (Bouwens et al. 2015; Robertson et al. 2015), and Ly- $\alpha$  emitting galaxies (Treu et al. 2012; Castellano et al. 2016; Kakiichi et al. 2016) constrain the end of the EoR to  $z \gtrsim 6$ , many important questions remain. When did the EoR begin? What is the relative contribution of rarer luminous galaxies versus more numerous faint galaxies to the budget of ionizing photons (e.g., Naidu et al. 2020; Hutter et al. 2021, 2023)? How does the reionization efficiency and the Ly- $\alpha$  escape fraction scale with the local density of galaxies?

One of the primary means of addressing these questions is through measurements of the rest-frame UV luminosity function (UVLF), which describes the co-moving volume density of galaxies as a function of their UV luminosity. Integrating the UVLF not only yields an estimate of the ionizing photon budget at a given redshift but also provides constraints on the unobscured cosmic star-formation rate density (see Madau & Dickinson 2014, for a review). Although deep surveys from HST and JWST have been and will continue to be instrumental for measuring the faint end of the UVLF (e.g., Oesch et al. 2018; Bouwens et al. 2021; Casey et al. 2023), larger survey areas are needed to definitively constrain the abundance of rare luminous sources on the bright end (see Fig. 5). Thanks to the combination of depth and area, the DAWN survey will robustly constrain the bright end of the UVLF to absolute magnitudes of  $M_{\text{UV}} \sim -24$  at  $z = 8\text{--}10$ , with sufficient depth to overlap at fainter magnitudes studied by HST (e.g., Bouwens et al. 2021) and JWST surveys (e.g., Casey et al. 2023; Donnan et al. 2023).

**Fig. 5.** Measurements of the ultraviolet luminosity function  $\phi$  at  $z = 8\text{--}10$  from the literature (Oesch et al. 2018; Bowler et al. 2020; Bouwens et al. 2021; Finkelstein & Bagley 2022; Adams et al. 2024; Donnan et al. 2023). The red and blue lines show extrapolations to the volume of the DAWN survey based on the best fitting Schechter and double power-law (DPL) functions, with the shaded regions showing associated Poisson uncertainties for the DAWN survey volume. Upper limits based on survey volume are indicated with the horizontal lines. The DAWN volume in each panel assumes an area of  $59 \text{ deg}^2$ , a redshift slice of  $\pm 0.5$  from the redshift bin center, and a Planck Collaboration: Aghanim et al. (2020)  $\Lambda\text{CDM}$  cosmology.

**Fig. 6.** Large-scale spatial distribution of the neutral hydrogen fraction at  $z \approx 7$  (neutral = black, white/gray=ionised) of the MHDEC (i.e.  $f_{\text{esc}}$  decreases with halo mass,  $M_h$ ) simulation presented in Hutter et al. (2023). The neutral hydrogen fraction shown here is averaged over 3 cells along the line of sight, where each cell has a comoving depth of  $312.5 h^{-1}\text{kpc}$  and the dimensionless Hubble constant  $h = 0.6777$ . The width and height of the box are given in comoving units and correspond to  $1^\circ$  at  $z = 7$ . Blue circles depict galaxies with UV luminosities of at least  $M_{\text{UV}} \geq -18$  and red stars the brightest galaxies in the simulation box with  $M_{\text{UV}} \geq -21$ .

Theoretical models predict that the most massive galaxies trace the large-scale structure (LSS) at high redshifts, with lower mass galaxies clustered around them (e.g., Mo & White 1996; Vogelsberger et al. 2014). They also predict that reionization proceeds more efficiently in these over-dense regions (e.g., Treu et al. 2012; Kakiuchi et al. 2016; Castellano et al. 2016). However, the details are still poorly understood (Mason & Gronke 2020; Naidu et al. 2020; Larson et al. 2022; Finkelstein & Bagley 2022). For example, what is the observational evidence for the

association between massive galaxies and LSS at high-redshifts (Hatfield et al. 2018; Harikane et al. 2022)?

