The masses of the ground and isomeric states in $^{124,125}\text{Ag}$ have been measured using the phase-imaging ion-cyclotron-resonance technique at the JYFLTRAP double Penning trap mass spectrometer. The ground states of ^{124}Ag and ^{125}Ag were found to be 30(250) keV and 250(430) keV less bound but 36 and 110 times more precise than in the Atomic Mass Evaluation 2020, respectively. The excitation energy of $^{124}\text{Ag}^m$, $E_x = 188.2(25)$ keV, was determined for the first time. The new precise mass values have been utilised to study the evolution of nuclear structure via two-neutron separation energies. The impact on the astrophysical rapid neutron capture process has been investigated via neutron-capture reaction rate calculations. The precision measurements indicate a more linear trend in two-neutron separation energies and reduce the mass-related uncertainties for the neutron-capture rate of $^{124}\text{Ag}(n,\gamma)^{125}\text{Ag}$ by a factor of around 100. The new mass values also improve the mass of ^{123}Pd , previously measured using ^{124}Ag as a reference.

I. INTRODUCTION

The region of the doubly-magic ^{132}Sn isotope is interesting from the point of view of nuclear structure and nuclear astrophysics studies. The rapid neutron capture process (r process) [1], which is responsible for the production of about 50% of the elemental abundances above iron [2], leads to a strong production of isotopes around $A \approx 130$, creating a so-called second r-process peak. Sensitivity studies have shown that the nuclear properties close to ^{132}Sn have the highest impact on the r-process abundances for different astrophysical scenarios [3, 4].

Several low-lying isomers in the region of ^{132}Sn , especially for $N < 82$, have been observed [5]. Their presence allows for studies of shell evolution [6] or isomeric yield

ratios [7, 8]. The properties of metastable states are also relevant for astrophysical calculations [9, 10]. However, the isomerism results in an additional difficulty in extracting nuclear properties such as masses, half-lives and beta-delayed neutron emission probabilities P_{xn} , crucial from the r-process point of view, as they are often challenging to identify and resolve from the ground state. Consequently, the extracted results can often be averages of the values of each long-lived state, mixed in an unknown proportion. This phenomenon has been observed in the extraction of, for example, the P_{1n} values and half-lives of the states in ^{131}In [11–13] or masses of the states in the even-A rhodium and odd-A ruthenium isotopes [14–16].

One of the isotopic chains known to host several isomers is silver ($Z = 47$). While the masses of these isotopes were measured up to ^{126}Ag , the utilised techniques did not provide enough resolving power to separate ground states from the long-lived isomers. As a result, the isomer excitation energies of $^{120,124}\text{Ag}$ are currently not known [5] while in the case of ^{122}Ag one of the proposed isomers was determined to be non-existent [17]. In addition, the uncertainty of the mass value of ^{125}Ag was increased by the Atomic Mass Evaluation 2020 (AME20) evaluators by a factor 2.5 while the result for ^{126}Ag was rejected as it was deemed unreliable [18].

With the advent of the phase-imaging ion-cyclotron-resonance (PI-ICR) technique [19, 20] implemented at Penning traps, it has become possible to resolve isomeric

states separated as little as 10 keV [18, 21]. This method has been already successfully applied to other silver isotopes [17, 22, 23]. Extraction of pure ground-state masses allowed for comparison with different theoretical models which resulted in a better understanding of the underlying nuclear structure.

In this work, we report the first high-precision mass measurements of the long-living states in $^{124,125}\text{Ag}$ using the PI-ICR technique at the JYFLTRAP double Penning trap [24]. We also report the first measurement of the $^{124}\text{Ag}^m$ excitation energy. The results are compared with six density-functional-theory-based theoretical models, commonly used in predictions of nuclear structure and astrophysical calculations. Additionally, the impact of the measurements on the mass of ^{123}Pd and the astrophysical reaction rates are discussed.

