Abstract

Background: Evidence from nationally representative studies in low- and middle-income countries (LMICs) on where patients are lost in the hypertension care continuum is sparse. This information, however, is essential for the effective design and targeting of health services interventions, and to assess progress in improving hypertension care. This study aimed to determine the cascade of hypertension care in 44 LMICs – and its variation between countries and population groups – by dividing the progression from need to successful treatment into discrete stages and measuring the losses at each stage.

Methods: We pooled individual-level population-based data collected between 2005 and 2016 from 44 LMICs. Hypertension was defined as systolic blood pressure (BP) $\geq$140 mmHg or diastolic BP $\geq$90 mmHg or reporting use of medication for hypertension. Among those with hypertension, we calculated the proportion who had i) ever had their BP measured, ii) been diagnosed, iii) been treated, and iv) achieved control. We disaggregated the hypertension care cascade by age, sex, education, household wealth quintile, body mass index, smoking status, country, and region. We used linear regression to predict – separately for each cascade step – a country's performance based on gross domestic product (GDP) per capita, allowing us to identify countries whose performance fell outside of the 95% prediction interval.

Findings: 1,100,507 participants were included of whom 192,441 (17.5%) had hypertension. 73.6% (95% CI, 72.9 – 74.3) of those with hypertension ever had their BP measured, 39.2% (95% CI, 38.2 – 40.3) were diagnosed, 29.9% (95% CI, 28.6 - 31.3) received treatment, and 10.3% (95% CI, 9.6 – 11.0) achieved control. Countries in Latin America and the Caribbean generally achieved the highest performance, while those in sub-Saharan Africa performed worst. Bangladesh, Brazil, Costa Rica, Ecuador, Kyrgyzstan, and Peru performed significantly better on

112 all care cascade steps than predicted based on GDP per capita. Being a woman, older, more

113 educated, wealthier, and not a current smoker were all positively associated with reaching each

114 of the four steps of the care cascade.

115 **Interpretation:** This study provides critical evidence for the design and targeting of health

116 policies and service interventions for hypertension in LMICs by detailing at what step and for

117 whom there are gaps in the care process in each study country. In addition, we have identified

118 countries that perform better than expected based on their economic development in a diversity

119 of world regions, which can guide policy decisions. Given the high disease burden caused by

120 hypertension in LMICs, nationally representative hypertension care cascades as constructed in

121 this study could be used as an important tracer of effective universal health coverage.

Research in context

Evidence before this study: We searched MEDLINE from January 1966 until January 2019 for studies with variations of the words 'hypertension', 'screened', 'aware', 'treated', and 'controlled' in the title or abstract. To date, the largest study of individual-level data to compare hypertension awareness, treatment, and control between low- and middle-income countries (LMICs) – and examine how these indicators vary among population groups within countries – was the Prospective Urban Rural Epidemiology (PURE) Study. However, the PURE study was based on a convenience – rather than random – sample of communities, used data from 2003 to 2009, and included only 14 LMICs.

Added value of this study: This is the first study based on nationally representative samples of adults in LMICs to determine where in the hypertension care process patients are lost, and how this varies between and within countries. We make four key additions to the current evidence base. First, we quantify for each of 44 LMICs the loss of individuals with hypertension at each step of the hypertension care cascade, which can guide national policy makers in whether to prioritise efforts to improve screening, diagnosis, initiation of treatment, or medication adherence and care retention. Second, we examine how the hypertension care cascade varies within LMICs between different population groups, providing important information on possible target groups for relevant interventions. Third, by benchmarking countries' performance against their Gross Domestic Product (GDP) per capita, this analysis identifies countries that performed better than expected based on their wealth and thus likely hold valuable policy lessons for countries at a similar level of economic development. Lastly, this study provides a benchmark of health system performance for managing hypertension in LMICs against which future progress can be compared.

