Abstract

27

It has been suggested that the degree of ecological diversity that characterizes a primate 28 community correlates positively with both its phylogenetic richness 29 and the time since the members of that community diverged (Fleagle and Reed 1999). It is 30 therefore questionable whether or not a community with a relatively recent divergence time 31 but high phylogenetic richness would be as ecologically variable as a community with 32 similar phylogenetic richness but a more distant divergence time. To address this question, 33 the ecological diversity of a fossil primate community from La Venta, Colombia, a Middle 34 Miocene platyrrhine community with phylogenetic diversity comparable to extant 35 platyrrhine communities but a relatively short time since divergence, was compared with 36 that of modern neotropical primate communities. Shearing quotients and molar lengths, 37 which together are reliable indicators of diet, for both fossil and extant species were plotted 38 against each other to describe the dietary "ecospace" occupied by each community. 39 Community diversity was calculated as the area of the minimum convex polygon 40 encompassing all community members. The diversity of the fossil community was then 41 compared to that of extant communities to test if the fossil community was less diverse 42 than extant communities while taking phylogenetic richness into account. Results indicate 43 that the La Ventan community was not significantly less ecologically diverse than modern 44 communities, supporting the idea that ecological diversification occurred along with 45 46 phylogenetic diversification early in platyrrhine evolution.

Studies of primate communities over the past decade have used multivariate "ecospace" to describe the ecological diversity that characterizes a given community (e.g., Fleagle and Reed 1996; Godfrey et al. 1997; Gilbert 2005; see also Novack-Gottshall 2007). A community's ecospace can be defined as the space it takes up on multivariate axes which represent a variety of ecological variables (including diet, locomotor and positional behavior, activity pattern, and body size) and describe the niche of each species present in the community (see Fleagle and Reed 1996). Such analyses have demonstrated a positive relationship between the ecological diversity of a primate community and the degree of phylogenetic richness in that community (Fleagle and Reed 1999). Similarly, primate communities whose members share a more ancient common ancestor tend to be more diverse than those communities whose members share a more recent ancestor (Fleagle and Reed 1999). Specifically, Neotropical primate communities, whose members diverged relatively recently (20 Ma) (Hodgson et al. 2009), are much less ecologically diverse than Old World primate communities (Fleagle and Reed 1999), whose members share a more ancient common ancestor (80-90 Ma for African and Asian communities: Eizirik et al. 2004; 40 to 65 Ma for the Malagasy communities: Yoder and Yang 2004). To date, studies correlating ecological diversity in primate communities with either phylogenetic diversity or time since divergence have not compared the ecological variation of

69 70 71

fossil primate communities with that of living communities. Such a comparison is especially apt when examining the affect divergence time has on platyrrhine communities because there is little variation in average time since divergence among most New World primate communities due to the fact that most modern subfamilies appeared relatively early in platyrrhine evolution

(Rosenberger et al. 2009). The fossil community from La Venta, Colombia (see Fleagle et al. 1997) demonstrates a degree of phylogenetic richness (i.e., number of taxa) comparable to modern communities (Rosenberger et al. 2009), with many taxa attributable to extant subfamilies (Fig. 1), yet with a time since divergence roughly one third that of modern platyrrhines. The positive relationship between ecological diversity and divergence time of primate communities (Fleagle and Reed 1999) predicts that the fossil primate community at La Venta would be less ecologically diverse than modern platyrrhine communities. However, because the phylogenetic richness of the primate community from La Venta is comparable to many modern platyrrhine communities, it is questionable whether the degree of diversity of the La Ventan primates would be less than that of modern primate communities with a similar degree of phylogenetic diversity, despite their shorter divergence time.

This study addresses this question by first examining how phylogenetic richness affects ecological diversity (as determined by variation in dental measurements related to diet and body size) in modern neotropical communities. The degree of ecological diversity of the La Ventan fauna is then compared to that of the modern communities while taking the number of taxa present in the community into account. It was predicted that modern communities with greater phylogenetic richness would be more ecologically variable than less rich communities, and that the La Ventan community would be less ecologically diverse than modern communities given its degree of phylogenetic richness. This comparison of the La Ventan fossil community to modern communities provides insight into whether ecological diversity has remained relatively static since the divergence of the major extant platyrrhine clades, or if ecological diversity continued to increase even after the initial adaptive radiation.