II. EXPERIMENTAL METHODS

The experiment was performed at the Ion Guide Isotope Separator On-Line (IGISOL) facility in Jyväskylä, Finland [25, 26]. The radioactive ion beam was produced in proton-induced fission by impinging a 25-MeV proton beam into a 15 mg/cm²-thick ^{nat}U target. The fission products were stopped in a helium-filled gas cell operated at about 300 mbar. Then, the ions were guided out by the gas flow into a sextupole ion guide, accelerated by a 30 kV potential difference and purified with respect to their mass-over-charge ratio m/q by a 55° dipole magnet. Subsequently, the beam was injected into a helium-filled radio-frequency quadrupole cooler-buncher [27]. From there, the bunched beam was delivered to the JYFLTRAP double Penning trap mass spectrometer [24].

At JYFLTRAP, the ions were first cooled, purified and centered in the first (preparation) trap by using a mass-selective buffer-gas cooling technique [28]. From there, the singly-charged ions of interest were sent to the second (measurement) trap, where their cyclotron frequency $\nu_c = qB/(2\pi m)$ in the magnetic field B was determined using the PI-ICR technique [19, 20, 29, 30]. In this method, the phases of the radial eigenmotions after an accumulation time t_{acc} are determined using a position-sensitive microchannel-plate detector (2D MCP). Using the polar angles of the magnetron (α_-) and reduced cyclotron (α_+) phase spots on the 2D MCP, the cyclotron frequency is obtained as:

$$\nu_c = \frac{\alpha_c + 2\pi(n_- + n_+)}{2\pi t_{acc}}, \quad (1)$$

where n_- and n_+ denote the number of revolutions the ions perform in the magnetron and reduced cyclotron motions during t_{acc} , respectively, while $\alpha_c = \alpha_+ - \alpha_-$ is the difference between polar angles of the phase spots.

Typical PI-ICR images obtained in this work for ^{124}Ag and ^{125}Ag are shown on Fig. 1. A phase accumulation time of $t_{acc} = 130$ ms was applied for ^{124}Ag and

$t_{acc} = 116$ ms for ^{125}Ag . With these accumulation times the ground and isomeric states could be resolved from each other (see Fig. 1).

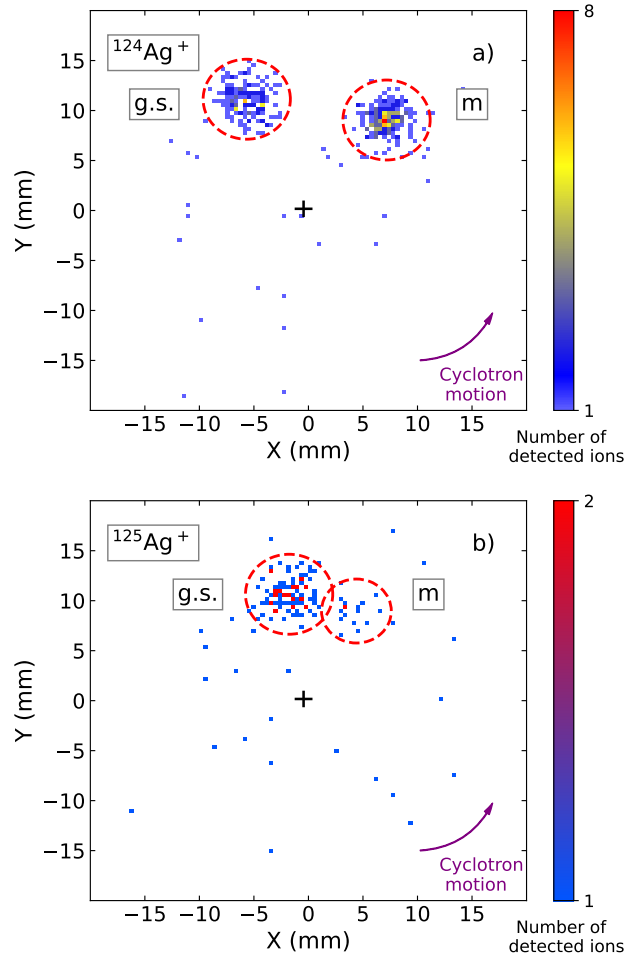

Figure 1. Projections of the ions' cyclotron motions onto the 2D MCP detector obtained with the PI-ICR technique for a) $^{124}\text{Ag}^+$ ions with the accumulation time $t_{acc} = 130$ ms and b) $^{125}\text{Ag}^+$ ions with the accumulation time of $t_{acc} = 116$ ms. The position of the center spots are indicated with the + symbol.