146   ***Implications of all the available evidence:*** The proportion of adults with hypertension lost at

147   each step of the hypertension care cascade varied widely between countries, with male, younger,

148   less educated, less wealthy, and currently smoking adults generally being less likely to reach

149   each cascade step. While the proportion who achieved control was low in all four regions

150   examined, countries in Latin America and the Caribbean had, on average, the best care cascade

151   indicators whereas countries in sub-Saharan Africa tended to have the lowest performance. Well-

152   designed and targeted interventions to improve hypertension care in LMICs are urgently needed.

153   More research is required to understand why some LMICs achieve substantially better

154   hypertension care cascade indicators than others and how the hypertension care cascade can be

155   improved most effectively in different settings.

Introduction

Hypertension is a major risk factor for several common non-communicable diseases (NCDs) in low- and middle-income countries (LMICs), particularly stroke, heart disease, and chronic kidney disease.[1] The prevalence of hypertension is increasing dramatically in LMICs.[2] In fact, the world regions with the highest hypertension prevalence are now thought to be sub-Saharan Africa, South Asia, and Central and Eastern Europe – all regions that are largely comprised of LMICs.[2]

Evidence regarding where in the hypertension care continuum from screening to successful treatment patients are lost to care, and how these patterns vary between and within countries, is essential to designing effective health services interventions to improve hypertension control. In addition, assessing the success of health systems in managing important – yet inexpensively treatable – NCD risk factors, like hypertension,[3] would be a useful measure of health system performance that could feasibly be tracked as part of national and international targets, such as the move towards universal health coverage.[4] Specifically, as LMICs undergo the epidemiological transition from acute communicable to chronic non-communicable diseases, such a health system performance measure could help track countries' progress in shifting health services away from mainly providing episodic care for acute conditions towards furnishing long-term, person-centred care for chronic conditions.

Estimates of health system performance for hypertension from population-based studies in LMICs are sparse.[5] This dearth of evidence – along with the projected rapid rise in the number of people with hypertension in these settings[6] – was the main reason for this collaboration's focus

179 on LMICs rather than high-income countries. In an effort to inform the design of health services

180 interventions and provide a cross-country comparison of health system performance for

181 managing hypertension, this study aimed to i) determine where patients in LMICs are lost to care

182 along the hypertension management continuum, and ii) how these patterns vary among countries

183 and population groups within countries.

184

185 **Methods**

186 **Data sources:**

187 We requested access to the most recent nationally representative World Health Organisation

188 (WHO) Stepwise Approach to Surveillance (STEPS) survey conducted since 2005 for all

189 countries that were, as per the World Bank, a LMIC at the time of the survey. This search led to

190 access to the individual-level data of 22 surveys (**Figure S1**). We preferred STEPS surveys

191 because they use the same standardised questionnaire, tend to sample a wide age range of adults,

192 and are the official method developed by the WHO for monitoring NCD risk factors at the

193 population level.[7] For LMICs for which we were unable to acquire an eligible STEPS survey, we

194 conducted a systematic search (**Text S1**), which led to the inclusion of an additional 22 survey

195 datasets (**Figure S2**). Detailed information on the sampling strategy of each survey is provided in

196 **Text S2**. Forty countries measured BP using a digital upper arm meter, two using a digital wrist

197 meter, and two using a manual mercury sphygmomanometer (**Table S1**). Thirty-five countries

198 measured BP three times, five two times, three two times with a third measurement if the first

199 two differed by a pre-defined margin, and one (the Seychelles) five times.

200

201 **Definition of hypertension:**

202   Hypertension was defined as systolic BP ≥140mmHg or diastolic BP ≥90mmHg or reporting use

203   of medications for hypertension. For participants with three BP measurements, we used the mean

204   of the last two measurements (last four for the Seychelles); for participants with only two

205   measurements, we computed the mean of both available measurements.

206

207   **Constructing the hypertension care cascade:**

208   We computed the percentage of all those with hypertension who had ever received a BP

209   measurement ('ever measured' [step 1]), had been diagnosed with hypertension by a healthcare

210   provider ('diagnosed' [step 2]), were currently taking anti-hypertensive medication ('treated'

211   [step 3]), and had a normal BP (systolic BP <140mmHg and a diastolic BP <90mmHg) plus

212   reported to have received relevant lifestyle advice and/or to be taking anti-hypertensive

213   medication ('controlled' [step 4]). In supplementary analyses, we show all results when defining

214   'treated' as having received relevant lifestyle advice or taking anti-hypertensive medication.