Diversity in the dietary ecology of the Middle Miocene fossil primate community at La Venta (see Kay and Madden 1997 for details regarding the paleoecology of La Venta) is here compared to that of nine modern neotropical primate communities (fig. 2, table 1). Extant communities were chosen such that a range of degrees phylogenetic diversity would be represented (see table 1 for a list of all species present at each site). The fossil community was limited to the five primate species associated with the La Ventan "Monkey Beds" sedimentary deposits (including *Aotus dindensis*, Cebupithecia sarmientoi, Mohanamico hershkovitzi, Neosaimiri fieldsi, and Stirtonia tatacoensis) (Fleagle et al., 1997; Hartwig and Meldrum, 2002) plus the one species found in deposits both above and below the Monkey Beds (*Patasola* magdalenae). Micodon kiotensis is also associated with the Monkey Beds but was not included as a member of the fossil community because the limited fossil remains of this genus do not allow for detailed analysis regarding its ecology (Rosenberger et al. 2009) and the specimens ascribed to this genus may actually be deciduous teeth of another La Ventan primate species such as *Neosaimiri* (Fleagle et al. 1997; Fleagle pers. comm.). The Monkey Beds date to slightly less than 13 Ma (Madden et al. 1997; Flynn et al. 1997; but see Takemura et al. 1992 for slightly older dates for younger La Ventan deposits) and are thought to represent a short enough period of time (approximately 15 ky; Kay and Madden 1997) that it is likely that the species found in this deposit co-existed.

Ecological diversity was determined through analysis of variation in shearing quotients (SQ) and length of the lower first molar (M₁), which respectively are indicative of diet (Kay 1975) and body size (Gingerich et al. 1982). Shearing quotients are a measure of the development of the molar shearing crests; low (negative) SQ values indicate rounded molar

cusps and are associated with largely frugivorous diets while high (positive) values indicate high-crested molars and are associated with largely folivorous (at large body sizes) or insectivorous (at small body sizes) diets (see Kay 1975; Ungar and Kay 1995). These measurements have been published for both fossil and extant taxa (Anthony and Kay 1993; Fleagle et al. 1997; Meldrum and Kay 1997; Currie Ketchum 2002) and are perhaps the only diet-related variables that are measurable for all species concerned, given that some fossil taxa are represented exclusively by dental remains. Measurements are species averages (see table 2 for values of all measurements used) and were not measured for the specific populations used in this study.

The M₁ length and SQ for each species were plotted against each other on a bivariate plot to determine the dietary "ecospace" occupied by each primate assemblage (fig. 3). Following Fleagle and Reed (1996), ecological diversity for each community was calculated as the area of the minimum convex polygon (MCP) that encompasses the position of all species of that community on the bivariate plot. MCPs were made from bivariate scatter plots made in Microsoft Excel. The scale of each plot was standardized (as in fig. 3) so that the MCP area for each community was directly comparable to those of all other communities. MCP areas were calculated by importing each plot into Adobe Illustrator 12.0, dividing each MCP into multiple triangles, and summing the areas of all constituting triangles. One mm of M1 length was given a value of 3.175 cm in Adobe Illustrator, while 10 SQ units were given a value of 2.25 cm

Phylogenetic diversity for each community was measured using three methods: 1) the number of species, 2) the number of genera, and 3) the number of subfamilies which make up the community. Traditional (conservative) species designations were used following Fleagle (1999). Based on Schneider (in Schneider and Rosenberger 1996), the following five subfamilies of

Atelinae, and Pitheciinae. Some researchers break the Platyrrhini down into additional (smaller) groups, but only these five subfamilies were used because they are now widely accepted as natural groupings (reviewed in Rylands et al. 2000; Rylands and Mittermeier 2009). The six fossil taxa constituting the Miocene community were considered to be stem or crown members of these subfamilies (fig. 1). Based on Fleagle and Kay (1997), Cebupithecia sarmientoi is placed within the Pitheciinae and Patasola magdalenae is placed with the Callitrichinae. Based on Rosenberger et al. (2009), Aotus dindensis is placed within the Aotinae, Neosaimiri fieldsi is placed within the Cebinae, Stirtonia tatacoensis is placed within the Atelinae, and Mohanamico hershkovitzi is placed within the Callitrichinae. It should be noted that the status of Mohanamico is disputed, with Kay (1990) arguing that it is likely a pithecine. However, whether one places this species within the callitrichines or the pithecines does not affect the current analysis because it does not change the number of species, genera, or subfamilies present in the Monkey Beds community.

