Re: PROGRAMME AFTER SHUT-DOWN

For the period that starts after the April-May shut-down of the PS, our group intends to continue to exploit the slow extracted proton beam (e₂) in the East Hall.

Presently, our programme is the following.

- a) To complete in a relatively short time the large angle elastic scattering measurements already started before the shut-down.
- b) To measure the bremsstrahlung spectrum produced by protons scattered nearly elastically at about 90° in the centre of mass.
- c) To measure μ meson pair production in nucleon-nucleon collisions.

Experiment a) is not discussed here, as it has already been approved. The aim of experiment b) is to measure the momenta and the angles of emission of the two protons produced in the reaction

$$p + p \rightarrow p_R + p_L + \gamma$$
,

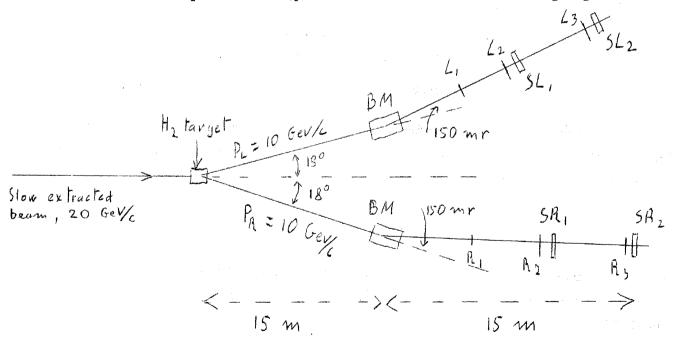

and reconstruct the spectrum of the γ -rays when the four-momentum transfer of both protons is near to the maximum. The primary proton energy will be about 20 GeV.

We believe that with the system of counters and of sonic spark chambers described below, the energy of the photon will be determined within 10 - 20 MeV, and its mass within about 50 MeV (thus excluding π -meson production) up to total γ -ray energies of 200 - 300 MeV.

Measurements¹) of proton-proton bremsstrahlung have so far been confined to energies below the meson production threshold (\leq 150 MeV). Their motivation was to obtain information on the nucleon-nucleon potential.

The method of observation proposed here, namely the accurate measurement of final state momentum vectors and deduction of the energy and mass associated with the momentum unbalance has not before been employed for bremsstrahlung experiments, but can clearly be used for the study of any charged particle "elastic" collision process at any energy and for a large range of momentum transfer. The amplitude for the emission of soft photons can be directly related²) to the matrix element of the strong interaction scattering process and data on the radiative "elastic" scattering could give information, for example, on the phase of the strong interaction scattering amplitude³).

The experimental layout is sketched in the following figure.

¹⁾ B. Gottschalk et al, Physics Letters 16, 294 (1965).
R.E. Warner, Physics Letters 18, 289 (1965).

²⁾ F.E. Low, Phys. Rev. 110, 974 (1958).

³⁾ H. Feshback and D.R. Jennie, Nuc. Phys. 37, 150 (1962).

A coincidence between the two counter telescopes L_1 L_2 L_3 and R_1 R_2 R_3 detects the two nearly dastic (as well as the truly elastic) protons \hat{p}_L and p_R , and triggers the four sonic spark chambers SL_1 SL_2 SR_1 SR_2 that locate the two trajectories within about 0.3 mm. At the distances and the momenta indicated in the Figure this uncertainty in track location gives rise to errors of about 10 MeV/c in the determination of the momenta and of about 0.2 milliradians in the determination of the directions. The energy and the mass of the unseen γ -ray can thus be measured with the precisions stated above.

The data from the sonic chambers, of dimensions around 40×50 cm² and similar to those already used last year by our group in the small angle scattering measurements, will be recorded on magnetic tape. The complete analysis of the events will be made off-line by the CERN CDC 6600 computer. Tests made utilizing the present facilities give us assurance that the background on the spark chambers will not be prohibitive.

The low rate of elastic plus inelastic events expected (about 30 per hour) make it advisable to monitor the behaviour of the sonic spark chambers and of the trigger system by means of an on-line analogue computer with display on a cathode-ray tube.

We expect to have chambers, analogue computer and analysis programmes ready by May 1966, and to be in position of taking data soon after the shut-down.

The hydrogen target and the shielding around it presently in use for the large angle scattering experiment will remain practically unchanged for the bremsstrahlung experiment. Four 2 m bending magnets (two on each side) will be needed and no quadrupoles.

The total running time necessary is expected to be about 20 days. However, maximum efficiency will be attained if this time is broken up in several periods of a few days each, over a span of several months.