215   More detail on the computation of the care cascade is provided in **Text S3**.

216

217   **Statistical analysis:**

218   None of the analyses presented in this manuscript were pre-specified. Countries were categorised

219   according to the regional groupings of the WHO regional offices whereby the European and

220   Eastern Mediterranean Region as well as the South-East Asia and Western Pacific Region were

221   merged to avoid having only two countries with data in a region. All analyses accounted for the

222   complex survey design using sampling weights. Our primary analyses weighted each country

223   proportional to its population size in 2015.[8] In supplementary analyses, we show all results when

224   assigning the same weight to each country.

225

226   We plotted the proportion of participants with hypertension in a country who reached each step

227   of the care cascade against countries' Gross Domestic Product (GDP) per capita (in constant

228   2011 international dollars as estimated by the World Bank[9]) in the year of data collection for the

229   survey to ascertain health system performance relative to a country's wealth. In addition, we

230   regressed – separately for each cascade step – the proportion of participants with hypertension

231   who reached the given step on sex, ten-year age group, education, household wealth quintile,

232   BMI group (BMI<18.5kg/m^2 [underweight], $18.5 \leq$ BMI<25.0kg/m^2 [normal weight],

233      $25.0 \leq$ BMI<30.0kgm^2 [overweight], and BMI≥ 30.0kg/m^2 [obese]), and a binary indicator for

234   current tobacco smoking. Specifically, we fitted uni- and multi-variable Poisson regressions with

235   a country-level fixed effect adjusting standard errors for clustering at the level of the primary

236   sampling unit. In 20 countries, household wealth quintile was computed based on a principal

237   component analysis of participants' answers to a suite of questions on key household dwelling

238   characteristics and household ownership of durable goods. Fourteen countries did not have these

239   data but did have data on household income, which we used instead to create household wealth

240   quintiles for these surveys. More detail is provided in **Text S4**. Household wealth, smoking, and

241   BMI data was not available for ten, six, and five countries, respectively (**Table S4**). These

242   countries were therefore removed from those regressions that included these variables as

243   independent variables. All analyses were complete case analyses.

244

245   **Ethics:**

246   This study received a determination of "not human subjects research" by the institutional review

247   board of the Harvard T.H. Chan School of Public Health on 9 May 2018.

248

249 **Role of the funding source:**

250 The funder had no role in study design, data collection, data analysis, data interpretation, or

251 writing of the report. PG and LMJ had full access to all the data in the study and had final

252 responsibility for the decision to submit for publication.

253

254 # Results

255 **Sample characteristics:**

256 The survey-level median response rate was 90.9% (interquartile range [IQR]: 81.5 – 95.6)

257 (**Table 1**). Among those interviewed, the percentage of participants with a missing outcome (BP

258 or response to the first cascade step) ranged from 0.0% in Belize, Romania, and the Seychelles to

259 30.2% in Mexico, whereby the survey-level median was 2.3% (IQR: 0.6 – 8.6). 1,100,507

260 participants with a non-missing outcome were included in the analysis. The survey-level median

261 age among these participants was 39.5 years (IQR: 34.8 – 44.5). 192,441 (17.5%) participants

262 had hypertension. Detailed sample characteristics are shown in **Table S2-4**.

263

264 **The hypertension care cascade by country and region:**

265 The prevalence of hypertension and undiagnosed hypertension by country and ten-year age

266 group is shown in **Table S5**. Among those with hypertension, 73.6% (95% CI, 72.9 – 74.3) ever

267 had their BP measured, 39.2% (95% CI, 38.2 – 40.3) had been diagnosed prior to the survey,

268 29.9% (95% CI, 28.6 - 31.3) were treated, and 10.3% (95% CI, 9.6 – 11.0) had achieved control

269 of their hypertension (**Figure S3**). 31.7% (95% CI, 30.6 – 32.7) of those with hypertension had

270 received relevant lifestyle or took anti-hypertensive medication (**Figure S4**). The estimates for

271 each cascade step were similar when assigning an equal weight to each country (**Figure S5-6**).