Statistical Analyses

To examine the relationship between phylogenetic and ecological diversity, a linear regression was used to test if each of the three measures of phylogenetic richness (i.e., number of species, genera, and subfamilies) was a significant predictor of ecological diversity in the extant communities. The area of the MCP of the La Ventan community was then compared to that of the extant communities, taking into account each measure of phylogenetic richness which was significant in the regressions. This was tested by measuring the vertical distance to the regression

line (i.e., the residual) on the plot of MCP area against phylogenetic richness for each of the extant communities (fig. 4); a positive value was given to those points above the regression line and a negative value to those below. The La Ventan community was then superimposed on the graph (based on its MCP area and phylogenetic richness) and its vertical distance from the regression line was measured. A special case t-test for comparing a single specimen against a sample (Sokal and Rohlf 1995) was then used to test if the residual of the La Ventan community differed significantly from those of the extant communities. Such a method allows for a test of whether or not the La Ventan community was less diverse while taking phylogenetic richness into account. Linear regressions were conducted using SPSS 15.0. The special case t-tests were conducted by hand.

Results

Among extant communities, ecological diversity (as measured by MCP area) varied considerably (Table 3) and was positively associated with each measure of phylogenetic richness. Each of the number of species (n=9, R²=0.537, p=0.025; fig. 5), the number of genera (n=9, R²=0.564, p=0.020; fig. 6), and the number of subfamilies (n=9, R²=0.597, p=0.015; fig. 7) were significant predictors of the area of the MCPs. When the La Ventan community is superimposed onto these plots, it consistently falls below the regression line (figs. 5-7). However, the degree to which the La Ventan community falls below the regression line is not significantly different from that of the extant communities, regardless of how phylogenetic richness was measured (number of species: t=-0.167, df=8, p>0.90; number of genera: t=-0.463, df=8, p>0.90; number of subfamilies: t=-1.567, df=8, p>0.10).

Discussion

As expected, the greatest diversity in dietary ecospace as measured by the area of the MCP was found in communities with the greatest degree of phylogenetic richness. This relationship held whether phylogenetic richness was defined as the number of species, number of genera, or number of subfamilies present in a given community. Differences in ecological diversity between the La Ventan fossil community and modern communities, however, were not significant. It thus seems that much of the ecological diversity that characterizes extant Neotropical primate communities occurred early in the adaptive radiation of modern platyrrhines (i.e., from 20 to 13 Ma) and that phylogenetic richness explains the degree of ecological diversity that characterizes platyrrhine communities to a greater extent than does the time elapsed since the members of that community diverged (see Fleagle and Reed 1999).

Despite the lack of a significant difference, it appears that some expansion in dietary ecospace has occurred among New World primates over the last 13 million years (fig. 8). This increase is related to both greater diversity in M₁ lengths among extant platyrrhines and a slight increase in SQs at both small and large body size, with the species of La Venta having lower SQs than many of their extant relatives. This may be indicative of an increased reliance on insectivory and folivory in some modern taxa relative to the species of the fossil community. However, Kay and Ungar (1997) found that although SQs of some Miocene catarrhines were low relative to their modern relatives, dental microwear indicated that the Miocene fauna were as folivorous as modern catarrhines with relatively high SQs. The authors argued that this may be an example of the "Red Queen effect" (see Van Valen 1973), in which these folivorous taxa became better adapted to the niche they already occupied as a means to compete with other contemporaneous

folivores. It is possible that a similar phenomenon occurred in the course of platyrrhine evolution; studies of microscopic dental wear in these fossil species would provide insight in this regard. In addition to an increase in SQs, some of the expansion of ecospace that has taken place over the last 13 million years is the result of a greater diversity of M₁ lengths among extant taxa relative to the species of the La Ventan Monkey Beds. If relatively recent platyrrhine communities, such as those which included *Protopithecus* and *Caipora*, were included among modern communities, the dietary ecospace would be considerably larger, as these taxa are up to twice the size of any modern New World primate (MacPhee and Horovitz 2002; Rosenberger et al. 2009).

Finally, the lack of a significant difference between La Venta and the extant communities may be due to a type II error. It is possible that if other fossil platyrrhine communities dating to the Middle Miocene were available for examination, a significant difference in ecological diversity between the extinct and extant communities could be found. However, because of the dearth of known fossil platyrrhine communities, this is not possible to test. Results may also change if additional discoveries increase the number of taxa known from the Monkey Beds or what we know about the ecology of the taxa already described. Indeed, a number of additional taxa, including Lagonimico, Nuciruptor, Stirtonia victoriae (Fleagle et al. 1997), and Miocallicebus (Takai et al. 2001) have been found in other La Ventan deposits and may eventually be known from the Monkey Beds, although their addition to the fossil community would not necessarily change the results or conclusion of the current study. Among the species known from other layers, lower dentition is available for three (Lagonimico, Nuciruptor, Stirtonia victoriae; Fleagle et al., 1997; Meldrum & Kay 1997. While their addition would indeed add somewhat to the fossil community's MCP area, this would also add to its