The magnetic field strength B was determined using $^{133}\text{Cs}^+$ ions ($\Delta_{lit.} = -88070.943(8)$ keV [31]) produced in an offline surface ion source [32]. The atomic mass M is determined from the cyclotron frequency ratio $r = \nu_{c,ref}/\nu_c$ between the reference ion and the ion of interest:

$$M = (M_{ref} - m_e)r + m_e, \quad (2)$$

where M_{ref} and m_e are the atomic mass of the reference ion and the electron mass, respectively. The ^{124}Ag isomer excitation energy E_x was extracted using the mass of $^{124}\text{Ag}^{gs}$ as a reference:

$$E_x = (r - 1)[M_{ref} - m_e]c^2, \quad (3)$$

with c being the speed of light in vacuum.

To account for the temporal fluctuations of the magnetic field, the measurements of the ion of interest and the reference ion were alternated. For the ^{124}Ag measurement, the ion of interest was collected for about seven minutes, followed by about two minutes of the reference ion. In case of the $^{124}\text{Ag}^m$ excitation energy both species were alternated every two minutes. For both states in ^{125}Ag , the silver ions were measured for about 25 minutes, followed by three minutes of ^{133}Cs . The electron binding energies are here negligible and were therefore not taken into account in the calculations. The systematic uncertainties, as reported in Ref. [30], were included to the final uncertainty of the cyclotron frequency ratios r . In the case of ^{124}Ag , the count-rate class analysis [33] up to three ions per bunch was also performed to take into account ion-ion interactions in the measurement trap.

III. RESULTS

The results of this work are summarized in Table I and compared to the literature values given in the Atomic Mass Evaluation 2020 (AME20) [31] for the ground states and NUBASE20 for the isomers [5]. All mass-excess values $\Delta = (M - Au)c^2$, where A is the atomic mass number and u is the atomic mass unit, were determined with a precision better than 8 keV.

The measured mass-excess value of ^{124}Ag , $\Delta = -66199.6(69)$ keV, agrees with the ISOLTRAP result ($\Delta_{\text{lit.}} = -66200(250)$ keV [36]), however, it is 36 times more precise. It should be noted that the AME20 value ($\Delta_{\text{lit.}} = -66230(250)$ keV [31]) is shifted by 30 keV with respect to the ISOLTRAP value to correct for the presence of the isomeric state which was estimated at $50(50)\#$ keV [18]. The isomer excitation energy, $E_x = 188.2(25)$ keV, was measured for the first time and it is $138(50)\#$ keV larger than the NUBASE20 extrapolation [5].

The order of the two long-lived states in ^{124}Ag is not established. The ratio of the number of measured ions of the isomer to the ground state is about 1.5 : 1 and the total length of the measurement cycle was about 400 ms. If the ground state is assumed to be the low-spin longer-lived state and the isomer high-spin and shorter lived, this ratio is about 2.5 : 1 at the moment of production, while for the reversed order, the ratio becomes about 1 : 1. The fact fission favors production of high-spin states [7, 8, 37] and that in less exotic odd-odd Ag isotopes isomers are the high-spin states [5, 17] suggests the order proposed in the literature [5] is correct.

The measured mass of ^{125}Ag , $\Delta = -64270.4(40)$ keV, agrees with the AME20 value of $\Delta_{\text{lit.}} = -64520(430)$ keV [31], however, it is 110 times more precise. It should be noted that the AME20 value originates from an Experimental Storage Ring (ESR) measurement at GSI [38] and the uncertainties were inflated by the evaluators by a factor 2.5, from 173 to 430 keV [18]. In this work, the low-lying isomer was resolved from the ground state

for the first time, see Fig. 1b. Its excitation energy, $E_x = 109.0(89)$ keV, is $11.9(89)$ keV (1.3σ) larger than the precise value known from the β -decay study [39]. The observed ground-state-to-isomer ratio of the number of ions at the 2D MCP after the phase accumulation time (about 19 : 1) supports the literature assignment of the ground state as the high-spin state [5].