As for experiment c), our plans are not yet definitive. A preliminary discussion about its feasibility is contained in the annexed paper by G. Matthiae and A. Silverman.

It seems that a preliminary, reduced version of it, that could give valuable information about background rates, could be realized very soon inside the shielding already built around the present hydrogen target of beam e_2 , and that these tests could be made while experiment $\ b$) is running.

AN EXPERIMENT TO MEASURE μ-PAIR PRODUCTION IN NUCLEON-NUCLEON COLLISIONS

G. Matthiae and A. Silverman

Yamaguchi (1), KAoll (2) and Chilton et al. (3), following a suggestion of Van Hove, have calculated the relation between W-meson and μ-pair production in nucleon-nucleon collisions, Assuming the validity of the CVC theory, Thus, the observation of μ-pairs, a simpler experimental problem, would be a very useful preliminary to a search for W-production. In this note we propose an experimental arrangement for observing μ-pairs with 2 GeV < Μμας 4 GeV. Μμα = invariant mass of the muon-pair. We consider this as a first step in a search for the W-meson and have designed the apparatus to be useful in such a search, but we do not wish to minimize the intrinsic interest in the μ-pair production, since it is related to the electromagnetic structure of the nucleon for large time-like momentum transfers.

A section through the experimental arrangement is shown in Fig. 1. The apparatus consists of a conical iron shield with apex at the target covering the angular range 20° - 30° . Embedded in the iron are scintillation counters to measure the ranges (2 GeV/c < P $_{\mu}$ < 5 GeV/c), and angles of the two muons observed in coincidence. The mass of the virtual Y-ray, Maxis to be measured to an accuracy of 15% with reasonably constant efficiency for 2 GeV < Max < 4 GeV. (See below for details).

Counting Rate

We have considered two equally unreliable methods for estimating the μ -pair cross section. (a) We relate the μ -pair production to the

⁽²⁾ N. H. Kmoll: Private communication.

⁽³⁾ F. Chilton, A. M. Saperstein and C. Shraumer (to be published).
Revised November 1965.

production of pion-systems of the same invariant mass, and make use of the rather sparse experimental information available for the pion production. (b) We use published W-meson cross sections and compute the μ -pair from References 1 - 3.

Fig. 2 shows schematically the situation in which a μ -pair (2a) and a π -pair (2b) of the same mass are produced. We assume that for every μ -pair final state, there is a corresponding π -pair final state for which $\max = M_{\pi\pi}$ and $\max = K_{\pi\pi}$. Then, one might guess that the ratio of the cross sections for these two equivalent configurations is something like

$$\frac{\int_{\mu u}}{\int_{\pi \pi}} \left(\frac{M_{\mu u} = M_{\pi \pi}}{E_{\mu u} = E_{\pi \pi}} \right) \simeq \frac{\lambda^2 f_8^2}{f_5^2}$$

where $\angle^2 = e^4 = (1/137)^2$ as usual

 f_{χ}^{2} = electromagnetic form factor for $\psi^{2} = M\mu u^{2}$

 $f(^2 = form factor for the strong interactions.$

Of course, nothing is known of either f_{ζ}^2 or f_{ζ}^2 .

We shall assume $\int \frac{\chi^2}{\sqrt{s^2}} = 1$. This is probably a better assumption

than the usual one that they are separately equal to unity. In fact, since the electromagnetic form factors have their origin in the strong interactions, the assumption may not be completely outragepus. We observe, rather diffidently, that these assumptions give approximately the same branching ratio for the decay of the S^0 or W^0 into Z_M 's as do more reliable computations. To obtain information of S_M we use two sources - the Aachen - Berlin - CERN collaboration (4) (8 GeV πp collisions) and Cavendish - Hamburg collaboration (5) (10 GeV pp collisions). Each of these gives $\frac{dS_M}{dm_{\pi\pi}} \simeq \frac{dS_M}{dm_{\pi\pi}} \simeq \frac{dS_$

⁽⁴⁾ Aachen - Berlin - CERN collaboration. Phys. Lett. 12, 356 (1965)

⁽⁵⁾ Cavendish - Hamburg collaboration. Oxford Conference, Sept. 1965.