Structures extending over  $0.25\text{--}1.0^\circ$  at  $z > 3$  are rare and the existing pre Euclid Deep Fields do not cover a sufficient contiguous area to capture them. Thus, a survey like DAWN is essential to probe the full range of reionization conditions in diverse environments, probing the same variety of structures in the real Universe as those found in cosmological simulations. According to the Millennium simulation (Springel et al. 2005), the DAWN survey will find  $\sim 125\text{--}250$  proto-structures, i.e., progenitors of modern day  $> 5 \times 10^{14} M_\odot$  clusters, and  $\sim 1250\text{--}2500$  regions with densities more than three times the mean density of the Universe at  $3 < z < 8$ . For example, the comoving volume of the DAWN survey at  $6.5 < z < 7.5$  will contain more than 100 DM halos with masses ( $M_{200}$ ) greater than  $10^{12} M_\odot$ ; with only  $5 \pm 2$  such massive halos expected in a survey like COSMOS (Despali et al. 2016). Figure 6 shows reionization bubbles around luminous galaxies at  $z \sim 7$  from the ASTREUS simulation framework (Hutter et al. 2023) in a similar area as the COSMOS field.

## 5.2. Galaxy stellar mass function

Among the most outstanding problems in astronomy today is understanding the nature and formation mechanism of the most massive galaxies ( $M_\star \gtrsim 3 \times 10^{10} M_\odot$ ) in the early Universe ( $z \gtrsim 2$ ). These rare systems are the best candidate progenitors of local early-type galaxies with  $M_\star \sim 10^{12} M_\odot$ . Some have been shown to be surprisingly mature, having no ongoing star-formation and well-formed discs in contrast with the hierarchical formation scenario (e.g., Toft et al. 2017). In a hierarchical model, the mapping between the galaxies and host dark matter haloes is controlled by the stellar mass-halo mass relation (SMHM). Different mappings generate different merger histories as well as different star formation histories (e.g. Grylls et al. 2019; Fu et al. 2022). The shape of the high- $z$  galaxy stellar mass function (SMF) is particularly valuable in this respect as it provides a benchmark for the evolution of galaxies at lower redshifts. For example, it has been shown that an abundance of massive galaxies at high redshift is more consistent with the nearly

**Fig. 7.** Stellar mass function,  $\Phi$ , measurements (hatched regions) from HST (S+21; Stefanon et al. 2021), the COSMOS field (W+22; Weaver et al. 2023), and JWST (N-C+23; Navarro-Carrera et al. 2024) in three redshift bins:  $z \sim 6$  (left), 7 (middle), and 8 (right). The dashed lines show extrapolations to higher masses for the DAWN survey volume (calculated in the same way as in Fig. 5) assuming the corresponding literature Schechter function fits, and the accompanying shaded regions show estimated uncertainties. Upper limits for empty bins for the respective survey are indicated with horizontal lines. Note that Due to the shallower IRAC data in EDF-S (see Table 2) the  $z \sim 8$  bin assumes a smaller effective area of  $39 \text{ deg}^2$ . The grey shaded regions indicate the theoretical upper limit of the SMF in each redshift bins based on the Despali et al. (2016) halo mass function assuming a fixed baryon fraction of 0.018 as in Weaver et al. (2023).

flat SFHs retrieved from galaxies at lower redshifts, which suggest that galaxies have grown much of their stellar mass at early epochs (Fu et al. 2022).

To understand the evolution of these systems one needs to address the following questions: How fast did massive galaxies build up their mass? Of those that have quenched, what mechanisms are responsible? What is the number density of different populations of galaxies at  $z = 3\text{--}8$ ? How does environment determine their existing and future mass?

Pursuing these questions with existing resources has already yielded surprises. While detailed follow-up of individual objects have clarified their unusual properties (e.g., Toft et al. 2017), statistical arguments as to their demographics – namely the galaxy stellar mass function (SMF) – have provided meaningful clues (Cole et al. 2001; Adams et al. 2021; McLeod et al. 2021; Stefanon et al. 2021; Weaver et al. 2022). Its shape and evolution with time is sensitive not only to star-formation histories and galaxy mergers, but also to the associated physical processes thought responsible for ceasing galaxy growth such as heating of gas by accreting central supermassive black holes or by supernovae explosions, gas removal by outflows, or by a host of other proposed scenarios (Dubois et al. 2013; Gabor & Davé 2015).