272   **Figure S7-10** shows the care cascade disaggregated by ten-year age group. The hypertension

273   care cascade for each country is shown in **Figure S11-12**.

274

275   Out of the four world regions examined, Latin America and the Caribbean had the best care

276   cascade indicators, while sub-Saharan Africa had the worst (**Figure 1** and **Table S6-7**). Fewer

277   than five percent of those with hypertension had achieved control in ten of 16 countries (63%) in

278   sub-Saharan Africa, compared to three of eight (38%) in South-East Asia and the Western

279   Pacific, one of ten (10%) in Europe and the Eastern Mediterranean, and zero of 10 countries

280   (0%) in Latin America and the Caribbean (**Table S8**). Within regions, there was substantial

281   variation among countries with Costa Rica being the best-performing country for each cascade

282   step in Latin America and the Caribbean. Other high-performing countries – relative to other

283   countries in their region – were Bangladesh, Namibia, and Romania. The relative differences

284   between regions and countries were similar when defining treatment as receiving lifestyle advice

285   or taking anti-hypertensive medication (**Figure S13**), weighting countries equally (**Figure S14-**

286   **15**), and disaggregating the care cascade in each region by ten-year age group (**Figure S16-17**).

287

288   **The hypertension care cascade by Gross Domestic Product per capita:**

289   GDP per capita was positively associated with a country's performance for each cascade step

290   (**Figure 2**). Countries that performed substantially better on all cascade steps than predicted

291   based on their GDP per capita in the year of the survey were Bangladesh, Brazil (excluding the

292   first step as the 95% prediction interval at Brazil's GDP per capita included perfect performance

293   for 'ever measured'), Costa Rica, Ecuador, Kyrgyzstan, and Peru ('ever measured' was not

294   assessed in Kyrgyzstan and Peru). Countries that performed significantly worse on all cascade

295 steps than expected based on GDP per capita were Albania ('ever measured' was not assessed),

296 Indonesia ('ever measured' was not assessed), Tanzania, Uganda, and South Africa. These

297 results were similar when defining treatment as receiving lifestyle advice or taking anti-

298 hypertensive medications (**Figure S18**), and when examining hypertension care cascade

299 indicators by GDP per capita separately for each ten-year age group (**Figure S19-22**).

300

301 **Individual-level predictors of cascade progression:**

302 Being a woman, in an older age group, and in a higher household wealth quintile were all

303 associated with a higher probability of reaching each cascade step in both uni- and multi-variable

304 regressions (**Table 2**). In addition, except for the controlled step in the multi-variable regression,

305 being overweight or obese was associated with a higher probability of reaching each cascade step

306 in all regressions. Furthermore, we found that i) higher educational attainment was positively

307 associated with reaching each cascade step once adjusted for age and sex; ii) current smokers had

308 a lower probability of reaching each cascade step than those who did not currently smoke; and

309 iii) being obese was associated with a higher RR of reaching each cascade step (with the

310 exception of the controlled step in the multi-variable regression) than being overweight. The

311 positive associations with education were strongest in low-income countries and weakest in

312 upper middle-income countries (**Table S9**). By region, these positive associations with education

313 were generally strongest in sub-Saharan Africa, and did not exist – or were significant in the

314 negative direction in some regression models – in the Europe and Eastern Mediterranean region

315 (**Table S10**). All regression results were similar when assigning the same weight to each country

316 (**Table S11-13**).

317

318 Stratifying the percent of participants with hypertension who reached each cascade step by sex,

319 age group, and education (**Figure 3**) demonstrates that i) the proportion achieving control was

320 less than 20% in all age and education group combinations; ii) in each educational attainment

321 category, less than half were diagnosed in age groups below 55 years; and iii) women had a

322 higher probability of reaching each cascade step than men in virtually all age and education

323 group combinations.