IV. DISCUSSION

Differences in the mass trends are associated with changes of the ground-state nuclear structure, such as shell closures or an onset of deformation [40–42]. The effect of the mass values reported in this work on these mass trends in the neutron-rich silver isotopes was studied by analyzing the two-neutron separation energies S_{2n} defined as:

$$S_{2n}(Z, N) = \Delta(Z, N - 2) - \Delta(Z, N) + 2\Delta_n, \quad (4)$$

where $\Delta(Z, N)$ is the mass excess of a nucleus with given proton (Z) and neutron (N) numbers and Δ_n is the mass excess of a free neutron. In addition, the two-neutron shell-gap energies δ_{2n} :

$$\delta_{2n}(Z, N) = S_{2n}(Z, N) - S_{2n}(Z, N + 2), \quad (5)$$

were also determined.

Figure 2 shows the two-neutron separation energies and shell-gap energies for Pd ($Z=46$) and Ag ($Z=47$) isotopic chains based on this work and recent JYFLTRAP publications [17, 22]. For comparison, AME20 values are also plotted.

While the refined S_{2n} values from this work agree with the AME20 evaluation [31] within one standard deviation, the deviations from a linear trend are largely removed with the new mass values, see Fig. 2a. This is more visible in the δ_{2n} values, which remain almost constant at around 530-590 keV for $73 \leq N \leq 76$ (see Fig. 2b). We note that our mass values shift the S_{2n} trend away from the point based on the mass of ^{126}Ag reported in Ref. [38], which providing an additional support for the AME20 evaluators decision to exclude them.

The experimental S_{2n} values were compared to six mass models commonly used for interpreting nuclear structure and for astrophysical applications, see e.g. Refs. [4, 44, 45]. Five of them are Density Functional Theory based: UNEDF0 [46], UNEDF1 [47], BSkG1 [45], BSkG2 [48] and BSkG3 [49] while the last one is the FRDM2012 model which is based on the combination of a finite-range liquid-drop model with a folded-Yukawa single-particle potential [50]. The results of this comparison are presented in Fig. 3.

While all the models from the BSkG* family overestimate the S_{2n} values for $A \geq 120$ by about 200-300 keV, they very well reproduce the slope of the curve. A similar behavior can be observed for the UNEDF0 model, however, the discrepancy between the theory and the experiment is larger and it reaches up to about 500 keV. On

Table I. The mass measurement results of the nuclides studied in this work together with their spin-parities J^π and half-lives $T_{1/2}$ from literature [34, 35]. Columns Ref. and $r = \nu_{c,\text{ref}}/\nu_c$ show the reference ions and the measured cyclotron frequency ratios, respectively. Corresponding mass-excess values Δ and isomer excitation energies E_x are tabulated and compared to the literature values $\Delta_{\text{lit.}}$ and $E_{x,\text{lit.}}$ from Refs. [5, 31]. The differences between this work and the literature $\text{Diff.} = \Delta - \Delta_{\text{lit.}}$ are also added. # indicates an extrapolated value.

Nuclide	J^π	$T_{1/2}$ (ms)	Ref.	$r = \nu_{c,\text{ref}}/\nu_c$	Δ (keV)	$\Delta_{\text{lit.}}$ (keV)	E_x (keV)	$E_{x,\text{lit.}}$ (keV)	Diff. (keV)
^{124}Ag	(2^-)	191(28)	^{133}Cs	0.932 459 075(56)	-66 199.6(69)	-66 230(250)			30(250)

^{125}Ag	$(9/2^+)$	176(3)	^{133}Cs	0.939 998 835(33)	-64 270.4(40)	-64 520(430)			250(430)
$^{125}\text{Ag}^m$	$(1/2^-)$	159(21)	^{133}Cs	0.939 999 716(64)	-64 161.4(79)	-64 420(430)	109.0(89)	97.1(5)	259(430)

Table II. Mass excesses of the $N = 77$ isotones from Ref. [43] compared to the values from AME20/NUBASE20 [5, 31] and the recalculated values based on the new mass of $^{124}\text{Ag}^{gs}$ from this work. # indicates an extrapolated value.