Massive galaxies are some of the best laboratories for testing galaxy formation theories. However, a comprehensive view of massive galaxy evolution cannot come from shallow large-area surveys like SDSS or GAMA, which are restricted to  $z < 0.5$ , nor from deep but narrow surveys like HUDF or CANDELS, which reach  $z \sim 9\text{--}10$  but only cover a total area of  $< 0.25 \text{ deg}^2$  (see Finkelstein 2016, for a review). Only a handful of high- $z$  detections have  $\sim 5 \times 10^{10} M_\odot$  in the small cosmic volume probed by HST, with no  $M_* > 10^{11} M_\odot$  candidates found at  $z > 5$ . Even the largest contiguous HST galaxy survey, COSMOS, has not detected massive galaxy candidates beyond  $z \sim 5$  (Weaver et al. 2023).

The DAWN survey will measure the shape and evolution of the SMF to  $z \sim 8$  with directly measured stellar masses from Spitzer/IRAC. Thanks to its large area coverage, the DAWN survey will reduce Poisson uncertainties by a factor of  $\sim 6$  compared to the Weaver et al. (2023) SMF from COSMOS and will pro-

vide the first robust constraints on the number density of ultra-massive galaxies ( $M_* > 10^{11} M_\odot$ ) at  $z = 6\text{--}8$  (see Fig. 7).

The large area of the DAWN survey will also improve measurements of the SMF for quiescent and star-forming galaxies as well as galaxies in different environments. Colour-colour selection criteria are often used to separate star-forming and quiescent galaxies (Williams et al. 2009; Arnouts et al. 2013; Ilbert et al. 2010; Davidzon et al. 2017; Gould et al. 2023). Weaver et al. (2023) only find 52 quiescent galaxies at  $z = 4.5\text{--}6.5$  in  $1.3 \text{ deg}^2$  of the COSMOS field which limited their analysis of the quiescent SMF to  $z < 4.5$ . Assuming a similar source density, the DAWN survey will detect  $\sim 2000$  quiescent galaxies at  $z = 4.5\text{--}6.5$  providing new constraints on the quiescent SMF in the early Universe. So far, measurements of the SMF as a function of environment have been limited to redshifts  $z < 3$  (Baldry et al. 2006; Peng et al. 2010; Papovich et al. 2018; Taylor et al. 2023b). The DAWN survey will not only expand this type of analysis to higher redshifts but will also be able to explore more extreme under- or over-dense environments thanks to the large contiguous areas of the EDFs.

### 5.3. Origins of large-scale structure at high-redshift

The current standard model for cosmology, Lambda Cold Dark Matter ( $\Lambda$ CDM), describes the growth of structure from density fluctuations in the primordial plasma to the LSS that we observe today. The  $\Lambda$ CDM model has been successful in describing the power spectra of galaxies and the CMB, but recent work has found tensions (Abdalla et al. 2022) in two of its key parameters:  $H_0$ , the Hubble rate at present day (e.g., Planck Collaboration: Aghanim et al. 2020; Riess et al. 2022), and  $\sigma_8$ , the amplitude of matter density fluctuations at present day (e.g., Planck Collaboration: Aghanim et al. 2020; Asgari et al. 2021; Heymans et al. 2021; Abbott et al. 2022; Amon et al. 2022). Both tensions arise between early (CMB-based) and late (galaxy-based) methods. While  $H_0$  has been measured across a wide range of redshifts,  $\sigma_8$  remains unconstrained at  $z \sim 3\text{--}7$ .