phylogenetic richness. Whether or not these species should be considered members of the fossil 237 community awaits further fossil discoveries. 238 239 Acknowledgements 240 241 Carolyn Currie Ketchum graciously sent me many of the dental measurements used in this study 242 prior to finishing her thesis, for which I am very much appreciative. Anthony Olejniczak 243 provided statistical advice. I also thank John Fleagle, Christopher Gilbert, Kristina Hogg, Bill 244 Jungers, and Biren Patel for helpful discussion. Pablo Stevenson provided sources for species 245 compositions of extant communities. BCI*	5	5	4	12.06
Magdalena	4	4	3	3.99
Raleighvallen	7	7	4	15.42
Maraca Island	5	4	2	9.34
Pucurui River	5	5	4	15.63
Jenerro Herera	9	8	5	12.02
Cocha Cashu	9	7	5	16.82
Tiningua	7	7	4	13.35
La Venta	6	6	5	10.36

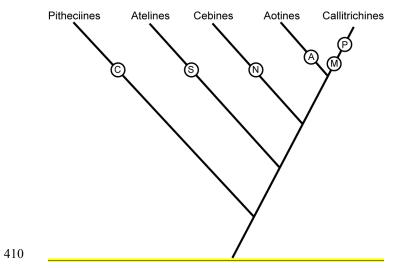

^{*} Barro Colorado Island

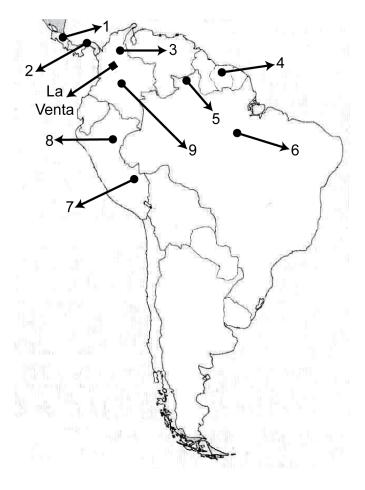

Figure captions **Figure 1.** Cladistic relationships of the extant platyrrhine subfamilies (based on Hodgson et al. 2009) and the placement of La Ventan taxa within those subfamilies. A= Aotus dindensis; C = Cebupithecia; S = Stirtonia; N = Neosaimiri; M = Mohanamico; P = Patasola. Figure 2. The location of La Venta and the nine extant communities examined in this study. 1. La Selva, Costa Rica. 2. Barro Colorado Island, Panama. 3. Magdalena Valley, Colombia. 4. Raleighvallen, Suriname. 5. Maraca Island, Brazil. 6. Pucurui River, Brazil. 7. Cocha Cashu, Peru. 8. Jenaro Herrera, Peru. 9. Tinigua, Colombia. Figure 3. An example of the method used to calculate ecological diversity for a given community. This figure shows the shearing quotients (SQs) plotted against the lengths of the first molars for the five species found in Barro Colorado, Panama. Ecological diversity was calculated as the area of the minimum convex polygon encompassing all species of the community (see Fleagle and Reed 1996). Figure 4. An example of the method used to test for differences in ecological diversity between

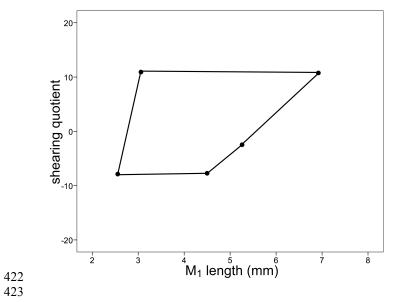

Figure 4. An example of the method used to test for differences in ecological diversity between the La Ventan fossil community and the extant communities. The diagonal line is the regression line based on the equation that describes the relationship between the phylogenetic richness (i.e., the number of taxa) of the extant communities and the area their minimum convex polygons.

Vertical lines are the vertical distance (i.e., the residual) of each community from the regression

line. The fossil community is superimposed on the graph and is not included in the regression equation. **Figure 5.** The relationship between the number of species at a site and the area of the site's minimum convex polygon. The La Ventan community is superimposed onto the graph. **Figure 6.** The relationship between the number of genera at a site and the area of the site's minimum convex polygon. The La Ventan community is superimposed onto the graph. **Figure 7.** The relationship between the number of subfamilies at a site and the area of the site's minimum convex polygon. The La Ventan community is superimposed onto the graph. Figure 8. Scatter plot of shearing quotients (SQs) and M₁ lengths (a proxy for body size) for all extant and fossil taxa included in the current study. Extant taxa show a greater degree of variation in SQs at both small and large body size and slightly more variation in M_1 lengths. A= Aotus dindensis; C = Cebupithecia; S = Stirtonia; N = Neosaimiri; M = Mohanamico; P = StirtoniaPatasola.