Isotope	J^π	AME20 [31] (keV)	Ref. [43] (keV)	This work (keV)
^{126}In	3^+	-77809(4)		
$^{126}\text{In}^m$	8^-	-77719(5)	-77707(266)	-77677(90)
^{125}Cd	$3/2^+$	-73348.1(29)		
$^{125}\text{Cd}^m$	$11/2^-$	-73162(3)	-73237(318)	-73207(196)
^{123}Pd	$3/2^+$ #	-60430(790)		
$^{123}\text{Pd}^m$	$11/2^-$ #	-60330(790)#	-60282(267)	-60253(95)

the other hand, the slope predicted by the FRDM2012 and UNEDF1 models is less steep, as can be clearly seen in Fig. 2b. Nevertheless, all the used models work relatively well and indicate similar trends of the two-neutron separation energies for more exotic species.

We note that the UNEDF1 model has been already unsuccessfully used to reproduce excitation energies of the low-lying isomers in the odd- A $^{103-123}\text{Ag}$ isotopes, see Ref. [22]. The discrepancy between the theory and the experiment was reduced after using a modified UNEDF1_{SO} functional with an increased spin-orbit strength [51]. This observation, combined with the fact that the UNEDF1 model does not correctly reproduce the two-neutron separation energy trend, supports the need of further improvements in the model.

With the new precise mass value of ^{124}Ag , the mass of ^{123}Pd reported in Ref. [43] can be re-evaluated. However, both ^{124}Ag and ^{123}Pd are known to have two long-lived states [5, 39] and it is unclear which ones were measured in Ref. [43], see Tab. II. Since the production method of ^{124}Ag from Ref. [52] is identical to Ref. [43] and the reported half-life of ^{124}Ag , $T_{1/2} = 205(17)$ ms [52], is consistent with the ground state ($T_{1/2} = 191(28)$ ms [35]) and not with the isomer ($T_{1/2} = 144(20)$ ms [35]), the recalculation of the ^{123}Pd mass was performed using the mass-excess value of the ^{124}Ag ground state.

In the case of ^{126}In and ^{125}Cd , the updated mass values from Ref. [43] agree with AME20. However, the large uncertainties do not allow for unambiguous determination which long-lived state was measured. The refined mass

value of ^{123}Pd together with the new mass of ^{119}Pd reported in Ref. [17] lead to a more linear trend in the S_{2n} values for the Pd isotopes, see Fig. 2. We note that also the δ_{2n} curves for both isotopic chains, silver and palladium, are now following a similar trend. We also note that the updated mass value of ^{123}Pd shifts the S_{2n} trend even further way from the point based on the ^{124}Pd mass reported in Ref. [38] which supports its rejection from AME20 [18].

The new mass values reported in this work result in a two orders of magnitude more precise neutron-capture Q -value for ^{124}Ag , $Q_{n,\gamma} = 6142(8)$ keV, with respect to the AME20 value of $Q_{n,\gamma} = 6360(500)$ keV [31]. Its impact on the astrophysical neutron-capture reaction rate of $^{124}\text{Ag}(n,\gamma)^{125}\text{Ag}$ was studied using the TALYS 1.96 code [53]. A comparison between the results obtained with both mass values from either this work (JYFLTRAP) or AME20 [31], as well as the ^{124}Ag value from AME20 combined with the mass of ^{125}Ag from the ESR measurement with the original 173 keV uncertainty [38], is presented in Fig. 4. The results are presented for $T \leq 10$ GK which is relevant for neutron captures in the r process, see e.g. Refs. [2, 54]. While the reaction rate calculated with the masses from this work agree with both AME20 and ESR values, it is about 20% lower and 100 times more precise. We have almost entirely removed the mass-related uncertainties in this reaction rate, which were up to around a factor of two with the AME20 values.