The second method of estimating down follows Ref. 1 - 3
from which:

$$\frac{d\sigma}{dm_{\mu\nu}} = \frac{e^4 2^3}{G 3\sqrt{2}} \frac{1}{M_W^3} \sigma_W \left(M_W = M_{\mu\nu}\right)$$

$$G = 10^{-5} Mp^{-2}$$

For \mathcal{C}_0 = 20 GeV, and \mathcal{M}_{ω} = 3 GeV, Chilton gives us \mathcal{C}_{ω} = 7 x 10⁻³² cm²

from which
$$\frac{\sqrt{5}}{\sqrt{3}m\mu\mu} = \frac{10^{-9} \frac{3}{3}}{10^{-5} \frac{7}{3}\sqrt{2}} \times 10^{-32}$$

$$= 5 \times 10^{-32} \text{ cm}^2/\text{GeV}.$$

We shall use the smaller estimate of the first method in calculating expected rates since there is good reason to believe that Chilton's cross section is too large. The use of $\frac{d\sigma}{dm_{pro}} = 5 \times 10^{-33} \text{ cm}^2/\text{GeV}$ is equivalent to inserting a form factor of $F^2 = 0.1$ in Chilton's result.

In order to calculate the expected counting rates we need to know not only but the angular and momentum distribution of the virtual 8-rays. We have calculated the efficiency of the detector shown in Fig. 1 for three different assumptions about these 8-ray distributions. (a) They are identical to the distribution computed by Chilton for the Ws. (b) They are produced forward and backward in the CM suptate with a phase space distribution in momentum. (c) They have the same distribution as XMM real particles produced in p-p collisions - which we call the "Cocconi" assumption (6). In the latter case, the distribution is given by

The results of these three calculations are shown in Table 1. The detection efficiencies are shown for various angular intervals as a function of $M_{\mu\nu}$. We shall assume that $E=1.0\times 10^{-2}$ for the interval $2~{\rm GeV} < M_{\mu\nu} < 4~{\rm GeV}$. This is almost certainly a rather pessimistic assumption. These efficiencies are calculated assuming the difference in the azimuthal angles of the two μ 's lies in the region $150^{\circ} < \Delta \phi < 210^{\circ}$.

We can calculate the expected counting rate from $N_{CR} = N_T N_P \frac{d\sigma}{dm_{\mu\nu}} \left(\Delta m_{\mu\nu}\right) \mathcal{E}$ We take $N_P = 10''$ protons $N_T = 4 \times 10^{23}$ protons/cm² then $N_{CR} = (4 \times 10^{23})(10'')$ 5 x 10^{-33} . 2. 10^{-2} = 4 counts/10'' protons.

Background

(a) Accidental rate

We assume the "Cocconi" formula for π -production $\frac{d^2G}{ds_{1\pi}d\rho_{\pi}} = \frac{N\pi}{2\pi} \frac{\rho_{\pi}^2}{\rho_{1}^2\rho_{1}} e^{-\rho_{\pi}/\rho_{1}} e^{-\rho_{\pi}/\rho_$

For $l_0 = 20 \text{ GeV}$ $l_1 = 2$ $l_2 = 0.18 \text{ GeV/c}$ $l_1 = 2.8 \text{ GeV/c}$.

From this we calculate the differential cross section for the decay much $\frac{d^2 G}{d \pi \mu d R \mu}$. The results for a decay path of 1 cm are shown in Fig. 3. We integrate these curves and average over angles to find the mean differential cross section for $\frac{R}{\mu} > 2 \text{ GeV/c}$.

for a decay path of one centimetre. We will assume a 20 cm decay path which allows 5 cm free flight before the much absorber. Then, the counting rate in each telescope of the detector is

$$N = N_{7} N_{p} \left(\frac{d6}{d5^{2}}\right) \left(d5\right)$$

$$\left(\mu > 2 \text{ GeV}\right)$$

$$= \left(4 \times 10^{23}\right) \left(10^{11}\right) \left(3 \times 10^{-32}\right) \left(20\right) \left(.037\right)$$

$$\sim 10^{3}$$

ఎ

The number of π 's that survive the absorber without interacting is less than this by a factor of 10 or more. We double this number to take into account muons from K-meson decay, so that the counting rate for each telescope is

$$N = 2 \times 10^3$$
 counts/10" protons. Then,

the accidental rate between any pair of telescopes is given by

$$(N_{Acc})_{pair} = (3 \times 10^{-9}) (2 \times 10^{3}) (2 \times 10^{3}) (10)$$

= 8 × 10⁻²

Here, we have assumed $2\Upsilon = 3\,\eta$ s and the pulse duration = 150 msec. Since we insist that the difference in azimuth between the two μ 's be in the region $150^{\circ} < \Delta \, \varphi < 210^{\circ}$, and each telescope subtends 30° in azimuth, there are six possible pairs. Thus, the total accidental rate (Nacc) Total = (6)(8) x 10^{-2} = 0.5 counts/10" protons.