324

325 **Discussion**

326 Overall, the performance of health systems in LMICs for managing hypertension was poor, with

327 less than half of those with hypertension having been diagnosed, less than a third taking anti-

328 hypertensive medications, and only one in ten achieving control. However, there was a large

329 degree of variation among regions and countries. Regionally, Latin America and the Caribbean

330 performed best and sub-Saharan Africa fared worst. Relative to GDP per capita, several

331 countries in Latin America and the Caribbean (Brazil, Costa Rica, Ecuador, and Peru) as well as

332 Bangladesh and Kyrgyzstan performed well. Together, these findings provide an important

333 benchmark of health system performance for managing hypertension in LMICs against which

334 future progress can be compared.

335

336 Within countries, we found that men were less likely to reach each step of the hypertension care

337 cascade than women, which may be due to multiple factors, such as a focus of primary

338 healthcare services on maternal and child health, gender norms concerning care-seeking, and

339 healthcare facility opening hours. As hypertension care services are strengthened in LMICs, it

340 will be crucial that health systems identify ways of engaging men in hypertension screening and

341   care to avoid further widening the existing gender gap in life expectancy.[10] In addition, given our

342   finding that those who were smokers and with overweight or obesity did generally not have a

343   higher probability of completing the hypertension cascade, it will be important for hypertension

344   services in LMICs to more consistently reach and retain those at the highest CVD risk. Lastly,

345   we observed that individuals with lower education and household wealth were generally more

346   likely to be lost to care prior to completion of the cascade. This finding is especially concerning

347   given that those of a lower socioeconomic status are likely less able to access high-quality care

348   for, and more likely to experience catastrophic healthcare expenditures from, CVD events.[11]

349   More optimistically, however, our findings also imply that well-designed investments in

350   improving hypertension care present an opportunity to reduce health inequalities between

351   socioeconomic groups in LMICs.

352

353   Relative to their GDP per capita, countries that performed particularly well in our analysis

354   included Costa Rica, Kyrgyzstan, and Bangladesh, implying that important lessons could be

355   learned from the approaches adopted by these health systems. We briefly outline three possible

356   reasons that may partially explain these countries' comparatively strong performance. First, they

357   have all established primary healthcare system structures at a highly local geographic level.

358   Costa Rica's EBAIS clinics each serve a population of 4,000 people and offer a full range of

359   primary care and health promotion services.[12] Similarly, Kyrgyzstan has established family

360   group practices that provide comprehensive primary healthcare, with each practice serving a

361   village of at least 2,000 inhabitants.[13] Bangladesh has invested since 2009 in the establishment of

362   approximately 14,000 community clinics, which are tasked with providing hypertension and

363   diabetes screening.[14] In addition, it has an extensive presence of informal providers, licensed and

364 unlicensed drug stores, and non-governmental organisations throughout the country,[15] which are

365 likely also playing an important role in meeting the population's demand for NCD care at a local

366 level. Second, the health systems of Costa Rica and Kyrgyzstan have implemented structures that

367 allow for effective community outreach for NCDs. Each of Costa Rica's community clinics

368 include at least one community health worker (CHW) who measures BP during home visits and

369 follows up at home with patients lost from care.[16,17] In addition, CHWs in Costa Rica hold health

370 promotion sessions – including on CVD prevention – in community settings, which can help in

371 the generation of demand for care. Kyrgyzstan has established village health committees, which

372 consist of volunteers who were trained by primary healthcare staff to provide basic health

373 promotion and care services, including for hypertension.[13] While Bangladesh has several large-

374 scale CHW programmes,[18] these mostly do not yet focus on NCDs.[18] However, moving forward,

375 the existence of these large-scale CHW programmes presents an important opportunity for the

376 country to further improve hypertension and NCD care. Third, anti-hypertensive medications are

377 generally both available and affordable in all three countries, which is not the norm in many