The $A \approx 120$ region shows very large variations in the calculated r-process abundances depending on the selected astrophysical conditions [55, 56]. Moreover, the weak r process in neutrino-driven winds of core-collapse supernovae can produce lighter r-process elements ($A \leq 130$) [57], whereas the main r process in dynamic ejecta of neutron-star mergers create dominantly heavier elements ($A \geq 120$) [58]. Thus, both weak and main r processes contribute to the abundances in the $A \approx 120$ region and, therefore, the astrophysical conditions producing these nuclei vary significantly [58]. We note that the solar-system r-process abundance uncertainties are also not negligible in this mass region [2, 59].

Since the astrophysical conditions and their individual contributions to the observed solar-system r-process abundances in this mass region are not well defined, comparisons of the solar abundances to the abundances

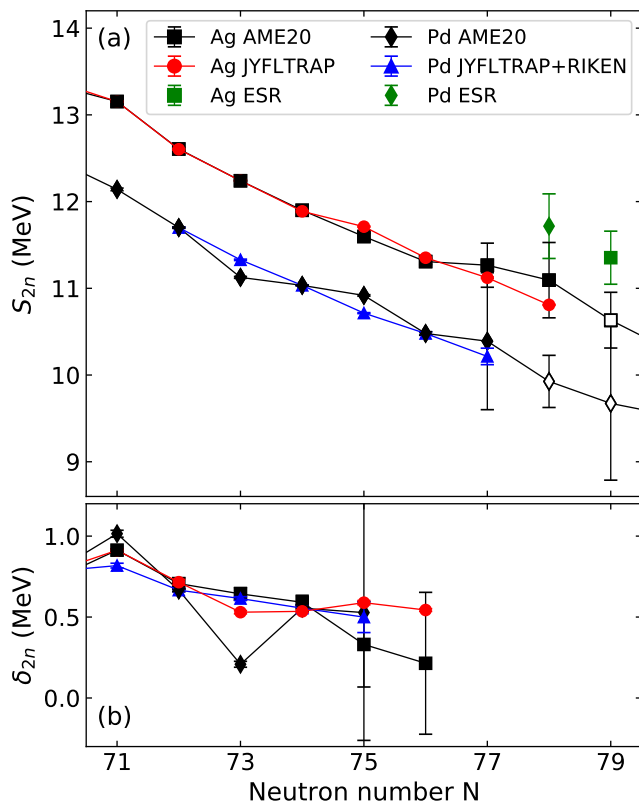

Figure 2. Two-neutron separation energies S_{2n} (panel a) and two-neutron shell-gap energies δ_{2n} (panel b) for the neutron-rich Ag and Pd isotopes. The black squares and diamonds are calculated using the AME20 values [31], the red circles are taken from this work for $^{124,125}\text{Ag}$, from Ref. [22] for $^{117,119,121,123}\text{Ag}$ and from Ref. [17] for ^{122}Ag , while the blue triangles are obtained using the recalculated mass of ^{123}Pd [43] based on the mass of ^{124}Ag from this work and the mass of ^{119}Pd from Ref. [17]. The green square and diamond indicates the S_{2n} values calculated using the ESR mass values of ^{126}Ag and ^{124}Pd , respectively, reported in Ref. [38] and rejected by the AME20 evaluators [18]. Empty squares indicate the values based on the AME20 extrapolations [31].

or abundance ratios $Y_A(125)/Y_A(124)$ calculated with the newly determined reaction rates are not meaningful. Nevertheless, the new masses will help to pin down the abundances for cases where the astrophysical conditions are well constrained, or if the abundances or abundance ratios can be measured from an astrophysical site.