The DAWN data set will allow us to measure galaxy clustering at these high redshifts. As galaxies are a biased tracer of the underlying matter distribution, we will assume a linear galaxy

**Fig. 8.** The redshift evolution of linear galaxy bias. The early prediction from Tegmark & Peebles (1998) is shown in solid grey, and more recent models separated by stellar mass from Moster et al. (2010) are shown as dashed grey curves. High- $z$  measurements for dropout-selected samples from Beck et al. (2020) and Harikane et al. (2022) are shown in red and green, respectively. Low- $z$  measurements for two stellar masses from Ishikawa et al. (2020) are shown in blue and purple. The DAWN survey will allow us to constrain bias as a function of redshift and stellar mass in the shaded region.

bias  $b_{\text{gal}}$ . This galaxy bias is similarly unconstrained at  $z \sim 3-7$  and is degenerate with  $\sigma_8$  in two-point clustering measurements. At high redshift, we can break this degeneracy by cross-correlating galaxy clustering measurements with CMB lensing, or by combining galaxy bias measurements with higher order statistics (e.g. Repp & Szapudi 2022). Using HSC data from SSP and the University of Hawaii (SSP+UH; Tanaka et al. 2017) in the  $\sim 2 \text{ deg}^2$  COSMOS field, Beck et al. (2020) measured linear galaxy bias out to  $z \sim 6$  for  $g$ ,  $r$ , and  $i$  band dropouts. We will extend this analysis to the full  $59 \text{ deg}^2$  of the DAWN survey and use its robust photometric redshifts to select our galaxy samples, which should reduce the uncertainties by more than a factor of three. By cross-correlating our galaxy clustering measurements with CMB lensing (e.g. Planck Collaboration: Aghanim et al. 2020), we can constrain  $\sigma_8$  at high-redshift and compare our result with constraints from previous work (Murphree et al. in prep).

The total volume of the DAWN survey out to  $z \sim 7$  will be about  $3.8 \text{ Gpc}^3$ . This volume is large enough to include several extreme density fluctuations. By applying advanced statistical techniques such as sufficient statistics and indicator functions, we can double this volume and make robust estimates of cosmological parameters (Wolk et al. 2015; Repp & Szapudi 2022). The DAWN data set will allow us to constrain parameters (see Fig. 8) well beyond the  $z \sim 2.5$  forecasted for the photometric Euclid data set (Euclid Collaboration: Ilić et al. 2022).

## 6. Summary

The DAWN survey is a deep multiwavelength imaging survey that covers  $\sim 59 \text{ deg}^2$  in the Euclid Deep and Auxiliary fields. Deep space-based NIR image data from Euclid NISP and Spitzer/IRAC form the core of the DAWN data set

along with complementary ground-based UV-optical data from CFHT/MegaCam, Subaru/HSC, and future observations from the Vera Rubin Observatory. The DAWN survey aims to provide catalogues for the widest area collection of extragalactic deep fields with consistent data reduction. These data will be essential for photometric redshift calibration of the Euclid Wide Survey and will be the reference data set for extragalactic studies in the Euclid Deep and Auxiliary fields.

The DAWN survey is designed to address a variety of science goals including measuring the galaxy stellar mass function to  $z = 8$ , mapping reionization, studying the formation of large-scale structure, and characterising the first quenched galaxies. Data collection for the survey is ongoing with the ground-based component planned to be completed in the next few years and the *Euclid* observations scheduled to be completed by 2030. A companion paper, Euclid Collaboration: Zalesky et al. (2024), will provide the first DAWN data release of photometric catalogues and galaxy physical parameters in EDF-N and EDF-F. Future publications will present subsequent data releases of image data and catalogues that include all of the DAWN fields. The DAWN data have immediate value for studying galaxy formation and evolution in the high-redshift Universe and that legacy value will only increase as the survey is completed.

## Appendix A: Image data footprints

Figures A.1 and A.2 show footprints of the image data compiled by the DAWN survey in the Euclid Deep and Auxiliary fields.

**Fig. A.1.** Footprints of the DAWN survey image data in the Euclid Deep Fields. Note that the Rubin/LSST footprint in EDF-S shows the expected pointing pattern for the EDF-S Deep Drilling Field and may change once the survey begins (Ivezic et al. 2019).

**Fig. A.2.** Footprints of the DAWN survey image data in the EAFs. The coloured lines show the extent of the image data indicated in the legend. Note that the EAF footprints are approximations based on the *Euclid* survey plan. Updated footprints that to reflect the actual *Euclid* coverage in the EAFs will be provided along with subsequent DAWN data releases.