378 LMICs.[19] In Costa Rica, these medications are fully covered under the Costa Rican social

379 security fund and widely available at primary care facilities.[17] In Kyrgyzstan, a 2015 survey

380 found that key anti-hypertensive medications were widely available and generally affordable to

381 the local population.[20] Similarly, in Bangladesh, the PURE study found that calcium-channel

382 blockers and ß-blockers were available in 43 and 49 of 55 communities, respectively, and only

383 7% of sampled households were unable to afford at least one type of anti-hypertensive

384 medication.[21]

385

386   While the hypertension care cascade is a useful measure of health system performance in

387   LMICs, there are important contextual factors beyond the health system that likely are

388   responsible for some of the differences in the success of hypertension management that we

389   observed between and within countries. Perhaps most importantly, the probability of reaching

390   each of the care cascade steps likely is affected by individuals' socioeconomic circumstances,

391   which in turn vary widely between and within countries. For instance, even if care is provided

392   free of charge, time lost from income-generating activities and transport costs can still pose a

393   substantial obstacle to accessing care for those with little income and savings.[22] Likewise,

394   individuals with a lower educational attainment may be less well-equipped to engage with

395   relevant health promotion messages and to actively negotiate an effective treatment plan with

396   healthcare providers. In addition to socioeconomic circumstances, epidemiological factors may

397   affect the hypertension care cascade. For instance, adults living in populations that are exposed

398   to a high risk of a fatal non-CVD event, such as through infectious diseases, may be less willing

399   to invest time, effort, and money into the prevention of CVD events. Similarly, even though

400   hypertension control can be achieved solely through medications, social and environmental

401   factors that affect BP – such as sodium content of the food supply,[23] air pollution,[24]

402   conduciveness of the physical environment to physical activity,[23] and social norms to diet, excess

403   weight, and exercise – likely also have an impact on the probability that individuals achieve

404   hypertension control, especially among adults with low medication adherence.

405

406   This study has several limitations. First and foremost, while many surveys used the same WHO

407   STEPS questionnaire to enquire about hypertension care and employed a similar approach to

408   measuring BP, there were some differences in how questions were phrased and translated into

409   local languages, and in how BP was measured (e.g., the exact model of BP meter). This may

410   have affected our estimates and thus be responsible for some of the variation that we observed

411   between countries and regions. Of note, however, is that the core elements of the questions asked

412   about hypertension care were the same across surveys. Second, the age range sampled in each

413   survey varied between countries. We have minimized potential bias from this data constraint by

414   showing each figure that compares countries or regions separately for each ten-year age group

415   (see **Figure S7-10, S16-17, and S19-22**). Third, while – to our knowledge – this study includes

416   the largest set of LMICs of any study on this topic thus far, the 44 LMICs in this analysis

417   (representing 67% of the population living in LMICs worldwide[8]) are not representative of all

418   LMICs globally. Specifically, it is possible that LMICs included in this analysis had better

419   hypertension care indicators because implementing a survey that was eligible for this study may

420   be a sign of a country's commitment to hypertension care. Fourth, the surveys were conducted at

421   different time points. Each country's performance should thus be interpreted as the performance

422   in the given survey year rather than as the country's current performance. To reduce bias from

423   secular trends when comparing countries against each other, we benchmarked performance

424   against each country's GDP per capita in the survey year (rather than current GDP per capita).

425   Fifth, even though the median percentage across countries of missing values for the variables

426   needed to ascertain the hypertension care cascade was only 2.3%, some countries had a

427   substantially higher proportion of participants with a missing outcome variable, which could

428   have resulted in selection bias. Sixth, due to data constraints, we used the same threshold in each

429   survey to define a BP that requires treatment. This approach, thus, ignored that guidelines in use

430   in some countries at the time of the survey may have defined eligibility for anti-hypertensive

431   medications differently, such as based on a global CVD risk or target-organ damage. Lastly,

432 because we did not include a previous hypertension diagnosis in our definition of hypertension,