Background - (b) Detection of $\pi\!\!\!/\!\!\!$ as $\mu\!\!\!-\!\!\!\!\!$ pairs according to our earlier assumption

$$\frac{\left(\frac{d\sigma_{\mu\mu}}{dm_{\mu\nu}}\right)}{\left(\frac{d\sigma_{\mu\mu}}{dm_{\mu\nu}}\right)} \simeq 2^{2} \quad \text{for} \quad M_{\mu\mu} = M_{\pi\pi}$$

$$= \frac{d\sigma_{\pi\pi}}{dm_{\pi\pi}}$$

Then, let $N_{\pi\pi}$ be the number of charged π -pairs which decay into μ 's and are detected as μ -pairs. Let $N_{\mu\mu}$ be the true μ -pairs, then

$$\frac{\mathcal{N}_{\mu\mu}}{\mathcal{N}_{\pi\pi}} \simeq \frac{\sqrt{2}}{\mathcal{C}_{5}^{2}}$$

where P_{N} = probability that a 2 GeV/c π will decay in 20 cm.

$$P_{\text{N}} = \frac{20 \times 1.4}{2.5 \times 20 \times 300} \simeq 2 \times 10^{-3}$$

$$\frac{1}{N_{\pi\pi}} \sim \frac{1}{2 \times 10^4 \cdot 4 \times 10^{-6}} \sim \frac{10}{2}$$

The situation should be considerably better than this, since the energy carried off by the neutrinos will cause the apparent mass of the decay μ -pair to be about half the mass of the parent π - pair. if our assumption about the cross sections is correct to an order of magnitude, we can expect the charged π-pair background to be small at all Muu.

It is easily shown that the background contributed by the neutral pions is an order of magnitude smaller than the charged pions.

It is perhaps unnecessary to point out that there are decisive experimental checks to determine whether the observed rates are due to directly produced μ 's or the decay of charged π 's.

We make the following observations about backgrounds:

- (a) The present arrangement is not optimized for signal to noise.
- $\int_{0}^{1} e^{it} dt$ indicate that if the $f_{\chi}^{2} = 10^{-3}$, the random rate and real rate will be approximately equal $\frac{1}{1000}$
 - (c) The present calculations refer to the mass interval 2 GeV < Muu < 4 GeV. A rough calculation indicates that the rate at which data can be obtained is <u>not</u> a strong function of $\eta_{\mu\mu}$. Therefore, it is likely that measurement can be made down to quite low $m_{\mu\nu}$, in particular in the region of the ρ -meson. This would appear to be very desirable.

Detector

The detector shown in Fig. 1 consists of $11 \times 12 = 132$ scintillators embedded in 85 tons of iron. The first scintillator in each telescope is a "Charpak" counter which, together with the target position, determines Θ_{11} to $\frac{+}{2}$ 2° for a 10 cm long target. The range is determined to $\stackrel{+}{-}$ 7%, and the difference in azimuth between the two muons $\Delta \varphi = \stackrel{+}{-}$ 30°. The invariant mass of the μ -pair is given by (neglecting 2 ${\eta_{\mu}}^2$)

$$\gamma \gamma_{\mu u}^2 = 2E_1E_2 (1 - \cos \theta_{12})$$

 E_{γ} = energy of one muon

 E_2 = energy of other muon

 θ_{12} = angle between the two muons

then
$$\sqrt{\left(\frac{\Delta m_{\mu u}}{m_{\mu u}}\right)^{2}} = \frac{1}{2} \sqrt{\left(\frac{\Delta E_{1}}{E_{1}}\right)^{2} + \left(\frac{\Delta E_{2}}{E_{2}}\right)^{2} + \left(\frac{\Delta (\cos \theta_{12})}{1 - \cos \theta_{12}}\right)^{2}}$$

Putting in the errors given above

$$\sqrt{\frac{\Delta m_{\mu u}}{m_{\mu u}}}^{2} = \frac{1}{2} \text{ 0.15 as stated earlier.}$$

Cost estimate of everything new

Electronics

The electronics can be very simple. We trigger on any coincidences between the first three scintillators in any of the appropriate six pairs of telescopes, and look at the output of all the scintillators. This type of electronics exists in sufficient quantity so that probably very little new would be required.

Of course, one could imagine beginning more modestly. Two telescopes, which, of course, reduces the counting rate by a factor of six, could certainly be assembled out of available components. Perhaps a reasonable compromise would be to buy the necessary iron for the total detector, but to start with only two telescopes.