V. SUMMARY AND OUTLOOK

The ground-state masses of neutron-rich silver isotopes ^{124}Ag and ^{125}Ag were measured with high precision, reducing their mass uncertainties by a factor of 36 and 110, respectively, as compared to AME20. The isomeric states were resolved and their excitation energies determined via mass measurements. The excitation energy of

Figure 3. Comparison of the experimental results for the Ag ($Z = 47$) isotopes to mass models BSkG1 [45], BSkG2 [48], BSkG3 [49], FRDM2012 [50], UNEDF0 [46], and UNEDF1 [47]. (a) Two-neutron separation energies S_{2n} and (b) differences ΔS_{2n} between two-neutron separation energies from this work and other JYFLTRAP measurements (S_{2n}^{JYFLTRAP}) [17, 22] and theoretical models or AME20 (S_{2n}^*), defined as $\Delta S_{2n} = S_{2n}^{\text{JYFLTRAP}} - S_{2n}^*$.

the ^{124}Ag isomer, $E_x = 188.2(25)$ keV, was reported for the first time in this work. The observed production ratios of long-lived states in both isotopes support the state ordering proposed in the literature.

The updated masses, while in agreement with the previous AME20 values [31], resulted in much more linear trends in two-neutron separation energies. The $^{124}\text{Ag}(n, \gamma)^{125}\text{Ag}$ reaction rate calculations performed using the TALYS 1.96 code [53] indicated about 20% decrease of reaction rate with two orders of magnitude reduction in mass-related uncertainties.

With the precise mass value of ^{124}Ag from this work, the mass of ^{123}Pd obtained using ^{124}Ag as a reference in Ref. [43], was redetermined. The new, more precise value for ^{123}Pd , together with the recent mass measurements of less-exotic palladium isotopes [17], resulted in a more linear S_{2n} trend for these isotopes, similar to the one observed in silver isotopes.

A comparison of two-neutron separation energies with

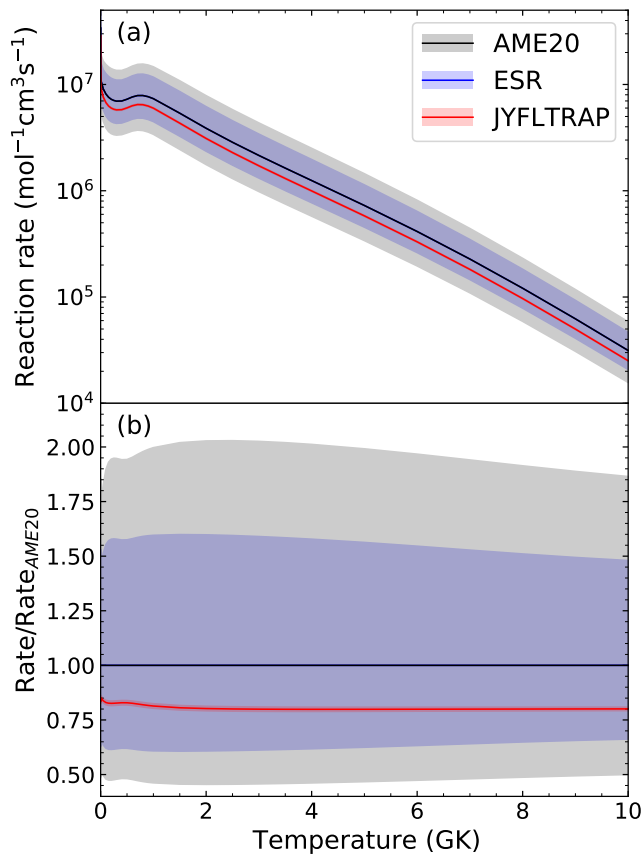

Figure 4. (a) Astrophysical reaction rates calculated with the TALYS 1.96 code [53] for the reaction $^{124}\text{Ag}(n, \gamma)^{125}\text{Ag}$ using the mass values from this work (JYFLTRAP, red), AME20 (black) [31] and the ^{125}Ag mass value from ESR (blue) [38]. (b) Reaction rate ratios with respect to the AME20 rate.

six commonly used mass models showed an overall good agreement between the experiment and theory. Although the S_{2n} values predicted by the mass models agree rather well within the known region, they show a larger scatter toward the shell closure at $N = 82$. To better understand the evolution of nuclear structure and the strength of the shell closure, studies of more exotic silver isotopes up to and crossing the $N = 82$ magic number are needed. This is an experimental challenge as the half-lives approach the limits of Penning-trap measurements while other methods might not provide high-enough resolving power to separate known long-lived isomeric states [5]. New experimental techniques might therefore be needed.