433 we may have falsely excluded some participants with hypertension from our care cascade

434 analysis. Our hypertension definition, however, is the same as was used in other studies of

435 hypertension care,[25-28] and yields conservative estimates for the care cascade under the

436 assumption that some of those who reported a previous hypertension diagnosis, but had a normal

437 BP and did not report to be on treatment, did, in fact, not have hypertension.

438

439 This study identified important variation in the hypertension care cascade between and within

440 countries, which can guide governments with regards to the design – such as whether to prioritise

441 efforts to improve screening, diagnosis, treatment initiation, or medication adherence – and

442 target groups of appropriate interventions and reforms. Given that hypertension is a major risk

443 factor for several of the most common causes of death in LMICs,[1] and that the condition can be

444 effectively controlled at a low cost,[3] the hypertension care cascade could be used as an important

445 tracer of health system performance in LMICs. Improving hypertension care, however, will be a

446 formidable undertaking requiring strong political will and financial commitments.

561

562 Figure 2. Hypertension care cascade indicators by GDP per capita[1,2,3,4,5,6]

563 [1] Gross Domestic Product per capita is shown in constant 2011 international dollars for the year

564 in which the survey was carried out.

565 [2] The grey ribbon depicts the point-wise 95% prediction interval.

566 [3] The vertical bars depict 95% confidence intervals.

567 [4] The p-values for the coefficients of the linear regressions of each cascade step onto GDP per

568 capita (with each country having the same weight) were <0.001 except for 'Controlled'

569 (p=0.0014)

570 [5] Country labels are not shown for the following countries in the "controlled" plot to avoid over-

571 crowding: Benin, Burkina Faso, Comoros, Ghana, Kenya, Liberia, Mozambique, Nepal,

572 Tanzania, Timor-Leste, Togo, and Uganda.

573 [6] The figure is shown separately for each ten-year age group in Figure S19-22.

574

Abbreviations: n=number; y=years; GDP=Gross Domestic Product.

[1] Values are unweighted (i.e., do not account for the complex survey design).

[2] Except for the percent missing, all values were calculated among those with a non-missing outcome variable (i.e., no missing BP measurement or questionnaire answer needed to calculate the hypertension cascade).

[3] Years in which the data collection for the survey was carried out.

[4] This includes both the household and the individual response rate.

[5] This is the percent of participants for whom the blood pressure measurement was missing or a who had a missing response for the survey question needed to ascertain whether the participant had reached the first step of the country's hypertension care cascade.

[6] This is the GDP per capita in constant 2011 international dollars (as estimated by the World Bank[9]) for the year in which data was collected for the survey.

[7] This is the response rate among women; the men's response rate in Peru was not available.

[8] This is the response rate for the 2006 wave of the survey (the most recent wave for which a response rate was published).

[9] This is the GDP per capita in constant 2007 international dollars using data from the Office of the Chief Government Statistician of Zanzibar.[29]

[10] The population estimate for Zanzibar was taken from the Tanzania Population Projection Report 2013-2035.[30]

[11] This is the median value with each country having the same weight.

[12] This is the interquartile range.

[13] This is the sum across all countries.

Table 2. Uni- and multi-variable regressions of each cascade step onto individual-level predictors[1]

	Ever BP measured		Diagnosed		Treated		Controlled	
	RR	P	RR	P	RR	P	RR	P

Abbreviations: BP=blood pressure; RR=Risk Ratio; P=P-value; Ref.=reference category;

[1] Standard errors were adjusted for clustering at the level of the primary sampling unit.

[2] These regressions included only one of the variables shown in the table and a binary indicator for each country (country-level 'fixed effects').

[3] This refers to having received some primary schooling or having completed primary school.

[4] This refers to having received some secondary schooling, having completed secondary school, or having received some type of tertiary education.

[5] These regressions included sex, age group, education, and a binary indicator for each country (country-level 'fixed effects').

[6] These regressions included sex, age group, education, household wealth quintile, BMI, tobacco smoking, and a binary indicator for each country (country-level 'fixed effects').
